CONTENTS OF ALL VOLUMES

List of Contributors *xvii*

Preface *xxxv*

VOLUME 1

Adult Congenital Heart Disease 1
D Briston and E Bradley

Adverse Impact of Delayed Electrical Activation of the Heart and Benefits of Cardiac Resynchronization 10
A Guha and EG Daoud

AL Cardiac Amyloidosis: Classification, Diagnosis, and Treatment 34
OK Siddiqi and FL Ruberg

Alcohol 49
C Matsumoto

Alcoholic Cardiomyopathy 58
A Voiosu, S Wiese, JD Hove, T Voiosu, F Bendtsen, and S Møller

Amyloid Cardiomyopathy 66
T Sher and MA Gertz

Anemia in Heart Failure 80
A Patel and NL Altman

Angiogenesis 85
N Warmke, AMN Walker, and RM Cubbon

Animal Models of Ischemic Heart Disease: From Atherosclerosis and Thrombosis to Myocardial Infarction 97
R Covarrubias, AS Major, and RJ Gumina

Ankle-Brachial Pressure Index and Pulse Wave Velocity in Cardiovascular Risk Assessment 111
H Tomiyama and A Yamashina

Aortic Aneurysm 123
M Singh, BA Ziganshin, and JA Elefteriades

Aortic Valve Replacement in Patients With Congestive Heart Failure 143
VJ Nardy, JA Crestanello, and NP Jaik

Arrhythmias in Cancer and Cancer Treatment: A Review 162
D Haddad, A Guha, F Awan, EG Daoud, and R Baliga

Arrhythmogenic Right Ventricular Cardiomyopathy 182
MR Afzal, C Evanson, A Cardona, K Rusk, and R Weiss

Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy 192
GM Orgeron and H Calkins

Athlete's Heart 205
LM Safi and MJ Wood

Atrial Tachycardia—Mechanisms and Management 212
J Ahmed and P LeLorier

Atrioventricular Node Reentrant Tachycardia 224
AG Carrizo, B Ballantyne, and A Baranchuk

ATTR Cardiac Amyloidosis: Classification, Diagnosis, and Management 242
JA Cowgill and JN Wight Jr.

Behavior Modification and Cardiovascular Disease 257
V Ramirez, B Starobin, and J Monti

Bicuspid Aortic Valve and Sports Activity 263
L Stefani, G Galanti, and N Maffulli

Bioinformatics Principles for Deciphering Cardiovascular Diseases 273
L Shu, D Arneson, and X Yang

Biomarkers in Heart Failure, Use of 293
PU Gandhi

Biomarkers in Ischemic Heart Disease 303
JT Neumann and RB Schnabel

Biomarkers: Heart Failure 315
SS Gogia and JE Ho

Biomarkers: Population Screening and Risk-Stratification 323
I Ratjen, RS Vasan, and W Lieb

Biophysics of Ablation—Radiofrequency and Cryoablation 334
JG Andrade, MW Deyell, and L Macle

Blood Pressure Variability Versus Blood Pressure Level in Risk Stratification 350
F-F Wei, K Asayama, A Hara, TW Hansen, Y Li, and JA Staessen

Brugada Syndrome 356
C Antzelevitch

Cardiac Anatomy, Physiology, and Pathophysiology 373
KN Hor and AJ Trask

Cardiac and Induced Pluripotent Stem Cells 384
A Salerno, W Balkan, K Hatzistergos, and JM Hare

Cardiac Arrhythmia in Heart Failure 394
T Okabe and SJ Kalbfleisch

Cardiac Biomechanics in Normal Physiology and Disease 411
KM Broughton

Cardiac Fibroblast 420
J Park and MD Tallquist

Cardiac Hypertrophy: Signaling and Cellular Crosstalk 434
D Tirziu

Cardiac Magnetic Resonance Imaging in Heart Failure 451
A Reynolds and KM Zareba

Cardiac Pacing and Monitoring: Past, Present, and Future 463
F Chalhoub and T Mela

Cardiac Regeneration and Stem Cells as Therapy for Heart Disease 468
AJ Favreau-Lessard and DB Sawyer

Cardiac Resynchronization Therapy 475
G Voros

Cardiac Transplantation 489
A Hasan

Cardiohepatic Interactions 514
J Shah and E Shao

Cardiopulmonary Exercise Testing 523
V Franco

Cardiovascular Complications and Management in Sarcoidosis: A Review 527
DJ Roberts, S Francis, JA Rosenblatt, and ST Coffin

Cardiovascular Disease and Obesity 535
Y Matsushita

Catecholaminergic Polymorphic Ventricular Tachycardia 542
PJ Kannankeril

Catheter Ablation for Atrial Fibrillation (Methods) 553
JG Andrade, MW Deyell, and L Macle

Catheter Ablation for Ventricular Tachycardia 566
RM John and WG Stevenson

Cellular Sinoatrial Node and Atrioventricular Node Activity in the Heart 576
HJ Jansen, TA Quinn, and RA Rose

Chronic Infections of the Heart 593
M Edwards, C Withers, and K Thakarar

Chronic Kidney Disease as a Risk Factor for Cardiovascular Disease 600
T Ninomiya

Clinical Assessment of the Cardiac Arrhythmia Patient 609
B Olshansky

Clinical Management of Inherited Arrhythmias 620
RL Jones and MV Perez

Clinical Trials for Atrial Fibrillation—What Do We Know? 630
DS Chew and SB Wilton

Complications of Pregnancy and Future Cardiovascular Risk 643
PH Andraweera, GA Dekker, M Arstall, T Bianco-Miotto, and CT Roberts

Comprehensive Lifestyle Modification for Hypertension and Lifestyle-Related Disease Under the New Guidelines 651
Y Kokubo and C Matsumoto

Computational Systems Biology for the VEGF Family in Angiogenesis 659
JC Weddell and PI Imoukhuede

Congenital Heart Valve Disease in the Adult 677
A Luk, J Alvarez, and J Butany

Coronary Anatomy 691
M Sivananthan

Coronary Artery Bypass Grafting 700
RS Kramer, JR Morton, RC Groom, and DL Robaczewski

Cyanotic Congenital Heart Disease 730
MS Renno and JA Johns

VOLUME 2

Dairy Products and Cardiovascular Diseases 1
M Yanagi, N Amano, and T Nakamura

Diabetes Mellitus 9
H Sone

Diagnosis and Imaging of Congenital Heart Disease 17
SR Fuchs and JH Soslow

Diagnosis of Non-ST-Elevation Myocardial Infarction (NSTEMI) 47
M Vafaie and E Giannitsis

Diet in Heart Failure 54
M Rozmahel, E Colin-Ramirez, and JA Ezekowitz

Dietary Fat and Risk of Cardiovascular Disease 60
ES Eshak, K Yamagishi, and H Iso

Digital Data (mHealth and Social Media) 90
R Bhattacharjee and T Hussein

Diseases of the Mitral Valve 98
L Mc Carthy and P Collier

Diuretic Therapy 107
A Vazir, V Sundaram, and AR Harper

Driving and Syncope 117
D Sorajja and W-K Shen

Echocardiography in Heart Failure 126
T Chen and JN Kirkpatrick

Echocardiography: Assessment of Valve Structure and Function 142
S Vallurupalli, A Siraj, and S Kenchaiah

Economics of Heart Failure 187
S Stewart, C Mainland, and A David

Electrocardiographic Monitoring Strategies (Holter, Implantable Loop Recorder, in Between) 197
H Nazzari, L Halperin, and AD Krahn

Electrophysiology Approaches for Ventricular Tachycardia 211
RM John and W Stevenson

Emergency Medicine Approach and Management of Traumatic Injuries: An Overview 221
E Lavine and E Legome

Environmental Air Pollution: An Emerging Risk Factor for Stroke 231
B Delpont, AS Mariet, C Blanc, Y Bejot, M Giroud, and J Reis

Environmental Risk Factors for Stroke and Cardiovascular Disease 238
J Reis, M Giroud, and Y Kokubo

Epidemiology of Atherosclerotic Cardiovascular Disease 248
N Townsend

Epigenomics 258
TA Turunen, M-A Väänänen, and S Ylä-Herttuala

Exercise and Cardiac Rehabilitation in Heart Failure 266
SR Schubert

Exercise, Physical Activity, and Cardiovascular Disease 274
A Bauman, M Alharbi, N Lowres, R Gallagher, and E Stamatakis

Extracorporeal Membrane Oxygenation 281
A Kilic

Familial Hypercholesterolemia 285
A Pirillo and AL Catapano

Frailty in Heart Failure Patients 298
S Pedraza, TA Barrett, and CM Hritz

Genetic Atrial Fibrillation 303
R Chia, A Mehta, H Huang, and D Darbar

Genetic Disorders Involving Valve Function 313
M Afshar and G Thanassoulis

Genetic Disorders of the Vasculature 327
AJ Brownstein, BA Ziganshin, and JA Elefteriades

Genetics of Heart Failure 368
A Briasoulis, R Asleh, and N Pereira

Heart Development 380
E Dees and S Baldwin

Heart Failure in African Americans 399
M Jame, S Jame, and M Colvin

Heart Failure in Cancer Patients 406
A Vallakati, B Konda, and R Baliga

Heart Failure in Low- to Middle-Income Countries 417
S Stewart, F Taylor, and AK Keates

Heart Failure in Minorities 429
ER Fox, ME Hall, JD Pollard, SK Musani, CJ Rodriguez, and RS Vasan

Heart Failure in the Elderly 437
S Katsanos and J Parissis

Heart Failure Monitoring 453
ES Shao

Heart Failure With Preserved Ejection Fraction 464
S Day

Heart Regeneration with Stem Cell Therapies 469
M Natsumeda, BA Tompkins, V Florea, AC Rieger, M Banerjee, W Balkan, and JM Hare

Heart–Lung Transplantation 484
B LeNoir, M Malik, and BA Whitson

Hemodynamic Changes of Pregnancy 489
P Divanji and NI Parikh

Hemodynamics of the Right Heart in Health and Disease 497
DM Gopal and A Alsamarah

Hormonal Therapy in the Treatment of Chronic Heart Failure 508
R Napoli, A Salzano, E Bossone, and A Cittadini

Hypertensive Heart Disease 517
MU Moreno, A González, B López, S Ravassa, J Beaumont, G San José, R Querejeta, and J Díez

Hypertrophic Cardiomyopathy 527
LK Williams

VOLUME 3

Imaging of Mitral Regurgitation 1
JB Strom, KF Faridi, and CW Tsao

Imaging: CT Scanning of the Heart and Great Vessels 12
M Eid, MH Albrecht, CN De Cecco, D De Santis, A Varga-Szemes, D Caruso, VW Lesslie, and UJ Schoepf

Imaging: Echocardiology—Assessment of Cardiac Structure and Function 35
D Bamira and MH Picard

Immune Mechanisms in Cardiac Physiology 55
SM Peterson, DJ Roberts, and S Ryzhov

Immune-Mediated Mechanisms of Atherosclerosis 68
M Bäck, DFJ Ketelhuth, S Malin, PS Olofsson, G Paulsson-Berne, Z-Q Yan, and GK Hansson

Implanted Pacemakers—Indications and Novel Programming 77
R Willems

Induced Pluripotent Stem Cell–Derived Cardiomyocytes in Advancing Cardiovascular Medicine 87
C Zhang, AG Cadar, and CC Hong

Infective Endocarditis in 21st Century 94
VV Kandasamy, S Pant, and JL Mehta

Inflammatory and Infectious Disorders of the Aorta 102
V Noori, B Nolan, and C Healey

Inotropes in Heart Failure 108
M Ginwalla and C Bianco

Interventions: Endomyocardial Biopsy 119
B Kherad, U Kühl, and C Tschöpe

Intra-aortic Balloon Pumps (IABP) and Percutaneous Ventricular Assist Devices (VADs) 126
NK Kapur and ML Esposito

Ion Channelopathy Genetics 132
A Adler and MH Gollob

Ischemic Cardiomyopathy 145
S Airhart and S Murali

Kidney in Heart Failure 155
DN Pratt and A Diez

Lead-Related Complications 166
B Mondesert and R Parkash

Left and Right Ventricular Remodeling 171
D Pinkhas and X Gao

Left Ventricular Assist Device (LVAD) and Circulatory Devices in Heart Failure 186
P Lee

Left-Sided Obstructive Congenital Heart Lesions: Including Hypoplastic Left Heart 200
CJ Prendergast and GT Nicholson

Lipid-Mediated Mechanisms in Atherosclerosis 214
Q Liu, J Martinez, J Hodge, and D Fan

Lipids and Cardiovascular Diseases: Epidemiologic Perspectives 221
T Okamura, D Sugiyama, T Hirata, K Kuwabara, and A Hirata

Long QT Syndrome and Torsade de Pointes 230
N El-Sherif, G Turitto, and M Boutjdir

Management and Care of Older Cardiac Patients 245
AA Damluji, A Ramireddy, and DE Forman

Management of Cardiac Sarcoidosis 266
L Alghothani and ED Crouser

Management of Patients With Implantable Cardiac Devices Referred for Magnetic Resonance Imaging: A Rapidly Changing Landscape 274
I Roifman and JA White

Management of Pregnancy With Underlying Congenital and Acquired Cardiac Disease 282
AM Moran

Management of Ventricular Tachycardia in Ischemic and Nonischemic Cardiomyopathy 292
A AbdelWahab, VP Kuriachan, GL Sumner, LB Mitchell, and J Sapp

Managing Cardiovascular Disease in Sport and Athletes 302
AB Shah and AL Baggish

Mechanisms of Cardiac Arrhythmias: Molecular and Cellular Perspective 316
P Zhabyeyev and GY Oudit

Medical Management of Left Ventricular Assist Devices 328
S Emani

Metabolomics in Cardiovascular Research 331
V Salomaa and M Inouye

MicroRNAs in Cardiac Development and Function 340
Y Tian

Microvasculature in Health and Disease 349
JE Beare, L Curtis-Whitchurch, AJ LeBlanc, and JB Hoying

Mitochondrial Bioenergetics in the Heart 365
EJ Lesnefsky, Q Chen, B Tandler, and CL Hoppel

Modern Considerations in ICD Therapy 381
TD Richardson and CR Ellis

MR Imaging of the Heart and the Great Vessels 388
U Neisius and C Tsao

Myocardial Perfusion Imaging 404
RB Morgan

Myocardial Repair 425
K Breckwoldt and T Eschenhagen

Myocarditis 440
ALP Caforio, G Malipiero, R Marcolongo, and S Iliceto

Myocarditis in Heart Failure 452
G Sinagra, J Artico, P Gentile, E Fabris, R Bussani, A Cannatà, and M Merlo

Neurohormonal Blockade 459
L Cunningham, W Kayani, and A Deswal

Neurological Regulation of the Circulation 477
DN Jackson, NM Novielli, and J Twynstra

Noninfective Inflammatory Disorders of the Pericardium 492
B Ravaee and BD Hoit

Non-ST-Elevation Acute Coronary Syndrome Prognosis 502
H Haghbayan, CP Gale, and AT Yan

Non-ST-Elevation Myocardial Infarction: Management 522
M Cimci, B Gencer, and M Roffi

Nutrition—Macronutrients 531
T Nakamura and S Kuranuki

Nutrition: Soy and Fish 538
Y Yamori, M Sagara, H Mori, and M Mori

Obesity and the Obesity Paradox in Heart Failure 546
AA Oktay, CJ Lavie, and HO Ventura

Oral Health and Cardiovascular Disease: Recent Findings and Future View With a Novel Aspect 565
T Ono, M Kida, T Kosaka, and M Kikui

Orthostatic Hypotension and Vasovagal Syncope 573
BH Shaw, Jessica Ng, and SR Raj

VOLUME 4

Palliative Care in Advanced Heart Failure 1
M Ginwalla and BP Dhakal

Pediatric Catheter Ablation 8
AE Radbill, FA Fish, and TP Graham Jr.

Perioperative Management in Heart Failure 37
C Mayeur and A Mebazaa

Peripartum Cardiomyopathy 42
LJ Hassen and S Roble

Peripheral Arterial Disease 49
K Matsushita, A Barleben, and M Allison

Pharmacogenomics of Antiarrhythmic Drug Therapy for Atrial Fibrillation 60
D Darbar

Pharmacology of Medications Used in the Treatment of Atherosclerotic Cardiovascular Disease 68
R Khatib and F Wilson

Physical Examination: Heritable Cardiovascular Syndromes 89
K Puri and JP Zachariah

Physical Examination: Normal Examination in Adult Acquired and Congenital Heart Disease 106
TR Schlingmann and JP Zachariah

Physiological Adaptations of the Heart in Elite Athletes 116
A D'Andrea, J Radmilovich, L Riegler, R Scarafile, B Liccardo, T Formisano, A Carbone, R America, F Martone, M Scherillo, M Galderisi, and R Calabrò

Practical Guide to Evidence-Based Management of Heart Failure in the Outpatient Setting 125
AM Maw, RL Page II, and RS Boxer

Preclinical Cardiovascular Imaging 143
I Pinz

Preeclampsia and Hypertension in Pregnancy 154
N Jafar, N Hippalgaonkar, and NI Parikh

Pregnancy and Cardiovascular Disease 160
R Neki

Proteomics 166
G Suna and M Mayr

Pulmonary Arterial Hypertension 181
R El Yafawi, ME Knauft, K Stokem, JM Palminteri, and JA Wirth

Pulmonary Embolism 195
SC Berngard and J Mandel

Pulmonary Hypertension 204
DR Fraidenburg and JX-J Yuan

Pulmonary Hypertension Associated With Left-Sided Heart Disease 223
DN Tukaye and V Franco

Quality Indicators for the Management of Acute Myocardial Infarction 230
O Bebb, M Hall, and C Gale

Recreational Drugs: Effects on the Heart and Cardiovascular System 240
B Starobin, S Jablonski, AM Andrle, and JB Powers

Relationship Between Vegetables and Fruits (Antioxidant Vitamins, Minerals, and Fiber) Intake and Risk of Cardiovascular Disease 249
J Ishihara, M Umesawa, C Okada, Y Kokubo, and H Iso

Remission and Recovery in Heart Failure 284
JS Guseh and JE Ho

Remote Monitoring of Cardiovascular Implantable Electronic Devices 292
B Plourde and R Parkash

Right Heart Catheterization 298
BC Lampert

Risk Factors for Cardiovascular Disease 307
EJ Teufel

Risk Prediction 315
H Yatsuya

Role of Coronary Artery Revascularization in Heart Failure 319
B Shukrallah, A Kilic, and T Lescouflair

Role of Digoxin in Heart Failure 323
A Bucca

Role of Echocardiography in Selection, Implantation, and Management of Left Ventricular Assist Device Therapy 327
M Dandel and R Hetzer

Salt and Blood Pressure 345
Y Yano

Sex and Gender Differences in Cardiovascular Disease 351
L Mathews, P Chandrashekar, M Prasad, VM Miller, K Sharma, T Sedlak, CN Bairey Merz, and P Ouyang

Sex Differences in the Physiology and Pathology of the Aging Heart 368
A Ghimire, AE Kane, and SE Howlett

Signaling in Cardiac Physiology and Disease 377
S Mukherjee, S Srikanthan, and SV Naga Prasad

Sinus Tachycardias: Inappropriate Sinus Tachycardia and Postural Tachycardia Syndrome 388
BH Shaw, J Ng, and SR Raj

Skeletal Muscle in Heart Failure 404
S Scheetz and R Baliga

Sleep and Circadian Cardiovascular Medicine 424
K Kario

Sleep-Disordered Breathing and Heart Failure Interactions and Controversies 438
WJ Healy and R Khayat

Socioeconomic Factors and CVD 442
M Kabayama and K Kamide

Stage A Heart Failure: Identification and Management of Heart Failure Risk Factors 446
KM Alexander and M Nayor

Stage B Heart Failure 456
J Aljabban, R Baliga, and I Aljabban

STEMI: Diagnosis 465
PE Puddu, E Cenko, B Ricci, and R Bugiardini

STEMI: Management 474
R Beatrice, M Olivia, E Cenko, and R Bugiardini

STEMI: Prognosis 489
E Cenko, B Ricci, and R Bugiardini

Structure and Function of the Adult Vertebrate Cardiovascular System 499
JD Schultz and DM Bader

Sudden Cardiac Death 511
GL Sumner, VP Kuriachan, and LB Mitchell

Surgical Management of Atrial Fibrillation 521
G Shanmugam, D Exner, and R Damiano

Takotsubo Syndrome 533
MH Tranter and AR Lyon

Tobacco and Cardiovascular Diseases 537
H Kanda and T Hisamatsu

Total Artificial Heart 545
T Lee and G Torregrossa

Transcriptomics in Cardiovascular Medicine 558
D Börnigen and T Zeller

Transcriptome and Epigenome Applications for Coronary Heart Disease Research 572
R Joehanes

Transplant Arteriosclerosis 582
JC Choy

Trends in the Incidence and Mortality of Cardiovascular Disease 593
J Hata

Ultrafiltration for the Treatment of Acute Decompensated Heart Failure 600
S Emani

Unstable Angina: Presentation, Diagnosis, and Management 606
P Manning and EH Awtry

Vascular Guidance Cues 616
D Valdembri, G Serini, and N Gioelli

Vascular Repair at the Interface of the Endothelium: The Roles of Protease-Activated Receptors and Neuregulin-1 627
CL Galindo, O Odiete, and JH Cleator

Vasculogenesis in Development 640
SC Chetty, K Choi, and S Sumanas

Ventricular Arrhythmias and Sudden Cardiac Death in Hypertrophic Cardiomyopathy 654
MA Cain and MS Link

Ventricular Assist Devices and Heart Transplantation 664
A Kinsella, Y Moayedi, V Rao, HJ Ross, and J Butany

Ventricular Fibrillation and Defibrillation 674
H Kawata and U Birgersdotter-Green

Ventricular Remodeling in Heart Failure 683
I Aquila and AM Shah

Ventricular Tachycardia in Ischemic and Dilated Cardiomyopathy: Mechanisms and Diagnosis 690
VP Kuriachan, GL Sumner, AA Wahab, J Sapp, and LB Mitchell

Ventricular Tachycardia in Structurally Normal Hearts 700
AG Bhatt and S Mittal

Wide QRS Complex Tachycardia: What is the Diagnosis? 725
S Wang and FR Quinn

Wolff–Parkinson–White and Preexcitation Syndromes 747
B Brembilla-Perrot

Zebrafish 759
X-XI Zeng and TP Zhong

Zebrafish as a Tool to Study Congenital Heart Diseases 771
AM Shafik and D Cifuentes

Index 779

PREFACE

The burden of cardiovascular disease is growing across the globe as the leading noncommunicable cause of morbidity and mortality. This is despite outstanding research that has improved our understanding of cardiovascular biology, the determinants of disease, and development of new therapies. We are optimistic that the next generation of scientists and clinicians will further these efforts and ultimately bring about changes that will reduce risk and improve outcomes for patients worldwide. We have assembled this encyclopedia with the explicit intent to provide this generation with easy access to past and current wisdom, with the hope that this helps to accelerate innovation in cardiovascular medicine.

This encyclopedia represents both a dream and a labor of love. The dream is to create a scientific compendium that recognizes that the methods and tools used to access and study the scientific literature have changed, with a burgeoning impact of digital technology—the so-called pocket book encyclopedia that is accessible on a smart phone fitting into medical overalls, and that can also be read as a textbook at a desk! These changes in the access of publications have been accompanied by the evolving need for studying different aspects of biology and disease as stand-alone chapters not necessarily read sequentially. Furthermore, as editors we recognize the fundamental importance of conveying knowledge through brilliantly illustrated texts that are profusely embedded with links to key references. The critical importance to use multimedia tools and to provide downloadable slides for educational purposes is reflected in this encyclopedia. Additionally, we want to ensure the feasibility of updating text, figures, and other reading material iteratively even after a publication date, recognizing the rapid advent of information and huge strides made in cardiovascular medicine every day. Thus, this work represents the end of the beginning of a live text that will metamorphose over time, being guided by the rapid strides and advances in both cardiovascular medicine and publication science.

Overall, we conceptualized this work as providing broad coverage of science and also serving the expansive needs of a readership that is quite diverse, that is, encompassing medical students, residents, fellows, and postdoctoral scientists interested in cardiovascular medicine. We hope the labor of love of an outstanding team of editors and a stellar group of authors is readily evident to the broad readership we have targeted.

Assembling this compendium had many challenges. Early on we made the choice to cover the broad range of cardiovascular biology, pathophysiology, epidemiology, and treatment of disease. We sought to assure equal coverage to foundational cardiovascular cellular and molecular biology as well as state-of-the-art treatments. Covering the breadth inevitably led to some overlap between some chapters, and yet we certainly have some residual gaps. We hope to have the opportunity to fill these gaps in future editions. There is also inevitable variation in the style and scope of articles in this multiauthor publication. We and the section editors felt it was more important to allow our expert authors freedom in how they chose to present their topic.

We invite feedback on how this encyclopedia can be improved as a resource for trainees worldwide. Undoubtedly, as noted above, there are gaps in content areas that need to be bridged in future iterations of this encyclopedia. We look forward to hearing from and listening to our readership about how the text can be better organized or better compiled to serve their scholarship better in future years.

This project was made possible through the hard work of many people from across the globe. We were pleased to have section editors and authors from around the world. Drs. Kessler and Schunkert, renowned cardiologists with an outstanding record of accomplishment in genetic research, have compiled a series of chapters on genetics and genomics. Dr. Baliga, a distinguished cardiologist and educator, has conceptualized a tour de force of chapters that capture all aspects of the heart failure syndrome, whereas Dr. DiSalvo, a master clinician and educator, has synthesized a fine tapestry of chapters focusing on diagnostic testing with key sections on cardiac imaging, interventions, and device therapy. Dr. Raj, an outstanding clinical investigator and

electrophysiologist, brought together an exemplary collection of chapters that offer coverage of a broad spectrum of topics in cardiac electrophysiology. Drs. Major and Liaw, both highly accomplished basic scientists and educators, were instrumental in identifying topics of fundamental importance to the field of cardiovascular biology and medicine. Dr. Lenihan, a pioneering clinical scientist and outstanding cardiologist, brought together a special set of articles that represent interactions between cardiovascular and other fields of medicine. Dr. Gale, a celebrated cardiologist with expertise in comparative effectiveness research and clinical cardiology, offers a series of stellar chapters underscoring various aspects of the pathogenesis and management of atherosclerotic cardiovascular disease. Dr. Kokubo, a leading preventive cardiologist with specialization in cardiovascular epidemiology, has orchestrated state-of-the-art chapters on cardiovascular epidemiology.

We would like to thank our colleagues at Elsevier who provided steadfast support of an exemplary nature throughout this long journey. Last but not the least, the editors would like to thank their families, their mentors, and their respective institutions for the constant encouragement, advice, and support over the years.

Glossary

ACHD *Adult congenital heart disease*: Field of medicine dealing with adult survivors of cardiovascular birth defects relating to their prior pathology as well as consequences of prior interventions.
ASD *Atrial septal defect*: A communication between the atria resulting from incomplete formation of the interatrial septum.
CHD *Congenital heart disease*: Field of medicine dealing with cardiology resulting from embryologic errors and structural problems present since birth.
CoA *Coarctation of the aorta*: A narrowing of the aorta, which may be defined or focal, commonly near to the juxtaductal region.
ES *Eisenmenger syndrome*: Disease state in which a previously left-to-right shunting lesions reverses and becomes right-to-left.
FALD *Fontan-associated liver disease*: Unique state of liver dysfunction found in the majority of patients who undergo single-ventricle palliation.
PAH *Pulmonary arterial hypertension*: Elevated blood pressure in the pulmonary vasculature.
PDA *Patent ductus arteriosus*: A fetal blood vessel connecting the pulmonary artery to the descending aorta.
VSD *Ventricular septal defect*: A communication between the atria resulting from incomplete formation of the interventricular septum.

Introduction

Congenital heart disease (CHD) is a term used to describe structural malformations of the heart and/or great vessels present since birth. CHD is the most common major birth defect present in approximately 8/1000 live births (Bernier et al., 2010; Marelli et al., 2014; Shuler et al., 2013). The term CHD has been used for decades and is generally accepted in reference to children, as prior to the past few decades, few palliative/surgical options were available that permitted survival into adulthood. In the past 50 years significant advances in medical, surgical, and interventional treatments have changed the face of CHD. There are now more adults living with CHD than children, making the field of adult congenital heart disease (ACHD) a relatively new subspecialty that focuses on the unique care needs of the adult patient who has survived with CHD. Adults with CHD vary in their presentation to the healthcare system, with many asymptomatic to those with significant cardiovascular disease including late sequelae from the original CHD anatomy and/or repair. Commonly, these patients may experience heart failure, arrhythmia including malignant variants, and extracardiac involvement. Each ACHD patient has unique needs reflective of underlying anatomy, prior surgical

procedures, catheter interventions, and other comorbid disease. Heterogeneity in any of these factors contributes to the complex care that this special population requires.

Etiology

There is no readily identifiable precise cause of CHD. However, there are some important associations with CHD. For instance, maternal infections such as rubella are associated with increased risk of CHD in the fetus. Pregnant women with diabetes mellitus, whether gestational or pregestational, are known to have fetuses with higher rates of CHD (Simeone et al., 2015). Some medications are associated with increased risk of CHD: isotretinoin, lithium, anticonvulsant medications, folic acid antagonists, and thalidomide among others (Ruedy, 1984). Genetics, and more specifically cardiogenetics, is an evolving field. While there are no universal known genetic associations with CHD, research has shown that CHD can result from: single-nucleotide polymorphisms, microdeletions, duplications, single-gene mutations, and aneuploidy (Fahed et al., 2015; Emer et al., 2015; Su et al., 2016). Trisomy syndromes are relatively common; for instance, Trisomy 21 (Down's syndrome) is associated with midline defects involving the endocardial cushions such as partial and complete atrioventricular septal defects. Meanwhile, specific genetic mutations in TBX5, NKX2-5, TLL1, and others have been associated with other CHD lesions. Regardless of the cause, once the alteration in normal embryologic development is sustained, CHD can result.

Embryology

To understand CHD, one must have a brief understanding of the embryologic basis of cardiac development. Errors at any of the steps in normal cardiovascular development may lead to CHD or even fetal demise. Cardiogenesis is dependent on multiple transcription factors and proteins interacting at specific times and locations throughout gestation and still is not completely understood. Cells destined to become cardiac structures are identified as early as 15 days and form a cardiac tube at approximately 21 days gestation. It develops into a sinus venosus structure, which ultimately forms atria, which receive venous structures as well as multiple primitive structures (Fig. 1). Over the following week, the bulboventricular region separates from the primitive atrium and ventricle, and the endocardial cushion forms and fuses dividing the atrioventricular canal into two segments. Around the same time, a septum forms in the primitive atrium both from the endocardial cushions and also from the ventral wall of the ostium primum. Also, the primitive ventricle undergoes septation via a distinct series of events, which lead to left and right ventricles forming side-by-side. The interventricular septum has contributions from neural crest cells of the endocardial cushion, the bulboventricular flange, and the inferior edge of the spiral septum of the conotruncus, which is the outflow chamber for the primitive ventricles. The conotruncus undergoes spiral septation allowing the aortic valve to move posteriorly to the left ventricle and the pulmonary valve to align with the anterior right ventricle. This series of developmental folds and morphologic relationships form the structurally recognizable normal anatomic heart and great vessels.

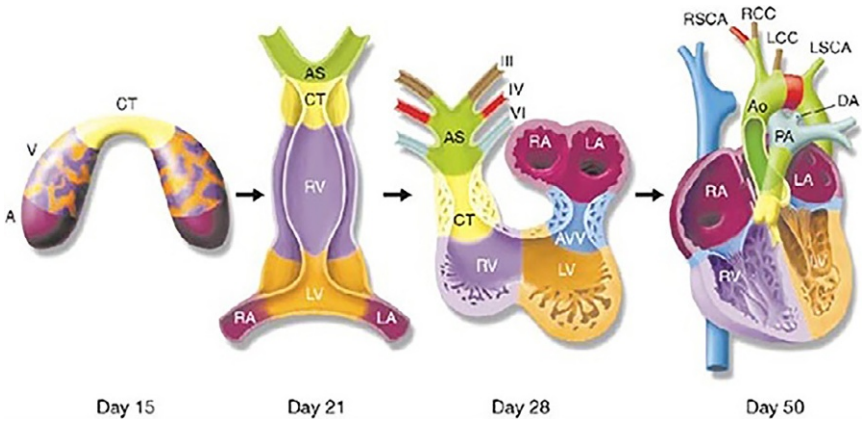

Fig. 1 Schematic of cardiac morphogenesis. Illustrations depict cardiac development with color coding of morphologically related regions, seen from a ventral view. Cardiogenic precursors form a crescent (left-most panel) that is specified to form specific segments of the linear heart tube, which is patterned along the anterior–posterior axis to form the various regions and chambers of the looped and mature heart. Each cardiac chamber balloons out from the outer curvature of the looped heart tube in a segmental fashion. Neural crest cells populate the bilaterally symmetrical aortic arch arteries (III, IV, and VI) and aortic sac (AS) that together contribute to specific segments of the mature aortic arch, also color coded. Mesenchymal cells form the cardiac valves from the conotruncal (CT) and atrioventricular valve (AW) segments. Corresponding days of human embryonic development are indicated. *A*, atrium; *Ao*, aorta; *DA*, ductus arteriosus; *LA*, left atrium; *LCC*, left common carotid; *LSCA*, left subclavian artery; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RCC*, right common carotid; *RSCA*, right subclavian artery; *RV*, right ventricle; *V*, ventricle.

Nomenclature

There are multiple systems of nomenclature to describe CHD, and none of them is universally accepted. Herein we will use the presence of cyanosis at birth (saturation ≤85%) as the initial delineation (cyanotic vs acyanotic lesions). An *acyanotic* lesion is typically the result of an obstructive lesion or a left-to-right shunt. Among *cyanotic* lesions, a right-to-left shunt must be present. For the interested reader, complex nomenclature practices can be reviewed (Anderson et al., 1984; Van Praagh, 1972).

Acyanotic Lesions

Obstructive lesions

Obstructive lesions include those affecting the right ventricular outflow tract such as pulmonary stenosis, and those affecting the left ventricular outflow tract, such as aortic stenosis (subvalvular, valvular, and supravalvular) and coarctation of the aorta (CoA). By definition, obstructive lesions restrict forward flow of blood. Symptoms are largely dependent on the location and severity of obstruction. Pulmonary stenosis is among one of the most common types of CHD, and it is variable in its pathology, occurring below, at, or above the valve level. Pathology varies and can include valvular dysplasia and/or doming of the pulmonary valve leaflet due to abnormal coaptation and valve function. Depending on the extent of obstruction, atrial level shunting may occur if an interatrial communication persists. If this is the case, oxygen saturation may be affected until the obstruction is palliated. Commonly, even after palliation, poststenotic dilation of the main pulmonary artery is seen.

In left ventricular outflow tract obstruction pathology is similar and can occur below, at, or above the valve level. Valvular pathology can include unicupsid, bicuspid, tricuspid, and quadricuspid aortic cusp variants with or without valvar dysplasia. Like pulmonary stenosis, poststenotic dilation commonly is seen (here of the aorta). Discrete and long-segment CoA subtypes may influence the type of intervention timing as well as age of presentation (including whether or not there is a well-developed spinal arterial system and dependent upon the presence of collateral blood vessels) (Fig. 2). Blood flow inferior to the diaphragm is

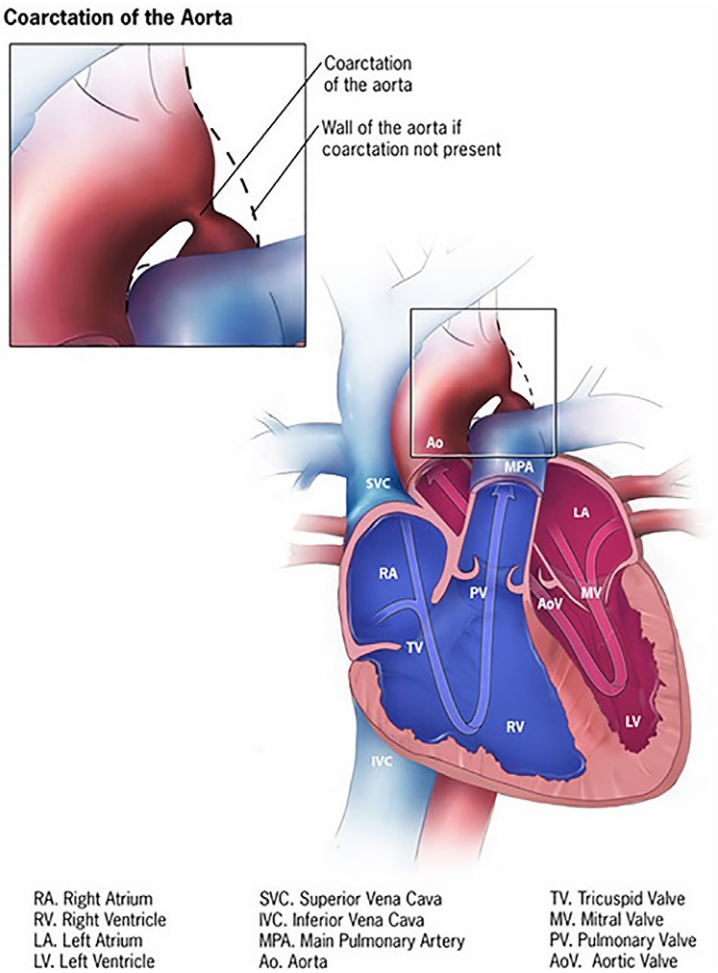

Fig. 2 Coarctation of the aorta is demonstrated here and represents an obstructive lesion of the aorta, which affects distal blood flow.

compromised by this lesion when the patent ductus arteriosus (PDA) closes, and collateralization occurs to supply blood distal to the level of obstruction. The proximal segment is sometimes dilated and is exposed to increased blood pressure while the distal segment is often diminutive because of decreased flow and with subsystemic pressure. It is not uncommon for adults to present with CoA undiagnosed. They typically have few if any symptoms, and the only finding may be hypertension.

Left-to-right shunts

Atrial septal defects (ASDs) constitute the most common ACHD lesion and occur when there is a defect in the septum between the atria. There are four major types, and all of them lead to varying degrees of the same shunting physiology (Fig. 3). ASDs typically lead to volume overload of the right atrium and ventricle. Over decades this volume-loading lesion may lead to elevated right-sided pressure and resistance, and in a minority of patients pulmonary arterial hypertension (PAH) may occur.

Ventricular septal defects (VSDs) are another common type of intracardiac shunt. Given the embryologic origin of the ventricular septum, a VSD can form in several locations. Commonly VSDs are seen in the membranous septum, which lies beneath the aortic valve. Other defect locations include: conal septum, adjacent to the tricuspid valve and within the muscular septum, and muscular septum (Fig. 4). Defects vary in size, number, and shape, making their physiology and anatomy strikingly disparate. Lesions can coalesce and atrioventricular canal defects occur when the endocardial cushions fail to fuse properly. This leads to failure of the mitral valve to form correctly, and a cleft in the left-sided atrioventricular valve is always present.

PDA is the persistence of a fetal vessel called the ductus arteriosus, which normally involutes in the first few days after birth. It is an artery connecting the aorta to the pulmonary artery (Fig. 5). Its persistence is more commonly seen in premature infants but may be seen in full term infants as well. The muscular artery's persistence leads to variable outcomes. If tortuous and narrow, then it acts as a resistor and protects the pulmonary vascular bed; however, it may be broad and straight, which may lead to pulmonary overcirculation and/or PAH early in life.

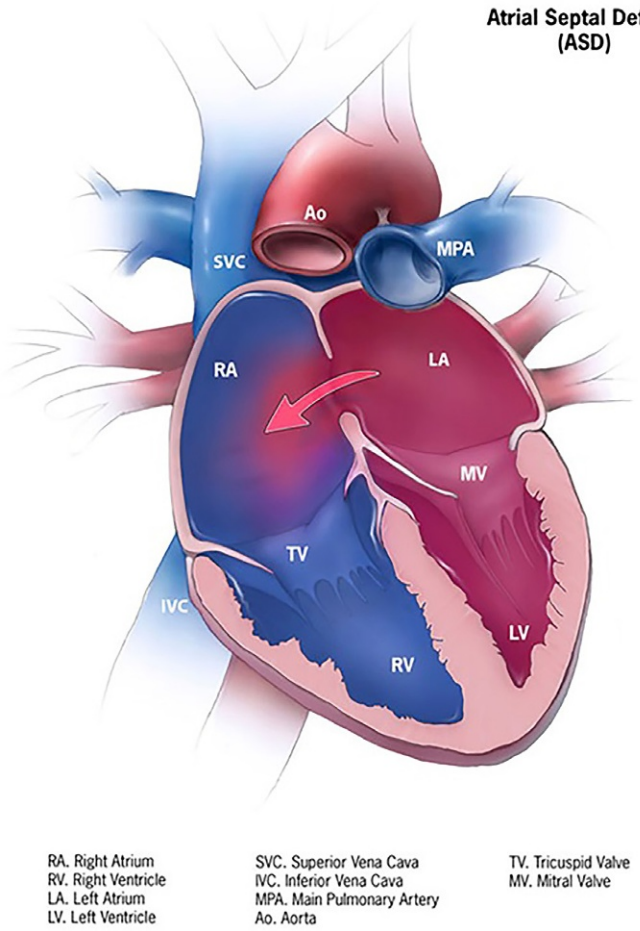

Fig. 3 Atrial septal defect is demonstrated here and represents a deficiency in the atrial septum that permits shunting of blood at this level.

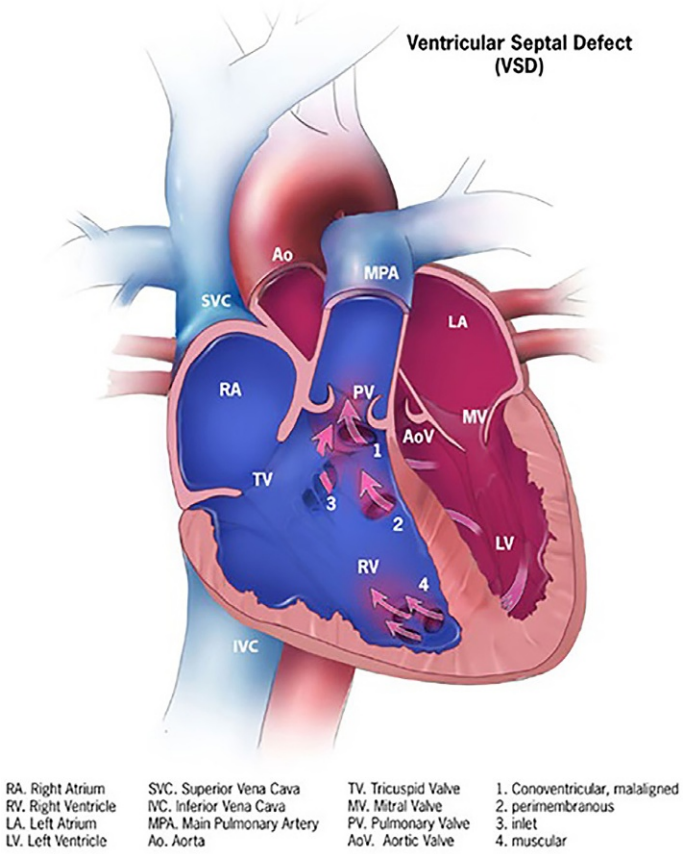

Fig. 4 Ventricular septal defect (VSD) is demonstrated here and represents a deficiency in any area of the ventricular septum that permits shunting of blood at this level. Levels of shunting include subarterial VSD (1), membranous VSD (2), inlet VSD (3), and muscular VSD (4).

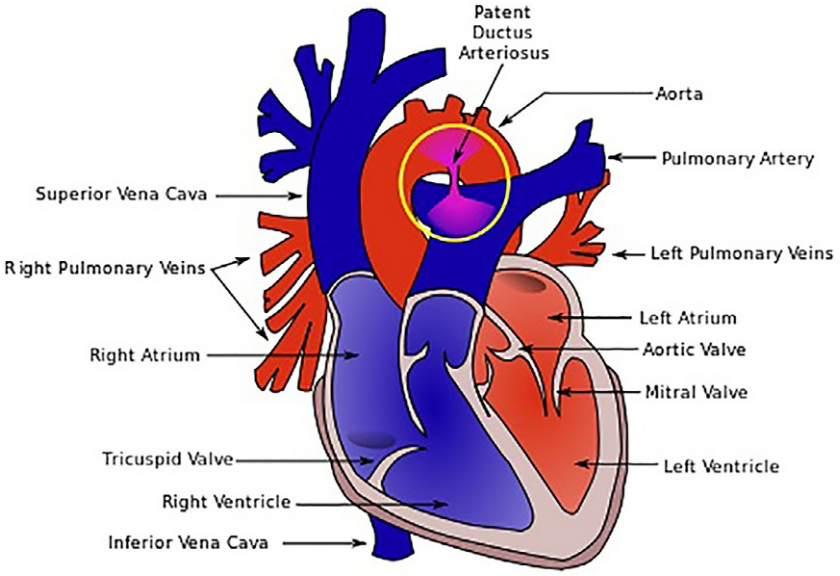

Fig. 5 Patent ductus arteriosus is demonstrated here and represents the continued existence of a fetal structure, which connects the aorta to the pulmonary artery.

Cyanotic Lesions

Cyanotic CHD requires the presence of right-to-left or deoxygenated-oxygenated blood shunting. This scenario may exist in the form of parallel circulations when two usually interdependent circulations do not distribute and receive blood from one another appropriately. Instead, they work in isolation and recirculate their own blood that each pumps out redundantly. Cyanotic CHD occurs in the presence of such parallel circulations, obstruction leading to decreased pulmonary blood flow, or mixture of arterial or venous blood.

In the unrepaired state (typically infants), Tetralogy of Fallot is the most common scenario where right-to-left shunting of blood occurs. This pathology occurs because of anterior–superior deviation of the conal septum leading to the presence of a VSD, pulmonary stenosis, right ventricular hypertrophy, and overriding aorta (Fig. 6). Coronary artery anomalies are sometimes seen, which may complicate surgical repair. ASDs are often present, which may lead to further shunting depending on the degree of right ventricular diastolic dysfunction. Lesions associated with pulmonary valve atresia also lead to right-to-left shunting whether at the atrial or ventricular level. Another cause of cyanotic CHD is complete transposition of the great arteries, where the aorta and pulmonary artery insert into the right and left ventricles, respectively. This ventriculoarterial discordance leads to a complicated physiologic state in which oxygenated blood is recirculated to the lungs and deoxygenated blood recirculates within the body. ASDs and VSDs as well as the PDA serve as shunts to allow for oxygenation of deoxygenated blood and circulation of oxygenated blood. This serious condition is incompatible with prolonged survival without surgical intervention. Any adult seen with this condition in the unrepaired state has survived strictly from mixing of oxygenated and deoxygenated blood at any the level of remaining shunt. Finally, mixture of arterial and venous blood may lead to net deoxygenated blood. Some examples of this are: atrioventricular valve atresia concurrent with an unrepaired shunt, total anomalous pulmonary venous return, in some cases partial anomalous pulmonary venous return, arteriovenous malformations, and truncus arteriosus. In truncus arteriosus for instance, cardiac output from the left and right ventricles join in a common outflow artery, termed the truncus. The lung gets blood via pulmonary arteries that emanate from the truncus arteriosus and sometimes also by PDA. The lungs are exposed to high pressure and volume overload, making early surgical repair important for normal cardiopulmonary development and competence.

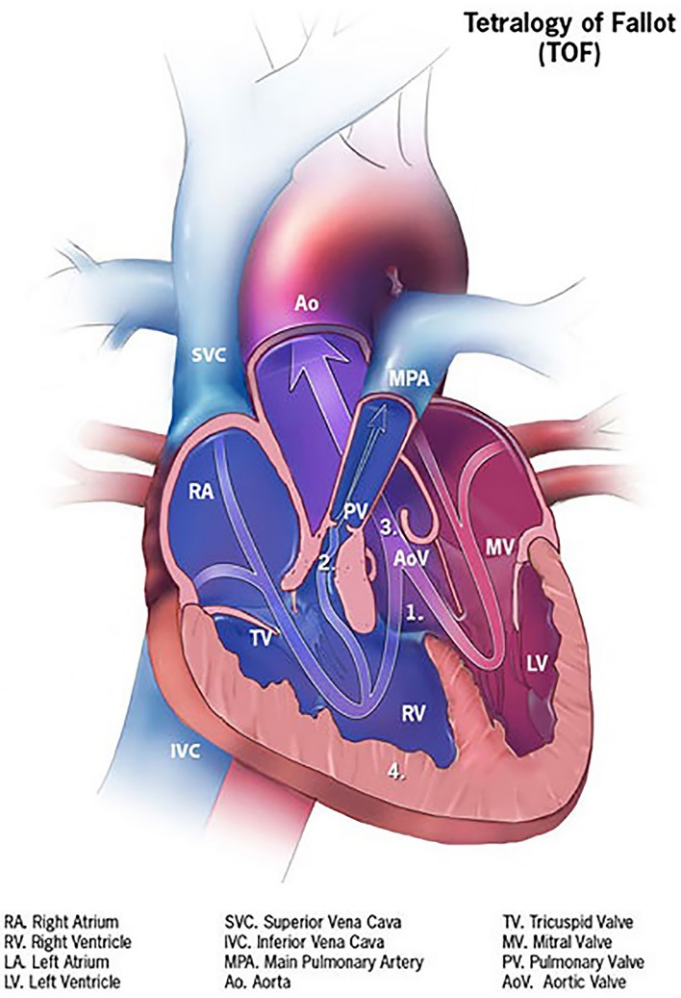

Fig. 6 Tetralogy of Fallot (TOF) is demonstrated here and is characterized by a series of findings, which occurs secondary to anterior deviation of the conal septum. It is exemplified by ventricular septal defect (1), pulmonary stenosis (2), aortic override (3) and right ventricular hypertrophy (4).

Single-ventricle patients represent a unique subpopulation of those with ACHD. These patients can have a diverse array of underlying CHD but ultimately have a similar palliative plan. Whether the systemic or pulmonary output is compromised, the first stage of surgical palliation ensures adequate cardiac output for both systems, adequate venous blood admixture at the atrial level and the integrity of the aortic arch (Fig. 7A). The *second stage*, commonly called a Bidirectional Glenn procedure or Bidirectional cavopulmonary anastomosis, redirects some of the systemic venous blood directly to the pulmonary arteries while permitting deoxygenated infradiaphragmatic blood flow to return to the heart (Fig. 7B). Finally, in the *third stage* which is commonly referred to as the Fontan completion, the deoxygenated venous blood that had been returning to the heart is redirected to the pulmonary artery leading to a circuit with only one pump and passive pulmonary blood flow as is required without a subpulmonary ventricle (Fig. 7C). Late findings in the Fontan-palliated patient are similar despite underlying native anatomy. The current standard modification performed is the extracardiac Fontan procedure (Fig. 8). We are just beginning to learn of both the late-cardiac and

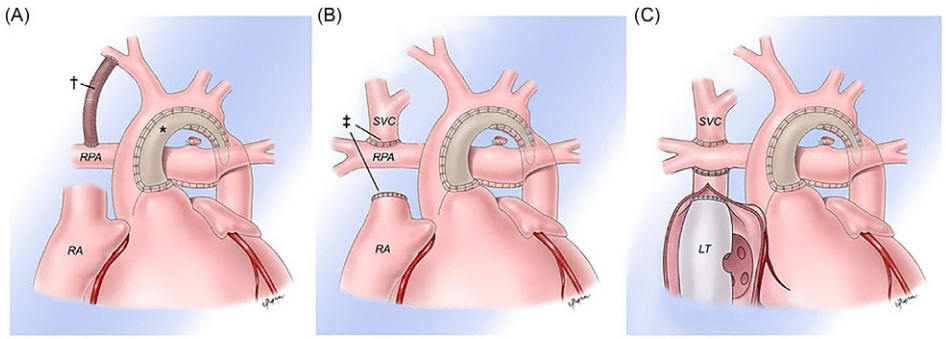

Fig. 7 The traditional three step palliation is demonstrated here. In A, the modified Blalock-Taussig-Thomas shunt is shown connecting the right subclavian artery to the right pulmonary artery along with an aortic arch reconstruction. In B, the superior vena cava is redirected to the pulmonary arteries and the Blalock-Taussig-Thomas shunt is taken down. In C, the sub-diaphragmatic blood is redirected to passively drain into the pulmonary artery.

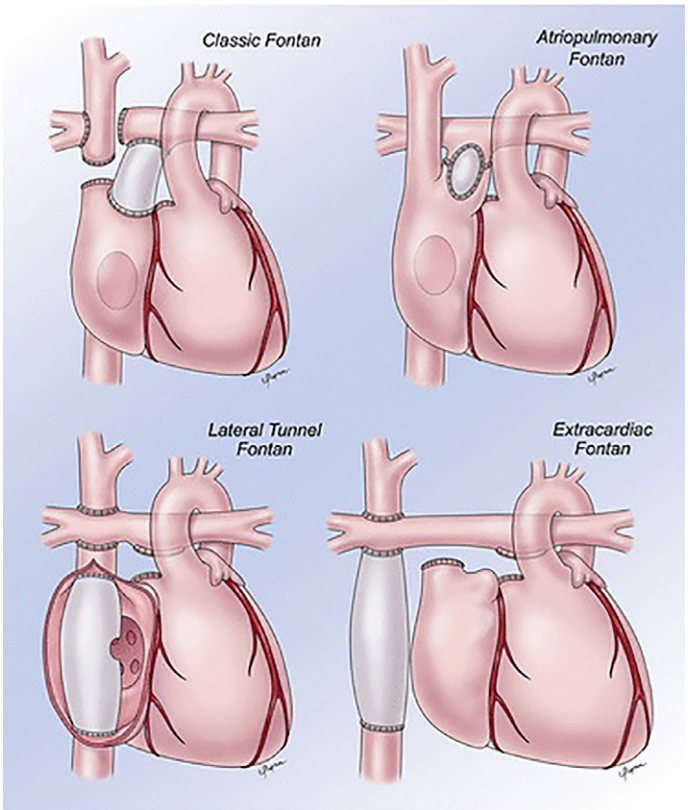

Fig. 8 Iterations of the third palliative surgery step are demonstrated here. The Classic Fontan was initially utilized with sub-diaphragmatic blood flowing only to the left lung and using the right atrium as a conduit. In the Atriopulmonary Fontan, the right atrial appendage is anastomosed directly to the main pulmonary artery. In the Lateral Tunnel Fontan, sub-diaphragmatic blood utilizes native right atrial tissue within the baffle as it ascends to the pulmonary artery. In the Extracardiac Fontan, a conduit is placed outside of the heart, which connects sub-diaphragmatic blood to the pulmonary artery.

extracardiac manifestations that result from this surgical procedure, as the first patients surviving this operation typically had the procedure in the early 1970s (Van Praagh, 1972).

Treatment

Prior to the 1950s, surgical interventions were not possible, and CHD was a harbinger of early death. However, with the advent of cardiopulmonary bypass, surgical interventions have become increasingly more complex and common. Since the 1960s, however, catheter interventions have been utilized and changed diagnosis and treatment of CHD (Rashkind and Miller, 1966). Since the 1970s, such procedures have eliminated the need for some open surgical procedures (King and Mills, 1974).

Transcatheter interventions are multiple and the details of them are beyond the scope of this article. They may be used to relieve valvar obstruction, dilate blood vessels, place stents, insert devices to occlude septal defects, coil anomalous vessels, and insert new valves, among other procedures. The benefits of transcatheter interventions are several: avoidance of thoracotomy/sternotomy including effects on respiratory mechanics, no requirement for cardiopulmonary bypass and therefore offer neurologic protection and potentially avert late neurocognitive abnormalities and shorter hospitalization, among others. The ability to place valve homografts in the pulmonary and aortic positions has revolutionized the treatment of CHD specifically as it relates to transcatheter pulmonary valve utilization particularly in Tetralogy of Fallot. It would be expected that these types of interventions will continue to develop and improve, offering more patients procedural success for treatment of CHD.

Surgical interventions for CHD are widespread and specific to the underlying type of CHD. Similar to transcatheter interventions, valvular interventions and septal defects may be intervened upon but in this case with direct visualization. Although percutaneous options are increasing, there are times where surgical intervention is preferred for precise repair, for example, when defect repair is in a location that intimately interfaces with the conduction system. Creation of shunts and placement of conduits largely remain procedures that require surgical intervention; however, newer percutaneous options are in study and may be on the horizon in the near future. Interventions on arteries and veins to ensure patency or redirect flow are also routinely preferentially performed surgically. Staged repairs over weeks to years are commonly utilized alone or in concert with transcatheter interventions, particularly in complex CHD such as the single-ventricle population. In the setting of dire circumstances, heart transplantation may be performed by congenital heart surgeons when other options are deemed too risky.

Cardiac Manifestations in ACHD

ACHD patients face several cardiovascular problems as they age. This may be the result of residual congenital lesions, or a result of the surgical palliation performed in childhood. Congestive heart failure is not uncommon, and although tolerable in youth, over time the same pressure–volume relationships may not be as well tolerated (Engelings et al., 2016). There remains a paucity of data about use of traditional heart failure medications in the CHD population, and it remains an important area of research (Book and Shaddy, 2014; Gurvitz et al., 2016). Medications may slow down this progression but reversal may not be possible (Stout et al., 2016). CHD patients with valvular heart disease typically progress independent of CHD and can compound existing hemodynamic derangements. Arrhythmia is another late common cardiac problem for many CHD patients (Moore, 2014). These issues can arise from scar tissue secondary to the original repair, for instance, the ventriculotomy scar in Tetralogy of Fallot, or from the abnormal hemodynamic milieu. PAH is a dreaded complication of CHD and is known to affect overall survival (Manes et al., 2014; Dimopoulos et al., 2014). This occurs when the mean pulmonary artery pressure is $\geq$25 mmHg, pulmonary capillary wedge pressure is $\leq$15 mmHg, and pulmonary vascular resistance is $>$3 Wood units. One common way that PAH develops is from an unrepaired nonrestrictive shunt. In this condition, such as is the case with an unrepaired VSD, a shunt that once went left-to-right reverses to right-to-left secondary to the increased pulmonary vascular resistance. This condition is known as Eisenmenger's syndrome (ES) and is associated with increased mortality and several extracardiac manifestations of CHD (Dimopoulos et al., 2014).

Extracardiac Manifestations of ACHD

ACHD patients have pathology extending beyond the cardiopulmonary system. For those who have single-ventricle physiology, the ingenious palliative Fontan operation has permitted survival into adulthood for those who otherwise might have died young; however, late problems in adulthood are commonplace (Hsu, 2015; Cohen et al., 2013). These patients typically remain at least mildly cyanotic and secondary erythrocytosis is common, as is coagulopathy. Peripheral skin and soft tissue changes, particularly in the legs, are frequent due to passive and often congestive systemic venous return via the Fontan circuit. Liver involvement is common, and in fact has its own unique term: Fontan-associated liver disease (FALD), because it is unlike other liver disease due to common mechanisms such as hepatitis or alcohol abuse. Nearly all adults with a prior Fontan will have histopathology consistent with liver fibrosis, if not cirrhosis (Pundi et al., 2016). Hyperenhancing liver nodules are not uncommon in the Fontan population, and there is an increased incidence of hepatocellular carcinoma compared to other types of CHD (Wells et al., 2016). Protein losing enteropathy may also occur in adulthood and is characterized by fluid retention, low albumin, and is generally poorly tolerated with no good treatment strategies available (Hsu, 2015).

In patients who have ES or cyanosis from unrepaired CHD, there is hematologic dysfunction characterized by coagulopathy and increased bleeding risk (Tay et al., 2011). Secondary erythrocytosis is responsible for microthorombi formation and the increased cell turnover of this state can also lead to gout and cholelithiasis (Shiina et al., 2011). Despite having increased hemoglobin and hematocrit, iron deficiency is common and contributes to bleeding diatheses and reduced oxygen delivery (Tay et al., 2011). Renal dysfunction manifests as reduced glomerular filtration rate and proteinuria. Severe infections are also more common with ES, in particular, cerebral abscesses and infective endocarditis. ES is truly a multisystem disease, even though the initial insult is cardiac in nature.

Other systemic problems that are frequently seen in ACHD patients include: orthopedic problems such as scoliosis, respiratory insufficiency/dysfunction typically in the form of restrictive lung disease commonly related to prior surgery, and renal dysfunction (Cohen et al., 2013; Fredriksen et al., 2001; Buelow et al., 2013). Many of these comorbid disease states are only beginning to be discovered, and we continue to evaluate their significance in this special population.

Conclusions

In summary, CHD is a heterogeneous disease state, where variable presentation is affected not only by the initial lesion, but also by surgical repair, and the normal aging process. Adults with CHD are a unique group of patients that require specialized cardiac and extracardiac medical care. It is crucial that these patients are cared for by physicians with expertise in their type of cardiovascular disease.

Introduction

Heart failure (HF) is a cardiovascular condition with a high mortality, ≈50% of people diagnosed with HF will die within 5 years (Writing Group Members et al., 2016). Mortality declines have been attributed to evidence-based approaches with implementation of multiple medical therapies targeting various pathophysiologic mechanisms and use of implantable cardiac defibrillators (ICD) for management of malignant ventricular arrhythmias (Merlo et al., 2014). One prognostic feature for HF patients is the duration of the QRS that is recorded on the surface 12-lead electrocardiogram. A QRS duration of ≥120 ms occurs in 30% of HF patients, and a prolonged QRS (Kashani and Barold, 2005) reflects slowed/delayed intraventricular conduction, which promotes abnormal activation sequence of the ventricular walls. This dyssynchronous activation leads to immediate and long-term adverse hemodynamic effects and adverse cellular and structural remodeling (Shaver et al., 1988). Attempts to reverse this pathophysiology by minimizing cardiac dyssynchrony is the goal of pacing both ventricles, termed biventricular (BiV) pacing, and thus providing cardiac resynchronization therapy (CRT). The purpose of this review article is to discuss the experimental and clinical findings associated with CRT, as well as advances in CRT technology (McAlister et al., 2007; Epstein et al., 2013).

Adverse Hemodynamics of Broad QRS

Left Bundle Branch Block Conduction Pattern

Native left bundle branch block conduction

With activation of the ventricle in the setting of a left bundle branch block (LBBB) pattern, the left ventricle (LV) is no longer activated via the left bundle branch and Purkinje fibers. Instead, electrical activation spreads from the right bundle branch.

 https://doi.org/10.1016/B978-0-12-809657-4.99658-3

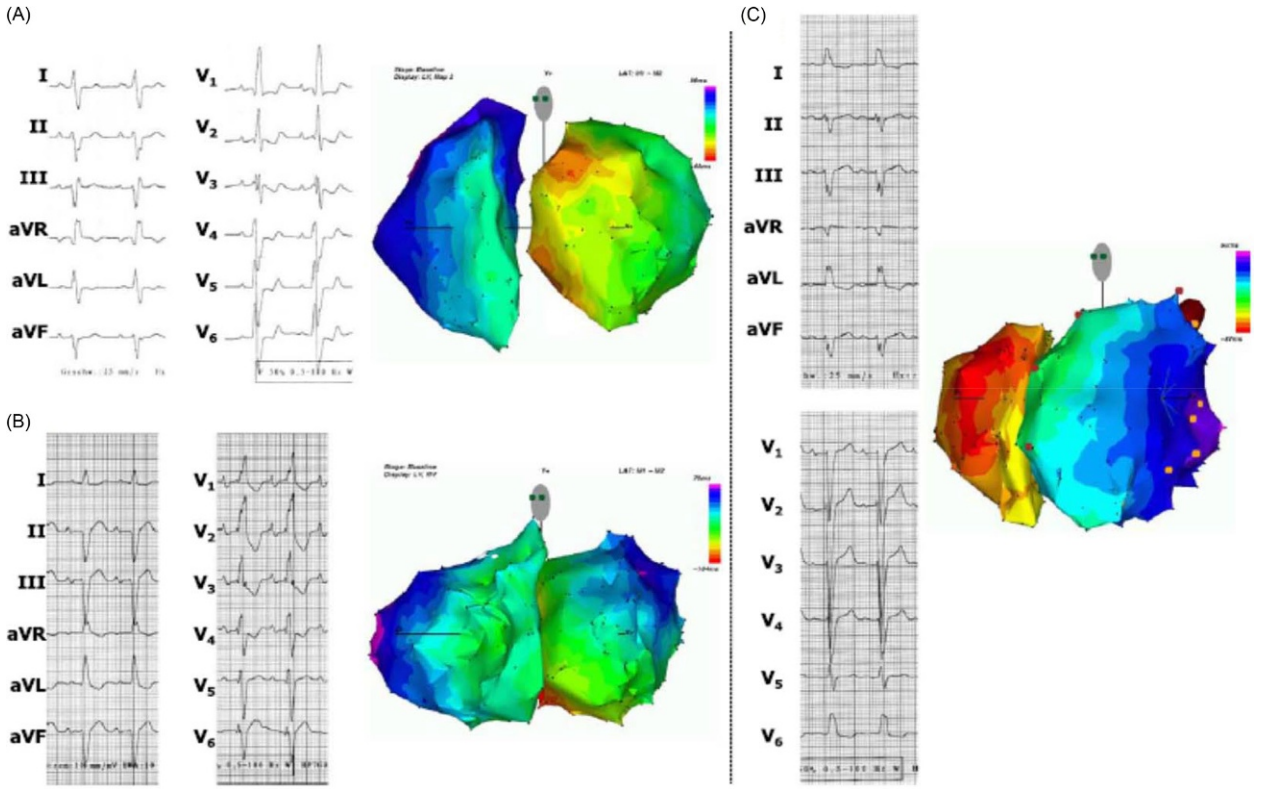

Fig. 1 Electroanatomic mapping and surface 12-lead ECG in a patient with right bundle branch block (RBBB; A), in a patient with RBBB masking left bundle branch block (LBBB; B), and in a patient with LBBB (C). The activation sequence is color coded by 10-ms isochrones (*red* indicates the earliest activation region, and *purple* indicates the latest activation region). With permission from Wolters Kluwer health, Inc. Auricchio A, et al. Does Cardiac Resynchronization Therapy Benefit Patients With Right Bundle Branch Block. Circulation: Arrhythmia and Electrophysiology 2014;7:532–542.

After conduction through the right bundle, which activates the right ventricle (RV) first, the LV is subsequently activated via slow muscle-to-muscle communication from the septum over to the lateral LV wall (**Fig. 1**). Since this activation is not through the rapid His–Purkinje system, the conduction time is slow (reflected by a prolonged QRS), and activation of the septum and the lateral LV walls does not occur concomitantly but rather sequentially, or dyssynchronously, leading to wasted cardiomechanics. This activation pattern has been confirmed in an elegant canine study (Russell et al., 2013). **Fig. 2** demonstrates how the dyssynchronous electrical activation of the LV causes the early activated septum to contract against a reduced load, which leads to prestretch of the LV lateral wall. This prestretch increases contractile force of the LV free wall, which in turn paradoxically stretches the septum later in systole. Both types of systolic stretching can be considered wasted work, which is the ratio of negative and positive work. This wasted mechanics leads to decreased maximum rates of rise and fall of the LV pressure (dP/dt_{max} and dP/dt_{min}), which in turn leads to increased end-diastolic volume (EDV) and end-systolic volume (ESV) and decrease of ejection fraction (EF) (Leyva et al., 2014).

Right ventricular pacing-induced LBBB

The DAVID (Dual Chamber and VVI Implantable Defibrillator) trial (Wilkoff et al., 2002) demonstrated that dual-chamber pacing (DDD mode at a rate of 70 ppm) was inferior to bradycardia-initiated RV pacing (VVI mode at 40 ppm). This surprising result reflects that pacing a high percent of time from the RV activates the RV and LV in a pattern identical to native conduction with a LBBB. Thus active intervention with DDD pacing, resulting in RV pacing, created a dyssynchronous and deleterious impact on RV and LV hemodynamics that did not occur with VVI RV pacing at a much lower frequency of RV stimulation (Akerstrom et al., 2014). The long-term effects of RV pacing have been described in many studies (Karpawich et al., 1999; Adomian and Beazell, 1986). These reports confirm that RV pacing causes adverse remodeling which leads to increased EDV and reduction in EF; correction of single-site RV pacing by addition of a LV lead for BiV pacing reverses these adverse effects (Leon et al., 2002).

Nonleft Bundle Branch Block Conduction Delay

Right bundle branch block

In HF patients with right bundle branch block (RBBB) (Fantoni et al., 2005), the earliest ventricular activation is at the septum (**Fig. 1A**) and, after a considerable delay (50–70 ms), the activation arrives at the RV septum. The activation front then proceeds toward the RV anterior wall and then to the right lateral wall and the outflow tract, which are the latest activated regions. In RBBB conduction, the LV walls are synchronously activated via the His-left bundle branch and Purkinje system.

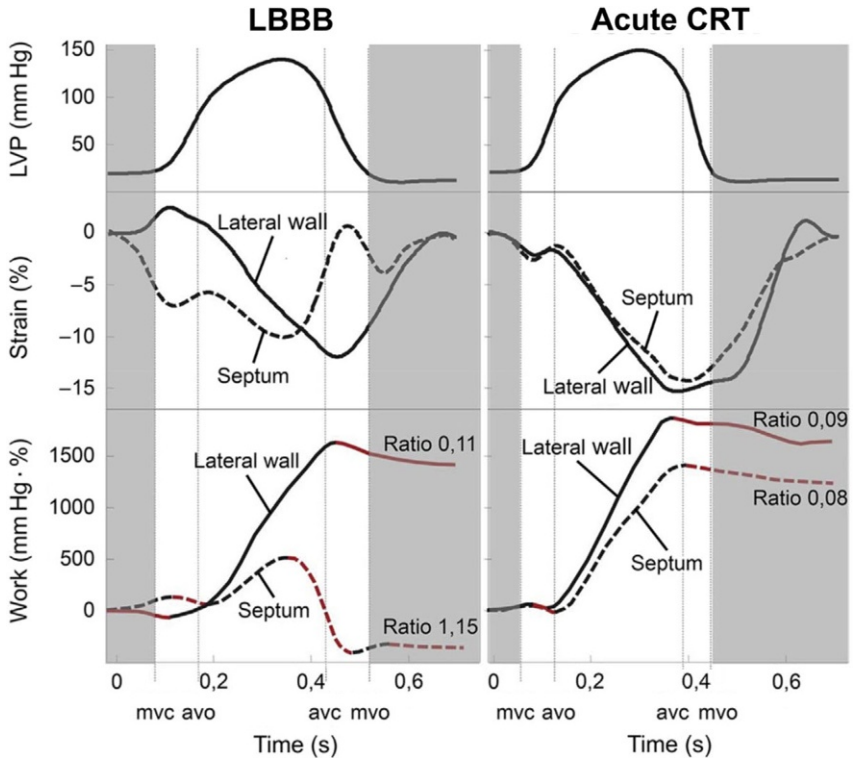

Fig. 2 Estimated LV pressure (top), strain (middle), and calculation of wasted work for the septum and lateral wall (bottom) in a representative patient with left bundle branch block (LBBB; left) and after treatment with cardiac resynchronization therapy (CRT; right). *Vertical lines* indicate valvular events measured by echocardiography. Negative and positive work during systole is marked as *red* and *black*, respectively. Wasted work ratios (WWRs) were calculated using cumulated work from MVC to MVO. *LVP*, left ventricular pressure; *MVC*, mitral valve closure; *MVO*, mitral valve opening. With permission from Russell K, et al. Am J Physiol Heart Circ Physiol 2013;305:H996–H1003.

In some HF patients with RBBB, there is a specific electrocardiographic pattern defined by Rosenbaum et al. (1973) as RBBB masking LBBB (Fig. 1B). In patients with RBBB masking LBBB, electroanatomic mapping data have demonstrated that not only RV activation is abnormally delayed, but also LV activation is delayed to a same degree as in patients presenting with LBBB (Fantoni et al., 2005).

The hemodynamic effects of RBBB are not well understood in humans. In the 1980s, Yasui et al. (Yasui et al., 1985) induced experimental RBBB in dogs with normal hearts and in dogs with moderate and severe RV hypertrophy. RBBB increased RV end-diastolic pressure, RV dP/dt_{max}, and stroke volume. This deterioration was related to the duration of the QRS complex. In multiple studies (Byrne et al., 2007; Takamatsu et al., 2008), a RBBB conduction does not significantly alter LV EF; however, there is dyssynchronous activation and deterioration in RVEF.

Non-specific interventricular conduction delay

There is no hemodynamic data in patients with non-specific interventricular conduction delay, which is a term applied to conduction patterns that are not compatible with a typical morphology of a bundle branch block or fascicular block (Eschalier et al., 2015). In an epidemiologic study (Aro et al., 2011), non-specific interventricular conduction delay pattern was associated with increased all-cause mortality, increased cardiac mortality, and elevated risk of arrhythmic death ($P < 0.001$).

Benefit of CRT

Alteration in Hemodynamics

The goal of CRT is to help correct/minimize the adverse impact of electrical dyssynchrony. By simultaneously delivering a pacing impulse to the RV and LV, the intended goal is to resynchronize activation of the ventricular walls. Since activation by the pacing stimuli is still via a muscle-to-muscle communication, rather than through the His–Purkinje system, the conduction pattern with BiV pacing is certainly not better than when compared to native conduction with a narrow QRS, but the intent of BiV pacing is to enhance synchrony when compared to native conduction with a wide QRS. A visual depiction of cardiac resynchronization is shown in Fig. 3 (Ghosh et al., 2011).

In an animal model of BiV pacing, total activation time and QRS duration is shortened compared with LBBB conduction and BiV stimulation results in an immediate improvement in hemodynamics (Strik et al., 2012b). Acutely, BiV pacing increases dP/dt_{max}

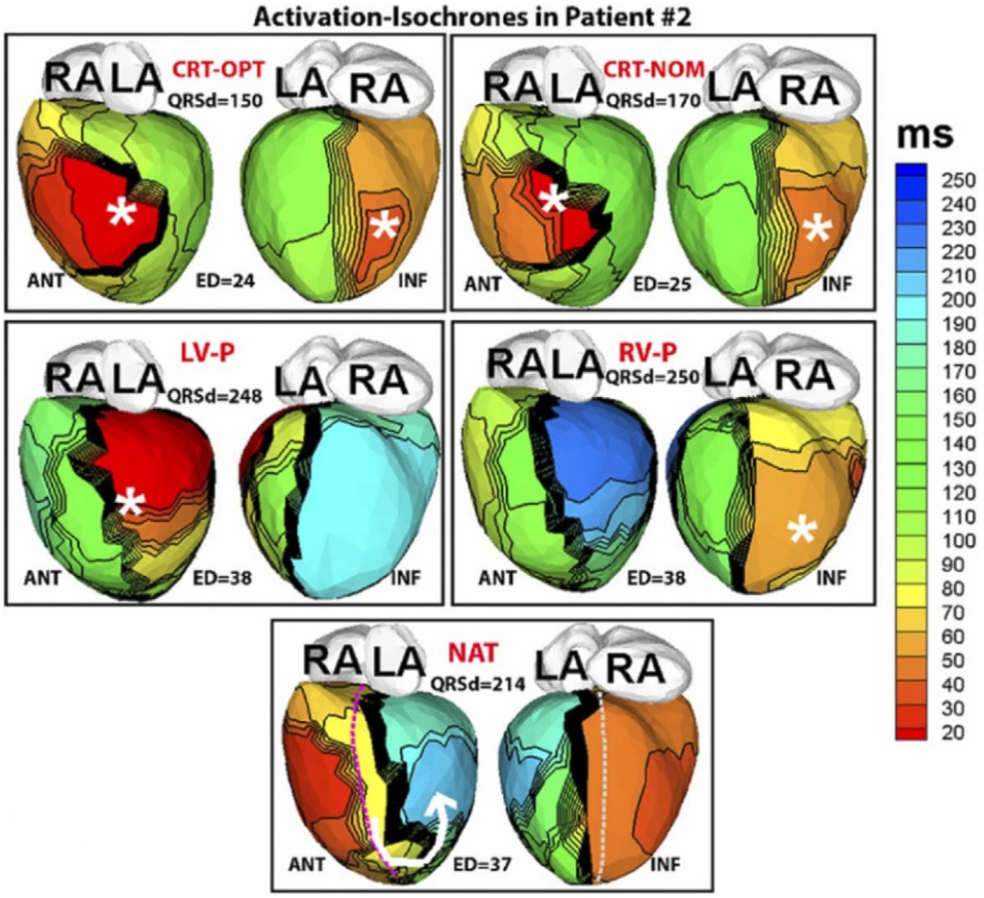

Fig. 3 Activation-isochrone maps in a patient who had a wide QRS (QRS duration QRSd = 215 ms) preimplant and responded well to CRT. Isochronal lines are depicted in *black*. *Thick black lines* indicate conduction block, while crowded *isochronal lines* indicate slow conduction. Pacing sites are indicated by asterisk. Each panel shows anterior (left, ANT) and inferior (right, INF) four-chamber views. Epicardial activation sequences are imaged during (1) optimal CRT settings (CRT-OPT), (2) nominal CRT settings (CRT-NOM), (3) LV pacing (LV-P), (4) RV pacing (RV-P), and (5) native sinus rhythm (NAT). QRS duration (QRSd) and electrical dysynchrony index (ED) computed from the epicardial activation maps (in milliseconds) are shown for each rhythm. *RA*, right atrium; *LA*, left atrium. The septal aspect of the epicardium is shown by *dotted lines* (*purple*, ANT view and *gray*, INF view) in the NAT panel. With permission from Ghosh S, et al. Heart Rhythm 2011;8(5):692–629.

often to pre-LBBB levels in animal model (Strik et al., 2012a) (**Fig. 2**) and increases about 10%–30% in human studies (Leclercq et al., 1998; Kass et al., 1999). An important additional finding is that this increase in dP/dt is without affecting LV end-systolic or end-diastolic pressures. This increase in dP/dt is thus without compromise in Starling mechanics. With increased dP/dt, there is also an increase in pulse pressure, cardiac index, and stroke work (Auricchio et al., 1999; Leclercq et al., 1998; Gold et al., 2005; de Roest et al., 2013). However, it should be noted that BiV pacing does not necessarily reduce QRS duration (see **Fig. 3**) (Leclercq et al., 1998; Kass et al., 1999; Lambiase et al., 2004). Also, hemodynamic improvement does not correlate to a specific change in QRS duration or morphology (Verbeek et al., 2002; Gold et al., 2012).

Chronically, BiV pacing results in extensive reverse-remodeling, reflected by improvements in pressure–volume loops (improvement of ESV and EDV and LV EF) recorded after 6–12 months of CRT (**Fig. 4**) (Steendijk et al., 2006,; de Roest et al., 2013). Although dP/dt_{max} improves in comparison to prepacing measurements, the value does not recover to normal (Vernooy et al., 2007).

Alterations in Cellular Physiology

The molecular aspects of reverse remodeling are explained in **Fig. 5** (Kirk and Kass, 2015) and **Table 1**. CRT helps reverse adverse changes in calcium handling (Aiba et al., 2009; Sachse et al., 2012; Nishijima et al., 2007; Li et al., 2015), increase expression of β receptors (Chakir et al., 2009; Vanderheyden et al., 2008; Chakir et al., 2011; Feldman et al., 1988), and change ion channel expression (Valdivia et al., 2005; Wagner et al., 2006; Aiba et al., 2013; Chakir et al., 2008; Nuss et al., 1999; Markowitz et al., 2009). CRT also helps increase sarcomere force by increasing sensitivity to calcium stimulation (Kirk et al., 2014; Shah et al., 2014; Orrego et al., 2011), increasing and organizing α-actinin (an integral myofilament Z-disk protein) (Lichter et al., 2014), and reducing cleavage of tethering protein desmin (Agnetti et al., 2014). CRT has been demonstrated to improve glucose metabolism (Lionetti et al., 2007; Lionetti et al., 2009; Nowak et al., 2003) and mitochondrial oxygen consumption (Agnetti et al., 2010). Lastly, various

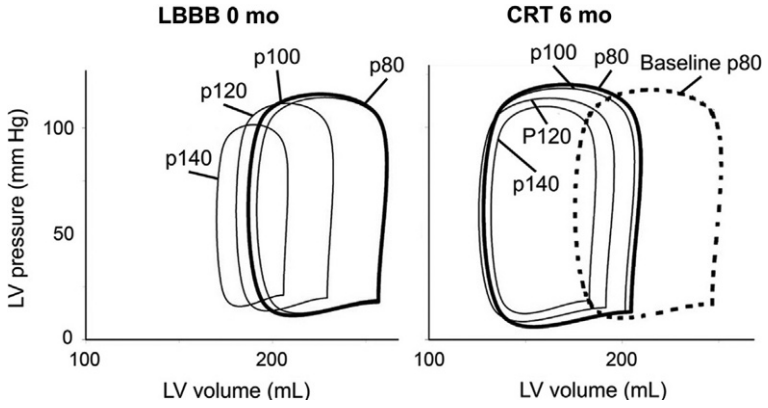

Fig. 4 Mean pressure–volume loops at baseline and after 6 months of CRT. Mean pressure–volume loops are based on mean end-systolic and end-diastolic pressures and volumes and are shown at heart rates 80, 100, 120, and 140 bpm. With permission from Steendijk P, et al. Circulation 2006;113(10):1295–1304.

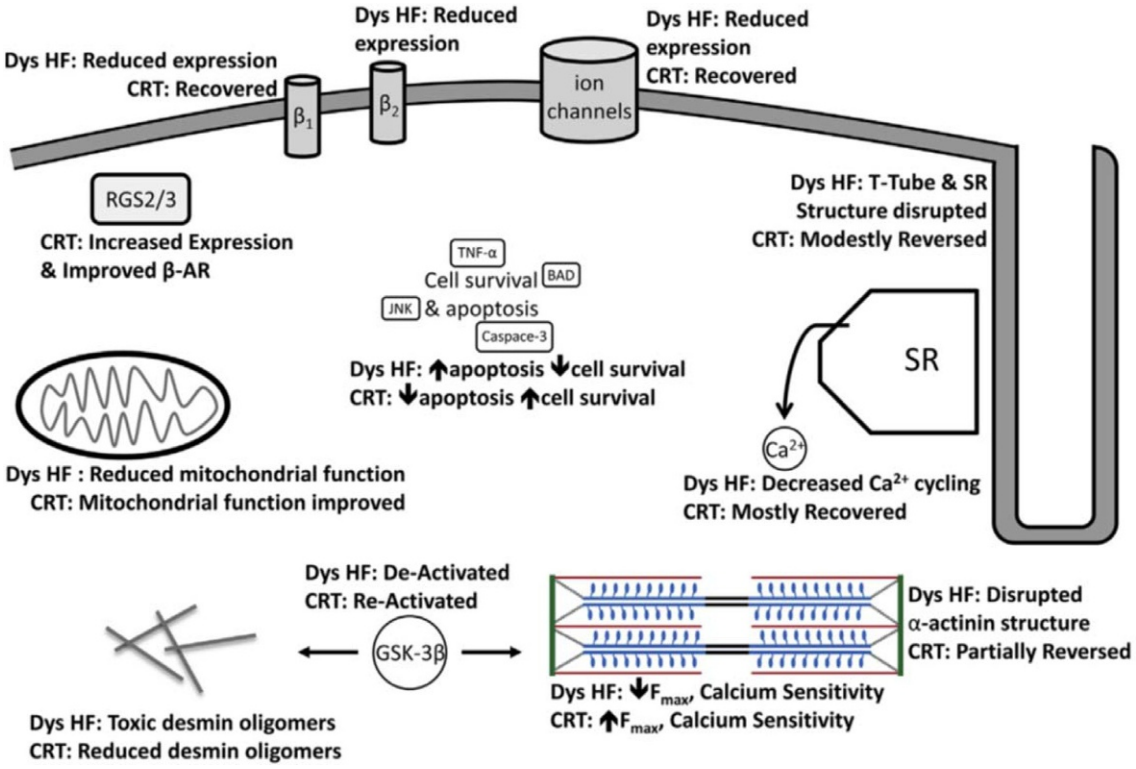

Fig. 5 Summary of molecular alterations in dyssynchronous HF (Dys HF) and CRT. *β-AR*, β-adrenergic receptor; *SR*, sarcoplasmic reticulum. With permission from Kirk JA and Kass DA. Card Electrophysiol Clin 2015;7(4):585–597.

antiapoptotic mechanisms are initiated with CRT: reduction in tumor necrosis factor α (Rordorf et al., 2014; Limongelli et al., 2014), increase in micro RNA-30d (Melman et al., 2015), and reduction in proapoptotic protein annexin-A5 (Ravassa et al., 2010).

Implantation of Biventicular Pacing System

Left Ventricular Lead Placement

When implanting a BiV pacing system, it is recommended to place the RV lead first because it is less likely to dislodge during manipulation of other leads, provides information about the position of the tricuspid valve and right atrial size, and can be used for backup pacing if, in the setting of LBBB, the right bundle suffers mechanical trauma with subsequent complete heart block.

Table 1 Chronic molecular changes seen with CRT

Molecular substrate	*Changes with HF*	*Changes with CRT*
Calcium handling	Restructuring of T-tubules	Improved structure
	Downregulation of sarcoplasmic reticulum	Improved structure
	Downregulation of ryanodine receptor	Improved structure
	Decreased calcium transients	Enhanced transients
β1 receptor	Downregulation	Upregulation
β2 receptor	Increased inhibitory G protein which inhibits β2 expression	Upregulation of RGS2/RGS3 which reduces inhibitory G protein hence upregulating the β2 receptor expression
Multiple ion channels	Increase in late activated Na currents	Reversal of current
Sarcomere force (F)	Reduced Ca sensitivity due to reduction in phos by GSK-3b	Increased calcium sensitivity by improved phos by GSK-3b
	Decreased α-actinin	Increased α-actinin partially
	Desmin reduction and increase in toxic cleavage products	Reversal of desmin migration and degeneration
Glucose metabolism	Uptake, hibernation, metabolic activity and energy turnover reduced	Normalization and harmonization of metabolomics
	Decreased anerobiosis	Increased mitochondrial oxygen consumption
Apoptosis	HF is pro-apoptotic via increase in TNF-α, cardiotrophin-1, Annexin-A5 and reduction in microRNA-30d	Reversal of these pro-apototic changes

CRT, cardiac resynchronization therapy; *GSK-3b*, glycogen synthase kinase 3b; *HF*, heart failure; *Na*, sodium; *phos*, phosphorylation; *RGS*, regulator protein of G protein; *TNF*, tumor necrosis factor.

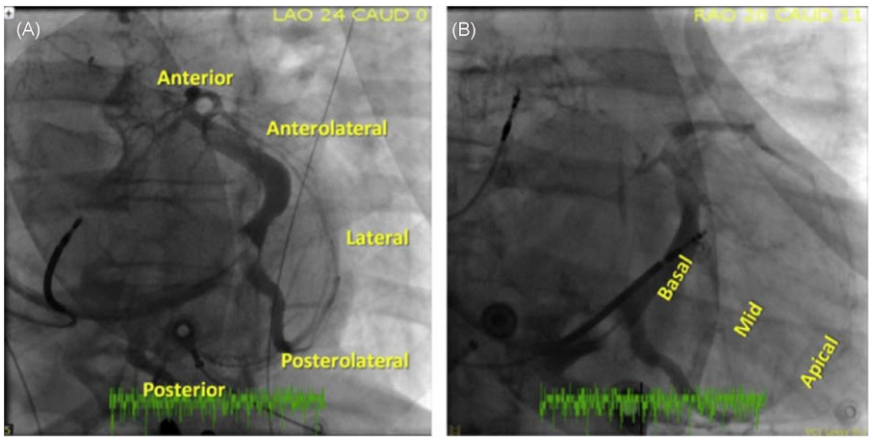

Fig. 6 Angiographic classification of CS anatomy. (A) The left anterior oblique (LAO) projection enables segmentation of the LV along the short axis, defining anterior, anterolateral, lateral, posterior, and posterior segments of the CS and its veins. (B) The right anterior oblique (RAO) projection shows the LV along the long axis, defining basal, mid, and apical segments. With permission from Roka A, et al. Card Electrophysiol Clin 2015;7(4):635–647.

LV pacing is achieved by delivering a pacing electrode to the LV epicardium via branches of the coronary sinus (CS). To cannulate the CS, venous access is achieved via central vein (typically axillary or subclavian vein), and guiding sheaths are manipulated into the right atrium under fluoroscopic guidance. Often through the use of a steerable electrophysiological catheter that is positioned in the CS body, guiding sheaths are advanced over the catheter into the CS. Once in the CS, a CS venogram is completed by balloon occlusion and hand-injection of contrast via a distal port (**Fig. 6**). The branches of the CS are named by their anatomic location, and there is considerable variation in anatomy. By defining the CS anatomy, the guiding sheaths and LV pacing electrode can be positioned into the most desired location. Most LV leads are implanted using over the wire technique, using a flexible coronary guidewire. For veins with acute takeoff, preshaped telescopic sheaths can be used (Jackson et al., 2013). Certain techniques like venoplasty (Luedorff et al., 2009) (angioplasty of vein using balloon catheter over wire), dilatation (Abben et al., 2010) of the collateral veins, and various other techniques using coronary balloons and guidewires can increase implantation success rate from the expected success rate of 92%–95%, to as high as 99%.

The goal of CS pacing is to position the lead in a lateral, basal, or mid-location, with a reasonable capture threshold (typically $<2/2.5$ V at 0.5 ms) and without phrenic nerve stimulation. Since the lateral region of the LV is activated last, the goal is to stimulate this region by the pacing electrode. In some patients, access to the CS is challenging due to presence of venous valves, such as the Thebesian valve located at the superior position of the CS os and the valve of Vieussens that is more distal in the CS (Noheria et al., 2013; Da Costa et al., 2012; Habib et al., 2009).

Complications of CRT

There are multiple complications with the procedure and the device during and after implantation. Complications are listed in **Table 2**; yet two large metaanalyses provide greater insight (McAlister et al., 2007; van Rees et al., 2011). In about 6123 patients (McAlister et al., 2007), CRT implant success rate was ~93% with periimplant mechanical complications occurring in 4.3% of procedures, and periimplant mortality of 0.3% of patients. Pneumothorax is reported in 0.5%–0.9% cases (van Rees et al., 2011; Peterson et al., 2009). The LV lead is a cause of many of the periimplant mechanical complications and mortality. The complications from LV lead have ranged from 1.9% to 4.6% based on multiple studies (Leon et al., 2005b; Alonso et al., 2001; Hansky et al., 2002; Nof et al., 2008), and this is contributed equally by coronary vein dissection (1.3%) and coronary vein perforation (1.3%) (van Rees et al., 2011). Lastly, lead dislodgement of the LV lead has been recorded from as low as 2.9% to as high as 10.6% in various clinical trials (van Rees et al., 2011). During the follow-up period of various trials (**Table 3**), 5% of devices malfunctioned, 1%–2% of patients had infections in the implant site requiring hospitalization, 6%–7% patients had lead-related problems, and pocket hematoma occurred in 2.4% of CRT recipients (van Rees et al., 2011). Phrenic nerve stimulation, which is another common complication of the LV lead, occurs in as many as 13% of patients and is more common at midlateral/posterior, and LV apical sites (Biffi et al., 2013).

Clinical Trials of CRT (Table 3)

Trials Enrolling NYHA Class III and Ambulatory Class IV With LV EF <35%

The first report utilizing CRT was by Cazeau et al. in 1993 (Cazeau et al., 1994). Multisite Stimulation in Cardiomyopathy (MUSTIC) was the first randomized study on CRT (Linde et al., 2002) and was followed by the first blinded randomized controlled trial, the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) study (Abraham et al., 2002). The MIRACLE trial demonstrated that CRT improves HF symptoms and quality of life, and these results were confirmed by the MIRACLE-ICD (Young et al., 2003) and the Pacing Therapies for Congestive Heart Failure study (PATH-CHF) (Auricchio et al., 2002).

Table 3 Randomized Trials of CRT arranged in chronological order with positive results presented in the last column

Trial	*Year*	*Pts*	*Study Design*	*Follow up (mo)*	*Enrollment QRS duration (ms)*	*Enrollment NYHA Class*	*EF (%)*	*% LBBB*	*SR/AF included?*	*Results (only significant values)*
MUSTIC-SR	2002	58	Single-blinded, crossover CRT pacing on or off	12	≥150	III Ischemic and nonischemic	≤35	87	SR	6-min walked distance increased by 20% ($P=0.0001$); QOL improved by 36% ($P=0.0001$); NYHA class improved by 25% ($P=0.0001$)
MUSTIC AF	2002	43	Single-blinded crossover CRT pacing on or VVI pacing	12	≥200	III Ischemic and nonischemic	≤35	NR	AF	6-min walked distance increased by 17% ($P=0.004$); QOL improved by 32% ($P=0.002$); NYHA class improved by 27% ($P=0.0001$)
MIRACLE	2002	453	Double-blinded, parallel control CRT pacing on or off	6	≥130	III, IV Ischemic and nonischemic	≤35	NR	SR	6-min walked distance increased (+39 vs. +10 m, $P=0.005$); NYHA class improved ($P<0.001$); QOL improved (−18.0 vs. −9.0 points, $P=0.001$); exercise time improved (+81 vs. +19 s, $P=0.001$); HF hospitalization reduced (8% vs. 15%, $P<0.05$); intravenous medications use reduced (7% vs. 15%, $P<0.05$); EF improved (+4.6% vs. −0.2%, $P<0.001$)
PATH CHF	2002	42	Single-blinded, crossover CRT pacing on or off	12	≥120	III, IV Ischemic and nonischemic	NR	97	SR	VO_2 increased ($P<0.05$); 6-min walked distance increased ($P<0.05$)
MIRACLE ICD	2003	369	Double-blinded, parallel control CRT-D with CRT pacing on or off	6	≥130	III, IV Ischemic and nonischemic	≤35	94	SR	QOL improved (−17.5 [−21 to −14] vs. −11.0 [−16 to −7], $P=.02$); NYHA class improved (−1 [−1 to −1] vs. 0 [−1 to 0], $P=.007$); VO_2 increased (1.1 vs. 0.1 mL/kg/min, $P=.04$); exercise time improved (+56 vs. −11, $P<0.001$)
Contak CD	2003	490	Single-blinded Phase I: crossover CRT-D with CRT pacing on or off Phase II: parallel control	6	≥120	II, III, IV Ischemic and nonischemic	≤35	46	SR	VO_2 increased (0.8 vs. 0.0 mL/kg/min, $P=0.030$); 6-min walked distance increased (+35 vs. +15 m, $P=0.043$); LV systolic volume improved (−4.0 mm vs. −0.7 mm, $P<0.001$); LV diastolic volume improved (−3.4 mm vs. −0.3 mm, $P<0.001$); LV ejection fraction improved (5.1% vs. 2.8%, $P=0.020$)
PATH CHF II	2003	89	Single-blinded, randomized, crossover controlled CRT in 120–150 vs >150 ms QRS duration with 3 mo active and then 3 mo inactive pacing	6	≥120	II Ischemic and nonischemic	≤35	88	SR	VO_2 increased 2.46 mL/min/kg ($P<0.001$); anaerobic threshold increased 1.55 mL/min/kg ($P<0.001$); QOL improved 8.1 points ($P=0.004$); 6-min walked distance increased 47 m ($P=0.024$)
MIRACLE ICD II	2004	186	Double-blinded, parallel control CRT-D with CRT pacing on/off	6	≥130	II Ischemic and nonischemic	≤35	83	SR	EF improved ($P=0.02$); LV systolic volume improved ($P=0.01$); LV diastolic volume improved ($P=0.04$); NYHA class improved ($P=0.05$)
COMPANION	2004	1520	Randomized CRT-D vs. OPT or CRT-D vs. OPT	~24	≥120	III, IV Ischemic and nonischemic	≤35	86	SR	Reduced all-cause mortality and hospitalization (CRTP 0.81, CRTD 0.8, $P<0.001$);QOL improved ($P<0.001$); NYHA class improved ($P<.001$); VO_2 increased ($P<0.001$)

(*Continued*)

Table 3 (Continued)

Trial	*Year*	*Pts*	*Study Design*	*Follow up (mo)*	*Enrollment QRS duration (ms)*	*Enrollment NYHA Class*	*EF (%)*	*% LBBB*	*SR/AF included?*	*Results (only significant values)*
PAVE	2005	184	Randomized single blinded CRT-P vs. dual chamber for chronic AF with AVN ablation for rate control	24	NR	I, II, III	NR	NR	AF	6-min walked distance increased (31% vs. 24%, $P=0.04$) (better in low EF and NYHA II, III); EF better (46% vs. 41%, $P=0.03$)
CARE-HF	2005	813	Randomized CRT-P vs. OPT	~30	≥120	III, IV Ischemic and nonischemic	≤35	95	SR	Reduced all-cause mortality and hospitalization (CRT 0.54, $P<0.001$); QOL improved (−10, $P<0.001$); NYHA class improved (0.6, $P<0.001$)
HOBIPACE	2006	30	Randomized blinded, crossover CRT CRT (on vs. off) with indication of pacing and low EF	6	NR	Ischemic and nonischemic	≤40	NR	30% AF	LV systolic volume improved (−16%, $P<0.001$); LV diastolic volume improved (−9%, $P=0.022$); EF improved (22.1%, $P<0.0002$); 6-min walked distance increased (31% vs. 24%, $P=0.04$); QOL improved (−18.9%, $P=0.01$); VO_2 increased (+12.5%, $P<0.0002$); pro-BNP improved (−31%, $P<0.002$)
RethinQ	2007	172	Double blind, parallel control CRT-D vs. ICD	6	<130	III Ischemic and nonischemic	≤35	NR	NR	VO_2 increased in >120 ms QRS group not in <120 ms group ($P=0.02$ vs. $P=0.45$)
REVERSE	2008	610	Single-blinded, parallel control CRT-D with CRT pacing on or off	12	≥120	I, II Ischemic and nonischemic	≤40	61	SR	LV end-systolic volume index improved ($P<0.0001$); time-to-first HF hospitalization delayed ($P=0.03$)
Albertsen et al.	2008	50	Randomized blinded CRT-P on vs. off chamber system with one indication of pacing due to heart block	12	NR	NR	NR	8	SR	Dyssynchrony improved ($P=0.02$); pro-BNP improved ($P=0.02$)
MADIT-CRT	2009	1820	Randomized CRT-D vs. ICD	29	≥130	I, II Ischemic and nonischemic	≤30	71	SR	Reduced all-cause mortality and HF hospitalization (CRT 0.66, $P<0.001$); women, QRS >150, lower NYHA class, non-AF better outcomes; LV systolic volume improved (57 mL vs. 18mL, $P<0.001$); LV diastolic volume improved (52 mL vs. 15 mL, $P<0.001$); EF improved (11% vs. 3%, $P=0.020$)
PACE	2009	177	Randomized blinded CRT-P on vs. off chamber system with one indication of pacing due to heart block	12	NR	NR	>45	NR	SR	EF improved (62% vs. 54%, $P<0.001$); LV systolic volume better (35.7 mL vs. 25.6 mL, $P<0.001$) outcomes similar at 2 years
RAFT	2010	1798	Double-blinded, randomized CRT-D vs. ICD	40	≥120	II, III Ischemic and nonischemic	≤30	72	SR/AF/ paced	Reduced all-cause mortality and HF hospitalization (CRT 0.75, $P<0.001$) mortality analysis not significant for NYHA III, QRS >150, lower NYHA class, LBBB better outcomes

COMBAT	2010	60	Randomized blinded, crossover CRT CRT (on vs. off) with indication of pacing and low EF	17.5	NR	II, III, IV Ischemic and nonischemic	≤40	NR	SR	NYHA class improved ($P<0.001$); LV systolic volume improved ($P<0.01$); LV ejection fraction improved ($P<0.001$); quality-of-life improved ($P<0.01$)
PREVENT-HF	2011	108	Randomized blinded CRT-P vs. dual chamber system with one indication of pacing	12	NR	I, II	NR	NR	10% AF	No difference in outcomes
NARROW CRT	2013	120	Randomized CRT-D vs. ICD	16	<120	II, III Ischemic only	≤35	NR	SR	Reduced composite HF mortality, VF and HF hospitalization (CRT 0.75, $P<0.028$); LV systolic volume improved (30 mL, $P=0.003$); LV ejection fraction improved (12%, $P<0.001$)
EchoCRT	2013	809	Parallel control CRT-D with CRT pacing on or off	24	<130	III, IV Ischemic and nonischemic	≤35	NR	SR	More deaths in CRT group ($P=0.02$); no benefit seen in any subgroup
LESSER EARTH	2013	85	Parallel control CRT-D with CRT pacing on or off	12	<120	Symptoms of HF and a 6-min walk <400 m Ischemic and nonischemic	≤35	NR	SR	Negative
BLOCK HF	2013	691	Randomized blinded CRT-P vs. dual chamber system with one indication of pacing due to heart block	37	NR	I, II, III	≤50	33%	52.8% AF	Reduced all-cause mortality and HF hospitalization (CRT 0.79, $P<0.05$)
BIOPACE	2015	1810	Randomized blinded CRT-P vs. dual chamber system with one indication of pacing (class 1)	67	NR	NR	NR	17%	25% AF	No change in mortality and HF hospitalization

A paradigm shift in compelling evidence in favor of CRT in patients with moderate to severe HF was the Cardiac Resynchronization—Heart Failure (CARE HF) (Cleland et al., 2005) and the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) (Bristow et al., 2004) trials that randomized patients to optimal medical therapy versus CRT (with a pacemaker in CARE HF; and, with or without a defibrillator in COMPANION). The endpoints of these two trials were "hard endpoints": all-cause mortality and hospitalization. It is noteworthy that only a few clinical trials demonstrated a reduction in total mortality with CRT and that the benefit of CRT was primarily based on the composite endpoint of all-cause mortality and hospitalization. Nonetheless, as HF hospitalizations are a major socioeconomic burden, reduction in hospitalization is a significant finding; also, metaanalyses (McAlister et al., 2007) support that CRT does result in a reduction in total mortality (**Table 3** and **Fig. 7**).

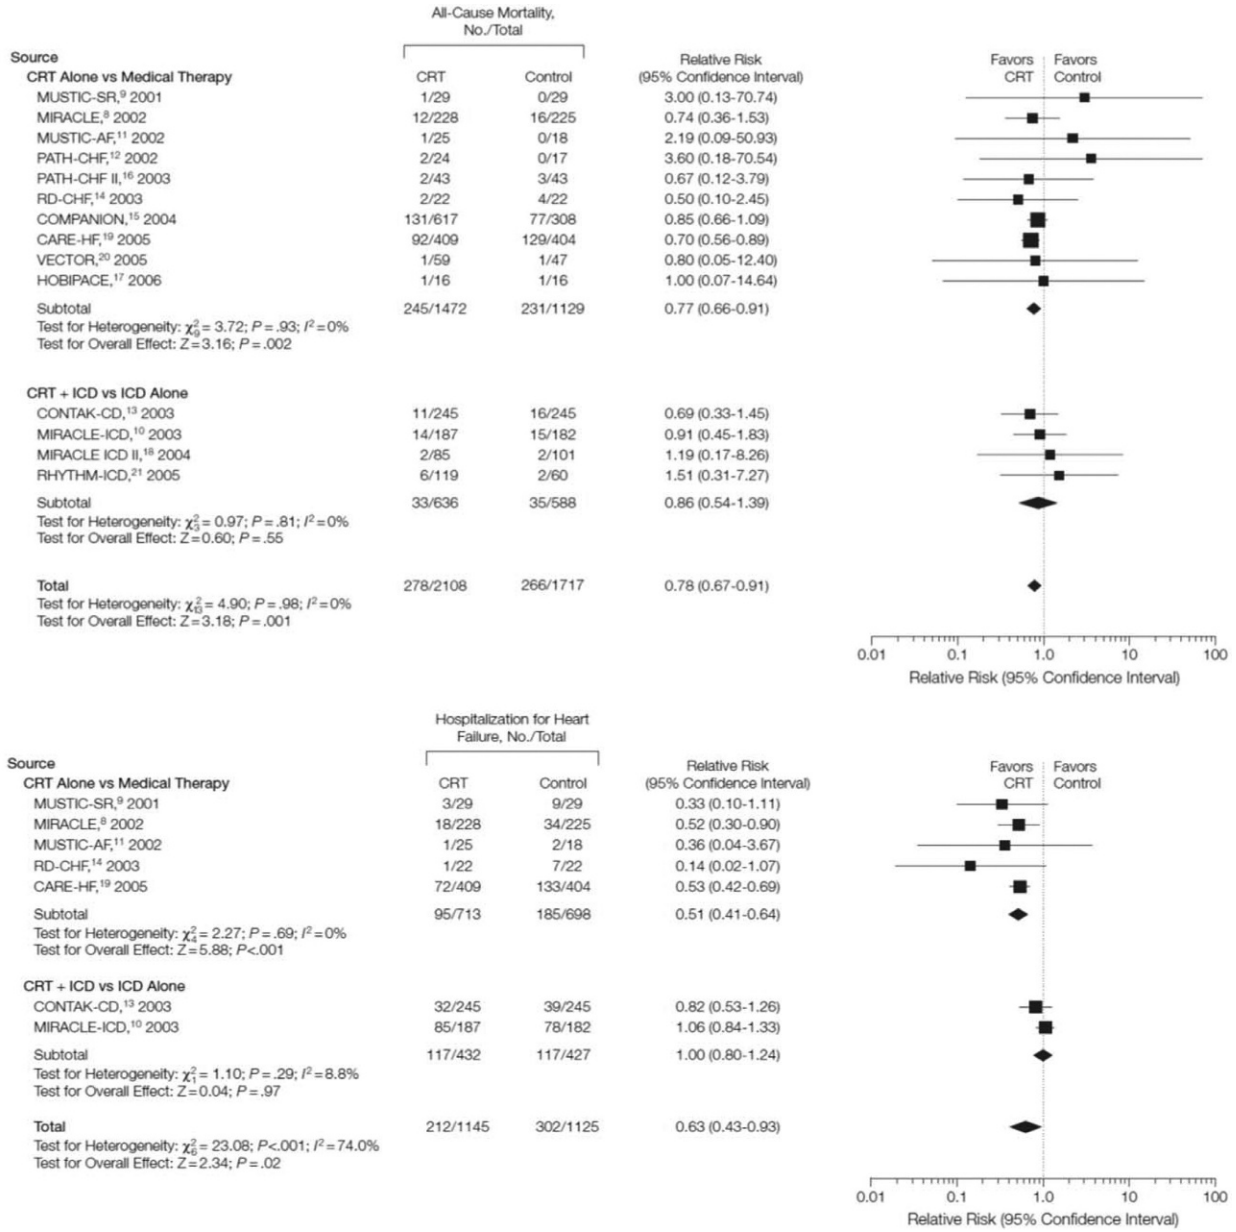

Fig. 7 Effect of CRT on all-cause mortality and proportion of patients hospitalized for heart failure (randomized trial data). *CRT*, cardiac resynchronization therapy; *ICD*, implantable cardioverter-defibrillator. Size of data markers indicates the weight of the study. With permission from McAlister FA, et al. JAMA 2007;297(22): 2502–2514.

Trials Enrolling NYHA Class I and II With LV EF <35%

The next group of patients evaluated was those with mild HF (NYHA Class I and II). The clinical trials enrolling this population of patients were MIRACLE-ICD II (Abraham et al., 2004), PATH-CHF II (Auricchio et al., 2003), Contak CD trial (Higgins et al., 2003), Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) trial (Linde et al., 2008), Multicenter Automatic Defibrillator Implantation Trial with CRT (MADIT-CRT) (Moss et al., 2009), and Resynchronization/Defibrillation for Ambulatory Heart Failure (RAFT) study (Tang et al., 2010). These trials consistently validated the benefits of CRT in patients with NYHA Class I and II symptoms. These trials have led to guidelines giving weaker recommendations for CRT in patients with ischemic cardiomyopathy with left ventricular ejection fraction (LVEF) ≤30%, QRS ≥150 ms and LBBB with NYHA Class I and Class II HF. Also patients with nonischemic cardiomyopathy with LBBB and QRS ≥120 ms with NYHA class II HF have a weak indication for CRT (Fig. 8).

High Degree of RV Pacing

In the DAVID trial (Wilkoff et al., 2002), RV pacing created a LBBB activation pattern and resulted in adverse cardiac performance. In a similar manner, clinical trials have demonstrated the value of CRT when used in patients with a high percent (>40%) of single-site RV pacing. The Biventricular Pacing for Atrioventricular Block and Systolic Dysfunction trial (BLOCK-HF) (Curtis et al., 2013) studied patients with NYHA class I–III HF and LV EF ≤50% with AV block, requiring frequent RV pacing (>40%). Patients with RV-only pacing, in comparison to patients with CRT, had more HF events, worsened LV function, and higher total mortality. Other smaller studies with a similar inclusion criteria of >40% RV pacing reported only minor clinical benefits, and no survival benefit, for

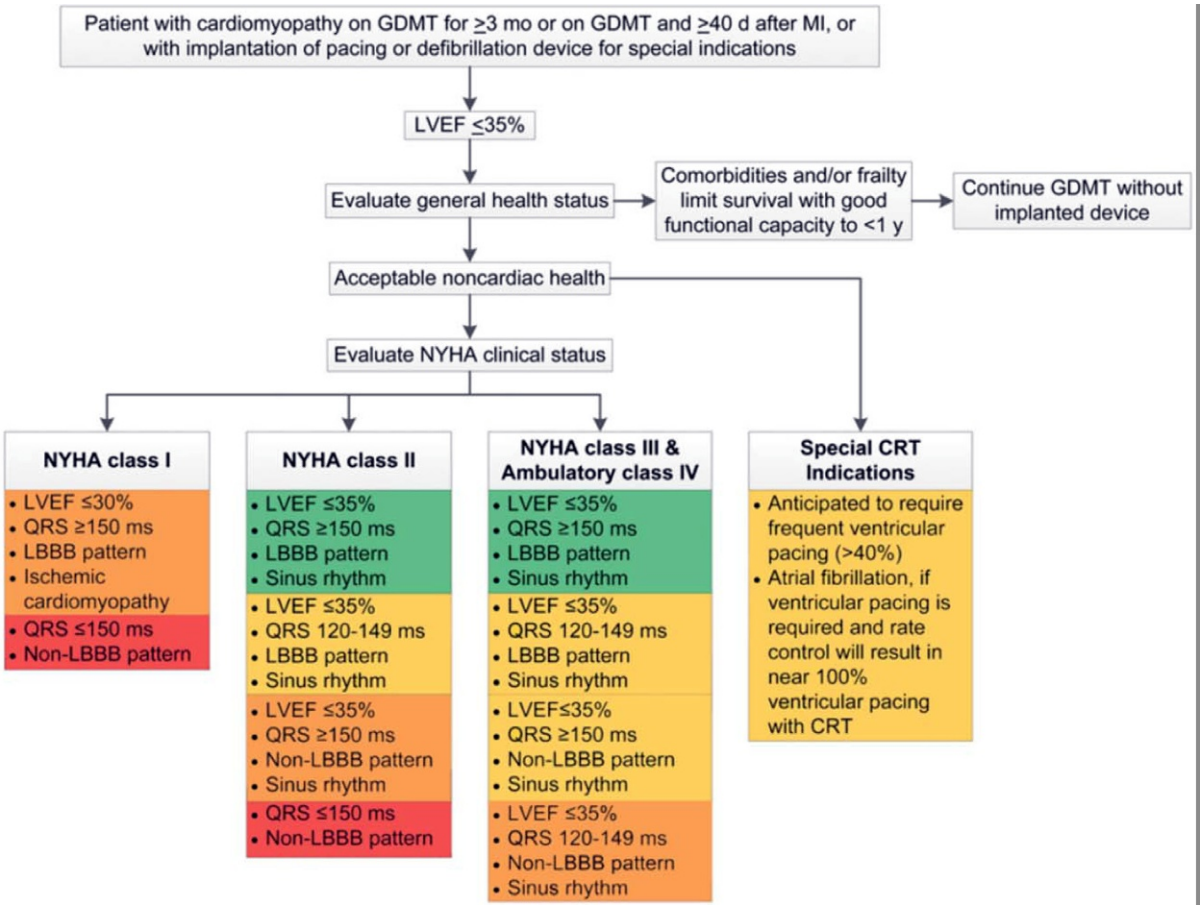

Fig. 8 2012 Indications for CRT therapy—algorithm. *CRT*, cardiac resynchronization therapy; *CRT-D*, cardiac resynchronization therapy defibrillator; *GDMT*, guideline-directed medical therapy; *ICD*, implantable cardioverter-defibrillator; *IV*, intravenous; *LV*, left ventricular; *LVEF*, left ventricular ejection fraction; *LBBB*, left bundle-branch block; *MI*, myocardial infarction; *NYHA*, New York Heart Association; *Green color*, Class 1; *Yellow color*, Class 2a; *Orange*, Class 2b; *Red*, Class 3 (or contraindicated). CRT compared to dual chamber pacing (Albertsen et al., 2008; Yu et al., 2009b; Stockburger et al., 2011; Kindermann et al., 2006; Martinelli Filho et al., 2010). However, BIOPACE (Biventricular pacing for atrIo-ventricular BlOck to Prevent cArdiaC dEsynchronization) trial (Funck et al., 2014) which was recently concluded suggests that there was no significant benefit for CRT over dual chamber pacing.

Patient Criteria for CRT

HF Patients

Consistent selection criteria for CRT have been LV EF of $\leq$35%, HF symptoms despite optimal medical therapy, and a broad QRS of $>$120 ms (Epstein et al., 2013) (**Table 4**; Vernooy et al., 2014). However, although these were the typical inclusion criteria, subsequent indications were modified to suggest the use of CRT in patients with a broader QRS duration, such as $\geq$150 ms. In general, CRT can be utilized for patients with advanced HF symptoms and a QRS of 120–150 ms, yet for mild HF symptoms, a broader QRS is recommended, $\geq$150 ms. The current guidelines for selection (summarized in **Fig. 8**) are hence based on the QRS duration, morphology, cause of HF, HF symptoms, and the need for high percent RV pacing.

Dyssynchrony Detected by Echocardiography

Numerous trials have evaluated if echocardiographic parameters are useful to identify patients who would respond to CRT. Even though echocardiographic dyssynchrony remains a prognostic marker for CRT response (Delgado et al., 2008; Hara et al., 2012; Haugaa et al., 2014; Gorcsan et al., 2004; Gorcsan et al., 2007; Gorcsan et al., 2010; Kutyifa et al., 2013; Risum et al., 2013; Sogaard et al., 2002; Suffoletto et al., 2006; Tanaka et al., 2010; Yu et al., 2009a), using echocardiographic data to guide therapy has not been shown to be of benefit (Chung et al., 2008); guidelines (European Heart Rhythm et al., 2012; Epstein et al., 2013) currently do not support echocardiographic mechanical dyssynchrony to influence patient selection.

Use of CRT in HF Patients With a Narrow QRS

Another area of investigation was the use of CRT in patients with HF but with only minimal QRS prolongation, but with evidence of echocardiographic dyssynchrony. Several studies and subgroup analysis (MADIT-CRT (Goldenberg et al., 2014), EchoCRT (Ruschitzka et al., 2013), Narrow CRT (Muto et al., 2013) trial, LESSER EARTH (Thibault et al., 2013), and RethinQ trial (Beshai et al., 2007) (Resynchronization Therapy in Normal QRS)) reported that CRT implantation using echocardiography-detected mechanical dyssynchrony as criteria in patients with QRS duration $<$120–130 ms does not improve HF outcomes. In particular, the EchoCRT trial (Ruschitzka et al., 2013) was stopped early due to increased mortality in the arm randomized to CRT, reinforcing the improved outcomes associated with narrow native QRS conduction rather than BiV pacing.

Table 4 Criteria for selection of patients and application of CRT

Criteria for patient selection	*RCT evidence*	*Single-center evidence*
QRS morphology	LBBB is the primary electrical substrate for CRT	Hearts without LBBB might be amenable to CRT if LV activation is delayed
Mechanical dyssynchrony	Adds no predictive value to CRT response in patients with definite (or definite lack of) electrical substrate	Might be predictive of CRT response in patients with intermediate QRS duration and non-LBBB morphology
Ischemic etiology and scarring	In patients with LBBB, ischemic etiology does not reduce clinical CRT response, but echocardiographic response might be reduced	LV pacing in a scarred region substantially impairs CRT response
LV lead position	No data from multi-center RCTs available	LV lead in a late-activated region improves CRT response, especially in patients with intermediate QRS duration and non-LBBB morphology of the QRS complex; the latest-activated region might differ between RV pacing and intrinsic LBBB rhythm
Percentage cumulative pacing	Almost any heart beat lost to biventricular pacing reduces the benefit of CRT, especially when the cumulative percentage is $<$95%	Atrioventricular-nodal ablation can substantially increase CRT benefit in patients with atrial fibrillation
Atrioventricular and interventricular optimization	No evidence of clinical benefit from atrioventricular or interventricular optimization, or from device-based algorithms Only the AdaptiveCRT algorithm has been associated with long-term benefit, and only in patients in whom LV fusion pacing was performed	Optimization of atrioventricular and interventricular delay improves acute hemodynamic response

CRT, cardiac resynchronization therapy; *LBBB*, left bundle branch block; *LV*, left ventricular; *RCT*, randomized controlled trial; *RV*, right ventricular.

High Percent RV Pacing

Whether CRT should be used for all patients requiring high percent of RV pacing is unclear. Evidence supports the use of CRT among patients with a depressed LV EF; however, in patients without HF or a depressed EF, the role of CRT among this population is not resolved. In favor of CRT is the concern for single-site RV pacing to promote a cardiomyopathy; the con opinion is that the benefit of CRT in patients without HF and without depressed LV EF has not been demonstrated. Other clinical features may impact cardiovascular performance in patients with preserved EF and chronic RV pacing such as gender, coronary artery disease, and other comorbidities (Herweg et al., 2015; Khurshid et al., 2014; Zhang et al., 2008; Dreger et al., 2012; Shimano et al., 2007; Ahmed et al., 2014; Hori et al., 2011; Daoud, 2015; Sweeney et al., 2003).

Nonresponse to CRT: Causes and Solutions

Although CRT helps improve symptoms and survival in most patients with HF, a large percent (30%–40%) of CRT recipients do not obtain clinical benefit and are considered clinical nonresponders (European Heart Rhythm et al., 2012; Yu and Hayes, 2013). The response rate hinges on five key elements (discussed later): appropriate patient selection, CRT implant techniques, appropriate CRT programming, patient follow-up, and multidisciplinary approach.

Nonresponse: Appropriate Patient Selection

Appropriate patient selection has been established by clinical trials (**Table 3**) and is summarized in the Appropriate Use Guidelines (Russo et al., 2013). The goal is to provide CRT to patients on optimal medical therapy and demonstrate dyssynchrony (determined solely by the QRS duration and morphology), presence of HF symptoms, and persistently depressed EF. Even with these guidelines, other features can contribute to nonresponse.

A common and important cause of nonresponse is reduction in the percent of BiV pacing. Since BiV pacing is the therapy, a low percent of BiV pacing (<96%) has been associated with increased HF, mortality, and need for transplant (Koplan et al., 2009; Hayes et al., 2011). For example, atrial fibrillation is common (~30%) (Dickstein et al., 2009) in HF population, and when AF occurs in patients with a CRT device, the irregular and often rapid native conduction through the His–Purkinje system appropriately results in inhibition of BiV pacing. In this setting, HF is exacerbated not only by the arrhythmia-induced absence of atrial contractility, irregular ventricular contraction, and rapid ventricular rate but also by the absence of CRT (Daubert, 2004; Wilton et al., 2011). Based on studies (Doshi et al., 2005), many investigators (Gasparini et al., 2008) recommend atrioventricular junction ablation in these patients to ensure 100% BiV pacing, while others support a conservative initial strategy, optimizing the medical treatment and programming the device to obtain a high percentage of ventricular pacing, and recommend reserving atrioventricular junction ablation only for patients with poor heart rate control (Tolosana et al., 2008; Delnoy et al., 2007; Khadjooi et al., 2008; Tolosana et al., 2012).

In a manner similar to AF, frequent premature ventricular contractions (PVCs) can inhibit BiV pacing (Cheng et al., 2012) and leads to worse outcomes (Ruwald et al., 2014). In a small study Lakireddy and colleagues (Lakkireddy et al., 2012) showed that radiofrequency ablation of PVC foci improves LV EF and NYHA class and promotes reverse remodeling hence enhancing CRT efficacy in nonresponders.

Other features that have been associated with reduced response to CRT include patients with dilated LV and severe mitral regurgitation indicate a lower probability of response (Diaz-Infante et al., 2005; Sweeney and Prinzen, 2008). The EAARN score which is based on preimplant risk factors (LV EF <22%; age ≥70 years, AF, renal dysfunction, and basal NYHA functional class IV) demonstrated an excellent prognosis and low mortality in patients with less risk factors, whereas those patients with three or more risk factors had a high mortality despite the benefits of the therapy (Khatib et al., 2014).

Patients with ischemic cardiomyopathy seem to have a poorer response to CRT and worse LV reverse remodeling (Diaz-Infante et al., 2005; Shanks et al., 2011). Poor conduction across extensive myocardial scar tissue (Sweeney and Prinzen, 2008) and ineffective LV remodeling of scar tissue (Ypenburg et al., 2007) may be the key determinants of the decreased response to CRT.

Female sex has been associated with higher response rates. The difference is thought to be due to difference in comorbidities, risk factors, response to medical treatment, greater nonischemic cardiomyopathy, higher LBBB morphology, and less myocardial scar (Loring et al., 2013b; Arshad et al., 2011; Leyva et al., 2011; Loring et al., 2013a; Bleeker et al., 2005).

Nonresponse: Appropriate CRT Implant Techniques

Even after selection criteria are met, lack of response to CRT is sometimes related to an inappropriate LV lead location (almost 21% of patients in one study) (Mullens et al., 2009). Apical lead position has been associated with increased mortality (Singh et al., 2011), whereas lateral, basal, or mid-ventricular position have shown good outcomes (Thebault et al., 2012; Singh et al., 2011).

Type of LV lead implanted in the CS has a great variability in outcomes. Typically, the LV lead is a bipolar lead, but recently quadripolar pacing electrodes have been developed. These four independent electrodes allow programming additional vectors and multiple pacing configurations, including multipoint pacing, which is pacing simultaneously from greater than two electrodes on the LV lead. Multiple studies of quadripolar pacing and multipoint pacing have described a lower rate of hospitalizations for HF

(Forleo et al., 2015), lower rate of surgical revision (Forleo et al., 2015), improved hemodynamics (**Fig. 9**) (Rinaldi et al., 2014; Pappone et al., 2015; Pappone et al., 2014; Zanon et al., 2016; Boriani et al., 2016; Forleo et al., 2016; Ploux et al., 2014; Shetty et al., 2014), overall good acute response to CRT (Rinaldi et al., 2014; Pappone et al., 2015; Zanon et al., 2016), improved mortality outcomes (Behar et al., 2015; Turakhia et al., 2016), and less complications (Forleo et al., 2011; Mehta et al., 2012; Boriani et al., 2016) (**Fig. 10**). There are clinical trials like MultiPoint Pacing IDE Study (Tomassoni, 2016) (MPP-IDE) and MOre REsponse on Cardiac Resynchronization Therapy with MultiPoint Pacing Study (Leclercq, 2016) (MORE-CRT MPP) which are underway which will clarify the role of quadripolar pacing in CRT. Preliminary data from the MPP-IDE study (Tomassoni et al., 2016) suggest that it is safe and shows high clinical response (87%) if the spacing between the electrodes is $\geq$30 mm with a 5 ms LV delay.

A goal of LV lead placement is to activate the latest activated region of the LV during native conduction. There are two techniques reported to help guide proper positioning of the LV lead during implantation. The first technique is the use of echocardiography. Echocardiographic guidance consists of radial strain timing toward the latest activation and away from radial strain segments with less than 10% thickening, considered to be likely scar (Khan et al., 2012; Saba et al., 2013; Marek et al., 2014; Sade et al., 2014). A second technique to guide LV lead placement is the measurement of the Q-LV lead timing. Q-LV timing refers to the time from onset of the surface QRS to the intracardiac electrogram recorded from the LV lead when placed in the final position of the CS branch. The goal is a Q-LV time of at least 50% of the QRS duration. Higher Q-LV represents higher likelihood of response and reduced timing (<50%) is associated with worse clinical outcome (Singh et al., 2006).

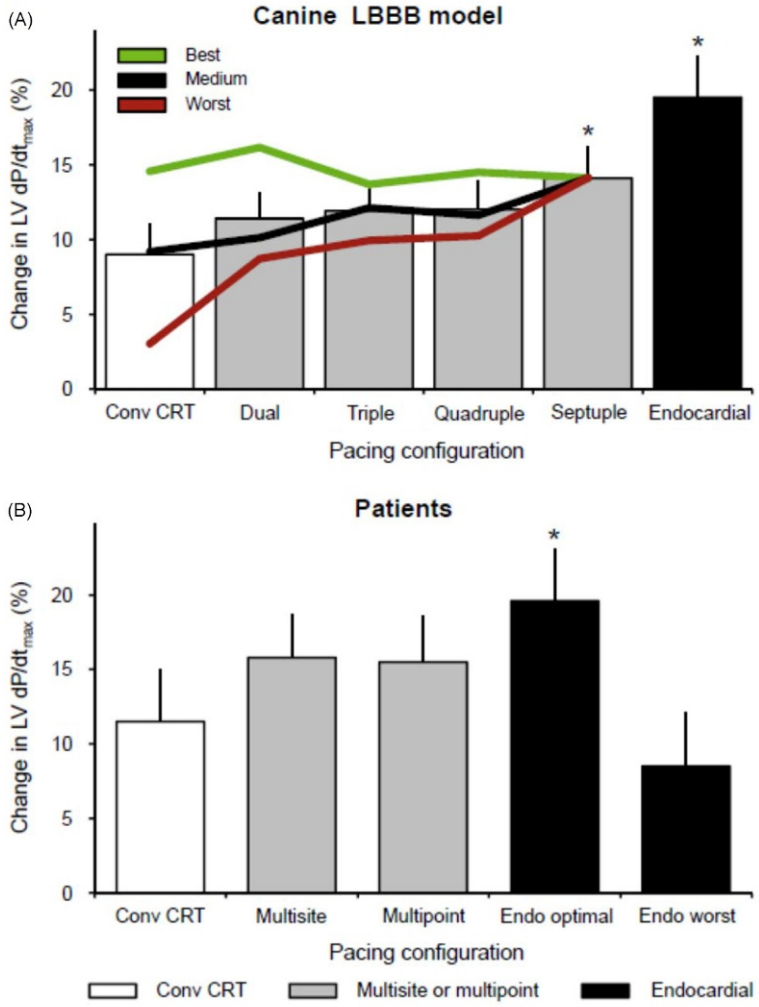

Fig. 9 Percentage change in LV dP/dt_{max} versus baseline during conventional (Conv) CRT (*white bars*), multisite or multipoint (*gray bars*), and endocardial pacing (*black bars*) measured in a canine LBBB model (A) and in patients (B). The values in the bars are presented as mean + SEM. The three lines in A are the pooled data for the two "worst," the three "intermediate," and two "best" single LV pacing sites (*red*, *black*, and *green*, respectively). $P \leq 0.05$ versus conventional CRT. With permission from Ploux S, et al. Heart Rhythm 2014;11(1):119–125; Shetty AK, et al. Europace 2014;16(6):873–879.

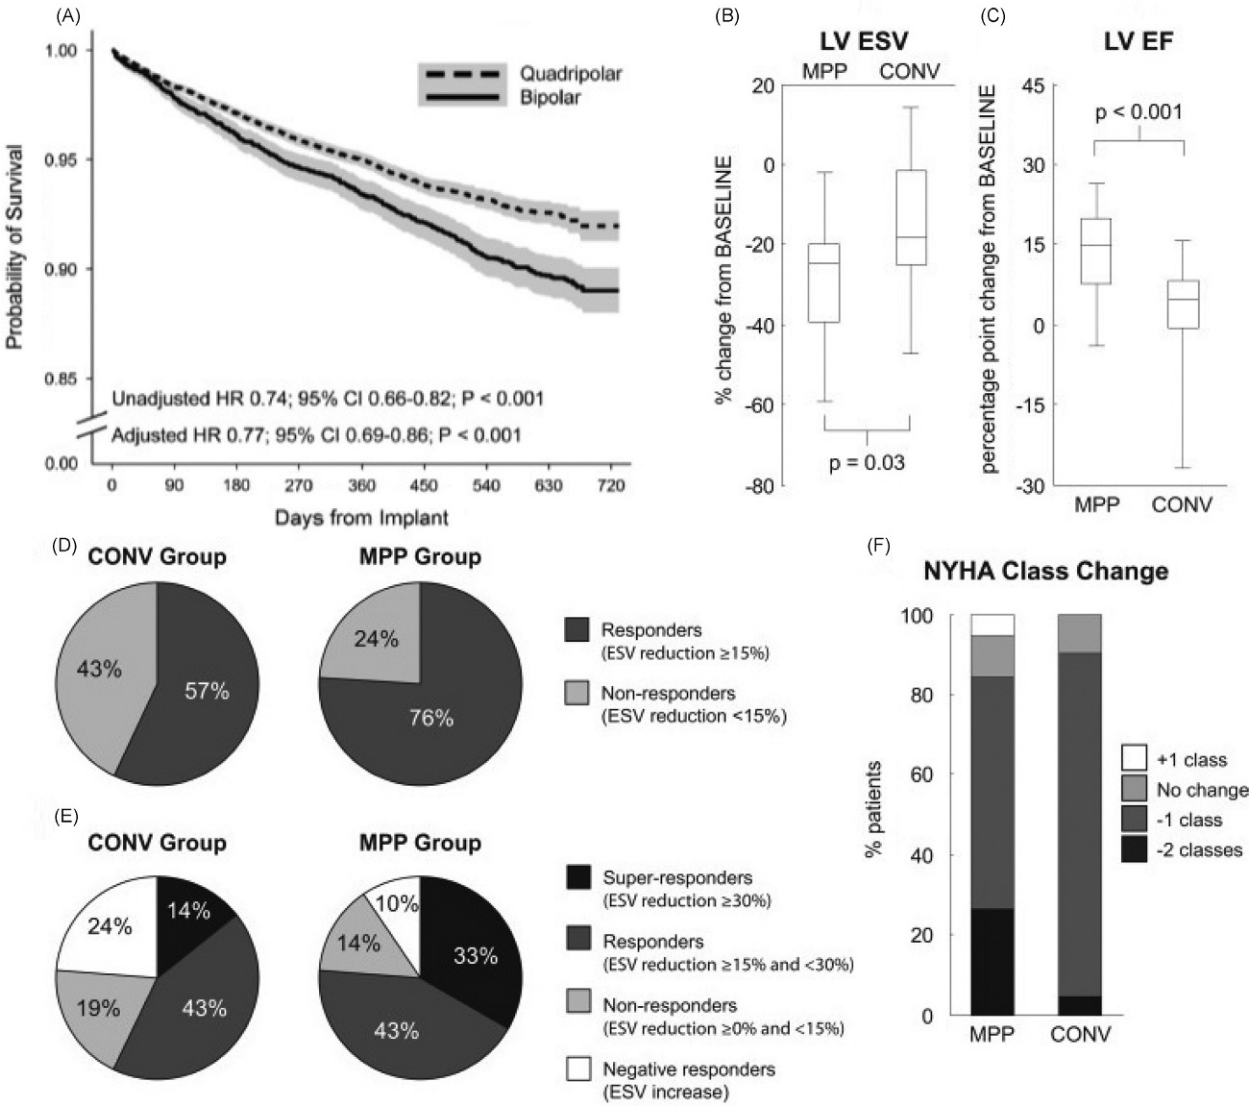

Fig. 10 (A) Kaplan Meier survival (lines) from all-cause mortality is shown with 95% CI (*shaded area*). Use of the quadripolar system was associated with a lower risk of death compared to the bipolar system. The quadripolar group was more heavily censored because these patients were implanted later in the observation period. (B, C, F) Change in echocardiographic and clinical parameters from BASELINE to 12-month follow-up. Boxplots show the median (central mark), 25th and 75th percentiles (box edges), and minimum and maximum values (whiskers). After 12 months, patients in the MPP group had significantly improved LV end systolic volume (LVESV) and LVEF compared to patients in the CONV group. (D and E) Response in MPP and CONV groups. CRT response at 12 months was defined by end-systolic volume LVESV decrease $\geq$15% relative to BASELINE and alive status. An additional analysis divided patients into super-responders with reduction in LVESV of $\geq$30% relative to BASELINE and negative responders with increase in LVESV relative to BASELINE or death during the observation period. *CI*, confidence interval; *CONV*, conventional cardiac resynchronization therapy; *CRT*, cardiac resynchronization therapy; *HR*, hazard ratio; *LVEF*, left ventricular ejection fraction; *LVESV*, left ventricular end-systolic volume; *MPP*, multipoint pacing; *NYHA*, New York Heart Association. With permission from Turakhia MP, et al. JACC: Clinical Electrophysiology 2016; Pappone C, et al. Heart Rhythm 2015;12(6):1250–1258.

Nonresponse: Appropriate CRT Programming

Finally, response to CRT has been suggested to be improved through techniques to optimize atrioventricular synchrony as well as synchrony of LV and RV events (termed VV timing). The two main techniques are echocardiography and the use of intracardiac electrogram events.

Echocardiography is used to time mechanical activation of events to guide CRT programming. Unfortunately, this technique has not been shown to be of benefit when applied universally but may be successful for an individual patient in whom other techniques to improve response to CRT have failed **Table 5** (Auger et al., 2013; Leon et al., 2005a; Cleland et al., 2005; Ellenbogen et al., 2010; Martin et al., 2012b; Sawhney et al., 2004; Chung et al., 2008; Abraham et al., 2012).

Table 5 Summary of the various methods of AV and VV interval optimization

	AV optimization	*Clinical trial using the algorithm*	*Results*	*VV optimization*	*Clinical trial using the algorithm*	*Results*
Echocardiography	Mitral inflow (Ritter method, iterative method, "fast and simple")	InSync III trial	Increased exercise capacity but no change in overall symptomatology	LV M-Mode (septal-posterior wall motion delay)	Abraham WT, et al. Am Heart J 2012;164 (5):735–41	NYHA class and HF composite score improved in VV optimized mode
		CARE-HF				
		SMART-AV	No difference in 6-mo change in LVESV, NYHA class, QOL, or 6-min walk			
		Adaptive CRT trial	Adaptive CRT was noninferior to echo optimization in clinical composite score (73.6% vs. 72.5% improved)			
	Aortic VTI	Sawhney NS, et al. Heart Rhythm 2004;1 (5):562–7	Mild improved in NYHA class, quality of life, ejection fraction	Tissue Doppler imaging	PROSPECT	No difference in optimized versus standard therapy
		Adaptive CRT trial	Adaptive CRT was noninferior to echo optimization in clinical composite score (73.6% vs. 72.5% improved)	Aortic VTI	InSync III trial	Increased exercise capacity but no change in overall symptomatology
					AdaptiveCRT trial	Adaptive CRT was noninferior to echo optimization in clinical composite score (73.6% vs. 72.5% improved)
Intracardiac electrogram-based	SmartDelay™	SMART-AV	No difference in 6-mo change in LVESV, NYHA class, QOL, or 6-min walk	Expert Ease™	DECREASE-HF	Non inferior compared to standard algorithm
		PEGASUS-CRT	No change in outcomes compared to standard delay			
	QuickOpt™	FREEDOM	No difference in 12-mo clinical composite score	QuickOpt™	FREEDOM	No difference in 12-mo clinical composite score
	AdaptivCRT™	Adaptive CRT trial	Noninferior to echo optimization in clinical composite score (73.6% vs. 72.5% improved)	AdaptivCRT™	Adaptive CRT trial	Noninferior to echo optimization in clinical composite score (73.6% vs. 72.5% improved)
QRS based	Fusion optimized intervals (FOI)	Arbelo E, et al. J Cardiovasc Electrophysiol 2014; 25(3):283–92	Improved acute hemodynamics	Fusion optimized intervals (FOI)	Arbelo E, et al. J Cardiovasc Electrophysiol 2014; 25(3):283–92	Improved acute hemodynamics

Another method to enhance AV/VV synchrony is based on intracardiac electrograms. These studies—SmartDelay™ (Ellenbogen et al., 2010), Quickopt™ (Abraham et al., 2010), and Adaptive CRT (Martin et al., 2012b)—did not demonstrate significant improvement when optimization was guided by altering the timing of activation of intracardiac electrograms (2016; Ellenbogen et al., 2010; Martin et al., 2012a; Rao et al., 2007; Abraham et al., 2012), but the AdaptivCRT™ (Daoud et al., 2016) have shown small modest benefits in reducing readmission (Singh et al., 2013) and noninferiority to echocardiography-guided synchronization techniques (Birnie et al., 2013) but no difference in mortality or morbidity (Martin et al., 2012b). QRS shortening using various algorithms have been associated with good clinical response and echocardiographic improvement (Lecoq et al., 2005; Hsing et al., 2011). Finally, fusion-optimized intervals (Arbelo et al., 2014), which uses fusion with intrinsic conduction to achieve the shortest possible QRS by BiV pacing with the intrinsic rhythm, have been found to improve acute hemodynamic response, but it is unclear if this will translate into long-term benefit (Arbelo et al., 2014) (**Table 4**).

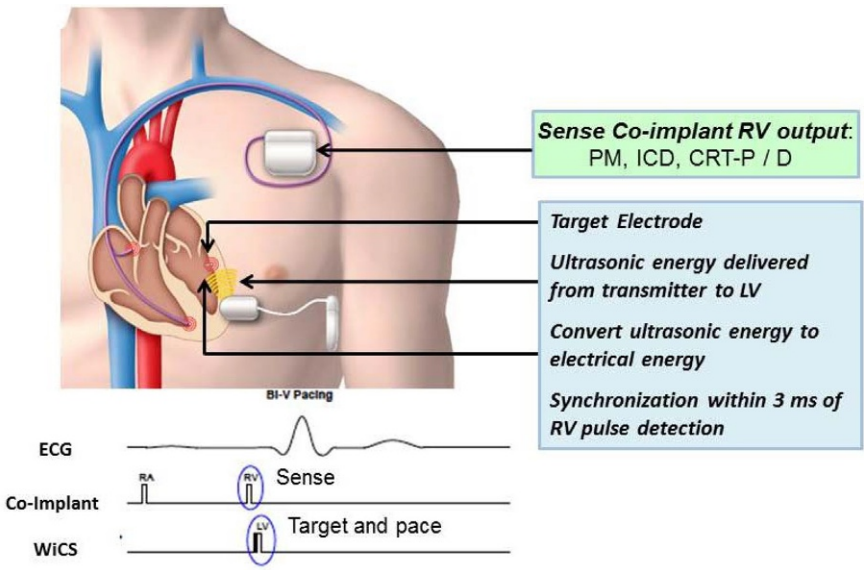

Fig. 11 Ultrasound-based wireless cardiac stimulation system (WiCS, EBR Systems), which includes a 9-mm leadless pacing electrode implanted at the endocardial mid-lateral LV free wall positioned using a retrograde aortic approach with a steerable 12 F sheath. The electrode is activated by a submuscular ultrasonic transmitter synchronized to a right ventricular pacing pulse of a standard pacemaker or implantable cardioverter defibrillator. *CRT-P/D*, cardiac resynchronization therapy with pacemaker/defibrillator; *ECG*, electrocardiogram; *ICD*, implantable cardiovertor-defibrillator; *LV*, left ventricle; *PM*, pacemaker. Nonresponse: Patient Follow-Up and Multidisciplinary Approach

Once the device is placed in a well-selected patient with proper programming with good remote monitoring, continued care and optimization of the patient care and device are required, which are best managed by a multidisciplinary approach (Hindricks et al., 2014; Mullens et al., 2009; Altman et al., 2012) (imaging, device programming, HF, and social support).

Future Technology

Future technology of CRT is to focus upon better stimulation models of the LV. MPP-IDE study (Tomassoni, 2016) and MORE-CRT MPP (Leclercq, 2016) are large multicenter clinical trials that are underway which compare standard quadripolar pacing to MPP. Another area of investigation for LV stimulation is direct LV pacing via an endocardial pacing electrode. The recently completed AlSync study (Morgan et al., 2016), assessed LV endocardial pacing achieved by LV lead placement via a transseptal puncture then across the mitral valve. This technique was successful in deploying the lead, but, even while on anticoagulation, patients had a high rate of stroke. Yet this study is launching a new area of investigation into direct LV endocardial stimulation and potentially offers access to all regions of the LV instead of only regions accessible by the CS branches, faster impulse propagation in the endocardium than compared to the epicardium, faster LV depolarization, and more physiologic LV stimulation (Bordachar et al., 2010). Additionally, direct LV pacing may be achieved by leadless stimulation powered by a remote source of ultrasound (**Fig. 11**) (Reddy et al., 2015). The role of CRT in non-LBBB patients has not been the sole study population for any CRT trial. The currently enrolling ENHANCE-CRT trial (Singh, 2013) randomizes patients with a non-LBBB native conduction to CRT implantation directed by the implanter's preference versus implant guided by Q-LV timing. Finally, the future of device optimization is also being evaluated with the advent of SonR hemodynamic sensor, which is embedded in the right atrial lead. This sonar sensor listens to the heart sounds as a surrogate for contractility. Based on this information, the AV and VV timing intervals are programmed on a weekly basis and has been shown to reduce HF hospitalization and mortality and improve the quality of life and NYHA class in ~1000 patients who were studied in the RESPOND-CRT study (Brugada et al., 2016).

Introduction

The systemic amyloidoses are a group of disorders characterized by organ deposition of misfolded protein fragments. Natural history, clinical manifestations, and treatment options for these disorders vary widely depending on the type of the abnormal protein. Cardiac amyloidosis is a disease of extracellular deposition of amyloid protein, often resulting in a restrictive cardiomyopathy. Cardiac involvement with amyloidosis most often occurs from misfolded immunoglobulin light chains (AL), produced by bone marrow plasma cells, or transthyretin (ATTR), formerly called prealbumin, manufactured by the liver. The heart may also rarely be involved with secondary (AA) amyloidosis, resulting from chronic inflammation, but this is not a common contributor to cardiac amyloidosis. Cardiac involvement may occur as part of a syndrome of systemic multiorgan involvement, as is frequently the case in AL amyloidosis, but the heart may also be the sole organ involved as typically seen in ATTR wild-type (formerly, senile) cardiac amyloidosis. It is imperative to accurately recognize cardiac involvement in systemic amyloidosis, as therapeutic options are constrained by reductions in cardiac function, and the degree of impairment serves as the principal determinant of prognosis and clinical course.

After a brief discussion about the historical background of the systemic amyloidoses and an introduction to other non-AL types of cardiac amyloidosis, this chapter will explore in depth the pathophysiology, diagnostic approach, and treatment options for AL cardiac amyloidosis.

Background

In 1854, the German pathologist Rudolph Virchow coined the term "amyloid" to describe macroscopically abnormal brain tissue which stained pale blue with iodine and violet after sulfuric acid was added. He postulated that this staining pattern suggested the presence of cellulose and derived the term "amyloid" from the Latin "amylum" and the Greek "amylon" (Cohen, 1986). Subsequent studies demonstrated the lack of carbohydrate in amyloid and it was eventually characterized as a protein. In 1927, light microscopic studies revealed the characteristic apple-green birefringence of amyloid protein when stained with Congo Red, and when viewed under polarized light (Divry and Florkin, 1927). Subsequent electron microscopy studies in the 1950s described the following common fibrillar ultrastructure underlying amyloid protein of diverse origins: all amyloid deposits comprise of nonbranching, rigid fibrils about 80–100 A in width and of varying lengths (Cohen and Calkins, 1959). These fibrils, in turn, are composed of filamentous subunits and are organized in a beta-pleated sheet configuration (Bonar et al., 1969; Glenner et al., 1974; Sunde and Blake, 1998). The nonfibrillar components of amyloid include serum amyloid P component, proteoglycans, and apolipoprotein E which is found in several types of amyloid. Serum amyloid P (SAP) is a pentagonal alpha globulin which is nearly identical to its counterpart found in amyloid tissue (Cathcart et al., 1965). As will be discussed later, SAP can serve as a target for both imaging and potentially dissolution of amyloid deposits.

Despite the common fibrillar ultrastructure, there is significant biochemical heterogeneity in amyloid deposits and more than 36 distinct amyloidogenic proteins have been identified in the animal kingdom (Sipe et al., 2016). However, three of these proteins play major causative roles in human amyloidosis. In the 1970s, amino acid sequencing of amyloid fibrils identified primary amyloidosis as being derived from immunoglobulin light chain fragments. This was initially termed amyloid B and is now referred

to as AL amyloid (Benditt et al., 1971). The same lab performed amino acid sequencing of amyloid tissue from patients with acute and chronic inflammation and identified a protein that they called amyloid A (Benditt et al., 1971). Finally, Costa et al. (1978) and Skinner and Cohen (1981) reported that transthyretin (formerly known as prealbumin) played a prominent role in the amyloid fibrils found in familial amyloid polyneuropathy. Since then, greater than 100 transthyretin (TTR) single-nucleotide polymorphisms have been identified (Connors et al., 2003), although a much smaller proportion have been implicated in cardiac amyloidosis. The systemic amyloidosis shares some homology with other protein folding diseases such as Alzheimer's dementia (precursor protein amyloid beta or Aβ) in that the final ultrastructure of the deposited protein is amyloid. This homology affords potential targets for both imaging and therapeutic intervention. There is no known association between the systemic amyloidosis and Alzheimer's dementia.

Transthyretin (TTR) Cardiac Amyloidosis

Formerly known as prealbumin, *TTR* is protein synthesized and secreted into the circulation by the liver, and plays a minor role in the transport of vitamin A (retinol) and thyroxine. Normally circulating as a stable tetramer, aging (wild-type ATTR) or genetic mutations (mutant ATTR) can cause the protein to dissociate into monomers which misfold and aggregate first as monomers and then oligomers with subsequent organ deposition. Wild-type (formerly referred to as senile systemic or senile cardiac) ATTR amyloidosis predominantly affects the heart with a striking male predominance (Ruberg and Berk, 2012). Prevalence increases with age, as demonstrated by numerous autopsy series that estimate up to 25% of patients over the age of 80 have demonstrable amyloid deposition by histopathology (Cornwell et al., 1983; Tanskanen et al., 2008). Recent evidence suggests that ATTR wild-type amyloidosis is an unrecognized cause of heart failure in the elderly (Mohammed et al., 2014), and may affect up to 10% of elderly heart failure patients (Gonzalez-Lopez et al., 2015).

In contrast, the prevalence and disease expression of mutant ATTR amyloidosis varies by mutation. Disease manifestations generally involve some combination of sensory and motor small fiber polyneuropathy and/or cardiomyopathy. Mutations, which represent single-nucleotide polymorphisms that follow an autosomal dominance inheritance pattern with variable penetrance, tend to have significant geographic variations with most pathological mutations resulting in significant polyneuropathy. Worldwide, three mutations are most commonly associated with cardiac amyloidosis. V30M (valine substitution for methionine at position 30; Met 30) is most common in Portugal, Sweden, and Japan, and its expression varies by geography, age, parental transmission, and gender (Rapezzi et al., 2010). The T60A (threonine to alanine substitution) mutation is also an important cause of cardiac amyloidosis and polyneuropathy and is particularly prevalent in Northwest Ireland and the United Kingdom (Reilly et al., 1995). In contrast, the V122I mutation (valine to isoleucine substitution) mutation is the most common mutation affecting the heart primarily, with an allele carrier rate of 3%–4% in the African American population (Jacobson et al., 1990; Jacobson et al., 1997). Penetrance of ATTR V122I amyloidosis is age dependent, and many patients do not live to reach the age of disease manifestation, typically the late 6th or 7th decade of life.

The diagnosis of amyloidosis relies on the identification of amyloid tissue by Congo red staining from an affected organ or from a surveillance biopsy typically taken from subcutaneous abdominal fat or the gastrointestinal tract, most commonly. Recent evidence suggests that ATTR amyloidosis can be diagnosed accurately without a tissue biopsy with use of the diagnostic bone-avid nuclear tracers Tc^{99m} pyrophosphate or Tc^{99m} DPD (3,3-diphosphono-1,2-propanodicarboxylic acid) and the absence of a plasma cell dyscrasia (Gillmore et al., 2016). Since treatment options for TTR and AL amyloidosis are completely different, identification of the precursor protein is imperative once amyloidosis has been identified. Immunohistochemistry can aid in identifying immunoglobulin κ and λ light chain fragments, TTR and AA protein (Ruberg and Berk, 2012); however diagnostic accuracy of immunohistochemistry is dependent upon the skill and experience of the pathology service at a given hospital. **Fig. 1** is an example of immunohistochemical stains identifying the origin of amyloid proteins in patients with cardiac amyloidosis. Precursor proteins are perhaps most accurately identified using liquid chromatography-tandem mass spectrometry at specialized amyloid centers (Vrana et al., 2009). Once TTR has been identified as the precursor protein, wild-type ATTR may be differentiated from mutant ATTR by sequencing of the *TTR* gene.

Treatment of ATTR cardiac amyloidosis hinges on management of heart failure symptoms. Diuretics are the mainstay of treatment as patients with amyloid cardiomyopathy do not typically tolerate treatment with ace inhibitors, angiotensin receptor blockers, beta blockers, or digoxin. Liver transplant may halt the progression of variant TTR amyloid cardiomyopathy, but organ progression is well recognized after transplantation of the liver alone (Ruberg and Berk, 2012). Small molecule inhibitors of TTR dissociation, including diflunisal (FDA approved, off-label indication) and tafamidis (European Medicines Authority approved), or agents that suppress TTR expression may be useful alternatives to liver transplantation in mutant ATTR amyloidosis and provide effective treatment options for ATTR cardiac amyloidosis (Maurer et al., 2015).

AL Cardiac Amyloidosis

Systemic AL amyloidosis is caused by a plasma cell dyscrasia resulting in overproduction and accumulation of immunoglobulin lambda (more commonly) or kappa light chains. These light chains are the precursor proteins resulting in amyloid fibril formation and organ deposition. Unlike multiple myeloma, a related plasma cell disorder, patients with AL amyloidosis usually have <20%

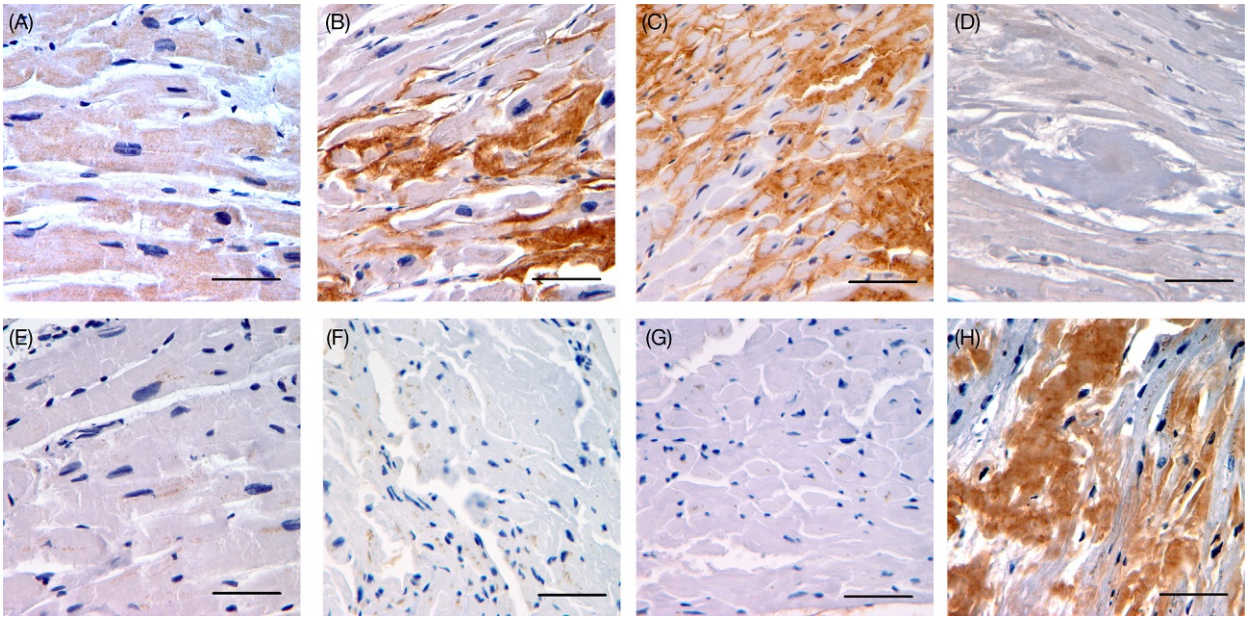

Fig. 1 Characteristic immunohistochemical staining for transthyretin (TTR, top row) and light chain (LC, bottom row) amyloid protein under light microscopy using control (A and E), wild-type (senile, SSA) transthyretin amyloidosis (B and F), variant transthyretin (ATTR) (C and G), and AL amyloidosis (D and H) cardiac biopsy samples. Control samples do not stain with either TTR or LC stains (A and E). TTR stains reveal significant peri-cellular staining in both wild-type (SSA) and variant ATTR samples (B and C), but not in the AL amyloidosis sample (D). In contrast, AL amyloid cardiac samples are markedly positive for LC stains (H), but transthyretin samples (F and G) do not reveal LC staining. Reproduced by permission from Greene, M. J., Sam, F., Soo Hoo, P. T., Patel, R. S., Seldin, D. C. and Connors, L. H. (2011). Evidence for a functional role of the molecular chaperone clusterin in amyloidotic cardiomyopathy. *American Journal of Pathology*, **178**, 61–68.

involvement of their bone marrow with a plasma cell clone. However, about 10% of patients with AL amyloidosis may have multiple myeloma (Hasserjian et al., 2007). AL amyloidosis may involve multiple organs, but renal and cardiac AL amyloidosis is the most common, with cardiac involvement seen in approximately 50% of cases (Merlini and Bellotti, 2003). The presence of cardiac involvement is the most important determinant of survival for patients with AL amyloidosis as historically, patients with untreated AL cardiac amyloidosis and congestive heart failure experience an overall median survival of only 6 months (Kyle et al., 1992). In sharp contrast, contemporary treatment with modern chemotherapeutic regimens, including high-dose melphalan-based chemotherapy and stem cell transplantation (discussed below) in eligible patients can extend median survival to >5 years, and for some, beyond a decade or longer (Madan et al., 2012).

Cardiac amyloidosis is an infiltrative disorder, characterized by expansion of the extracellular space due to amyloid fibril deposition. The resulting increase in biventricular wall thickness leads to ventricular stiffness, manifesting as an infiltrative, restrictive cardiomyopathy. Atrial infiltration is common, predisposing patients to atrial fibrillation, particularly in conjunction with elevated LA pressures from restrictive LV filling. Atrial infiltration also contributes to atrial electromechanical dissociation, despite the presence of normal sinus rhythm on ECG, with an associated risk of atrial thrombus formation and thromboembolism (Stables and Ormerod, 1996; Feng et al., 2007, 2009). Diffuse valvular thickening is often noted as well, resulting in regurgitant lesions but not stenosis. Additionally, perivascular deposition may be seen with arterial and arteriolar involvement. Coronary microvascular dysfunction is an uncommon but well-recognized feature in cardiac amyloidosis that can precipitate ischemia and infarction (Tsai et al., 2011). Sensitive measurements of cardiac perfusion by PET imaging have demonstrated diminished coronary flow reserve in patients with suspected small vessel amyloid infiltration (Dorbala et al., 2014a). The histologic distribution of amyloid infiltration and the resultant restrictive cardiomyopathy is generally similar in TTR and AL cardiac amyloidosis; however, the pattern of amyloid deposition can differ with diffuse pericellular and reticular deposits in AL amyloidosis and nodular deposits in TTR amyloidosis (Kristen et al., 2016).

In addition to interstitial infiltration, there is clear evidence for direct light chain toxicity to the cardiomyocyte which may contribute to organ dysfunction and the rapidly progressive nature of this disease (Brenner et al., 2004; Shi et al., 2010; Diomede et al., 2014). Further investigation has suggested that this light chain proteotoxicity derives from lysosomal dysfunction and impairment of autophagy which leads to the generation of reactive oxygen species and impaired intracellular calcium homeostasis (Guan et al., 2014). This sequence of events eventually leads to cell death. Amyloidogenic light chain-induced cell necrosis and apoptosis also lead to abnormalities in arteriolar reactivity that can contribute to microvascular dysfunction (Migrino et al., 2011), and may precipitate an imbalance in the generation and degradation of extracellular matrix protein undermining the organized structure of the cardiac contractile apparatus (Biolo et al., 2008). Thus, there is ample evidence that direct light chain toxicity contributes to the pathophysiology of AL cardiac amyloidosis, in addition to the restrictive physiology caused by direct extracellular protein infiltration.

Clinical Features of AL Cardiac Amyloidosis

Symptoms of heart failure, particularly dyspnea on exertion and profound peripheral edema, are the most common presenting symptoms of cardiac amyloidosis (Falk et al., 2016). These are manifestations of high filling pressures in the setting of a restrictive cardiomyopathy. Exertional syncope is an advanced sign of an inability to augment cardiac output with exertion and is associated with a particularly poor outcome (Chamarthi et al., 1997). Atrial infiltration and soft tissue infiltration may precede symptoms of heart failure by several years and present as atrial fibrillation and bilateral carpal tunnel syndrome respectively, although they are commonly unrecognized as signs of systemic amyloidosis. The prevalence of atrial fibrillation is about 10% in AL cardiac amyloidosis and up to 40% in patients with wild-type TTR cardiac amyloidosis (Longhi et al., 2015). Peripheral edema, in addition to being a sign of diastolic heart failure, is also commonly seen due to nephrotic syndrome associated with renal amyloidosis. Therefore, heart failure with signs of nephrotic syndrome is a strong indicator of systemic AL amyloidosis and must be evaluated accordingly.

Systemic thromboembolic events, particularly ischemic strokes, may also be the initial signs of cardiac amyloidosis (Zubkov et al., 2007). Both venous and arterial thromboembolic events may be seen with AL amyloidosis (Freeman et al., 2012). Intracardiac thrombi are common and were present in one-third of patients with cardiac amyloidosis in one autopsy study (Feng et al., 2007). Advanced diastolic dysfunction and atrial fibrillation were most strongly associated with intracardiac thrombi; however anticoagulation can mitigate the likelihood of systemic embolization (Feng et al., 2009).

In addition to arterial thromboembolic disease, microvascular involvement of coronary and peripheral arterioles may result in angina and claudication, including jaw claudication. Peripheral and autonomic neuropathies are common due to nervous system involvement. Low cardiac output coupled with an autonomic neuropathy often leads to significant hypotension and orthostasis, greatly complicating diuresis (Sugiyama et al., 2014; Matsuda et al., 2011).

The physical exam in patients with AL amyloidosis may reveal orthostatic hypotension. There may be significant tongue enlargement. Macroglossia is seen in up to 10% of patients with AL amyloidosis, and is considered pathognomonic for the AL type. Periorbital ecchymosis may be subtle, but can be seen in AL amyloidosis (Falk et al., 2016). The liver may be enlarged due to hepatic infiltration with amyloid protein or due to right heart failure. Peripheral neuropathy may be noted, is predominantly sensory, and may be subtle in patients with AL amyloidosis. This is in contrast to patients with mutant ATTR amyloidosis who often have a progressive sensorimotor peripheral neuropathy, depending on the particular transthyretin mutation.

The cardiac exam reveals signs of elevated filling pressures. Ascites and peripheral edema may be a part of anasarca that is seen in patients with nephrotic syndrome due to renal involvement. As will be discussed below, valvular thickening and valvular regurgitation are relatively common and these murmurs may be auscultated as well. S3 and S4 gallops, which are commonly associated with diastolic heart failure, are not usually appreciated in cardiac amyloidosis until advanced heart failure with systolic dysfunction ensues.

Electrocardiogram

Low limb voltages on ECG, especially in the setting of increased left ventricular wall thickness on echocardiogram, is a classic feature of cardiac amyloidosis. Unlike the myocyte hypertrophy, which leads to increased QRS voltages in hypertrophic cardiomyopathy, the extracellular volume expansion due to amyloid fibril deposition is responsible for the low QRS voltages in the setting of increased wall thickness in cardiac amyloidosis. Depending on the method used to define low QRS voltage, the prevalence of low voltage in cardiac amyloidosis ranges from 60% using the Sokolow index (S wave in V1 + R wave in V5 or V6 $<$1.5 mV) to 34% using QRS voltage $<$0.5 mV in each limb lead and 13% when using QRS voltage $<$1.0 mV in each precordial lead (Cyrille et al., 2014). Pseudo infarct patterns are common as well and can be seen in approximately 50% of patients with AL cardiac amyloidosis (Murtagh et al., 2005). Pseudo infarct patterns may also be seen with an unusual QRS axis in cardiac amyloidosis. In addition, atrioventricular block may be seen in up to 22% of patients with cardiac amyloidosis. Intraventricular conduction delays and bundle branch blocks are also common ECG features of cardiac amyloidosis (Huang et al., 2015). Finally, ECG-defined left ventricular hypertrophy can also be observed in approximately 10%–15% of patients with AL amyloidosis, but this likely reflects preexisting hypertensive heart disease, with superimposed amyloidosis (Murtagh et al., 2005). **Fig. 2** is an example of characteristic ECG abnormalities seen in cardiac amyloidosis.

Echocardiography

Two-dimensional echocardiography is the cornerstone of diagnosis of cardiac amyloidosis and is the imaging modality which most often raises suspicion for cardiac involvement (**Fig. 3**). Indeed, international consensus criteria for the identification of cardiac involvement in AL amyloidosis have relied upon a septal thickness more than 12 mm though this is changing with contemporary imaging techniques and the advent of biomarker data (Gertz et al., 2005). Symmetrically increased LV wall thickness, often $\geq$15 mm, in the setting of a nondilated ventricle, can be an indicator of cardiac amyloidosis, but is not specific for the type of amyloidosis (Rapezzi et al., 2009). Wall thickness is generally more prominent in patients with transthyretin cardiac amyloidosis at

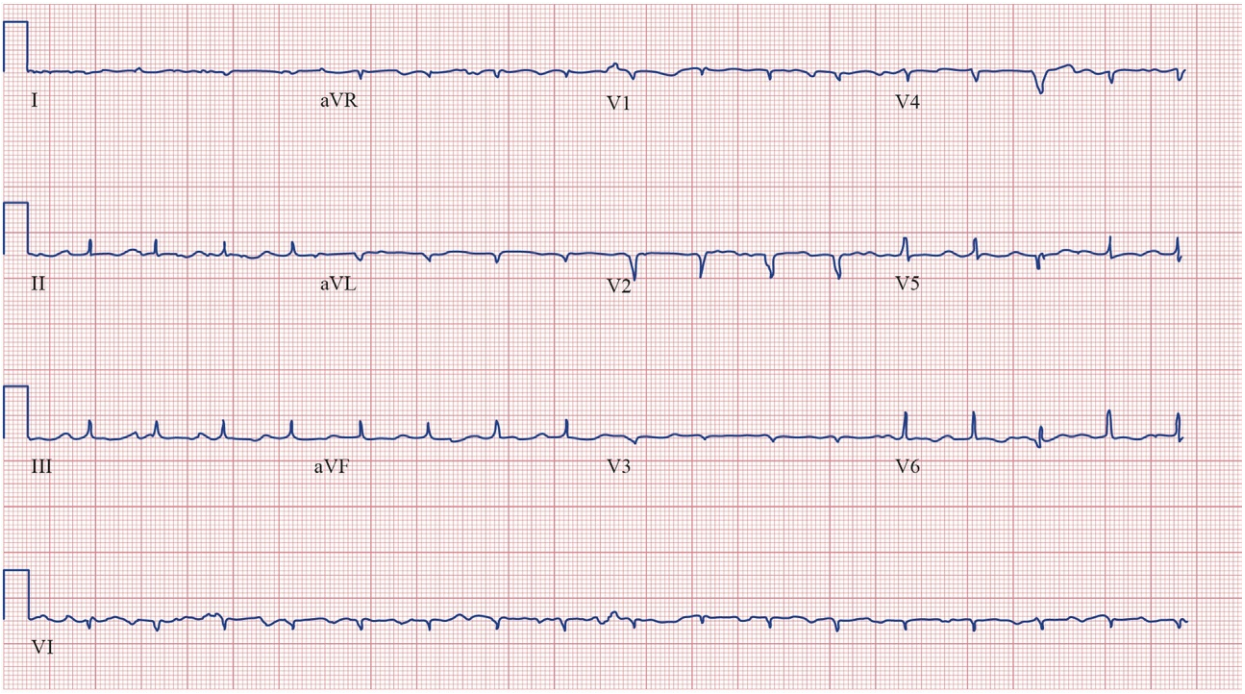

Fig. 2 Electrocardiography in cardiac amyloidosis. ECG from a patient with cardiac amyloidosis reveals low voltages, 1st degree AV delay, and a septal infarct pattern.

diagnosis, as patients with AL amyloidosis tend to become symptomatic earlier on in the disease course. RV wall thickness is also commonly increased due to amyloid infiltration (Cacciapuoti, 2015). Indices combining low QRS voltage on ECG with increased LV wall thickness have high sensitivity and specificity for diagnosis of cardiac amyloidosis (Cheng et al., 2011). Historically, "granular sparkling" or "speckling" of the myocardium was felt to be a marker of amyloid infiltration, and hence, felt to be diagnostic of cardiac amyloidosis. With advances in digital image analysis techniques, myocardial speckling has a low sensitivity and specificity for diagnosis of cardiac amyloidosis (Picano et al., 1991; Rahman et al., 2004).

Global LV systolic function, as assessed by the ejection fraction, is usually preserved until advanced stages of disease, but impairments in systolic deformation as measured by global longitudinal strain are often evident early in the course of the disease (Piper et al., 2010). Global longitudinal strain (GLS) is an accurate marker of systolic dysfunction in cardiac amyloidosis and can help discriminate between early and more advanced stages of the disease (Bellavia et al., 2007). In addition to a decline in global longitudinal strain, there are regional differences in systolic deformation with cardiac amyloidosis such that longitudinal strain is relatively preserved at the apex and is more significantly diminished at the basal and mid LV cavity (Senapati et al., 2016). An apical to basal ratio >2.1 conferred high discriminative capacity for cardiac amyloidosis identification (Liu et al., 2013). Furthermore, baseline two-dimensional global longitudinal strain is an independent predictor of survival in patients with AL cardiac amyloidosis with a global longitudinal strain value of approximately -11% accurately differentiating survivors from nonsurvivors at a follow-up of over 1200 days (Buss et al., 2012). Longitudinal strain measures can also identify an early cardiac improvement following treatment for AL amyloidosis as patients achieving complete response demonstrated significant improvement in the apical to basal longitudinal strain ratio, compared to nonresponders (Salinaro et al., 2016).

Amyloid infiltration results in biventricular stiffening and diastolic dysfunction, often presenting as heart failure with preserved EF (HFpEF). The trans-mitral flow pattern is abnormal due to diastolic dysfunction with elevated filling pressures (pseudonormalized or a restrictive pattern) and atrial mechanical dysfunction, even in the setting of sinus rhythm (Mohty et al., 2013). Low or even absent trans-mitral A velocities may commonly be encountered in patients with an advanced restrictive cardiomyopathy (Dubrey et al., 1995) despite sinus rhythm. A trans-mitral A velocity of less than 30 cm/s was associated with intracardiac thrombi in AL cardiac amyloidosis patients without atrial fibrillation (Feng et al., 2009). A consequence of advanced diastolic dysfunction and high filling pressures is atrial enlargement, which, unlike ventricular dilation, is commonly seen in cardiac amyloidosis and may be an independent predictor of decreased survival (Mohty et al., 2011).

In addition to atrial infiltration, there is often infiltration of the interatrial septum. Increased RV wall thickness and RV systolic dysfunction, as denoted by a tricuspid plane systolic excursion (TAPSE) <1.4 cm, may be seen and each are independent predictors of adverse outcomes (Bodez et al., 2016). Valvular thickening is often noted due to amyloid deposition and this, along with elevated filling pressures, may lead to significant valvular regurgitation (Mohty et al., 2013). Small pericardial effusions are common, but cardiac tamponade in cardiac amyloidosis is very rare (Navarro et al., 1992; Bodez et al., 2016).

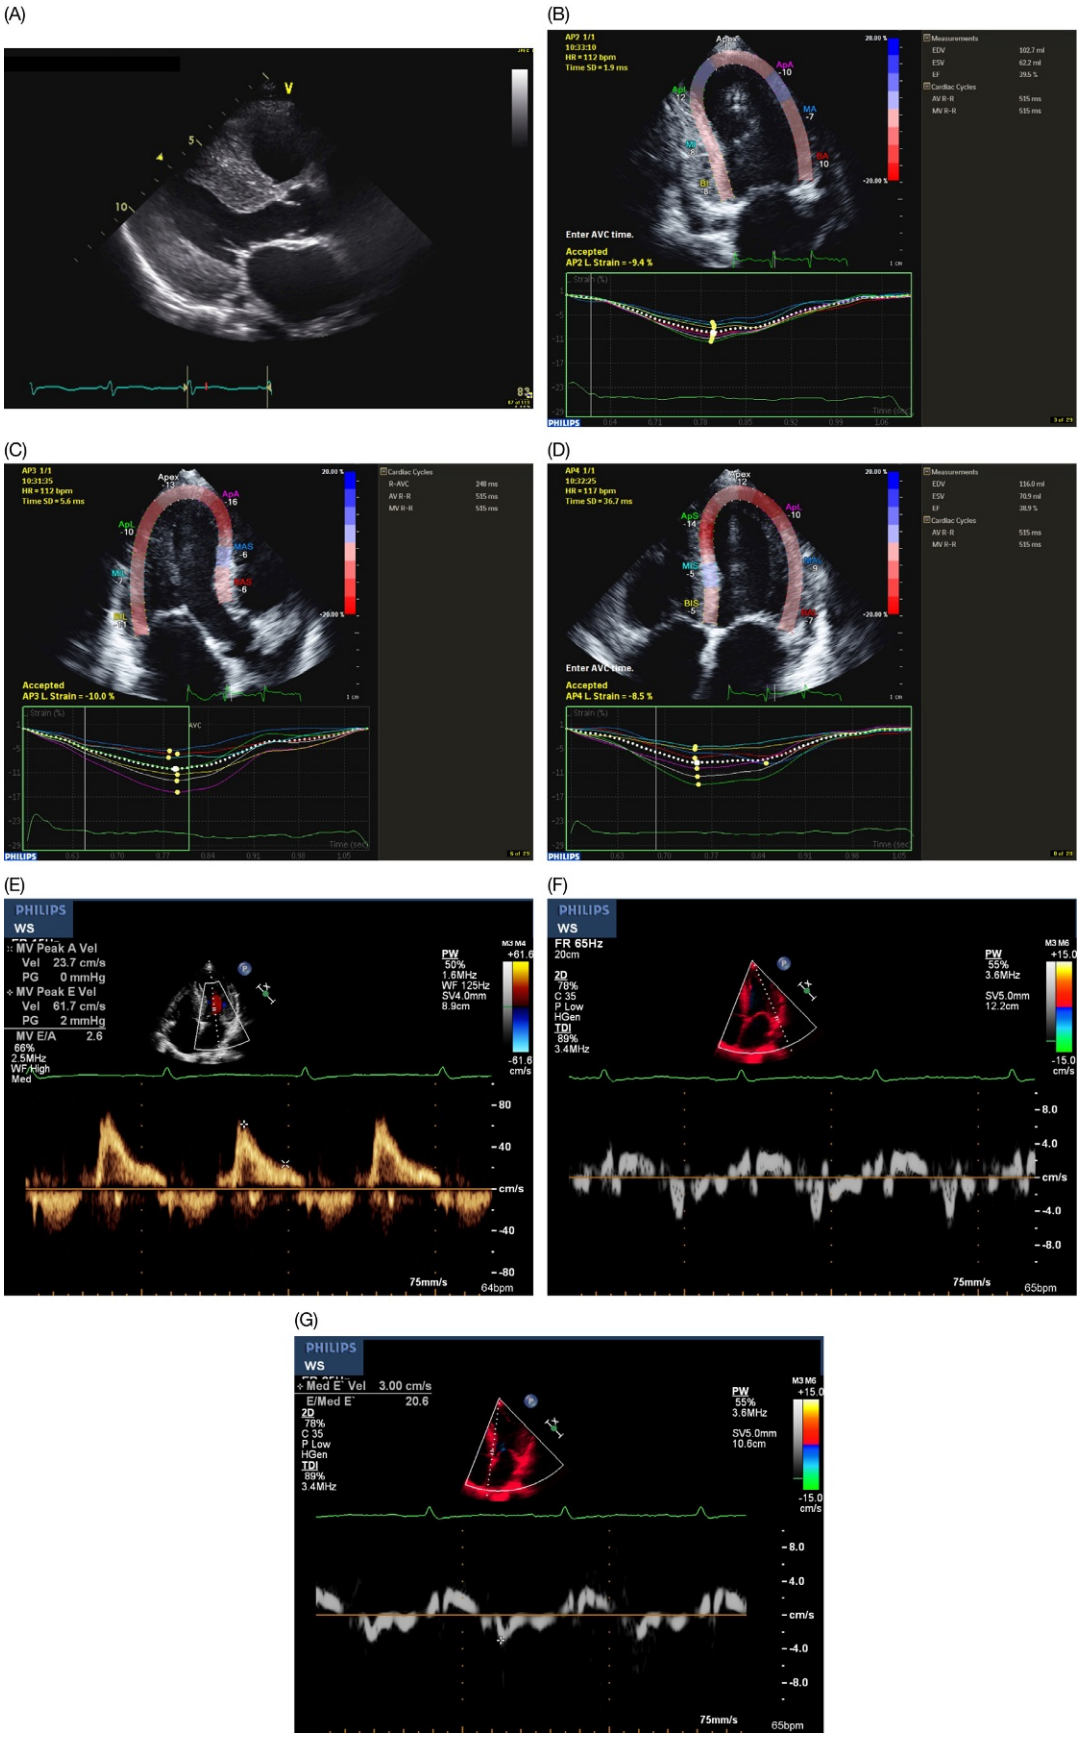

Fig. 3 Echocardiography in cardiac amyloidosis. Parasternal long-axis view depicting severely increased wall thickness, with granular sparkling, which may be seen in cardiac amyloidosis (A). Longitudinal strain in apical 4-, 2- and 3-chamber views showing severely reduced global longitudinal strain (GLS) of -9.3% (B–D). Diastology in amyloidosis, revealing a restrictive trans-mitral filling pattern and low mitral annulus tissue Doppler velocities (E–G). Low trans-mitral A velocity is suggestive of atrial electromechanical dissociation and may increase the risk for atrial clot formation (see text).

Cardiac Magnetic Resonance (CMR) Imaging

While echocardiography is appropriately the first-line imaging test used to detect cardiac amyloidosis, cardiac MRI (CMR) is useful in equivocal cases and can help risk stratify patients beyond the usual clinical and laboratory risk markers.

As discussed above, cardiac amyloidosis involves the interstitial deposition of protein fibrils leading to an expansion of the extracellular volume (ECV) and eventually, myocardial fibrosis (Ishikawa et al., 1996). Late gadolinium enhancement (LGE) imaging using CMR has proven effective in identifying ECV expansion and endomyocardial fibrosis (Wu et al., 2001; Moon et al., 2003; McCrohon et al., 2003). Cardiac amyloidosis has a characteristic pattern of diffuse subendocardial LGE with CMR that is associated with clinical heart failure (Ruberg et al., 2009) and survival (Austin et al., 2009). At autopsy, this subendocardial pattern of LGE appears to correlate more with amyloid deposits rather than fibrosis (Maceira et al., 2005). However, many different patterns from subendocardial to transmural have been seen in cardiac amyloidosis (Syed et al., 2010), and therefore the presence of LGE in a noninfarct pattern in a patient with systemic amyloidosis should be considered highly suggestive of cardiac involvement (**Fig. 4**). In fact, in patients with multiple myeloma, CMR has sensitivity and negative predictive values of 100% and specificity and positive predictive values of 80% and 81%, respectively, for diagnosis of AL cardiac amyloidosis (Bhatti et al., 2016). Additionally, LGE by CMR is an independent predictor of mortality in patients with AL cardiac amyloidosis and has prognostic value beyond the usual clinical and laboratory data (Boynton et al., 2016).

In addition to LGE, myocardial and blood pool handling of gadolinium products are also abnormal in cardiac amyloidosis (Maceira et al., 2005). This results in a higher blood T1 and a lower myocardial T1 in cardiac amyloid patients with a smaller difference in T1 between blood and myocardium. For this reason, contemporary LGE imaging in cardiac amyloidosis is best performed using the phase-sensitive inversion recovery (PSIR) technique that has superior accuracy compared to conventional LGE imaging (Fontana et al., 2015).

LGE is very useful for differentiating abnormal from normal myocardium, but this presupposes regions of normal are present. Amyloidosis is a diffuse disease, and in many instances, there is no "normal" myocardium to contrast. For this reason, quantitative imaging techniques including T1 mapping and extracellular volume fraction (ECV) determination have been recently explored in cardiomyopathic disease such as amyloidosis. Extracellular volume (ECV) measurement from pre- and postcontrast T1 mapping has shown promise for detection of cardiac amyloidosis (Mongeon et al., 2012; Banypersad et al., 2013). Similarly, native T1 quantification, without the need for contrast, can differentiate AL cardiac amyloidosis from AL amyloidosis without cardiac involvement, albeit with considerable overlap (Karamitsos et al., 2013). Of the two quantitative techniques, ECV appears the most reproducible (not subject to field strength or technique differences) and confers the highest resolution to determine the severity of amyloid deposition (Fontana et al., 2015).

Diminished left atrial function as determined by CMR, expressed by a LA EF of $<16\%$, is associated with a worse functional status, biomarkers, and increased two-year mortality in patients with cardiac amyloidosis (Mohty et al., 2016). Impairment of coronary microvascular function can also be demonstrated by first-pass perfusion differences between AL cardiac amyloid patients with normal LVEF, AL cardiac amyloid patients with LV systolic dysfunction, and healthy controls (Li et al., 2016). Finally, while a CMR scoring system was useful in differentiating AL cardiac amyloidosis from TTR cardiac amyloidosis, the reproducibility of this measure was only fair, limiting its applicability (Dungu et al., 2014).

Nuclear Scintigraphy

In 1977, the bone-avid tracer technetium diphosphonate was found to bind to amyloid deposits, thus providing a potent imaging tool for visualizing the distribution of amyloid protein (Kula et al., 1977). This led to the development of several other

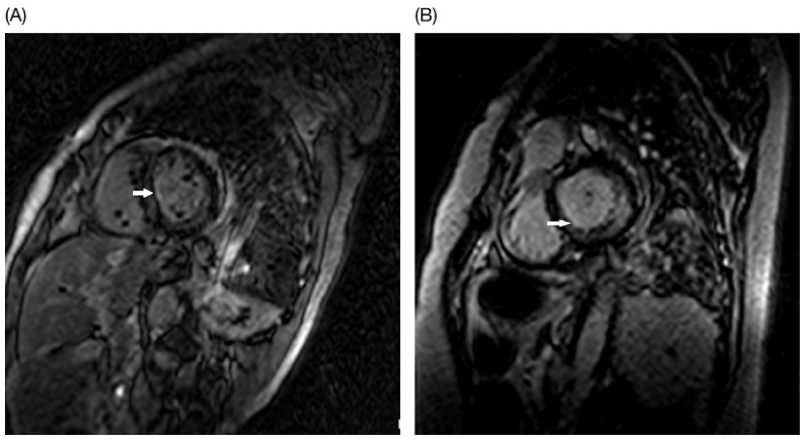

Fig. 4 Short-axis cardiac MR images revealing a patchy subendocardial late gadolinium enhancement (LGE) pattern (*white arrows*) consistent with cardiac amyloidosis in two separate subjects.

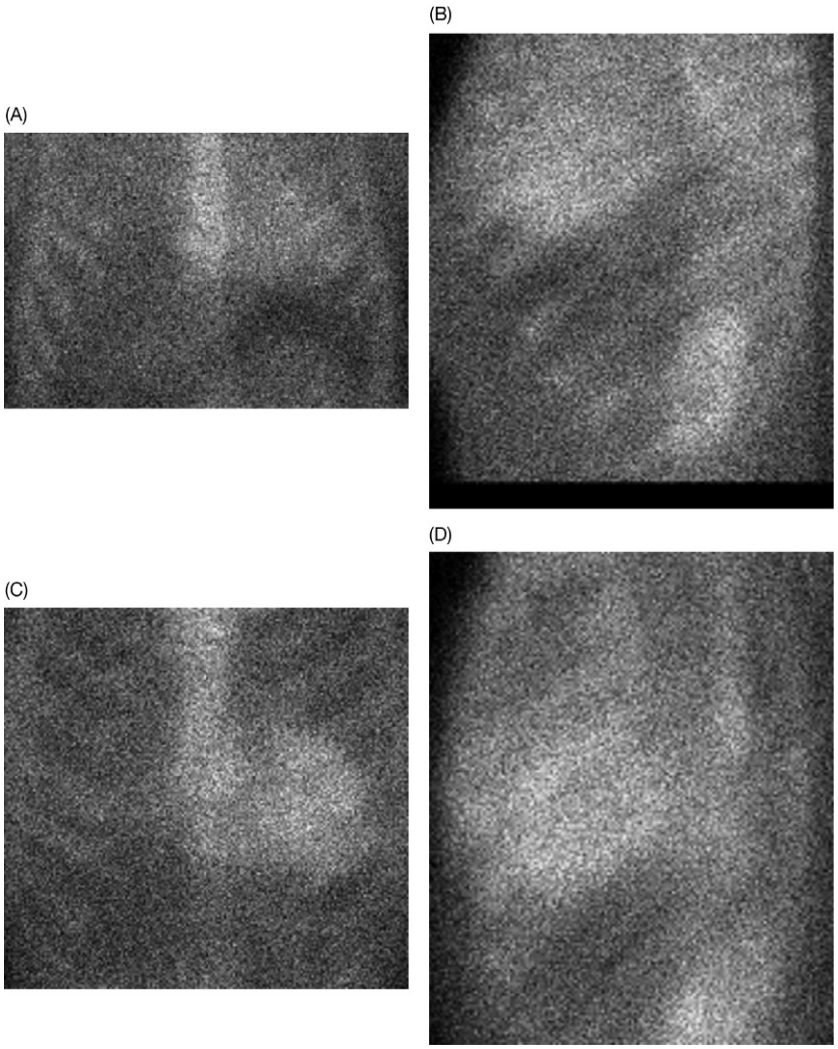

Fig. 5 Tc99m pyrophosphate scans in AP and lateral projections revealing a qualitative Grade 1 (equivocal) uptake (A and B) in a patient with AL amyloidosis, and Grade 3 (strongly positive) uptake (C and D) by the heart when compared to the surrounding ribs in a patient with ATTR wild-type amyloidosis.

phosphate-based isotopes, including ^{99m}Tc-PYP (pyrophosphate) and ^{99m}Tc-DPD (3,3-diphosphono-1,2-propanodiacarboxylic acid), which have a specific avidity for ATTR amyloid deposits. An international consensus document, supported by data from over 1000 patients, has confirmed the utility of the bone-avid compounds for the highly accurate identification of ATTR amyloidosis (Gillmore et al., 2016), and differentiation from AL amyloidosis. ^{99m}Tc-PYP is now starting to be used clinically in the United States and is highly useful for the detection of ATTR cardiac amyloidosis, but it is not useful for identification of AL (**Fig. 5**). A PYP scan that does not show uptake, or shows mild grade 1 uptake, is completely consistent with AL amyloidosis.

In addition, there is increasing evidence that amyloid-specific PET tracers can identify cardiac amyloidosis, specifically the AL type. Dorbala and colleagues reported the utility of 18-F florbetapir to identify cardiac involvement in AL disease (Dorbala et al., 2014b), and similarly, the 11-C Pittsburgh B compound (PiB) has been shown effective in AL identification (Lee et al., 2015).

Pepys and colleagues in the United Kingdom developed a radiolabeled serum amyloid P (SAP) tracer which binds amyloid deposits (Hawkins et al., 1990). This I^{123}-labeled SAP scan has the unique advantage of being able to map the distribution of amyloid within the body, thus providing an accurate estimate of amyloid burden that can be followed with treatment. However, this scan is not useful for identification of cardiac amyloidosis.

Table 1 summarizes the main features of the various imaging modalities used to detect cardiac amyloidosis.

Cardiac Biopsy/Histology

While advances in imaging have greatly enhanced our ability to detect cardiac amyloidosis and to differentiate AL cardiac amyloidosis from ATTR cardiac amyloidosis, histology from a tissue biopsy remains the gold standard for diagnosis of amyloidosis. In fact, it is essential that amyloid be identified by Congo red (or similar) amyloidosis specific stain prior to any chemotherapy

Table 1 Summary of imaging findings used to diagnose cardiac amyloidosis

Modality	*Imaging features*
Echocardiogram	1. Increased ventricular wall thickness 2. Advanced diastolic dysfunction 3. Granular sparkling of the myocardium may be seen 4. Apical to basal strain ratio >2 5. Global longitudinal strain <−11% associated with increased mortality 6. Pericardial effusion may be present
Cardiac MRI	1. Diffuse or subendocardial late gadolinium enhancement (LGE) 2. LGE is in a noncoronary pattern 3. Extracellular volume (ECV) expansion by T1 mapping
Tc99m pyrophosphate scan	1. Cardiac uptake greater than uptake by surrounding ribs (grade 3 uptake) is diagnostic of transthyretin cardiac amyloidosis in the setting of an absence of a plasmal cell dyscrasia 2. AL cardiac amyloidosis may have no uptake or mild uptake, not equal to surrounding ribs (grade 0 or 1)

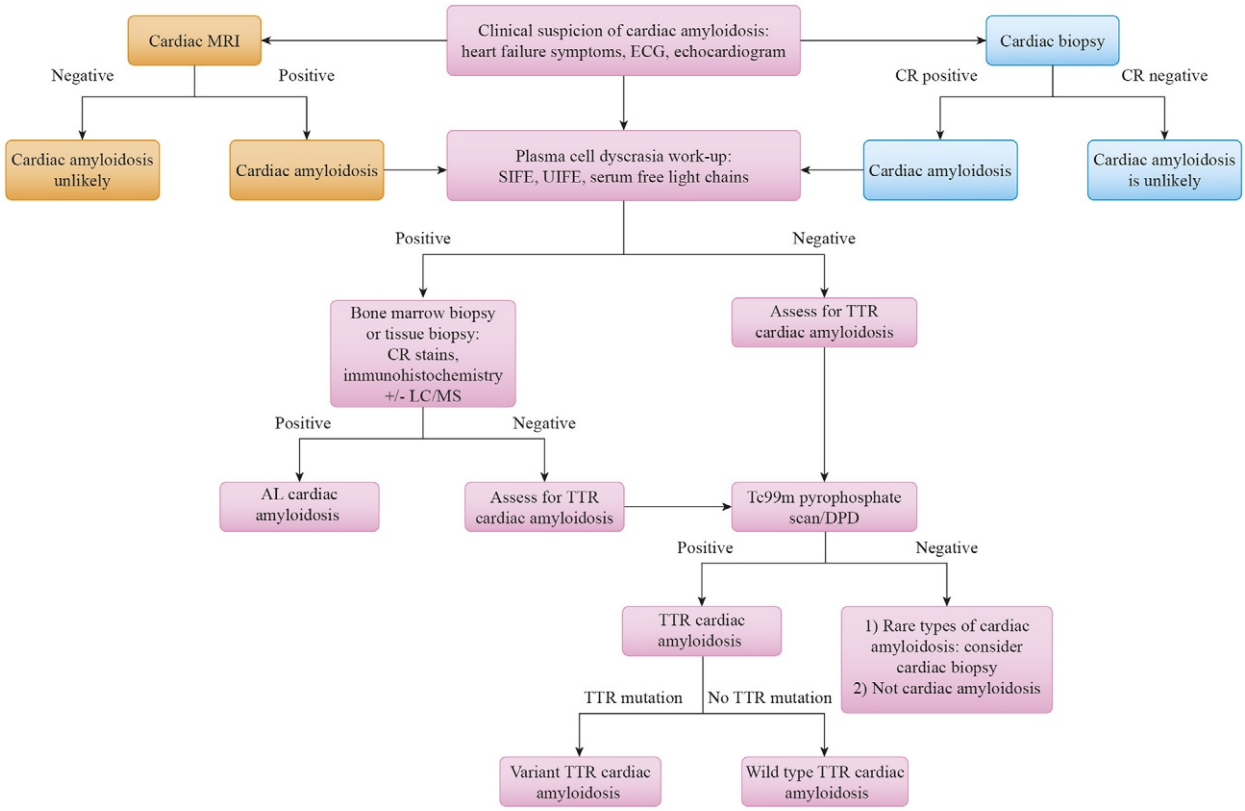

Fig. 6 Decision algorithm for diagnosis of cardiac amyloidosis.

administration. It is also critical to define the precursor protein by blood testing or tissue specimen analysis prior to treatment. Monoclonal gammopathies (MGUS) are relatively common in ATTR amyloidosis, occurring in up to 10% of patients (Connors et al., 2016). As such, AL and ATTR can be confused if the proper diagnostic algorithm is not followed. Figure 6 describes a diagnostic approach to identification of cardiac amyloidosis and differentiation between AL and ATTR cardiac amyloidosis.

Abdominal fat aspirate can be safely performed in the outpatient setting and, in experienced hands, Congo red staining has a sensitivity of 70%–90% for diagnosis of systemic AL amyloidosis (Gertz et al., 1988; Libbey et al., 1983). Thus, cardiac amyloidosis can be inferred in the setting of consistent noninvasive cardiac testing results and a positive extra-cardiac biopsy.

The histologic techniques employed to type the precursor protein include immunohistochemistry and immunofluorescence, immunogold electron microscopy, and laser dissection, liquid chromatography tandem mass spectrometry (LC/MS/MS) which is considered the gold standard for diagnosis. LC/MS/MS is only performed at a few specialized centers worldwide. Immunohistochemisty and immunofluorescence are commonly performed, but accuracy varies with experience, while immunogold electron

microscopy is very uncommonly performed. In most circumstances, an abdominal fat aspirate yields too little tissue for typing, while solid organ biopsies such as renal or gastrointestinal are more commonly pursued.

In patients with a plasma cell dyscrasia with equivocal cardiac imaging findings, or when AL cardiac amyloidosis needs to be differentiated from ATTR cardiac amyloidosis in the setting of a MGUS, an endomyocardial biopsy should be performed. All endomyocardial biopsies undergo Congo Red or Alcian Blue staining to assess for amyloidosis. Immunohistochemistry and immunogold electron microscopy is performed for confirmation and to identify the precursor protein. As above, mass spectrometry may be performed at specialized centers, if the above investigations are equivocal or unavailable. At experienced centers, cardiac biopsies can be performed with a very low risk of complications. However, with the advances in imaging summarized above, endomyocardial biopsies are no longer routinely required for the diagnosis of cardiac amyloidosis. Quantification of amyloid deposition degree in the heart is challenging and difficult to perform reproducibly, but has been reported (Kristen et al., 2016).

Prognosis

The prognosis of patients with AL amyloidosis has dramatically improved over time, with a four-year overall survival of around 90% for successfully treated patients with stem cell transplantation in the contemporary era (Muchtar et al., 2017). For patients with cardiac involvement successfully treated with stem cell transplantation, median overall survival is >10 years (Madan et al., 2012). The Mayo Biomarker Stage is a risk score using pretreatment serum cardiac troponin T (*c*TnT) and N-terminal pro-brain natriuretic peptide (NT-proBNP) to stratify patients. Using threshold values of *c*TnT <0.035 microg/L and NT-proBNP <332 ng/L, patients were classified in stages I, II, or III, if both biomarkers were negative, if one was positive, or if both were positive, respectively. In the original derivation cohort, around a third of the patients were classified in each category. Median survivals were 26.4, 10.5, and 3.5 months (Dispenzieri et al., 2004). This score was subsequently enhanced with the addition of a fourth metric, the absolute difference in serum free light chains. Patients were assigned one point each for free light chain difference $\geq$18 mg/dL, *c*TnT $\geq$0.025 ng/mL, and NT-proBNP $\geq$1800 pg/mL, resulting in stages I through IV with a total of 0–3 points respectively. This modified staging system resulted in improved risk stratification with mean overall survival ranging from 94.1 months for stage 1–5.8 months for stage IV (Kumar et al., 2012). Stage 1 patients likely have no clinically important cardiac amyloidosis. These staging systems help to highlight patients at the highest risks for death for whom intensification of therapy must be considered.

Therapy

The goal of medical therapy in AL cardiac amyloidosis is twofold: relieving symptoms of the infiltrative cardiomyopathy through diuresis and optimization of hemodynamics, and treatment of the underlying plasma cell dyscrasia which is the source of the amyloidogenic light chains. While there is excellent evidence-based data for chemotherapeutic regimen selection, there is only anecdotal experience for symptom-based therapy.

Standard cardiomyopathy therapy with beta blockers and angiotensin-converting enzyme inhibitors/angiotensin receptor blockers is not well tolerated in AL cardiac amyloidosis, owing to hypotension. In fact, a common presentation scenario is a patient in whom a beta blocker was administered for cardiomyopathy who subsequently developed profound hypotension and fatigue. AL amyloidosis patients depend greatly on heart rate and contractility to maintain cardiac output, and beta blockade interferes with this adaptation. Autonomic neuropathy is commonly seen in patients with AL cardiac amyloidosis, increasing the incidence of hypotension and postural symptoms with the use of afterload reducing agents. Low-dose beta blockers may be used with caution for rate control in cardiac amyloid patients with atrial fibrillation or atrial flutter. If tolerated, doses typically should not exceed 50 mg daily of metoprolol. Tolerance of high dose beta blockade suggests that cardiac amyloidosis is not present or not clinically important.

For atrial dysrhythmias, particularly fibrillation or flutter, amiodarone may be used for rhythm control in these patients, and is the most widely selected agent. Other antiarrhythmic agents are generally avoided, but some can be used with caution including propafenone and dofetilide. Patients with amyloid cardiomyopathy are very sensitive to digoxin, which often leads to bradycardia. Digoxin has significant affinity for amyloid fibrils, to which it binds strongly in cardiac tissue from patients with cardiac amyloidosis (Rubinow et al., 1981). This interaction likely increases the local concentration of digoxin, leading theoretically to its adverse effects in these patients, and for this reason has been largely avoided clinically. Similarly, calcium channel blockers bind to amyloid fibrils, resulting in a potentiation of their negative inotropic effects, and worsening systolic heart failure in patients with cardiac amyloidosis (Pollak and Falk, 1993; Gertz et al., 1985).

Loop diuretics are often the mainstay of heart failure therapy. Increasing doses of diuretic are often required as the disease progresses. Significant right-sided heart failure often leads to ascites and gut edema. Thus, diuretics such as torsemide and bumetanide may have better oral absorption in these patients. Thiazide diuretics such as metolazone may be used to potentiate the effect of loop diuretics. Aldosterone antagonists including spironolactone and eplerenone are well tolerated and may be used adjunctively for diuresis and for treating hypokalemia which may result from aggressive diuresis. Patients with AL amyloidosis commonly have renal involvement which manifests as nephrotic syndrome. These patients may have profound lower extremity edema without other signs of heart failure. Diuretics are also used in these patients for treatment of their edema. A particularly challenging case is of the patient with AL cardiac amyloidosis with autonomic dysfunction leading to significant symptomatic

orthostatic hypotension. Such patients often require therapy with midodrine to support their blood pressure so they can be diuresed. Another challenging phenotype is the AL amyloidosis patient with LV outflow obstruction owing to chamber size and wall thickness, mimicking hypertrophic cardiomyopathy (Dinwoodey et al., 2008). There is no intentional experience with septal reduction surgery in AL amyloidosis; a small case series has been reported of patients with presumed HCM who were found to have cardiac amyloidosis by cardiac histology at surgery (Helder et al., 2014).

Atrial and ventricular arrhythmias are common in patients with cardiac amyloidosis. Atrial arrhythmias may be amenable to catheter ablation, but the risk of recurrence remains high, especially in the setting of atrial fibrillation (Tan et al., 2016), and the continued high risk of thromboembolic events warrants continued treatment with therapeutic anticoagulation. No clear guidelines exist for placement of ICDs and the rates of appropriate ICD therapies are high in patients with AL cardiac amyloidosis (Hamon et al., 2016). However, the overall mortality remains high, with pulseless electrical activity (PEA) being the dominant cause of death. Studies to date have not shown a survival benefit with ICD implantation for primary or secondary prevention (Kristen et al., 2008; Lin et al., 2013). Therefore, ICDs are likely not associated with a significant mortality benefit and their routine use in AL cardiac amyloidosis is not recommended. Our general practice is to place devices for true secondary prevention episodes including aborted sudden death and/or documented sustained VT/VF.

Definitive therapy is aimed at treating the underlying plasma cell dyscrasia. Since light chain toxicity contributes to the pathogenesis of cardiac amyloidosis, reducing the burden of circulating light chains leads to an improvement in cardiac function, even if the underlying amyloid deposits persist (Palladini et al., 2006). The goal of antiplasma cell therapy is the attainment of the complete hematologic response (CR), defined as the normalization of the affected light chain concentration, normalization of the bone marrow, and absence of monoclonal bands in serum and urine. Attainment of CR has been shown as a marker of long-term survival and organ-specific improvement. In the heart, a 30% reduction in NT-pro-BNP defines the organ-specific response, and this has been associated with a slight reduction in wall thickness and improvement in LVEF (Madan et al., 2012). The alkylating agent melphalan and the proteasome inhibitor bortezomib are most commonly used as first-line chemotherapy, the latter is often used in combination with cyclophosphamide and dexamethasone as part of the CyBorD regimen. First-line induction chemotherapy with CyBorD results in a hematologic response in around 60% of patients, with a cardiac response seen in about 20% of patients (Mikhael et al., 2012; Venner et al., 2012). Patients with cardiac involvement have a lower rate of achieving complete remission, with a response rate of about 40%, but with a two-year survival of 67% in responders (Palladini et al., 2015). Another class of immunomodulatory drugs, derived from thalidomide, and known as IMiDs have shown some promise in the treatment of patients with multiple myeloma and AL amyloidosis (Knight, 2005). Lenalidomide and pomalidomide are two drugs in this class that have been used as second-line agents in the treatment of AL amyloidosis. A recent phase 2 trial of pomalidomide and dexamethasone in patients who had previously been treated with melphalan, bortezomib, or other agents revealed a hematologic response rate of 68% and a survival benefit (Palladini et al., 2017). High-dose melphalan chemotherapy followed by autologous stem cell transplantation (HDM/SCT) represents a major therapeutic advance in the field, especially for patients without significant cardiac involvement as assessed by serum cardiac biomarkers (Comenzo et al., 1996). The hematologic response rate (CR or partial response) to HDM/SCT exceeds 70%, with a median survival of 7.6 years and more than half of all responders enjoying a prolonged survival of greater than 10 years (D'Souza et al., 2015; Sanchorawala et al., 2015). It is important to note that HDM/SCT is selected as the treatment of choice in patients deemed to be at acceptable risk for the procedure; thus the highest risk and sickest patients are not treated with this regimen. Transplant-related mortality remains high in patients with significant cardiac involvement (Mayo biomarker stage 3) and these patients are generally excluded from consideration of ASCT, except at specialized referral centers. In fact, the only randomized clinical trial of HDM/SCT vs. melphalan and dexamethasone did not identify a survival benefit, largely related to excessive peri-transplant mortality in the SCT arm (Jaccard et al., 2007).

Patients with advanced cardiac involvement also do not tolerate full doses of chemotherapy, and often need to undergo reductions in CyBorD and melphalan doses. While the majority of patients with AL cardiac amyloidosis do not achieve complete hematologic response with chemotherapy, those who do can enjoy prolonged survival (Palladini et al., 2015).

New antiplasma cell therapies are currently in clinical trials. These include the second-generation oral proteasome inhibitor ixazomib, and multiple myeloma drugs such as the proteasome inhibitor carfilzomib, the antiplasma cell antibody daratumumab, and the antibody elotuzumab, which stimulates the immune system by activating a lymphocyte signaling pathway (Palladini and Merlini, 2016). Another novel approach currently in development involves RNA interference targeting lambda light chain production and hence reducing the burden of amyloidogenic protein (Zhou et al., 2014). In addition to targeting clonal plasma cell populations and reducing the production of light chains, there is also interest in targeting amyloid deposits and reducing organ damage. The antibiotic doxycycline can inhibit amyloidogenesis and has been shown to improve survival when added to standard chemotherapy in a small trial (Wechalekar et al., 2015). Finally, immune therapy consisting of manufactured antibodies that are specific for misfolded light chain have shown promise. The monoclonal antibody NEOD001 (Prothena) targets amyloid fibrils and a phase I/II trial in AL amyloidosis patients resulted in a cardiac response rate of 50% (Gertz et al., 2016). A phase 3 trial of NEOD001 is currently underway. Other amyloid-specific antibodies are presently in development.

Orthotopic heart transplantations (OHT) have historically been controversial in patients with cardiac amyloidosis due to the risk of amyloidosis recurrence in the transplanted organ and the risk of progression of the noncardiac underlying disease. Without treatment of the underlying plasma cell dyscrasia, patient's who undergo OHT in cardiac amyloidosis have a one-year survival of around 60% and a five-year survival of 30% (Dubrey et al., 2001). This initial experience with OHT occurred in the context of aggressive treatment of the plasma cell dyscrasia followed by a heart transplant. Unfortunately, this strategy is not applicable to most patients with advanced heart failure who would be eligible for OHT because they would be too high risk for HDM/SCT.

Nevertheless, in carefully selected patients without other extra cardiac manifestations of amyloidosis, there was a transplant-related mortality of 18% and median survival was 76 months after heart transplant and 57 months after stem cell transplant (Lacy et al., 2008).

A more contemporary strategy is to first perform OHT followed by HDM/SCT. As reported by Semigran and colleagues, this approach yields a 5-year survival rate of 60% that is similar to nonamyloid cardiomyopathy treated with OHT (Dey et al., 2010; Gray Gilstrap et al., 2014). Another study from the National Amyloidosis Centre in the United Kingdom reported a median survival of 9.7 years when OHT was followed by HDM/SCT (Sattianayagam et al., 2010). These efforts and others have resulted in the inclusion of cardiac amyloidosis as an acceptable indication of OHT in the 2016 Listing Criteria of the International Society for Heart and Lung Transplantation (Mehra et al., 2016).

Conclusion

Amyloidosis is a disease of protein misfolding that leads to end organ deposition and dysfunction. In AL amyloidosis, abnormal plasma cell production of amyloidogenic light chains commonly deposits in organs such as the heart and kidneys. Heart involvement leads to significant morbidity and, without effective treatment, leads to reduced survival. Thus, early determination of cardiac involvement is critical. Echocardiography forms the cornerstone of noninvasive diagnosis of cardiac amyloidosis. Cardiac MRI is more sensitive, particularly for diagnosis of early or subclinical cardiac amyloidosis and is often used when echocardiography is equivocal. Endomyocardial biopsy remains the gold standard for diagnosis of cardiac amyloidosis, and can also help identify the origin of the amyloid protein by immunohistochemistry or laser microdissection and mass spectrometry. While early experience with this disease suggested a median survival of only 1 year in the context of heart failure symptoms, advances in plasma cell therapy have dramatically extended survival to beyond 10 years.

Aggressive therapy in advanced disease patients with tandem heart and autologous stem cell transplantations can significantly prolong survival, especially in those patients who achieve hematologic remission. Newer treatment approaches are targeting amyloid fibrils with the goal of disrupting amyloid deposits, and prompting reabsorption, in end organs. In contrast to just 20 years ago, AL amyloidosis is now a treatable disease, and in particular if recognized early in its course, long-term survival can be achieved.

Introduction

Over the last two decades, multiple observational and experimental studies have suggested an association between light-to-moderate alcohol consumption and a reduced risk of cardiovascular disease (CVD), mainly driven by a decrease in the risk of coronary heart disease (CHD) and ischemic stroke. While it is difficult to design randomized controlled trials (RCTs) to evaluate the causal relationship between alcohol consumption and the risk of CVD, accumulating evidence strongly suggests a causal relationship between light-to-moderate alcohol consumption and a reduced risk of CVD. However, alcohol intake is also known to have complex physiological, psychological, and social effects, and health care providers should remain cautious about recommending alcohol consumption to their patients for reducing the risk of CVD.

In this article, we shall discuss recent evidence on the association between alcohol consumption and the risks of multiple types of CVD and intermediate CVD end points, along with the underlying mechanisms. We shall also consider the associations between alcohol consumption and the risk of CVD in subpopulations classified according to the sex, ethnicity, comorbidities, etc. and whether the type of alcoholic beverage may have a bearing on the association between alcohol consumption and the risk of CVD. Finally, we shall provide some guidance for patient counseling and discuss the public health implications and potential adverse effects of recommending alcohol consumption for CVD prevention.

Definition of Alcohol Consumption

Alcoholic beverages contain different amounts of alcohol, and the amount of alcohol in the same types of alcoholic beverages may also vary among countries. Thus, "light-to-moderate alcohol consumption" may be defined differently in different research projects. Based on the American Heart Association (AHA) guideline and the European Society of Cardiology (ESC) guideline, moderate alcohol consumption is defined as intake of 20–30 g of pure alcohol/day for men and intake of 10–20 g of pure alcohol/day for women, and "heavy drinking" is defined as consumption of 15 drinks (each drink containing roughly 14 g of pure alcohol) or more per week for men and consumption of eight drinks or more per week for women. Furthermore, "binge drinking" is defined as consumption of five or more drinks on a single occasion for men and consumption of four or more drinks on a single occasion for women, according to the statement of the National Institute on Alcohol Abuse and Alcoholism (**Table 1**).

The pathology and etiology differ among various types of CVD; therefore, the association between alcohol consumption and the risk of CVD also varies according to the type of CVD under discussion. We shall now discuss the association between alcohol consumption and the risk of CVD for various types of CVD.

Table 1 Typical standard serving sizes of various alcoholic beverages

Beverage	*Ounces (oz)*	*Milliliters (mL)*	*Approximate grams of pure alcohol per serving (g)*
Wine	4	118.3	10.8
Beer	12	354.9	13.2
Liquor/spirits	1.5	44.4	15.1

Alcohol and CVD

Coronary Heart Disease

The favorable association between light-to-moderate alcohol consumption and CVD risk is mainly driven by the reduced risk of atherosclerotic CVDs, namely, CHD and ischemic stroke, associated with such consumption.

Multiple observational studies from diverse regions and countries have reported a J- or U-shaped association between alcohol consumption and the risk of CHD and CHD mortality. Despite the great heterogeneities in the population characteristics, size, study duration, and adjustments for confounding factors, a large number of observational studies have consistently reported an association between moderate alcohol consumption and a roughly 20–45% reduction in the risk of CHD as compared with that in nondrinkers (Kono et al., 1991; Mancia et al., 2013; Marques-Vidal et al., 1996; Mukamal et al., 2005b; Steyn et al., 2005). A meta-analysis of 29 observational studies involving 549,504 subjects reported a pooled adjusted relative risk (RR) (95% confidence interval (CI)) of CHD in alcohol drinkers versus nondrinkers of 0.71 (0.66–0.77); it also revealed that the greatest degree of risk reduction for CHD was associated with consumption of 15–29.9 g/day (Ronksley et al., 2011). There is always the argument about potential confounding by healthy lifestyle factors in light-to-moderate drinkers and the potential bias arising from inclusion of sick quitters to the nondrinking referent group. However, the findings of studies in which lifelong nondrinkers and ex-drinkers were evaluated separately argue against this "healthy-drinker hypothesis" (Ronksley et al., 2011) and suggest the robustness of the favorable association between light-to-moderate alcohol consumption and the risk of CHD.

The potential underlying mechanism for the J-shaped association between alcohol consumption and the risk of CHD still remains to be clearly elucidated. It is speculated that elevation of the serum levels of high-density lipoprotein cholesterol (HDL-C) and improvement of the glucose metabolism by moderate alcohol consumption, as discussed later, are the main factors responsible for the J-shaped association between alcohol consumption and the risk of CHD. In addition, the effects of alcohol consumption on the coagulation/fibrinolysis systems (Brien et al., 2011; Salem and Laposata, 2005; Collins et al., 2009; Wannamethee et al., 2003; Zhang et al., 2000; Ridker et al., 1994), oxidative stress status (Addolorato et al., 2008; Blackhurst and Marais, 2006; Estruch et al., 2011), inflammation (Albert et al., 2003; Avellone et al., 2006; Wang et al., 2008), and endothelial function (Suzuki et al., 2009; Teragawa et al., 2002) may also play important roles in the potential favorable effect of moderate alcohol consumption on the risk of CHD. However, previous studies, including experimental studies and clinical studies, have not yielded consistent results, and the potential effects of moderate alcohol consumption on these parameters still remain under debate.

Stroke

Stroke is classified as ischemic stroke (embolic stroke, thrombotic stroke, and lacunar stroke) or hemorrhagic stroke (intracerebral hemorrhage and subarachnoid hemorrhage). The pathophysiology differs among different types of strokes; therefore, the relationships between alcohol consumption and the risk of each type of stroke may also be different.

Ischemic stroke shares important risk factors with arteriosclerotic CHD; therefore, the favorable effect of alcohol consumption on the risk of ischemic stroke is similar to that on the risk of CHD. A meta-analysis of 35 observational studies that evaluated the relationships between alcohol intake and the risks of ischemic stroke and hemorrhagic stroke separately demonstrated a J-shaped association between alcohol consumption and the risk of ischemic stroke. The moderate drinkers (alcohol intake, 12–24 g/day) showed the greatest degree of risk reduction for ischemic stroke as compared with the risk in nondrinkers, with an RR (95% CI) of 0.72 (0.57–0.91) (Reynolds et al., 2003). In contrast, heavy drinkers (alcohol intake, >60 g/day) showed an increased risk of ischemic stroke, with an RR (95% CI) of 1.69 (1.34–2.15) as compared with nondrinkers (Reynolds et al., 2003). However, the associations between alcohol consumption and each subtype of ischemic stroke (embolic stroke, thrombotic stroke, and lacunar stroke) still remain unclear. Some observational studies that have attempted to evaluate the relationships between alcohol consumption and each subtype of ischemic stroke have failed to reveal any differential associations between alcohol consumption and the risks of each subtype of ischemic stroke (Mukamal et al., 2005a; Ohira et al., 2006). One of the reasons for this may be the lack of sufficient statistical power to detect the associations because of the relatively small numbers of patients with each subtype of ischemic stroke. In this context, it must be noted that the different pathophysiology of each subtype of ischemic stroke may also differentially affect the risk reduction associated with alcohol consumption. For example, among the major risk factors for embolic ischemic stroke is atrial fibrillation (AF) and for lacunar ischemic stroke is hypertension (HTN). Both AF and HTN are associated with heavy alcohol drinking, as discussed later. Therefore, we need further study to establish strong evidence for the associations between alcohol consumption and the risk for each of the subtypes of ischemic stroke.

In contrast to ischemic stroke, no J-shaped association has been detected between alcohol consumption and the risk of hemorrhagic stroke; in fact, heavy alcohol consumption has been shown to be consistently associated with an increase in the risk of hemorrhagic stroke, regardless of the subtype (cerebral hemorrhage or subarachnoid hemorrhage). A previous meta-analysis conducted by Reynolds found an increased risk of hemorrhagic stroke, regardless of the subtype, associated with heavy drinking (>60 g/day), with an RR (95% CI) of 2.18 (1.48–3.20), and also revealed a positive linear association between alcohol consumption and the risk of hemorrhage stroke (Reynolds et al., 2003). In regard to the subtypes of hemorrhagic stroke, another meta-analysis of 25 observational studies reported an increased risk of intracranial hemorrhage associated with heavy alcohol consumption (mean cutoff 56 g/day), with an odds ratio (OR) (95% CI) of 3.36 (2.24–5.12) (Ariesen et al., 2003). A meta-analysis by Feigin reported an increased risk of subarachnoid hemorrhage associated with heavy drinking (>150 g/week), with an OR (95% CI) of 2.1 (1.5–2.8) (Feigin et al., 2005). The fact that HTN, the risk of which is also increased in heavy drinkers, is among the strongest risk factors for hemorrhagic stroke may be one of the underlying reasons for the positive association between alcohol consumption and the risk of hemorrhagic stroke. As for other possible mechanisms, increased platelet activity and prothrombotic activity induced by alcohol consumption may also affect this association (Deykin et al., 1982; Mukamal et al., 2001, 2005b; Hendriks et al., 1994; Rimm et al., 1999).

Heart Failure

Heart failure (HF) has a complex pathophysiology and varied etiologies, including CHD, HTN, valvular disease, arrhythmias, and cardiomyopathy (including alcoholic cardiomyopathy (ACM)). Nonetheless, a number of studies have reported a U-shaped association between alcohol consumption and the risk of HF. The Framingham Heart Study reported a lower risk of HF associated with moderate alcohol consumption (8–14 drinks/week for men and 3–7 drinks/week for women), with a hazard ratio (95% CI) of 0.41 (0.21–0.81) for men and 0.49 (0.25–0.96) for women (Walsh et al., 2002). Because one of the strongest predisposing factors for HF is CHD, this association could be driven by the association between moderate alcohol consumption and a lower risk of CHD. The Physicians' Health Study reported the absence of an association between moderate alcohol consumption and the risk of HF in patients without antecedent CHD (Djousse and Gaziano, 2007). On the other hand, the Cardiovascular Health Study reported a lower risk of HF associated with moderate alcohol consumption even after accounting for myocardial infarction (Bryson et al., 2006). Therefore, it still remains to be clarified whether the lower risk of HF associated with moderate alcohol consumption is due to suppression of the risk of CHD by the alcohol intake. However, a reduced risk of HF associated with moderate alcohol consumption has been reported quite consistently, and it is possible that some other factors, including systemic arterial dilation (Greenberg et al., 1982) and reduction of the pulmonary arterial wedge pressure (Vlachopoulos et al., 2003), are also responsible for the favorable association between moderate alcohol consumption and the risk of HF.

Alcoholic Cardiomyopathy

Chronic and excessive alcohol consumption leads to ACM. ACM is classified among the acquired forms of dilated cardiomyopathy (DCM) and is diagnosed through the exclusion of other causes in patients with a long history of heavy alcohol consumption. The reported prevalence of ACM among DCM patients is about 23–47% (Guzzo-Merello et al., 2014). Even though the precise amount of alcohol intake and duration of exposure to alcohol that can cause ACM have not yet been established, intake of over 80 g/day of alcohol for at least 5 years has been used as a prerequisite for establishing the diagnosis of ACM in many studies. However, it should be noted that this amount does not take into account the sex or body mass index, even though the heart in women may be affected by consumption of smaller amounts of alcohol due to the lower BMI of women as compared with men. The mechanism underlying the development of ACM has not yet been clearly elucidated; however, changes in the level of oxidative stress, alterations of the mitochondria, protein synthesis, gene expression and calcium transport, apoptosis, and changes in the myofilament structure and function associated with alcohol and acetaldehyde accumulation are some of the speculated putative mechanisms (Guzzo-Merello et al., 2014).

Atrial Fibrillation

A phenomenon called "holiday heart" has been reported to be associated with binge drinking (Greenspon and Schaal, 1983; Rich et al., 1985). Also, chronic heavy alcohol consumption has been consistently reported to be associated with an increased risk of development of AF (Conen et al., 2008; Mukamal et al., 2005c). On the other hand, inconsistent results have been reported in regard to the association between moderate alcohol consumption and the risk of AF (Samokhvalov et al., 2010). Nonetheless, several meta-analyses have reported a positive linear association between alcohol consumption and the risk of AF (Kodama et al., 2011; Larsson et al., 2014; Samokhvalov et al., 2010). A recent meta-analysis of prospective studies involving 79,019 subjects reported a linear association between alcohol consumption and the risk of AF, with an RR (95% CI) of 1.12 (1.02–1.23) associated with consumption of 7–14 drinks/week, of 1.18 (1.03–1.35) associated with consumption of 15–21 drinks/week, and of 1.43 (1.25–1.65) associated with consumption of >21 drinks/week (p for trend <0.0001) as compared with nondrinkers; in addition, an increment of 1 drink/day was associated with an 8% increase in the risk of AF (Larsson et al., 2014). Therefore, it seems that not only heavy drinking but also moderate drinking is associated with an increased risk of AF. The mechanism of alcohol-related AF is complex, and several factors appear to influence this association: decreased vagal tone,

Table 2 Association of alcohol intake and risk of developing cardiovascular disease (CVD)[a]

Coronary heart disease (CHD)	• J-shaped association • Moderate drinking is associated with 20–45% reduction of CHD
Ischemic stroke	• J-shaped association • Moderate drinking is associated with 30% reduction of ischemic stroke • Increased risk by heavy drinking
Hemorrhagic stroke	• Increased risk with heavy drinking
Subarachnoid hemorrhage (SAH)	• Increased risk with heavy drinking
Congestive heart failure (CHF)	• J-shaped association • Light-to-moderate alcohol intake is associated with 30–50% reduction of CHF
Alcoholic cardiomyopathy (ACM)	• Increased risk with over 80 g/day drinking during at least 5 years
Atrial fibrillation (AF)	• Increased risk with heavy drinking • Increased risk with binge drinking

[a]Compared with nondrinkers.

increased adrenergic drive, cardiac conduction interference, and refractory period shortening are some of the speculated mechanisms (Tonelo et al., 2013; **Table 2**).

Alcohol and Intermediate CVD End Points

HTN and Blood Pressure

Even though several clinical studies have reported a decrease of the blood pressure (BP) by acute alcohol consumption (Abe et al., 1994; de Lorimier, 2000), chronic heavy alcohol consumption is causally associated with elevation of the BP and HTN. A number of observational studies, including meta-analyses, have consistently reported a higher risk of HTN in heavy alcohol drinkers (Taylor et al., 2009). A meta-analysis of 12 observational studies conducted by Taylor reported a linear dose–response relationship between alcohol consumption and the risk of HTN in men, with an RR of 1.09 for consumption of 10 g/day, of 1.57 for consumption of 50 g/day, and of 2.49 for consumption of 100 g/day. Also, several RCTs have suggested an association between alcohol consumption and elevation of the BP (Taylor et al., 2009). For example, Zilkens reported that alcohol consumption for 4 weeks raised the ambulatory systolic BP, regardless of the type of alcoholic beverage consumed. They reported an increase of the systolic BP by 1.7 and 2.2 mmHg in association with heavy consumption of beer (41 g of alcohol) and red wine (39 g of alcohol), respectively (Zilkens et al., 2005). Moreover, a meta-analysis of 15 RCTs reported a dose-dependent decrease of the BP associated with a reduction of alcohol consumption in heavy drinkers, with a significant reduction of the mean (95% CI) systolic and diastolic BP by −3.31 (−2.52 to −4.10) and −2.04 mmHg (−1.49 to −2.58 mmHg), respectively (Xin et al., 2001). It is estimated that in about 5–24% of cases, HTN is associated with alcohol consumption (Friedman et al., 1983; Milon et al., 1982). However, in regard to the association between light-to-moderate alcohol consumption and the risk of BP elevation/HTN, a previously reported meta-analysis by Taylor reported a lower risk of HTN among light alcohol drinkers (<5 g/day), after which a linear dose–response relationship was found, with RRs of 1.81 and 2.81 for alcohol consumption of 50 and 100 g/day, respectively, among women (Taylor et al., 2009). Furthermore, an observational study conducted by Okubo reported a J-shaped association between alcohol consumption and BP changes, with a threshold effect at 18 mL (=14.2 g)/day (Okubo et al., 2001). Therefore, it seems at least moderate alcohol consumption may not have any effect of inducing HTN or increasing the BP.

In regard to the mechanism of elevation of the BP by heavy alcohol consumption, no solid evidence has been established. However, increase in the sympathetic nervous activity, stimulation of the renin–angiotensin–aldosterone system, and increase of the intracellular Ca^{2+} concentration in the vascular smooth muscle, increase in oxidative stress, and endothelial dysfunction are some of the speculated mechanisms underlying the elevation of the BP by heavy alcohol consumption (Marchi et al., 2014).

Dyslipidemia and Lipids

Alcohol consumption is known to increase the plasma level of HDL-C, which is established as a major protective factor against CHD. Many observational studies and RCTs, including meta-analyses, have reported a dose–response association between alcohol consumption, including heavy alcohol consumption, and the plasma HDL-C level. A meta-analysis of 47 RCTs showed a mean difference from the baseline serum HDL-C of 0.072 mmol/L (95% CI; 0.024–0.119) for alcohol consumption of 12.5–29.9 g/day and of 0.103 (0.042–0.540) and 0.141 mmol/L (0.042–0.240) for alcohol consumption of 30–60 and >60 g/day, respectively (p for trend = 0.013) (Brien et al., 2011). It is regarded that alcohol may increase the plasma HDL-C level by modulating the HDL composition, HDL function, and/or HDL-related metabolic factors (Brinton, 2012); however, the mechanism underlying the increase of the serum HDL-C by alcohol has not yet been clearly elucidated. Also, the reason for the lack of any beneficial effect of the increase of the plasma HDL-C level by heavy alcohol consumption on the CVD risk remains unclear. However, it is speculated that the adverse effects by heavy alcohol consumption, including elevation of the BP, increase of the oxidative stress, endothelial dysfunction, and inflammation, may offset any beneficial effect of elevated HDL-C on the risk of CVD.

On the other hand, low-density lipoprotein cholesterol (LDL-C), a risk factor for CHD, may not be remarkably affected by alcohol consumption. A meta-analysis of short-term RCTs has reported the absence of any significant association between alcohol consumption and the plasma LDL-C levels (Brien et al., 2011). However, this meta-analysis showed high heterogeneity, and given the inconsistent results from some observational studies, the association of alcohol consumption with the serum LDL-C appears to vary according to the population characteristics. Observational studies carried out in a Japanese population and Danish population reported an inverse association between alcohol consumption and the plasma LDL-C (non-HDL-C) level (Tolstrup et al., 2009; Wakabayashi and Groschner, 2009). In contrast, an observational study carried out in an elderly Italian population reported a positive association between alcohol consumption and the serum LDL-C. Further investigations are needed to clarify the association between alcohol consumption and the serum LDL-C (Perissinotto et al., 2010).

Multiple observational studies have reported an association between heavy alcohol drinking and increased plasma triglycerides (TG) (Park and Kim, 2012; Ruidavets et al., 2010; Tolstrup et al., 2009). However, in addition to the reported linear relationship between alcohol consumption and TG, some studies have shown a J-shaped association between alcohol consumption and the serum TG (Ruidavets et al., 2002; Whitfield et al., 2013). RCTs of carbohydrate-free alcohol reported a reduction of the serum TG by moderate alcohol consumption in women (Davies et al., 2002). However, the inconsistent results warrant further exploration of the relationship between alcohol consumption and the serum TG, along with mechanistic explanations.

Type 2 Diabetes Mellitus and Glucose Metabolism

Moderate alcohol consumption appears to have a favorable effect on glucose metabolism. Multiple studies have reported beneficial effects of moderate alcohol consumption on the insulin sensitivity, fasting blood glucose, and hemoglobin $A1_C$ levels (Davies et al., 2002; Harding et al., 2002; Maraldi et al., 2006; Sierksma et al., 2004). A number of observational studies, including two meta-analyses, have shown a U-shaped association between alcohol consumption and the risk of type 2 diabetes mellitus (T2D) (Baliunas et al., 2009; Rimm et al., 1999). A recent meta-analysis of 20 cohort studies also reported a U-shaped relationship between alcohol consumption and the risk of T2D. As compared with the case in lifetime abstainers, moderate alcohol consumption (22 g/day in men and 24 g/day in women) was associated with a reduced risk of T2D among both men and women (RR (95% CI) in men, 0.87 (0.76–1.00); RR in women, 0.60 (0.52–0.69)). Some trials have also reported improvement of the insulin sensitivity associated with consumption of red wine in a healthy population (Beulens et al., 2006; Sierksma et al., 2004). The report from the Nurses' Health Study of attenuation of the positive association between glycemic load and the incidence of T2D by higher alcohol consumption ($\geq$15 g/day) (Mekary et al., 2011) lends support to the evidence that moderate alcohol consumption has a favorable effect on the risk of T2D. The biological mechanism underlying the U-shaped relationship between alcohol consumption and T2D is still a matter of debate. Improvement of the insulin sensitivity by elevation of the adiponectin levels induced by moderate alcohol consumption is speculated as one of the potential mechanisms for this association (Beulens et al., 2006, 2008; Imhof et al., 2009).

Alcohol and the Risk of CVD/Intermediate CVD End Points in Subpopulations Classified According to Variables Such as the Sex, Ethnicity, and Genetic Factors

Available data from diverse populations (different sex and ethnicities) have consistently shown a lower risk of CHD in light-to-moderate alcohol drinkers. Yet, it should be noted that the magnitude and threshold of the protective effect of moderate alcohol consumption against CHD may differ according to sex and ethnicity. For example, the definition of moderate alcohol consumption differs between men and women (20–30 g/day for men and 10–20 g/day for women), due to the generally smaller body size, lower levels of alcohol-metabolizing enzymes, and higher proportion of body fat in women as compared with men. In fact, some studies have reported this difference; they have demonstrated that a higher amount of alcohol consumption was associated with a greater degree of risk reduction for CHD or intermediate CHD end points in men as compared with women (Di Castelnuovo et al., 2002; Taylor et al., 2009). In regard to the differences in the effect of alcohol consumption on the risk of CVD related to the ethnicity, the majority of observational studies that have reported a favorable association between moderate alcohol consumption and CHD risk are reported from Western countries. As one of the exceptions, the study on a Kaiser Permanente cohort reported an inverse association between alcohol consumption and the risk of HF in Caucasians, Asians, and African Americans (Klatsky et al., 2005). Furthermore, the interaction between genetic factors and the effect of alcohol on the risk of CVD should be also considered. Alcohol dehydrogenase (ADH) and acetaldehyde dehydrogenase (ALDH) are key enzymes metabolizing alcohol, and there are significant genetic differences in the rate of alcohol metabolism between Asian and Western populations. Some studies have evaluated the interaction between alcohol consumption and the ADH/ALDH expression status, as genetic factors, on the risk of CVD. For example, Hines reported that in subjects who were homozygous for the slow-oxidizing ADH3 allele, moderate alcohol consumption was associated with an increase in the serum levels of HDL-C (Hines et al., 2005). Yet, the results of studies evaluating the interactions between genetic factors and alcohol consumption on the risk of CVD are not consistent (Heidrich et al., 2007; Jensen et al., 2009; Whitfield et al., 2003). There might be many genes affecting the association between alcohol consumption and the risk of CHD, and each of these genes may play a small role, but a potentially larger role in combination with multiple other genes. Further evidence is needed to shed further light on the impact of genetic factors on the association between alcohol consumption and the risk of CVD.

Alcohol and CVD Risk in Subjects at a High Risk for CVD

The potential cardioprotective effect of moderate alcohol consumption is observed not only in the healthy population but also in subjects at high risk for CHD, such as patients with T2D, HTN, etc. Patients with a history of CHD also appear to benefit from moderate alcohol consumption for secondary prevention of CHD and protection against CHD mortality. However, the potential beneficial effect of alcohol consumption on the risk of CHD is limited to moderate alcohol consumption, and excessive drinking has adverse effects, for example, in patients with T2D. Perneger reported that consumption of more than 2 drinks/day was associated with a fourfold higher risk of end-stage renal disease among diabetic patients (Perneger et al., 1999), and Kohner reported a higher incidence of diabetic retinopathy among alcohol drinkers as compared with those who abstained from alcohol (Kohner et al., 1998).

Also, the potential interaction of alcohol with medications should be considered. Many patients with a history of CVD and also those at a high risk for CVD take multiple medications. For example, the effect of the anticoagulant warfarin is enhanced by alcohol consumption, which may increase the risk of major bleeding (Fiumara and Goldhaber, 2009). Also, alcohol consumption can enhance the effects of vasodilators such as hydralazine and nitroglycerin to cause hypotension.

Difference in Potential Cardioprotective Effect Among Different Types of Alcoholic Beverages

It still remains controversial as to whether there are differences in the cardioprotective effect among different types of alcoholic beverages. Since the majority of observational studies have demonstrated a consistently positive association between moderate alcohol consumption and a reduced risk of CVD regardless of the type of alcoholic beverage, it may be reasonable to assume a cardioprotective effect of pure alcohol per se. Observational studies evaluating the effects of moderate consumption of red wine in France (Renaud et al., 1998), beer in Germany and Hawaii (Keil et al., 1997; Kagan et al., 1981), and distilled spirits in Japan (Kitamura et al., 1998) have all shown an ~45% reduction in the risk of CHD as compared with that in nondrinkers. A large-scale observational study, the Copenhagen City Heart Study, showed a J-shaped relationship between alcohol consumption and all-cause mortality among both beer and sprit drinkers (Gronbaek et al., 2000). A meta-analysis of 11 observational studies analyzing the effects of drinking wine, beer, and spirits reported a similar J-shaped relationship between wine and beer consumption and the incidence of CVD (Costanzo et al., 2011).

On the other hand, each type of alcoholic beverage contains different nonalcohol components that could exert additive cardioprotective effect over that of alcohol itself. For example, red wine is enriched in polyphenols such as anthocyanins, flavan-3-ols, and resveratrol, which may exert beneficial effects on the lipid profile and platelet aggregation. Beer also contains a variety of nonalcohol components, such as amino acids, minerals, and some kinds of polyphenols such as phenolic acid, prenylated chalcones, flavonoids, and catechins, different from those in red wine. In contrast, spirits do not contain any significant amounts of polyphenols as compared with red wine and beer.

The aforementioned nonalcohol components, especially polyphenols, can cause discrepancies in the effects of different types of alcoholic beverages on the risk of CVD. For example, a randomized crossover trial reported that moderate consumption of red wine had greater antioxidant effect as compared with that of gin (Estruch et al., 2011). Also, one RCT showed improved endothelial function associated with consumption of red wine, but not with that of beer or vodka (Huang et al., 2010). Therefore, alcoholic beverages enriched in polyphenols, especially red wine, may have enhanced cardioprotective effects as compared with alcoholic beverages not containing or containing lower amounts of polyphenols.

Guidance for Patient Counseling and the Public Health Implications of Alcohol Consumption

While there are hardly any RCTs demonstrating the causal relationship between moderate alcohol consumption and a reduced risk of CVD, accumulating evidence from many observational and experimental studies strongly suggests such a causal relationship.

However, from a public policy standpoint, encouragement of patients for moderate alcohol consumption should be weighed carefully by physicians, as alcohol consumption also has numerous physiological and psychological adverse effects. Not only can indiscriminate alcohol consumption increase the risk of some CVDs such as cerebral hemorrhage, ACM, AF, and HTN, it can also increase the risk of noncardiac diseases such as liver cirrhosis and of some types of cancer (breast, colorectal, and hepatocellular cancer) (Giovannucci et al., 1995; WCRFAIFC Research, 2010). In fact, in the United States, nearly 88,000 people die annually from alcohol-related causes, making alcohol the fourth leading preventable cause of death (Stahre et al., 2014). In a survey conducted in 2014, 16.3 million adults aged 18 years or older (6.8% of the population in this age group) were detected to have an alcohol use disorder (SAMHSA, 2014b). Therefore, recommendation to start moderate alcohol consumption for reducing the risk of CHD may not be judicious. However, given the fact that 87.6% of people aged 18 years or older have had alcohol at some point in their lifetime and that 56.9% of the entire population reported having consumed alcohol during the previous month in the United States (SAMHSA, 2014a), health care providers may advise people who are seeking to improve their cardiovascular health that light-to-moderate alcohol consumption may reduce the risk of CHD. As a matter of fact, major organizations such as the AHA and the ESC have refrained from promoting blanket recommendation of alcohol consumption for the prevention of CHD but recommend limitation of alcohol consumption to 1 or 2 drinks/day (moderate drinking) to individuals who choose to consume alcohol (Krauss

et al., 2000; Goldberg et al., 2001; Mosca et al., 2011; Perk et al., 2012). Under this circumstance, it must be borne in mind that there are also certain populations that should not/are not allowed to drink any alcohol, for example, children and adolescents, pregnant women, patients with a history of alcohol abuse, patients with severe liver disease and/or certain other health conditions, and persons with specific religious beliefs.

Needless to say, health care providers should give advice on alcohol consumption after carefully taking into account the characteristics of individual subjects (sex, age, lifestyle, risk of CVD and intermediate CVD end points, potential for abuse/addiction, the presence/absence of liver disease, etc.); in other words, blanket recommendation to all cannot be provided, and the recommendation should be tailored to the needs of individual subjects.

Conclusion

Accumulating evidence strongly suggests that light-to-moderate alcohol consumption is associated with a reduced risk of CVD, especially CHD. However, given the potential adverse physiological and psychological effects of alcohol consumption, health care providers should remain cautious while recommending light-to-moderate alcohol consumption to their patients for reducing the risk of CVD, by carefully taking into account the characteristics of individual patients.

Introduction

Alcohol or ethanol is a toxin responsible for a significant proportion of the total disease burden in the modern world, especially in economically advanced societies. Chronic consumption of large quantities of alcohol leads to a dose-related increase in mortality, morbidity and a reduction in quality of life. Due to its' biochemical nature and the small molecular size, ethanol is easily absorbed in the proximal digestive tract and freely traverses into the intracellular environment where it affects organelles and various metabolic pathways. Evidence of the detrimental effect of alcohol on the cardiovascular system and especially the myocardium has been available for a long time, but new insight into what constitutes risk for developing alcoholic cardiac dysfunction has recently been achieved (Laurent and Edwards, 2014). Starting from clinical and epidemiological observations, the concept of alcoholic heart muscle disease or "alcoholic cardiomyopathy" (ACM) emerged and this condition is currently considered one of the most common causes of nonhereditary dilated cardiomyopathy (Japp et al., 2016).

Pathological Effects of Alcohol on the Myocardial Cells

Ingested ethanol (CH_3-CH_2-OH) is rapidly absorbed in the stomach and upper part of the small bowel and, once present in the systemic circulation, it diffuses freely into cells throughout the organism. The main site of metabolism is the liver where alcohol dehydrogenase and aldehyde dehydrogenase act sequentially to transform alcohol into acetaldehyde and then nontoxic acetate in a stepwise, rate-limited fashion (Edenberg, 2007). Both alcohol and acetaldehyde induce toxic effects on skeletal and myocardial muscle cells through a variety of mechanisms that lead to myopathy and cellular necrosis (Piano and Phillips, 2014). A variety of pathogenic pathways have recently been hypothesized but contradictory findings have rendered the identification of a key central mechanism responsible for ACM difficult (Rodriguez et al., 2015; Seiva et al., 2009; Matyas et al., 2016). Increased oxidative stress, impaired mitochondrial bioenergetics, accelerated protein catabolism, and altered calcium handling leading to apoptosis and myocardial cell death are the main putative mechanisms involved.

Oxidative stress is currently the most studied hypothesis of alcohol-induced cardiac dysfunction (Seiva et al., 2009). Experimental studies have shown that repeated exposure to ethanol results in excess free radical production, decreased glutathione levels, increased catalase activity, and signs of lipid peroxidation and protein damage (Matyas et al., 2016). Antioxidant enzymes such as catalase, glutathione peroxidase, and superoxide dismutase are responsible for the protection of the cellular environment from oxidative stress by stimulating the breakdown of deleterious reactive oxygen species (ROS) (Espinosa-Diez et al., 2015). Chronic ethanol exposure requires a rise in enzymatic activity in order to counteract ROS and a deficiency in antioxidant function has been documented in both experimental models (Fahimi et al., 1979; Kino, 1981) and patients with ACM and sudden cardiac death (Vikhert et al., 1986). Proteins are major targets of oxidative stress (Davies, 2016) and myofilament dysfunction has been traced back to oxidative stress (Ribiere et al., 1992; Edes et al., 1986; Avner et al., 2010; Santos et al., 2011 Apr 1).

Recently, the importance of an alcohol-induced increase in the expression of cytochrome P450 2E1 (CYP2E1) has been underlined (Jing et al., 2012). CYP2E1 offers an alternative pathway for alcohol metabolism and elegant studies have demonstrated a reduction in oxidative stress by pharmacological inhibition of the cytochrome (Zhang et al., 2013). Use of agents with antioxidant properties or inhibition of reactive-oxygen generation resulted in alleviation or prevention of functional or ultrastructural myocardial damage in several studies (Khanna et al., 2007; Rao et al., 2015).

Chronic ethanol feeding was found to result in increased expression of angiotensin II and its' AT1 receptor leading to the assumption that angiotensin II plays a critical role in alcohol-induced cardiac nitrate damage, cell death, remodeling, and cardiomyopathy (Tan et al., 2012; Cheng et al., 2006). Genetic susceptibility to the development of left ventricular failure in alcohol consumers due to a polymorphism of the angiotensin-converting enzyme has also been proposed (Fernández-Solà et al., 2002).

Mitochondrial damage observed in cardiomyocytes after chronic alcohol exposure is a common finding in histopathological studies. In addition to generating reactive oxygen species mitochondria are also targets for free radicals and suffer from a reduced capacity for DNA repairing (Marzetti et al., 2013). Analysis of tissue fragments collected through cardiac biopsies has shown myocardial mitochondrial enlargement and disorganization as well as increased numbers and altered intracellular distribution (Ferrans et al., 1965; Hibbs et al., 1965). Fatty acid ethyl esthers, which are products of alcohol interaction with fatty acids, are found in increased concentrations in the circulation and cardiomyocytes of alcohol abusers. These molecules can attach to mitochondria and disrupt their function (Kaphalia et al., 2004). Perturbation of lipid metabolism and intracellular accumulation of triglycerides (Zhong et al., 2012) may also contribute to decreased myocardial contractility (Yoerger et al., 2006).

There are several other important molecular mechanisms linked to cardiac injury in chronic alcohol abuse such as increase in intracellular calcium (Samak et al., 2016 Dec 13), decrease of myofilament sensitivity to calcium, excitation-contraction coupling, decrease of contractile proteins, and disproportion between myofibrils and neurohormonal signaling (Guzzo-Merello et al., 2014). An investigation of differentially expressed microRNAs and their value in predicting ACM is also ongoing and has yielded promising results so far (Jing et al., 2015).

Many of these pathogenic pathways converge in apoptosis and, indeed, myocyte loss leading to ventricular dysfunction and dilatation seems to be the driving force of ACM (Fernandez-Sola et al., 2006). Overexpression of pro-apoptotic proteins has been demonstrated in a myocyte cell culture system exposed to alcohol (Chen et al., 2000) but this finding has not yet been confirmed by other studies (Jänkälä et al., 2001). Alcohol also affects cardiac repair mechanisms by inhibiting myocyte proliferation through the decrease in myocardial expression of insulin-like growth factor-1 (Borrisser-Pairó et al., 2013). However, the inherent difficulty of reproducing the effects of long-term alcohol abuse in animal models with only weeks of toxic exposure underlines the caution required in adapting these findings to clinical research and practice.

Apart from the direct toxic effect on the cardiomyocytes which leads to ACM, alcohol may also induce heart damage indirectly, by acting on different components of the cardiovascular system (**Fig. 1**).

Histopathological Changes

A direct relationship between unhealthy patterns of alcohol use and cardiac dysfunction was first inferred from clinical experience and necroptic studies performed in the 19th century (Münzinger, 1877). Since then several studies have confirmed the typical macroscopic and microscopic aspects of ACM by autopsy or endomyocardial biopsy. These histopathological findings have been

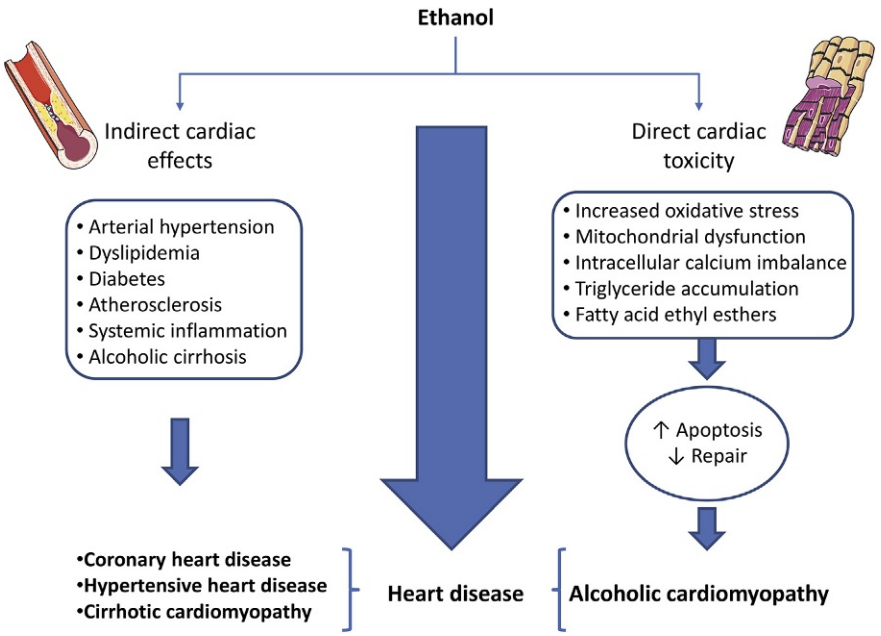

Fig. 1 The effects of chronic ethanol consumption on the pathogenesis of heart disease. Ethanol directly affects the structure and function of the cardiac muscle leading to alcoholic cardiomyopathy but also acts as trigger or risk factor for other conditions associated with heart disease.

thoroughly described and are concordant between reports but they are not pathognomonic (Maisch, 2016). In patients with ACM the heart chambers are generally dilated with increased overall mass and thinned ventricular walls. Interstitial patchy fibrosis and fatty infiltration are common (Tobin et al., 1967). Cardiomyocytes are atrophic or hypertrophic, with distorted myofibrils, enlarged nuclei, pronounced dilation of sarcoplasmic reticulum, lipid accumulation, and mitochondrial enlargement with crest alterations (Teragaki et al., 1993; Fernandez-Sola et al., 1994). This appearance is not specific to alcoholic cardiomyopathy and cannot differentiate it from idiopathic or chronic inflammatory cardiomyopathy.

Definition of Alcoholic Cardiomyopathy

Cardiomyopathy is currently defined as a disease of the heart muscle that is "sufficient to cause structural and functional myocardial abnormality in the absence of coronary artery disease, hypertension, valvular disease, and congenital heart disease" (Elliott et al., 2008; Arbustini et al., 2014). The direct implication of this definition is that correct diagnosis requires exclusion of other frequent conditions that lead to cardiac dysfunction. Chronic alcohol consumption is probably responsible for a significant proportion of cases of nonfamilial cardiomyopathy, but the lack of a specific diagnostic test hinders proper epidemiologic conclusions. This problem is compounded by three key issues: the fact that the cut-off for alcohol use predisposing to cardiomyopathy is still debated, the concurrent alcohol-induced conditions that affect heart structure and function, and the low reliability of self-reported alcohol use.

Excessive Alcohol Use

Assessment of alcohol consumption is based on the standard "drink" containing a fixed amount of pure alcohol. According to the U.S. Department of Health "moderate drinking is up to 1 drink per day for women and up to 2 drinks per day for men" while heavy drinking is defined by 5 or more drinks on the same occasion on each of 5 or more days in the past 30 days (health.gov).

The relationship between dose and risk of the developing cardiovascular disease in alcohol abusers is the focus of intense study. The current opinion is that alcohol is related to cardiovascular risk according to a J or U-shaped curve (Costanzo et al., 2010; Petrone et al., 2014). While alcohol abuse is clearly a risk factor for cardiovascular events, an increasing amount of evidence points to a reduced cardiovascular mortality following low-to-moderate alcohol intake. This has led to the assumption that complete abstinence may not be compulsory even in chronic alcohol abusers with organ damage (Guzzo-Merello et al., 2015b; Nicolás et al., 2002). However, a high degree of bias is frequent even in large studies reporting the benefits of moderate consumption (Fillmore et al., 2007) and recent data suggests that these benefits may be overestimated or absent altogether (Gonçalves et al., 2015; Knott et al., 2015; Fernández-Solà, 2015).

It is generally acknowledged that consumption of at least 80 g alcohol/day for a minimum of 5 years is required in order to consider alcohol as the cause of dilated cardiomyopathy (Urbano-Marquez et al., 1989; Lee and Regan, 2002). While laboratory measurements of mean corpuscular volume, liver enzymes or carbohydrate deficient transferrin (Arndt, 2001) can be helpful, the diagnosis of chronic alcohol abuse in clinical practice and large studies hinges on patient history, in-depth interviews and questionnaires. The notoriously unreliable patient self-reporting of alcohol use probably results in systematic underestimation of consumption which could affect our conception of the relevant cut-off for dangerous use. Variation in individual rates of alcohol metabolism, patterns of drinking and choice of drink, gender and body mass index also play significant roles in individual susceptibility to alcohol-induced organ damage. Furthermore, the existence or development of comorbidities can contribute to cardiac dysfunction in this vulnerable population. Chronic excessive alcohol use disturbs the metabolism of lipids and carbohydrates, alters vascular motor function and has a proinflammatory effect (Athyros et al., 2008). This translates into higher risk of atherosclerosis and hypertension with ensuing coronary artery disease and ischemic heart disease, further complicating the diagnostic work-up.

Diagnosis and Main Features

ACM is a form of dilated cardiomyopathy characterized by the presence of left ventricular dilatation and dysfunction, sometimes accompanied by similar right ventricular alterations. The exact prevalence of alcoholic cardiomyopathy is difficult to ascertain due to its' long initial asymptomatic period, the need to exclude other causes of heart disease, and the reliance on self-reported alcohol consumption. An alcoholic etiology is considered likely in 20%–40% of cases of idiopathic cardiomyopathy (Laonigro et al., 2009).

While it can remain asymptomatic for years (Cerqueira et al., 1991), chronic severe alcohol-induced injury to the myocardium can manifest through a classical clinical picture of low-output heart failure. New onset fatigue, exertional dyspnea and orthopnea, peripheral edema, nocturia, and increased or irregular heart rate are frequently encountered on first presentation in these decompensated patients (McKenna et al., 1998).

The earliest echocardiographic abnormalities in asymptomatic heavy drinkers are an increase in end-systolic and diastolic left ventricular (LV) volumes and diastolic dysfunction. Only a minor fraction of the patients develop thickening of the posterior wall and systolic dysfunction (Zambrano et al., 1974; Lazarević et al., 2000). A symptomatic diastolic dysfunction is a relatively frequent

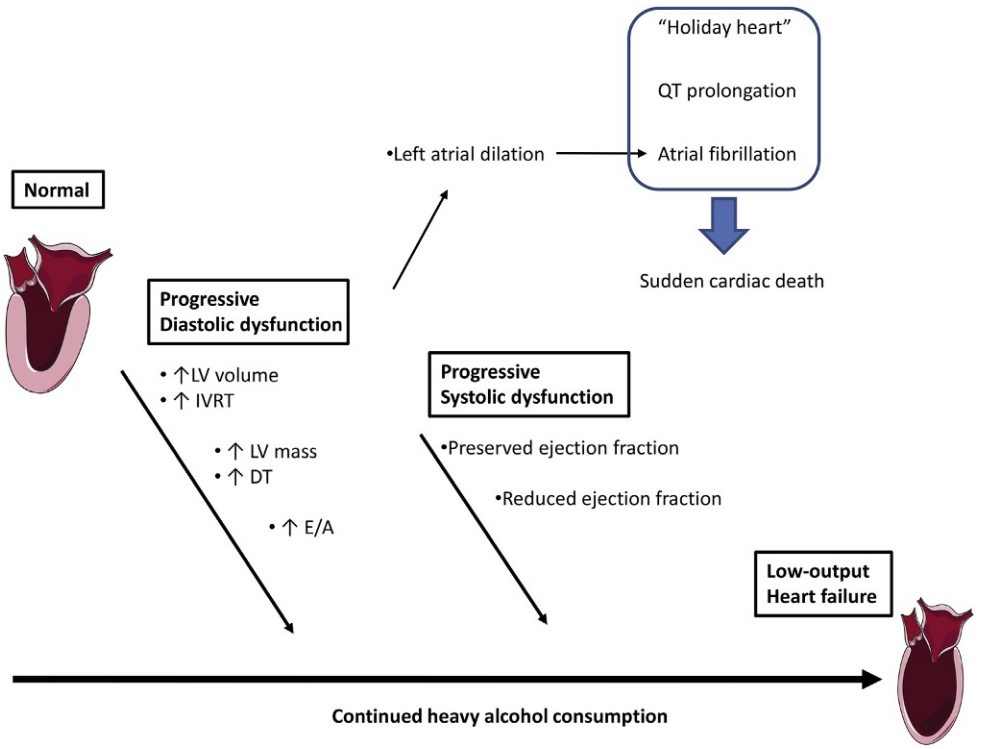

Fig. 2 The progression of cardiac dysfunction in chronic heavy alcohol consumption. Initial echocardiographic abnormalities such as altered diastolic function of the left ventricle can slowly progress toward overt heart failure. An increased risk of life-threatening arrhythmia is documented in patients with alcoholic cardiomyopathy and includes acute and chronic rhythm disturbances.

finding in chronic alcohol abusers (Kupari et al., 1990; Fernández-Solà et al., 2000) and there is some evidence that the duration of consumption and cumulative dose of alcohol are directly associated with the severity of the diastolic dysfunction (Urbano-Marquez et al., 1989). Lazarević et al. reported that echocardiographic changes in alcoholics were progressive (**Fig. 2**): an initial increase in LV volume and prolongation of the isovolumetric relaxation time are followed by an increase in LV mass and prolongation of the deceleration time, with subsequent decrease in the E\A ratio (Lazarević et al., 2000).

A mild decrease in left ventricular ejection fraction is initially asymptomatic and has been demonstrated by comparing heavy drinkers to moderate drinkers or abstainers (Yousaf et al., 2014; Li et al., 2016a). A further reduction in the systolic function marks the progression from heart failure with preserved ejection fraction (>50%) toward heart failure with reduced ejection fraction (<50%), with ominous prognostic implications (Ponikowski et al., 2016).

Left atrial dilatation and functional impairment are more frequently observed in heavy drinkers (Kocabay et al., 2015) and their role as an intermediary phenotype linking left ventricular dysfunction to the development of atrial fibrillation is a novel and intriguing concept (McManus et al., 2016). While binge drinking has been known to induce arrhythmia ("holiday heart syndrome" (Ettinger et al., 1978)), atrial fibrillation is much more common with chronic heavy drinkers with underlying cardiomyopathy being more susceptible (Samokhvalov et al., 2010). Studies have also revealed that alcohol abusers have prolonged QT intervals (Li et al., 2016b) and these patients are more predisposed to the development of ventricular tachycardia and sudden cardiac death (Wannamethee and Shaper, 1992; Guzzo-Merello et al., 2015a). This predilection is probably due to the combination of the direct toxic effect of alcohol on the cardiomyocytes and the structural and functional alterations of the myocardium and conduction system in ACM.

The prevalence of left ventricular dysfunction and dilated cardiomyopathy in chronic consumers is not gender-biased but women seem to be more susceptible to the toxic effects of alcohol even when accounting for differences in body mass index. Consistently lower total lifetime doses of ethanol in women than in men with ACM are reported in epidemiologic studies showing that LV ejection fraction might be affected more and earlier in women exposed to the same doses of alcohol (Urbano-Márquez et al., 1995; Fernández-Solà et al., 1997).

Recent progress in characterizing ACM has been made possible through technological developments of functional cardiac imaging such as cardiovascular magnetic resonance with late gadolinium enhancement (LGE CMR) and echocardiographic speckle-tracking. These techniques have been validated in patients with nonischemic dilated cardiomyopathy (Mewton et al., 2011; Iles et al., 2015) and the regional differences in signal intensity on LGE CMR allow the assessment of myocardial fibrosis and are of prognostic importance (Yamada et al., 2014; Chimura et al., 2016).

Prognosis and Therapy

Excessive alcohol consumption is responsible for 5.1% of the global burden of disease and injury (World Health Organization, 2014) and accounts for 1 in 10 deaths among working-age adults in the United States (Stahre et al., 2014). Cardiovascular events make up an important fraction of alcohol-related morbidity and ACM has been shown to influence outcome. Initial long-term follow-up data showed higher survival rates in patients with alcoholic etiology who discontinued drinking compared to patients with idiopathic cardiomyopathy (Guzzo-Merello et al., 2014; Brinkley et al., 2014). In contrast, studies performed after the introduction of beta-blockers, angiotensin-converting enzyme inhibitors, and implantable devices report worse transplant-free survival in chronic alcohol consumers (Prazak et al., 1996; Guzzo-Merello et al., 2015b). However, all studies are in concord on the value of maintaining abstinence in reducing morbidity and mortality in alcoholic cardiomyopathy (Gavazzi et al., 2000) and reversibility of mild to moderate ventricular dysfunction is to be expected in abstainers.

Alcohol reduction or total abstinence are the mainstay in the treatment of ACM as they can improve systolic and diastolic function and prevent further cardiovascular complications. In other regards, the management of ACM is the management of the resulting congestive heart failure. Conventional pharmacotherapy is based on beta-blockers, angiotensin-converting enzyme inhibitors, aldosterone antagonists, and loop diuretics. Implantable devices and surgical ventricular remodeling are sometimes indicated, with heart transplant being the curative alternative. Stem-cell therapy with intracoronary injection of $CD34^{+}$ cells resulted in improvement of systolic function, increased exercise tolerance, and a significant survival benefit in a long-term follow-up study (Vrtovec et al., 2013). A recent randomized controlled trial with a one year follow-up confirmed a mild improvement in LV ejection function and clinical symptoms in patients treated with autologous bone-marrow derived cells and granulocyte colony-stimulating factor (Hamshere et al., 2015). Novel and unconventional therapies are currently being explored in order to alter and possibly reverse the natural history of the disease (Sisakian, 2014; Fernández-Solà and Planavila Porta, 2016).

Alcoholic Cardiomyopathy and Cirrhosis

Assessment of the specific influence of alcohol on the cardiovascular function is more difficult in alcohol abusers with chronic liver disease. Proof of this is the fact that the hyperdynamic circulation typical of cirrhosis first described 60 years ago was initially attributed to chronic alcohol use, the overwhelming cause of liver disease at that time (Kowalski and Abelmann, 1953). Later studies revealed that etiology was irrelevant in the pathogenesis of the cardiohemodynamic disturbances encountered in cirrhotic patients (Møller and Bernardi, 2013).

The partial overlap between alcoholic cardiomyopathy and the more recently described "cirrhotic cardiomyopathy" (Wiese et al., 2014), an entity characterized by a latent cardiac dysfunction and inadequate response to stress, poses a distinct problem to the clinician and researcher. Since ethanol abuse is frequent in cirrhotic patients, distinguishing between the role of alcohol and liver disease in cardiovascular dysfunction can be impossible in the clinical setting. As the phenotype may change with disease progression the differential diagnosis becomes even more problematic. Echocardiography, electrocardiography, and serum biomarkers of cardiac dysfunction are common tools and essential to the detection of cardiac impairment. Left ventricular dysfunction is the most studied abnormality encountered in both alcoholic and cirrhotic cardiomyopathies. Prolongation of the QTc interval, electromechanical uncoupling and elevation of pro-brain natriuretic peptide or troponins do not help differentiate between the two.

However, despite their similarities there are some differences worth noting. ACM is a form of dilated cardiomyopathy with typical albeit nonspecific histopathological changes and leads to low-output heart failure and an increased risk of arrhythmia and sudden cardiac death. By contrast, cirrhotic cardiomyopathy is, at least initially, characterized by high-output heart failure due to a hyperdynamic circulatory state with minimal histopathological changes and no reported increase in arrhythmic events. A slow but gradual progression to overt heart failure is more frequent in ACM while cirrhotic patients generally manifest reversible cardiac dysfunction when confronted with acute intravascular volume change or further vasodilation (e.g., insertion of transjugular intrahepatic portosystemic shunt, sepsis, paracentesis, liver transplantation).

A noteworthy point is the observation that cirrhosis is not a prerequisite for ACM as structural and functional alterations compatible with ACM have been described in chronic consumers of alcohol without advanced liver disease. This would suggest the existence of various yet uncharacterized phenotypes that determine different patterns of end-organ damage in the case of sustained injury due to alcohol. Further investigation into the cell-specific mechanisms that predispose the hepatocyte and cardiomyocyte to alcohol-induced damage seems worthwhile.

Lacking stringent diagnostic criteria the integration of all the data from clinical and paraclinical investigations is mandatory for distinguishing between these two entities, with the understanding that a complete differentiation may not be feasible in all cases.

Summary and Conclusions

Chronic alcohol abuse increases cardiovascular morbidity and mortality. Ethanol and its metabolites negatively influence cardiac function both directly, through their toxic cellular effect, and indirectly, by disrupting the complex metabolic and hemodynamic

homeostasis. Alcoholic cardiomyopathy is a form of dilated cardiomyopathy that occurs after years of chronic high-dose alcohol consumption. Diagnosing this condition is hindered by the lack of pathognomonic signs and a specific diagnostic test. Further difficulties in identifying and managing alcoholic cardiomyopathy stem from the long period of clinical latency, subtle initial manifestations and frequent cardiovascular comorbidities that cloud the clinical picture. Echocardiography and electrocardiography are useful in detecting ACM, but differentiating it from cirrhotic cardiomyopathy in patients with concomitant advanced liver disease is difficult. A slow progression toward overt low-output heart failure and unfavorable outcome is frequent but reversible in abstainers. Cessation of alcohol consumption is paramount for improving prognosis and standard pharmacological and interventional therapy is indicated according to the severity of heart failure. Further research into the pathogenesis of ACM and exploring novel therapies are vital to improving the management and care of these patients.

Introduction

Amyloidosis is a unique, yet remarkably heterogeneous group of diseases characterized by the deposition of misfolded protein precursors in the extracellular space in various tissues. Amyloid fibrils of diverse protein origins are resistant to proteolytic cleavage under physiological condition, and the characteristic uniformity of beta-pleated sheet configuration among all forms of amyloidosis forms the basis of characteristic staining of amyloid fibrils by Congo red, a feature essential for establishing the diagnosis on histopathologic examination (Fig. 1; Picken, 2010). Widely divergent precursor proteins (more than 30 currently known) can cause amyloidosis and lead to diseases belonging to infectious (prion disease), neoplastic (immunoglobulin light-chain systemic amyloidosis), neurodegenerative (Alzheimer's disease), and hereditary (familial amyloidosis) groups of disorders (Sipe et al., 2012). The heart is a frequently involved organ in systemic amyloidosis, and amyloid cardiomyopathy is the most common cause of death in these patients.

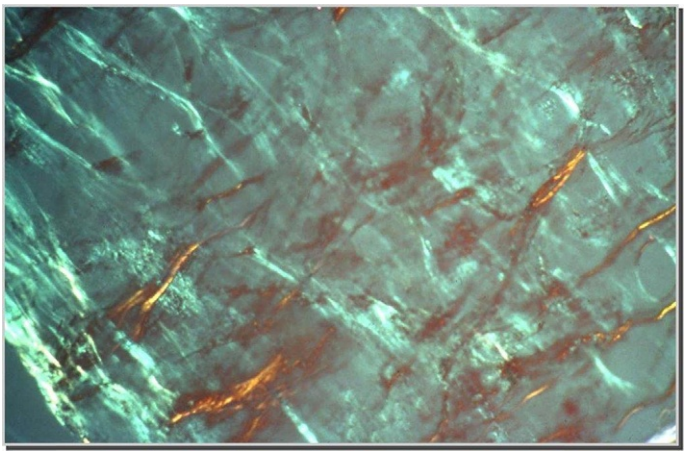

Fig. 1 Apple green birefringence of Congo red stained endomyocardial biopsy under polarized microscopy.

 https://doi.org/10.1016/B978-0-12-809657-4.11051-8

Amyloid Heart Disease

Heart is one of the most common organs involved in amyloidosis. Amyloidogenic proteins can involve any part of the heart, including the myocardium (atrial, ventricular, and interventricular septum), the valvular tissue, the perivascular space around and within small blood vessels, and the conduction system (Falk and Dubrey, 2010). Gross pathological examination of the heart infiltrated with amyloidosis reveals characteristic thickening of all four cardiac chambers and interventricular septum (Fig. 2). Biatrial enlargement with small- to normal-sized left ventricular cavity is a unique feature of amyloid cardiomyopathy. Microscopically, amyloid deposition is seen in the extracellular space, which results in separation and distortion of myocardial cells and electromechanical dissociation. It is important to recognize that different amyloid proteins can result in similar pathological findings and there is no characteristic deposition pattern in the myocardium unique to any subtype. Furthermore, cardiac involvement can occur at any stage of the disease and may be the initial presentation, incidentally discovered during evaluation of other symptoms or discovered on postmortem examination (Falk, 2005).

Types of Amyloid Cardiomyopathies

Various forms of cardiac amyloidosis and the clues to differentiate them are tabulated in Table 1, and the common types are elaborated later.

Immunoglobulin Light-Chain (AL) Amyloid Cardiomyopathy

Immunoglobulin light-chain amyloidosis (primary systemic amyloidosis or AL amyloidosis), the most common systemic amyloidosis in the United States and Western Europe, is a neoplastic disease of plasma cells, where transformed clonal plasma cells in the bone marrow produce amyloidogenic light chains. With an approximate incidence of 2500 new cases each year, AL is a very rare disease (Kyle et al., 1992). Mostly, AL occurs de novo, but in a minority of patients, it can evolve from preexisting multiple myeloma (the most common plasma cell malignancy) and non-Hodgkin lymphomas such as Waldenström's macroglobulinemia. Cardiac involvement is often very advanced and is seen in 50% of the cases (Gertz et al., 1999). AL cardiomyopathy is the most aggressive form of amyloid heart disease and is the sole reason for the poor prognosis associated with amyloidosis. Patients with AL frequently present with congestive heart failure (CHF) from restrictive physiology. Peripheral edema from right heart dysfunction is a very common feature often associated with ascites and hepatomegaly. Atrial dysrhythmias are common and can be complicated by mural atrial thrombus. Embolic stroke may be the first presentation of the disease (Seldin et al., 2011). Ventricular arrhythmias also

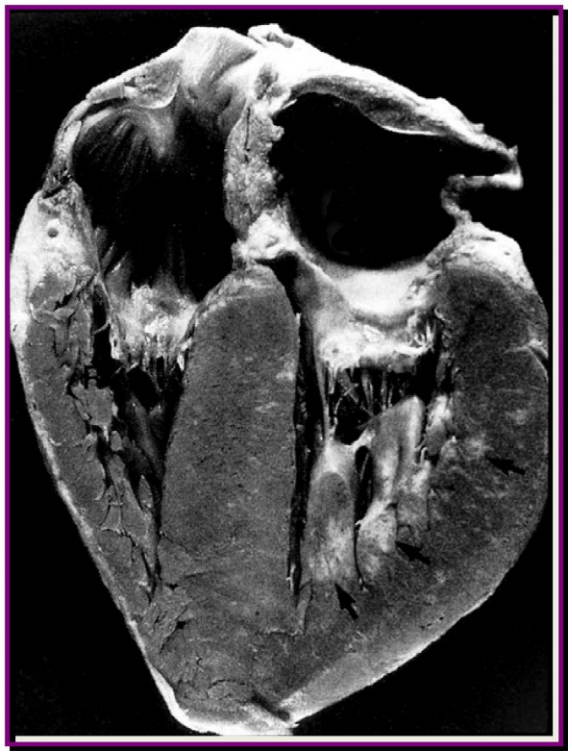

Fig. 2 Heart from an AL patient. Note thickened interventricular septum and left ventricular posterior wall.

Table 1 Common types of cardiac amyloidosis

Characteristics	*AL*	*ATTR Mutant*	*ATTR Wild*	*AA*	*AANF*
Common name amyloidosis	Primary (immunoglobulin light-chain) systemic amyloidosis	Familial transthyretin amyloidosis	Senile systemic amyloidosis	Secondary amyloidosis	Isolated atrial
Incidence/ prevalence	2000–3000 cases per year	Variable in different races Val122Ile variant in 4% of African–Americans Val30Met variant in Caucasians	Males older than 70 years Incidence increases with age	Uncommon	Common
Precursor protein	Immunoglobulin light chain	Mutant TTR	Wild-type TTR	SAA protein	Atrial natriuretic peptide
Clinical organ involvement	Heart, kidney, liver, peripheral nerves, autonomic nerves, GI tract, soft tissue	Heart, nerves, GI tract, autonomic nerves	Heart, rarely nerves	Kidney, liver, GI tract. Very rarely heart	Cardiac atria
Salient features	Low QRS voltage Pseudoinfarct pattern on ECG IVS thickness seldom >1.9 cm Rapid progression	IVS thickness frequently severe	IVS thickness frequently severe Relatively indolent disease		
Treatment	Chemotherapy (standard or stem-cell transplant)	Liver transplant	Supportive care	Treat inflammation	No specific treatment
Prognosis/ survival	Poor, 3–5 months if present with CHF	8–10 years from presentation	5–8 years from diagnosis	Generally good	Good

IVS, interventricular septum; *TTR*, transthyretin.

Table 2 Syndromes in AL amyloidosis (Mayo Clinic experience)

Syndrome	*Patients, %*
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22
Carpal tunnel syndrome	21
Neuropathy	17
Orthostatic hypotension	12

occur, but are not a common presenting feature, possibly because patients succumb to sudden cardiac arrest before the diagnosis is established. Patients can also present with typical angina pectoris from myocardial ischemia due to amyloid infiltration of small vessel walls, which can, at times, be very frustrating as cardiac catheterization reveals normal epicardial coronaries (Falk and Dubrey, 2010; Ogawa et al., 2001). Multiorgan involvement is very common in AL patients. The kidney, peripheral nerves, autonomic nerves, liver, and GI tract are frequent extracardiac sites of disease (Table 2; Gertz et al., 1999). Soft-tissue infiltration is rare but gives rise to classic clinical exam findings such as shoulder pad sign, muscle infiltration (Figs. 3 and 4), macroglossia (Fig. 5), and periorbital purpura (Kyle and Greipp, 1983). Small- and medium-sized blood vessel ischemia from involvement by amyloid can cause symptoms of jaw claudication, and patients can be misdiagnosed as having giant cell arteritis. Mucocutaneous bleeding from amyloid angiopathy and acquired deficiency of circulating coagulation factors, in particular factor X, can be a prominent presenting feature (Choufani et al., 2001).

Wild-Type Transthyretin Cardiomyopathy

Also called senile systemic amyloidosis (SSA), wild-type transthyretin is caused by systemic deposition of amyloid fibrils derived from a native (wild-type) circulating plasma protein transthyretin (TTR) (Westermark et al., 1990). For reasons that remain unclear, SSA is predominantly seen in males. Autopsy series have commonly identified wild-type TTR amyloid deposits in the hearts of older males with some series reporting an incidence as high as 25% in subjects 80 years of age or older. Many patients with SSA may not develop clinically significant end-organ damage, despite histological or echocardiographic evidence of amyloidosis. SSA typically presents with progressive decline in energy and symptoms of CHF, often with normal systolic function (Ng et al., 2005). The diagnosis is often delayed in these patients until they have multiple hospitalizations for CHF. Increased myocardial thickness is often blamed on systemic hypertension or hypertrophic cardiomyopathy. Almost half of SSA patients may have symptomatic

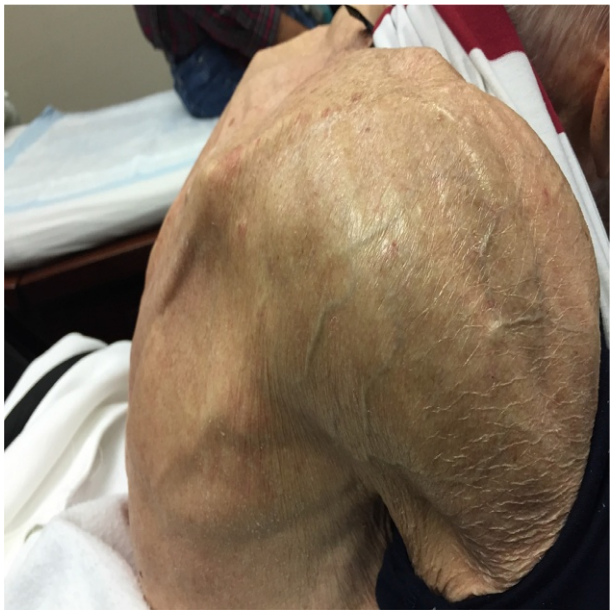

Fig. 3 Shoulder fat-pad sign in a patient with advanced AL.

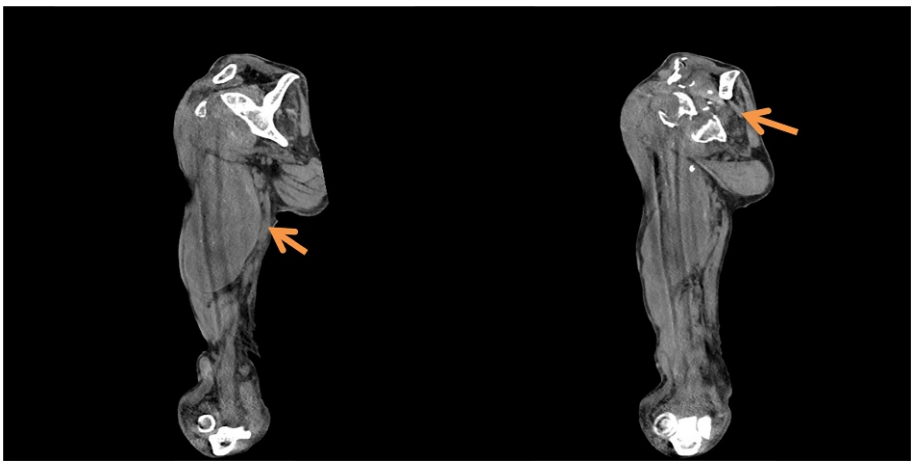

Fig. 4 Amyloid arthropathy.

Fig. 5 Macroglossia from amyloid infiltration of tongue. This can be a formidable problem in patients with AL.

median neuropathy presenting as carpal tunnel syndrome. This is in contrast to familial TTR amyloidosis, where manifestations of peripheral neuropathy and gastrointestinal involvement are frequently seen in addition to cardiomyopathy. With the increasing availability and frequent use of echocardiography, the recognition of SSA is expected to increase significantly in near future.

Familial Amyloid Cardiomyopathy

In heredofamilial amyloidosis, the amyloid deposits are derived from misfolded forms of several proteins such as TTR, apolipoprotein, fibrinogen, and leukocyte chemotactic factor 2 (Gertz et al., 1992). Familial ATTR is the most common type of familial amyloid cardiomyopathy (FAC). More than 100 pathogenic mutations have been described in the *TTR* gene on chromosome 18 (Connors et al., 2000). In familial ATTR, the specific TTR mutant determines the clinical presentation, and the peripheral nerves and the heart are the most common sites of involvement. Autonomic dysfunction and GI tract involvement can be severe and can cause significant malabsorption and protein-losing enteropathy (Plante-Bordeneuve and Said, 2000; Benson, 2005). One particular TTR variant allele, Val122Ile, is found in 4% of African–Americans and is a frequently overlooked cause of cardiomyopathy in African–American males (Jacobson et al., 1997). Despite the high prevalence of this variant, the overall prevalence and incidence of FAC in African–Americans remains low, possibly owing to failure to recognize the etiology of the CHF. In Caucasians, the Val30Met mutant is the most commonly reported TTR variant with high penetrance presenting as early-onset (30–40 years of age) peripheral neuropathy and relatively late-onset (50–60 years of age) cardiomyopathy (Tojo et al., 2008). The most common TTR mutant in the Caucasian population of the United States is T60A.

Variants of fibrinogen A-alpha, apolipoprotein A-I, and A-II account for other rare types of familial amyloidosis and can involve the heart; however, renal involvement predominates in these non-TTR familial amyloidoses (Benson et al., 2001; Hamidi Asl et al., 1998).

Secondary Systemic Amyloid (AA) Cardiomyopathy

Secondary systemic (AA) amyloidosis results from excessive production and misfolding of the acute-phase reactant serum amyloid A protein. AA is common in developing countries and in the Mediterranean basin due to a high prevalence of chronic infections and auto-inflammatory disorders, such as familial periodic fever syndromes (van der Hilst et al., 2005). In the United States and Western Europe, it is rare and usually results from unrecognized or treatment refractory chronic autoimmune disorders such as rheumatoid arthritis and inflammatory bowel disease (Hazenberg and van Rijswijk, 2000). Nephrotic syndrome is the most common presentation, but involvement of gastrointestinal and hepatobiliary systems leading to malabsorption syndrome and/or hepatosplenomegaly can be seen. Involvement of endocrine organs, such as thyroid and adrenal gland, can be seen and may result in adrenal insufficiency (Hazenberg and van Rijswijk, 2000). Cardiac involvement in AA is rare and even if severe by echocardiogram, seldom results in clinically significant cardiomyopathy.

Isolated Atrial Amyloidosis

Isolated atrial amyloidosis (IAA) results from deposition of atrial natriuretic peptide derived amyloid in cardiac atria (Millucci et al., 2012). Unlike other cardiac amyloidoses, this form is almost always localized to the atria and can only be diagnosed on histological examination of atrial tissue. The incidence of IAA increases with age and appears to be more common in patients with atrial diseases such as rheumatic heart disease. Recent studies have reported a very high incidence of IAA on the histopathologic examination of the explanted hearts from patients with dilated and hypertrophic cardiomyopathies and raise important questions about the possible role of IAA in the pathogenesis of these conditions (Millucci et al., 2011).

Pathogenesis of Amyloid Cardiomyopathy

Organ tropism of specific amyloid proteins is poorly understood and is illustrated by familial ATTR as certain TTR mutations result in exclusive familial amyloid polyneuropathy (FAP) while others in exclusive FAC, yet still, others cause FAP/FAC overlap syndromes. This organ tropism is also recognized in AL where restricted usage of certain variable regions of light-chain gene segments during immunoglobulin gene rearrangements can result in generation of amyloidogenic light chains with particular affinity for the kidney (λ_{6a}*family*) or heart (λ_{III}*family*) (Perfetti et al., 2002, 2012). It is likely that in addition to the characteristics of the amyloidogenic protein, organ distribution is also determined by local factors operating in the involved organ.

Historically, mechanical infiltration of the myocardium and resultant physical myocardial distortion was identified as the main mechanism underlying cardiac dysfunction. Recent advances in molecular biology and genetic engineering have provided several pieces of evidence that suggest that additional mechanisms are operating and may be more important in myocardial damage than simply the infiltration. Myocardial thickening and mass is more pronounced in SSA than in AL cardiomyopathy, yet patients with SSA cardiomyopathy survive for many years with just supportive care, while survival of AL patients with comparable or even "milder" cardiac involvement by imaging studies is considerably shorter. This is further corroborated by animal studies whereby the infusion of amyloidogenic light chains purified from AL patients resulted in significant myocardial dysfunction in the absence of

amyloid fibril deposits in mice (Liao et al., 2001; Mishra et al., 2013). The exact cellular mechanism underlying this toxicity is not known; however, increased generation of oxygen free radicals and induction of cardiomyocyte apoptosis have been suggested as possible causes (Brenner et al., 2004).

Diagnosis of Amyloid Cardiomyopathy

Amyloidosis is a great masquerader and like many rare diseases is very often diagnosed at late stages. This is especially true in AL where the rapid disease progression coupled with a lack of specificity in patient's symptoms results in delayed diagnosis and poor outcomes. Amyloidosis and in particular AL should be suspected in patients presenting with proteinuria, unexplained CHF (especially diastolic heart failure), new onset peripheral neuropathy especially with bilateral carpel tunnel syndrome, new onset autonomic dysfunction, otherwise unexplained weight loss, and hepatomegaly in the absence of known liver disease (Gertz et al., 1999; Table 2).

Patients should undergo a thorough physical examination with particular attention to signs of volume overload, orthostatic hypotension, macroglossia, amyloid purpura, hepatosplenomegaly, peripheral edema, and sensory neuropathy. Initial laboratory studies should include complete blood counts, renal and liver function profiles, serum electrolytes, coagulation profile, serum protein electrophoresis with immunofixation, 24 h urine protein electrophoresis, immunofixation, and nephelometric measurement of serum immunoglobulin-free light chains and troponin T and N-terminus of the prohormone brain natriuretic peptide (NT-ProBNP) (Gertz, 2010). The common abnormalities noted in these initial studies in amyloidosis, particularly in AL patients, are summarized in Table 3. The diagnosis of amyloidosis must be confirmed by histological examination of an optimal biopsy. Sites to consider for the biopsy include abdominal wall subcutaneous fatty tissue (fat-pad aspirate and fat-pad biopsy), vascular submucosa of the GI tract (minor salivary glands in mouth, labial soft tissue, and rectal biopsy), or bone marrow biopsy. In our experience, at the Mayo Clinic, a combination of bone marrow biopsy and abdominal subcutaneous fat-pad aspirate yields the diagnosis of AL amyloidosis in 85% of patients (Gertz et al., 1999).

Endomyocardial biopsy is the gold standard for the diagnosis of cardiac amyloidosis. Heart biopsy is not needed when less invasive biopsy has established a diagnosis of amyloidosis (Pellikka et al., 1988). The biopsy tissue should be stained with amyloid-binding stains such as Congo red or sulfated Alcian blue. Optimal staining by an experienced pathologist is important as we have seen false positive and false negative cases when biopsies done elsewhere are reviewed at the Mayo Clinic. Once a histological diagnosis is established, the next step is to determine the type of amyloid protein. Immunohistochemistry has been most commonly used for amyloid typing; however, its sensitivity is relatively low especially for AL. At the Mayo Clinic, we routinely use laser capture microdissection and mass spectrometry, the gold standard proteomic typing technique, to determine the subtype in all patients with amyloidosis (Klein et al., 2011; Brambilla et al., 2012; Vrana et al., 2009). The accurate determination of amyloid type is especially important to exclude familial ATTR as it can clinically mimic light-chain amyloidosis, and up to 10% of patients with non-AL cardiomyopathy can have coexisting monoclonal gammopathy of undetermined significance, which can lead to the misdiagnosis of AL in these patients (Comenzo et al., 2006). If TTR is identified as the precursor protein, DNA testing should be performed on peripheral blood to identify a possible gene mutation to differentiate between SSA and familial ATTR (Table 4).

After establishing the diagnosis, the next step in the management of patients is to determine the extent of organ involvement. The heart is the most important organ involved in amyloidosis; therefore, determination of the presence and degree of cardiac amyloidosis is imperative. Various diagnostic procedures providing critical clues to the diagnosis and severity of cardiac amyloidosis are reviewed later.

Electrocardiography

Electrocardiography (ECG) abnormalities are frequently overlooked in amyloidosis patients. Low QRS voltage can be seen in up to two-thirds of patients with AL (Hongo et al., 2000). It is less common in non-AL amyloid heart disease. Low ECG voltage in the presence of the echocardiographic findings of increased myocardial thickness is highly suggestive of advanced amyloid heart

Table 3 Recommended diagnostic testing for a histological diagnosis of amyloidosis

- CBC, creatinine level, alkaline phosphatase level
- Serum and 24 h urine total protein, electrophoresis, and immunofixation
- Serum immunoglobulin-free light-chain assay
- Marrow biopsy
- Quantitative immunoglobulins
- N-terminal pro-B natriuretic peptide level, serum troponin levels, uric acid level
- Echocardiography with Doppler
- Confirmation that amyloid deposits are of Ig origin (i.e., laser capture microdissection followed by mass spectroscopy)

CBC, complete blood cell count.

Table 4 Common abnormalities in AL cardiomyopathy and their prognostic impact

Prognostic factor	*Comment*
Clinical findings:	
● Congestive heart failure and exertional syncope	● Patients presenting with exertional syncope have a median survival of 2 months
● Jaundice	● Jaundice and hyperbilirubinemia is usually a preterminal finding
Laboratory findings:	
● Thrombocytosis	● Indicator of splenic involvement
● Howell–Jolly bodies	● Indicator of advanced disease
● Elevated bilirubin	● Often a preterminal finding
● Elevated creatinine	
● Elevated free light-chain levels	● Important factors that have been incorporated into four-stage prognostic model
● Elevated troponin T	
● Elevated BNP (NTpro-BNP)	
Echocardiogram findings:	
● Interventricular septum thickness	● Median survival 1 versus 4 years if thickness $>$ or $<$1.5 cm
● Short mitral deceleration time	● Poor outcome for patients with deceleration $<$150 ms
● Decreased fractional shortening	● Poor outcomes for patients with fractional shortening $<$20%

disease. Bundle branch abnormalities can be seen in up to 40% of patients with ATTR. Additional ECG abnormalities include loss of the R-wave in leads V1–V3, resulting in a "pseudoinfarction" pattern. Patients with a pseudoinfarction pattern on ECG frequently undergo an unrevealing coronary angiogram. Rarely, patients can present with true myocardial ischemia due to amyloid infiltration of small intramyocardial arteries (Hongo et al., 2000).

Cardiac Biomarkers

Myocardial damage from amyloidosis results in leakage of intracellular proteins and enzymes into the circulation. Cardiac troponin T (cTnT) and NT-ProBNP are two such markers that have made a significant impact in the diagnosis and monitoring of patients with AL cardiomyopathy (Merlini et al., 2016; Palladini et al., 2010). The Mayo Clinic staging system is a prognostic scoring system that has been derived based on the levels of serum-free light chains, cTNT, and NT-ProBNP in 801 previously untreated AL patients and can separate patients into four prognostic groups with median survival of patients with stage I, II, III, and IV disease of 94, 40.3, 14, and 5.8 months, respectively (Fig. 6; Kumar et al., 2012a).

Cardiac Imaging

Cardiac imaging remains the cornerstone of evaluation of patients suspected of having amyloid heart disease.

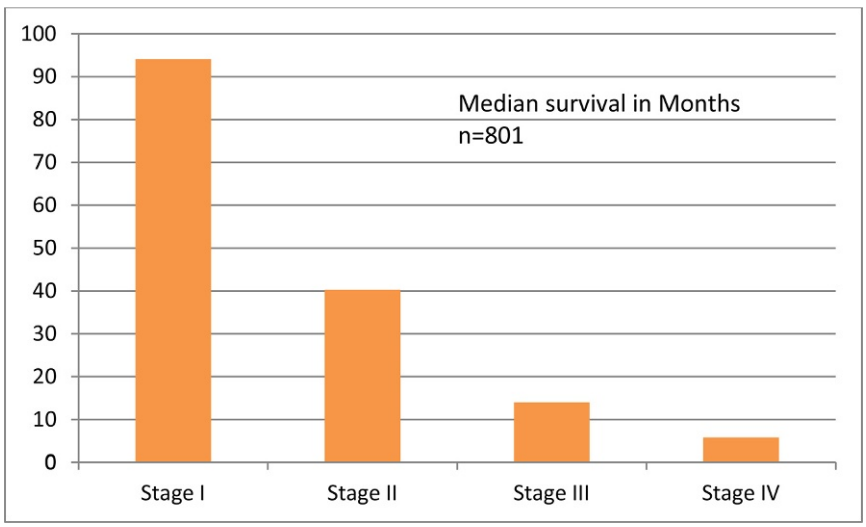

Fig. 6 Prognostic staging system in AL—patients are assigned a score of 1 for each of dFLC $\geq$ 18 mg/dL, cTnT $\geq$ 0.025 ng/mL, and NT-ProBNP $\geq$ 1800 pg/mL leading to scores of 0–3 points creating stages I through IV, respectively. *dFLC*, difference of involved and uninvolved light chains; *cTnT*, cardiac troponin T; *NT-ProBNP*, N-terminus of the prohormone BNP.

Echocardiography

A 2-D echocardiogram can be an invaluable tool for evaluating patients with amyloid cardiomyopathy (Falk and Dubrey, 2010; Tsang and Lang, 2010). Normal ejection fraction and absence of LV dilatation in patients presenting with heart failure should lead cardiologists to suspect cardiac amyloidosis. Thickening of the right ventricular free wall and biatrial enlargement, along with diffuse valvular thickening, are all features suggestive of amyloid cardiomyopathy (Tsang and Lang, 2010). In advanced stages, atrial standstill and intramural thrombus can be seen (Fig. 7).

Measurement of myocardial flow velocities with Doppler almost always reveals longitudinal systolic dysfunction, despite "preserved" LV ejection fraction calculated from myocardial contraction along its short axis (Elliott et al., 2000). The impairment of long-axis LV contraction is especially visible in strain and strain rate imaging (Koyama and Falk, 2010).

Echocardiography with standard Doppler also provides important prognostic information. In a Mayo Clinic series of 132 AL patients, an interventricular septal (IVS) thickness of >1.5 cm was associated with a median survival of <1 year as compared with that of 4 years in patients with an IVS thickness of <1.5 cm (Klein et al., 1991). Transmitral Doppler studies serve as a good index of restrictive physiology seen in amyloid cardiomyopathy, and a short mitral deceleration time (<150 ms) has been associated with shorter survival in AL patients. Basal systolic strain measured on regional strain and strain rate assessments is superior to Doppler flow measurements in predicting clinical outcomes (Koyama and Falk, 2010). A large observational study identified longitudinal strain and 2-D global longitudinal strain as important prognostic factors in patients with amyloid cardiomyopathy (Buss et al., 2012). Importantly, the 2-D global longitudinal strain remained an independent predictor of prognosis even in patients with preserved LV ejection fraction (Koyama and Falk, 2010). Novel echocardiographic techniques, such as feature- and speckle-tracking imaging, allow dynamic frame-by-frame myocardial motion analysis during the cardiac cycle and can help to distinguish between amyloid cardiomyopathy, hypertensive heart disease, and hypertrophic cardiomyopathy (Tsang and Lang, 2010). Evolving echocardiographic techniques are expected to help differentiate between various forms of diastolic dysfunction and represent an opportunity for early diagnosis of amyloid heart disease that can have a profound impact on outcome in amyloid cardiomyopathy.

Magnetic resonance imaging

Contrast-enhanced cardiac magnetic resonance imaging (MRI) is a promising diagnostic modality and is being increasingly utilized in the assessment of myocardial diseases. Besides accurate measurements of myocardial thickness, the kinetics of gadolinium enhancement can provide very specific clues about cardiac amyloidosis. The finding of ventricular wall and IVS thickening associated with diffuse, delayed gadolinium enhancement of the subendocardium is very suggestive of cardiac amyloidosis (Fig. 8; Vanden Driesen et al., 2006). Phase-contrast MRI, like Doppler echocardiography, can provide useful information about the flow dynamic parameters such as mitral deceleration times, early to late ratio of LV diastolic filling and mitral peak inflow velocity (Maceira et al., 2005). Novel techniques, such as magnetic resonance (MR) relaxometry, can characterize the physical

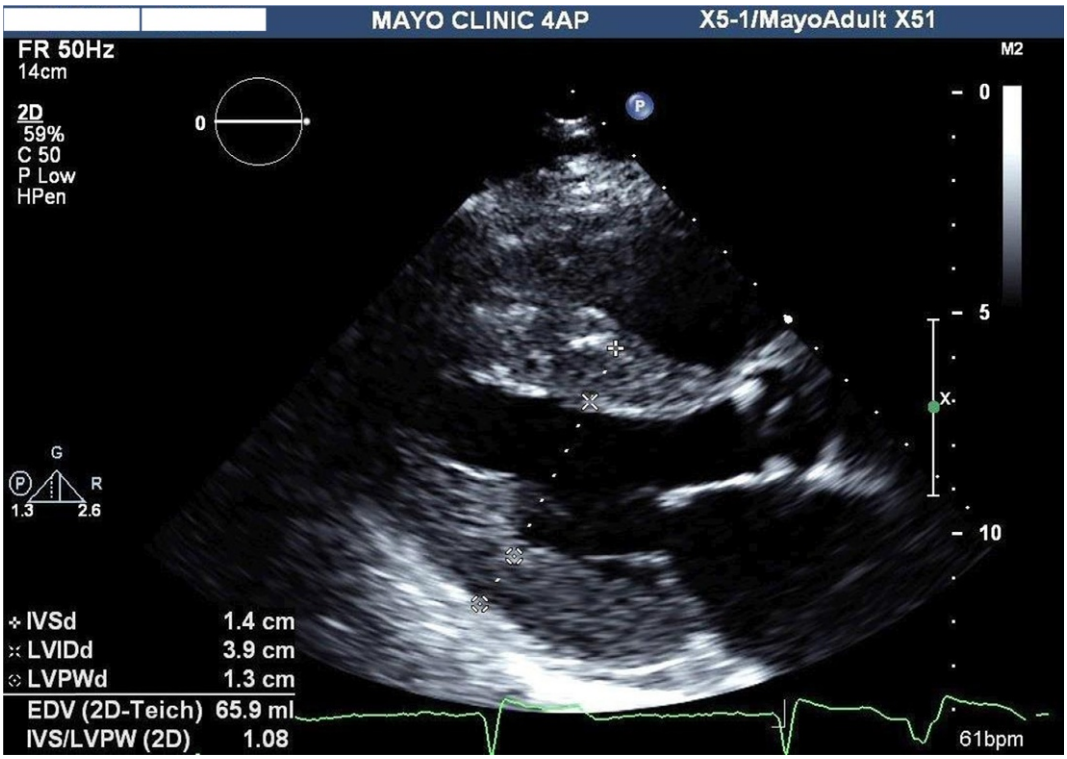

Fig. 7 Echocardiogram in a patient with AL cardiomyopathy.

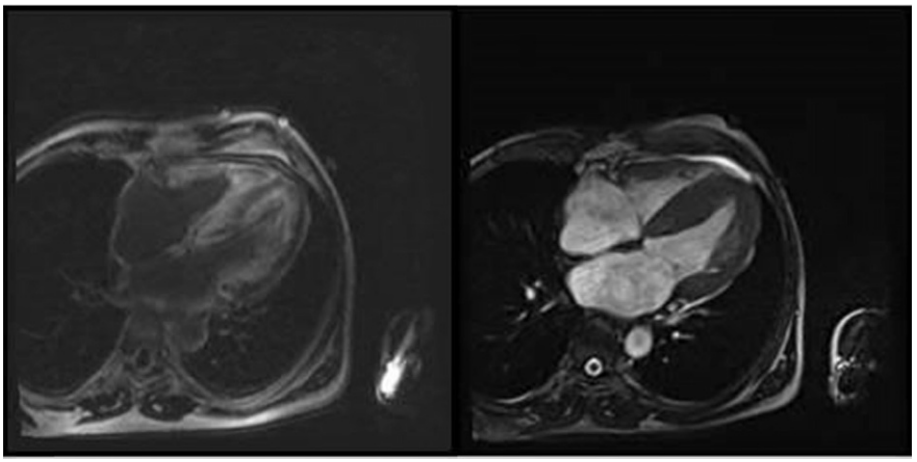

Fig. 8 A and B, MRI in amyloid cardiomyopathy.

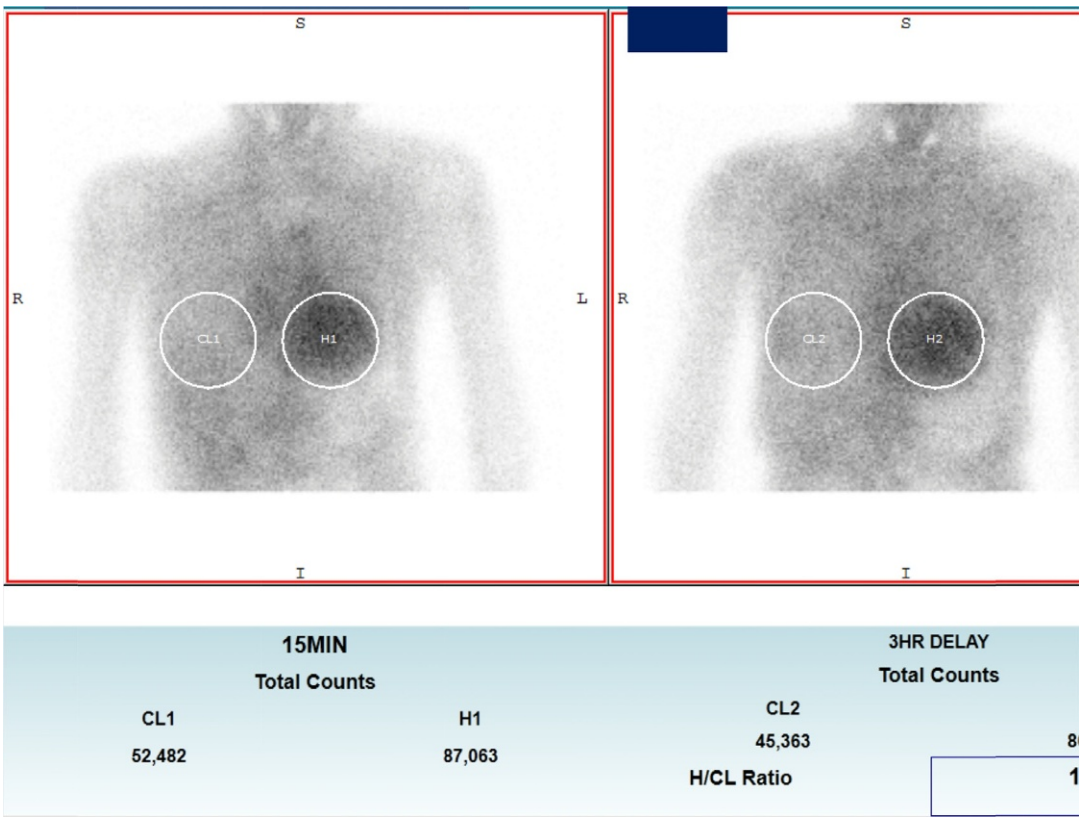

Fig. 9 Technetium 99 PYP scan in ATTR cardiomyopathy.

composition of the tissues and assess their dynamic properties (Rubinshtein et al., 2009). By providing functional assessment of the heart, these newer MR techniques can not only help establish early diagnosis but also serve as a useful tool for assessment of organ response to treatment. Despite these important advancements, the use of cardiac MR in amyloidosis may be limited due to the presence of pacemaker/defibrillators. Renal impairment increases the risk of gadolinium-induced nephrogenic systemic sclerosis.

Nuclear-medicine-based imaging

^{123}I–labeled SAP component scanning (SAP scan) is the prototype of nuclear medicine tests used for imaging tissue amyloid burden (Hawkins et al., 1998). This test does not accurately assess myocardial involvement. Technetium (^{99m}Tc)-based isotopes can identify cardiac involvement with TTR amyloidosis but have variable sensitivity and specificity for other types; for example, technetium pyrophosphate is a sensitive marker of cardiac amyloidosis with preferential myocardial uptake in ATTR compared with AL (Fig. 9).

Intense Tc99m PYP uptake in a patient with echocardiographic evidence of amyloid cardiomyopathy and no evidence of plasma cell dyscrasia is a strong evidence of TTR cardiac amyloidosis. Recently, in a small study, *N*-[methyl-^{11}C]2(4′methylamino-phenyl)-6-hydroxybenzothiazole (^{11}CPIB)-based PET imaging appeared promising as it identified cardiac amyloid deposits in all patients with AL or ATTR amyloid heart disease, while it was negative in healthy controls (Glaudemans et al., 2009; Antoni et al., 2013). The role of nuclear-based techniques in assessing systemic and, more importantly, cardiac amyloid burden is evolving. Additional studies are needed to help identify the appropriate isotope-scanning technique that can not only assess the disease burden but also reliably differentiate between various types of amyloidosis.

Management of Amyloid Cardiomyopathy

Management of amyloid heart disease depends upon the type of amyloid.

AL Cardiomyopathy

Treatment of AL involves the use of systemic chemotherapy to treat the underlying plasma cell dyscrasia to eliminate the production of amyloidogenic light chains. Systemic therapy improves organ function, quality of life, and survival of patients. Serum-free light-chain assay and cardiac biomarkers (*c*TnT and NT-proBNP) are invaluable in monitoring response to treatment (Gertz et al., 2005). While the ultimate goal of therapy in AL is improvement in organ function, the main aim of systemic therapy is to achieve hematologic response as indicated by reduction in the circulating burden of amyloidogenic light chains. Hematologic response precedes the organ response and has been shown to be a strong predictor of not only organ improvement but also overall survival (Gertz et al., 2007). Patients who achieve a complete hematologic remission (CR; i.e., normal serum-free light-chain levels and a normal K/L ratio and no evidence of clonal plasma cells) have a 66%–86% chance of organ improvement and 5-year survival approaching 70% (Dispenzieri et al., 2006). Improvement in organ function and survival is also noted in patients who achieve partial hematologic remission (i.e., at least 50% reduction from baseline in involved free light-chain levels).

Oral melphalan and dexamethasone (MelDex) has been the most common regimen used for the treatment of AL and has demonstrated hematologic response rates of over 60%, with 30%–40% of patients achieving CR. Organ improvement is noted in a third of patients with median survival as long as 5 years (Palladini et al., 2004; Sanchorawala et al., 2010). Treatment with newer antiplasma cell agents, such as proteasome inhibitors and immunomodulatory drugs, has demonstrated significant activity in patients with relapsed AL. Bortezomib has demonstrated hematologic response rates of 80% or more in combination with steroids and alkylating agents, and these combinations are moving to the frontline treatment of AL (Kastritis et al., 2010). Lenalidomide and pomalidomide are thalidomide analogs and have demonstrated response rates of over 50% in patients with relapsed disease (Palladini et al., 2012). While these newer agents are highly effective in AL, their use can be challenging because of potential cardiotoxicity, and their safety and superiority over MelDex have not been prospectively demonstrated. Myeloablative chemotherapy followed by autologous peripheral blood stem-cell rescue (stem-cell transplant (SCT)) has been very effective in eliminating the amyloidogenic plasma cell clone. In a large series of patients, SCT has demonstrated overall hematologic response rates of 75% and CR rates of 38% (Gertz et al., 2010). Median overall survival of patients who achieved CR was not reached, while it was 107 months for those with partial hematologic remission. Patients who achieved CR after SCT have been reported to have a 10-year survival approaching 60% (Sanchorawala et al., 2007). While SCT is very effective, it is associated with a high risk of complications including a high treatment-related mortality. Early experience reported a mortality in excess of 20% in the United States and >40% in a small European series. High transplant-related mortality has been attributed to inclusion of patients with advanced cardiac disease. The availability of cardiac biomarkers and the use of stringent selection criteria have significantly improved the transplant-related mortality to <5% in experienced centers (Gertz et al., 2011; Comenzo and Gertz, 2002). At the Mayo Clinic, active New York Heart Association class III or IV heart failure, an LV ejection fraction <45%, advanced cardiac stage by biomarkers, a systolic BP <90 mmHg, and more than two organ involvement are considered contraindications for SCT. In patients with less severe involvement, a risk-adapted approach is used to select an appropriate dose of melphalan as conditioning for SCT. Using these stringent criteria, only 25% of amyloidosis patients qualify for SCT at diagnosis (Sher et al., 2016a).

Generally, if an AL patient is a suitable candidate and bone marrow plasma cell percentage is <10%, we recommend proceeding with SCT as soon as the diagnosis is made. In all other patients, combination therapy with MelDex or with newer agents is recommended.

Immunotherapy is being actively explored for the treatment of AL. Recently, in a phase I/II study NEOD 001, a monoclonal antibody against epitopes expressed by amyloidogenic light chains has been found to be well tolerated by AL patients who achieved control of their plasma cell dyscrasia with systemic therapy. Improvement in biomarkers of organ dysfunction was seen in several patients, and this is undergoing active investigation in combination with systemic therapy in newly diagnosed patients in a phase III study (Gertz et al., 2016). Daratumumab, a monoclonal antibody against CD 38, a protein routinely expressed on plasma cells in multiple myeloma and AL, has shown to be remarkably effective in AL including in patients with who progressed after SCT and multiple other treatments (Sher et al., 2016b).

Supportive care remains the cornerstone of management of AL cardiomyopathy and includes managing the cardiac manifestations of the disease and complications of systemic chemotherapy. Management of heart failure can be very challenging in AL, as these patients cannot tolerate several medications used for routine therapy of heart failure from other causes.

Angiotensin-converting-enzyme inhibitors (ACEIs) and angiotensin receptor blockers are particularly difficult to use due to the risk of hypotension. The negative inotropic effect of beta-blockers can precipitate acute CHF in a patient with stable heart failure. Digitalis derivatives and atrioventricular nodal-blocking calcium channel blockers can cause significant dysrhythmias as their intracardiac concentration may increase due to increased binding to amyloid fibrils. Patients with atrial hypokinesis and standstill are at risk of developing mural thrombus and subsequent embolization and stroke (Gertz et al., 2015). Such patients should be treated with anticoagulation with close attention to the risk of bleeding as it is significantly increased in AL patients. Orthostatic hypotension can be a problem and should be managed with the use of compression stockings, fludrocortisone, droxidopa, and alpha-adrenergic agonist midodrine. Volume overload can be a recurrent and difficult to treat problem; salt restriction and use of loop diuretics and metolazone along with strict monitoring of blood pressure and orthostatic responses can be helpful in difficult cases. We prefer torsemide as the diuretic of choice. Patients with dysrhythmias pose a particular challenge. The role of cardiac pacemakers in AL cardiomyopathy is controversial, as no clear survival advantage has been demonstrated with their use as primary prevention or as treatment of common cardiac dysrhythmia. Pacemaker placement should be considered on an individual basis especially in patients who present with high-grade atrioventricular block. Unlike non-AL cardiomyopathies, even automatic implantable cardioverter–defibrillator may not help the failing heart in AL as electromechanical dissociation is common (Kristen et al., 2008; Lin et al., 2013).

Doxycycline has been shown in in vitro studies to inhibit the formation of amyloid fibrils and to disaggregate formed fibrils by disrupting the beta-pleated structure of the amyloid fibrils. Mayo Clinic examined the survival in patients following stem-cell transplantation based on biological randomization of the anti-infective prophylaxis in the first year following ASCT Of 455 evaluated patients; 77% received oral penicillin that is the standard of care for antibacterial prophylaxis following ASCT at Mayo Clinic, while 23% received oral doxycycline as the prophylaxis agent due to history of penicillin allergy. Among patients who achieved hematologic response to ASCT, oral doxycycline was associated with a longer overall survival (median not reached compared with 161 months, respectively, $P = 0.04$) (Kumar et al., 2012b).

Heart transplantation is an option in AL; however, the vast majority of patients with AL cardiomyopathy will not qualify for a heart transplant due to significant extracardiac involvement, rapid disease progression, and the lack of control of the plasma cell dyscrasia (Kpodonu et al., 2005; Hosenpud et al., 1991). Moreover, the outcomes of heart transplantation in AL cardiomyopathy have been inferior compared with that for other cardiomyopathies. These poor outcomes are primarily due to progression of AL, as a heart transplant does not address the production of amyloidogenic light chains. Use of SCT after heart transplant has been reported in a small series with 1- and 5-year heart transplant survival rates of 82% and 65%, respectively (Lacy et al., 2008). These numbers do not compare favorably to the outcomes achieved by heart transplant for other conditions. A heart transplant is feasible in highly selected patients with AL cardiomyopathy; the ideal candidate will be a younger patient with isolated or predominant heart involvement who is also a candidate for SCT within 6–12 months after cardiac transplant.

Familial/Hereditary Amyloid Cardiomyopathy

The management of FAC consists of supportive care and addressing the source of amyloidogenic protein. The liver is the most dominant source of production of amyloidogenic protein precursors, and as such, orthotopic liver transplantation (OLT) is the only proved treatment for ATTR, fibrinogen-related and apolipoprotein-related amyloidosis (Suhr et al., 2005). Mutant ATTR is the most common indication for liver transplantation for familial amyloidosis worldwide. It is very important to recognize that efficacy of OLT is dependent upon the particular TTR mutation. The 5-year survival after OLT is 82% in patients with Val30Met TTR variant compared with 59% in non-Val30Met patients. Interestingly, progression of amyloid heart disease may occur in patients with ATTR after liver transplantation (Herlenius et al., 2004). This is caused by deposition of wild-type TTR produced from the transplanted liver on already established nidus of amyloid deposits in the heart. This phenomenon is particularly noticeable in the Ala60 mutation where progression of amyloid cardiomyopathy is common after liver transplantation. Combined liver and heart transplantation should be considered in this situation if no other significant systemic involvement is noted. Unlike ATTR, fibrinogen- and apolipoprotein A-related amyloid cardiomyopathy does not appear to progress significantly after liver transplantation.

Recent advancements in our understanding of the pathogenesis of amyloidosis have resulted in the emergence of novel therapies in ATTR. Stabilizing TTR agents such as tafamidis meglumine, a small molecule that stabilizes the native TTR tetramer, and diflunisal, a NSAID, has shown to inhibit dissociation to an amyloid fibril monomer in laboratory studies (Lozeron et al., 2013). Tafamidis has been approved in Europe and Japan for the treatment of FAP (caused by ATTR) by demonstrating improved symptom control in these patients and is under active clinical testing in FAC patients. Recently, messenger RNA-based silencing of the TTR mRNA with short interfering RNA (siRNA) has been shown to significantly decrease the circulating levels of circulating TTR (Suhr et al., 2015). Early clinical trials have confirmed the feasibility of this therapy, and an ongoing large phase III study will help assess the effectiveness of this modality compared with the current standard of supportive care. If proved successful, these therapies may obviate the need for liver transplantation.

Heart failure in ATTR is generally milder, and medications such as ACEIs and beta-blockers are better tolerated in ATTR compared with AL. Outcomes of cardiac transplant in non-AL amyloid cardiomyopathies are significantly better compared with those in AL cardiomyopathy; therefore, a diagnosis of cardiac amyloidosis early in the disease course will result in better organ transplantation outcomes. All patients with FAC must be offered genetic counseling and testing for early diagnosis in first-degree relatives.

Wild-Type TTR Cardiomyopathy

Treatment of SSA is predominantly supportive. The usual principles of management of CHF apply in SSA. As a majority of these patients are older, cardiac transplantation is not routinely used in SSA, except in the occasional younger patient with good organ system function and the absence of advanced systemic amyloidosis. Trials of tafamidis and siRNA are being planned in SSA.

Prognosis of Amyloid Heart Disease

The prognosis of cardiac amyloidosis is highly dependent upon the underlying amyloid protein. AL patients with symptomatic CHF and advanced cardiac stage, as determined by biomarkers, have a median survival of 3–5 months. Despite significant advancements made in antiplasma therapy in the last two decades, the early mortality (~40% in 1 year) has not significantly changed in AL, with death usually resulting from progressive cardiac failure and/or fatal arrhythmias. In patients with less severe cardiac involvement, systemic chemotherapy improves survival. The staging system based on cardiac biomarkers and serum-free light chains provides critical information about prognosis as patients with stage I cardiac disease have a median survival of 94 months compared with 5.8 months for stage IV disease (Fig. 6; Kumar et al., 2012a). The prognosis is significantly better in familial and SSA cardiac amyloidosis despite advanced cardiac infiltration as assessed by imaging studies compared with AL. In familial ATTR, the type of mutation in the TTR gene influences prognosis; for example, in a large series of patients with the Ala60 variant, median survival from the time of diagnosis was 3.4 years. Generally, median survival in SSA and familial ATTR ranges between 5 and 8 years.

Introduction

While anemia is a common comorbidity seen in patients with heart failure (HF), its role in prognosis and therapy is evolving. The prevalence of anemia in HF with reduced ejection fraction (HFrEF) has been reported to be 10%–50% in inpatient cohorts and 19%–23% in outpatient cohorts (Triposkiadis et al., 2016). Many studies have shown anemia is an independent predictor of mortality in HF patients (Berry et al., 2016; Sanchez-Torrijos et al., 2006; Szachniewicz et al., 2003; Groenveld et al., 2008). Anemia has been shown to correlate with reduced exercise capacity (Ebner et al., 2016; Kalra et al., 2003) and NYHA (Silverberg et al., 2000) class in heart failure patients. In this article, we will focus on iron deficiency (ID) anemia, which is the most common form of anemia. We will discuss the importance of separating ID from ID anemia, particularly in the population of HF patients. We also summarize the two major randomized controlled trials in the area of ID in congestive heart failure. Finally, we will discuss the impact and management of anemia of chronic disease and the impact of erythropoietin supplementation in HF patients.

Etiologies of Anemia

The World Health Organization defines anemia as a condition in which the number of red blood cells is insufficient to meet the body's physiologic needs (WHO, 2011). The circulating volume of red blood cells is represented by surrogate lab values, most commonly hemoglobin and hematocrit. The World Health Organization defines anemia as a hemoglobin <13.0 g/dL in a male and as a hemoglobin <12.0 g/dL in a nonpregnant female (WHO, 2011). Anemia has multiple causes which can be broken down into two general categories: excessive red blood cell loss or inadequate RBC production. Chronic or acute blood loss, autoimmune destruction of blood cells, and mechanical hemolysis are a few of the more common causes of excessive red blood cell loss. Causes of inadequate production include ID, hemoglobinopathies, nutritional deficiencies, bone marrow malignancies, chronic kidney disease, chronic infection, and chronic inflammation. However, of all these varied etiologies, ID anemia is the most common form of anemia among all patient groups and is extremely common in patients with heart failure (WHO, 2011; Tim Goodnough et al., 2017; Cleland et al., 2016) (**Fig. 1**).

Hemodynamic Effects of Anemia

The hemodynamic contribution of anemia to the pathophysiology of patients with HF is multifactorial. Most intuitively, a change in hemoglobin directly changes the oxygen carrying capacity of blood, impacting the end-organ delivery of oxygen. Oxygen delivery also depends on cardiac output and vascular distribution, which can be altered by anemia-induced decreases in systemic vascular resistance. In essence, anemia causes increased oxygen extraction by tissues, and requires a higher cardiac output and a more rapid circulatory time to keep up with demand (Duke and Abelman, 1969). In a study by Anand et al., four anemic patients with congestive symptoms and high cardiac output underwent hemodynamic and neurohormonal evaluations. Their results were compared with normal controls as well as HF controls without anemia (Anand et al., 1993). Anemic patients had a 50% reduction in renal blood flow, with a hormonal response that consisted of plasma increases in norepinephrine, renin–angiotensin–aldosterone hormones, and atrial natriuretic peptides (Anand et al., 1993). Similar hormonal derangements are well described in the clinical syndrome of HFrEF and contribute to disease progression. In patients with heart failure, concomitant neurohormonal and

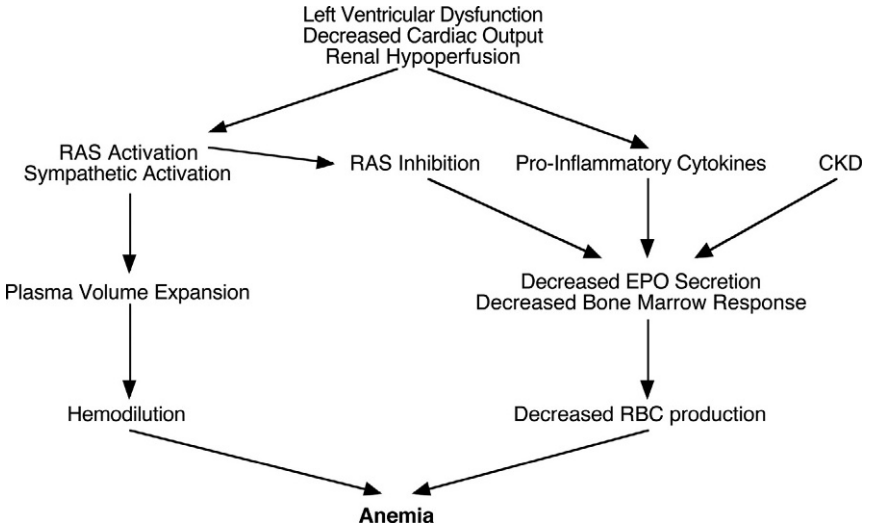

Fig. 1 Potential causes of anemia in chronic heart failure. (RAS: Renin-Angiotensin-Aldosterone System, CKD: Chronic Kidney Disease, EPO: Erythropoeitin, RBC: Red Blood Cell). proinflammatory cytokine activation favors the development of anemia of chronic disease. This manifests as altered iron utilization, inappropriate erythropoietin production, and a depression in hematopoiesis.

Iron Defiency Without Anemia

Another important concept in congestive heart failure is not only that of anemia, but also of ID, with and without clinical anemia. Two-third of the body's iron is stored in the hemoglobin of red blood cells: 25% is stored in mobilizable stores as ferritin, and 15% is bound to myoglobin in muscle tissue and a variety of enzymes involved in oxidative metabolism (Abbaspour et al., 2014). The importance of iron in oxidative metabolism and other processes like fatty acid oxidation may provide an explanation as to why ID even without anemia can have consequences in the patient with heart failure (Jankowska et al., 2011; Haas and Brownlie, 2001) at the cellular level. Low cellular iron reserves can result in a decrease in activation of the mitochondrial respiratory chain. This leads to reduced ATP production, causing a reduction in exercise capacity and increasing fatigue (Bayeva et al., 2013; Guzman Mentesana et al., 2014).

Mechanisms of ID and Anemia

The mechanisms of ID and anemia in HF are multifactorial and an area of active investigation. Iron absorption, storage, and distribution through the body is a tightly regulated system that is controlled mainly by two pathways: the conservation of iron from the destruction of red blood cells through the mononuclear phagocytic system, and the absorption of ingested iron in the gut (Tim Goodnough et al., 2017; Ebner and von Haehling, 2013). Hepcidin, a peptide hormone synthesized by the liver, is felt to be the "master regulator" of iron metabolism in the body (Singh et al., 2011). Hepcidin induces a block in duodenal iron absorption and recycling through the mononuclear phagocytic system (Singh et al., 2011). In HF, there is an increase in TNF-alpha and IL-6 which can contribute to ID and anemia in several ways: reduced erythropoietin production in the kidney, hepcidin-induced failure of iron absorption from the gut, and hepcidin-induced trapping of iron in iron stores of macrophages (Tim Goodnough et al., 2017; Silverberg et al., 2011). In the initial phases of HF, hepcidin is upregulated, which results in the development of ID (Jankowska et al., 2013). Over time, as the disease process progresses, the opposite occurs with hepcidin downregulation, potentially in an attempt to reverse prior ID (Jankowska et al., 2013). There may also be a contribution from heart failure-induced cardiorenal syndrome which could worsen or potentiate ID in mechanisms similar to that of CKD (Silverberg et al., 2011).

There have been two pivotal clinical trials conducted to determine the impact of ID and anemia on patients with heart failure.

Ferric Carboxymaltose in Patients With Heart Failure and ID (FAIR-HF)Anker et al., 2009

Anker et al. were the first to study ID with or without anemia in a multicenter, double-blind, randomized, placebo-controlled parallel group study conducted across 75 sites (Anker et al., 2009). Major inclusion criteria in the study included stable ambulatory HF patients with ID, with NYHA class II symptoms and left ventricular ejection fraction (LVEF) <40% or NYHA class III symptoms

and LVEF <45%. Patients were included if they had ID, defined as a ferritin <100 ng/mL or ferritin 100–300 ng/mL with an iron saturation of <20%, and a hemoglobin between 9.5 and 13.5 g/dL. Patients with uncontrolled hypertension, other significant heart disease, inflammation, or significantly impaired liver or renal function were excluded. Patients were randomized in a 2:1 fashion to receive ferric carboxymaltose versus placebo. Those randomized to the treatment iron received ferric carboxymaltose dose equivalent of 200 mg of iron weekly until iron repletion was achieved and then every 4 weeks during the maintenance phase. A total of 459 patients were enrolled and 304 patients were in the treatment arm, with primary endpoints being improvement in patient global assessment (PGA) at week 24 and improvement in NYHA class. At 24 weeks, 50% of the treatment group were improved by PGA, while only 28% of the placebo group were improved by PGA ($P<0.001$). NYHA class had also improved to I or II in 47% of the treatment group as compared with 30% in the placebo arm at 24 weeks ($P<0.001$). Secondary outcomes of 6-minute walk time distance (6MWT), Kansas City Cardiomyopathy Questionnaire (KCCQ) score, and EuroQol five dimensions questionnaire (EQ-5D) were all improved at 24 weeks in the treatment group as well. There was no difference in side effects leading to premature discontinuation in either group. FAIR-HF was the first large-scale randomized controlled trial that showed iron repletion would be a viable target for HF therapy.

Beneficial Effects of Long-Term Intravenous Iron Therapy With Ferric Carboxymaltose in Patients With Symptomatic Heart Failure and ID (CONFIRM-HF) Ponikowski et al., 2015

Based on the improvement in 6MWT (a secondary endpoint) in the FAIR-HF trial, the investigators of CONFIRM-HF set out to evaluate iron repletion in ambulatory iron deficient heart failure patients using 6MWT as their primary endpoint (Ponikowski et al., 2015). CONFIRM-HF was a multicenter, double-blind, randomized, placebo-controlled, parallel group study conducted over 41 sites. Major inclusion criteria included ambulatory HF patients with ambulatory NYHA class II or III symptoms, EF <45%, BNP >100, or NT-proBNP >400, who were iron deficient as defined by ferritin <100 ng/mL or 100–300 ng/mL with TSAT <20%, and a hemoglobin <15 g/dL. Patients with uncontrolled hypertension, infection, clinical evidence of current malignancy, or significantly impaired liver or renal function were excluded. There was no lower limit to hemoglobin but patients having an immediate need for transfusion were excluded. Patients were randomized in a 1:1 fashion to receive ferric carboxymaltose or placebo. Patients in the treatment arm received between 500 and 2000 mg of iron within the first 6 weeks of the study, and thereafter patients received 500 mg of iron each at weeks 12, 24, and 36 if ID was still present. A total of 304 patients were randomized with 152 in the treatment arm and 152 in the placebo arm. The primary endpoint of the study was 6MWT at 24 weeks. At baseline, 6MWT was similar between treatment and placebo groups [288 +/−98 m vs. 302 +/−97 m, respectively]. At 24 weeks, there was a significant improvement of 6MWT by 33 +/−11 m when compared with the placebo arm ($P=0.002$). Functional and quality of life secondary endpoints included change in PGA, 6MWT distance, fatigue score, KCCQ, and EQ-5D at 6,12,24,36, and 52 weeks. PGA was improved at week 12 onward, NYHA from week 24 onward, 6MWT distance at weeks 36 onward, fatigue score week 12 onward, KCCQ at 12, 24, and 52 weeks, and EQ-5D at 36 weeks. Outcome-related secondary endpoints showed no mortality benefit seen in the 1-year follow-up period, however there was a statistically significant reduction in the combined secondary endpoint of hospitalizations due to worsening HF or death. There was no difference in the side-effect or safety endpoints leading to premature discontinuation in either group. The CONFIRM-HF study showed using the functional endpoint of 6MWT those patients who were iron replete independent of anemia status improved their functional capacity. At 24 weeks, there was a difference in 6MWT of 33 m +/−11 m. This was statistically significant at each follow-up interval in the secondary analysis (out to 52 weeks), which confirmed the findings in the secondary analysis of FAIR-HF.

Anemia of Chronic Disease

Defined by a reduced serum iron and transferrin concentration and a low total iron binding capacity along with a normal to high ferritin level, anemia of chronic disease is a prevalent entity in the heart failure population, with incidence varying in the literature. Erythropoiesis is dependent on a number of mechanisms, many of which can be altered in patients with heart failure. Erythropoietin is produced in the kidney. The primary stimulus for erythropoietin production is low serum oxygen content (Anand, 2008), which occurs due to a reduction in renal blood flow and glomerular filtration rate in patients with HF. However, the amount by which erythropoietin production rises is blunted in comparison with the severity of anemia (Opasich et al., 2005).

In addition, heart failure results in an overall active proinflammatory state, including elevated levels of tumor necrosis factor-α, interleukin (IL)-6, CRP, and other proinflammatory cytokines, which inhibit erythropoiesis in the kidney via a series of complex mechanisms (Jelkmann, 2009).

In patients with heart failure who develop anemia without ID, alternate methods of therapy are often considered. Trials using darbepoetin alfa (Swedberg et al., 2013; Pfeffer et al., 2009) to correct hemoglobin to a target level of 13.0 g/dL showed no reduction in death, cardiovascular events, or HF hospitalizations, but did result in a concomitant increase in fatal and nonfatal strokes. The medical community has therefore steered away from the use of EPO-analogs to treat mild anemia in heart failure.

Recommendations

Anemia and, more specifically, ID have been shown to be associated with worse outcomes and symptoms in heart failure patients. The treatment of ID in particular can help improve quality of life and improve functional capacity. Currently, the only guidelines for screening for ID are provided by a consensus document of the Spanish Society of Internal Medicine and Spanish Society of Cardiology. They recommend laboratory screening for ID by monitoring ferritin and iron saturation is performed at diagnosis of HF, during episodes of decompensation, and annually for stable outpatients with HF (Manito et al., 2016). We feel these are reasonable recommendations; the current body of evidence currently only supports iron repletion in stable outpatients with heart failure. There is no evidence for or against treatment or monitoring of ID in the inpatient setting, but given the potential for improved outcomes and the relatively low risk of harm, we generally replete patients with intravenous iron in the inpatient setting, when appropriate. In those diagnosed with ID, we would also recommend screening at 3 months after repletion to ensure iron stores continue to be robust. This also allows for a determination of whether more aggressive iron repletion is necessary or whether the patient can go onto a maintenance regimen of iron repletion. In addition to these recommendations, patients with ID should undergo age-appropriate screening for other common causes of ID, that is, gastrointestinal losses due to bleeding sources, including malignancy. There is limited data for the route of iron repletion and all positive evidence for iron repletion has been studied via the parenteral route. The IRON-HF study compared iron repletion of eight patients with IV iron and seven patients with oral iron. It showed that both preparations corrected the hemoglobin levels, but parenteral iron only was associated with an increase in peak VO2 over a 3-month follow-up period (Beck-da-Silva et al., 2013). Based on the current body of evidence we would recommend when possible in a real world setting to use parenteral iron and if not possible then default to oral iron repletion.

Future

Recent evidence has suggested that iron can be a novel target at least for symptoms of congestive heart failure. The mechanisms of ID are multifactorial and per our discussion earlier, there is a suggestion that parenteral treatment of ID in stable outpatients with congestive heart failure leads to functional and symptomatic benefits. The signal toward improvement of hospitalizations in CONFIRM-HF is intriguing and lays the groundwork for future larger scale studies to investigate this question. Currently, there are several interesting studies in the area of parenteral iron repletion which will answer important questions. Preliminary data from the effect of ferric carboxymaltose on exercise capacity in patients with iron deficiency and chronic heart failure (EFFECT-HF—NCT01394562) study (completed in 2016) show an improvement in peak oxygen consumption (VO2), an important prognostic marker in heart failure, with IV Iron repletion versus placebo. The study to compare ferric carboxymaltose with placebo in patients with acute heart failure and iron deficiency (AFFIRM-AHF—NCT02937454) will aim to evaluate the effect of iron infusion on the population of patients hospitalized with acute heart failure. Primary endpoints will include HF hospitalizations after randomization and composite HF hospitalizations with an endpoint of cardiovascular death. Future research will likely continue to evaluate the beneficial effects of iron repletion not only on symptoms, but also on morbidity- and mortality-related outcomes.

Another important question for future research is the difference between parenteral iron and oral iron for treatment in HF patients. This remains an important logistical question, as ease of implementation and cost remain major differences between the two routes of repletion. The oral iron repletion effect on oxygen uptake in heart failure (IRONOUT-HF) study seeks to improve understanding of the question by comparing oral iron repletion to placebo in 225 patients with NYHA II–IV HF and LVEF $\leq$ 40%. Preliminary results have suggested no change in peak VO2 with oral iron repletion compared with placebo. Continued research into iron repletion for ID should seek to answer the above questions, along with seeking to definitively answer the question of whether there is a mortality or morbidity benefit to iron repletion. The question of how to manage patients with anemia who are not iron deficient is a difficult one, and ongoing close monitoring of these patients will have to occur, along with ensuring they are appropriately replete in Vitamin B12 and folic acid stores.

Glossary

Angiogenesis The sprouting of new blood capillaries from preexisting vasculature
Hypoxia Insufficient tissue oxygen abundance
Mural cell Cells that surround EC, including pericytes and vascular smooth muscle cells
Notch A cell surface signaling molecule involved in many important developmental processes including vascular branching and maturation
Pericyte Specialized mural cells which surround microvascular EC
Phalanx cell Quiescent, closely interlocked EC, present in stable blood vessels
Shear stress The physical force exerted by blood flow in vessels
Stalk cell Proliferating EC forming the base of a new vessel sprout
Tip cell The EC selected to guide the advancement of new vessel sprouts
Vasculogenesis De novo formation of vascular cells during embryogenesis

Introduction

The vascular system has permitted the evolution of complex multicellular organisms by overcoming the limitations of diffusion as a means of delivering oxygen and metabolic substrates. It has been estimated that the adult human vasculature has a surface area similar to a soccer pitch, emphasizing its pervasiveness and capacity to influence health (Aird, 2005). However, the vasculature is much more than a passive transport system; for example, it actively regulates tissue perfusion, leukocyte trafficking, and hemostasis (Aird, 2005). More recently, it has even been shown to regulate processes such as bone marrow stem cell quiescence (Itkin et al., 2016) and systemic metabolism (Kubota et al., 2011). Hence, we have also evolved highly regulated processes to ensure that the vascular system remodels appropriately in response to changing physiological demands.

Angiogenesis, the sprouting of new capillaries from the existing microvasculature, was first described in the 18th century, but its potential as a therapeutic target was not proposed until the 1970s when Judah Folkman hypothesized its requirement for cancer growth (Folkman, 1971). We now recognize abnormal angiogenesis to contribute to many diseases (Carmeliet, 2003), which are often characterized by insufficient or excessive neovascularization. However, this distinction may be overly simplistic since it

neglects the importance of new vessel quality, and overlooks the cooccurrence of "excessive" and "insufficient" angiogenesis in some disease processes (e.g., diabetes). This may explain why therapeutic manipulation of angiogenesis has not been uniformly successful (Potente et al., 2011), and supports the need for more nuanced therapeutic approaches. In this article, we discuss contemporary understanding of the process of angiogenesis, outline how this is dysregulated in common diseases, examine current therapeutics, and speculate how recent advances may improve therapeutic approaches.

The Origins of the Vascular System

In vertebrates, the vascular system develops early during embryogenesis in a process called vasculogenesis, where angioblasts (vascular progenitor cells) form de novo from the mesoderm and aggregate as a primordial capillary plexus. Vessel sprouting enlarges this primitive vasculature, which then remodels and matures into a hierarchical network of arteries, veins, and capillaries, which is required for effective circulation of blood (Potente et al., 2011). However, arteriovenous specification is determined before the onset of blood circulation, suggesting regulation by genetic factors, rather than shear stress generated by flow. In zebrafish, the cardinal vein develops by segregation and selective migration of venous angioblasts from the common vessel primordium, which later forms the dorsal artery, and this process is highly regulated (Herbert et al., 2009).

Differential sensitivity to vascular endothelial growth factor (VEGF), with subsequent alterations in Notch signaling, appears important in initiating endothelial cell (EC) arteriovenous fate (Swift and Weinstein, 2009). Moreover, EphrinB2 and its corresponding receptor EphB4 are also differentially expressed in arteries and veins before the onset of circulation (Wang et al., 1998; Gerety et al., 1999), and their interaction regulates angioblast migration and arteriovenous segregation (Herbert et al., 2009). Notch signaling suppresses venous fate by enhancing EphrinB2 expression, and simultaneously inhibiting EphB4 expression. Notch signaling in arteries is stimulated by VEGF, while venous phenotype appears to be actively promoted by chicken ovalbumin upstream promoter-transcription factor II (COUP-TFII), which suppresses Notch, so promoting EphB4 expression (Kuijper et al., 2007).

Adjacent to the blood-containing vasculature, the body develops a lymphatic system during embryogenesis to maintain fluid homeostasis. COUP-TFII-expressing venous EC give rise to lymphatic EC, which migrate and build primitive lymph sacs to develop the lymphatic vasculature further (Yang and Oliver, 2014).

Defining Angiogenesis

The formation of new capillaries from preexisting blood vessels is termed angiogenesis, and is distinct from vasculogenesis, which only occurs in utero. Angiogenesis is traditionally defined as the process of capillary sprouting from preexisting vasculature, and is most strongly induced by low tissue oxygen tension (hypoxia), although can be promoted by other biological processes, as discussed later. Besides classical "sprouting angiogenesis," new vessels can also emerge from preexisting ones by "splitting angiogenesis," often termed intussusception; in this case, transluminal pillars develop, which expand to separate two new vessels. Intussusception occurs as a result of altered blood flow during development or physical exercise, and under pathological conditions (e.g., tumorigenesis) (Makanya et al., 2009; Gianni-Barrera et al., 2013). Remodeling of the vasculature by either form of angiogenesis is essential during postnatal development, and in response to many physiological phenomena, to ensure the vascular system is matched to the changing local demands.

The Process of Angiogenesis

Sprouting angiogenesis occurs in response to proangiogenic molecular signals (in particular, VEGF), which activate EC, resulting in the extension of protrusions called filopodia that sense the origins of angiogenic signals (Phng and Gerhardt, 2009). EphrinB2 has been shown to be essential for VEGF/VEGF receptor (VEGFR) internalization, and accordingly VEGF signal transduction (Sawamiphak et al., 2010; Wang et al., 2010). Moreover, Neuropilin1 acts as a coreceptor for VEGF and is pivotal in effecting normal VEGFR activation (Lanahan et al., 2013; Bjo et al., 2014), further emphasizing the intricate regulation of angiogenic growth factor signaling.

Upon growth factor signaling, EC must break down their enveloping basement membrane, which they share with mural cells (pericytes and vascular smooth muscle cells), in order to allow formation of a "tip cell" that guides the new vessel sprout. To achieve this, tip cell filopodia secrete matrix metalloproteases (MMPs), such as MMP1 (Potente et al., 2011), to enzymatically digest basement membrane proteins. This liberates further proangiogenic factors to support sprouting, although antiangiogenic factors are also released to prevent excessive sprouting and ensure adequate stability of neovessels (Nyberg et al., 2005). Mural cell detachment is facilitated by release of Angiopoietin 2 (Ang2) from EC (Maisonpierre et al., 1997), which is thought to be stored in Weibel–Palade bodies (Augustin et al., 2009). Ang2 competitively binds the EC receptor Tie2, which disrupts the Ang1/Tie2 signaling required to maintain vascular quiescence (discussed later) (Maisonpierre et al., 1997).

Once an endothelial tip cell has emerged, it is followed by proliferating endothelial "stalk cells," which extend the new sprout toward proangiogenic growth factor gradients detected by the tip cell. The decision of EC to adopt tip or stalk status is critical to

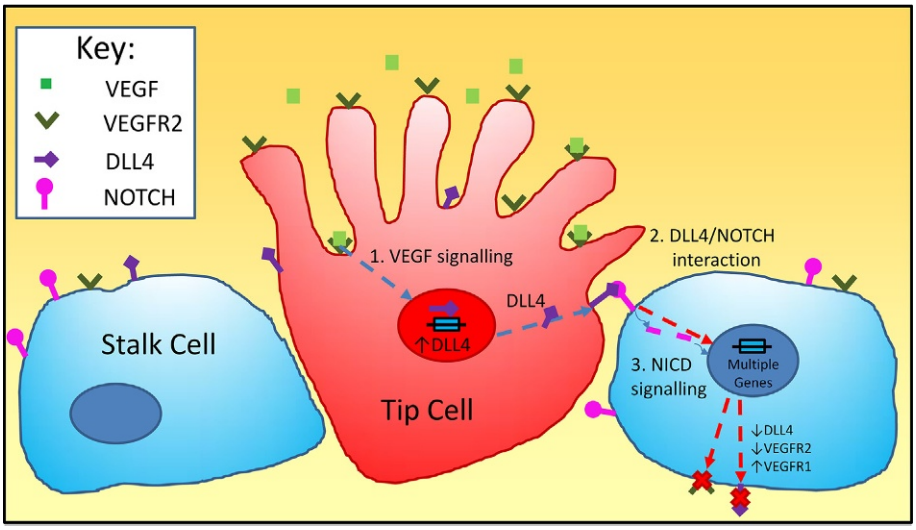

Fig. 1 Lateral inhibition during tip/stalk selection. During angiogenic sprouting, endothelial cells (EC) with higher levels of VEGF signaling express greater concentrations of cell surface Dll4, which interacts with Notch on neighboring EC. This molecular interaction results in cleavage of the Notch intracellular domain (NICD), which translocates to the nucleus and modulates gene expression, resulting in suppression of VEGFR2 and Dll4, along with increased expression of the antiangiogenic VEGF receptor VEGFR1. This communication is dynamic and bidirectional, with the cells expressing most Dll4 at any instant becoming tip cells, which actively inhibit tip cell fate in their neighbors.

effective angiogenesis, since an excess of either phenotype would cause excessive or inadequate sprout formation, respectively. Therefore, an intercellular communication system has evolved whereby EC compete to suppress tip cell status in their neighbors, in a process called "lateral inhibition," which has parallels across biology (e.g., branching during lung or glandular development) (Fig. 1). Critical to this intercellular competition are the cell surface molecules Notch and Delta-like ligand 4 (DLL4), which are differentially expressed in tip and stalk cells, with higher DLL4 and lower Notch in "successful" tip cells. Proangiogenic VEGF signaling via VEGFR2 enhances EC surface expression of DLL4, which binds to Notch1 receptors on neighboring EC. This binding causes enzymatic cleavage of Notch, freeing its intracellular domain to induce gene expression changes, including feedback inhibition of DLL4 and VEGFR2 (Phng and Gerhardt, 2009). Accordingly, only those EC with the greatest DLL4 expression can become a leading tip cell, whereas remaining cells are forced to adopt stalk status (Jakobsson et al., 2010). Notch signaling also influences intercellular adhesion mediated by VE-cadherin, further promoting tip/stalk cell rearrangement during angiogenesis (Bentley et al., 2014), and importantly, tip/stalk fate is dynamic and frequently changes during the sprouting process (Jakobsson et al., 2010). The ratio of tip cells to stalk cells is of great importance in establishing adequate vasculature, with deletion of either DLL4 or Notch 1 being embryonically lethal (Krebs et al., 2004). Interestingly, the excessive sprouting associated with DLL4 inhibition results in decreased tumor perfusion and size (Thurston et al., 2007).

The developing sprout needs to establish a lumen and integrate within appropriately perfused circuits if it is to make a persistent contribution to the vasculature; inadequately perfused sprouts will rapidly regress. Lumen formation by stalk cells is established by processes called cell and cord hollowing, in which cellular vesicle transport and repulsive membrane interactions, respectively, create a space for blood flow between or within EC (Strilić et al., 2009). New vessel circuits are then established by sprout anastomosis, a phenomenon where neighboring tip cells fuse by forming VE-cadherin junctions, which can be orchestrated by tissue macrophages (Fantin et al., 2010).

New vessel maturation and stabilization is achieved by basement membrane matrix deposition and mural cell recruitment (Fig. 2). Platelet-derived growth factor (PDGF) is secreted by tip and stalk cells and binds to heparan sulfate proteoglycans at the cell surface (Abramsson et al., 2007). PDGF, together with the epidermal growth factor HB-EGF, stimulates mural cell migration and proliferation (Stratman et al., 2010), resulting in pericyte recruitment occurring simultaneous to sprout elongation (Armulik et al., 2011). PDGF/PDGF receptor-β (PDGFRβ) signaling is crucial to stabilize EC-pericyte interactions in the neovasculature, and disruption of this signaling pathway is lethal during embryogenesis (Lindahl et al., 1997). After initial pericyte recruitment, Ang1/Tie2 signaling is crucial to the maturation process, and also maintains pericyte coverage in quiescent vessels; developmental defects in either Ang1 or Tie2 have been demonstrated to be lethal (Suri et al., 1996). Interestingly, recent research has also demonstrated that reciprocal regulation of Tie1/2 receptors is required during sprouting angiogenesis (Savant et al., 2015), with the orphan receptor Tie1 mediating complex regulation of Tie2 activity, and hence Ang signaling. In quiescent EC, Tie1 expression is reduced, allowing Tie2 signaling in response to pericyte-derived Ang1. Tie1 expression increases in remodeling in stalk cells, where it unexpectedly sustains Tie2 activation, yet greater Tie1 expression in tip cells disrupts Tie2 activity, which is required for normal sprouting. Hence complex Tie1/Tie2 interactions ensure breakdown of the basement membrane and mural cell detachment so that sprout formation can be initiated, but also promote effective maturation and quiescence of new sprouts. EphrinB2 signaling is also involved in mural cell recruitment, with global- (Adams et al., 1999) and mural cell-specific (Foo et al., 2006) deletion causing

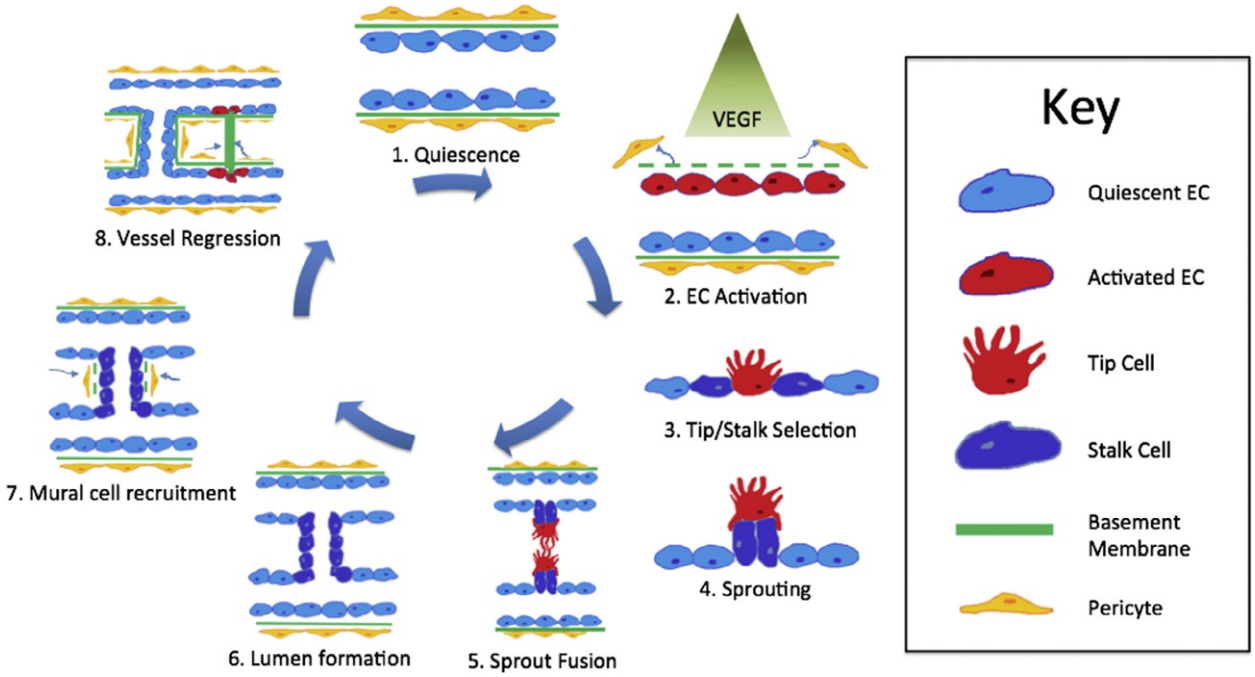

Fig. 2 Progression from vascular sprout to mature vessel. When a quiescent vessel (1) experiences increased concentrations of proangiogenic growth factors (2), endothelial cells (EC) become activated, releasing cytokines and enzymes that promote pericyte shedding and basement membrane degradation. EC with the highest levels of VEGF signaling become selected as tip cells, which actively induce stalk cell phenotype in their neighbors (3—see also **Fig. 1**). Tip cells migrate toward the greatest concentrations of proangiogenic growth factors, with following stalk cells proliferating to form a vascular sprout (4). Sprouts then anastomose (5) with the assistance of macrophages to form vascular loops, which then form perfused lumens (6) that mature as migrating pericytes envelop the vessel and contribute to basement membrane deposition (7). Finally, neovessels experiencing low flow selectively regress (8), with this cycle continuing iteratively until a mature vascular plexus is formed, which matches local blood supply to demand.

vascular anomalies including defective mural cell attachment, along with embryonic or postnatal lethality. Pericyte recruitment progresses alongside vascular basement membrane deposition, with both EC and pericytes secreting collagen type IV, laminin and fibronectin, thereby further enhancing neovascular stabilization (Stratman et al., 2009).

EC within new vessels further mature by developing a quiescent "phalanx" phenotype, characterized by closely interlocked nonmigratory nonproliferative cells, which is promoted by Notch signaling (Ehling et al., 2013). Blood flow then promotes remodeling of the vasculature, with regression or "pruning" of poorly perfused vessels. The expression of Krüppel-like factor 2 (KLF2) mediates blood flow-induced changes in EC gene transcription, such that when a vessel is not perfused, shear stress and hence KLF2 signaling is low, and the vessel regresses (Potente et al., 2011). Depending on the vascular bed, cell adhesion molecules such as VE-cadherin and N-cadherin, and tight junctions allow cell–cell contact and barrier function. VE-cadherin also diminishes VEGFR2 signaling to suppress proangiogenic VEGF activity (Potente et al., 2011), and in order to survive in this quiescent milieu, EC and pericytes express prosurvival signals, such as VEGF and Ang1, respectively. Thereby, VEGF operates in an autocrine manner, activating the PI3K/Akt pathway in EC, to promote survival (Lee et al., 2007; Warren and Iruela-Arispe, 2010).

Modulation of Angiogenesis

Hypoxia is probably the most potent stimulus for angiogenesis, and the expression of hypoxia-inducible factors (HIFs) and prolyl hydroxylase domain (PHD)-containing enzymes allow exquisite cellular oxygen sensitivity. Adequate tissue perfusion permits oxygen-dependent hydroxylation of HIFs by PHDs, which targets them for proteasomal degradation. When oxygen is limited, PHDs remain inactive, so HIFs are not degraded and can alter gene transcription (e.g., increased VEGF) to increase angiogenesis, and so oxygen supply (Aragones et al., 2009; Ivan et al., 2001). HIF1α is required for hypoxia-induced autocrine VEGF/VEGFR2 expression, and accordingly EC proliferation and migration (Tang et al., 2004). Hence, oxygen levels modulate VEGF expression, and adequate oxygenation of phalanx EC reduces VEGF expression to a prosurvival level. Further, HIF1α can modulate EC fate; activation of DLL4/Notch signaling by HIF1α suppresses COUP-TFII, and supports arterial cell fate (Diez et al., 2007), which may be important in augmenting tissue perfusion. The role of EC HIF2α is less well understood, but appears only to partially overlap HIF1α function, and is crucial in promoting maturation of new arteries in a Notch-dependent manner (Skuli et al., 2012).

Low oxygen levels are often accompanied by decreased nutrient supply, which can also modulate angiogenesis (**Fig. 3**). For example, AMP-dependent kinase (AMPK) is activated by energy depletion, associated with hypoxia and glucose deprivation,

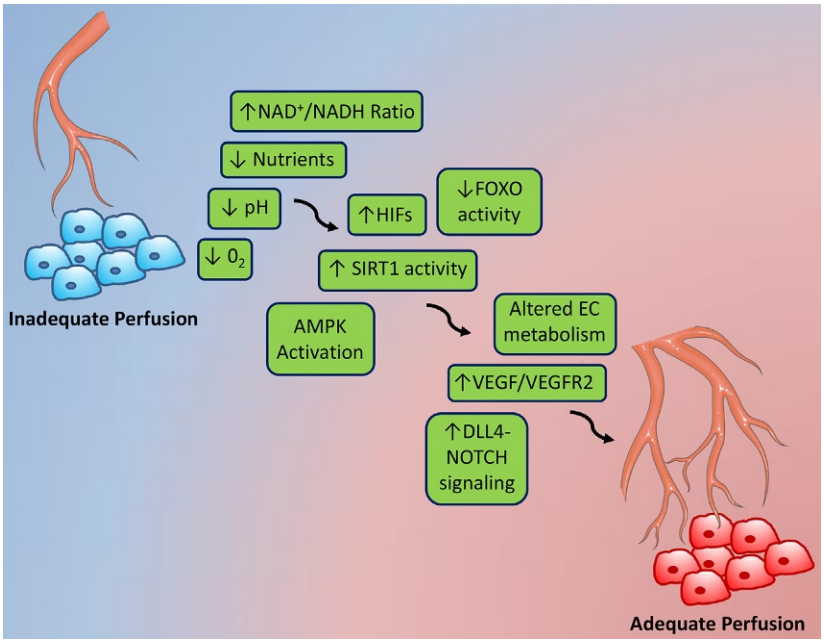

Fig. 3 Processes that induce angiogenesis. Inadequate tissue perfusion results in hypoxia, acidosis, nutrient scarcity, and rising NAD^+/NADH ratio (reflecting reduced catabolism of metabolic substrates). These phenomena are detected by an array of molecular sensors (a small selection of which are illustrated), including hypoxia inducible factors (HIFs), AMP-dependent protein kinase (AMPK), NAD^+-dependent deacetylases (e.g., Sirtuin1 or SIRT1), and Forkhead transcription factors (FoxOs). Cumulatively, these sensors orchestrate a molecular response, including increased VEGF production and signaling, increased Dll4/Notch signaling, and altered endothelial cell (EC) metabolism, which promote angiogenesis, and aim to restore adequate tissue perfusion. Elements of this figure were adapted from images made freely available by Servier Medical Art (http://www.servier.com/Powerpoint-image-bank).

and stimulates catabolic pathways in order to generate ATP (Long and Zierath, 2006); it is also a potent stimulus for VEGF expression (Ouchi et al., 2005). Low cellular nutrient supply is also associated with an increase in the NAD^+/NADH ratio, which is sensed by deacetylating enzymes called Sirtuins, which can augment proangiogenic gene expression and modify the activity of proteins such as Notch (Potente et al., 2007; Phng et al., 2011). Notably, PHD enzymes also require 2-oxoglutarate (an aerobic metabolite of the Kreb's cycle) in order to hydroxylate HIFs, so under nutrient deprivation HIFs are less susceptible to degradation (Aragones et al., 2009). Beyond the scope of this discussion, many other transcription factors regulate EC responsiveness to nutrient deprivation, including peroxisome-proliferator-activated receptors (PPARs) and forkhead box proteins (e.g., FOXOs) (Aragones et al., 2009).

Beyond oxygen and nutrient supply, inflammation is another major modulator of angiogenesis. Inflammation is characterized by tissue invasion of inflammatory cells, such as neutrophils, monocytes, and macrophages, which secrete an array of vasoactive cytokines and growth factors. In acute inflammation, cytokines induce vessel dilation to enhance blood flow and increase vascular permeability, allowing more cells to invade and repair tissue damage (Szade et al., 2015; Muller, 2003). However, in persistent chronic inflammation, EC become activated and undergo a proangiogenic switch, where interleukins and tumor necrosis factor α (TNFα) can stimulate sprouting (Jackson et al., 1997). For example, TNFα induces the transcription factor NFκB, resulting in EC Ang2 expression and initiation of the sprouting process (Pober and Sessa, 2007; Imhof and Aurrand-Lions, 2006). Moreover, macrophages can secrete classical proangiogenic factors, such as VEGF, further driving vascular sprouting, but often in a poorly coordinated manner resulting in abnormal vascular structure and function (Jackson et al., 1997).

Angiogenesis and Vascular Heterogeneity

Beyond the clear differences between arterial, venous, lymphatic, and capillary EC, there is notable heterogeneity across microvascular EC, which reflects the diverse requirements of organ- or tissue-specific vascular beds. Whereas neurovascular EC form a restrictive "blood–brain barrier" to regulate cellular and molecular transit to the brain parenchyma, renal glomerular EC are fenestrated to facilitate blood filtration (Nolan et al., 2013). Besides the heterogeneity of EC in function (e.g., permeability, thermoregulation, or vasomotor tone), EC also differ in shape. For example, arterial EC are longer than venous EC, and possess a higher surface area; when arterial segments were surgically inverted, EC realign with flow within 10 days, demonstrating EC remodeling in response to shear stress (Aird, 2007). Endothelial heterogeneity has been attributed to genetic and (micro) environmental factors, as each EC responds to its local environmental biomechanical and biochemical milieu (Aird, 2007). Thereby, EC function as an organotypic cell niche, secreting angiocrine factors which modify the tissue parenchyma, yet also

responding to parenchymal signals that reciprocally manipulate vascular behavior (Rafii et al., 2016). Hence, even after the process of angiogenesis has formed or extended a vascular bed, this neovasculature must then adapt its form and function to its environment.

Diseases Associated With Abnormal Angiogenesis

While it is beyond the scope of this article to offer a detailed description of angiogenic abnormalities associated with the range of human diseases (Table 1), some key themes emerge by considering a few important examples. In particular, these serve to highlight our evolving and incomplete appreciation of the processes that cause abnormal angiogenesis, but also emphasize the potential value of effective therapeutics.

Inherited Disorders

Many rare genetic disorders interfere with angiogenesis and vascular patterning. While these generally represent the most extreme forms of vascular abnormality, elucidating their mechanisms has transformed our understanding of how blood vessels develop and mature. One important example is hereditary hemorrhagic telangiectasia, which causes diffuse arteriovenous vascular malformations, resulting in problems such as chronic gastrointestinal bleeding and high-output heart failure (Dupuis-Girod et al., 2010). It is caused by mutation of proteins involved in the TGF-β signaling system, which mediates complex endothelial–mural cell interactions during maturation of newly formed vessels (Mahmoud et al., 2011). Another interesting example is cerebral cavernous malformations, which are friable and disordered vascular growths, associated with mutations in a range of genes that have recently been shown to converge on mitogen-activated protein kinase signaling (Zhou et al., 2016). Excessive signaling through this pathway in EC causes abnormal venular dilatation in mice, similar to human malformations, although the precise mechanism of this remodeling remains unclear. These examples illustrate the nuanced regulation of normal vascular development and quiescence, although the contribution of these specific mechanisms to noninherited diseases associated with abnormal angiogenesis is unclear.

Cancer

It has long been recognized that tumors are highly vascular, leading Judah Folkman to make his seminal hypothesis that tumor growth is dependent on angiogenesis, and that this could be therapeutically targeted (Folkman, 1971). Moreover, blood vessels are frequently the conduit through which tumors spread to distant sites, a process called metastasis. Although current antiangiogenic therapies have not achieved dramatic responses in most cancers (discussed later), it remains accepted that angiogenesis is crucial to tumor biology, and continues to be an enticing therapeutic target. However, as our understanding of tumor vasculature evolves, it is becoming clear that reducing the abundance of vessels in tumors may be an overly simplistic therapeutic goal. For example, tumor perfusion is heterogeneous (Hensley et al., 2015), and often impaired as a result of abnormal vascular architecture (Stylianopoulos and Jain, 2013). Moreover, some have even speculated that adverse tumor environments, characterized by ischemia and acidosis caused by inadequate perfusion, result in evolutionary pressure favoring selection of more aggressive tumor clones (Potente et al., 2011). Recent data have also highlighted the possibility of tumor vascular mimicry, a process by which cancer cells may form a perfused network, independent of vascular cells, suggesting antiangiogenic therapies alone may be inadequate (Wagenblast et al., 2015). As discussed later, such observations are leading to the development of entirely novel therapeutic approaches.

Table 1 Examples of diseases associated with abnormal angiogenesis

Organ or tissue	*Diseases associated with "excessive" or abnormal angiogenesis*	*Diseases associated with "impaired" angiogenesis*
Multiorgan	Cancer, infectious diseases, vasculitic, and autoimmune disorders (e.g., systemic sclerosis)	
Cardiovascular	Monogenic vascular disorders (e.g., hereditary hemorrhagic telangiectasia), atherosclerotic plaque	Diabetes (except retinopathy), critical limb ischemia, lymphedema
Nervous system	Multiple sclerosis	Amyotrophic lateral sclerosis, Alzheimer's disease
Gastrointestinal	Inflammatory bowel disease	
Skin	Psoriasis, eczema	
Reproductive system	Endometriosis	Preeclampsia
Ocular	Diabetic retinopathy, wet age-related macular degeneration, retinopathy of prematurity	
Adipose	Obesity	
Musculoskeletal	Rheumatoid arthritis	Fracture nonunion
Respiratory	Asthma, primary pulmonary hypertension	Bronchopulmonary dysplasia

Some disorders may overlap across multiple organs or tissues, and as discussed in the text, it is important to note that the distinction between excessive and impaired angiogenesis is imperfect, for example, in the case of diabetes.

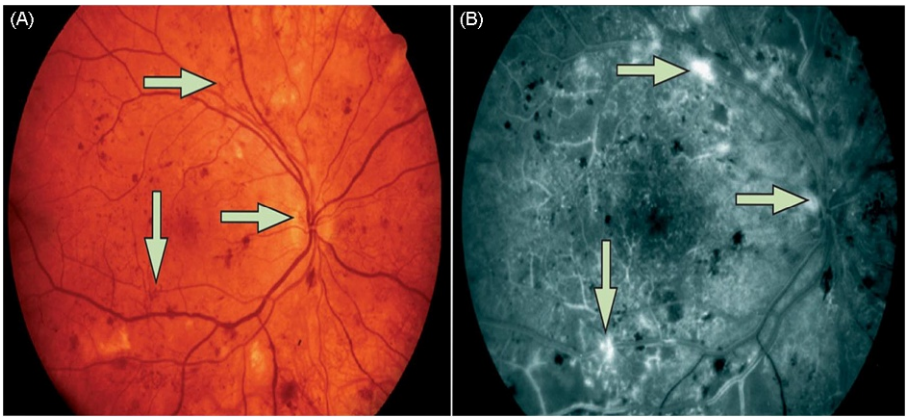

Fig. 4 Diabetic retinopathy. Retinal photomicrograph (A) and corresponding fluorescein angiogram (B) illustrating new vessel formation (*arrows*) around the macula, with associated leakage from abnormal neovessels indicated by intense white signal on angiography. Yellow exudates and red hemorrhages are also seen throughout the retina (A). Adapted from Cheung, N., Mitchell, P. and Wong, T. Y. (2016). Diabetic retinopathy. *Lancet* **376** (9735), 124–136, with permission from Elsevier.

Diabetes

Diabetic retinopathy provides a vivid illustration of the microvascular abnormalities that affect many vascular beds in people with diabetes (Fig. 4). In its early stages, it is associated with a loss of pericytes, which leads to capillary regression, along with the development of microaneurysms and vascular leakage (Hammes et al., 2011). These abnormalities cause retinal ischemia, which promotes angiogenesis, although the resulting neovasculature is of poor quality, frequently resulting in hemorrhage and inadequate retinal perfusion. Ultimately, visual impairment or blindness can ensue, although excellent glycemic and blood pressure management can substantially reduce the risk of microvascular complications (Holman et al., 2008a,b). The renal vasculature is also sensitive to the metabolic disturbances of diabetes, resulting in abnormal thickening and leakage of the glomerular capillary–podocyte interface. This impairs its filtration properties, which can culminate in renal failure (Reidy et al., 2014). Myocardial infarction, stroke, and limb ischemia are the principal causes of morbidity and death in people with diabetes (Booth et al., 2006), and angiogenesis is a crucial part of the adaptive response to these. Diabetes impairs the neovascularization of many ischemic tissues (Cubbon et al., 2012), and this is thought to explain some of the increased morbidity after major cardiovascular events in people with diabetes (e.g., more frequent gangrene after limb ischemia). The diminished angiogenesis in some vascular beds, coexisting with "excessive" angiogenesis in the retina is often described as a paradox. However, while there are clear differences in pathology across vascular beds, it is reasonable to generalize that diabetes causes loss of capillaries, and impairs the capacity to form structurally and functionally normal neovessels.

Age-Related Macular Degeneration (ARMD)

The "wet" form of ARMD is associated with abnormal retinal angiogenesis, and represents one of the major successes of antiangiogenic therapy. Although the pathophysiology remains incompletely understood, wet ARMD is characterized by abnormal neovascularization of the macula by vessels originating from the choroidal layers, as a result of increased local VEGF expression. These new vessels are prone to leakage and hemorrhage, which cause further retinal injury, eventually culminating in central visual field loss (Holz et al., 2014). Various anti-VEGF therapeutics (antibody- or trap-based, as discussed later) have proven able to stabilize or regress visual loss in phase-3 clinical trials, resulting in their widespread therapeutic use (Holz et al., 2014). Nevertheless, these therapies are limited by the need for repeated local injection, and can only address one facet of this multifactorial disease process.

Therapeutic Manipulation and Its Pitfalls

Growth Factor Administration and Gene Therapies to Promote Angiogenesis

Preclinical studies in the 1990s led to great excitement about the potential of recombinant growth factors, or gene therapy to promote angiogenesis in ischemic diseases. The first description of plasmid-based VEGF-A gene therapy in a patient with critical limb ischemia was published 20 years ago by Jeffrey Isner's group (Isner et al., 1996), and was soon followed by promising phase I trial data in patients with critical limb ischemia and myocardial ischemia (Baumgartner et al., 1998; Losordo et al., 1998). However, even these studies began to hint at potential challenges, with some recipients developing transient local edema (Baumgartner et al., 1998), perhaps predictably given that VEGF is known to enhance vascular permeability (Senger et al., 1983). More importantly, subsequent blinded randomized controlled trials have failed to demonstrate meaningful improvements in

relevant outcomes, such as limb salvage (Rajagopalan et al., 2003). Possible reasons for these disappointing data include: the inability of individual growth factors to promote effective angiogenesis; inappropriate magnitude, duration, and distribution of growth factor expression; growth factor resistance associated with disease states; ineffective stimulation of large vessel growth; and the inability of animal models to mimic human disease. Ongoing clinical trials of gene therapy and recombinant growth factors will address some of these issues (Cooke and Losordo, 2015).

Cell Therapies to Promote Angiogenesis

More recently, "cell therapy" has emerged as a potential approach to harness angiogenesis, with transplanted cells either directly forming neovessels or indirectly promoting endogenous vessel growth via paracrine mechanisms. Although early trials of bone marrow mononuclear cells (BMMCs) in the context of ischemic heart disease had aimed to regenerate myocardium, improvements in myocardial perfusion were often more notable than changes in ventricular function (Perin et al., 2004). While it now appears unlikely that BMMCs meaningfully improve ventricular function (Fisher et al., 2015), meta-analysis of early (phase I/II) clinical trials in the context of refractory angina supports their capacity to improve myocardial perfusion (Khan et al., 2016). However, while preclinical models suggest that BMMCs can augment angiogenesis (Kamihata et al., 2001), this may not be the mechanism of increased perfusion in humans (Stempien-Otero et al., 2015). Although many other lineages are being evaluated in clinical trials, perhaps the most relevant to angiogenesis are c-Kit$^+$ cells. In the SCIPIO phase I trial, ex vivo expanded autologous myocardial c-Kit$^+$ cells were infused into the coronary arteries of patients with ischemic cardiomyopathy (Bolli et al., 2011). A substantial improvement in ventricular function was noted using magnetic resonance imaging, in association with alterations in scar properties, which could be due to myocardial regeneration and/or increased local perfusion. Recent preclinical studies have shed important light on this, by showing that tissue-resident c-Kit$^+$ cells frequently act as local vascular endothelial progenitor cells (Liu et al., 2015; Sultana et al., 2015), and can promote substantial angiogenesis after transplantation (Fang et al., 2012). Many other cell lineages also offer potential to promote angiogenesis (e.g., induced pluripotent stem cells), but available evidence remains limited to preclinical studies (Zhang and Xu, 2014).

Antiangiogenic Therapies

As introduced earlier, therapeutic inhibition of angiogenesis is well established in the routine management of some ocular diseases and cancers. Currently available therapies use a number of approaches, including monoclonal antibodies, fusion proteins, and small molecule inhibitors, to interfere with proangiogenic ligands, their receptors, or downstream intracellular signaling cascades. VEGF-A is the principal target of the most established therapies (e.g., Bevacizumab, or Avastin—a humanized monoclonal antibody targeting VEGF-A, used in a limited number of advanced cancers; Ranibizumab or Lucentis—an antibody fragment targeting VEGF-A, used in wet ARMD; Sunitinib or Sutent—a small molecule multiple-target tyrosine kinase inhibitor, used in some advanced cancers). Although it is beyond the scope of this article to discuss these agents in depth (for excellent review see Ye, 2016), it is important to acknowledge their limitations, and significant side effects. The hope that antiangiogenic therapy would offer a step-change in cancer therapy has been tempered by experience with Bevacizumab, which is only licensed for use in a limited set of advanced cancers, and achieves modest increases in overall or progression-free survival. For example, when added to standard chemotherapy regimens, Bevacizumab has been shown to prolong overall survival of women with advanced cervical cancer by 3.7 months (Tewari et al., 2014). Moreover, its detrimental impact on the wider vasculature can cause treatment-limiting hypertension, renal dysfunction, and vascular thrombotic events, emphasizing the important role of VEGF-A in normal physiology. Such issues are common to many cancer therapies, and do not detract from the therapeutic paradigm of manipulating tumor vasculature, but clearly emphasize the need to better understand tumor angiogenesis before developing new therapies. A number of excellent review articles discuss factors that may allow more effective translation of antiangiogenic therapies (Ye, 2016; Potente et al., 2011), and some of these are highlighted in the following section.

Recent Advances

Our understanding of the fundamental processes regulating angiogenesis has advanced substantially over that past decade, and these insights are likely to be important in the development of more effective and less toxic therapies to modulate angiogenesis. It is impossible to discuss fully the breadth and depth of these advances, so we instead summarize some key developments.

Vascular Endothelial Metabolism

Metabolism broadly describes the chemical reactions upon which all life depends, such as generating energy from degrading substrates, or synthesizing proteins and nucleic acids. While the chemical reactions mediating these processes are well understood, their role in regulating cell biology is only beginning to emerge. Recent studies have shown that the vascular endothelium is unusual in the way it utilizes the classical energy substrates, glucose and fatty acids, and these observations are particularly important to angiogenesis.

Firstly, EC use glycolysis as their predominant energy source, in spite of abundantly available oxygen in the vascular lumen; this is a very inefficient way of producing energy (i.e., ATP) from glucose, when compared with oxidation of glucose. When EC glycolysis is partially inhibited, no impact is noted on cell survival, but the motility of cells is substantially reduced, and this is associated with impaired angiogenesis (De Bock et al., 2013). Importantly, this glycolysis appears to occur predominantly in the actively remodeling lamellipodia (or foot processes) required for cell migration, where mitochondria are not in proximity to supply ATP. Furthermore, it was shown that reducing glycolysis could override genetic cues (i.e., reduced Notch signaling) that promote EC tip cell formation, suggesting that metabolism is downstream of growth factor-induced angiogenic sprouting. Indeed, preclinical tumor studies have gone on to show that mice with reduced EC glycolysis have slower tumor growth (Xu et al., 2014), and pharmacological inhibition of glycolysis can reduce other forms of pathological angiogenesis (Schoors et al., 2014).

More recently, it has also been shown that EC rely on metabolism of fatty acids in an unexpected way, with important implications during angiogenesis (Schoors et al., 2015). It is generally assumed that fatty acid oxidation (FAO) is used by cells to produce energy required for homeostatic and anabolic processes. However, in EC it was shown that long-chain fatty acids, such as palmitate, are partially oxidized to provide a carbon source for nucleotide synthesis. Inhibition of FAO does not result in an EC energy deficit, but instead causes a profound reduction in proliferation, and therefore impairs angiogenesis. This use of fatty acids is relatively specific for ECs, and may represent an alternative target for antiangiogenic therapies.

Broader regulation of metabolism has also emerged as an important mechanism by which EC quiescence is maintained, thereby suppressing angiogenesis. The transcription factor FOXO1, which is repressed by many proangiogenic growth factors, appears to impair EC glycolysis and mitochondrial oxidation (Wilhelm et al., 2016). Activation of FOXO1 in ECs impairs their proliferation and reduces angiogenesis in vivo, with inhibition of FOXO1 resulting in the opposite effect. These data suggest the growth factors that modulate EC responses during sprouting angiogenesis do so, at least in part, by modulating metabolism, again highlighting the potential of EC metabolism as a therapeutic target.

Vascular Normalization

In spite of pronounced vascularization, tumors are often poorly perfused, suggesting that their vasculature is structurally and/or functionally abnormal. This can result in local ischemia, acidosis, and increased interstitial pressure, which may drive the formation of aggressive tumor clones; moreover, this is likely to impair delivery of chemotherapy. Electron microscopy of tumor vessels has revealed pronounced irregularity of the luminal surface, with a loss of cell–cell contacts and frequent luminal filopodial protrusions, in stark contrast with the typical organized phalanx pattern of EC in normal vessels (Mazzone et al., 2009) (**Fig. 5**). By reducing the expression of the oxygen sensor PHD2 in EC, effectively promoting hypoxia sensing, it was possible to restore (or "normalize") the typical vessel architecture, although this had no impact on the number of tumor vessels. Crucially, this was associated with marked increases in tumor perfusion, but with corresponding decreases in tumor metastasis. This observation poses a major challenge to prior assumptions about what therapeutic modulation of tumor vasculature should achieve—in other words, perhaps normalization of vessels, rather than destruction of vessels may be a more effective strategy. More recent work has shown that tumor vessel normalization can be achieved in preclinical models by administration of chloroquine (Maes et al., 2014), suggesting that this established malaria and rheumatoid arthritis therapy could be repurposed in cancer clinical trials.

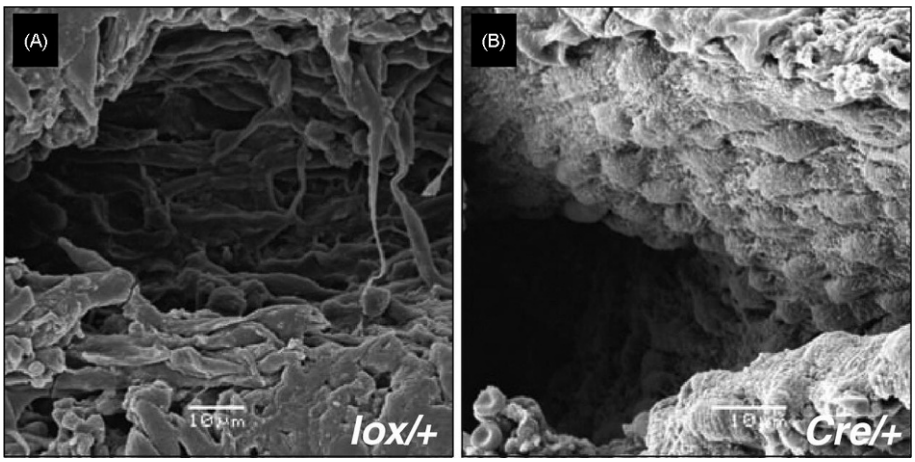

Fig. 5 Endothelial normalization. Scanning electron micrographs of tumor microvessel in control (A) and PHD2$^{\pm}$ (B) mice, illustrating the abnormal irregular endothelial morphology of tumor vessels, which is normalized to an organized phalanx endothelial morphology by PHD2 haploinsufficiency. Adapted from Mazzone, M., et al. (2009). Heterozygous deficiency of PHD2 restores tumor oxygenation and inhibits metastasis via endothelial normalization. *Cell* **136** (5), 839–851, with permission from Elsevier.

Endothelial Shear Sensing in Angiogenesis

The vasculature is continually exposed to the mechanical force of blood flow, which exerts shear stress upon EC. It is well recognized that these mechanical forces influence vascular remodeling and angiogenesis, but the nature of this relationship and its underlying mechanisms are continuing to emerge. Recently, it has been shown that sprouting angiogenesis can be induced and sustained when a threshold of local shear stress is exceeded, and that this may offer a homeostatic mechanism regulating shear forces across a vascular network (Galie et al., 2014). Interestingly, it has also been shown that perception of shear stress regulates EC metabolism by reducing glycolysis and mitochondrial content, which presumably results in cellular quiescence in mature perfused vessels (Doddaballapur et al., 2015). Another important finding from recent research is the role of an ion channel called Piezo1 in EC shear sensing, or mechanotransduction (Li et al., 2014). Piezo1 was previously known as a sensor of noxious mechanical stimuli, but when knocked down in EC, prevents the usual shear stress-induced calcium influx and cellular alignment with blood flow. Moreover, a lethal failure of vascular development occurred in mice with EC deletion of Piezo1, which was associated with marked failure of vascular patterning into arteries, veins, and capillaries. These observations serve to highlight the importance of the physical and biochemical environment encountered during angiogenesis, and may help design additional therapeutic approaches.

Antiangiogenic Splicing of VEGF-A in Disease

Alternative splicing of VEGF-A, resulting in paradoxically antiangiogenic "VEGF-Axxxb" isoforms (Woolard et al., 2009), was described over a decade ago (Woolard et al., 2004). More recent studies have now shown this to be a common and potentially modifiable phenomenon in diseases associated with increased and impaired angiogenesis. For example, it is now apparent that the antiangiogenic VEGF-A165b isoform is increased in the ischemic muscle of patients with peripheral vascular disease (Kikuchi et al., 2014). Preclinical studies suggest inflammation, typical in many patients with peripheral vascular disease, could induce changes in the splicing of VEGF-A, resulting in more antiangiogenic isoforms. Importantly, recombinant antibodies against VEGF-A165b could rescue impaired angiogenesis in these preclinical models, whereas recombinant VEGFA-165b impaired angiogenesis. Increased production of VEGF-A165b has also been implicated in the impaired vascularization of adipose tissue in people with obesity (Ngo et al., 2014), a phenomenon that is thought to promote adipose inflammation, insulin resistance, and diabetes. Conversely, reduced splicing of antiangiogenic VEGF-A isoforms has been noted in human cancer (Woolard et al., 2004). Importantly, it now appears that the splicing factors responsible for determining whether pro- or antiangiogenic VEGF-A isoforms are produced are the serine/threonine protein kinases 1/2 (SPRK1/2), and these could be a therapeutic target in the modulation of pathological angiogenesis (Nowak et al., 2010).

Summary

Remodeling of the vasculature is integral to normal development and physiology, and so has evolved many complex regulatory mechanisms, which when perturbed can contribute to diverse disease processes. It is clear that while our knowledge of angiogenesis has advanced substantially over recent decades, there remains much to be discovered if we are to develop safe and highly effective therapeutic strategies that can improve health by modulating angiogenesis. In particular, it appears likely that these will need to reconsider historic dogma regarding how angiogenesis causes disease, and what a therapeutic strategy should aim to achieve. For example, it may be that restoration of normal tissue-specific vessel quality is more important than manipulating vessel abundance. Given the unique access of the vascular system to most tissues, more effective therapeutic manipulation offers major opportunities to manage disease and improve health.

Introduction

Coronary heart disease (CHD) is a complex human pathologic condition that is predominated by atherosclerosis (AS). The development of AS in the vasculature involves increased lipid accumulation in the artery walls as well as chronic inflammation propagated by a variety of cell types. The potentially fatal or debilitating effects of atherosclerosis are due to the rupture of unstable plaques and the subsequent thrombosis of epicardial vessels. This acute thrombosis leads to myocardial ischemia and subsequent myocardial infarction if not treated promptly with reperfusion therapies. Myocardial infarction remains one of the leading causes of heart failure. Each year, over 1 million people in the United States suffer a myocardial infarction (MI) (Mozaffarian et al., 2016). While the majority of patients survive their initial MI, despite optimal medical therapy, more than 300,000 patients each year develop debilitating chronic heart failure due to adverse cardiac remodeling leading to an increased need for hospital-based care.

Although modern medicine has made significant advancements in the ability to lower lipids, inhibit thrombosis, promptly reperfuse the heart, and modify adverse postmyocardial infarction remodeling, CVD remains the leading cause of morbidity and mortality in the developed world. Therefore, understanding mechanisms of atherosclerosis, thrombosis, and myocardial infarction are imperative for the development of new effective therapies. To this end, the use of animal models has proved invaluable to elucidating our understanding of atherosclerosis, thrombosis, myocardial injury, and heart failure. Indeed the premise of the NIH Consortium for preclinicAl assESsment of cARdioprotective therapies (CAESAR) was to address translation from animal models to humans (Lefer and Bolli, 2011a; Jones et al., 2015). However, the reality is that no one animal model recapitulates the complexities of human ischemic heart disease. The goal is to attempt to recapitulate portions of a disease

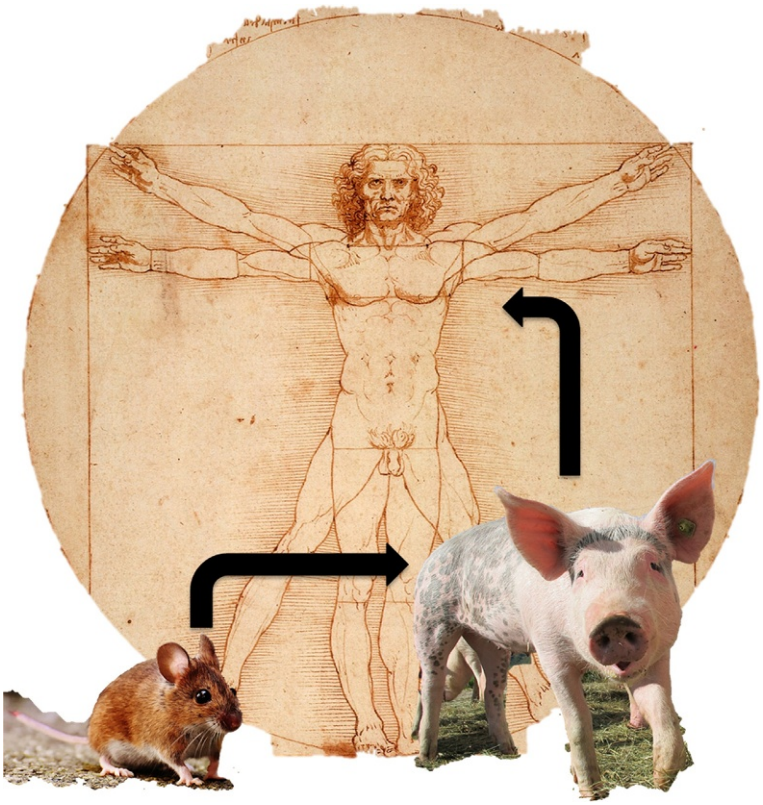

Fig. 1 Modern progression of animal models in the research and discovery for ischemic heart disease. No animal model completely recapitulates the complexity of human cardiovascular disease. Small animal models provide proof-of-concept studies that can be validated in large animal studies to provide the necessary data to proceed to human studies. spectrum that will translate from small to large animal studies and then to the treatment of human disease (Fig. 1). The current chapter will review the various animal models that are available to study: (A) atherosclerosis, (B) thrombosis, and (C) myocardial ischemia-reperfusion injury and infarction-induced heart failure.

Atherosclerosis

Background

Initiation of atherosclerosis

Atherosclerosis is one of the most common forms of cardiovascular disease. It typically occurs when lipid accumulates in the subendothelial space of the artery wall. This lipid, most commonly low-density lipoprotein (LDL), can then be modified by oxidation (oxLDL) or other inflammatory stimuli into a form that triggers the migration and extravasation of monocytes to the site of "injury" (reviewed in Glass and Witztum, 2001). These infiltrating monocytes differentiate into macrophages and begin the arduous process of trying to remove the accumulated cholesterol and lipid. If the lipid burden becomes such that macrophages cannot efficiently remove it, the lipid accumulates in the cell, and the macrophages take on a foam-like appearance when observed by microscopy and are therefore called "foam cells." Through their production of chemokines such as MCP-1, they recruit more monocyte/macrophages to the atherosclerotic plaque, and the vicious cycle continues. As the lesion progresses, a necrotic core forms that is filled with foam cells, oxidized lipid, and dead and dying cells. This necrotic core can be contained by a fibrous cap, maintained mainly by collagen production by smooth muscle cells (SMCs). These SMCs can likewise develop into foam cells as they accumulate cholesterol. In addition to SMCs and macrophages, $CD11c^{+}$ dendritic cells (DCs) and T cells are major components of the plaque. Macrophages and DCs present antigen to T cells which can modulate local inflammatory responses, producing interferon-gamma which can inhibit smooth muscle cell production of collagen and therefore compromise plaque stability.

Plaque rupture and thrombosis

It is now commonly accepted that the atherosclerotic plaque size is not necessarily as critical as the stability of the plaque (Finn et al., 2010; Niccoli et al., 2014). Specifically, a plaque that is large but stable might be more desirable than a smaller unstable lesion.

This is mainly due to the predisposition of unstable plaques to rupture and induce a thrombus, the main culprit in myocardial infarction and stroke. Plaque rupture is more likely to occur at the shoulder of the lesion due in part to this being the site of neovascularization and increased expression of adhesion molecules that promote invasion of macrophages, T cells, and mast cells (O'Brien et al., 1996; van der Wal et al., 1998). T cells have been shown in both human and animal-derived plaques to correlate with plaque rupture (Weyand et al., 2008; Watanabe et al., 2007). One possible role of T cells in this process is that their production of interferon-gamma (IFN-γ), an inflammatory cytokine can inhibit SMC production of collagen (Wang et al., 2007; Hansson et al., 1988). The inhibition of SMC function coupled to macrophage production of matrix-degrading enzymes (matrix metalloproteinases or MMPs) and continued apoptosis and necrosis of macrophages and SMCs create the perfect environment for the erosion of the protective fibrous cap and eventual rupture and thrombus formation. The mechanisms of this process are detailed in later sections in this chapter. Here we will discuss the animal models that have been developed to study atherogenesis and plaque rupture with a particular focus on mouse models.

Animal Models of Atherosclerosis

As with any model of human disease, there are many practical and biological considerations when deciding on an appropriate animal model of atherosclerosis for your research questions (Daugherty et al., 2017). Practical considerations may include size, the ability of your institution to house and maintain the animal, the cost of the animal, and cost to house the animal. Also, it is important to consider your endpoint of interest. For example, if you require an animal model that has a lipid profile and an atherosclerotic lesion very similar to humans or if you are conducting preclinical trials for new therapies, then a nonhuman primate model might be most appropriate. However, this would not be the best choice if you have a limited research budget, your institution does not have a primate facility, or you are interested in understanding the mechanisms of atherosclerosis that might require multiple studies and the use of genetically altered animals. In this case, the mouse model would be superior to the nonhuman primate model. Swine are known to have a cardiovascular system of similar size and physiology as humans and therefore, if this is an important parameter for your research, using a porcine model of cardiovascular disease might be most appropriate (Rodrigues et al., 2005). In general, although there are always exceptions, the larger the animals, the more closely it models the human disease whereas smaller animals may have several caveats to consider, they are much easier to house, genetically manipulate and the availability of test reagents is greater, especially for mouse models (**Fig. 2**). In this chapter, we will discuss the pros and cons of common animal models of atherosclerosis. Our primary focus will be on mouse models as these are the most extensively used in the field.

Mouse models of atherosclerosis

For several decades, the mouse has been the primary small animal model for human atherosclerosis. Due to their small size, mice are much easier to handle compared to some of the larger models of atherosclerosis, including rats and rabbits. Also, mice are more affordable to house, with multiple mice usually housed per cage. These practical advantages of mouse models apply to any experimental study of human disease. Unfortunately, wild-type mice are inherently resistant to atherosclerosis (Morrisett et al., 1982). Even when placed on high-fat diets that contain cholic acid (termed the Paigen diet, 15% fat, 1.25% cholesterol, 0.5% cholic acid), the majority of mouse strains develop fatty streak lesions at best (Paigen et al., 1987). Also, mice notoriously do not suffer from spontaneous plaque rupture. This may be due, in part, to the fact that mice carry most of their cholesterol in the HDL fraction with very low levels of LDL, VLDL, or triglycerides in circulation. Also, mice lack CETP (Tanigawa et al., 2007), and their physiology (i.e., blood pressure, heart rate, size, metabolism, etc) is quite different from man. Unlike pigs and nonhuman primates, mice are less similar to humans as it relates to their lipoprotein profiles and susceptibility to cardiovascular disease.

Perhaps the greatest advantage that mice have over larger animals is their ability to be genetically manipulated. Because of this, there have emerged two central genetic models of human atherosclerosis in mice: the apolipoprotein E-deficient mouse (apoE$^{-/-}$) (Zhang et al., 1992) and the LDL receptor-deficient mouse (LDLr$^{-/-}$) (Ishibashi et al., 1993). Both of these genetically modified mouse strains have been experimentally and genetically manipulated in every way imaginable attempt to model the human

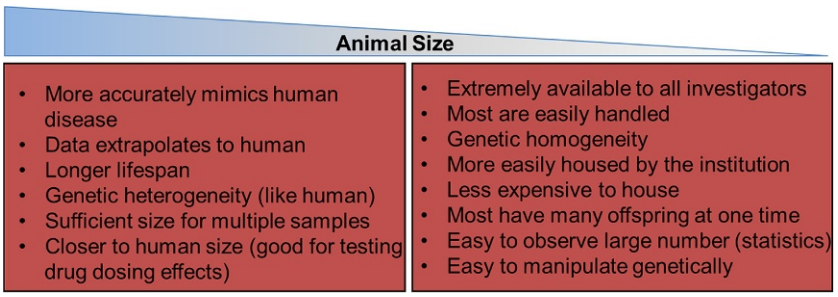

Fig. 2 Advantages of animal models of atherosclerosis based on size. In general, as you move from larger to smaller animal models you lose the close relationship between your model and human physiology, size, and genetic heterogeneity. With smaller animal models, you gain the ability to test several subjects (increase statistical power), minimize financial burden, and gain the ability to easily manipulate genes and protein expression using state-of-the-art genetic tools.

condition more accurately. The contribution of these two mouse strains to our current understanding of human CVD is immense. The remainder of this section will discuss the general features of these mouse models including both advantages and disadvantages of each.

The apoE$^{-/-}$ mouse model of atherosclerosis

Apo E is a protein associated with VLDL, LDL, and some species of HDL (Krieger and Herz, 1994; Mahley and Ji, 1999; Mahley, 1988). Its primary function is to promote uptake LDL as it promotes binding of this lipoprotein to the LDLr. In humans, there are three major isoforms of apoE, apoE2, apoE3, and apoE4 (reviewed in Mahley, 1988). ApoE3 is the most common isoform of apoE and binds the LDLr with high affinity (Mahley, 1988). ApoE3 is associated with protection from cardiovascular outcomes. ApoE4, on the other hand, is less commonly expressed in humans but is more closely associated with adverse cardiovascular outcomes, autoimmunity, and susceptibility to Alzheimer's Disease (Zhao et al., 2017; Mahley, 2016; Huang, 2010). ApoE2 is the least commonly expressed isoform of apoE and is associated with decreased lipoprotein clearance and a human genetic disease termed type III hyperlipoproteinemia (Phillips, 2014).

ApoE$^{-/-}$ mice were first reported in the atherosclerosis literature in 1992 when Nobuyo Maeda, at the University of North Carolina, Chapel Hill, and Jan Breslow, at the Rockefeller University, New York, first described their cardiovascular phenotype (Piedrahita et al., 1992; Plump et al., 1992). The apoE gene was inactivated in mouse embryonic stem cell genome by homologous recombination, and the resulting homozygous animal was devoid of all circulating apoE (Piedrahita et al., 1992). These studies demonstrated that absence of apoE in mice induces spontaneous hypercholesterolemia with an accumulation of cholesterol in mainly the chylomicron and VLDL fractions (**Fig. 3**) (Zhang et al., 1992; Plump et al., 1992). Also, atherosclerosis was evident in the aortic sinus of 8-week old apoE$^{-/-}$ mice without the need for feeding diets rich in fat, cholesterol, or cholate (Zhang et al., 1992). When compared to wild-type mice, apoE$^{-/-}$ animals typically have total cholesterol levels approximately four times higher with HDL levels about half of their normal counterparts (Zhang et al., 1992). Triglycerides were relatively normal, making the apoE$^{-/-}$ mice fairly similar to humans who possess reduced levels of apoE. Also, it was determined that the VLDL particle in apoE$^{-/-}$ mouse circulation was perhaps different than the human counterpart, containing a higher apoB48:apoB100 ratio and more closely resembling a chylomicron fragment than an LDL particle.

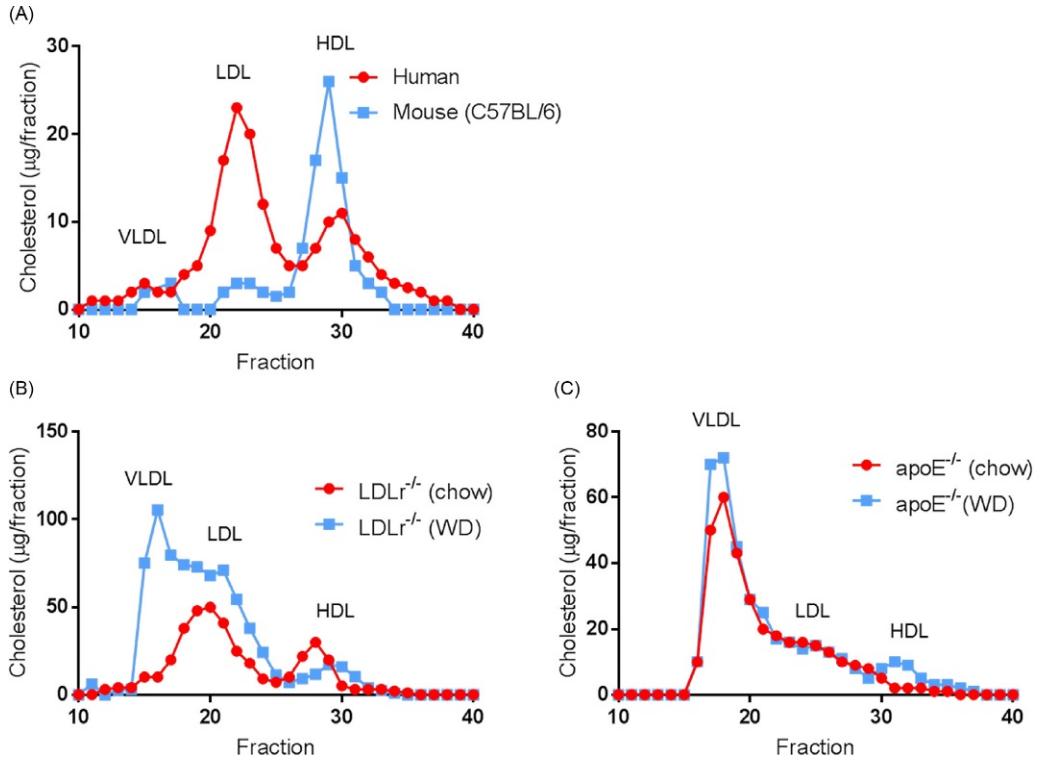

Fig. 3 Representative FPLC plots of human and mouse plasma lipoproteins. (A) Size separation of lipoproteins in plasma of humans (red circles) versus normal C57BL/6 mice (blue squares). (B) Comparison between LDLr$^{-/-}$ mice on chow (red circles) versus Western diet (blue squares). (C) Comparison between apoE$^{-/-}$ mice on chow (red circles) versus Western diet (blue squares). All data are hypothetical but represent what one might observe in a typical FPLC plot of lipoprotein profiles.

Another advantage of the apoE$^{-/-}$ mouse is that, when fed a normal chow diet, their atherosclerotic lesions are similar in complexity to human lesions (Ghiselli et al., 1981; Smith and Breslow, 1997; Nakashima et al., 1994). Lesion composition can be altered by feeding a high-fat diet containing cholesterol (Nakashima et al., 1994; Reddick et al., 1994). In this case, lesions are enriched for foam cells, likely due to the greater than 1000 mg/dl serum cholesterol levels that can be obtained when apoE$^{-/-}$ mice are fed diet. Classic studies by Russell Ross describe lesion progression in apoE$^{-/-}$ with both high fat and normal chow feeding (Nakashima et al., 1994). In this study, Nakashima et al. examined ApoE$^{-/-}$ mice either a chow diet or a Western-type diet and examined mice at ages ranging from 6 to 40 weeks. Lesions in animals fed either chow or Western diet developed lesions in the aortic root and the branch points of the aorta. Lesion progression progresses from the root to the lesser curvature of the aortic arch, the branches of the brachiocephalic artery and right common carotid artery and branch points at the mesentery and renal arteries and iliac bifurcation (Nakashima et al., 1994). If left long enough, apoE$^{-/-}$ mice on both diets eventually develop lesions along the thoracic and abdominal aorta with Western diet-fed mice developing lesions in this area much earlier than normal chow-fed mice. The classic description of lesion histology included adherence of mononuclear cells and formation of early foam cells and fatty streaks and the eventual appearance of fatty streaks that contained both macrophages and smooth muscle cells. Nakashima et al. described severe atherosclerosis in the coronary arteries that eventually led to a significant narrowing of the artery lumen (Nakashima et al., 1994). This occurred without any signs of myocardial infarct. It is now well established that mice are not great models of human myocardial infarct despite significant coronary artery involvement. Models of myocardial infarct are covered in another section of this chapter.

The LDLr$^{-/-}$ mouse model of atherosclerosis

Homozygous deletion of LDL receptor in humans leads to the genetic disorder termed familial hypercholesterolemia or FH (Hobbs et al., 1990). The LDLr is responsible for efficient removal of LDL particles from tissues and circulation. Uptake is facilitated by the apolipoprotein B-100 component of LDL binding with high affinity to the LDLr. It was previously known that defects in the LDLr led to hypercholesterolemia in Watanabe-heritable hyperlipidemic (WHHL) rabbits (reviewed below and in Shiomi et al., 2013). One year after the first description of apoE$^{-/-}$ mice, Joachim Herz's group generated and published a new model of atherosclerosis: the LDLr-deficient mouse (Ishibashi et al., 1993). Mice homozygous for the LDLr deletion require Western diet feeding to obtain extremely elevated levels of circulating cholesterol (Ishibashi et al., 1993). This is likely due to VLDL in mice containing apoE-48 and not apoB-100, the primary proteins associated with VDL and LDL, leading to clearance of these lipoproteins in the liver independent of LDLr. LDLr$^{-/-}$ mice develop early lesions, which similar to the apoE$^{-/-}$ model and in humans are mainly composed of lipids and macrophages with the presence of some T cells; typically lesions contain very few B cells (Roselaar et al., 1996; Zhou and Hansson, 1999). LDLr$^{-/-}$ mice develop fatty streaks when left on a chow diet and more complicated lesions when fed a Western diet (Herijgers et al., 1997; Merat et al., 2000). Necrotic cores with caps composed mainly of macrophage foam cells are evident in these advanced lesions. However, unlike advanced lesions in humans and plaques observed in apoE$^{-/-}$ mice fed a Western diet, lesions in LDLr$^{-/-}$ mice do not form what might be considered a legitimate fibrous cap (Nakashima et al., 1994; Ishibashi et al., 1994).

Although one could argue that apoE$^{-/-}$ mice develop lesions more similar in cellular content to human lesions, LDLr$^{-/-}$ animals have one major advantage over apoE$^{-/-}$, the ability to receive bone marrow from any LDLr-competent animal without compromising atherogenesis. Specifically, it was demonstrated by Fazio et al. that if you rescue lethally irradiated apoE$^{-/-}$ mice with bone marrow from apoE-competent animals, in this case, the apoE produced by the macrophages is sufficient to restore normal serum lipids and protect the animal from atherosclerosis (Fazio et al., 2002). This same group demonstrated that this was not the case for LDLr$^{-/-}$ mice in which restoration of LDLr expression in the hematopoietic compartment via bone marrow transplant had no effect on serum lipids, atherosclerosis progression, or lesion composition (Fazio et al., 1997). Therefore, the LDLr$^{-/-}$ mouse does not require backcrossing to whatever genetic model one wishes to study and may accelerate studies; especially in cases of immunity and atherosclerosis where the entire immune system can be manipulated to study its role in atherosclerosis.

It should be mentioned that neither the apoE$^{-/-}$ nor the LDLr$^{-/-}$ mouse are appropriate models of plaque rupture and resulting myocardial infarction. Regardless of the complexity or size of the plaque, these animals simply do not suffer actual cardiovascular events that would recapitulate the human condition. This gap in the field was alleviated somewhat by the development of the SR-BI, apoE double knockout mouse (Braun et al., 2002, 2003; Trigatti et al., 2000). SR-BI (Scavenger receptor-BI) serves as the receptor for HDL and is critical for normal reverse cholesterol transport and removal of excess cholesterol from tissues and cells and cholesterol handling in the liver (Trigatti et al., 2000). By knocking this receptor out on the apoE$^{-/-}$ mouse, the ability to handle cholesterol in any capacity is essentially lost. SR-BI, apoE double knockout mice develop severe coronary atherosclerosis leading to spontaneous infarction and very early death (Braun et al., 2002, 2003; Trigatti et al., 1999). Therefore, as with any animal model, choosing the right animal to test your hypothesis and understanding the endpoints and readouts are key to making sure you are using the right system to answer your specific question.

Large Animal Models of Atherosclerosis

There are numerous animal models of atherosclerosis (Lee et al., 2017). The choice of model depends on the ultimate goal of your study. Large animal models afford several advantages over smaller models such as mice. For example, studying pharmacokinetics

might be more appropriate in a larger animal where the dose and kinetics would be similar to humans. The metabolic rate of a rodent is much faster than man and therefore is often not translatable (Gordon, 2017). This section will discuss the common large animal models of atherosclerosis and their utility in scientific discovery.

Watanabe heritable hyperlipidemic rabbits

Watanabe Heritable Hyperlipidemic (WHHL) rabbits, described by Yoshio Watanabe (Watanabe, 1980), are a strain of rabbits that suffers from hyperlipidemia and spontaneously develop aortic atherosclerosis in 100% of animals by 5 months and older. At even older ages (older than 15 months), Watanabe described the presence of xanthoma of digital joints in the majority (63%) of rabbits (Watanabe, 1980). The animals have an accumulation of LDL cholesterol that leads to foam cell formation and atherosclerosis. It was later discovered that the defect in these animals is a decrease in LDLr due to genetic deletion (Tanzawa et al., 1980). Homozygous WHHL rabbits may be a better model for the genetically equivalent human disease, Familial Hypercholesterolemia (FH), and its associated atherosclerosis, as macrophage foam cells and human-like cellular composition are present very shortly after fat feeding (Rosenfeld and Ross, 1990; Tsukada et al., 1986; Rosenfeld et al., 1986). Heterozygous WHHL rabbits fed cholesterol-containing high-fat diets develop atherosclerotic lesions similar to that seen in humans (Atkinson et al., 1989). Cholesterol-fed, heterozygous WHHL rabbits gain lipoprotein profiles with cholesterol in the VLDL and LDL size range (Atkinson et al., 1989). This leads to the appearance of atherosclerotic plaques in the thoracic and abdominal aortas by 12 weeks of diet feeding. By 24 weeks of diet feeding, the WHHL rabbits had developed complicated plaques characterized by foam cells, cholesterol clefts, calcification, and necrotic cores covered by a fibrous cap (Atkinson et al., 1989). The WHHL rabbit continues to be a popular animal model of atherosclerosis and can be consistently seen used in current research.

Porcine model

Pigs are considered an appropriate model for numerous reasons. The anatomy and the physiology of the porcine circulatory system, for the most part, closely resemble the human. This may make it more appropriate to translate findings from the pig about wound healing, lipoprotein metabolism, and development of atherosclerosis in human disease. For example, a recent study by Fenning et al (Fenning et al., 2015). demonstrated that pigs develop lesions in the coronary arteries as well as in the abdominal aorta in a site-specific manner similar to human. These studies demonstrate that similar to human cardiovascular disease, lesions in various vascular beds of the pig are not identical and therefore might benefit from different treatment. One example of this is associated phospholipase A_2 (Lp-PLA_2), an enzyme important in atherogenesis as it mediates the formation of oxidized lipoproteins in the artery wall (Fenning et al., 2015; Wilensky et al., 2008). In clinical studies, Lp-PLA_2 levels and activity have been shown to be increased in individuals with cardiovascular disease (Ge et al., 2016; Yang et al., 2017) and in association with other diseases where atherosclerosis is a comorbidity such as hypertension (Kim et al., 2017), psoriasis (Vachatova et al., 2016), and chronic kidney disease (Wang et al., 2016). As these differences in disease in different vascular beds are more difficult to study in smaller animals, one can surmise why studying atherosclerosis in the pig can be a valuable preclinical tool.

In addition to the spontaneous development of fatty steaks, the pig model is also useful for studying diet-induced atherosclerosis in the context of hypercholesterolemia. When fed a high-cholesterol diet for short periods of time, pigs develop fatty streak lesions predominately in the abdominal aorta (Fenning et al., 2015). Not surprising, long-term feeding of pigs with high cholesterol diets resulted in increased atherosclerosis in coronary vessels. In both cases, lesion composition and morphology closely resembles that seen in humans. While the pig is an excellent large animal model to study atherosclerosis, obvious drawbacks include the cost of maintaining and housing the animals, their size, and the difficulties of handling.

Non-human primate models

In 1954, Taylor et al. described the formation of spontaneous atherosclerosis and hyperlipidemia in rhesus monkeys (TAYLOR et al., 1962). This was associated with increased ingestion of dietary fat. Although many studies have demonstrated varied degrees of severity of atherosclerosis in different species of monkeys, the nonhuman primate model has the advantage of having a human-like lipoprotein profile. This is characterized by levels of LDL and HDL comparable to humans, an attribute associated with expression of CETP (an important protein absent in the more commonly used mouse models) (Strong and McGill, 1967; Clarkson et al., 1976; Rudel et al., 1985). Near human lipoprotein profiles have made the nonhuman primate and attractive model to study potential new therapies. However, the expense of working with nonhuman primates becomes one large disadvantage to this model.

Nonhuman primates have been critical in testing new potential therapies. Two of the most recent examples include the microRNA-33 inhibitor and monoclonal antibodies to proprotein convertase subtilisin/kexin type 9 (PCSK9) (Rayner et al., 2011; Chan et al., 2009; Liang et al., 2012). Studies using African green monkeys demonstrated the utility of inhibiting microRNA-33 on improving HDL cholesterol levels and decreasing atherosclerosis burden (Rayner et al., 2011). More recent studies with monoclonal antibodies to PCSK9 in cynomolgus monkeys showed that a single injection reduced serum cholesterol by 80% and this decrease was maintained for at least 10 days (Chan et al., 2009). Similar results were observed by Liang et al. (Liang et al., 2012), where monoclonal antibody-mediated blocking of PSCK9 binding to the LDLr, and thereby inhibiting its degradation, reduced LDL in cynomolgus monkeys with normal or diet-induced hyperlipidemia. When combined with a statin this effect was amplified. While neither of the PCSK9 inhibition studies in nonhuman primates examined atherosclerotic outcomes, they do demonstrate that nonhuman primates are an invaluable first-step model for pharmacokinetic and efficacy testing before moving to phase I clinical trials.

Animal Models of Arterial Thrombosis

Background

In humans, plaque instability can result in rupture of atherosclerotic lesions and subsequent vessel thrombosis (Lusis, 2000; Burke and Virmani, 2007). Without immediate medical attention, coronary artery thrombosis results in myocardial cell death and can lead to diminished cardiac function with hemodynamic instability causing cardiogenic shock and electrical instability causing lethal ventricular arrhythmias (Anderson and Morrow, 2017). Current treatments to restore coronary vessel patency after a thrombotic event involve establishing patency of the vessel via balloon angioplasty and drug-eluting stent placement (Anderson and Morrow, 2017). When done promptly, these corrective procedures reduce the risk of cardiovascular complications and sudden death (Anderson and Morrow, 2017). The use of animal models to study the physiological progression of thrombotic events has proved invaluable in understanding mechanisms of disease and has led to current treatments available in clinical practice.

Acute injury model of thrombosis

As discussed above, the formation of an unstable atherosclerotic lesion in humans precedes plaque rupture and thrombosis (Lusis, 2000; Burke and Virmani, 2007). There are no animal models that effectively recapitulate this pathology; therefore the majority of thrombosis research relies on acute injury to the blood vessel while monitoring thrombus formation via changes in blood flow measured by placing a Doppler flow probe downstream of the site of vessel injury (Li et al., 2016; Bonnard and Hagemeyer, 2015). Also, imaging methods can be employed to visualize and quantify the formation of a thrombus (Falati et al., 2002; Celi et al., 2003). Previously used methods of thrombus initiation include mechanical disruption of the vascular endothelium with wire injury, laser-induced injury, and chemical-induced injury with ferric chloride (Westrick et al., 2007; Cooley, 2012). The most popular animal models used to decipher mechanisms of arterial thrombosis include nonhuman primates (Myers, 2012), pigs (Fuster et al., 1991), dogs (Badylak et al., 1988), rabbits (Abela et al., 1995), rats (Kurz et al., 1990), and mice (Dörffler-Melly et al., 2000), but others used less often include ferrets (Schumacher et al., 1996), sheep (Kim et al., 2010), and zebra fish (Jagadeeswaran, 2005).

Small Animal Models of Thrombosis

Small animal models of thrombosis have the potential for rapid screening and discovery, high availability, low cost, and reproducibility of results, making them ideal for routine use in the laboratory.

Mice

The most widely used small animal model in research and discovery of human arterial thrombosis is the mouse (NIESWANDT et al., 2005). The most common model used in mice is the ferric chloride ($FeCl_3$) model of arterial injury (Kurz et al., 1990) that was initially developed in rats (see below). In brief, the common carotid artery or mesenteric artery is exposed, a flow probe is placed on the artery to monitor blood flow, and $FeCl_3$ is applied to the vessel outer vessel surface at a defined concentration for a specified period, usually 3 min. $FeCl_3$ results in a free radical-induced injury that disrupts the vascular endothelium but with limited collagen exposure in the subendothelial matrix (Eckly et al., 2011). Subsequent work has also suggested that the erythrocyte-mediated platelet adherence to the endothelium is responsible for the initiation of thrombus formation (Barr and Chauhan, 2013). Regardless of the mechanisms, the degree of injury, and therefore the rapidity of thrombosis, can be modulated by the concentration of the ferric chloride and the time of exposure (Wang and Xu, 2005; Li et al., 2013). Furthermore, using transgenic mice treated with $FeCl_3$-induced arterial thrombosis, the role of the platelet fibrinogen receptor, glycoprotein IIb/IIIa (Ni et al., 2000), the platelet ADP receptor, $P2Y_{12}$ (Andre et al., 2003), platelet endothelial adhesion molecule-1 (Falati et al., 2006), inhibitors of factor Xa (Hechler et al., 2011), cyclooxygenase 1/2 (Riehl et al., 2011), and microparticles (Thomas et al., 2009), have been elucidated. Indeed, $FeCl_3$ vascular injury model has demonstrated the antithrombotic roles of clinically approved platelet aggregation inhibitors, including aspirin (WANG et al., 2006), clopidogrel (Wang and Xu, 2005), and ticagrelor (Patil et al., 2010).

In addition to the $FeCl_3$ vascular injury model, laser-guided injury via Rose Bengal (Thacker et al., 2012), and electrolytic-induced vascular injury models of arterial thrombosis (Kusada et al., 2007) have been employed in mice. Both Rose Bengal and electrolytic-induced injury also induce an oxidative stress injury (Cooley, 2012). However, these models can be difficult given the need for lasers for Rose Bengal or the techniques necessary for electrolytic induced injury.

Rats

As mentioned above, the $FeCl_3$ model was initially developed in rats (Kurz et al., 1990), but it has been used ubiquitously. Thrombi resulting from $FeCl_3$ application have been shown to contain activated platelets, fibrin deposition, and erythrocytes (Kurz et al., 1990). In addition to this, the physical crush model (Hill-West et al., 1994), external heating of the carotid artery (Lenfors et al., 1993), and intimal tuck model (Nayak and Deschler, 2005) have been adapted to the rat vasculature. Despite all these methods, the ease and relatively low cost of the $FeCl_3$ model remain the gold standard for investigating thrombosis in rats. An additional factor that strengthens the use of rats in the laboratory is the ability to manipulate expression levels of thrombotic molecules such as tissue factor by retroviral vectors (Hasenstab et al., 2000). Although the number of transgenic rats expressing proteins relevant for cardiovascular disease is low, future development of rats with knockout or overexpression of proteins involved in arterial thrombosis will allow for the application of previously developed techniques such as the $FeCl_3$ model of arterial thrombosis.

Large Animal Models of Thrombosis

In the interest of safeguarding human health, the majority of compounds designed to treat arterial thrombosis must be tested in the largest animal available that most closely resembles human cardiovascular physiology. This is especially important when large conduit blood vessels are the subject of scrutiny. However, cost and availability prevent nonhuman primate models from being used routinely as a method of discovery and research. The following section will review the large animals available to study arterial thrombosis. Similar to small animals, thrombosis research in large animals requires a blood vessel insult that initiates thrombus formation culminating in vessel occlusion.

Canine model

Early studies by Folts et al. pioneered the methodology used in arterial thrombosis which required using a vascular clamp to physically crush the endothelium followed by applying a plastic cylinder around the coronary artery to produce a stenosis (Folts et al., 1976). This method leads to thrombus formation and cyclic flow reduction to near zero with a sudden spontaneous return to near control levels. These landmark studies led to a significant increase in our understanding of thrombus formation (Folts et al., 1982; Folts, 1991). In addition to the Folt's model, electrical vascular injury has also been used to initiate thrombus formation in the coronary arteries of dogs (Romson et al., 1980). Differences in platelet hyperactivity appear to play a more prominent role in the propagation of thrombi in adult mongrel dogs than in humans (Strony et al., 1993). Ethical concerns and availability of dogs have caused them to be a less popular model than the porcine model.

Porcine model

Typically, swine are easier to handle and more affordable than nonhuman primates. The pig's large arteries, while smaller than human and nonhuman primates, are still significantly larger than those of small rodents, therefore providing surgically or percutaneous approaches. Also, the pig's coagulation and fibrinolysis system have a high degree of overlap between pigs and human (Münster et al., 2002). Several models have been used. The initial open-chest porcine model involved physically crushing the aortic vessel leading to a fibrin-rich and platelet-rich thrombi (Lin et al., 2000). Besides physical crush, electrical stimulation of the common carotid artery (Kohda et al., 1999) and balloon injury can be used to generate thrombi in pigs (Morishige et al., 2003). The drawbacks to the porcine model include the higher rate of plasma coagulation (Sondeen et al., 2013) and a lack of fully developed antibody and molecular probes (Münster et al., 2002; Napoli et al., 2006). Therefore, these issues should be kept in mind when proceeding with swine studies.

Non-human primates

The baboon is arguably the ideal model that most resembles human thrombogenic physiology. Initiation of a thrombotic process in baboons may require dual injuries such as forceps crush and thrombin administration (Flameng et al., 1986; Herijgers and Flameng, 1991). This approach has been essential in measuring the effects of monoclonal antibodies and small molecules on the size of thrombi through the arterial wall. Another useful nonhuman primate is the cynomolgus macaque. Studies with these animals have used the Rose Bengal model to target the exposed saphenous artery and activate the intravenously injected chemical Rose Bengal to release reactive oxygen species causing local vascular endothelial injury. This method has been useful in studying the effects of agents that inhibit thrombotic molecules such as plasminogen activator inhibitor-1 (PAI-1) (Izuhara et al., 2010). While the nonhuman primate models have been essential in the preclinical use of antithrombotic compounds, their large size, high cost, the required surgical expertise, and equipment make nonhuman primates an unsuitable model for routine laboratory use.

Models of Myocardial Injury and Ischemic Heart Failure

Background

The choice of the animal model and the model of myocardial injury requires careful consideration. Large animal models more closely approximate the human heart but are more costly, have limited molecular probes, and require specialized experimental setups (Houser et al., 2012; Wheeler et al., 2012; Ishikawa et al., 2014). As outlined in **Fig. 2**, while small animal models are phylogenetically distinct from humans, potentially limiting the translation of findings, they do allow for assessment of gene overexpression and knockout to provide proof-of-principle studies. Here we will focus on two models that are routinely employed to induce myocardial injury, the ischemia-reperfusion injury model, and the coronary artery ligation model. These two models are distinct in their measures and require further discussion. With myocardial ischemia-reperfusion models, a coronary artery is occluded with either a suture (small and larger animal models) or a percutaneous coronary balloon (large animal models). After a designated period of occlusion, the obstruction is removed to restore flow in the vessel (reperfusion). This model has been used extensively to assess how pharmacologic or genetic interventions impact myocardial infarct size. In contrast, coronary artery ligation models of myocardial infarction do not reperfuse, and therefore can be used to examine the response to a completed infarct and the impact on myocardial remodeling. It should be noted that in murine and rat models, the generation of thrombotic occlusion in the coronary arteries of mice is not experimentally possible to date. Furthermore, neither of the myocardial injury models employs thrombus formation; therefore, the contribution of platelet activation is underestimated in these models. The aim of this section is to describe and highlight the features of some commonly used animal models of ischemic myocardial injury.

Small Animal Models

Mouse and Rat models

Mouse models of myocardial injury have been extensively used by investigators to decipher the contribution of specific cells, proteins, and signaling pathways to myocardial injury and remodeling (Salto-Tellez et al., 2004; Gao et al., 2010a). Myocardial ischemia- reperfusion injury is most commonly induced in mice by coronary artery occlusion with a surgical ligature. As an alternate to surgical ligature, cryogenic injury has been used to cause myocardial damage because it can give a more reliable area of injury. However this technique has not been used extensively (van den Bos et al., 2005a,b). We have extensively used the suture method to induce myocardial infarction in mice (Mital et al., 2011; Cai et al., 2011; Zhang et al., 2017; Smith et al., 2016a). To induce myocardial infarction, mice are anesthetized with either isoflurane or Ketamine/Xylazine injection. Following intubation, a left-sided thoracotomy is performed, and the left coronary artery is either temporarily (ischemia-reperfusion) or permanently ligated with a suture. Ischemia is verified by the change in tissue color distal to the suture. It should be noted that while there is variability in murine coronary anatomy (Kumar et al., 2005; Chen et al., 2017), induction of predictably sized infarcts in C57BL/6 mice is possible (Ahn, 2003). Therefore, the investigator should be careful to use in-bred strains such as C57BL/6 to ensure uniformity. After verifying ischemia, the suture is tied for permanent coronary ligation studies, or loosened at a designated time for reperfusion. The surgical incisions of the chest and skin are closed, and mice are recovered. Infarct size can be measured at 24–72 h using tetrazolium staining, and cardiac function can be measured by a variety of methods including echocardiography (Gao et al., 2011), MRI (Buonincontri et al., 2013), or invasive hemodynamic measurements (Pacher et al., 2008; Zhang et al., 2017; Smith et al., 2016b). Long-term studies to assess the impact of inflammation and fibrotic scar tissue formation can be measured accurately to gain insight into the postinfarct remodeling process (Prabhu and Frangogiannis, 2016). Investigators must be aware of several critical issues with these models. First, the time of ischemia affects the infarct size in mice (Redel et al., 2008). Furthermore, the degree of inflammation and fibrosis, and therefore LV remodeling, is directly proportional to the initial infarct size (Christia et al., 2013). Therefore, it is necessary to demonstrate equal infarct size between groups when comparing the subsequent remodeling responses in between these groups of mice.

Another uniqueness of the mouse coronary artery ligation model is the finding that after infarction, mice like humans can suffer cardiac rupture (Gao et al., 2005, 2010b; Fang et al., 2007). Rupture rates for several mouse strains have been reported (Gao et al., 2005). Furthermore, the incidence of cardiac rupture is proportional to the infarct size and the amount of inflammation (Gao et al., 2010b).

Rat models have been a mainstay in cardiovascular research. Temporary and permanent ligation of the left anterior descending artery has been used to generate myocardial injury and heart failure (Bader, 2010). Because the techniques are comparable to those described above for the mouse, we will not review these models here. It should be noted that because genetically modified rats are not as readily available as mice, the use of rat models for proof-of-concept studies on gene expression is limited. However, numerous studies have employed rat models of ischemic cardiac injury to evaluate pharmaceutical approaches (Wayman et al., 2003).

Large Animal Models of Myocardial Injury

The early animal models of myocardial infarction were developed and reported in dogs as early as 1948. Canine studies are complicated by the fact that evaluation of collateral blood flow must be conducted given that dogs have developed collaterals that can be recruited during ischemia (Leong-Poi et al., 2005). Ischemic heart disease has also been studied in nonhuman primate models (baboons and rhesus monkeys) (reviewed Camacho et al., 2016). However, due to ethical and cost considerations, these species are not widely employed. Indeed, the National Heart Lung and Blood Institute Consortium for preclinicAl assESsment of cARdioprotective therapies (CAESAR) uses only mouse, rabbit, and pig to examine the efficacy of cardioprotective modalities (Jones et al., 2015; Lefer and Bolli, 2011b).

Swine

Swine are considered a superior large animal model for studies of acute myocardial infarction and ischemic cardiomyopathy (ICM) (McCall et al., 2012), with heart size, coronary vessel size, and collateral coronary circulation comparable between humans and swine. One of the most widely used models for the induction of myocardial infarction MI in swine is balloon occlusion of the left anterior descending artery. Indeed, we have used this model to demonstrate that with myocardial ischemia-reperfusion injury transgenic swine overexpressing CD39, a vascular nucleotidase, have a significant reduction in myocardial infarct size (Wheeler et al., 2012). To create reproducible large infarct size, a percutaneous transluminal coronary angioplasty dilation catheter was placed just proximal to the first diagonal branch and inflated to occlude distal flow. Myocardial infarct size (Ellenbroek et al., 2016) and myocardial function can be measured by a variety of methods including echocardiography (Ellenbroek et al., 2016; Ballo et al., 2017), CT (Boudoulas et al., 2012), MRI (Arunachalam et al., 2017), or invasive hemodynamic measurements (Ellenbroek et al., 2016).

A caveat of this model is that it requires specialized equipment, dedicated surgical facilities, and skilled personnel, thereby limiting the number of laboratories able to conduct these studies. Another caveat of this model is the fact that there is no thrombotic occlusion. To understand whether platelet activation and thrombus formation contribute additional injury or an altered profile of inflammatory mediators requires further studies. Other models have also been employed to examine ischemic injury including:

(a) surgical ligation of the LAD or LCX coronary artery in the pig (Ishikawa et al., 2014; Gálvez-Montón et al., 2014), (b) gelatin sponge embolization (Sakaguchi et al., 2003), (c) coronary coil deployment (Gálvez-Montón et al., 2014), and (d) intracoronary ethanol administration . Finally, a critical caveat with the porcine model is that dissection of molecular mechanisms is limited due to a less than robust array of molecular probes for swine proteins.

Summary

Atherosclerosis and thrombosis contribute to a significant proportion of morbidity and mortality in the world. No animal model completely recapitulates the complexity of human cardiovascular disease (**Fig. 1**). However, small and large animal models of atherosclerosis, thrombosis, and myocardial injury are invaluable tools through which numerous laboratories have contributed to understanding the intricacies of atherosclerosis, thrombosis, and myocardial infarction.

Introduction

The ideal tool for assessing the risk status for cardiovascular disease is one that is simple to use and applicable to a large number of subjects (Naghavi et al., 2003). For classifying the cardiovascular risk status of individuals, until now, practice guidelines recommend use of the Framingham Risk Score or other similar cardiovascular risk prediction models, which are based on the traditional risk factors for cardiovascular disease (Wilson et al., 1998; National Cholesterol Education Program Expert Panel on Detection, 2001). However, the traditional risk factors alone do not appear to be adequate to determine the risk of cardiovascular disease (Magnus and Beaglehole, 2001; Brindle et al., 2003). Several biochemical markers, such as the serum levels of C-reactive protein and B-type natriuretic peptide, have also been used, but these add only moderate value to the standard risk factors (Wang et al., 2006). Under these circumstances, the usefulness of physiological markers reflecting vascular pathophysiological abnormalities has received attention for cardiovascular risk assessment. Among these markers, the ankle-brachial pressure index (ABI) and pulse wave velocity (PWV) are markers that are simple to measure and applicable to a large number of subjects (Aboyans et al., 2012; Townsend et al., 2015; Vlachopoulos et al., 2015).

Ankle-Brachial Pressure Index

Rationale for Use as a Cardiovascular Risk Marker

The ABI denotes the ratio of the systolic blood pressure measured at the ankle to that measured in the arm. Because atherosclerotic stenosis is rare in the arteries of the upper extremities, this ratio practically reflects the severity of stenosis of the arteries of the lower extremities. A particular caution is that the blood pressure should be measured in both the arms and the higher value of the two should be used for calculating the ABI (Aboyans et al., 2012). An interarm systolic blood pressure difference of >10/15 mmHg implies subclavian artery stenosis, which is one of the high-risk factors for cardiovascular events (Clark et al., 2012).

In the systemic arterial tree, the caliber of the vessels decreases progressively from center to the periphery, and this tapering causes elevation of the systolic blood pressure at the periphery as a peaking phenomenon (**Fig. 1**, upper panel). In addition, tapering and branching of the arteries from the center to the periphery increase the arterial resistance, which generates a reflected pressure wave directed toward the center (Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007). Summation of the forward pressure

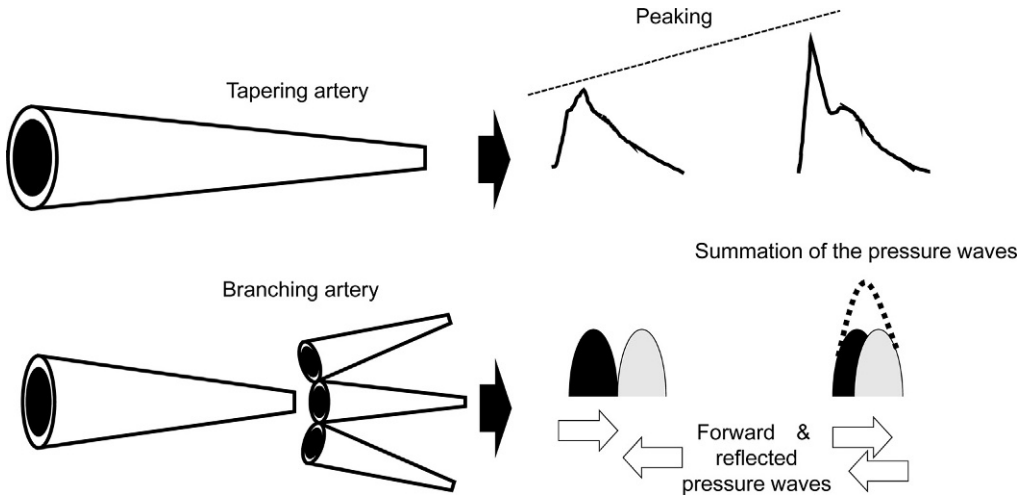

Fig. 1 Mechanisms amplify the systolic blood pressure from the proximal to the distal sites in arteries.

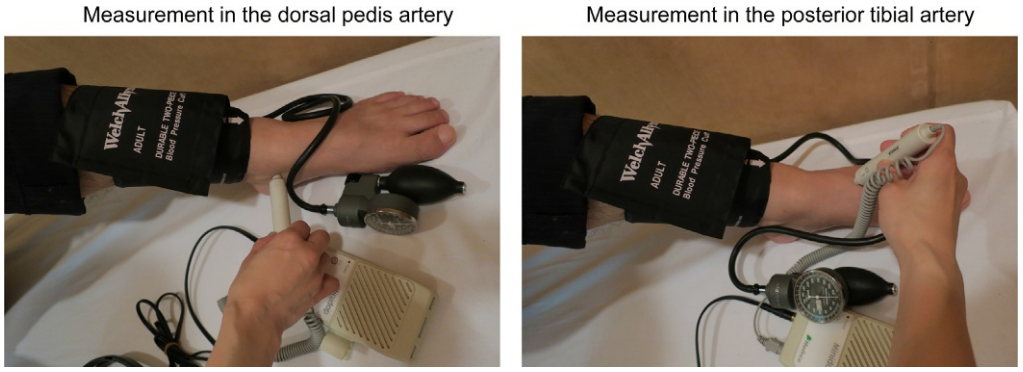

Fig. 2 Ankle-brachial pressure index measurement by the Doppler method.

wave generated by cardiac contraction and the reflected pressure wave also increases the blood pressure at the periphery (Fig. 1, lower panel). These mechanisms amplify the systolic blood pressure from the proximal to the distal sites in arteries.

According to the American Heart Association (AHA) Scientific Statement 2012 (Measurement and interpretation of ABI), values $\leq$0.90 usually signify peripheral arterial disease (PAD) (Aboyans et al., 2012). Previous reports have indicated that both the sensitivity and the specificity of ABI $\leq$0.90, as measured by the Doppler method, to detect >50% stenosis of the arteries of the lower extremities are nearly 90% and 95%, respectively (Carter, 1968; Yao et al., 1969). However, more recent meta-analyses have demonstrated high specificity values (80–99%), but a wide range of sensitivity (20–80%) (Lin et al., 2013; Xu et al., 2010). The ABI value of 0.90 is not a binary cutoff value to identify PAD, and the diagnostic threshold of ABI for peripheral arterial stenosis may vary. For example, Guo et al. (2008) reported that the cutoff value of ABI of 0.95 was associated with 91% sensitivity and 86% specificity to identify significant stenosis of the arteries of the lower extremities in subjects who had undergone conventional digital subtraction angiography as a screening test for PAD. A low ABI value may reflect severe stenosis and be associated with lower walking performance (McDermott et al., 2002), although the association of a low ABI with functional impairment of the lower extremities is less consistent (Aboyans et al., 2012). Despite the presence of lower limb peripheral arterial stenosis, the ABI is high ($\geq$1.40) in some cases; this could be a result of incompressible calcification of the arterial wall. In such cases, the toe-brachial index is useful to identify PAD, and Aboyans et al. (2008) reported that 80% of subjects with high ABI have significant stenosis in lower extremities.

Measurement of the ABI

Several methods are available for measuring the ABI, such as the Doppler method, the oscillometric method, and plethysmography (Aboyans et al., 2012; Vlachopoulos et al., 2015). Most clinical studies till date have used the Doppler method to measure the ABI, and the AHA Scientific Statement 2012 (Measurement and interpretation of ABI) and a position paper from the European Society of Cardiology (ESC) Working Group on peripheral circulation recommend measurement of the ABI by the Doppler method (Aboyans et al., 2012; Vlachopoulos et al., 2015). In the Doppler method, the blood pressure is measured using a Doppler probe in the lower limbs, followed subsequently by measurement in the posterior tibial and dorsal pedis arteries (Fig. 2). On the other hand, in the

Fig. 3 Ankle-brachial pressure index measurement by the oscillometric method.

oscillometric method, which is relatively simpler and requires less training, the blood pressure is measured simultaneously in both the upper and lower extremities by wrapping pressure cuffs (Fig. 3). However, the blood pressure in the posterior tibial artery and dorsal pedis artery cannot be measured separately in the oscillometric method.

Validity, Reproducibility, and Generalizability of ABI

As mentioned earlier, the ABI as measured by the Doppler method has a high specificity for identifying significant stenosis in the arteries of the lower extremities. Similarly, when the ABI was assessed by the oscillometric method, a cutoff value of 0.87 yielded a sensitivity of 84% and specificity of 89% for the detection of 75% stenosis in the lower limb arteries as measured by magnetic resonance angiography (Ichihashi et al., 2014). A review article reported that the average sensitivity and specificity of ABI determined by the oscillometric were $69 \pm 6\%$ and $96 \pm 1\%$, respectively, for the diagnosis of PAD (Verberk et al., 2012). Aboyans et al. (2012) reported that the area under the receiver operator characteristic curve to identify PAD was higher for ABI measured by the Doppler method than for ABI measured by the oscillometric method. However, both the Doppler method and the oscillometric method have been demonstrated to show acceptable reproducibility for measurement of the ABI (Holland-Letz et al., 2007; Richart et al., 2009).

For systolic blood pressure values of <70 mmHg as assessed by the Doppler method, the oscillometric method overestimates the values (Kornø et al., 2009); this finding suggests that the Doppler method may be preferable for measuring the ABI intended at estimating the severity of peripheral arterial stenosis. On the other hand, ABI measurement by the Doppler method needs to be performed by skilled examiners, and both didactic learning and experimental learning are required (Aboyans et al., 2012). In regard to screening for PAD in general practice, Nexøe et al. (2012) suggested that neither the recommendation for use of the Doppler method to measure the ABI nor the measurement of the ABI itself was warranted in general practice due to the low specificity of the assessments. In addition, the time required for the measurement (10–15 min per person) is another issue in general practice (Bendermacher et al., 2012; Davies et al., 2014).

Risk Factors Associated With Abnormal ABI and Recommended Indications for ABI Measurement

Advanced age, gender (male sex), obesity, hypertension, diabetes mellitus, smoking, hypercholesterolemia, and hypertriglyceridemia are risk factors associated with ABI <0.90 (Fowkes et al., 2013). The prevalence rate of ABI <0.90 increases with age in both sexes: <5% in persons aged <50 years, 8–15% in persons aged 50–80 years, and 20% in persons aged >80 years (Fowkes et al., 2013). Selvin and Erlinger (2004) reported that in a cohort with a PAD prevalence rate of 4.4%, the prevalence of persons with versus without hypertension was 6.9% versus 2.2%, the prevalence of smokers versus nonsmokers was 6.8% versus 3.1%, and the prevalence of persons with versus without diabetes was 10.8% versus 3.6%. Accordingly, the clinical recommendations for measurement of the ABI are as follows: persons aged ≥ 18 years with walking impairment or claudication, or nonhealing wounds in the lower extremities, persons aged 50–69 years with a history of smoking or diabetes, and persons aged ≥ 70 years (Olin et al., 2010). In addition, the Trans-Atlantic Inter-Society Consensus (TASC) II proposed measurement of the ABI in subjects with a Framingham risk score between 10% and 20% in 10 years (Norgren et al., 2007). Chronic renal insufficiency is also a risk factor for PAD (Ix et al., 2009) and is an indication for measuring the ABI (Norgren et al., 2007).

Clinical Perspectives

Clinical perspectives of ABIs were summarized in Table 1. Abnormal ABI has two clinical implications: it indicates the existence of PAD and also indicates a high-risk state for cardiovascular disease.

Table 1 Summary of the clinical perspectives of ankle-brachial pressure index and pulse wave velocity

++, good; +, acceptable; ±, limited; −, not acceptable.

Peripheral arterial disease

A low ABI is a risk factor for amputation (Hämäläinen et al., 1999). ABI ≤0.90 has a high specificity for the diagnosis of PAD. However, the Walking and Leg Circulation Study reported that up to a half of the patients with PAD do not exhibit exertional leg pain or atypical leg pain (McDermott et al., 2002), and that PAD is asymptomatic in about 50% of all patients (Olin et al., 2010). Therefore, all subjects with ABI ≤0.90 need evaluation to determine the severity of PAD and specialist consultation for the management of PAD. In contrast, the sensitivity of ABI to identify PAD is only modest. Therefore, in subjects with symptoms suggestive of PAD, but ABI >0.90 (especially ABI 0.90–0.99), postexercise ABI measurement should be considered to screen for the presence of PAD.

High-risk status for cardiovascular disease

In the Reduction of Atherothrombosis for Continued Health (REACH) Registry study, of the patients with symptomatic atherothrombosis, a significant proportion (15.9%) had symptomatic polyvascular disease (Bhatt et al., 2006). Thus, the prevalence rate of cardiovascular disease is high in patients with PAD. On the basis of a review of 18 cohorts studies, the US Preventive Services Task Force reported that ABI ≤0.90 is associated with future coronary artery disease and cardiovascular events, independent of the Framingham risk scores; on the other hand, the significance of ABI >1.30/1.40 as a marker to predict future cardiovascular events is inconsistent (Lin et al., 2013). As compared to aggregate data meta-analysis, meta-analysis of individual participant data collected from all studies is considered as the gold-standard approach to evidence synthesis (Stewart et al., 2015). The Ankle Brachial Index Collaboration Study Group conducted a meta-analysis of individual participant data of 24,955 men and 23,339 women derived from a general population, none of whom had a history of coronary artery disease. They found a reverse J-shaped association of ABI with cardiovascular death. The ABI associated with the lowest cardiovascular risk was 1.11–1.20, and hazard ratio for 10-year cardiovascular mortality associated with ABI ≤0.90 (reference ABI 1.11–1.20) was 2.9 in men and 3.0 in women after adjusting for the Framingham risk scores (Ankle Brachial Index Collaboration, 2008). ABI ≥1.40 was also found to be a significant predictor of cardiovascular events in both men and women. In addition, Emdin et al. (2015) reported that PAD is also a predictor of atrial fibrillation and chronic kidney disease. Irrespective of these findings, it may be difficult to make optimal treatment decisions based on quantitative risk assessment (Aboyans et al., 2012).

ABI 0.09–0.99 is defined as borderline ABI (Rooke et al., 2011), and the Ankle Brachial Index Collaboration Study Group reported that men and women with values of the ABI of 0.91–1.10 also had higher mortality and event rates than those with ABI in the normal range (1.11–1.40). Recent studies have confirmed these findings (Tanaka et al., 2016; Natsuaki et al., 2014). Therefore, it is proposed that ABI in the borderline range be considered as representing a high-risk state for cardiovascular disease.

ABI measurement for cardiovascular risk assessment is feasible. However, the US Preventive Services Task Force concluded that currently available evidence is insufficient to assess the balance between the benefits and risks of ABI measurement as a screening tool for PAD and cardiovascular disease risk assessment (Lin et al., 2013). In **Fig. 4**, the bar graphs represent the number of subjects in each ABI category by the Ankle Brachial Index Collaboration Study Group (Ankle Brachial Index Collaboration, 2008). In this study, while the hazard ratio for death was high for ABI ≤0.90, only 7.4% (1841/24,955 men) and 8.1% (1901/23,339 women) of the study subjects had ABI ≤0.90. On the other hand, the ABI was >0.90 in more than 90% of the study subjects, and 4625 of the 5582 deaths in men (82.8%) and 3480 of the 4342 deaths in women (80.1%) were observed in these subjects. Thus, there are limitations to identifying subjects with a high cardiovascular risk on the basis of the ABI ≤0.90 alone, and the development of some additional approach for screening such high-risk subjects is proposed.

ABI as a Tool for Monitoring Patients During Management of PAD

A report of the American College of Cardiology Foundation (ACCF)/AHA Task Force on Performance Measures, the American College of Radiology, the Society for Cardiac Angiography and Interventions, the Society for Interventional Radiology, the Society for Vascular Medicine, the Society for Vascular Nursing, and the Society for Vascular Surgery 2010 recommend measurement of the ABI at 5-year intervals in adults with PAD (Olin et al., 2010), and the Multi-Ethnic Study of Atherosclerosis study, in which none of the participants had clinical cardiovascular disease at the time of enrollment, reported that over a median follow-up of 9.8 years,

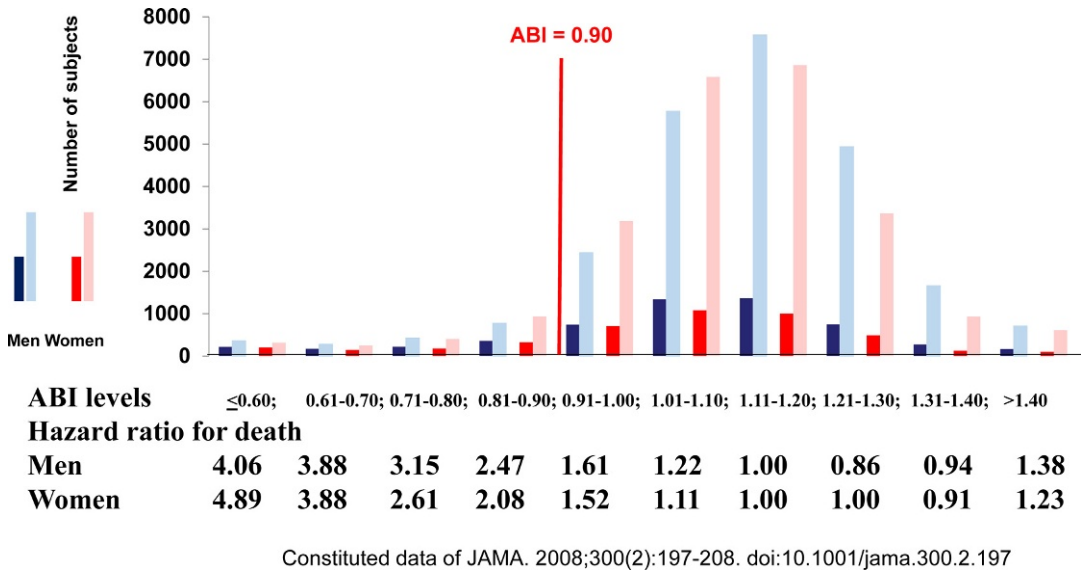

Fig. 4 Relationship between the hazard ratio for death and the number of subjects in each ankle-brachial pressure index level. *Abbreviations*: *dark color bars* represent subjects with cardiovascular events and *light color bars* represent subjects without cardiovascular events. Constituted data of Ankle Brachial Index Collaboration, Fowkes, F. G., Murray, G. D., Butcher, I., et al. (2008). Ankle brachial index combined with Framingham Risk Score to predict cardiovascular events and mortality: A meta-analysis. *JAMA* **300**(2), 197–208. https://doi.org/10.1001/jama.300.2.197.

221 of the 5591 participants (4%) showed decrease of the ABI to ≤0.90, and 89 of the 5591 participants (1.6%) showed increase of the ABI to >1.40 (Garimella et al., 2015).

Cronenwett et al. examined the clinical course of 91 men with mild intermittent claudication. Over a mean follow-up period of 2.5 years, a decrease of the ABI by at least 0.15 was associated with an increased operation rate and symptom progression (Cronenwett et al., 1984). Increase of the ABI by 0.15 following revascularization was predictive of absence of residual stenosis >50% (Decrinis et al., 1994); however, ABI measurement was not useful to predict revascularization failure (Barnes et al., 1989). While exercise therapy or medication (ramipril, an angiotensin-converting enzyme inhibitor) improves the symptoms related to limb ischemia, ABI did not reflect this symptomatic improvement (Parmenter et al., 2015; Kurklinsky and Levy, 2013). Thus, in patients with PAD, ABI monitoring might be applicable to monitor the progression of the disease state, but it might have some limitations in relation to assessment of the effects of PAD treatment.

Summary

ABI is used as a diagnostic tool for PAD and for cardiovascular risk assessment. For assessing the severity of PAD and the progression of the disease, especially in patients with severe PAD, ABI measurement by the Doppler method may be more suitable. For cardiovascular risk assessment, on the other hand, both the Doppler method and oscillometric method are applicable, although the oscillometric method may have the advantage of being applicable to a large number of subjects.

Arterial Stiffness

Rationale for Use as a Cardiovascular Risk Marker

Atherosclerosis, arteriosclerosis, and arterial stiffness

Atherosclerosis and arteriosclerosis are phenotypes of atherosclerotic vascular damage. The arterial wall is composed of three layers (i.e., the intima, including the endothelium, media, and adventitia); atherosclerosis begins from the intima, while the pathological alterations of arteriosclerosis are mostly observed in the media (Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007). The structure of the arterial wall differs from the proximal sites to the periphery; the arterial tree can be simply classified as being composed of three categories of vessels: the elastic arteries, muscular arteries, and arterioles. The components of the media layer differ between the elastic and muscular arteries. A high content of elastic fibers is observed in the medial layer of the elastic arteries, while the vascular smooth muscle cell layer is dominant in the medial layer of the muscular arteries (Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007). Age and elevated blood pressure (pulsatile stress) are major factors associated with the degeneration of elastic fibers, increase of the collagen content, and proliferation of the vascular smooth muscle. Elevated blood pressure is also associated with vascular smooth muscle cell hypertrophy (Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007). Then, arteriosclerosis is a diffuse, but segmental abnormality (elastic/muscular arteries).

Arteries are reported to have the function of efficiently delivering blood to the peripheral organs and of maintaining this delivery function (Tomiyama et al., 2016). Thus, the most important functions of the arterial tree are its function as a conduit for blood (delivery of blood to organs) and its cushioning (dampening) effect (to generate continuous blood flow/reduce exposure of the arterial tree to the cardiac pulsatile energy) (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Tomiyama et al., 2016; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010). Atherosclerosis, a focal abnormality in the arterial tree, causes organ ischemia via arterial stenosis/obstruction. On the other hand, arteriosclerosis is thought to contribute to the initiation/progression of cardiovascular disease via different mechanisms (i.e., impaired cushioning function). The elastic arteries play a dominant role in cushioning against and dampening the pressure oscillations that result from intermittent ventricular ejection (i.e., the Windkessel effect) and transforming the pulsatile flow into a steady flow for supplying oxygen to the tissues (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Tomiyama et al., 2016; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010). This elasticity has beneficial effects on the cardiovascular system, such as facilitating organ blood supply during diastole, especially in the heart, reduction of the cardiac afterload, and/or protection of the arterial wall and microvasculature from the mechanical stresses generated by cardiac contractions (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Tomiyama et al., 2016; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010). The structural changes of the arterial wall associated with arteriosclerosis increase the arterial stiffness; furthermore, elevated blood pressure and/or increase of the vascular tone can also functionally increase the arterial stiffness. Thus, not only structural stiffness but also functional stiffness exerts harmful effects on the cardiovascular systems.

How does arterial stiffness serve as a cardiovascular risk factor?

Increased arterial stiffness directly increases the cardiac afterload because of the elevated cardiac contractile pressure needed for ejection of blood into the aorta. In the arterial tree, the arteries branch and taper toward the periphery, associated with increase of the arterial resistance. Reflection of the pulse wave (from the periphery to the heart) occurs at sites of abrupt increase of the arterial resistance, such as at sites of arterial branching. Increased arterial stiffness increases the travel speed of the reflected pressure wave, thereby augmenting the summation of the forward pressure wave (from the heart to the periphery) and reflected pressure wave in the aorta during the cardiac systolic phase (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010), which further increases the cardiac afterload (**Fig. 5**).

Increased arterial stiffness affects the coronary blood supply via two mechanisms. First, the cushioning effect of the elastic aorta involves its expansion during systole to store some amount of the blood ejected from the heart, and then delivery of this stored blood to the tissues during diastole. Since the coronary arteries are mostly perfused during diastole, the amount of this stored blood is an important determinant of the coronary blood flow (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Tomiyama et al., 2016; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010). With increased arterial stiffness, the amount of stored blood in the aorta during systole is decreased, which is associated with a reduced coronary arterial blood supply (**Fig. 6**). In regard to the second mechanism, in the healthy condition of the arterial tree, since the speeds of propagation of the forward pulse wave (heart to periphery) and the reflected pulse wave (periphery to the heart) are not so high, the reflected wave returns to the central aorta during diastole (**Fig. 5**, left figure) (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010;

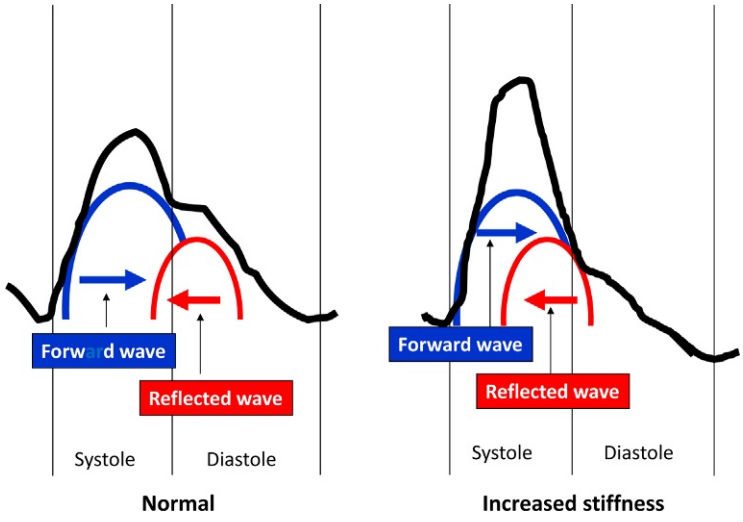

Fig. 5 Central hemodynamics in cases with/without increased arterial stiffness.

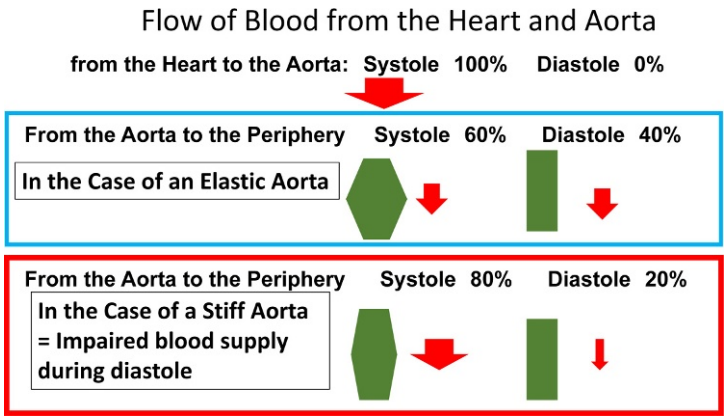

Fig. 6 Conduit function of the large arteries in the presence/absence of increased arterial stiffness.

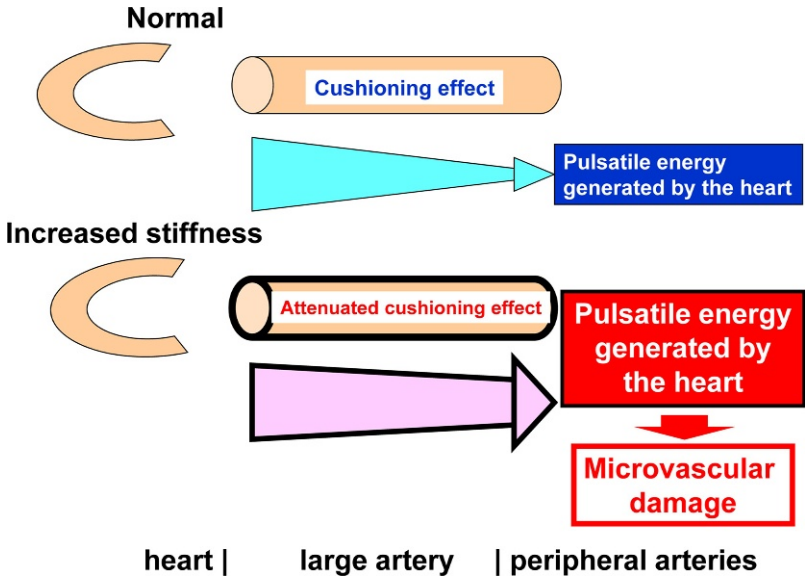

Fig. 7 Cushioning effect of the large arteries on the pulsatile energy generated by the heart. When the cushioning effect is attenuated, the pulsatile energy causes peripheral vascular damage.

O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010). This phenomenon increases the diastolic blood pressure and contributes to the maintenance of the coronary blood supply. When the arterial stiffness is increased, elevation of the diastolic pressure by the reflected pulse wave is reduced, resulting in impairment of the coronary blood supply, because the reflected pulse wave returns during systole as a result of increase of the pulse wave propagation speed (Fig. 5, right figure).

Increased arterial stiffness attenuates the cushioning effect of the elastic arteries, and this attenuation amplifies the pulsatility and increases the transmission of pulsatile energy to the peripheral microcirculation (Fig. 7). The specific gravity of mercury is 13, and therefore, a cardiac contraction energy of 140 mmHg is equivalent to the pressure needed for ejection of water to a height of 182 cm ($13 \times 140/10$). Exposure of small vessels to highly pulsatile flow causes microvascular damage, especially, in high-blood flow organs such as the brain and kidney (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Tomiyama et al., 2016; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010), the so-called pulsatile nephropathy and encephalopathy (O'Rourke et al., 2010).

Measurement of the PWV

PWV reflects segmental arterial elasticity. Contraction of the left ventricle generates a pulse wave which is propagated throughout the arterial tree. PWV is calculated as the distance traveled by the pulse wave divided by the time taken to travel the distance (path length) (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016; McDonald, 1968). Increase of the arterial stiffness is associated with increase of the propagation speed of the pulse wave in the arteries. PWV can be measured in any arterial segment

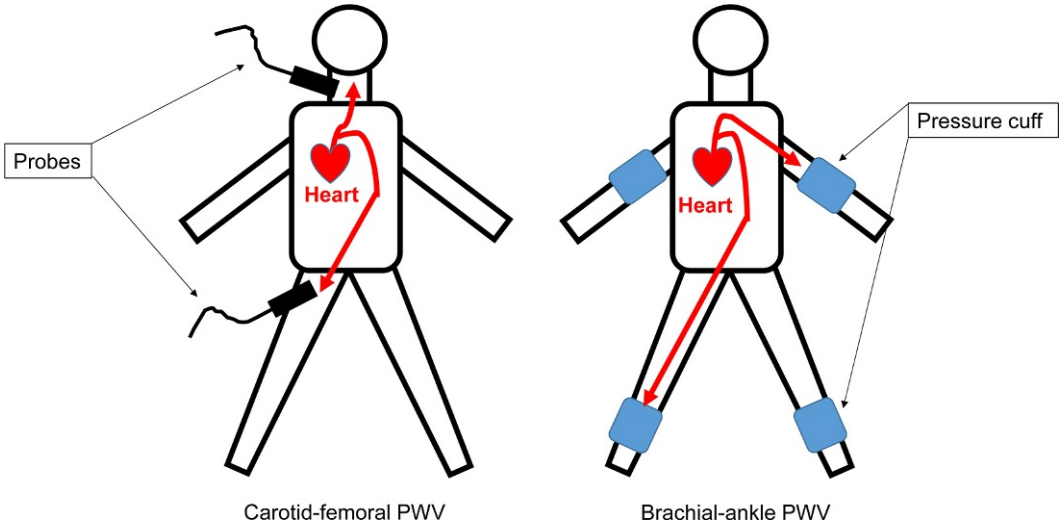

Fig. 8 Schema of carotid-femoral pulse wave velocity and brachial-ankle pulse wave velocity. *Abbreviation*: *arrows*, directions of the pulse wave traveling from heart.

between two pulse-wave palpable regions (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016; McDonald, 1968). In biomechanics, the Moens–Korteweg equation describes the relationship of the PWV with factors related to the blood vessels; this equation is $PWV^2 = E \cdot h / r \cdot p$, where E is the elastic modulus, h is the vessel wall thickness, r is the vessel radius, and p is the blood density. According to this equation, the increase in the vessel wall thickness and/or the decrease in the vessel diameter would result in an increase of the PWV. In addition, age and blood pressure also exert a strong influence on the PWV (Weber et al., 2009).

Conventionally, carotid-femoral PWV is used for assessment of the central arterial stiffness (**Fig. 8**) (Townsend et al., 2015; Vlachopoulos et al., 2015), and recently, mainly in Asia, the brachial-ankle PWV has been measured (**Fig. 8**). In addition, a single-point estimation of the PWV has recently become available, although it is not yet fully established (Weber et al., 2015). In the measurement of the carotid-femoral PWV, the pulse wave is detected by tonometry, Doppler, or oscillometry, and the path length is measured superficially (Townsend et al., 2015; Vlachopoulos et al., 2015). In the measurement of the brachial-ankle PWV, the pressure wave is detected by oscillometry after tying pressure cuffs around the four extremities, and the path length is calculated from the height (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016). Basically, PWV is calculated as the travel speed of the pulse wave between two points on the same artery. However, in the aforementioned procedures, the carotid-femoral PWV is obtained by subtracting the heart-carotid artery PWV from the heart-femoral artery PWV, and the brachial-ankle PWV is calculated by subtracting the heart-brachial artery PWV from the heart-ankle PWV (**Fig. 8**) (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016). These issues are pointed as methodological limitations.

Validity, Reproducibility, and Generalizability of PWV Measurements

The PWVs (carotid-femoral PWV and brachial-ankle PWV) have been demonstrated to show a close correlation to the central arterial stiffness measured by the gold-standard invasive method (Weber et al., 2009; Yamashina et al., 2002). Acceptable reproducibility of these measurements has been reported (i.e., the interobserver Pearson's correlation coefficient r was 0.97 for the carotid-femoral PWV and 0.98 for brachial-ankle PWV) (Yamashina et al., 2002; Mitchell et al., 2004). Usually, skilled personnel and exposure of the inguinal region of the subject are required for carotid-femoral PWV measurement. Therefore, application of this method is mostly limited to research institutes (Mancia et al., 2013). A simple oscillometric method to measure the carotid-femoral PWV has also become available recently (Townsend et al., 2015; Müller et al., 2013). On the other hand, the brachial-ankle PWV can be measured simply by just wrapping a pressure cuff around each of the four extremities (**Fig. 8**) (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016; Yamashina et al., 2002). One of the limitations of measurement of the brachial-ankle PWV is that this parameter reflects not only elastic arterial stiffness but also muscular arterial stiffness (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016; Yamashina et al., 2002). Even so, the brachial-ankle PWV has been demonstrated to show a close correlation to the carotid-femoral PWV (Tanaka et al., 2009). In addition, the ABI can also be measured simultaneously when this oscillometric method is used for measuring the brachial-ankle PWV.

Risk Factors Associated With Increased PWV and Recommended Indications for PWV Measurement

In a systematic review, the contribution of age, blood pressure, and other conventional risk factors for cardiovascular disease to the carotid-femoral PWV was examined, and it was found that the contribution of risk factors other than the age and blood pressure was

small or insignificant (Cecelja and Chowienczyk, 2009). Elevated blood pressure causes functional increase of the arterial stiffness via increasing the arterial wall tension (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama and Yamashina, 2010; O'Rourke and Hashimoto, 2007; Najjar et al., 2005; O'Rourke, 2015; Safar, 2007; Laurent and Boutouyrie, 2007; O'Rourke et al., 2010), and also structural increase of the arterial stiffness via causing structural changes of the arterial wall. Abnormal glucose metabolism and/or metabolic syndrome also increase arterial stiffness (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016). Furthermore, increase of the PWV was observed in subjects with disease states often associated with cardiovascular disease, such as renal dysfunction, pulmonary dysfunction, osteoporosis, and sarcopenia (Tomiyama et al., 2005a; Kimoto et al., 2006; Hirose et al., 2003; Ochi et al., 2010).

The ACCF/AHA guidelines for the assessment of cardiovascular risk in asymptomatic adults do not recommend measurement of the PWV for assessing cardiovascular risk (Greenland et al., 2010). However, based on the evidence accumulated after the publication of this guideline, the ESC guideline recommends measurement of the carotid-femoral PWV in subjects at intermediate risk (Mancia et al., 2013); in addition, a position paper of the European Society of Cardiology Working Group on peripheral circulation proposes measurement of the carotid-femoral PWV in subjects with hypertension and/or diabetes mellitus (Vlachopoulos et al., 2015). For the case of the brachial-ankle PWV, measurement is recommended in subjects with hypertension, diabetes mellitus, chronic kidney disease (stage III–V), and/or coronary artery disease without impaired systolic cardiac function (Tomiyama et al., 2016).

Clinical Perspectives

Clinical perspectives of PWVs were summarized in **Table 1**. Several longitudinal studies conducted in the general population have demonstrated elevated PWV as a predictor of future cardiovascular events, independent of conventional markers such as the Framingham risk scores (Vlachopoulos et al., 2010, 2012; Ben-Shlomo et al., 2014). Furthermore, PWV is valuable as a predictor of the prognosis in patients with renal insufficiency, acute coronary syndrome, stroke, and heart failure (Levisianou et al., 2013; Sung et al., 2011; G□secki et al., 2012; Tomiyama et al., 2005b; Kitahara et al., 2005; Meguro et al., 2009). Aggregate data meta-analysis and independent participant data meta-analysis have been conducted for the carotid-femoral PWV. Vlachopoulos et al. conducted aggregate data meta-analysis in 17 longitudinal studies (6 studies were community-based/general population and 4 studies were subjects with end-stage renal disease) with 15.877 participants. Then, carotid-femoral PWV by 1 m s^{-1} increase corresponded to increase the risk 14% for cardiovascular events, 15% for cardiovascular death, and 15% for all-cause mortality (Vlachopoulos et al., 2010). Ben-Shlomo et al. conducted individual participant data meta-analysis for carotid-femoral PWV in 16 longitudinal studies (8 studies were community-based/general population) with 17,635 participants. Then, a1-standard deviation of carotid-femoral PWV increase corresponded to increase the risk 45% for cardiovascular events, 41% for cardiovascular death and 22% for all-cause mortality (Ben-Shlomo et al., 2014). Vlachopoulos also conducted aggregate data meta-analysis for the brachial-ankle PWV in 18 longitudinal studies (3 studies were community-based/general population and 5 studies were in subjects with end-stage renal disease) in 8169 participants. In their study, increase of the brachial-ankle PWV by 1 m s^{-1} corresponded to a 12% increase of the risk for cardiovascular events, 13% increase in the risk for cardiovascular death, and a 6% increase of the all-cause mortality (Vlachopoulos et al., 2012). The cutoff values of the carotid-femoral PWV and brachial-ankle PWV for predicting the cardiovascular risk status are 10 and 18 m s^{-1} (Townsend et al., 2015; Vlachopoulos et al., 2015; Tomiyama et al., 2016).

Increased arterial stiffness is also a risk factor for the progression of organ damage. Increased PWV has been identified as a predictor of the development of hypertension, progression of renal function decline, and/or cognitive decline (Kaess et al., 2012; Yambe et al., 2007; Chen et al., 2011; Zeki Al Hazzouri et al., 2013). These findings support the concept of pulsatile encephalopathy/nephropathy (O'Rourke et al., 2010).

Monitoring for the Managements

PWV as a tool for monitoring patients during treatment?

The 2013 European Society of Hypertension/ESC Guidelines for the management of arterial hypertension reported that the sensitivity to detect treatment-induced changes, time taken for change, and the prognostic value of change of the carotid intima-media thickness and carotid plaque thickness assessed by carotid ultrasound examination are limited (Mancia et al., 2013). Therapeutic lifestyle modifications (exercise, smoking cessation, weight reduction, salt restriction) have been shown to reduce the PWV (Tanaka and Safar, 2005; Petersen et al., 2015; Tomiyama et al., 2010; Jablonski et al., 2013). Medications for hypertension, diabetes mellitus, and/or dyslipidemia have also been shown to reduce the PWVs (Wu et al., 2015; Rizos et al., 2010; Adji et al., 2011; Tomiyama et al., 2011; Hongo et al., 2008), although the differences in the effects among the drug classes used in the treatment of each of these risk factors have not yet been fully clarified. Guerin et al. reported that improvement of the carotid-femoral PWV by an angiotensin-converting enzyme inhibitor was associated with a better prognosis in patients with end-stage renal disease (Guerin et al., 2001). Orlova et al. (2010) reported that an improvement of the brachial-ankle PWV obtained after 6 months of conventional therapy is predictive of a more favorable prognosis in patients with coronary artery disease. Thus, improvement of the PWV has the potential to be a surrogate endpoint reflecting improvement of the prognosis in patients receiving treatment, but further evidence is needed.

Summary

Increased arterial stiffness, as reflected by the PWV, is an independent risk factor not only for cardiovascular disease but also for progression of organ damage. As compared to atherosclerosis, which contributes to the occurrence of cardiovascular events via causing arterial obstruction/stenosis, arterial stiffness contributes to the occurrence of cardiovascular disease via harmful pathophysiological consequences, such as increased cardiac afterload, impaired coronary blood flow supply, and/or microvascular damage. Lifestyle modification and/or treatment of risk factors for cardiovascular disease improve the PWV. Thus, PWV has the potential to be a management marker (i.e., reflecting not only the prognosis but also the effect of treatment on the prognosis).

Introduction

Management of aneurysms of the aorta has progressed significantly since the pioneering efforts of Debakey and Cooley over 50 years ago (Cooley, 2001). The traditional surgical techniques have been refined, and the focus has moved toward gaining a fuller understanding of aortic pathology. Disease prevention, refinement of patient selection and technique, together with advances in technology are changing our armamentarium. This article reviews current insights into research and clinical aspects of aortic aneurysm disease.

Definitions

Aneurysms (Greek: aneurysma "to dilate") (Aneurysm, 2016) are localized pathological dilatations of arteries. Although left ventricular aneurysms also exist, the term is usually restricted to *blood vessels* that exceed particular size thresholds. These thresholds may be defined by absolute diameters (adjusted for normal age, sex, and body size variations), or stipulated relative to the diameter

of unaffected adjacent segments. A more general definition designates any dilatation greater than 150% of the normal diameter of the affected artery to be aneurysmal (Goldfinger et al., 2014). The focal dilatation characteristic of aneurysms contrasts with the generalized, modest dilatation and elongation observed with normal aging (termed ectasia) (Elefteriades et al., 2017).

Aortic dissection is a disease process in which blood penetrates into the wall of the aorta through a discrete tear in the inner layer of the artery. Under pressure, this blood separates the layers, creating a false lumen that can propagate longitudinally. The antegrade or retrograde extension of this false lumen can cause complications, including aortic rupture. Dissection is often an acute event superimposed on a chronically degenerated aorta (Elefteriades et al., 2012), which may (usually) or may not (rarely) be aneurysmal. Variants of aortic dissection include penetrating aortic ulcer (which resembles a duodenal ulcer of the aorta) and intramural hematoma (a concentric accumulation of blood in the wall of the aorta, without an intimal tear) (**Fig. 1**; Elefteriades, 2008).

Aortic rupture is a complete, transmural breach of the vessel wall, with blood penetrating all the way through the adventitia. This can occur in the context of aneurysm or dissection, as well as from trauma (aortic transection). Rupture may occur into the pericardium (causing tamponade), thoracic cavity, peritoneal cavity, or retroperitoneal space. Hemorrhage may be restrained by the fibrous tissue and structures surrounding the aorta ("contained" rupture). In the absence of this, "free" rupture usually results in exsanguination. These often-confused terms—dissection, rupture, and transection—are shown schematically in **Fig. 2** (Elefteriades et al., 2012).

Classification

Aortic aneurysms can be classified by location within the arterial tree, by morphology, as well as by etiology. The aorta can be anatomically divided according to body segment (**Fig. 3**; Isselbacher, 2005). The part of the aorta superior to the diaphragm is known as the thoracic aorta, while that below is the abdominal aorta. The thoracic aorta is further subdivided into ascending and descending parts, with an intervening aortic arch. The abdominal aorta tends to be divided into segments demarcated by the renal arteries, namely, suprarenal and infrarenal. Any of these segments may be subject to aneurysmal dilatation, but thoracic aortic aneurysm and abdominal aortic aneurysm (AAA) are considered distinct disease entities. Indeed, aneurysms of the aorta may be so extensive as to cover more than one of these named parts (e.g., thoracoabdominal aneurysms).

Aneurysms are also distinguished by morphology, specifically by their shape and the nature of their walls. The wall of a true aneurysm maintains the normal trilaminar structure of an artery (intima, media, adventitia), whereas a false aneurysm does not (even the adventitia is violated). False aneurysms (also known as pseudoaneurysms) represent small ruptures of the artery that are contained by the surrounding tissues. In terms of shape, dilatation may affect some or all of the circumference of the artery. Hence saccular aneurysms are outpouchings of an arc of the vessel wall, whereas fusiform aneurysms involve the entire vessel circumference.

Finally, aortic aneurysm is a predominantly an acquired disease. Aneurysms can occur de novo or develop in the context of prior aortic dissection. Moreover, particular congenital lesions predispose to aneurysm formation, the tendency toward which is strongly inherited (i.e., bicuspid aortic valve—see later).

Histology and Embryology

The aortic wall, like that of all elastic arteries, has a trilaminar structure consisting of a tunica intima, media, and adventitia. Most of the mechanical properties of the aorta can be attributed to the media (with the strong collagen component and the stretchable elastin component), although the adventitia is also recognized as a strong layer that maintains aortic diameter and holds stitches when performing surgery on the vessel (Sanz et al., 2007). The media comprises cellular elements (including smooth muscle cells) and structural proteins (notably elastin and collagen) that form the extracellular matrix (ECM). These components are arranged into lamellar units—concentric layers of elastin with interspersed cells and collagen (Wolinsky and Glagov, 1967). Some have likened the layered nature of the aortic wall to the structure of lasagna. The number of lamellar units in the aortic wall is generally

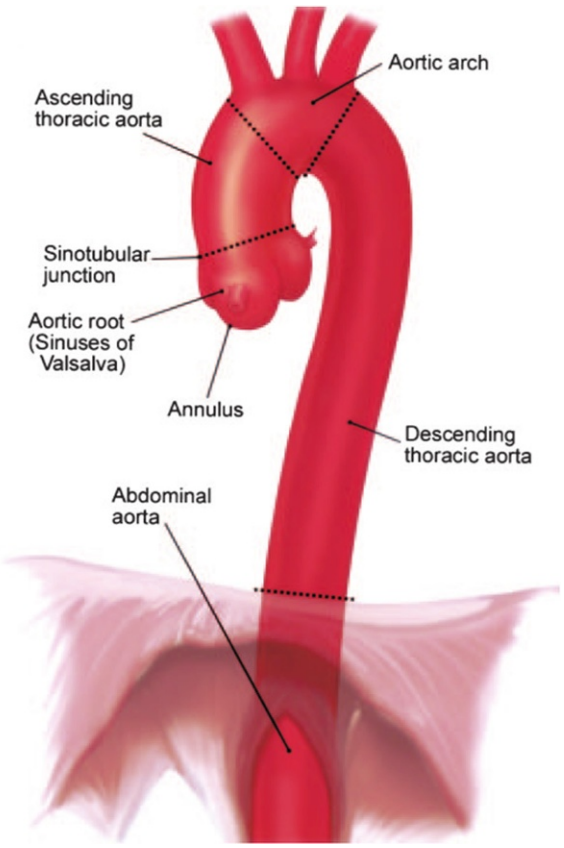

Fig. 3 The parts of the aorta (NB infrarenal aorta not shown). Reprinted with permission from the Massachusetts General Hospital Thoracic Aortic Center.

proportional to the luminal pressure and wall stress that the vessel must withstand, but the number of lamellae is conspicuously low in the infrarenal human aorta (Wolinsky and Glagov, 1969). Elastin, by virtue of its great distensibility, absorbs systolic pressure and contributes to vessel recoil that maintains diastolic forward flow (the "Windkessel effect") (Parker, 2009). Collagen, with its greater tensile strength, is responsible for the aorta's resistance to rupture and deformation (Sanz et al., 2007).

Embryologically, different anatomic portions of the aorta have distinct origins with characteristic structural properties. The ascending aorta and arch are derived from the neural crest, while the descending aorta (distal to the ligamentum arteriosum) originates from mesodermal somites, and the abdominal aorta from splanchnic mesoderm. The thoracic aorta is more distensible, with a vascular outer media, in contradistinction to the abdominal aorta, which is less distensible and has an avascular media. Quantitative differences in the ECM components also exist. These differences influence the susceptibility of the sections of the aorta to various pathological processes.

Pathophysiology

The development of aortic aneurysms can be understood from a number of vantage points. We now have insights into this disease from the molecular biological level up to the engineering level. Ultimately, aneurysm formation results from the combined effects of inherited, degenerative, mechanical, and hemodynamic factors (Elefteriades et al., 2017). Interestingly, aortic aneurysms tend to segregate into two distinct patterns that align with the embryology of the vessel. Aneurysms of the ascending aorta and arch are characterized by cystic medial degeneration (see later), whereas descending and abdominal aneurysms tend to be "arteriosclerotic" (**Fig. 4**; Elefteriades and Farkas, 2010).

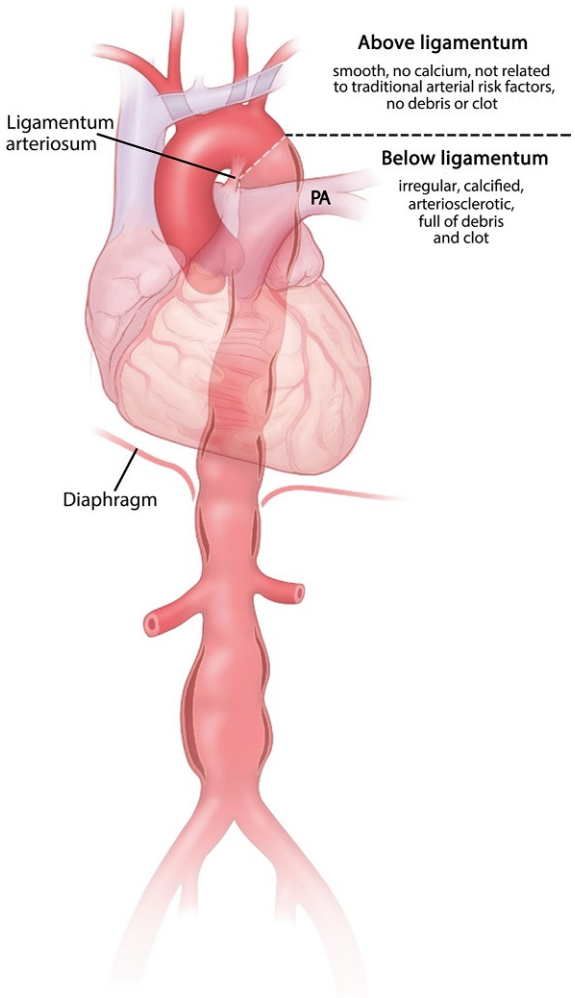

Fig. 4 Distinct patterns of aortic aneurysm disease. Reprinted with permission from Elefteriades, J. A. and Farkas, E. A. (2010). Thoracic aortic aneurysm. Clinically pertinent controversies and uncertainties. *Journal of the American College of Cardiology* **55**, 841–857.

Histological analysis of tissue from thoracic aneurysms often reveals a well-defined pattern known as cystic medial degeneration (previously termed cystic medial necrosis (CMD)). CMD is characterized by the triad of elastic fiber fragmentation, loss of vascular smooth muscle cells (VSMCs), and proteoglycan deposition (Goldfinger et al., 2014) (filling the degenerative voids and providing the "cystic" appearance). A mild form of CMD seems to accompany normal aging; however CMD appears to be accelerated by hypertension and connective tissue diseases such as Marfan syndrome (see later).

A number of overlapping processes are involved in the pathogenesis of aneurysms, namely, ECM destruction, chronic inflammation, cytokine activation, and dysfunction of VSMCs (Wassef et al., 2001; **Fig. 5**; Hackmann et al., 2007). The aortic wall exists in a state of dynamic equilibrium between formation and degradation of ECM components. VSMCs are responsible for collagen and elastin production in addition to serving a contractile function. Matrix metalloproteinases (MMPs) mediate proteolysis and are naturally inhibited by tissue inhibitors of metalloproteinases (TIMPs). An altered ratio of MMP to TIMP activity, together with quantitative (or qualitative—see later) defects in VSMCs, may result in a net proteolytic state that compromises structural integrity of the aortic wall, paving the way for vessel dilatation. Excessive MMP activity has been demonstrated in cases of thoracic and AAA, in addition to altered TIMP levels (Thompson, 1996; Koullias et al., 2004; Kuivaniemi et al., 2015).

Of note, the role of VSMCs is controversial, as these cells have been shown to play seemingly contradictory roles in vascular remodeling. Increased VSMC apoptosis has been implicated in AAA formation, thereby suggesting a (deficient) protective role (Yamanouchi et al., 2010). Conversely, the ability of VSMCs to induce inflammation and MMP production hints at a destructive influence on the ECM (Airhart et al., 2014; Kim and Weintraub, 2016). Moreover, defects in VSMC contractile function have also been suggested as a mechanism contributing to thoracic aortic aneurysm formation (Milewicz et al., 2017).

Chronic inflammation and the role of inflammatory cytokines have also been implicated in the loss of structural integrity of the aortic wall. Inflammatory infiltrates have been observed in both thoracic and aortic aneurysms (Botta et al., 2007), and levels of certain inflammatory cytokines are elevated in some aneurysms (although not consistently so) (Peshkova et al., 2016). Cytokines such as interleukin-1β and tumor necrosis factor-alpha also appear to influence MMP expression (Yoshimura et al., 2006). Transforming growth factor beta (TGF-β) deserves particular attention. This cytokine is expressed by VSMCs and modulates MMP activity. Dysregulated TGF signaling plays a major role in the Marfan syndrome (Matt et al., 2009), while mutations in the TGF-β receptor gene result in the Loeys–Dietz syndrome (see later) (Loeys et al., 2006).

Posttranscriptional regulation of the genes involved in the processes outlined above has also been connected to aneurysm formation. Intracellular micro-RNAs (miRs) are involved in this regulation and have been implicated in the development of many cardiovascular diseases (Raffort et al., 2016). Alterations in the levels of particular miRs in smooth muscle cells from human abdominal aortic aneurysmal tissue have been associated with reduced gene or protein expression of collagen (Cheuk and Cheng, 2014). Animal models of thoracic aortic aneurysms have shown the beneficial effect of miR blockade in the prevention of aneurysm formation (Merk et al., 2012). Nevertheless, the role of miRs in the pathogenesis of human aortic aneurysm remains unclear.

The pathophysiology of the descending and abdominal aorta seems to be distinct from ascending and arch disease, especially as relates to atherosclerosis. However, overlapping pathophysiology exists regarding inflammation, ECM degradation and VSMC apoptosis (Wassef et al., 2001; Kuivaniemi et al., 2015). It has been noted clinically that patients with ascending aortic aneurysms have relatively limited systemic atherosclerosis. This finding was corroborated by evidence from imaging studies that found degree of calcification and intima-media thickness (both markers of (late and early) atherosclerosis) to be reduced in ascending thoracic aneurysm patients (Achneck et al., 2005; Hung et al., 2012). Moreover, the incidence of myocardial infarction was also low in these

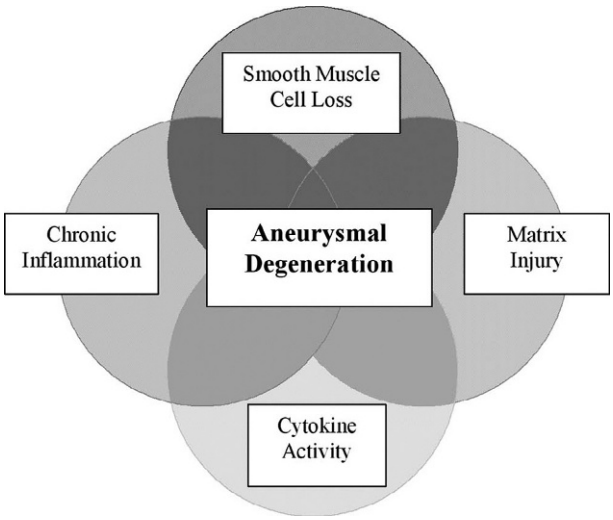

Fig. 5 The overlapping processes involved in the pathogenesis of aortic aneurysm. Reprinted with permission from Hackmann, A. E., Thompson, R. W. and LeMaire, S. A. (2007). In: Elefteriades, J. A. (ed.) *Acute aortic disease*, pp. 309–330. London: Informa Healthcare.

patients (Chau and Elefteriades, 2014). A causal link remains unclear although we speculate that higher MMP activity and altered hemodynamics of ascending aortic disease may play a role in this peculiarity (Chau et al., 2014).

Biomechanical Perspectives

From the mechanical perspective, aneurysm rupture occurs when the mechanical stresses acting on the aortic wall exceeds the maximum wall strength (Vorp and Vande Geest, 2005). The law of Laplace is often used to describe the forces acting on the walls of aneurysms. It states that the wall tension is proportional to luminal pressure and the radius of the vessel ($t = pr$) (Valentinuzzi and Kohen, 2011). However, this is an oversimplification as it assumes an idealized cylindrical shape; in reality aneurysms have complex geometries with irregular distributions of wall tension (Lasheras and The, 2007). The law of Laplace does not allow for local failure in complex geometric forms, which is often the inciting event in aortic ruptures (Gasser, 2016). Moreover, dissections are known to occur at small aortic dimensions (Pape et al., 2007). In vivo studies with epiaortic echocardiography demonstrate that ascending aortic distensibility diminishes, and wall stress increases, as the vessel diameter increases (Koullias et al., 2005). Engineering analyses using biaxial mechanical testing provide further evidence of aortic stiffening with dilatation; the resultant rise in wall stress increases risk of aneurysm rupture and dissection (Martin et al., 2013).

Etiology

Thoracic aortic aneurysms can be broadly classified into syndromic and nonsyndromic categories, with the former manifesting systemic features and the latter manifesting aortic disease alone. The etiology of AAAs is similar to thoracic in some cases. However, it must be stressed that most cases of AAAs do not presently have a clearly defined specific etiology.

Syndromic Thoracic Aortic Aneurysms

Thoracic aortic aneurysm is a feature of a number of well-described syndromes, the presence of which permits directed screening to aid diagnosis and therapy. These syndromes are often described as connective tissue disorders, the most prominent being Marfan syndrome.

Marfan syndrome

Marfan syndrome occurs due to an autosomal dominant mutation in the FBN1 gene, resulting in synthesis of defective fibrillin-1. Among other functions, fibrillin-1 modulates TFG-β signaling. Marfan patients exhibit elevated TGF-β signaling, which upregulates MMP production, resulting in increased ECM degradation. Histologically, this manifests as CMD. With a prevalence of 2-3 per 10,000 people (Judge and Dietz, 2005), Marfan patients have characteristic features, chiefly dolichostenomelia (long, thin extremities), ligamentous redundancy or laxity, ectopia lentis, aortic or mitral valve incompetence, and ascending aortic dilatation (Loeys et al., 2010). The ascending aortic dilatation has a typical morphology—annuloaortic ectasia (see later)—and the aortas of these patients have a strong propensity for rupture and dissection (Milewicz et al., 2005).

Ehlers–Danlos syndrome

The vascular form of Ehlers–Danlos syndrome (also designated "type IV") predisposes to aortic aneurysm and dissection due to defective type III collagen secondary to mutations in COL3A1 (Pepin et al., 2000).

Loeys–Dietz syndrome

Aneurysm formation (and arterial tortuosity) forms one of a triad of features characteristic of Loeys–Dietz syndrome. This syndrome is caused by mutations in TGF-β receptor 1 or 2. Other features include hypertelorism (widely-spaced eyes) and bifid uvula or cleft palate. These patients tend to have a particularly aggressive form of aortic aneurysm, as evidenced by early onset and rapid growth rate, as well as a high rate of premature aortic dissection (Loeys et al., 2006; Loeys et al., 2005).

Nonsyndromic Thoracic Aortic Aneurysms

The majority of nonsyndromic thoracic aneurysms are sporadic, often attributed to hypertension or atherosclerosis or simply labeled idiopathic. Nevertheless, the etiology is becoming clear in certain cases, as outlined later.

Bicuspid aortic valve

Bicuspid aortic valve refers to the presence of two leaflets instead of the normal tricuspid aortic valve morphology. This represents the most common congenital malformation of the heart, affecting 1.3% of the population (Michelena et al., 2015). Also associated with aortic coarctation, this inherited condition predisposes to aneurysm formation due to a *bona fide* "aortopathy" and not simply the result of poststenotic dilatation, as was once believed (Fedak et al., 2016). Aortic dilatation occurs at an accelerated rate,

especially in the presence with valvular dysfunction (stenosis, regurgitation). Aneurysms seem to result due to a complex interplay between genetic predisposition and hemodynamic consequences of the abnormal valve (Fedak et al., 2016; Padang et al., 2013).

Familial thoracic aneurysm and dissection (TAAD) syndrome

The strong heritability of thoracic aortic aneurysm suggests a familial syndrome without specific identifiable genetic defects. Family history studies have revealed that up to 20% of probands with ascending thoracic aortic aneurysms have a family member with known aneurysm disease (Biddinger et al., 1997; Albornoz et al., 2006), casting new light on cases previously attributed to other causes (or considered idiopathic). Multiple inheritance patterns exist, with autosomal dominance and reduced penetrance being most common. Multiple gene mutations have been found to cause familial TAAD (Brownstein et al., 2017; Ziganshin et al., 2015a).

Other causes

Rare causes of aneurysm include infection as well as particular inflammatory diseases. Infective (mycotic) aneurysms present mostly as localized, saccular dilatations. Syphilitic (luetic) aneurysms are a distinct subset of infective aneurysms, now almost of historical interest in developed countries. Inflammatory aneurysms often develop in the ascending aorta or arch as the result of an aortitis, in the context of Takayasu's disease, Behcet's disease, or giant cell arteritis (among others) (Goldfinger et al., 2014; Elefteriades et al., 2017).

Abdominal Aortic Aneurysms

Although AAAs can also develop in the context of connective tissue disorders, they are predominantly a degenerative phenomenon classically attributed to atherosclerosis (Isselbacher, 2005). However this assertion has become controversial in light of evidence showing conflicting associations between AAA and the traditional atherosclerotic risk factors (Lederle et al., 2003; Lederle et al., 1997). It has been suggested that immunologically mediated mechanisms may reconcile this discrepancy (Peshkova et al., 2016). Family history remains an important risk factor, suggesting an underlying genetic component, although not as powerfully or consistently as in thoracic aortic aneurysm disease.

Genetics of Thoracic Aneurysms

The genetic basis of thoracic aortic aneurysm formation has begun to be elucidated, and a number of candidate genes associated with this disease are now known. These genes are involved in ECM matrix regulation, smooth muscle function, and TGF-B signaling pathways. Furthermore, the MYLK (Wang et al., 2010) and ACTA2 (Guo et al., 2007) genes are specifically implicated in aortic dissection. The presence of mutations in these genes has the potential to influence the natural history of aneurysm disease, and hence its management on an individualized basis. Moreover, the prospect of routine whole-exome sequencing may enable prophylactic surgery (Brownstein et al., 2017; Ziganshin et al., 2015a).

Risk Factors

Despite many advances in our understanding of the mechanisms of aneurysm formation, the majority of aortic aneurysm disease does not have a clear pathogenesis. Various risk factors have been associated with an increased incidence of the disease—including family history of aneurysm disease, age, male sex, cigarette smoking, coronary artery disease, cerebrovascular disease, and hypercholesterolemia (Kent, 2014; Ahmed et al., 2016).

Natural History

Studies of large patient databases have characterized the behavior of aortic aneurysms, allowing evidence-based decisions regarding frequency of surveillance and timing of referral for surgical intervention before dissection or rupture can occur. Aneurysm diameter emerges as the major criterion for decision-making. It should be noted that *symptomatic* aneurysms affecting any portion of the aorta mandate surgery regardless of aortic size, as this generally heralds impending rupture. This point, that "symptoms trump size," is often overlooked and deserve strong emphasis.

In terms of disease progression, thoracic aortic aneurysm is an indolent disease with an average growth rate of 1 mm per year. Growth of aneurysms increases as a function of size (**Fig. 6**) and varies by aneurysm location (Elefteriades et al., 2015a). Although the abdominal aorta may sometimes dilate quickly, this is unusual for the thoracic aorta; a report of putative rapid growth of the thoracic aorta is usually explained by nonmeaningful oblique measurements across the aortic arch (Elefteriades and Farkas, 2010).

The importance of size is reflected by data showing that the risk of complications—rupture, dissection, or death—increases with aneurysm diameter (**Fig. 7**; Elefteriades and Farkas, 2010). Furthermore, the cumulative lifetime incidence of complications (dissection or rupture) increases sharply at particular aortic diameters (6 cm ascending, 7 cm descending—**Fig. 8**; Coady et al., 1997). Thus, the major criterion for surgical referral is maximum aortic size, with patients ideally operated on well before their

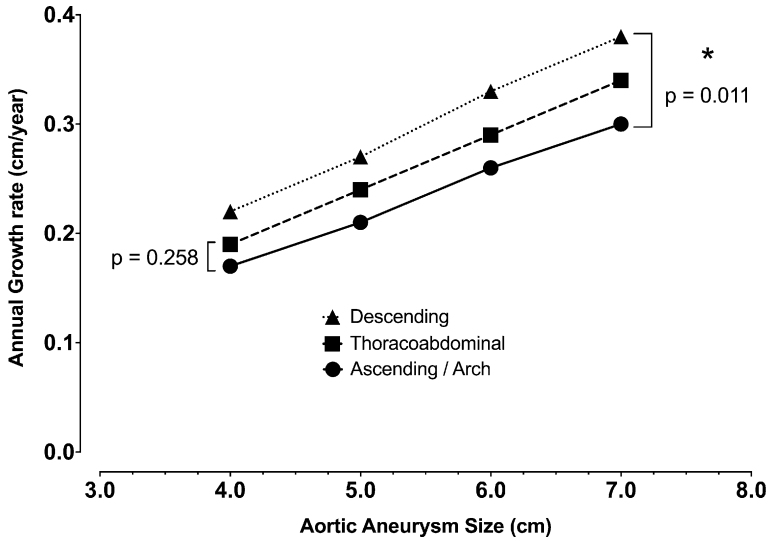

Fig. 6 Annual growth rates of the aorta. Reprinted with permission from Elefteriades, J. A., et al. (2015). Indications and imaging for aortic surgery: size and other matters. *Journal of Thoracic and Cardiovascular Surgery* **149**, S10–S13.

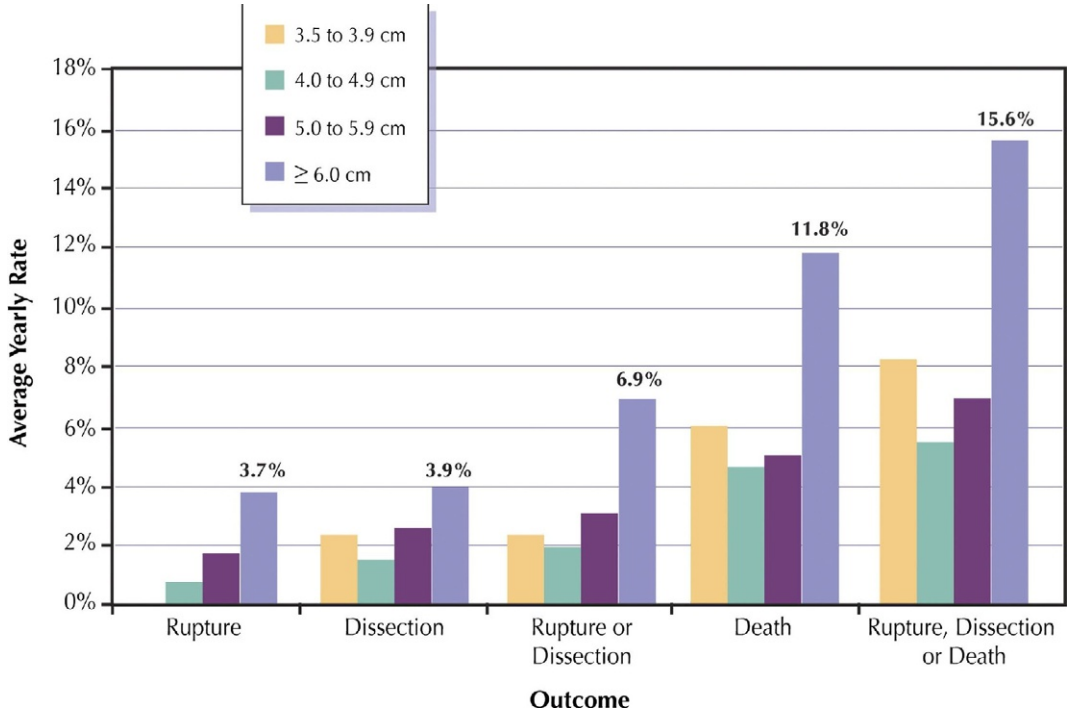

Fig. 7 Average annual rates of rupture, dissection, or death by aneurysm size. Reprinted with permission from Elefteriades, J. A. and Farkas, E. A. (2010). Thoracic aortic aneurysm. Clinically pertinent controversies and uncertainties. *Journal of the American College of Cardiology* **55**, 841–857.

aneurysms reach these dangerous dimensions. Patient size has also been shown to be a useful metric, with aortic size adjusted for body surface area correlating well with risk of complications (Davies et al., 2006). The so-called aortic body size index is most useful at the extremes of size—for very small or very large patients.

The etiology of disease also influences management decisions. Patients with syndromic aneurysms (Marfan syndrome, Ehlers–Danlos syndrome, Loeys–Dietz syndrome), bicuspid aortic valve, or familial cases may be at risk of complications at relatively small aortic diameters. Such patients are therefore often managed more aggressively, with lower size thresholds for surgical referral. Fig. 9 outlines our surgical intervention criteria (Elefteriades, 2008), while Fig. 10 (Brownstein et al., 2017) shows the intervention criteria for specific mutations.

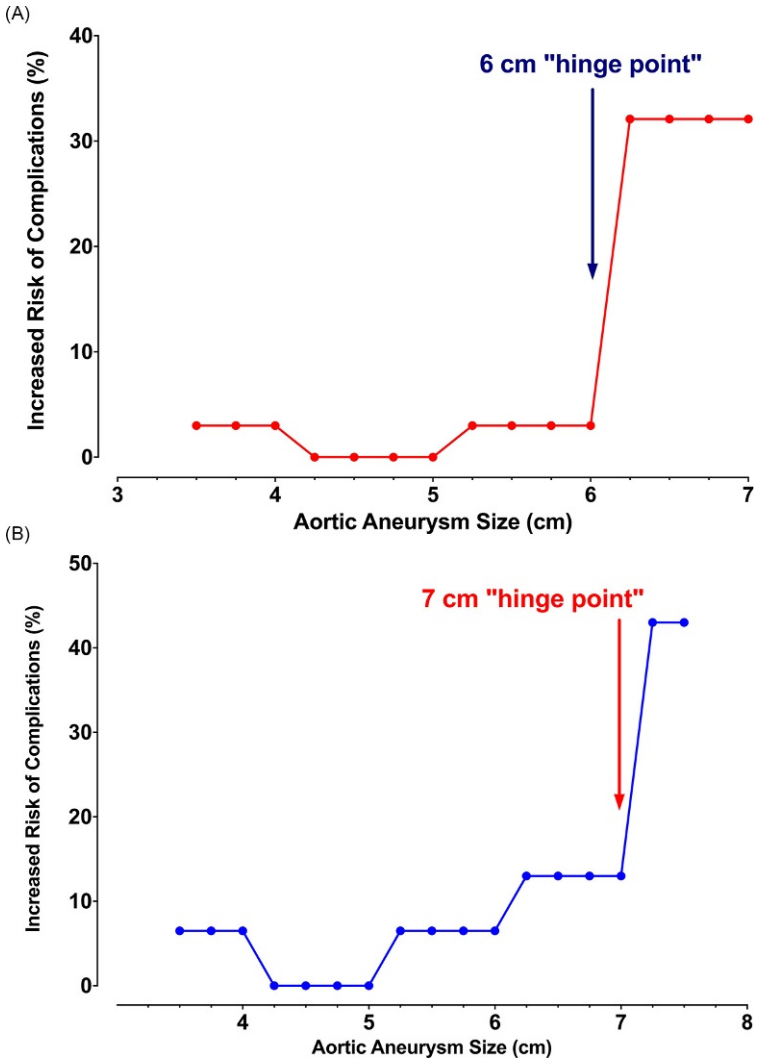

Fig. 8 Percentage increased risk of complications as function of aortic size. Panel A: ascending aorta, Panel B: descending aorta. Modified with permission from Coady, M. A., et al. (1997). What is the appropriate size criterion for resection of thoracic aortic aneurysms? *Journal of Thoracic and Cardiovascular Surgery* **113**, 476–491.

APPENDIX

The Yale Center for Thoracic Aortic Disease Recommended Surgical Intervention Criteria for Thoracic Aortic Aneurysms

1. Rupture
2. Acute aortic dissection
   a. Ascending requires urgent operation
   b. Descending requires a "complication-specific approach"[28]
3. Symptomatic states
   a. Pain consistent with rupture and unexplained by other causes
   b. Compression of adjacent organs, especially trachea, esophagus, or left main stem bronchus
   c. Significant aortic insufficiency in conjunction with ascending aortic aneurysm
4. Documented enlargement
   a. growth ≥1 cm/yr or substantial growth and aneurysm is rapidly approaching absolute size criteria
5. Absolute size (cm)

	Marfan's	Non-Marfan's
Ascending	5.0 cm	5.5 cm
Descending	6.0 cm	6.5 cm

Fig. 9 Yale Aortic Institute guidelines for surgery of thoracic aortic aneurysms. NB Marfan size criteria apply for patients with family history of aneurysm. Reprinted with permission from Coady, M. A., Rizzo, J. A. and Elefteriades, J. A. (1999). Developing surgical intervention criteria for thoracic aortic aneurysms. *Cardiology Clinics* **17**, 827–839.

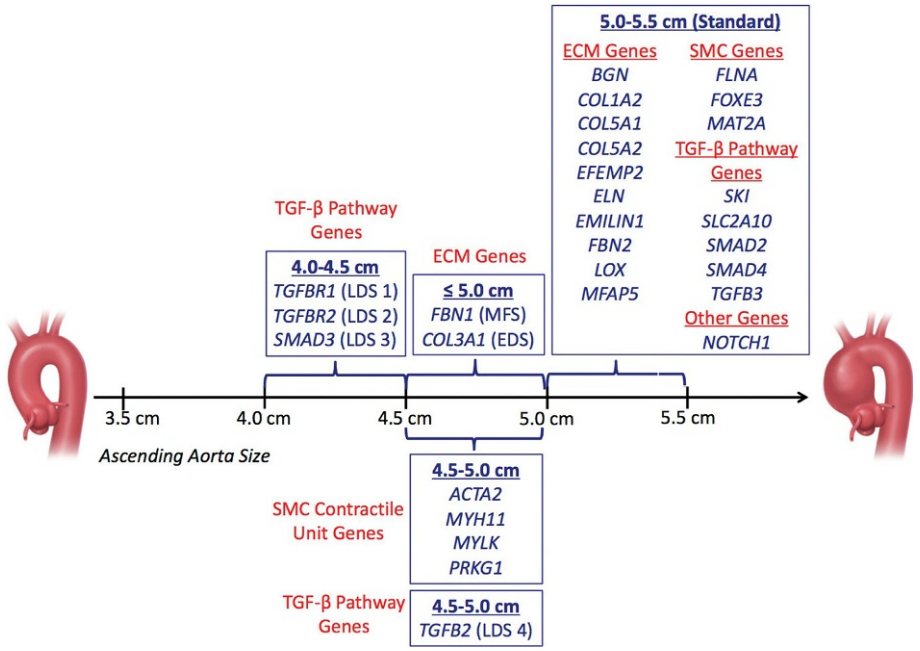

Fig. 10 Simplified schematic illustration of ascending aorta dimensions for prophylactic surgical intervention divided by gene category: ECM genes, SMC contractile unit and metabolism genes, and TGF-β signaling pathway genes. *ECM*, extracellular matrix; *LDS*, Loeys–Dietz syndrome; *MFS*, Marfan syndrome; *SMC*, smooth muscle cell; *EDS*, Ehlers–Danlos syndrome. Reprinted with permission from Brownstein, A. J. et al. (2017). Genes associated with thoracic aortic aneurysm and dissection: an update and clinical implications. *Aorta* (*Stamford*) **5**, 11–20.

AAAs also exhibit growth rates that vary with initial aneurysm diameter. Multiple studies have characterized the natural history of AAA. Smoking has been shown to accelerate aneurysm growth, while diabetes and peripheral arterial disease are associated with reduced growth rates (Brady et al., 2004; Vega de Céniga et al., 2006). The risk of rupture also increases with size (Cronenwett et al., 1985; Nevitt et al., 1989); thus, threshold for intervention is aneurysm diameter of 5.5 cm (Chaikof et al., 2009). Rapid expansion further portends rupture and should also prompt surgical referral (>0.5 cm/year thoracic aorta (Hiratzka et al., 2010), >0.7 cm/year abdominal aorta (Chaikof et al., 2009)).

Precipitation of Aortic Dissection or Rupture

Knowledge of the pathophysiology, natural history, and genetics of aortic aneurysms has enabled us to understand more reliably the onset of their acute complications. In particular, the role of hypertensive surges as the inciting trigger for aortic dissection has been demonstrated in the context of extreme physical exertion. We speculate that this may also account for the curious observation that aortic events occur at times of great emotional stress (Hatzaras et al., 2007). Although a full understanding remains elusive, we propose the following sequence of events (**Fig. 11**; Elefteriades and Farkas, 2010):

1. Genetic predisposition—The patient's genotype defines their propensity for aortic aneurysm formation (or dissection).
2. Medial degeneration—The structural integrity of the aortic wall is compromised by a combination of ECM destruction, cytokine activity, chronic inflammation, and smooth muscle cell loss.
3. Aneurysm formation—The weakened aorta progressively dilates, increasing wall stress.
4. Hypertensive episode—Sudden surges in blood pressure, often at moments of extreme exertion or emotion, result in wall stress exceeding the ultimate tensile strength of the aortic wall.
5. Acute event—The aorta dissects and/or ruptures.

Epidemiology

Data from the Centers for Disease Control and Prevention (CDC), together with statistics from other countries, suggest that aortic aneurysm is being diagnosed at a greater frequency (Acosta et al., 2006; Clouse et al., 1998; Best et al., 2003). However, an accurate knowledge of the epidemiology of aortic aneurysm (particularly thoracic) is difficult to ascertain due to a number of methodological challenges. These include referral center bias, unknown presence of latent cases, misdiagnosis, confusion in terminology, and limitations of administrative databases (Elefteriades and Rizzo, 2007).

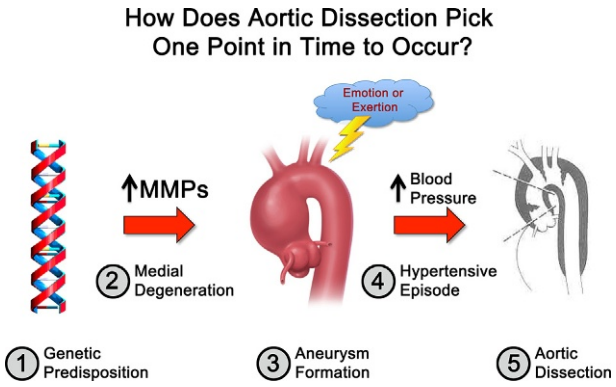

Fig. 11 Proposed series of events that result in aneurysm dissection or rupture. Modified with permission from Hatzaras, I. S., et al. (2007). Role of exertion or emotion as inciting events for acute aortic dissection. *American Journal of Cardiology* **100**, 1470–1472.

Nevertheless, CDC data show that aortic aneurysm accounted for 9,988 deaths in 2015 (National Center for Injury Prevention and Control, 2015). Prevalence of thoracic aortic aneurysm is difficult to obtain for the reasons outlined above. However, the incidence of thoracic aortic aneurysm has been reported as 10.4 per 100,000 population, equally distributed between men and women, although women are 12 years older than men at diagnosis (Clouse et al., 1998). The prevalence of AAA is 5.5% in the over-65 age group and is considerably higher in men (Li et al., 2013).

Reasons for the apparent increase in diagnosis of aortic aneurysms remain unclear although the aging population undoubtedly contributes to this phenomenon. Moreover, there is evidence for a true increase in incidence rather than merely increased detection due to the rising use of 3-D diagnostic imaging (Acosta et al., 2006; Clouse et al., 2004).

With regard to acute complications of aneurysm disease, acute aortic dissection has an incidence of 3.5–6/100,000 (Clouse et al., 2004; Howard et al., 2013), while the incidence of ruptured thoracic aortic aneurysm is 3.5–6/100,000 (Clouse et al., 2004; Johansson et al., 1995). Ruptured AAA has an incidence of 10.6/100,000 equally distributed between the sexes. This rises to 46 per 100,000 men in their 60s, and more than 100 per 100,000 men in their 70s (Acosta et al., 2006).

AAA Screening

Screening enables identification of asymptomatic patients and permits appropriate surveillance or operative management to reduce morbidity and mortality related to AAA rupture. The U.S. Preventive Services Task Force recommends (LeFevre, 2014) one-time screening with ultrasonography for all men aged 65–75 who have ever smoked, with high certainty of overall moderate benefit. If the patient does not have an aneurysm at age 65, he is almost certain never to die from AAA. Selective screening of nonsmokers is recommended on the basis of professional judgment or patient preferences. Insufficient evidence has been found for screening of women, reflecting the male preponderance of the disease. No appropriate general population screening regimens have been established or validated for thoracic aortic aneurysms.

Biomarkers

The silent nature of aneurysm disease and the devastating consequences of its complications warrant the discovery of a biomarker. An ideal biomarker should not only detect aortic aneurysms but also provide some assessment of rupture/dissection risk without the need for actual aortic tissue. (Unlike other organs, the aorta is not amenable to biopsy.) Moreover, the biomarker should help identify at-risk populations.

A better understanding of the pathogenesis of aneurysm formation may guide the search for biomarkers. For example, an appreciation of the role of inflammation in aneurysm formation has led to the investigation of aneurysm-related RNA signatures in circulating leukocytes. The distinct gene expression in peripheral blood cells of thoracic aneurysm patients has shown promise as a marker of thoracic aortic aneurysm in the general population, with a sensitivity and specificity of 72% and 90% (**Fig. 12**) (Wang et al., 2007). A similar philosophy has been applied to cytokines. Advanced glycation end-products (AGEs) have recently been implicated in the formation of thoracic aortic aneurysm (Prasad et al., 2016). The presence of soluble receptors for these AGEs (sRAGE) detectable in the peripheral circulation makes this another candidate for an aneurysm biomarker. miRs, intracellular regulators of gene transcription, have also been discovered in the circulation and present another potential biomarker of aneurysm disease. Studies have shown differential miR expression in the blood of patients with AAA relative to controls (Stather et al., 2015).

A number of other biomarkers are under investigation but sadly most do not detect aneurysm disease before its acute complication. As such they do not fulfill the true clinical need.

Clinical Features

Symptoms

The vast majority of aortic aneurysms are asymptomatic. Symptomatic cases (5%–10%) (Elefteriades et al., 2017) present with pain due to stretching of aortic tissue and/or compression of adjacent structures.

The site of the pain provides some indication of aneurysm location. Hence ascending and arch aneurysms present with retrosternal pain, while descending aneurysms present with interscapular back pain. Abdominal aneurysms may cause throbbing abdominal, left flank, or lower back pain.

Compressive symptoms are often associated with arch aneurysms. Impingement on the esophagus may cause dysphagia (the so-called dysphagia lusoria), while airway compression may result in dyspnea and stridor. Compression of the superior vena cava results in facial plethora and edema of the neck and upper limbs. Furthermore, the aneurysm may stretch the recurrent laryngeal nerve causing hoarseness. Descending aneurysms may erode into adjacent lung or esophagus, presenting with hemoptysis and hematemesis, respectively.

In addition to pain, AAAs may compress the duodenum, left iliac vein, left ureter, bladder, and testicular veins. The resultant symptoms include nausea and vomiting, left lower limb swelling, urinary symptoms, and varicocele, respectively.

Signs

Depending on their location, ascending aneurysms may present with the murmur of aortic valve regurgitation due to stretching of the aortic annulus and subsequent poor leaflet coaptation, rendering the valve incompetent. Descending aneurysms generally have no signs. Depending on body habitus, AAAs may be palpated as a pulsatile, expansile mass in the epigastrium.

Acute Complications: Dissection and Rupture

The clinical features of aortic dissection are legion. The possibility of cardiac, neurological, abdominal, and vascular symptoms and signs justifies its "great masquerader" label (Isselbacher, 2007). Aortic dissection classically presents as sudden, severe, tearing chest pain. As with aneurysms, the location of the pain is instructive, and its radiation provides some indication of distal extension. The associated features of hemodynamic instability, dyspnea, syncope, pulse deficit, peripheral neurological deficit, and other signs can be attributed to occlusion of branch vessels, disruption of the aortic valve (with subsequent acute aortic regurgitation), and aortic rupture (**Fig. 13**; Elefteriades et al., 2012).

Aortic rupture presents with features dependent on the location of the event. Rupture into the pericardium manifests features of cardiac tamponade, but most ruptured thoracic aortic aneurysms present with chest pain and hypotension secondary to hemorrhage into the thoracic cavity. Ruptured AAA classically presents as sudden abdominal/flank pain and hypotension in the presence of a pulsatile mass. However, this triad is only present in a third of cases (Brady and Chaikof, 2012). The pain often radiates to the testicles, rectum, or groin. Other features include hematemesis and melena in the setting of rupture into the duodenum, or

congestive heart failure due to rupture into the adjacent vena cava (Silen, 2010). Retroperitoneal rupture may be contained and hence present as back pain without hypotension.

Investigations

There are no laboratory tests that aid in the diagnosis of aortic aneurysm. Imaging remains the cornerstone of diagnosis.

Although quick, inexpensive, and easily available, chest radiography has a limited role in the diagnosis of aortic aneurysm. However, the humble chest radiograph may reveal the contours of the thoracic aorta nicely. Aneurysms may manifest as mediastinal widening on the frontal projection, with a prominent aortic knob and lateral bulging of the normally crisp stripe representing the descending aorta (Danias, 2007).

Echocardiography can clearly image the proximal ascending aorta and can provide information regarding aortic valve morphology and function. Transthoracic echocardiography often reveals aneurysms incidentally while investigating suspected valvular disease. Transesophageal echocardiography (TEE) enables visualization of all parts of the thoracic aorta except the distal ascending and aortic arch. This is due to poor acoustic penetration owing to the intervening trachea and left main bronchus (the "blind spot" of TEE) (Mahajan et al., 2008).

Computed tomography (CT) and CT angiography have become modality of choice for imaging the aorta. Their inherent high resolution, fast image acquisition, ability to visualize the entire aorta, and wide availability make this modality very valuable. Three-dimensional image reconstruction can also enable detailed analysis of aneurysm morphology, while ECG gating minimizes motion artifact (Muhs et al., 2006; Schlösser et al., 2008). However, CT has a number of important limitations that must be borne in mind. The most proximal ascending aorta is suboptimally assessed if the axial planes are too coarse. Dimensions of aortic valve annulus may be spurious due to distortion of the valve plane into a more vertical orientation by enlargement of the ascending aorta. Indeed, aortic tortuosity may result in nonorthogonal slices and therefore yield inaccurate measurements (Elefteriades and Farkas, 2010).

Finally, the effect of cumulative radiation exposure due to multiple examinations, and also the possibility for contrast-induced nephropathy, cannot be ignored. Contrast-enhanced CT is ideal for the detection of aortic dissection due to its excellent ability to detect the inciting intimal tear, extent of the dissection process, and morphology of the true and false lumens (Danias, 2007).

Magnetic resonance imaging provides full, multiplanar imaging of the aorta without utilizing radiation or nephrotoxic contrast agents. However, long image acquisition times and incompatibility with pacemakers, automatic implantable defibrillators, and metallic implants, together with more limited availability, restrict the applicability of this imaging modality (Gaztanaga et al., 2011) to acute aortic dissection patients.

Abdominal ultrasonography is the preferred method for imaging AAAs with near perfect sensitivity and specificity (LaRoy et al., 1989). Although operator dependent, this noninvasive modality is also ideal for surveillance of asymptomatic cases. CT is a more reproducible imaging modality and is useful for preoperative planning as well as postoperative assessment (Brady and Chaikof, 2012).

"Guilt by Association" Paradigm

The silent nature of thoracic aortic aneurysms means this dangerous condition is often only discovered incidentally during imaging studies performed for other diagnostic reasons. However certain clinical and anatomical associates have been identified that may suggest the presence of thoracic aneurysms (Elefteriades et al., 2015b) and encourage diagnostic imaging of the aorta. These so-called Guilt by association factors include intracranial aneurysm, AAA, bovine aortic arch configuration, renal cyst, positive thumb-palm sign, family history, and temporal arteritis (**Fig. 14**; Elefteriades et al., 2015b; Dumfarth et al., 2015; Kuzmik et al., 2010; Ziganshin et al., 2016; Hornick et al., 2012).

Treatment

Medical Therapy

Medical treatment for aortic aneurysms remains limited. The goals of therapy are arrest of aneurysm growth and prevention of complications (dissection or rupture). These goals are approached through aggressive risk factor management, avoidance of strenuous activity, and pharmacological reduction of hemodynamic stress on the aortic wall (Hackmann et al., 2007).

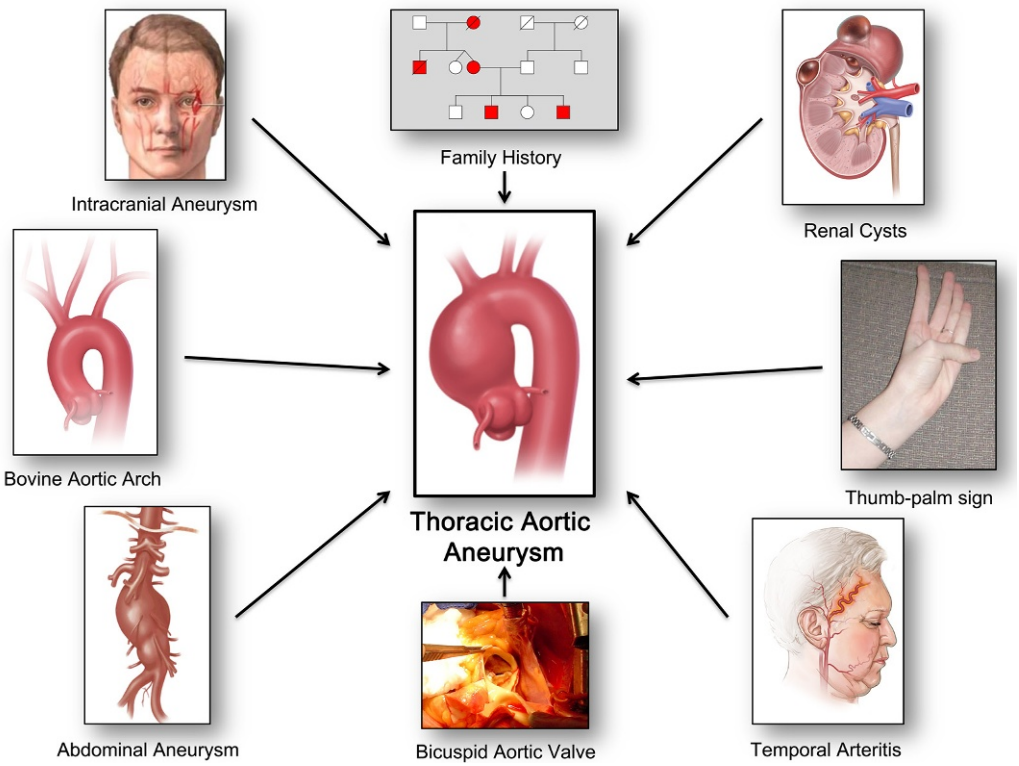

Fig. 14 "Guilt by association" factors linked to thoracic aortic disease. Reprinted with permission from Elefteriades, J. A., Sang, A., Kuzmik, G. and Hornick, M. (2015). Guilt by association: paradigm for detecting a silent killer (thoracic aortic aneurysm). *Open Heart* **2**, e000169.

Thus far, drug therapy has proved to be largely ineffectual. The role of beta adrenergic antagonists remains controversial. These drugs are of theoretical benefit through their reduction of blood pressure, and as anti-impulse therapy to reduce the rate of rise of arterial pressure (dP/dT_{max}) (Sanz et al., 2007). However, there is little robust evidence for their efficacy in slowing the rate of aortic dilatation (**Table 1**; Ziganshin et al., 2015b). Moreover, they are of no benefit in prevention of the clinical end-points of dissection or death (Ziganshin et al., 2015b). The initial success of angiotensin receptor blockers in reducing the rate of aneurysm growth (Brooke et al., 2008) was not borne out in larger clinical trials (Lacro et al., 2014; Forteza et al., 2016). The MMP inhibitor doxycycline also failed to slow the growth of AAA despite promising results in animal models (Meijer et al., 2013). Statins have demonstrated some effectiveness in reducing AAA growth (Takagi et al., 2012), as well as a protective effect in thoracic aortic aneurysms (Stein et al., 2013).

Surgical Therapy

Surgery for aortic aneurysms varies according to the location of the aneurysm. In general, operative management aims to eliminate the risk of rupture or dissection by resection of the aneurysmal segment and its replacement with a synthetic graft. Made of polyethylene terephthalate (Dacron), these grafts are durable and nonthrombogenic, thereby avoiding the need for long-term anticoagulation therapy.

Ascending Aortic Aneurysms

Treatment of ascending aneurysms requires a detailed understanding of the anatomy of the ascending aorta. Extending from the aortic valve annulus to the origin of the innominate (or brachiocephalic) artery, the ascending aorta consists of a proximal sinus portion connected to a tubular portion, with an intervening sinotubular junction. The sinus portion is commonly referred to as the aortic root and contains the three sinuses of Valsalva from which the coronary arteries arise. The involvement of these subcomponents guides the surgical management of ascending aortic aneurysms. Three common patterns exist (**Fig. 15**; Elefteriades et al., 2017)—supracoronary aneurysm, annuloaortic ectasia, and diffuse tubular enlargement.

Supracoronary aneurysms are confined to the tubular portion of the ascending aorta, distal to the coronary artery ostia. These represent the most common form and are treated using a tube graft. Annuloaortic ectasia refers to dilatation of the aortic annulus together with the proximal aorta, giving rise to a "flask-like" morphology. This is typically seen in Marfan syndrome. Treatment involves replacement of the aortic valve and root, often using a composite valve-graft (the modified Bentall procedure). These root replacements have recently been shown to achieve a *normal* life expectancy for affected patients, an outlook identical to an age- and sex-matched population (Mok et al., 2017). Valve-sparing techniques include the David procedure ("reimplantation" technique) and the Yacoub procedure ("remodeling" technique) (Milewicz et al., 2005). These popular methods preserve the patient's own aortic valve. Tubular diffuse enlargement shares features of the other two configurations, with mild dilatation of the aortic annulus and proximal ascending aorta, but with more subtle and uniform ascending aortic dilatation. Treatment is often based on patient age, with composite valve-grafts used in younger patients, as this protects against late dilatation of the proximal aortic root. A more limited approach, utilizing a supracoronary tube graft, may suffice in older patients.

Aortic Arch Aneurysms

Aortic arch surgery is complicated by the need to consider cerebral protection during the operation. Resection of arch aneurysms requires special management of the brachiocephalic vessels that supply the head and arms (innominate, left common carotid, and left subclavian arteries). These arteries are often surgically detached from the native aortic arch as "Carrel patches," whereby two or three vessels are excised *en bloc* with a rim of aortic tissue and subsequently reattached to an aortic graft (**Fig. 16**; Ziganshin et al., 2014). Alternatively, prefabricated branched grafts may be used and the arch vessels anastomosed individually.

Cerebral protection is achieved through the use of deep hypothermic circulatory arrest (DHCA). Hypothermia reduces the metabolic rate of tissues and, in this context, enables a short period of ischemia without complications. At 18°C, cerebral metabolic rate is reduced to 17% of normal (McCullough et al., 1999), enabling approximately 40 minutes of safe circulatory arrest during which the arch can be managed in a bloodless field (Ziganshin et al., 2014). If this time interval is insufficient, direct cerebral perfusion techniques are required to prevent neurological sequealae (Hagl et al., 2001). DHCA and perfusion techniques have been developed to the point that neurologic function is fully and reliably preserved in the vast majority of patients (Elefteriades and Ziganshin, 2015).

Furthermore, arch aneurysms often extend into the descending aorta. The repair of such extensive aneurysms in a single operation is anatomically awkward and prohibitively risky. Hence a staged approach is often taken, with an initial ascending and arch "Elephant trunk" procedure facilitating a subsequent more distal completion procedure (Borst et al., 1983).

Descending and Thoracoabdominal Aneurysms

Repair of these often extensive lesions, particularly thoracoabdominal aneurysms (**Fig. 17**; Elefteriades et al., 2017), requires careful attention to perfusion of the abdominal viscera and spinal cord to prevent ischemic complications, while the aortic cross clamp is applied (Crawford et al., 1986). Spinal cord injury is a particular concern (Griepp and Griepp, 2015). Although the blood supply to

the spinal cord is segmental, a significant portion is delivered via the "artery of Adamkiewicz." Its identification with spinal CT angiography enables preoperative planning to prevent its occlusion (Yoshioka et al., 2003).

Protective techniques to reduce the risk of paraplegia include left heart bypass (left atrium to femoral artery), cerebrospinal fluid drainage (Coselli et al., 2002), mild systemic hypothermia (Griepp and Griepp, 2015), and branch vessel attachment (via the inclusion technique) (Kouchoukos et al., 2013). Moreover, spinal cord monitoring allows intraoperative assessment of spinal cord injury (Conrad et al., 2007). Although these techniques have rendered substantial improvements in safety, paraplegia continues to be a dreaded potential complication of extensive thoracoabdominal aortic replacement procedures.

Abdominal Aneurysms

AAAs can be repaired via the traditional open surgical approach or by endovascular means (endovascular aneurysm repair—EVAR). Open surgical repair involves suturing a tube graft within the aneurysm sac, whereas EVAR involves the placement of an "endograft" within the aneurysm. Endografts are polyester or PTFE modular grafts surrounded by a wire frame that are packaged into a small configuration that can be deployed via the femoral or iliac arteries (Brady and Chaikof, 2012). With its lower early mortality rates,

EVAR has shown benefit in the context of ruptured AAA (Veith et al., 2009). However, its use is contingent on patients having suitable anatomy, as well as various other technical and logistical aspects. EVAR has been used for treatment of descending thoracic aneurysms (thoracic EVAR, TEVAR) (Dake et al., 1994), but its applicability to typical fusiform degenerative aneurysms remains controversial (Elefteriades and Percy, 2007).

EVAR has a number of problematic complications including endoleak (Bashir et al., 2009), graft migration, and occlusion of the iliac limbs of bifurcated grafts. Endoleak is the most common complication and refers to continued flow into the aneurysm sac after deployment of the endograft. Also, EVAR patients require regular follow-up at 6–12 monthly intervals with surveillance CT scans to monitor for adverse events (Brady and Chaikof, 2012).

The benefit of EVAR must be assessed in light of the indolent nature of aortic aneurysms. Given that aneurysms grow slowly, short-term follow-up cannot yet provide solid evidence for its benefit versus surveillance and medical management alone. Medium-term results are required to assess the true effectiveness of this therapy.

Conclusion

Aortic aneurysm is a clinically silent, but highly virulent, disease. Although the role of surgery is well-established, much work remains to be done with regard to diagnosis of latent cases and identification of those patients at high risk of dissection or rupture. Greater understanding of disease pathogenesis may provide better therapeutic targets and reveal a much sought-after diagnostic biomarker. Whole-exome sequencing promises to identify causative mutations, while improved imaging and engineering analyses have the potential to refine decision-making beyond merely size criteria. Moreover, evolution of endovascular techniques will expand our management options and hopefully yield improved future outcomes. These advances will pave the way for management of this disease on a truly individual basis.

Introduction

Angina-type chest pain, syncope, and congestive heart failure (CHF) are common manifestations of aortic stenosis (AS) with CHF typically being the late, end-stage result that links AS and aortic regurgitation (AR) (Brown et al., 2009a; Iung et al., 2003). In general, CHF in the setting of aortic valve disease carries a dismal prognosis. Patients with AS and CHF have an expected survival of less than 2 years when treated medically (Ross and Braunwald, 1968). More contemporary data demonstrated that the median survival of patients with medically treated AS is 1 year and at 5 years 93.6% of the patients are dead (Monin et al., 2003; Kapadia et al., 2015; Leon et al., 2010; Varadarajan et al., 2006; Brown et al., 2008; Clavel et al., 2008; Pai et al., 2008; Tribouilloy et al., 2009) (**Table 1**).

[a]Data not provided. Estimated from Kaplan Meier survival curve.

Patients with heart failure symptoms secondary to AR also have a dismal prognosis with only 50% of the patients alive after 3 years (Kamath et al., 2009).

Surgical aortic valve replacement (SAVR) is currently the standard treatment for symptomatic severe AS. In general, it is associated with low peri-procedure morbidity and mortality, symptomatic improvement, and improvement in long-term survival (Brown et al., 2009b; Surgeons TSoT, n.d.). On average, the expected survival after SAVR is approximately 80%–85% at 5 years, 65%–75% at 10 years, and 45%–55% at 15 years (David et al., 2001; Dellgren et al., 2002; Stahle et al., 1997). The functional status, comorbidities, and age of each individual patient have been shown to significantly affect outcomes (Cohen et al., 1999). While patients with normal preoperative left ventricular ejection fraction (LVEF) have an estimated 15-year survival of 62.3%, the presence of left ventricle (LV) dysfunction significantly reduces the long-term survival after aortic valve replacement (AVR). It is 47.6% for those with LVEF 35%–49%, 41% for LVEF 20%–34%, and 36.9% for LVEF <20% (Une et al., 2015).

Many patients with aortic valve disease and CHF are not candidates for surgery given their age, comorbidities, frailty, or the presence of advanced cardiac disease that make their surgical risk unacceptable (Iung et al., 2003; Pellikka et al., 2005). However, with the introduction of transcatheter aortic valve replacement (TAVR), patients who are considered at high or extreme risk for surgery may still be able to experience a benefit similar to those who undergo SAVR. Several studies comparing TAVR to SAVR in extreme, high, and intermediate risk patients have demonstrated similar procedural, short-term, and medial-term outcomes (Mack et al., 2015; Deeb et al., 2016; Leon et al., 2016a,b; Reardon et al., 2016). Despite their high operative risk, most of these patients can benefit from either SAVR or TAVR. Both have been shown to improve their symptoms, cardiac function, and long-term survival when compared to medical management. In this chapter we will review the indications for surgical and transcatheter management of aortic valve disease, with particular attention to the outcomes of patients with advanced heart failure symptoms (NYHA class III–IV) and left ventricular dysfunction (LVEF ≤35%).

Aortic Stenosis and Congestive Heart Failure

AS is mainly considered a disease of the elderly (Nkomo et al., 2006; Lindroos et al., 1993). It is estimated that 2.8% of the population older than 70 years have symptoms related to AS (Nkomo et al., 2006; Lindroos et al., 1993). Of them, 40%–60% have NYHA class III–IV symptoms, and only one third of patients with LVEF ≤35% will eventually proceed to SAVR (Iung et al., 2003; Pai and Varadarajan, 2010; Bach, 2011).

Severe AS is defined a valve area of ≤1 cm^2 with a mean aortic valve gradient of at least 40 mmHg and a peak velocity greater than 4 m/s (Nishimura et al., 2014). The left ventricular outflow obstruction caused by severe AS leads to chronic pressure overload of the LV. To compensate, the LV hypertrophies in order to decrease wall stress. The magnitude and adequacy of that ventricular remodeling and the associated changes in systolic ventricular function determine the clinical presentation, hemodynamic characteristics, response to treatment, and ultimately prognosis (Olson et al., 1987; Carabello, 2006; Brogan et al., 1993; Chukwuemeka et al., 2006).

There are three mechanisms AS can lead to heart failure symptoms: (1) *Diastolic dysfunction*: it is the result of LV hypertrophy, increased wall thickness, and a decreased LV volume to mass ratio. LV end diastolic pressure (LVEDP) increases due to worsening compliance and is not directly from systolic failure (Bonow et al., 2008; Gaasch et al., 1976; Hess et al., 1984; Murakami et al., 1986). Because of the multiple pathophysiologic mechanisms and variable compensatory responses, AS can be viewed as multiple clinical entities based on ejection fraction, stroke volume (SV), and gradient. (2) *Systolic dysfunction secondary to afterload mismatch*: If the hypertrophic process is inadequate to compensate for the increased afterload, wall stress increases and the ejection fraction falls. This condition is called "afterload mismatch" and limits fiber shortening (Olson et al., 1987; Carabello, 2006; Brogan et al., 1993; Chukwuemeka et al., 2006; Bonow et al., 2008). There are two subgroups within this category: (a) preserved SV and therefore elevated transaortic gradients and (b) reduced SV and therefore low transaortic gradient. This last group is difficult to differentiate from the next one. (3) *Systolic dysfunction secondary to intrinsic myocardial dysfunction*: Persistently elevated wall stress, inadequate blood supply, and superimposed ischemia or infarction, myocardial fibrosis, and abnormalities of calcium handling further depress myocardial contractility. As before, these patients have diminished SV and low transvalvular gradients (Carabello, 2006; Bonow et al., 2008). If myocardial dysfunction is secondary to afterload mismatch, SAVR/TAVR is associated with good outcomes. If intrinsic myocardial dysfunction predominates, the response to valve replacement is less favorable with higher operative mortality and less LVEF improvement after SAVR/TAVR. Despite this, these patients have a significantly better prognosis with SAVR/TAVR when compared to medical management alone (Carabello, 2006; Chukwuemeka et al., 2006; Connolly et al., 1997, 2000; Baron et al., 2016; O'Sullivan et al., 2015; Lauten et al., 2014; Conrotto et al., 2016) (**Fig. 1**).

CHF Secondary to AS With Normal Left Ventricular Function and Normal SV

When the LV hypertrophic compensation is adequate, the wall stress normalizes and the left ventricular function is maintained (**Fig. 1**; Nishimura et al., 2014; Olson et al., 1987; Chukwuemeka et al., 2006). These patients have normal left ventricular function and SV as evidenced by a normal or supra-normal ejection fraction. Therefore, the transvalvular gradient is elevated. LVEDP is elevated secondary to decreased compliance from diastolic dysfunction and increased afterload.

These patients respond very well to SAVR and or TAVR. Their surgical risk tends to be low with the risk adjusted operative mortality around 1.6%–2.3%, which has steadily declined over the last 10 years (Brown et al., 2009a; Surgeons TSoT, n.d.).

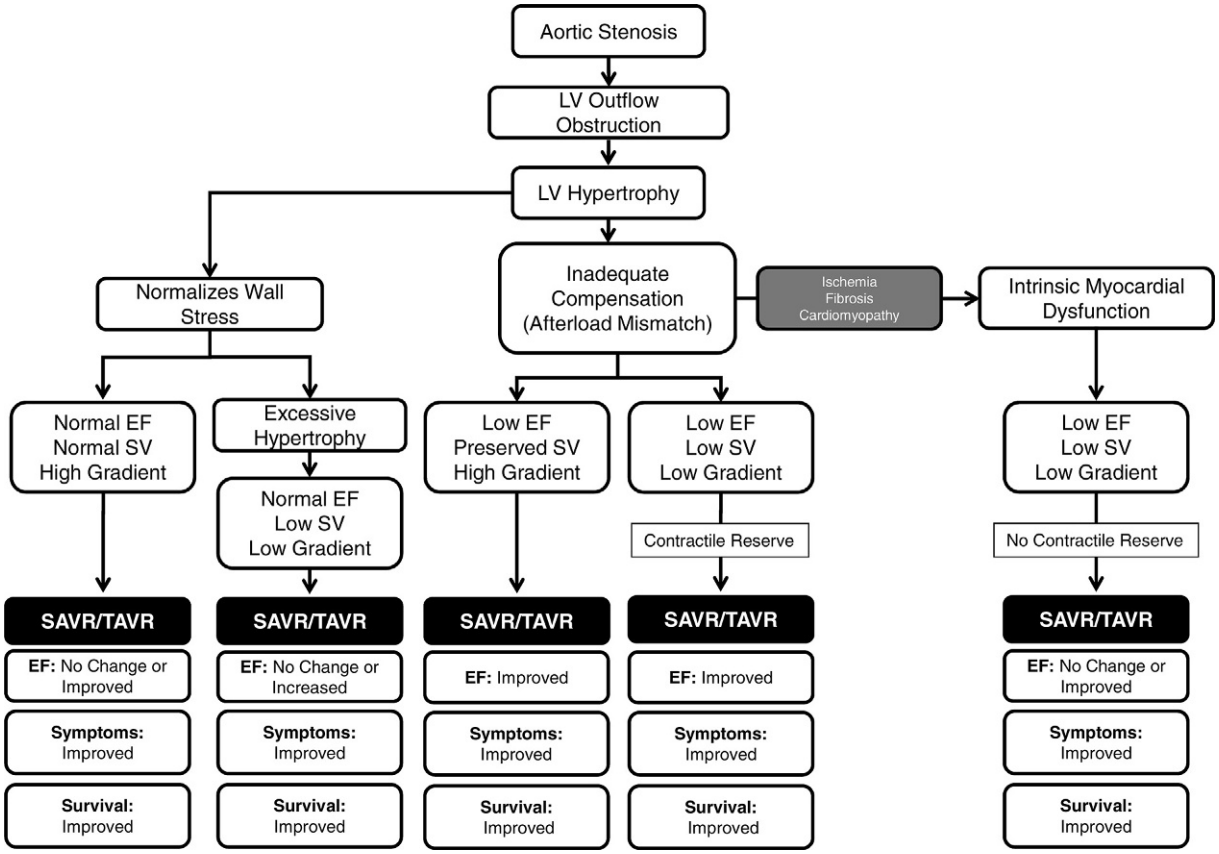

Fig. 1 Mechanisms responsible for heart failure in aortic stenosis and response to aortic valve replacement.

The presence of heart failure symptoms and LV dysfunction increase operative mortality (Brown et al., 2009a; Surgeons TSoT, n.d.). For example, patients with CHF symptoms and a LVEF <30% have an operative mortality of 5.2% (Brown et al., 2009a).

SAVR has been shown to effectively alleviate symptoms and improve quality of life (Vahanian and Otto, 2010). Patients with normal LVEF have a long-term survival similar to that expected for an age- and sex-matched population after AVR (Kvidal et al., 2000). However, there is an excess mortality for patients with NYHA class III–IV symptoms (Vahanian and Otto, 2010; Malaisrie et al., 2010; Kvidal et al., 2000) and for patients with LV dysfunction (Hannan et al., 2009). Even small decrement in LVEF will have negative impact in survival regardless of symptoms (Hannan et al., 2009; Dahl et al., 2015; Mihaljevic et al., 2008).

Valve replacement decreases ventricular afterload. This in turn is associated with improved LVEF and regression of LV hypertrophy and LV mass (Connolly et al., 1997; Pantely et al., 1978; Kennedy et al., 1977). One study demonstrated that LVEF improved by 6.8 EF points after SAVR. The improvement became evident at 6 months and was sustained for up to 10 years after surgery (EF $56 \pm 4\%$ preoperatively, $63 \pm 3\%$ at 0–6 months, $63 \pm 5\%$ at 7–24 months, and 63 ± 4 at 25–120 months) (Sharma et al., 2004). Some studies showed no change in LVEF after AVR in patients with normal LVEF. Compared to the delayed effect of LVEF, LV mass regression was more pronounced in the first six months after surgery. It reached maximal regression at 24 months and also was sustained for up to 10 years (181 ± 26 g/m^2 preoperative vs. 124 ± 27 g/m^2 at 6 months, 117 ± 15 g/m^2 at 24 months, and 113 ± 14 g/m^2 at 120 months after SAVR) (Une et al., 2015; Sharma et al., 2004).

TAVR for AS with normal left ventricular function and normal SV

The PARTNER 1 trial was the first trial of balloon-expandable TAVR in the United States. This trial showed superior survival of TAVR versus medical management improving median survival from 12 to 32 months in inoperable patients (Kapadia et al., 2015). In high-risk patients, long-term survival with TAVR was found equivalent to SAVR (median survival 40 months) (Mack et al., 2015). In the CoreValve US Pivotal trial using a self-expanding valve, high-risk patients undergoing TAVR had lower mortality compared to SAVR at 3 years (32.9% vs. 39.1%)(Deeb et al., 2016). At 5 years, hemodynamic valve performance was stable with no structural valve deterioration; however, there was an increased incidence of moderate to severe AR in the TAVR groups which impacted survival (Kapadia et al., 2015; Mack et al., 2015; Deeb et al., 2016; Daubert et al., 2017; Kodali et al., 2015).

In the TAVR population LV mass regression was observed among survivors at 1-year follow-up (144 ± 42 mm to 131 ± 39 mm) though it was not as significant as previously reported in the SAVR population. Similarly, the EF change in this group also was not significant (Gotzmann et al., 2012). However, there was significant improvement in functional class with the percentage of patients in NYHA III/IV decreasing from 83% preoperatively to 5.5% at 1 year and 7.7% at 3 years (Deeb et al., 2016).

CHF Secondary to AS With Normal Left Ventricular Function and Low Transvalvular Gradient (AVA $\leq$0.8 cm^2, EF $\geq$ 50%, Mean Aortic Valve Gradient<40 mmHg) (Table 2)

This condition is referred as "paradoxical low-flow low-gradient AS" (LFLG). These patients have a disproportionate amount of LV hypertrophy than necessary to compensate for the increased afterload and wall stress leading to thicker ventricles, smaller left ventricular cavities with a restrictive filling pattern (diastolic dysfunction), and intrinsic myocardial dysfunction secondary to myocardial fibrosis (Pai et al., 2008; Nishimura et al., 2014; Hannan et al., 2009; Herrmann et al., 2011; Dumesnil et al., 2010; Pibarot and Dumesnil, 2010). The low transvalvular gradient results from decreased flow across the aortic valve secondary to low SV or prolonged systolic ejection period (**Fig. 1**; Tarantini et al., 2011; Nishimura et al., 2014).

This group represents 9%–35% of patients with severe AS and normal LVEF (Pai et al., 2008; Lauten et al., 2014; Pibarot and Dumesnil, 2011; Herrmann et al., 2011; Tarantini et al., 2011; Hachicha et al., 2007; Le Ven et al., 2013; Parikh et al., 2015). Since they have preserved LVEF and low transvalvular gradient, they are commonly overlooked in clinical practice. The small aortic valve area (AVA) is often attributed to calculation error and the severity of their stenosis is erroneously underestimated (Pibarot and Dumesnil, 2011; Matsumura et al., 2008). Therefore, they are 40%–50% less likely to be referred to surgery (Pibarot and Dumesnil, 2011; Hachicha et al., 2007).

The majority of these patients are in NYHA functional class III–IV at presentation. (Gotzmann et al., 2012; Herrmann et al., 2011; Tarantini et al., 2011). Because they are at a more advanced stage of their disease, they have a worse prognosis than patients with normal EF and high gradient AS (Dumesnil et al., 2010; Hachicha et al., 2007).

While their operative risks may be elevated, several studies have demonstrated that these patients have better survival when treated with SAVR compared to medical management (**Table 2**). The operative mortality is highly variable and ranges between 2.7% and 18%. Given their severe left ventricular hypertrophy, diastolic dysfunction, and decreased systemic arterial compliance, these patients will often have low cardiac output syndrome postoperatively and typically require in addition to meticulous myocardial protection during surgery, aggressive volume resuscitation, vasopressors, and even more invasive hemodynamic cardiopulmonary support (Dumesnil et al., 2010).

Pai studied the outcomes of patients with severe paradoxical LFLG AS (EF $\geq$55%, and a mean transvalvular gradient <30 mmHg) treated by either surgery or medical management (Pai et al., 2008). He compared by propensity score matching 18 patients who underwent SAVR with 14 patients who did not have surgery. One- and five-year survival were 92% and 88% in the SAVR group compared with 82% and 10% in the non-SAVR group. Multiple other series have confirmed these findings and have also found that LVEF and NYHA functional class were improved after surgery (**Table 2**; Tarantini et al., 2011; Hachicha et al., 2007).

The Cleveland Clinic reported recently in a contemporary cohort of SAVR patients with paradoxical LFLG severe AS had significantly worse short- and long-term outcomes as compared to the standard severe AS (EF >50%, high gradient). In addition to this they also found that low stroke volume index (SVi, $\leq$35 mL/m^2) is an independent predictor of worse outcomes (Parikh et al., 2015). Similarly, in a recent meta-analysis, Dayan et al. confirmed both the increased operative mortality with paradoxical LFLG AS compared to other subtypes of severe AS and the beneficial effect of AVR on mortality compared to medical management (Dayan and Vignolo, 2015).

TAVR for AS with normal left ventricular function and low transvalvular gradient (AVA $\leq$0.8 cm^2, EF $\geq$ 50%, mean aortic valve gradient <40 mmHg)

In a subanalysis of the PARTNER 1 trial, Hermann et al. demonstrated that in inoperable patients with SVi $\leq$35 mL/m^2 and preserved LVEF, TAVR reduced 1-year mortality compared with medical management and that there was a trend to benefit at 2 years (66% with medical management vs. 35% with TAVR at 1 year $P=0.02$; 77% with medical management vs. 57% with TAVR at 2 year $P=0.06$). There was no difference in high-risk patients between SAVR and TAVR in 2-year mortality (39.0% vs. 38.3%. P 0.69). There was however an improved 1-year survival with TAVR compared to AVR (Herrmann et al., 2013).

Similar to the findings after SAVR, the outcome of paradoxical LF LG AS after TAVR was worse than in patients with preserved LVEF and high aortic valve gradient. (Gotzmann et al., 2012; Le Ven et al., 2013). Additionally, in all studies this group does better than patients with reduced LVEF and low gradient AS (Gotzmann et al., 2012; Le Ven et al., 2013; Herrmann et al., 2013).

The SVi is an important predictor for all patients with paradoxical LF LG that have a valve replacement procedure, whether SAVR or TAVR. LeVen demonstrated that a low SVi in patients with paradoxical LF LG undergoing TAVR have an increased risk of 30-day mortality (Le Ven et al., 2013). Furthermore, in the PARTNER 1 trial there was a 50% increase in 2-year all-cause mortality in low SVi compared with patients with normal SVi. The impact of low SVi on subsequent mortality was independent in multivariable analysis and was a more powerful predictor of outcome than LVEF or mean transvalvular gradient (Herrmann et al., 2013).

Left ventricular EF did not change after TAVR in this subgroup of AS. LV mass regression was also not significantly higher than patients with high gradients (pre TAVR 155 ± 49 g/m^2 and post TAVR 134 ± 33 g/m^2, $P=0.008$) (Gotzmann et al., 2012).

CHF Secondary to AS With Low LVEF

Low preoperative left ventricular function is the major predictor of outcomes in patients with AS (Connolly et al., 2000; Malaisrie et al., 2010; Kvidal et al., 2000; Hannan et al., 2009; Gotzmann et al., 2012; Moat et al., 2011). The incidence of left ventricular dysfunction in patients with severe AS varies among different studies and with the threshold used. 5.4% of patients in the Society of Thoracic Surgeons database who had isolated SAVR between 1997 and 2006 had LVEF <30% (Brown et al., 2009a). The Euro Heart

[a]Data not provided. Estimated from Kaplan Meier survival curve.

Survey of Valvular Heart Disease showed that 2.9% of the patients who underwent SAVR had LVEF <30% and 16.4% had LVEF between 30% and 50% (Iung et al., 2003). In other SAVR series, the incidence ranges from 12% to 21% depending on the LVEF threshold used (Chukwuemeka et al., 2006; Kulik et al., 2006). In a study from an echocardiography database, 26% of patients with severe AS had LVEF ≤35% and 23% had a mean transvalvular gradient ≤30 mmHg (Pai et al., 2008). Only one third of them had AVR (Pai et al., 2008).

The Transcatheter Valve Therapies Registry showed that 7% of the patients undergoing TAVR had an LVEF <30%, while 25% of patients had an LVEF between 30% and 50% (Baron et al., 2016). The prevalence of low LVEF was similar in the U.K. Transcatheter Aortic Valve Implantation Registry (Duncan et al., 2015).

In patients with severe AS and LVEF <50%, the impact of TAVR versus SAVR on LV functional recovery is still controversial (Elmariah et al., 2013; Clavel et al., 2010). Clavel et al. found that TAVR was associated with better LVEF recovery compared with SAVR at 1 year (Clavel et al., 2010). Passeri et al. also found a significant improvement in LV recovery in patients with LV dysfunction (EF <50%) who underwent TAVR. There was an absolute increase in LVEF by 10% or more at 30 days in 48.7% of patients undergoing TAVR (Passeri et al., 2015). Elmariah et al. performed a post hoc analysis of the PARTNER trial and found patients with LV dysfunction had a mean LVEF increase from 35.7 ± 8.5% to 48.6 ± 11.3% ($P < 0.0001$) 1 year after TAVR and from 38.0 ± 8.0% to 50.1 ± 10.8% after SAVR ($P < 0.0001$). They also identified those with a previous permanent pacemaker as a subgroup less likely to have improvement in EF at 30 days and those with higher mean aortic gradients as a subgroup more likely to have improvement. Despite the improvement in EF with TAVR, there was still no difference in the rate or degree of LV functional improvement when comparing TAVR to SAVR in patients with severe AS and LVEF <50% at baseline. They concluded that TAVR was a feasible alternative to SAVR for this population (Elmariah et al., 2013).

CHF secondary to AS with low LVEF and high transvalvular gradients (Table 3)

The subgroup of patients with severe AS and reduced LVEF, *who* are still able to generate trans-aortic gradients ≥40 mmHg, benefit significantly from SAVR (Pai et al., 2008; Connolly et al., 1997; Kulik et al., 2006; Flores-Marin et al., 2010; Powell et al., 2000; Vaquette et al., 2005; Halkos et al., 2009) (**Fig. 1**, **Table 3**). They represent 20% of the patients with severe AS and low LVEF (Kulik et al., 2006).

The 30-day mortality can range from 9% to 19.5%. Significant predictors of operative mortality were preoperative myocardial infarction, coronary artery disease (CAD), and cardiomegaly.

Symptomatic improvement occurred in the majority of patients after SAVR. Most patients were in functional class I or II at late follow-up. LVEF improved early after SAVR and continued to improve at late follow-up (Sharma et al., 2004; Vaquette et al., 2005). The improvement in LVEF was usually more pronounced than in patients with preserved LVEF and severe AS (Sharma et al., 2004). Greater AS severity (smaller AVA and higher mean gradients), better preoperative ejection fraction, less remodeled ventricles, and the absence of CAD or previous myocardial infarction were associated with improvement in LVEF (Connolly et al., 1997; Matsumura et al., 2008; Flores-Marin et al., 2010).

Long-term survival ranged from 77% to >90% at one year and from 58% to 71% at 5 years. In the absence of CAD, survival of patients with severe aortic and reduced left ventricular function with elevated gradients was similar to the expected survival of the overall population (Connolly et al., 1997). Independent predictors of long-term survival by multivariate analysis are listed in **Table 4**.

TAVR

In patients with low LVEF and high gradients treated with TAVR, no difference was found in the procedural and 30-day mortality when compared to patients with LVEF ≥50% and high gradients (Conrotto et al., 2016; Gotzmann et al., 2012; Passeri et al., 2015; Elhmidi et al., 2014). However, at longer follow-up, patients with high gradients and low LVEF did worse than patients with high gradients and preserved LVEF. At 6 months there was a twofold higher mortality among patients with LVEF ≤35% compared to >50% (26.9% vs. 15%, $P = 0.03$) (Elhmidi et al., 2014). But when compared to patients with low gradients, those with high gradients still had better outcomes (Gotzmann et al., 2012).

Improvement in LVEF occurs early (within 48 h) after TAVR in two third of patients with reduced LVEF. This early recovery is associated with improved clinical outcomes (Dauerman et al., 2016). Surprisingly, one study showed that LV dysfunction (LVEF ≤35%) is actually an independent predictor of LV function recovery (Elhmidi et al., 2014). Even if LVEF fails to improve early after TAVR, the LVEF is still expected to increase by more than 10% points in 40% of the patients by 6 months and in 50% of them by 12 months (Dauerman et al., 2016). Significant improvements in LVEF (44 ± 6% to 53 ± 9%, $P < 0.001$) and LV mass regression (171 ± 43 units to 135 ± 33 units, $P = 0.003$) at 1 year have also seen in this subgroup (Gotzmann et al., 2012).

CHF secondary to AS with low LVEF and low transvalvular gradients (Table 5)

This subgroup is typically referred to as "classical low-flow low-gradient" and tend to be the most clinically challenging patients to manage because of the severity from both the CHF and AS. They have more advanced myocardial dysfunction secondary to (a) afterload mismatch and therefore reversible or (b) the combination of afterload mismatch *and* intrinsic myocardial dysfunction that will not reverse with valve replacement (Carabello, 2006; Hwang et al., 1989). While most patients experience some benefit from SAVR, the subgroup that potentially benefits the most are those with reversible myocardial dysfunction. Hence, identifying patients with reversible dysfunction is of paramount importance. Reversible myocardial dysfunction secondary to afterload mismatch is associated with the presence of contractile reserve (increase in the SV ≥20%) with the infusion of low-dose

dobutamine while patients without contractile reserve are believed to have intrinsic and therefore irreversible myocardial dysfunction (Monin et al., 2001, 2003; Nishimura et al., 2002, 2014; Steinhauser and Stone, 2007) (**Fig. 2**). The determination of irreversible myocardial dysfunction by the absence of contractile reserve is not perfect since a large number of patients without contractile reserve will still benefit from SAVR (Monin et al., 2003; Tribouilloy et al., 2009; Quere et al., 2006).

The dobutamine challenge also helps to differentiate patients with low cardiac output and true severe AS from those with low cardiac output and mild AS or pseudo AS by examining the changes in AVA, SV, and mean aortic valve gradient (**Fig. 2**). Patients with true severe AS respond to the dobutamine-induced increase in SV with an increase in the mean gradient, while the calculated AVA remains low. Patients with pseudo-severe AS may or may not increase their mean gradient, but the hallmark is that the AVA will actually increase. Patients with pseudo-severe AS do not benefit from SAVR (Monin et al., 2001, 2003; Steinhauser and Stone, 2007; Nishimura et al., 2002).

The presence of contractile reserve has prognostic implications for patients treated either with SAVR or with medical management. It helps predict the operative risk as well as the long-term survival of patients with low EF low gradient AS. Operative mortality in patients with contractile reserve is significantly lower (5%–7%), compared to those without contractile reserve (26%–33%) (Monin et al., 2003; Tribouilloy et al., 2009; Nishimura et al., 2002).

Long-term survival and functional status after SAVR is also influenced by the presence contractile reserve. In a multicenter study by Monin, they demonstrated that patients with contractile reserve had improved 1-year (90% vs. 60%) and a 5-year (74% vs. 37%) survival after SAVR compared to those without contractile reserve. In the same study, NYHA functional class improvement occurred in 84% of patients with contractile reserve versus in 45% of patients without (Monin et al., 2003). In a subsequent substudy, Quere analyzed the outcomes of patients who survived SAVR and showed that contractile reserve did not influence long-term survival suggesting that the contractile reserve is only a primary determinant of surgical risk (Quere et al., 2006).

In spite of the high operative mortality and limited long-term survival associated with SAVR in patients without contractile reserve, AVR still significantly improved their prognosis compared to medical management. Monin demonstrated that 1- and 5-year survival with or without contractile reserve was better for patients treated with SAVR than for patients who received medical therapy (**Tables 1** and **5**; Monin et al., 2003).

Tribouilloy demonstrated on 81 patients with low-flow/low-gradient AS without contractile reserve that SAVR was associated with lower 5-year mortality (13% vs. 54%) when compared to medical therapy, despite the 22% surgical mortality. In addition only 9% of the SAVR patients had heart failure symptoms at follow-up compared with 81% of the medically managed patients (Tribouilloy et al., 2009). Clavel et al. (2008) demonstrated in the same group of patients that SAVR was only associated with improved overall survival compared with medical management in the subset of patients with more severe stenosis (AVA <1.0 cm^2). This lack of improvement was likely due to the high operative mortality (18%) (Clavel et al., 2008). Once operative mortality was

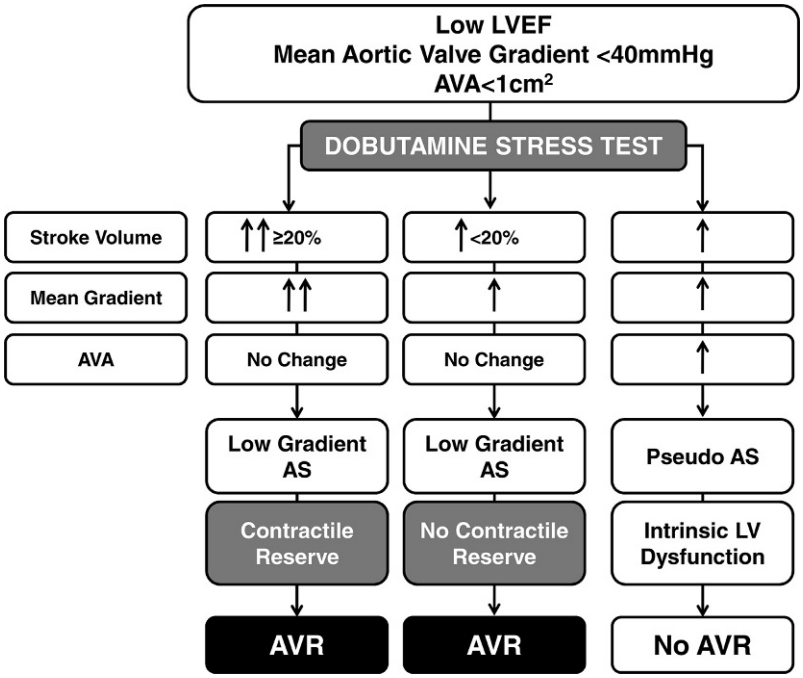

Fig. 2 Dobutamine stress test for the determination of contractile reserve and aortic stenosis severity.

excluded, patients who survived SAVR had excellent late survival compared with patients treated medically (70% vs. 50%) (**Table 5**; Clavel et al., 2008).

Early postoperative improvement in ejection fraction is associated with improved long-term survival and functional status (Quere et al., 2006; Morris et al., 1993). Connoly demonstrated that LVEF improved in 74% of the survivors. LVEF improved $10 \pm 14\%$ units. Positive change in LVEF was associated with female sex and smaller preoperative AVA (Connolly et al., 2000).

Quere demonstrated that LVEF improvement can be observed in patients without contractile reserve after SAVR (Quere et al., 2006). 83% of patients with and 65% of the patients without contractile reserve obtained $\geq 10\%$ improvement in LVEF after SAVR. The magnitude of the improvement was similar regardless of the presence of contractile reserve. Contractile reserve was not a predictor of improvement in LVEF after SAVR. Therefore, absence of contractile reserve does not always predict irreversible myocardial dysfunction. Higher preoperative mean aortic valve gradient and absence of multi-vessel CAD were associated with improvement in LVEF after SAVR (Quere et al., 2006). A small recent study looking specifically at Global LV Longitudinal Strain (GLS) showed a twofold increase in operative mortality with resting GLS <9% compared to GLS >9%. However, beyond 30 days, there was no difference in survival between the groups (Dahou et al., 2015).

TAVR

In the GARY registry, LF LG AS was present in 11.7% of patients undergoing TAVR (Lauten et al., 2014). This cohort experiences a higher 30-day (7.8% vs. 4.9%) and 1-year mortality (32.3% vs. 19.8%) compared to other groups (Lauten et al., 2014; Gotzmann et al., 2012). They also had higher rates of low cardiac output syndrome, cardiopulmonary resuscitation, and mechanical circulatory support during the post TAVR period (Lauten et al., 2014; Schaefer et al., 2015). While the outcomes may be worse compared to other AS subgroups undergoing TAVR, there is evidence to suggest patients should still proceed with TAVR. The PARTNER trial shows that TAVR and SAVR improved 30-day, 1-year and 2-year mortality (25% vs. 7.4% at 30 days, 59% vs. 25% at 1 year, 76% vs. 46% at 2 year) for LF AS compared to medical management (O'Sullivan et al., 2015; Pibarot and Dumesnil, 2011). However, when comparing SAVR to TAVR, the 30-day (5.6% vs. 9.5%), 1-year (25.9% vs. 23.3%), and 2-year mortality (42.9% vs. 37.1%) were similar in this subgroup of patients (Elmariah et al., 2013; Herrmann et al., 2013). Improvement in SV at discharge after TAVR is associated with improved outcomes (Anjan et al., 2016).

After 1 year, the improvement in LVEF was similar after both transcatheter and surgical valve replacement, with most of this improvement occurring within the first 30 days (O'Sullivan et al., 2015; Elmariah et al., 2013). Mean LVEF increased from $35.7 \pm 8.5\%$ to $48.6 \pm 11.3\%$ ($P < 0.0001$) at 1 year after TAVR and from $38.0 \pm 8.0\%$ to $50.1 \pm 10.8\%$ after SVAR($P < 0.0001$). Fifty three percent of TAVR patients and 62.3% of SAVR had normalized their LVEF a year after the procedures ($P = 0.34$) (Elmariah et al., 2013). Other studies suggest LV function improved more in TAVR patients compared to SAVR (Clavel et al., 2010). This discrepancy is likely attributed to the superior hemodynamics of TAVR valves and exclusion of CAD in the PARTNER trial (O'Sullivan et al., 2015; Elmariah et al., 2013). Dauerman et al. showed in the self-expanding CoreValve trials that early LVEF recovery (defined as a LVEF increase of $\geq 10\%$ at 30 days) occurred in 62% patients but it was not associated with improved 1-year

survival (Dauerman et al., 2016). In the PARTNER trial early improvement in LV function was associated with reduced rates of all cause and cardiac mortality in the TAVR group at 1 year, but not in the SAVR group (Elmariah et al., 2013). Higher baseline LVEF, previous permanent pacemaker, previous MI, and low gradient (<40 mmHg) were associated with reduced likelihood of early LVEF improvement (Elmariah et al., 2013; Dauerman et al., 2016). More recently SVi (<35 mL/m^2) and low baseline aortic valve gradient (<40 mmHg) have been identified as more powerful predictors of poor outcomes than LVEF or gradients alone (Le Ven et al., 2013; Herrmann et al., 2013). The presence of CAD or incomplete revascularization has also been associated with increased 1-year mortality in LFLG AS (O'Sullivan et al., 2015).

Predictors of outcomes

Long-term outcomes in severe AS with low LVEF and low transvalvular gradients are not accurately predicted by the presence of contractile reserve alone (Quere et al., 2006).Thus other factors should be considered to risk stratify patients before SAVR. Several studies have identified independent predictors of early mortality, long-term survival, and improvement in LVEF and functional class (**Table 4**).

Predictors of 30-day mortality include CAD (as defined by previous MI, multi-vessel CAD, and concomitant coronary arteries bypass graft surgery (CABG)), which likely indicates the presence of intrinsic and probably irreversible myocardial dysfunction secondary to fibrosis or myocardial infarction (Tribouilloy et al., 2009; Connolly et al., 1997; Flores-Marin et al., 2010; Powell et al., 2000; Levy et al., 2008; Rothenburger et al., 2003). In addition, concomitant CABG increases the operative time and complexity of the surgery. Surrogates for more advanced left ventricular dysfunction are low mean transaortic gradients, absence of contractile reserve, and dilated LV (Monin et al., 2001, 2003; Tribouilloy et al., 2009; Flores-Marin et al., 2010; Vaquette et al., 2005; Levy et al., 2008; Rothenburger et al., 2003). The increased mortality with small prosthesis size may be the result of high residual aortic valve gradient and incomplete relief of the LV outflow obstruction (Connolly et al., 2000). Patients with LV dysfunction tolerate poorly residual aortic gradient and patient prosthesis mismatch (PPM) since they are highly sensitive to increased afterload (Connolly et al., 2000; Kulik et al., 2006; Blais et al., 2003; Ruel et al., 2006). PPM results in decreased survival, lower freedom from heart failure, and incomplete left ventricular mass regression (Kulik et al., 2006; Ruel et al., 2006). PPM should be avoided by implanting prosthesis with superior hemodynamic performance and considering the prosthetic effective orifice area indexed to body surface area at the time of SAVR. Some have advocated the use of stentless valves (Bevilacqua et al., 2002). Transcatheter aortic valves may have an advantage in this group since they have better hemodynamic performance with larger postoperative AVA and lower transvalvular gradient than surgically placed valves (Kulik et al., 2006; Smith et al., 2011).

Other factors associated with early mortality are common predictors of increased surgical risk (age, presence of comorbidities, advanced functional status, emergency surgery, and female gender) (**Table 4**).

SAVR is the main factor associated with long-term survival, LVEF improvement, and improved functional status in patients with low LVEF and low gradient AS (Monin et al., 2003; Pai et al., 2008; Tribouilloy et al., 2009; Pereira et al., 2002). This reinforces the notion that even risky, SAVR provides a significant survival advantage to these patients compared to medical management alone.

Other factor negatively associated with long-term survival was presence of CAD (Pai et al., 2008; Tribouilloy et al., 2009; Connolly et al., 1997; Levy et al., 2008). As in early mortality, CAD indicates intrinsic myocardial dysfunction. Factors associated with ventricular dysfunction (contractile reserve, low preoperative mean gradient, pre- and postoperative low cardiac output, remodeled ventricles, and atrial fibrillation) also negatively affected long-term survival (Monin et al., 2001, 2003; Tribouilloy et al., 2009; Connolly et al., 1997; Tarantini et al., 2011; Flores-Marin et al., 2010; Vaquette et al., 2005; Halkos et al., 2009; Levy et al., 2008). Early improvement in LVEF predicted long-term survival indicating that most of myocardial dysfunction was reversible secondary to afterload mismatch (Vaquette et al., 2005). Advanced age, comorbidities, and elevated EuroSCORE also predicted decreased survival (Pai et al., 2008; Vaquette et al., 2005; Halkos et al., 2009; Levy et al., 2008; Pereira et al., 2002).

Improvement in LVEF is another factor that helps predict early and late survival (Connolly et al., 1997; Elmariah et al., 2013; Matsumura et al., 2008; Powell et al., 2000; Vaquette et al., 2005; Dauerman et al., 2016; Quere et al., 2006; Pereira et al., 2002). In addition, the presence of systemic hypertension was negatively associated with improvement in LVEF. It was presumed that systemic hypertension was associated with myocardial fibrosis. The only independent factor associated with improved functional status at late follow-up was the early improvement in LVEF >10 ejection fraction units (Vaquette et al., 2005).

Many of the variables associated with adverse outcomes are similar to those associated with adverse outcomes in the general population of AS patients. Hannan identified age >60 years, LVEF <50%, CHF, myocardial infarction less than 24 h before surgery, lower body surface area, previous cardiac operation, and several comorbidities as independent predictors of 30-day mortality(-Hannan et al., 2009). Factors associated with increased long-term mortality were concomitant CABG, age >60, small body surface area, emergency status, and comorbidities (Hannan et al., 2009). Mihaljevic identified the following risk factors as associated with early death: older age, LV dilatation, and smaller prosthetic size. Risk factors for late death were older age, greater degree of AS, greater LV mass index, smaller prosthetic size, LV dysfunction, and advanced symptoms. Risk factors associated with advanced symptoms include calcific AS and severe LV dysfunction (Malaisrie et al., 2010).

PPM after SAVR has been shown to have a negative impact on short- and long-term survival (Head and Mokhles, 2012). In high risk surgical candidates with severe AS, PPM occurs more frequently (60% vs. 40%) and is more severe (28% vs. 19.7%) in patients undergoing SAVR compared to TAVR. While there is no randomized trial comparing the incidence and outcomes of PPM after SAVR versus TAVR, there is some data to suggest high-risk patients, who are susceptible to PPM or have a small aortic annulus, should undergo TAVR instead of SAVR (Pibarot and Weissman, 2014).

Percutaneous Aortic Valvuloplasty

Percutaneous balloon aortic valvuloplasty is an alternative for patients with severe acquired AS and LV dysfunction who are not candidates for SAVR or TAVR. Percutaneous aortic valvuloplasty was associated with temporary reduction of transvalvular gradients (from 55 to 29 mmHg), increase in the AVA (mean increase 0.3 cm^2), improvement in left ventricular performance, and symptomatic improvement (Passeri et al., 2015; Anon, 1991). However, it had several disadvantages: (1) it was associated with a 25% risk of complications, (2) the improvement was short lived with recurrence of the symptoms within a few months and (3) there was no survival benefit (Anon, 1991; Otto et al., 1994; Lieberman et al., 1995; Nishimura et al., 1991; Kapadia et al., 2010). With the advent of transcatheter aortic valve implantation, aortic valvuloplasty has reemerged as a procedure for the treatment of AS (Tissot et al., 2011). It is usually utilized in patients with CHF or cardiogenic shock to stabilize them and bridge them to TAVR or to a high-risk AVR (Kapadia et al., 2010; Tissot et al., 2011).

Future of TAVR Technology

As the technology improves and access challenges are overcome this technology will be ubiquitous. At the present time TAVR is FDA approved for extreme risk, high risk, and intermediate risk patients who have severe AS. Outcomes in these trials (Kapadia et al., 2015; Leon et al., 2010; Nkomo et al., 2006; Lindroos et al., 1993; Pai and Varadarajan, 2010; Bach, 2011; Passeri et al., 2015; Dauerman et al., 2016; Hwang et al., 1989; Tissot et al., 2011) as shown above are equivalent to surgery and in some cases even better. Low risk trials are underway and results will be available in the next few years.

As the technology is being deployed in lower risk and younger patients, there are several issues that still require attention particularly as the life expectancy of the lower risk population is significantly longer. New generation devices will address perivalvular regurgitation and post procedure conduction disturbances requiring pacemaker. The questions regarding durability, leaflet thrombosis, and stroke rate will need to be addressed before widespread applicability in younger population (Hamm et al., 2016; Holmes and Mack, 2015). Five-year data from the PARTNER trial demonstrates that valve performance and cardiac hemodynamics are stable after implantation in both TAVR and SAVR in patients alive at 5 years.

Aortic Regurgitation and CHF

Aortic insufficiency leads to both pressure and volume overload on the LV (Nishimura et al., 2014; Chukwuemeka et al., 2006; Bekeredjian and Grayburn, 2005). Volume overload (increased preload) results from the diastolic regurgitant volume. Increased afterload is the result of the increased aortic SV (regurgitant volume plus forward SV) that leads to systolic arterial hypertension. The increase in wall stress leads to compensatory LV dilatation and eccentric hypertrophy. These changes decrease wall stress and preserve ejection fraction. Progressive LV dilatation overcomes those compensatory mechanisms leading to myocardial dysfunction and decreased EF. At this point, LV function will improve after SAVR. Persistent regurgitation and further increase in wall stress lead to further systolic dysfunction secondary to ischemia and myocardial fibrosis (Holmes and Mack, 2015; Bekeredjian and Grayburn, 2005). At this stage, when the ventricle is severely dilated, intrinsic myocardial dysfunction becomes the predominant mechanism responsible for LV dysfunction and SAVR is less likely to improve LV function. However, even without LVEF improvement, SAVR will improve loading conditions and facilitate CHF management (Nishimura et al., 2014).

CHF secondary to severe AR has several commonalities with the one secondary to severe AS. It is common, its medical management results in poor outcomes, and it is undertreated.

In the Euro Heart Survey, AR was the third most common valve pathology after AS and mitral regurgitation. Only one third of those patients were treated surgically. That proportion is even lower in patients with left ventricular dysfunction: only 22% of patients with LVEF between 30% and 50% and 3% of patients with LVEF<30% were treated with AVR (Iung et al., 2003; Kamath et al., 2009; Supino et al., 2006).

A review of the STS database reinforces the notion that AR in CHF and low LVEF is undertreated: 47% of isolated AVR patients had some degree of AR. 52% were in NYHA class III–IV but only 5% had LVEF <30% (Brown et al., 2009a).

The natural history of asymptomatic severe AR with normal LVEF and normal ventricular dimensions is benign (Nishimura et al., 2014; Bekeredjian and Grayburn, 2005; Bonow et al., 1991; Borer et al., 1998). However, once CHF, ventricular dilatation, or LV dysfunction develop, the prognosis of medically treated patients is poor. Survival ranges from 20% to 50% at 5 years and the majority of patients are in NYHA class III–IV (Kamath et al., 2009; Bekeredjian and Grayburn, 2005; Sionis et al., 2010; Khandhar et al., 2009). Thus, surgery is recommended when (a) patients become symptomatic (ACC-AHA guidelines class I and European Society of Cardiology (ESC) guidelines class IB), (b) the LVEF is ≤50% independently of symptoms (ACC-AHA guidelines class I and ESC class IB) or (c) the LV dilates (left ventricle end diastolic diameter (LVEDD) >75 mm or left ventricle end systolic diameter (LVESD) >55 mm, ACC-AHA guidelines class IIa) (Nishimura et al., 2014; Khandhar et al., 2009). The ESC guidelines recommends surgery with lesser degree of LV dilatation (LVEDD >70 mm or LVESD >50 mm, class IIaC) (Khandhar et al., 2009).

The surgical outcomes of patients with advanced CHF (NYHA class III–IV) and severe LV dysfunction (LVEF ≤35%) secondary to chronic AR have only been studied in a few series (**Table 6**).

[a]Data not provided. Estimated from Kaplan Meier survival curve.

The operative mortality in this group was high (**Table 6**). Operative mortality was four times higher in low ejection fraction patients than in patients with normal EF (14% vs. 3.7%) (Chaliki et al., 2002). Concomitant procedures and advanced NYHA class increased operative mortality (Chaliki et al., 2002). Klodas demonstrated that patients in NYHA class III–IV had a six time higher operative mortality (7.8% vs. 1.2%) (Klodas et al., 1997).

AVR improves long-term survival compared to medical management. One-year survival ranged from 80% to 99%. Five-year survival ranged from 60% to 80%. The only study that compared medical management with SAVR showed that SAVR improved 1-year survival from 65% to 88% and 5-year survival from 37% to 70% (**Table 6**; Kamath et al., 2009). After adjusting for baseline variables SAVR was associated with a significantly lower hazard of mortality (HR 0.59, 95% CI 0.42–0.98, $P < 0.04$) (Kamath et al., 2009).

Other independent predictors of long-term survival were preoperative LVEF, NYHA class, and age (Chaliki et al., 2002). Five-year survival for patients with LVEF <35% was 60% compared with 85% for patients with normal EF. This survival, although better than with medical management, was 65% lower than the expected survival of an age- and sex-matched population (Chaliki et al., 2002). This suggests that SAVR does not completely reverse the myocardial dysfunction induced by long-standing AR.

Other factor associated with poor long-term survival was dilated LV as identified by indexed LV dimensions. Patients with LVESDi $\geq$20 mm/m^2 and LVEDDi $\geq$30 mm/m^2 had worse long-term survival independently of their preoperative LVEF and NYHA functional class (Brown et al., 2009b). Previous studies have shown that extreme LV dilatation (LVEDD $\geq$80 mm) did not prevent improvement in LV function after SAVR (Klodas et al., 1996).

Even patients with extremely reduced LVEF (LVEF <20%) achieved a survival advantage with SAVR compared to medical management (Kamath et al., 2009). Severe pulmonary hypertension (systolic pulmonary pressure >60 mmHg) and functional mitral regurgitation adversely affect long-term survival (Pai and Varadarajan, 2010; Khandhar et al., 2009). SAVR and mitral valve repair were also associated with a better survival than medical management (Pai and Varadarajan, 2010; Khandhar et al., 2009).

SAVR results in symptomatic improvement. The majority of patients remain free of CHF symptoms after SAVR (Rothenburger et al., 2003; Chaliki et al., 2002).

Similar to AS the impairment in LVEF in AR is related to a combination of (a) afterload mismatch and (b) intrinsic myocardial dysfunction. LVEF improvement after AVR will depend on the relative contribution of each mechanism. SAVR resulted in LVEF improvement in the majority of patients with severe LV dysfunction (Brown et al., 2009b; Chaliki et al., 2002). The improvement is more pronounced in patients with lower preoperative EF (Brown et al., 2009b; Chaliki et al., 2002). The time course of LVEF improvement shows a modest initial decrement in EF followed by a gradual improvement over the course of the next 6 months (Brown et al., 2009b; Senechal et al., 2011). Maximal LV regression after SAVR may take up to 4 years (Une et al., 2015). Late improvement in LVEF was associated with the presence of early LV reverse remodeling defined as a 10% reduction in LVEDD (Senechal et al., 2011). LVEF decreased significantly late after AVR in patients with no early LV reverse remodeling. Preoperative LV SV >97 mL was the best independent predictor of early reverse remodeling (Senechal et al., 2011).

Heart transplantation and mechanical circulatory support should be considered as an alternative treatment in this group of patients (Christie et al., 2010). However, in spite of the high operative mortality most patients with CHF secondary to severe AR with severely reduced LVEF greatly benefit from SAVR (Chaliki et al., 2002). Most patients achieved lasting symptomatic improvement and improvement in their ejection fraction. Long-term survival is better than the one after heart transplantation without the side effects and complications of immunosuppression and rejection.

TAVR

Percutaneous options for treatment of pure AR are undergoing feasibility trials across the world (Roy et al., 2013; Seiffert et al., 2014; Zhu et al., 2015). Absence or minimal calcification of the native aortic cusps in pure AR increases the valve embolization or residual paravalvular regurgitation. Excessive oversizing carries a subsequent hazard for aortic root rupture or incomplete valve expansion. Limited data is available from trials and registries in patients who are not candidates for surgery. The implantation success is greater than 95%; however, there is an increased risk of double valve placements (Roy et al., 2013; Seiffert et al., 2014). Thirty-day mortality and one-year mortality were elevated (Roy et al., 2013; Seiffert et al., 2014).

Conclusions

The prognosis of patients with CHF secondary to aortic valve disease with left ventricular dysfunction is poor. AVR, although risky, is associated with improved long-term survival, improved ventricular function, and functional class compared to medical management. TAVR provides a new alternative for those patients particularly for those who are considered inoperable or at high risk for surgery. The decision to intervene in these patients is challenging. They should be systematically evaluated by the heart valve team where cardiologist, imaging specialist, cardiac surgeons, interventional cardiologist, and nurse coordinators consider the severity of their cardiac disease, surgical risk, comorbidities, frailty, other factors that may limit their life expectancy, and the risk-benefit ratio of different treatment strategies as well as the patient preferences and values (Iung et al., 2003; Otto et al., 2017; Chikwe and Adams, 2010). These factors should be carefully considered to risk stratify and guide the decision to perform surgery or TAVR.

Introduction

This article provides a comprehensive review of the cardiac arrhythmias that occur in the setting of cancer. The first section reviews chemotherapy-associated arrhythmias and is organized by class of medication. **Table 1** serves as a reference from which readers can quickly identify the scientific literature utilized in the discussion that follows. Next follows a discussion on the QT interval, a time interval acquired from the electrocardiogram (ECG) that is associated with dangerous, potentially lethal ventricular arrhythmias. The utility of using the QT interval as a predictor of ventricular arrhythmias is assessed. Prevention and management of QT interval prolongation is included. The second section reviews cardiac arrhythmias associated with radiation therapy. It begins with a discussion of the risk of arrhythmia in patients receiving radiation. Next follows a discussion of radiation therapy in patients with cardiac implantable electronic devices (CIEDs), which include pacemakers and implantable cardioverter-defibrillators (ICD). Risk of CIED malfunction and a discussion on whether CIEDs should be relocated prior to radiation therapy are included.

Multiple cardiac arrhythmias are reviewed in this article. Cardiac arrhythmias can arise from different regions of the heart and have varying degrees of clinical significance. Atrial arrhythmias include bradycardia, atrial fibrillation, atrial flutter, and supraventricular tachycardia (SVT). Ventricular arrhythmias include ventricular tachycardia (VT) and ventricular fibrillation (VF). Arrhythmias can also originate between the atria and ventricles at the atrioventricular (AV) junction. These are called AV conduction blocks and for the purposes of this article are grouped with atrial arrhythmias. **Table 2** provides definitions for the cardiac arrhythmias discussed in this article. There are many additional arrhythmias that are beyond the scope of this article, which focuses on the most common and significant types.

Chemotherapy-Induced Arrhythmia

Arrhythmia Risk by Class

Alkylating agents

Arrhythmias

- Cyclophosphamide and ifosfamide
  - Atrial fibrillation is rarely documented, but one study did note 11.8% of 34 patients having transient atrial fibrillation (Yusuf et al., 2009).
  - QTc interval prolongation by an average of 21 milliseconds (ms) has been reported.

	Tyrosine kinase inhibitors	Loffi et al. (2015)

  - AV block was documented in 4 of 39 breast cancer patients receiving cyclophosphamide, but they also received anthracyclines (Ando et al., 2000).
  - SVT is limited to rare case reports.
- Melphalan
  - Melphalan is given prior to autologous peripheral blood stem cell transplant for non-Hodgkin's lymphoma and multiple myeloma.
  - Atrial fibrillation occurs in 8%–22.5% of patients receiving melphalan.
  - One study reported SVT in 3% of patients receiving melphalan.
- Cisplatin and carboplatin
  - Cisplatin is associated with transient atrial fibrillation when it is administered into the intrapericardial or intrapleural space for metastatic cancer with malignant effusion with rates ranging from 12% to 32%.

Table 2 Definitions of arrhythmia types

Cardiac origin	*Arrhythmia type*	*Definition*
Atria	SA node dysfunction Sinus bradycardia	A slow heart rhythm originating from the SA node with heart rate <60 bpm
	AV node dysfunction AV block	An aberration in electric conduction between the atria and ventricles that often presents with a slow heart rhythm. The dysfunction can localize at various points between the SA node and ventricles with differing clinical significance
	Atrial fibrillation	Disorganized electric activity throughout the atria that disrupts SA to AV node conduction and presents with irregularity of both heart rate and rhythm
	Atrial flutter	A closed-loop electric circuit within an atrium that causes reentrant, often rapid, conduction through the AV node producing an arrhythmia with regular rhythm
	SVT	An arrhythmia with heart rate >100 bpm and not caused by atrial fibrillation or flutter. Etiologies include ectopic atrial focus and reentrant conduction loops between atria and ventricles
Ventricles	QT prolongation	A manifestation of delayed electric repolarization following depolarization of the cardiac conduction system that is measured from the ECG
	Monomorphic VT	At least three consecutive beats originating from a ventricular focus with heart rate >120 bpm. Monomorphic VT is termed "nonsustained" if the rhythm lasts less than 30 s and "sustained" if it lasts ≥30 s
	Polymorphic VT	A rapid heart rhythm (heart rate >100 bpm) originating from the ventricles with continuously varying QRS interval and morphology seen on electrocardiography. Polymorphic VT carries a risk of degeneration to VF. In patients with congenital long QT syndrome, this arrhythmia is referred to as torsades de pointes
	VF	Disorganized electric activity throughout the ventricles that prevents coordinated ventricular contraction. The arrhythmia causes cardiac arrest and can be fatal if not rapidly reversed

SA, sinoatrial; *AV*, atrioventricular; *bpm*, beats per minute.

- When delivered into intrapericardial or intrapleural space, nonsustained monomorphic VT occurs in 8% of patients.
- SVT has been documented when used alongside etoposide, and atrial fibrillation has been documented when used alongside a cyclin-dependent kinase inhibitor, but these were single occurrences.
- Bradycardia has been reported in a single case report.

Mechanism of action Alkylating agents prevent cell division by cross-linking DNA strands, generating abnormal base pairing, and inducing DNA strand breaks. They are known to cause acute perimyocarditis and heart failure syndromes, but arrhythmias can also result (Guglin et al., 2009). Arrhythmias are thought to arise from direct cardiotoxicity to myocytes and ischemic damage from coronary vasospasms and intracapillary microthrombi (Tamargo et al., 2015; Kupari et al., 1990).

Anthracyclines

Arrhythmias

- QT prolongation occurs in 11.5%–14.2% of patients with an average prolongation of 14–25 ms.
- Eleven cases of polymorphic VT have been reported, and sudden cardiac death has resulted.
- In one study, 15.2% of patients receiving doxorubicin developed SVT.
- In one study, 12.1% of patients receiving doxorubicin developed nonsustained monomorphic VT.
- In one study, 10.3% of patients receiving doxorubicin developed paroxysmal atrial fibrillation.
- In one study, 3.4% of patients receiving doxorubicin developed bradycardia.
- There is a case report of complete heart block requiring a pacemaker following doxorubicin therapy.

Mechanism of action Anthracyclines inhibit DNA and RNA synthesis by intercalating between base pairs on nucleic acid chains and via topoisomerase binding, thereby preventing cell growth and division (Geisberg et al., 2012). In vitro doxorubicin administration causes arrhythmias in neonatal rat cardiomyocyte cultures (Lampidis et al., 1980), a phenomenon that is blocked by esmolol pretreatment, suggesting that anthracyclines impact beta-adrenoceptor-mediated changes in cardiomyocyte calcium gradients (Gorelik et al., 2003). Further, doxorubicin increases peak current through L-type calcium channels in rat cardiomyocytes (Keung et al., 1991) and inhibits sarcoplasmic reticulum function in rabbit cardiomyocytes (Earm et al., 1994). Action potential prolongation following doxorubicin administration has been demonstrated in vitro (Binah et al., 1983) and may be mediated by sarcoplasmic reticulum calcium leak and inhibition of rectifier potassium currents causing a delayed rise but increased peak intracellular calcium concentrations (Wang and Korth, 1995). Sarcoplasmic calcium-ATPase function is potently inhibited by doxorubicinol, a doxorubicin metabolite, in canine cardiac cells (Boucek et al., 1987).

Antimetabolites

Arrhythmias

- 5-Fluorouracil
  - QT prolongation can occur, but malignant ventricular arrhythmias are rare and often occur in the setting of coronary ischemia or coronary vasospasm rather than directly mediated through the chemotherapeutic agent.
  - SVT occurred in 8.8% of patients in one study.
  - Sinus bradycardia occurs in 2.9%–12%.
  - Nonsustained monomorphic VT occurs in 3.7%–7.4% of patients.
  - Sustained monomorphic VT has been documented in a case report.
  - Atrial fibrillation has been documented in case reports, and incidence may approximate 2.9%.
  - AV block is limited to rare case reports.
- Capecitabine and gemcitabine
  - There was a case of QTc prolongation from 413 to 492 ms followed by polymorphic VT.
  - There was a case of VF felt to be secondary to coronary vasospasm.
  - Atrial fibrillation/flutter was documented in 1.1% of patients treated with capecitabine and in occasional case reports following gemcitabine.
- Fludarabine
  - Atrial fibrillation occurred in 6.1%, and atrial flutter occurred in 2.2% of patients who received fludarabine in preparation for hematopoietic stem cell transplantation.
- Methotrexate
  - There have been isolated case reports of atrial fibrillation, bradycardia, and nonsustained monomorphic VT.

Mechanism of action Antimetabolites are associated with coronary vasospasm mediated through either endothelial nitric oxide synthase-associated direct toxic effects on vascular endothelium or endothelium-independent protein kinase C-mediated vasoconstrictive pathway (Alter et al., 2006; Porta et al., 1998). Other proposed mechanisms include direct endothelial damage causing microvascular thrombus formation and interruption of myocardial cellular metabolism (Becker et al., 1999). The myocardial supply–demand mismatch theory is consistent with ECG findings of ST segment deviation or inversion, pathological Q waves, and decrease in QRS amplitude (de Forni et al., 1992; Tamargo et al., 2015).

Antimicrotubule agents

Arrhythmias

- Taxanes are associated with asymptomatic bradycardia in 2.9%–30%.
- Nonsustained monomorphic VT has been reported with rates as high as 9.1%.
- Sustained monomorphic VT, SVT, AV block, and atrial fibrillation are limited to rare case reports.
- QT prolongation of 2–9 ms is associated with eribulin.

Mechanism of action Antimicrotubule agents prevent cell division by directly interacting with tubulin to stabilize microtubules. They produce cardiotoxicity by reducing coronary flow via vasoconstriction, likely causing the observed conduction abnormalities (Alloatti et al., 1998). They also induce histamine release, which causes bradycardia and AV conduction delays (Rowinsky et al., 1993; Tamargo et al., 2015).

Arsenic trioxide

Arrhythmias

- QT prolongation occurs in 38%–100% and often exceeds a 60 ms increase.
- Nonsustained monomorphic VT occurs in 17%–50% of patients.
- There are at least five reported cases of polymorphic VT.

Mechanism of action Arsenic trioxide increases cardiac calcium currents and reduces trafficking of the human ether-a-go-go-related gene (hERG)-mediated rapid (I_{kr}) and slow (I_{ks}) delayed rectifier potassium channels from the endoplasmic reticulum to the cell membrane (Ficker et al., 2004; Chiang et al., 2002; Drolet et al., 2004; Cubeddu, 2009).

Cytokines

Arrhythmias

- Interferons
  - Eight percent of patients receiving interferon alpha developed SVT, and 12% developed atrial fibrillation.
  - Nonsustained monomorphic VT occurred in 35% of patients receiving interferon gamma.
  - Sustained monomorphic VT and polymorphic VT are limited to case reports.
- Interleukins
  - 9.9%–21.5% of patients receiving IL-2 developed arrhythmia, almost exclusively SVT.
  - Atrial fibrillation and ventricular arrhythmias are limited to rare case reports.

Histone deacetylase inhibitors

Arrhythmias

- QTc prolongation of an average of 14.4 ms is reported.
- Ventricular arrhythmias, atrial fibrillation, and SVT are limited to rare case reports.

Mechanism of action Histone deacetylases modulate histone acetylation, which regulates DNA compaction and ultimately gene expression. Histone deacetylase inhibitors interfere with this process, thereby inducing cell cycle arrest, redifferentiation, and apoptosis (Cuni et al., 2017). The mechanism by which they cause arrhythmias is unclear.

Monoclonal antibodies

Arrhythmias

- Rituximab
  - 2.3% of patients developed bradycardia, and 1.5% developed atrial fibrillation.
  - Nonsustained monomorphic VT is limited to rare case reports.
  - Polymorphic VT occurred in one patient.
- Trastuzumab
  - Sinus bradycardia is reported in 15% of patients, and syncope has resulted.
- Alemtuzumab and nivolumab
  - Atrial fibrillation, sustained monomorphic VT, and AV block are limited to rare case reports.

mTOR inhibitors

Arrhythmias

- There is a case report of bradycardia in a liver transplant patient.
- In adults, SVT is limited to one patient receiving tacrolimus. In the pediatric population, 22.7% of patients receiving tacrolimus had SVT, but these patients also received either azathioprine or mycophenolate mofetil.
- QT prolongation has been demonstrated in multiple animal models, and there are case reports from transplant patients using mTOR inhibitors for immunosuppression.
- Sustained monomorphic VT and polymorphic VT are limited to rare case reports.

Mechanism of action Tacrolimus is a calcineurin inhibition, while sirolimus blocks IL-2 receptor-dependent signal transduction. Both bind FK-binding protein 12 (FKBP12). FKBP12 binds ryanodine receptors in the sarcoplasmic membrane, and this interaction stabilizes calcium currents in cardiomyocytes. Gene knockout or mutation of FKBP12.6 or the ryanodine receptor in mouse models exhibits diastolic sarcoplasmic calcium leaking, atrial fibrillation, and catecholamine polymorphic VT (Li et al., 2012; Sood et al., 2008; Jiang et al., 2010). Overexpression or stabilization of FKP12.6 protects against catecholamine polymorphic VT in mice (Vinet et al., 2012; Gellen et al., 2008; Lehnart et al., 2006). Impaired calcium trafficking may cause action potential prolongation and early after depolarizations (Fauconnier et al., 2005). The arrhythmogenic effects may also be caused by dysregulation of cardiomyocyte sodium currents (Maruyama et al., 2011).

Nonreceptor tyrosine kinase inhibitors

Arrhythmias

- Ibrutinib
  - Atrial fibrillation ranges in incidence from 5.1% to 10.7%. Often, the atrial fibrillation persists despite medical treatment.
  - Ibrutinib also causes platelet dysfunction, which complicates thromboembolic prophylaxis of atrial fibrillation (Yun et al., 2017; Vrontikis et al., 2016).
- Ribociclib
  - QTc prolongation occurred in 9% of patients at 600 mg/day dosing and 33% of patients at >600 mg/day dosing.

Mechanism of action The increased risk of atrial fibrillation in ibrutinib use is thought to be due to decreased phosphoinositide 3-kinase (PI3K)-Akt activity as a result of Bruton tyrosine kinase and tec protein tyrosine kinase inhibition (McMullen et al., 2014). Ribociclib is a cyclin-dependent kinase 4/6 inhibitor (Infante et al., 2016).

Proteasome inhibitors

Arrhythmias

- Bradycardia was reported in 2.9% of patients.
- Atrial fibrillation was reported in 2.9% of patients.
- AV block, atrial fibrillation, and SVT are limited to rare case reports.

Mechanism of action Bortezomib is a 26S proteasome inhibitor used to treat multiple myeloma. By upregulating the adrenergic GRK2, bortezomib may be protective against malignant ventricular tachyarrhythmias in the setting of myocardial ischemia (Yu

et al., 2005; Huang et al., 2008). However, in the absence of myocardial ischemia, this same mechanism may predispose to bradyarrhythmias and AV conduction abnormalities (Enrico et al., 2007).

Thalidomide and analogs

Arrhythmias

- Bradycardia occurs in 12%–53% of patients with several requiring pacemaker implantation.
- QT prolongation and AV block are limited to rare case reports.

Mechanism of action Sinus bradycardia is likely mediated by inhibition of dorsal motor neurons by reduced TNF-α levels (Palumbo et al., 2008; Hinterseer et al., 2006). Coronary artery spasm is a less frequently proposed mechanism (Ali et al., 2013).

Topoisomerase inhibitors

Arrhythmias

- Topoisomerase I inhibitors
  - Atrial fibrillation was reported in 9.5% of patients receiving irinotecan, but they also received carboplatin and paclitaxel.
  - Sustained monomorphic VT and bradycardia are limited to rare case reports.
- Topoisomerase II inhibitors
  - QT prolongation of an average of 64 ms has been reported but resolved within 24 h of infusion.
  - There are 31 cases of ventricular arrhythmia-associated cardiopulmonary arrest occurring within four hours of amsacrine (AMSA) infusion, 14 of which being fatal.
  - The majority of cases of VF occurred in the setting of profound hypokalemia.

Mechanism of action Irinotecan may cause bradycardia by transient noncompetitive inhibition of acetylcholinesterase (Dodds and Rivory, 1999; Miya et al., 1998). Though amsacrine may not directly reduce potassium levels, it does cause acute hypomagnesemia (Seymour, 1993) and blocks cardiac hERG-mediated rectifier potassium currents (Thomas et al., 2004).

Tyrosine kinase inhibitors

Arrhythmias

- QT prolongation has been associated with cabozantinib, ceritinib, crizotinib, dasatinib, erlotinib, gefitinib, imatinib, lapatinib, nilotinib, osimertinib, sorafenib, sunitinib, vandetanib, and vemurafenib.
- The most pronounced QT prolongation has been associated with vandetanib (36.4 ms), nilotinib (25.8 ms), lapatinib (23.4 ms), and sunitinib (22.4 ms).
- VF has been associated in a case report with vandetanib.
- Bradycardia is common following crizotinib with incidence reaching 42%–69%. The average decrease in heart rate is approximately 25 bpm, and patients can have severe bradycardia with heart rates less than 45 bpm.

Mechanism of action Tyrosine kinase inhibitors reduce hERG phosphorylation and in turn inhibit rectifier potassium currents (Zhang et al., 2003, 2008, 2012; Barros et al., 1998; Davis et al., 2001). However, downregulation of PI3K also cause decreased L-type calcium current, decreased peak sodium ion current, and increased persistent sodium current (Lu et al., 2012).

QT Monitoring

The QT interval is used as a surrogate for risk of polymorphic VT, and drugs that prolong the QT interval are felt to increase risk. There is not a consensus definition of QTc prolongation, but the most common definition is QTc >450 ms in men, >470 ms in women, or an increase of 60 ms from baseline (Yusuf et al., 2008). Polymorphic VT almost always occur in patients with a QTc of ≥500 ms, but the true association between QTc duration and risk of malignant arrhythmia is unknown (Piekarz et al., 2006; Bednar et al., 2002) as there are no trials assessing the correlation between QTc interval and patient outcomes (Strevel et al., 2007). Further, there are medications associated with polymorphic VT that do not significantly lengthen the QT interval (Morganroth, 1993). Drug-induced QT prolongation is almost always caused by blockade of hERG association rectifier potassium outflow channels, but not all medications that block hERG potassium channels cause significant QT prolongation (Sanguinetti and Mitcheson, 2005).

Prior to testing for QTc prolongation in clinical trials, several preclinical experiments are performed using animal models and in vitro assays using nonhuman cells transfected with hERG (Sharma et al., 2017). The latest innovations in development involve human-induced pluripotent stem cells. Patient-specific hiPSCs can be induced to differentiate into cardiomyocytes, endothelial cells, and cardiac fibroblasts (**Fig. 1**).

These cells can be used for in vitro studies on chemotherapy-associated cardiomyopathy and high-throughput cell contractility assessments. The results from these analyses can then be used to develop cardiac safety indexes for chemotherapeutic agents (Sharma et al., 2017).

The 2005 International Conference on Harmonization E14 guideline advised clinical QT prolongation evaluation of all nonantiarrhythmic drugs seeking approval at up to maximally tolerated dosing (Food and Drug Administration HHS, 2005; Shah, 2005). The participants for these trials were intended to be healthy volunteers with normal baseline ECG, but given the

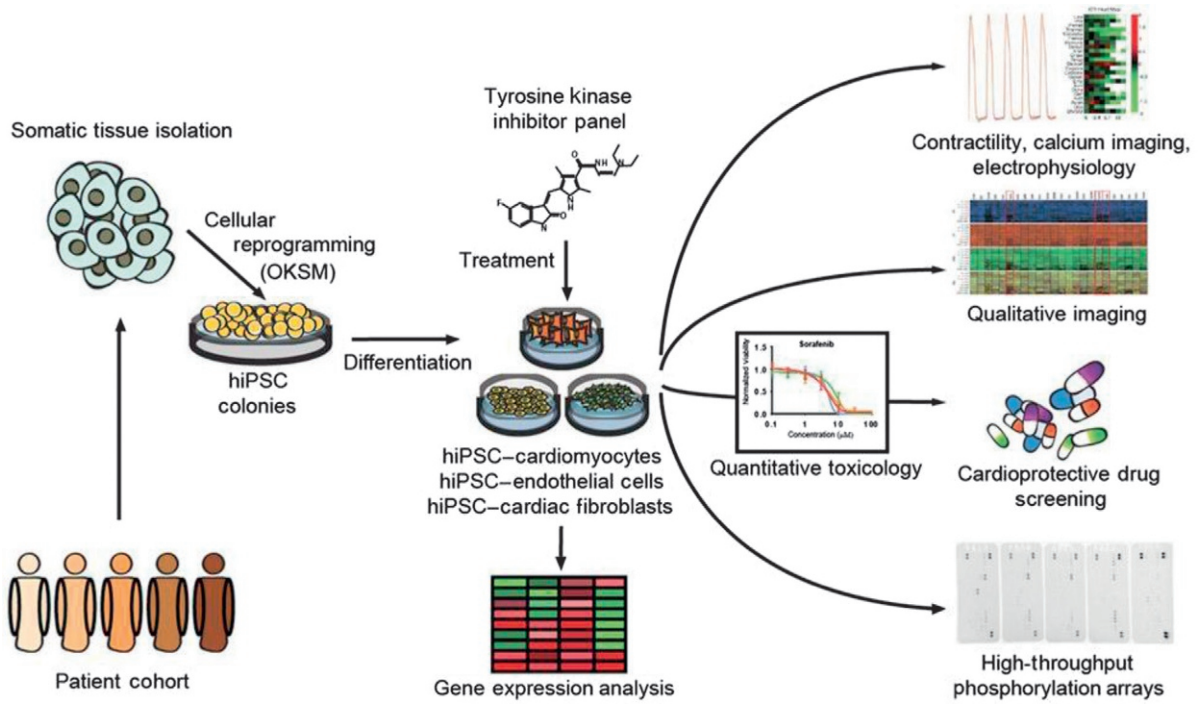

Fig. 1 Using hiPSC-CMs made from somatic tissue samples. hiPSCs were differentiated into hiPSC-CMs, hiPSC-ECs, and hiPSC-CFs. Purified cardiomyocytes were treated with TKIs and examined for alterations in cell viability, contractility, cellular signaling, and gene expression. Reproduced from Sharma, A., Burridge, P. W., Mckeithan, W. L., Serrano, R., Shukla, P., Sayed, N., Churko, J. M., Kitani, T., Wu, H., Holmstrom, A., Matsa, E., Zhang, Y., Kumar, A., Fan, A. C., Del Alamo, J. C., Wu, S. M., Moslehi, J. J., Mercola, M. and Wu, J. C. (2017). High-throughput screening of tyrosine kinase inhibitor cardiotoxicity with human induced pluripotent stem cells. *Science Translational Medicine* **9**, 377.

adverse effects of chemotherapy, it would not be ethical to carry out such studies on cancer medications in healthy patients. Instead, clinical trials are used to evaluate for drug-induced QTc prolongation in chemotherapies (Shah et al., 2013; Rock et al., 2009; Morganroth et al., 2010; Shah and Morganroth, 2012). Individuals with cancer have higher incidence of baseline QT prolongation (Varterasian et al., 2003, 2004; Cuni et al., 2017; Naing et al., 2012), receive additional QT-prolonging medications (Yusuf et al., 2008; Piekarz et al., 2006), and frequently have electrolyte abnormalities. Treatment regimens often include multiple chemotherapeutic agents at a time, making it difficult to determine which agent is responsible for a given outcome or effect (Tamargo et al., 2015). Thus, evaluating the propensity for chemotherapeutic agents to prolong the QTc interval is less straightforward than evaluating in other clinical settings.

The clinical trials used to assess QT prolongation in chemotherapies likely underestimate rare adverse events due to limited sample size and short follow-up times. Postmarketing safety reporting can improve awareness of rare adverse events, but there is no ICD-10 code for QT interval prolongation (Schwartz and Woosley, 2016). Further, only symptomatic cases are reported, and such reports do not include total number of patients receiving medications, so frequency estimations are impossible (Cuni et al., 2017; Tuccori et al., 2015).

Prevention and Management of QT Prolongation

There are multiple mechanisms in place to counteract repolarization abnormalities; thus, QT prolongation is only thought to occur when compensatory mechanisms are impaired. Prevention of QT prolongation centers around minimization of factors that deplete this repolarization reserve (Cuni et al., 2017). Careful family history can suggest congenital long QT syndromes and cardiac risk factors. Laboratory evaluation identifies electrolyte abnormalities that should be corrected, especially hypokalemia and hypomagnesemia. Renal and hepatic insufficiencies are important considerations when considering the pharmacokinetics of a given chemotherapy. Medication reconciliation must be performed to identify concomitate medications that predispose to electrolyte disturbances (such as diuretics) or cause QT prolongation (antiarrhythmics, antibiotics, antifungals, antidepressants, antipsychotics, antiemetics, and antihistamines) (Cuni et al., 2017). The QT interval should be monitored while administering medications with QT prolonging potential, and these medications should be infused slowly. Uvelin et al. and Tisdale have developed algorithm for management of patients with prolonged QT, which is adapted and presented in **Table 3** (Uvelin et al., 2017; Tisdale, 2016). When polymorphic VT does occur, the algorithm in **Table 4** should be implemented promptly to terminate the arrhythmias and prevent degeneration into VF.

Table 3 Prevention of QT prolongation and ventricular arrhythmias

1. Assess the risk for arrhythmia occurrence on admission
   - Measure the QT interval on ECG using Bazett's formula or QT nomogram
   - Corrected QTc >500 ms carries significant risk of polymorphic VT
   - If there is a prolonged QTc, what is the likely cause of this? Look at
     - Patient characteristics
     - Usage of medication prolonging the QT interval
2. Assess the risk for arrhythmia occurrence daily in patients with known risk factors
   - Compare QTc on admission to subsequent days
   - Compare QTc before and after administration of drugs that potentially prolong QT interval
3. Avoid coadministration of two or more medications that prolong QTc
4. Avoid the use of QTc interval-prolonging drugs in patients with QTc >450 ms
5. Avoid the use of QTc-prolonging drugs in patients with heart failure and left ventricular ejection fraction <20%
6. Adjust doses of renally eliminated QTc-prolonging drugs in patients with acute kidney injury or chronic kidney disease
7. Avoid the use of QTc-prolonging drugs in patients with congenital long QT syndromes
8. Reduce dose or discontinue QTc-prolonging drugs if the QTc interval increases to ≥60 ms or to ≥500 ms. Closely monitor QT interval with serial ECGs until the QTc normalizes
9. Beware of the presence of more than one risk factor for polymorphic VT at the same time—for example, electrolyte imbalances and administration of QT-prolonging medication
10. Slow infusion and continuous ECG monitoring mandatory when administering QT-prolonging medication intravenously
11. Correction of electrolyte disturbances
    - Give daily potassium and magnesium supplementation in patients on diuretics
    - Maintain potassium levels at >4.0 mmol/L
12. Patients with known congenital long QT syndrome—same guidelines. These patients should be on a regular β1 adrenergic receptor antagonist

Table 4 Therapeutic options for polymorphic VT

1. Identify and stop the offending agent immediately
2. Call for help
3. If hemodynamically unstable, defibrillate patient
4. If hemodynamically stable, administer magnesium sulfate
   - 1–2 g intravenously administered over 15 min with continuous ECG monitoring
   - Can repeat dosing twice
   - Maintain magnesium levels >1 mmol/L
5. Consider lidocaine administration
   - Bolus 1–1.5 mg/kg body weight
   - Follow with 2 mg/h continuous intravenous infusion
6. Increase heart rate if bradycardia is present
   - Isoproterenol 2–10 mcg/min continuous intravenous infusion or temporary overdrive electric pacing
   - In congenital long QT interval syndrome, use temporary overdrive electric pacing
7. If no bradycardia and persistent polymorphic VT following magnesium, defibrillate patient

Radiation-Induced Arrhythmia

Risk of Arrhythmia

Radiation therapy has become more precise over time allowing for lower doses and reduced risk for long-term adverse effects (Specht et al., 2014). Despite this, arrhythmias are still a known late adverse effect of mediastinal radiation therapy. In 703 patients with Hodgkin's lymphoma and a mean follow-up of 9 years, 16% had an arrhythmia. Most of these patients, however, also received anthracyclines, vinca alkaloids, or both (Maraldo et al., 2015). In cancers with worse prognosis, higher radiation dose can be used as risk of late adverse effects is less of a concern. In 112 patients receiving radiation therapy for stage III non-small-cell lung cancer, atrial fibrillation/flutter occurred in 8.9% patients. This population received a high heart dose (mean 20 Gy) deemed acceptable due

to expected prognosis of less than 2 years (Wang et al., 2017). There are multiple studies evaluating the association between heart radiation dose and cardiovascular adverse effects, but these center more on common sequelae such as myocardial infarction, heart failure, pericarditis, or valvular heart disease than on arrhythmias (Hancock et al., 1993; Hooning et al., 2007; van Nimwegen et al., 2015).

Radiation and CIEDs

Radiation can cause CIED malfunction via direct irradiation to the device (Hurkmans et al., 2005a,b; Mouton et al., 2002; Rodriguez et al., 1991; Brambatti et al., 2015), indirectly due to scattered radiation of neutrons produced by the linear accelerator (Zecchin et al., 2016), or electromagnetic interference from the linear accelerator and betatrons (Brambatti et al., 2015; Makkar et al., 2012; Solan et al., 2004; Marbach et al., 1978; Yerra and Reddy, 2007). The degree of device malfunction varies from temporary changing to interference or safety mode during the radiation therapy session, persistent change to interference or safety mode requiring device reprogramming, to total device failure with cessation of pulse generation (Souliman and Christie, 1994).

Radiation therapy causes device malfunction both in vitro (Zaremba et al., 2014) and in porcine model (Zaremba et al., 2013). In a study of 560 patients with CIED undergoing radiation, Zaremba et al. reported the annual rate of radiation treatment in this population increasing by 199% between 2003 and 2012. In device evaluations after radiation, pacemaker malfunction was 2.5%, while ICD malfunction was 6.8% with the majority of malfunctions being electric resets. There were no life-threatening events or device removals (Zaremba et al., 2015). Brambatti et al. evaluated 261 patients with CIEDs receiving radiation and reported 14.6% requiring device reprogramming and 3.4% undergoing device repositioning to the contralateral side. Three patients experienced inappropriate ventricular pacing, and one patient had a power-on reset of the device (Brambatti et al., 2015). In 69 patients with CIEDs receiving radiation, Makkar et al. reported two patients with resets of ICD with loss of historic diagnostic data, but there were no cases of device malfunction or premature battery depletion over the 6-month follow-up (Makkar et al., 2012). Predictors of CIED malfunction include high beam energy ($\geq$15 MV), neutron-producing radiation, and abdominal/pelvic radiation, while CIED radiation dose does not predict device malfunction (Grant et al., 2015; Zaremba et al., 2015). Device malfunction risks during radiotherapy are summarized in **Table 5** (Viganego et al., 2016).

Due to perceived association of CIED radiation dose and increased risk for device malfunction, there are institution-based standard guidelines currently used to determine when a device should be relocated (Brambatti et al., 2015; Makkar et al., 2012). International guidelines express similar concern about this potential link (in particular when receiving 10 Gy radiation to the CIED or when there is high pacing dependence) and advocate for consideration of device relocation (Hurkmans et al., 2012; Salerno et al., 2016). However, there are trials reporting no association between incident CIED radiation dose and device malfunction and advocate against device relocation (Grant et al., 2015). Further, various guidelines recommended safe radiation dose limits that differ significantly and thus are unreliable (Hudson et al., 2010). With limited available data and the lack of consensus between different guidelines, the decision on whether to relocate a CIED should be multidisciplinary – including cardiologists and oncologists combined input – and on a patient-specific basis (Carrillo, 2012; Zaremba et al., 2016). Manufacturer-based recommendations on RT in patients with a CIED are summarized in **Table 6** (Viganego et al., 2016), and a patient-specific recommendation based on risk stratification is summarized in **Table 7** (Viganego et al., 2016).

Table 5 Cardiac implantable electronic device complications due to RT

Type of CIED failure	*Frequency*
Permanent damage	Rare
Early battery depletion	Rare
Temporary loss of sensing	Uncommon
Transient oversensing or EMI	Uncommon
Temporary pacing inhibition	Uncommon
Temporary loss of capture	Rare
Temporary increase in pacing thresholds	Uncommon
Very rapid pacing	Very rare
Temporary increased sensor rate or change in pacing rate	Common
Power-on reset or revision to safety mode	Common, especially if neutron-producing[a]
Increase battery charge time, decreased shock energy	Rare, described at radiation dose above recommended tolerance
Complete CIED failure (the loss of output/sensing)	Rare, described at radiation dose above recommended tolerance

RT, radiotherapy; *EMI*, electromagnetic interference; *CIED*, cardiac implantable electronic device.

Introduction

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also known as arrhythmogenic right ventricular dysplasia, is a heritable heart-muscle disorder that predominantly affects the right ventricle (Corrado et al., 2017). Macroscopically, there is a scarred appearance with fibrous or fibrofatty replacement of myocardium. These pathologic changes primarily involve the inflow tract, outflow tract, and/or apex of the right ventricular (RV) (Basso et al., 1996). However, more recent data has noted involvement of the posterolateral LV with sparing of the RV apex early in the disease (Protonotarios and Tsatsopoulou, 2004). The RV myocardial scarring initially produces typical regional wall motion abnormalities but later may involve the free wall and become global, producing RV dilation and systolic dysfunction. Tissue replacement can also involve areas of the LV with relative sparing of the septum. In addition, electron microscopy has revealed gap junction abnormalities of desmosomes in the RV myocardium, consistent with mutations in genes encoding desmosomal proteins responsible for ARVC/dysplasia (ARVC/D) in most patients (Crossman et al., 2015).

Clinical perspectives of ARVC/D initially developed from experience with patients who presented with arrhythmias of RV origin and/or sudden death (Hulot et al., 2004). However, additional information regarding the clinical features and course of subjects has developed based on electrocardiographic (EKG) abnormalities and by cascade family screening (Baranchuk et al., 2015; Zhang et al., 2014). Presentation is most common between the ages of 10 and 50 years, with a mean age at diagnosis of approximately 30 years. The disease is virtually never diagnosed in infants or toddlers and is rarely identified before the age of 10 (Philips and Cheng, 2016).

Historical Background

ARVC/D was described by Giovanni Maria Lancisi in 1736 in his book *De Motu Cordis et Aneurysmatibus* (Taylor, 2009). He reported a family with disease recurrence in four generations: the affected members presented with palpitations, heart failure, dilation and aneurysms of the RV, and sudden death. Doctors Marcus, Nava, and Thiene reported the first clinical and pathologic series of

 https://doi.org/10.1016/B978-0-12-809657-4.10912-3

patients with ARVC/D in the 1980s (Taylor, 2009; Basso et al., 2009). Marcus et al. in 1982 reported the disease in adults, first emphasizing the origin of arrhythmias from the RV and the histopathological substrate consisting of fibrofatty replacement of the RV free wall, accounting for epsilon wave and ventricular arrhythmias of RV origin with left bundle branch block (LBBB) morphology (Basso et al., 2009). Nava et al. first proved familial occurrence with an autosomal dominant pattern of inheritance and variable penetrance in 1987–88. In 1988, Thiene et al. observed an impressive series of sudden deaths in the young (≤35 years), with pathology consisting of ARVC/D, most occurring during effort, and all characterized by inverted T waves in the right precordial leads on EKG and apparently benign ventricular arrhythmias of LBBB morphology (Basso et al., 2009). They accounted for 20% of all sudden deaths in the young and for the first time acknowledged that ARVC/D is another important cause of sudden death in that age group (Basso et al., 2009). Diagnostic imaging was then implemented to visualize the RV, either noninvasively through echocardiogram or invasively through angiography. Signal-averaged EKG proved to be a sensitive tool to detect delay in the electrical impulse transmission in the RV myocardium (Gallo et al., 2016; Bae et al., 2014; Kamath et al., 2011). Improvements in diagnostic procedures led to the proposal of diagnostic criteria, whether major or minor, based upon RV dysfunction or structural alterations at imaging, tissue characterization at biopsy, repolarization or depolarization abnormalities and arrhythmias on the EKG, as well as family history of sudden death (**Table 1**) (Calkins, 2015). ARVC/D was included among cardiomyopathies in the revised World Health Organization (WHO) classification in 1995 (McKenna et al., 1994). The first gene defect was discovered in the recessive variant of the disease from the Naxos island consisting of a cardiocutaneous syndrome of ARVC/D, palmoplantar keratosis, and woolly hair. A deletion was detected in the gene encoding plakoglobin, a cell junction protein (Coonar et al., 1998; McKoy et al., 2000). Thereafter, other genes encoding cell junction proteins were found defective in the dominant, classical form of ARVC/D: desmoplakin, plakophilin-2, desmoglein-2, and desmocollin-2. Other variants of the disease were explained by mutation of the ryanodyne 2 receptor and transforming growth factor β 3 genes. The discovery of these gene mutations allowed preliminary genotype–phenotype correlations to be made. The implantable cardioverter defibrillator (ICD) represented a major advance in therapy (Calkins, 2015). Finally, electroanatomic mapping proved to be a sensitive tool for identifying areas of fibrofatty replacement with low-amplitude electrical activity (Mussigbrodt et al., 2017; Orgeron and Calkins, 2016; Pathak and Garcia, 2017; Yin et al., 2017).

Table 1 Task force criteria for the diagnosis of ARVD published in 2010

I. Global and/or regional dysfunction and structural alterations	Major	Two-dimensional echocardiogram: regional RV akinesia, dyskinesia, or aneurysm AND 1 of the following (end-diastole): PLAX RVOT ≥32 mm (corrected for body size [PLAX/BSA] ≥19 mm/m^2) PSAX RVOT ≥36 mm (corrected for body size [PSAX/BSA] ≥21 mm/m^2) Fractional area change ≤33% MRI: regional RV akinesia or dyskinesia or dyssynchronous RV contraction and 1 of the following: Ratio of RV end-diastolic volume to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) RV ejection fraction ≤40% RV angiography: regional RV akinesia, dyskinesia, or aneurysm
	Minor	Two-dimensional echocardiogram: regional RV akinesia or dyskinesia AND 1 of the following (end-diastole): PLAX RVOT ≥29 to <32 mm (corrected for body size [PLAX/BSA] ≥16 to <19 mm/m^2) PSAX RVOT ≥32 to <36 mm (corrected for body size [PSAX/BSA] ≥18 to <21 mm/m^2) Fractional area change >33% to ≤40% MRI: regional RV akinesia or dyskinesia or dyssynchronous RV contraction AND 1 of the following: Ratio of RV end-diastolic volume to BSA ≥100 to <110 mL/m^2 (male) or ≥90 to <100 mL/m^2 (female) RV ejection fraction >40% to ≤45%
II. Tissue characterization of the wall	Major	Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy

(*Continued*)

Table 1 (Continued)

	Minor	Residual myocytes 60%–75% by morphometric analysis (or 50%–65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. Repolarization abnormalities	Major	Inverted T waves in right precordial leads (V1, V2, and V3) or beyond in individuals >14 years of age (in the absence of complete RBBB QRS≥120 ms)
	Minor	Inverted T waves in leads V1 and V2 in individuals >14 years of age (in the absence of complete RBBB) or in V4, V5, or V6 Inverted T waves in leads V1, V2, V3, and V4 in individuals >14 years of age in the presence of complete RBBB
IV. Depolarization/conduction abnormalities	Major	Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of the T wave) in the right precordial leads (V1 to V3)
	Minor	Late potentials by SAECG in ≥1 of 3 parameters in the absence of a QRS duration of ≥110 ms on the standard ECG: Filtered QRS duration (fQRS) ≥114 ms Duration of terminal QRS <40 μV (low-amplitude signal duration) ≥38 ms Root-mean-square voltage of terminal 40 ms 20 μ Terminal activation duration of QRS ≥55 ms measured from the nadir of the S wave to the end of the QRS, including R′, in V1, V2, or V3, in the absence of complete RBBB
V. Arrhythmias	Major	Nonsustained or sustained ventricular tachycardia of left bundle branch morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)
	Minor	Nonsustained or sustained ventricular tachycardia of RVOT configuration, LBBB morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL) or of unknown axis >500 ventricular extrasystoles per 24 h (Holter)
VI. Family history	Major	ARVC/D confirmed in a first-degree relative who meets current Task Force criteria ARVC/D confirmed pathologically at autopsy or surgery in a first-degree relative Identification of a pathogenic mutation categorized as associated or probably associated with ARVC/D in the patient under evaluation
	Minor	History of ARVC/D in a first-degree relative in whom it is not possible or practical to determine whether the family member meets current Task Force criteria Premature sudden death (<35 years of age) due to suspected ARVC/D in a first-degree relative ARVC/D confirmed pathologically or by current Task Force Criteria in second-degree relative

Inheritance Patterns

Two patterns of inheritance have been described in ARVC/D: (1) autosomal dominant form, which is most common, and (2) autosomal recessive form (e.g., Naxos disease, Carvajal syndrome) in which ARVC/D is part of a cardiocutaneous syndrome including hyperkeratosis of the palms and soles and woolly hair. Patients with multiple gene mutations tend to present earlier and with more frequent ventricular tachyarrhythmias, heart failure, and LV dysfunction. Clinical features associated with mutations in each of the associated genes are discussed separately (Campuzano et al., 2013; Hershberger et al., 2009; Lodder and Bezzina, 2013).

Clinical Presentation

Symptoms

The majority of patients ultimately diagnosed with ARVC/D are symptomatic on presentation. The principle symptoms associated with ARVC/D are dizziness, palpitations, and syncope. However, as many as 40% of persons diagnosed with ARVC/D are asymptomatic, coming to attention following screening triggered by a definite diagnosis in a family member. In one of the largest reported series of 130 patients at a tertiary referral center, palpitation was the most common symptoms (67%) followed by syncope (32%) and atypical chest pain (27%) (Hulot et al., 2004).

Sudden Cardiac Death

Sudden cardiac death (SCD) occurs in patients with ARVC/D and can be the first presentation of the disease. In a review, from France, of forensic autopsies (mean age 34 years, males and females equally represented), 200 (10.4%) were associated with ARVC/D. Three-quarters of episodes occurred during routine daily activities, 10% during the perioperative period, and only 3.5% while participating in sports (Tabib et al., 2003).

Ventricular Arrhythmias

Arrhythmogenic cardiomyopathy is distinguished from dilated cardiomyopathy by a higher propensity toward ventricular arrhythmia exceeding the degree of ventricular dysfunction. Ventricular arrhythmias can range from frequent ventricular premature beats (PVC) to sustained ventricular tachycardia (VT) (Nava et al., 2000). The most common ventricular arrhythmia is sustained or nonsustained monomorphic VT that originates in the RV producing a LBBB pattern (Pathak and Garcia, 2017). VT may originate from the RV inflow tract, RV apex, or RV outflow tract. When VT arises from the RV outflow tract, it may be difficult to distinguish ARVC/D from idiopathic RV outflow tract tachycardia. The frequency of various ventricular arrhythmias in ARVC/D differs along with the severity of the disease and varies from 80% to 95%. The incidence of PVCs in patients with Naxos disease is as high as 92%, as well as a higher incidence of sustained ventricular arrhythmias and SCD. Although most of these arrhythmias appear to arise from the RV, histopathologic abnormalities (fibrosis and/or adipose tissue) in the LV and His bundle and its branches were commonly observed at autopsy in a series of patients with ARVC/D and SCD (McKenna et al., 1994).

Supraventricular Tachyarrhythmia

Supraventricular tachyarrhythmia (SVT) is present in up to 25% of patients with ARVC/D referred to for the treatment of ventricular arrhythmias; less often, SVT may be the only arrhythmia present. In decreasing order of frequency, supraventricular arrhythmias in these patients include atrial fibrillation, atrial tachycardia, and atrial flutter (Camm et al., 2013; Tonet et al., 1991).

Left-Dominant Arrhythmogenic Cardiomyopathy

The pathologic process in classic ARVC predominantly involves the RV and sometimes extends to the LV. In contrast, patients with left-dominant arrhythmogenic cardiomyopathy (also known as left-sided ARVC or arrhythmogenic left ventricular cardiomyopathy) have pathological changes that predominantly involve the LV (Di Bella et al., 2009; Sen-Chowdhry et al., 2008).

Asymptomatic Presentation

Approximately 40% of patients are asymptomatic when ARVC/D is identified as part of screening of affected family members. ARVC/D is often suspected due to the presence of nonspecific EKG or echocardiographic abnormalities, or ventricular arrhythmias on Holter or exercise testing in the context of a positive family history.

Diagnostics Criteria

An international task force proposed guidelines in the form of a qualitative scoring system with major and minor criteria in 1994 (McKenna et al., 1994). The task force revised the guidelines in 2010 to improve diagnostic sensitivity, mostly for the clinical screening of family members, by providing quantitative criteria for diagnosing RV abnormalities and adding molecular genetic criteria (**Table 1**) (Marcus et al., 2010a). However, the diagnosis remains problematic because of the low specificity of EKG abnormalities, multiple causes of RV arrhythmias, difficulties in the use of imaging to assess RV structure and function, and the sometimes puzzling results of genetic testing.

Electrocardiogram

Abnormalities of EKG are both related to depolarization and repolarization. The pathognomonic abnormality of repolarization is epsilon wave. The repolarization abnormalities are T wave inversion (**Fig. 1** and **Table 1**).

Signal-Averaged Electrocardiogram

Signal-averaged electrocardiogram (SAECG) is an example of high-resolution EKG. The SAECG is a computerized technique for detecting subtle abnormalities in the surface EKG that are not visible to the naked eye. It is calculated by computing the arithmetic mean of multiple EKG complexes. SAECG records ventricular signals of very low magnitude. These are also called ventricular late potentials. The purpose of signal averaging is to improve the signal-to-noise ratio to facilitate the detection of low-amplitude bioelectric potentials. Averaging multiple QRS complexes (or p waves) "reinforces" the consistent ventricular component while diminishing the inconsistent noise components, thus improving the signal-to-noise ratio (**Fig. 2**).

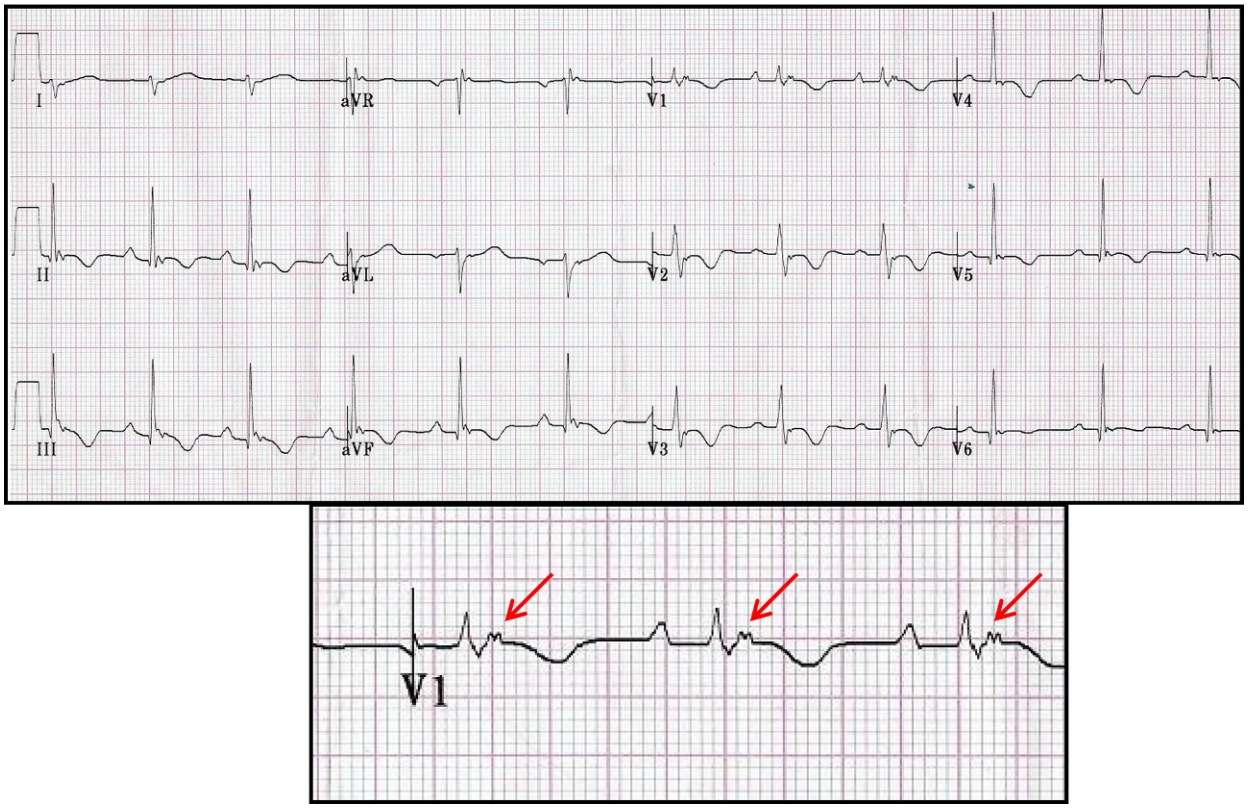

Fig. 1 An EKG showing Epsilon waves and T wave inversions. *Arrows* are pointing at Epislon waves.

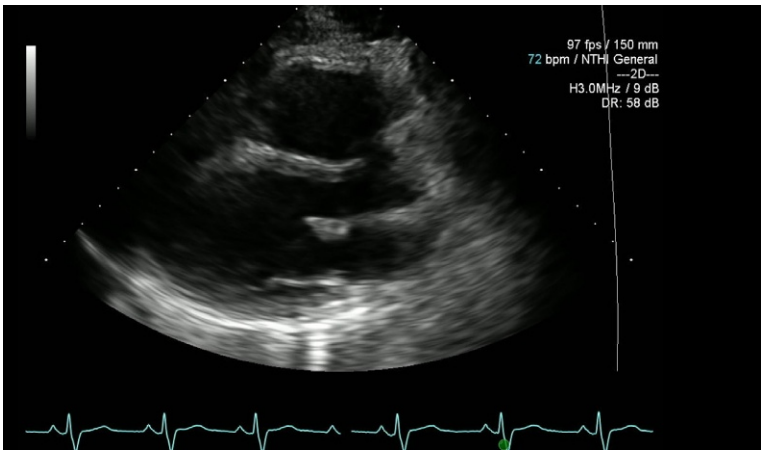

Fig. 2 A two-dimensional transthoracic echocardiogram image showing enlarged RVOT diameter.

Cardiac Magnetic Resonance for Diagnosis of ARVC/D

Cardiac magnetic resonance (CMR) imaging is a critical tool for evaluating functional and structural cardiac abnormalities in subjects being examined for ARVD/C. According to the CMR imaging criteria described by the 2010 TFC, the presence of regional RV akinesia, dyskinesia, or dyssynchronous RV contraction is essential to meet criteria for ARVC/D diagnosis. Subsequently, based on different degrees of RV end-diastolic volume index (RVEDVI) enlargement and quantitative assessment of RV ejection fraction (RVEF), major or minor criteria are fulfilled (Marcus et al., 2010b). Some MRI studies suggest that RV fatty infiltration and late gadolinium enhancement are common in these patients; however, reliance on subjective assessment of RV fibrofatty infiltration by CMR has been proven to be problematic and for this reason these pathologic findings are not included in the current task force criteria (Fig. 3; Rastegar et al., 2016).

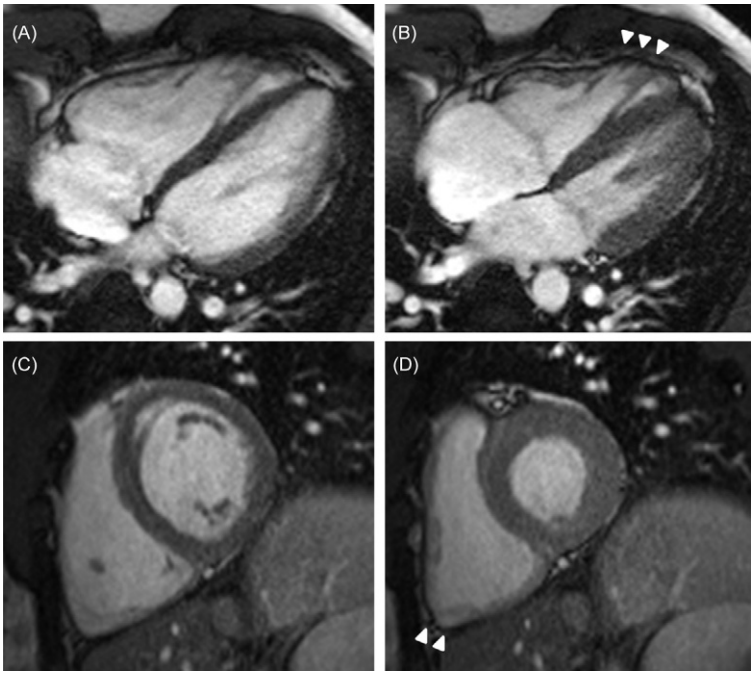

Fig. 3 Four-chamber (top panels) and short-axis (bottom panels) bright blood images in a male subject presenting with syncope. End-diastolic images are shown in the left panels, while end-systolic images in the right panels. The right ventricle is dilated (RVEDVI = 115 mL/m^2) with mild systolic dysfunction (RVEF = 41%). Evidence of apical dyskinesia (*white arrowheads* in panel B). Small outpouching area is also noted in the systolic short-axis image (*white arrowheads* in panel D). Overall these findings meet major MRI criteria for ARVC.

Misdiagnosis of ARVC/D Using CMR

Misdiagnosis of ARVC/D is a well-recognized problem. In many cases, CMR misinterpretation is the cause of overdiagnosis of ARVC/D. It is important to realize that, although CMR may be regarded the standard of reference for evaluation of RV morphology and function, the use of CMR alone is not the "gold standard" for ARVC/D diagnosis. Rather, the TFC prescribe the use of multiple diagnostic tests. Great caution must be employed when the only abnormality in a presumed ARVC/D patient is found on CMR, as it is uncommon for ARVC/D patients to have a normal EKG and Holter monitor but an abnormal CMR.

Genetics of ARVC/D and Family History

Several desmosomal gene mutations have been found in patients with ARVC/D. The estimated overall rate of successful genotyping among patients meeting the diagnostic criteria for ARVC established by the international task force is approximately 50%. The most commonly affected gene is plakophilin 2 (PKP2) (in 10%–45% of patients), followed by desmoplakin (DSP) (10%–15%), desmoglein 2 (DSG2) (7%–10%), and desmocollin-2 (DSC2) (2%). Screening of nondesmosomal genes only marginally affects the detection rate for mutations. Genotyping is most often used to identify a mutation that is considered likely to be causal in a proband who fulfills phenotypic diagnostic criteria, and thus to identify gene carriers among family members by means of mutation-specific genetic testing. Genotyping to confirm the diagnosis in an isolated patient with a borderline or questionable phenotype is not indicated on a routine basis. The true prevalence of disease-causing mutations has yet to be determined. Therefore, a negative genetic test does not exclude the possibility that the phenotype is due to a mutation of an unknown disease-causing gene. On the other hand, the interpretation of an apparently positive genetic test for ARVC is made more challenging by the difficulty in differentiating causative mutations, especially missense mutations, from nonpathogenetic variants and polymorphisms, mainly because of the lack of functional or biologic studies that confirm the pathogenetic effects of gene variants. The prognostic value of genotyping also remains to be elucidated. Patients with multiple desmosomal gene mutations are likely to have a more severe phenotype and may have an increased lifetime risk of malignant arrhythmias and SCD.

Genetic counseling should be sought for interpretation of the commercially available genetic tests for ARVC. Otherwise, critical information regarding the complexity of genetic data and their limitations for clinical diagnosis and prognosis may not be made clear when the results of such tests are reported.

Clinical Management

Risk Stratification

The estimated overall mortality varies among studies, ranging from 0.08% to 3.6% per year (Corrado et al., 2017). The clinical course of ARVC is characterized by the occurrence of arrhythmic events, which can cause sudden death, and the impairment of biventricular systolic function, which can lead to death from heart failure. Recent studies have shown that annual mortality in the index patients and family member is less than 1% (Zorzi et al., 2016; Groeneweg et al., 2015). The mortality was initially overestimated because it was based on studies at tertiary referral centers, which predominantly included high-risk patients.

Prognosis

The prognosis for patients with ARVC depends largely on the severity of arrhythmias and ventricular dysfunction (Priori et al., 2015). Prior cardiac arrest due to ventricular fibrillation and sustained VT are the most important predictors of life-threatening arrhythmic events during a follow-up. Major risk factors include unexplained syncope, nonsustained VT on ambulatory monitoring or exercise testing, and severe systolic dysfunction of the right ventricle, left ventricle, or both. Although intracardiac electrophysiological (EP) testing has traditionally been used to assess the risk of ventricular arrhythmias, the prognostic value of VT or ventricular fibrillation induced by programmed ventricular stimulation in patients with asymptomatic ARVC remains unclear.

Sports Restrictions

The aims of clinical management of ARVC are to reduce the risk of SCD and improve the quality of life by alleviating arrhythmic and heart failure symptoms. Restriction from intense sports activity is regarded as an important preventive tool for both healthy gene carriers and clinically affected persons in order to protect them from the risk of exercise-related malignant arrhythmic events and disease development or progression. The available evidence indicates that family members with a negative phenotype (either healthy gene carriers or those with an unknown genotype) do not need any specific treatment other than sports restriction; however, lifelong clinical assessment with the use of noninvasive tests at least every 2 years is warranted because of the age-related penetrance and progressive nature of ARVC. The risk of SCD during exercise may be due in part to increased stress on the RV. The association with exercise and RV stress and the frequent induction of arrhythmia by isoproterenol infusion suggest a role for catecholamines. Data obtained from exercise questionnaires and interviews indicate a strong association of endurance training with disease development and arrhythmic risk, supporting three decades of anecdotal observations that endurance sport is particularly dangerous in ARVC/D and should be avoided. Studies have also shown that patients with a desmosomal mutation require far less exercise to develop ARVC/D than patients who are mutation and family history negative. Based on this data, patients with ARVC/D should avoid competitive and endurance exercise. Only low intensity activity (e.g., walking, golf) should be advised. Although a specific cut-off for what level of exercise is safe is not well defined, any activity that causes symptoms of palpitations, presyncope, or syncope should be avoided (Maron et al., 2015).

Pharmacotherapy

Despite limited supportive data, beta-blockers are currently recommended for all clinically affected persons, for both prevention of arrhythmias and reduction of RV wall stress. In patients with ventricular arrhythmias, antiarrhythmic drug therapy offers the potential to ameliorate symptoms, although there is no proof that it confers protection against SCD. Amiodarone, alone or in association with beta-blockers, and sotalol are the most effective drugs, combining the synergistic effects of class III antiarrhythmic properties and beta-adrenergic blockade. The potential for serious cumulative toxic effects precludes long-term therapy with amiodarone, especially in younger patients. Patients in whom right or left heart failure develops are treated with standard pharmacologic therapy, including angiotensin-converting-enzyme inhibitors, angiotensin II receptor blockers, beta-blockers, and diuretics. Therapy with oral anticoagulants is reserved for patients with atrial fibrillation or thromboembolic complications (Hulot et al., 2004).

Catheter Ablation

Catheter ablation is a therapeutic option for patients who have episodes of sustained, monomorphic VT. However, it should be regarded as a palliative rather than curative therapeutic approach because of the high frequency of subsequent recurrences of VT and the unproven efficacy of ablation as a means of preventing SCD (Marchlinski et al., 2004). The poor long-term outcome has been attributed to the progressive nature of ARVC, which leads to the development of multiple arrhythmogenic foci over time. The epicardial location of some VT reentry circuits, which reflects the propensity of ARVC lesions to originate and progress from the epicardium, may also explain the failure of conventional endocardial mapping and catheter ablation (Thiene et al., 1988). Several studies have shown the feasibility and efficacy of epicardial catheter ablation for patients in whom one or more endocardial procedures have been unsuccessful. Radiofrequency ablation and medical therapy with antiarrhythmic agents are usually reserved to prevent or reduce ICD shocks.

Defibrillator Therapy

Although randomized trials of defibrillator therapy have not been performed, data from observational studies have consistently shown that it is effective and safe. Patients who benefit most from defibrillators are those who have had an episode of ventricular fibrillation or sustained VT (Groeneweg et al., 2015). It remains uncertain whether defibrillator therapy is appropriate for primary prevention of SCD among patients with one or more risk factors and no prior major arrhythmic events. In asymptomatic patients with no risk factors and in healthy gene carriers, there is generally no indication for prophylactic defibrillator implantation because of the low risk of arrhythmias and the significant risk of device- and electrode-related complications during long-term follow-up (estimated rate, 3.7% per year) (Wichter et al., 2004).

Therapies on the Horizon

Current therapeutic approaches to ARVC are palliative and partially alleviate symptoms and the risk of SCD but do not prevent the development or progression of the disease process. A definitive curative treatment will require a deeper knowledge of the biologic mechanisms and environmental factors involved in the pathogenesis of ARVC. A recent observation concerns a small molecule designated SB216763, which is an activator of the Wnt signaling pathway. This molecule has been shown to prevent or reverse phenotypic manifestations of ARVC induced by overexpression of defective plakoglobin in a zebrafish model, as well as in rat cardiac myocytes (Asimaki et al., 2014). Although this drug is of interest as a potential mechanism-based therapy of ARVC, it has not yet been studied in humans.

Cardiac Transplantation

Cardiac transplantation is the ultimate therapy for patients with untreatable arrhythmias (e.g., incessant storms of VT or fibrillation) or congestive heart failure that is refractory to pharmacologic and nonpharmacologic therapies (Tedford et al., 2012).

Pregnancy Counseling

Genetic counseling should be performed in ARVC/D patients and their partners when planning a pregnancy, delineating the dominant inheritance mode with variable penetrance in ARVC/D (Agir et al., 2014; Murray et al., 2013; Iriyama et al., 2013; Hodes et al., 2016; Herrey, 2014). In women with ARVC/D, increased circulatory demand during pregnancy and delivery may in theory precipitate disease progression and trigger symptoms, that is, ventricular arrhythmias. Larger studies of pregnancy in women with ARVC/D are lacking, but case reports have indicated that pregnancy in ARVC/D is generally well tolerated. In severe ARVC/D cases, a moderate risk of disease progression and arrhythmia has been observed from the last trimester until 2–3 months postpartum. In women with RV failure including significant LV involvement, larger studies are lacking, but pregnancy may impose additional risks that need to be addressed at prepregnancy counseling. The influence of repeated pregnancies on RV size and function as well as worsening of symptoms is not known. Pregnancy in women with ARVC/D needs to be addressed by a multidisciplinary team involving cardiologists, obstetricians, and anesthesiologists at a tertiary center. During pregnancy we advocate clinical workup at 3 and 7 months of gestation, as well as at 2–3 months postpartum, including 12-lead EKG, 24-h Holter monitoring and echocardiography, and additional visits if symptoms occur. Antiarrhythmic medication should be continued throughout pregnancy, but may be altered if there are contraindications. Beta-blocker medication is generally well tolerated, and flecainide may also be maintained during pregnancy. Amiodarone is usually regarded as contraindicated during pregnancy due to teratogenicity and high rates of abnormal thyroid function in the newborn. Ideally, indications for ICD should be reassessed before pregnancy. Arrhythmias during pregnancy may warrant ICD implantation. ICD discharge and external electrical cardioversion in case of VT are generally well tolerated by the fetus. In female ARVC/D patients without arrhythmias or abnormal contractile function, vaginal delivery is preferred. In cases with symptomatic ARVC/D, a cesarean section during epidural anesthesia is advocated. Telemetry monitoring during delivery should be continued in 24 h postpartum. In cases with maternal antiarrhythmic medication, the child should be transferred to the neonatal unit for 24-h observation.

Summary

ARVC/D is a genetically determined and heritable form of cardiomyopathy. It is characterized pathologically by the replacement of myocytes by adipose and fibrous tissue and leads to RV failure, arrhythmias, and SCD. The estimated prevalence of ARVC/D in the general population ranges from 1 in 2000 to 1 in 5000. Men are affected more frequently than women, with an approximate ratio of 3:1. ARVC/D can be inherited as an autosomal dominant disease with reduced penetrance and variable expression. Autosomal recessive inheritance is also described. Twelve genes have been identified which are linked to ARVC/D, encoding several components of the cardiac desmosome. Dysfunctional desmosomes resulting in defective cell adhesion proteins, such as plakoglobin (JUP), desmoplakin (DSP), plakophilin-2 (PKP-2), and desmoglein-2 (DSG-2), consequently cause loss of electrical coupling between cardiac myocytes, leading to myocyte cell death, fibrofatty replacement, and arrhythmias. Diagnosis is based on a combination of characteristic abnormalities in family history, electrocardiography, cardiac imaging, as well as endomyocardial

biopsy. Therapeutic options remain limited due to the progressive nature of ARVC/D. Competitive athletics should be avoided. Individuals with ARVC/D and a history of resuscitation from SCD, syncope, the very young, and those with marked RV involvement are at the highest risk for arrhythmic death. The presence of left ventricular (LV) involvement is also a risk factor. Patients who meet the Task Force criteria for ARVC/D are at high risk for SCD and should be considered for ICD placement for primary or secondary prevention, regardless of EP testing results. The role of the EP study and catheter ablation in ARVC/D remains poorly defined, and is frequently used as a palliative measure for patients with refractory VT. Sotalol has been shown to be effective in patients with ARVC/D for inducible as well as noninducible spontaneous VT. Heart transplantation is considered in patients with progressive heart failure and intractable recurrent ventricular arrhythmias.

Introduction

Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is an inherited cardiomyopathy characterized pathologically by replacement of the cardiac myocytes with fibrofatty tissue (Fig. 1); this predisposes patients to ventricular arrhythmias (VA), right ventricular failure, and increased risk of sudden cardiac death (SCD). Although structural involvement of the right ventricle predominates, a left dominant form is also seen. In most patients in the United States, structural abnormalities of the right ventricle predominate.

Since ARVD/C was first described in 1982 (Marcus et al., 1982), significant advances have been made in the understanding of the different aspects of this disease. The revision of the task force criteria (TFC) for the diagnosis of ARVD/C in 2010 (Marcus et al., 2010) improved diagnostic sensitivity by taking into account new magnetic resonance imaging (MRI) technology to evaluate cardiac structural abnormalities and new knowledge about genetic testing and electrocardiographic abnormalities.

The treatment of ARVD/C is aimed at properly risk stratifying patients that would benefit from an implantable cardioverter defibrillator (ICD) for the prevention of SCD. Antiarrhythmic drugs and catheter ablation are also commonly used to improve quality of life by preventing VA. Another important consideration in patients with ARVD/C is exercise restriction, since there is increasing evidence supporting the role of exercise as key environmental factor for the development and progression of this disease.

Although there is a lack of rigorous evidence on how to treat and risk stratify patients with ARVD/C, research efforts from many expert groups around the world have helped to a better understanding of the disease and its management.

The purpose of this article is to review the current knowledge of the natural history, clinical presentation, diagnosis, and management of patients with ARVD/C.

Clinical Presentation and Natural History

ARVD/C is a rare inherited cardiomyopathy, with an estimated prevalence of 1 per 5000 individuals (Peters et al., 2004). Patients usually present during the second to fifth decade of life with symptoms that can be attributed to the presence of VA, such as presyncope, syncope, and palpitations with progression to heart failure being uncommon (Groeneweg et al., 2015; Dalal et al., 2005).

Although ARVD/C is predominantly a disease of the right ventricle (Jain et al., 2008; Rastegar et al., 2014, 2015; Bhonsale et al., 2015), involvement of the left ventricle (LV) may occur. Left-dominant arrhythmogenic cardiomyopathy is usually present with arrhythmias of LV origin and the absence of significant right ventricular (RV) systolic dysfunction (Bhonsale et al., 2015; Sen-Chowdhry et al., 2008).

The presentation, clinical course, and survival outcomes of a cohort of 439 index patients who met 2010 TFC for ARVD/C have also been reported (Groeneweg et al., 2015). The mean age at presentation was 36 ± 14 years, and mutations were identified in 63% ($n = 276$). Most patients were symptomatic at presentation ($n = 419$). Forty-eight (11%) presented with cardiac arrest, 25 were resuscitated, and 23 died, and the diagnosis was established at autopsy. An additional 220 (50%) patients presented with a sustained ventricular arrhythmia. During follow-up, 139/171 and 212/245 patients received an ICD for primary and secondary prevention of SCD, respectively. Close to half (48%) of the patients that did not have an ICD implanted ($n = 65$) had sustained VA during follow-up. Recurrent sustained VA was seen in 72% ($n = 301$) index patients at follow-up. After a median follow-up of 7 years, 10 (3%) of patients with an ICD died (3 with heart failure, 2 SCD, 2 of a combination of arrhythmias and heart failure, and

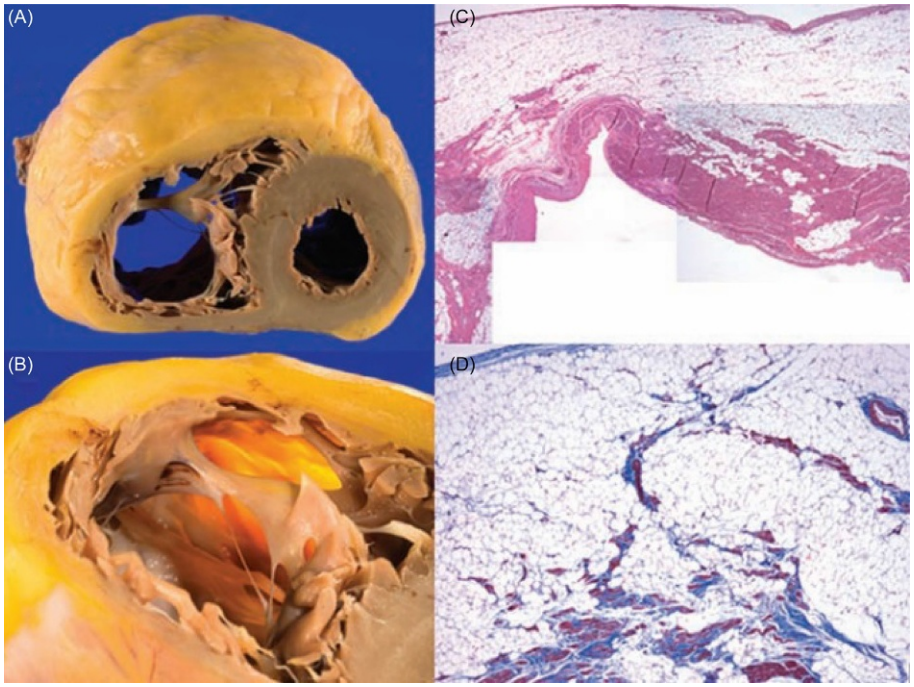

Fig. 1 (A—upper left) Gross specimen of an explanted heart showing a massive right ventricular (RV) with extensive fat that replaced entire RV epicardium leaving a thin rim of fibrotic endocardium. Also note the relative sparing of the left ventricle and the interventricular septum. (B—lower left) Near total fatty replacement of the RV wall with loss of myocytes renders the RV translucent. (C—upper right) Transmural low-resolution histopathologic image shows the fat replacement extending from epicardium to the endocardium. (D—lower right) Trichrome staining reveals fibrous tissue interspersed with fat tissue characteristic of this disease. Reproduced with permission from Tandri, H., Asimaki, A., and Dalal, D. et al. (2008). Gap junction remodeling in a case of arrhythmogenic right ventricular dysplasia due to plakophilin-2 mutation. *Journal of Cardiovascular Electrophysiology* **19**(11), 1212–1214.

3 of noncardiac causes). Eleven (17%) patients without an ICD died (10 SCD and 1 with heart failure). During long-term follow-up, 54 patients (13%) developed symptomatic heart failure, and 18 (4%) underwent cardiac transplantation with 4 dying during follow-up. Overall, 391/416 index patients (94%) who presented alive were alive at the last follow-up. In conclusion, long-term outcome of patients with ARVD/C was favorable in those that were diagnosed and treated appropriately with progression to heart failure being uncommon. ICD implantation reduced the incidence of SCD during follow-up (**Fig. 2**).

Dalal et al. (2005) studied 100 patients diagnosed with ARVD/C with a total of 47 patients received an ICD with 62% ($n=29$) receiving an appropriate ICD therapy at follow-up. Twenty-three patients died at presentation (21 SCD and 2 noncardiac deaths) and 11 died during follow-up (10 SCD and 1 biventricular heart failure). After a median follow-up of 6 years, the majority of patients ($n=66$) were alive (44 had an ICD, 5 had signs of heart failure, 2 had heart transplant, and 18 were on drug therapy), showing that once diagnosis of ARVD/C is established and patients undergo ICD implantation, the mortality is low.

Te Riele et al. (2015) compared a cohort of 75 pediatric-onset cases of ARVD/C (mean age at presentation 15.3 ± 2.4 years) with 427 adult patients (mean age at presentation 38.6 ± 13.4). The authors observed that pediatric patients were more likely to present with SCD ($p=0.003$) or resuscitated cardiac arrest, compared with adults who presented most commonly with sustained ventricular tachycardia (VT) ($p=0.359$). However, once ARVD/C is diagnosed, survival free from sustained ventricular tachycardia, cardiac transplantation, and death was similar between the two groups after more than 8 years of follow-up.

Pathophysiology and Genetics

The genetics of ARVD/C supports the hypothesis that this is a disease of desmosomal dysfunction. Although the pathogenesis of ARVD/C is not fully understood, it is believed that abnormalities in the desmosomal proteins may lead to impaired mechanical coupling between individual cells, which then causes myocyte uncoupling resulting in inflammation, fibrosis, and adipocytosis. This is especially true in situations that increase myocardial strain, such as exercise (Orgeron and Calkins, 2016). This remains an active area of investigation.

ARVD/C is commonly inherited in an autosomal dominant manner with incomplete penetrance and variable expressivity. Genetic testing of probands and family members has become a very important part of the diagnosis and screening of ARVD/C since desmosomal mutations can be found in up to 60% of affected individuals (Groeneweg et al., 2015; Den Haan et al., 2009). Thus, the lack of an identifiable mutation does not exclude the disease.

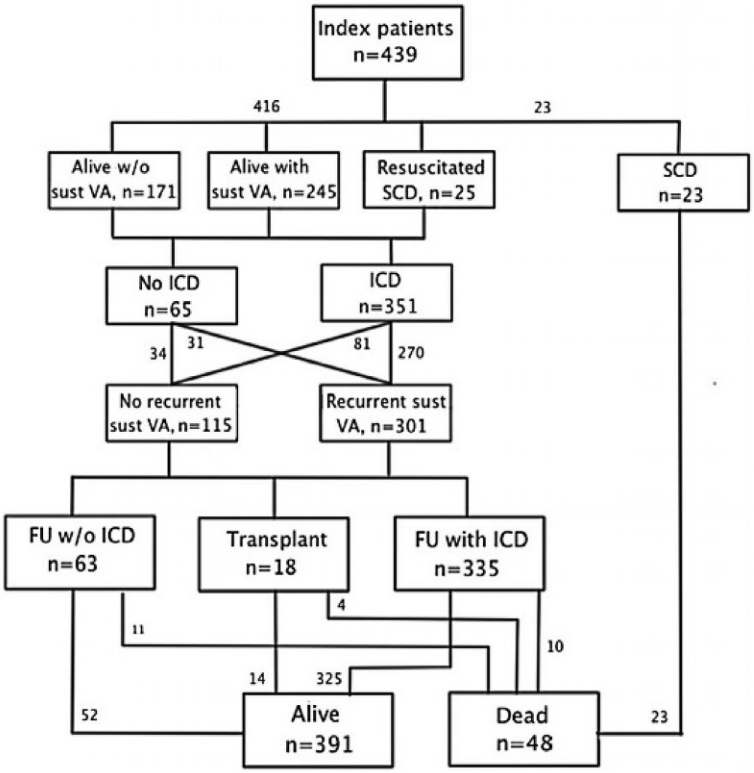

Fig. 2 Schematic representation of the presentation, clinical course, and outcome in arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) index patients. The majority presented with sustained ventricular arrhythmias (VA) and received an implantable cardioverter defibrillator (ICD) during follow-up. Reproduced with permission from Groeneweg, J., Bhonsale, A., and James, C. et al. (2015). Clinical presentation, long-term follow-up, and outcomes of 1001 arrhythmogenic right ventricular dysplasia/cardiomyopathy patients and family members. *Circulation Cardiovascular Genetics*, **8**(3), 437–446.

In a minority of cases, ARVD/C can also be inherited in an autosomal recessive pattern as part of a cardiocutaneous syndrome such as Naxos disease or Carvajal syndrome (Protonotarios and Tsatsopoulou, 2004). The identification of a plakoglobin (JUP) mutation that affects a key component of desmosomes in Naxos syndrome led to several studies investigating their role in other arrhythmogenic cardiomyopathies. Posteriorly, several ARVD/C-associated mutations were identified: plakophilin-2 (PKP2), desmoplakin (DSP), desmoglein-2 (DSG2), and desmocollin-2 (DSC2) (Bhonsale et al., 2015; Den Haan et al., 2009). Mutations in several nondesmosomal genes such as cardiac ryanodine receptor (RyR2), phospholamban (PLN), transmembrane protein 43 (TMEM43), titin, and transforming growth factor β3 (TGFβ3) have also been observed in atypical forms of ARVD/C.

The genetic findings of 577 patients from 241 unrelated families, selected based on the presence of an ARVD/C-related mutation, have been reported (Bhonsale et al., 2015). The majority of participants in the study, 80% ($n=463$), were carriers of a PKP2 mutation, with fewer heterozygous carriers for other mutations associated with ARVD/C (31 DSG2, 31 PLN, 19 DSP, 8 DSC2, 2 JUP, and 1 TMEM43). Four percent ($n=22$) of participants carried two or more pathogenic mutations. The authors observed that patients presenting with SCD/ventricular fibrillation (VF) were younger (median 23 vs. 36 years) than those presenting with sustained monomorphic VT. They also noticed that patients with more than one mutation had earlier occurrence of sustained VT/VF, lower VT/VF free survival and more frequent left ventricular dysfunction, heart failure, and cardiac transplantation than those with only one mutation. Lastly, men were more likely to be symptomatic probands, and they had earlier and more severe arrhythmic expression.

Diagnosis of ARVD/C

The diagnosis of ARVD/C is made through a scoring system with major and minor criteria, based on demonstrating a combination of ventricular dysfunction and structural alterations, tissue characterization, electrocardiographic repolarization/depolarization abnormalities, VA, family history, and genetic testing. A definite diagnosis is made if a patient has "4 points", with a major criterion equal to 2 points and a minor criterion equal to "1 point". A borderline diagnosis is made with "3 points" and a possible diagnosis with "2 points." The original 1994 TFC were updated and published in 2010; their aim was to increase diagnostic sensitivity by integrating new knowledge and technology (Marcus et al., 2010).

It is important to note that there is no gold-standard diagnostic test for ARVD/C. On initial evaluation, all patients should have a physical exam and comprehensive clinical history that includes information about family history of sudden death and arrhythmias; an ECG, 24 h Holter monitoring, signal-averaged ECG, and comprehensive imaging of both ventricles should also be obtained. If the initial workup is suggestive but not diagnostic of ARVD/C, an electrophysiological study should be considered to establish the diagnosis. Right ventriculography and endomyocardial biopsy were also used to aid in the diagnosis of ARVD/C in the past, but they are rarely used currently (Orgeron and Calkins, 2016).

ECG abnormalities are extremely frequent in patients with ARVD/C (Nasir et al., 2004; Te Riele et al., 2013a; Jain et al., 2009). T-wave inversion (TWI) in the right precordial leads (V1–V3) is a major diagnostic criterion, and it is the most common ECG manifestation of ARVD/C. TWI in leads V1 and V2 is a minor criterion. The presence of incomplete or complete right bundle branch block (RBBB) makes the interpretation of known depolarization abnormalities difficult, and it is commonly found in patients with severe cardiac structural abnormalities (Jain et al., 2009). TWIs through V3 still appear to be the feature with the optimal sensitivity and specificity. However, in patients with complete RBBB, R/S ratio <1 in V1 seems to provide the optimal sensitivity and specificity in diagnosing ARVD/C (Jain et al., 2009). T-wave inversion beyond V3 in patients with complete RBBB is also a feature of ARVD/C. Epsilon waves, which are distinct low-frequency deflections in the ECG that occur following the QRS and before the T wave, are uncommon and a marker of advanced ARVD/C. The new diagnostic criteria for ARVD/C include terminal activation delay, which is defined as a prolonged duration of time (>55 ms) from the S wave to the termination of the QRS complex as a minor criterion for ARVD (Marcus et al., 2010) (**Fig. 3**).

A signal-averaged ECG (SAECG) is considered abnormal if one or more of the following criteria are present: (1) filtered QRS duration (fQRS) >114 ms. (2) Terminal low-amplitude (<40 μV) signal duration ≥ 38 ms. (3) Root-mean-square voltage of the terminal 40 ms of the filtered QRS complex (RMS40) <20 μV. A positive SAECG is considered a minor criterion (Marcus et al., 2010).

Holter monitoring is commonly used for the evaluation of frequent premature ventricular contractions (PVCs) and sustained/nonsustained ventricular tachycardia. A left bundle branch block (LBBB) morphology is consistent with the diagnosis of ARVD/C. The presence of 500 PVCs or more per 24 h is considered a minor criterion (Marcus et al., 2010), and it is frequently found in patients with ARVD/C. Bhonsale et al. (2011) reported that patients with higher PVC burden were more likely to receive an appropriate ICD intervention (**Fig. 4**). Other options such as implantable loop recorders, exercise testing to induce VT, or extending the duration of Holter monitoring can be used in the event that a Holter monitor does not capture any arrhythmia.

Echocardiography is the most widely available tool for the assessment of ventricular structure and function. Global or segmental wall motion abnormalities with cavity dilation, hypertrophic RV trabeculation, and systolic dysfunction are some of the findings on a transthoracic echocardiogram that are suggestive of ARVD/C. Right ventricular outflow tract (RVOT) dilation (diameter >30 mm) has been reported to have the highest sensitivity and specificity of echocardiographic parameters in diagnosing ARVD (Marcus et al., 2010). Cardiac MRI (CMR) imaging is the imaging modality of choice in evaluating the right ventricle in ARVD/C (Jain et al., 2008; Rastegar et al., 2014, 2015; Bhonsale et al., 2015; Te Riele et al., 2013b, 2014; Vigneault et al., 2016). CMR has the benefit of providing tissue characterization and identification of intramyocardial fat and fibrosis in addition to assessment of ventricular structure and function (**Fig. 5**). Although MRI is a very important diagnostic tool, it can also be a common cause for misdiagnosis (Bomma et al., 2004). The major and minor criteria for ARVD/C on echocardiogram and CMR are listed in **Table 1**.

Endomyocardial biopsies have been reported to have diagnostic value in the past (Asimaki et al., 2009) especially when the diagnosis is unclear or there is need to rule out a competing diagnosis. However, the test appears to have low diagnostic sensitivity

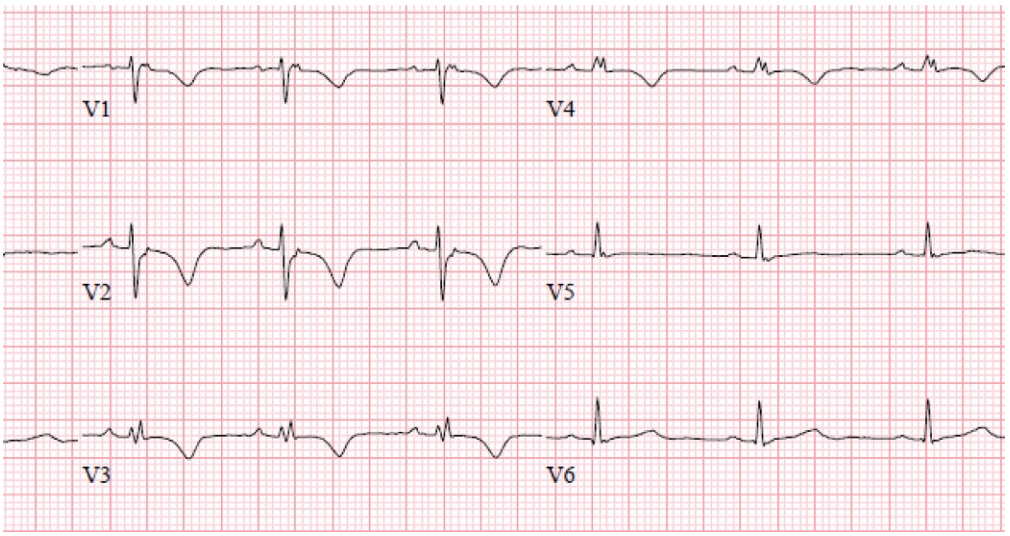

Fig. 3 ECG of a patient with ARVD/C that shows T-wave inversions from V1 to V4 and the presence of an epsilon wave in V1–V2 and terminal activation delay.

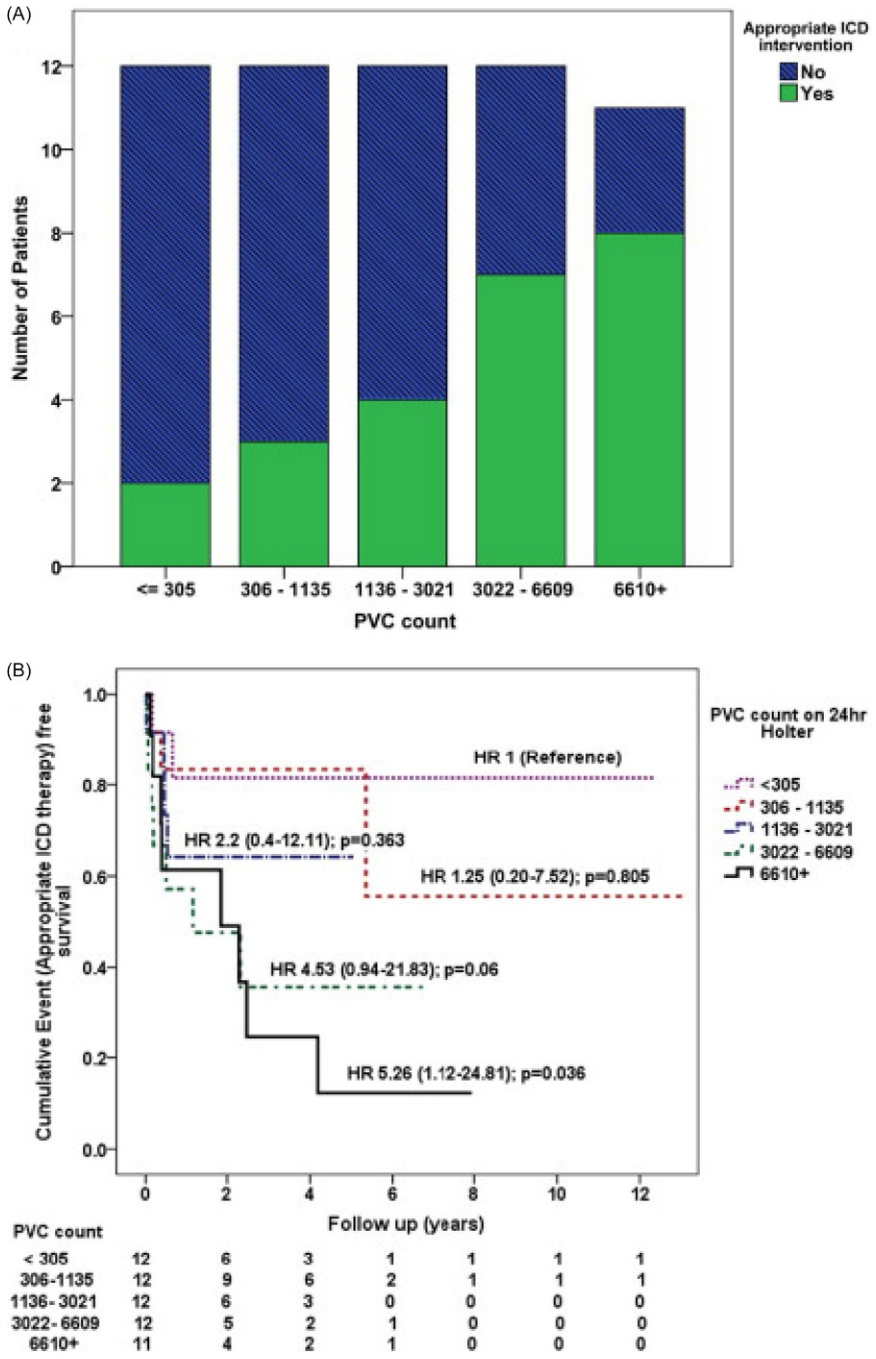

Fig. 4 (A) Relationship between patients experiencing appropriate implantable cardioverter-defibrillator (ICD) therapy and patient groups stratified according to increasing premature ventricular complex (PVC) count. (B) Cumulative survival free of appropriate ICD therapy among patient groups (pentiles) stratified according to increasing PVC count and unadjusted hazard ratio for these patient groups demonstrating progressively increasing risk with worsening PVC burden. Reproduced with permission from Bhonsale, A., James, C. A., and Tichnell, C. et al. (2011). Incidence and predictors of implantable cardioverter-defibrillator therapy in patients with arrhythmogenic right ventricular dysplasia/cardiomyopathy undergoing implantable cardioverter-defibrillator implantation for primary prevention. *Journal of the American College of Cardiology*, **58**, 1485–1496.

for several reasons including patchy distribution of the disease and the presence of similar patterns to that observed in ARVD/C in other diseases such as sarcoidosis and giant cell myocarditis. For these reasons, they are rarely performed nowadays.

The role of genetic testing in the diagnosis of ARVD/C is now well established and is considered a major diagnostic criterion (Marcus et al., 2010). More than 60% of ARVD/C probands are found to have a mutation (Groeneweg et al., 2015; Den Haan et al., 2009). The most important utility of this test is in the cascade screening of family members. Asymptomatic gene carriers are likely to

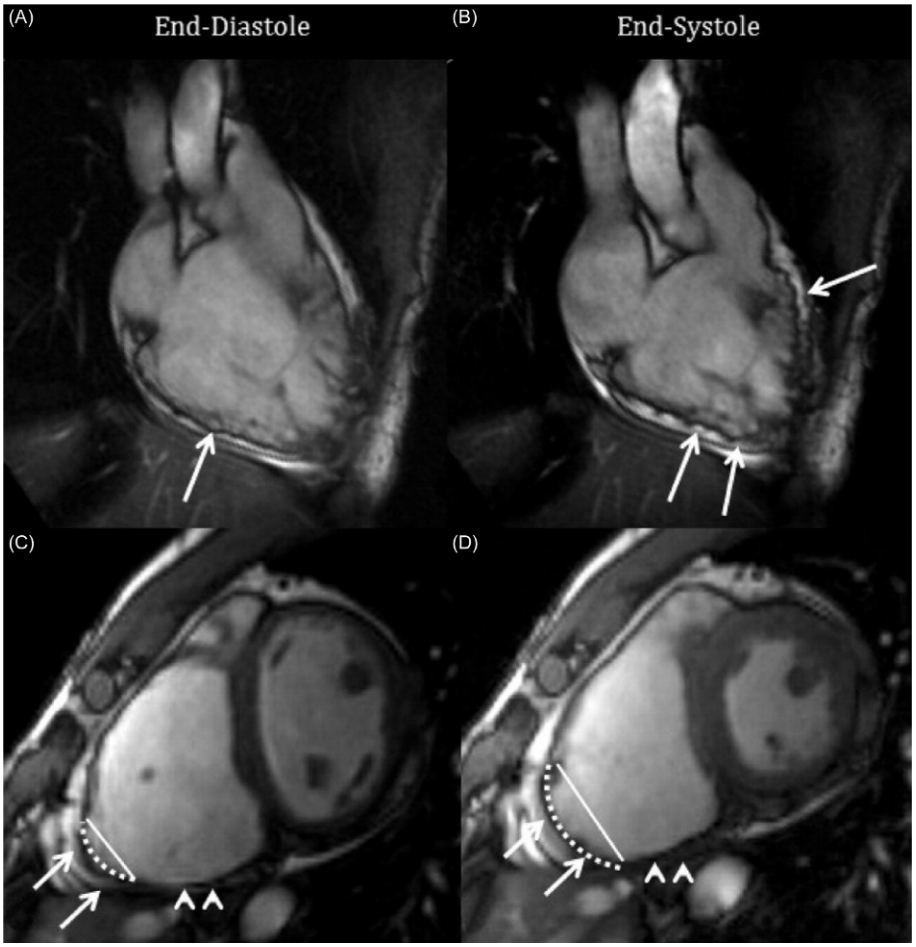

Fig. 5 Cardiac MRI of a patient with ARVD/C. Bright blood images in the right ventricular outflow tract (RVOT) plane obtained in end-diastole (A) and end-systole (B) show microaneurysms *(arrows)* in the RV free wall with persistent bulge in both phases. Short-axis bright blood images obtained in end-diastole (C) and end-systole (D) demonstrate dyskinesis at the acute angle of the RV and hypokinesis in the inferior wall *(arrowheads)*. Reproduced with permission from Calkins, H. (2015). Arrhythmogenic right ventricular dysplasia/cardiomyopathy-three decades of progress, *Circulation Journal*, **79**(5), 901–913.

require life-long monitoring due to age-dependent penetrance, while noncarriers are unlikely to have the disease and serial screening is generally not required (Calkins, 2015).

The diagnosis of ARVD/C should be considered in individuals without known heart disease, who present with frequent PVCs or symptomatic ventricular tachycardia, especially if there is LBBB morphology with superior axis, if the VT occurs in a patient with T-wave inversions in the right precordial leads, or if the LBBB VT ECG pattern is not typical of idiopathic RVOT VT (Calkins, 2013).

The differential diagnosis for ARVD/C should include cardiac sarcoidosis, idiopathic RVOT VT, and VT arising from the aortic root. For patients that present with symptoms of RV systolic heart failure, RV infarct or pulmonary hypertension should be considered. Dilated cardiomyopathy should also be kept in mind when there is evidence of biventricular heart failure and biventricular arrhythmogenic cardiomyopathy when there is significant ventricular ectopy (Calkins, 2013).

Management

The management of patients with ARVD/C has four components. The first step is making sure that ARVD/C is indeed the correct diagnosis. The second step involves accurate risk stratification of patients and to establish the need to have an ICD implanted. The third step consists in minimizing ICD therapies with either medications, catheter ablation, or both. The fourth step is preventing progression of the disease, mostly through exercise restriction. Each of these will be examined in detail:

Establishing an Accurate Diagnosis

The first step is to establish an accurate diagnosis of ARVD/C. Misdiagnosis of ARVD/C is common due to the lack of awareness of the 2010 TFC and misinterpretation of MR imaging (Bomma et al., 2004).

Table 1 2010 TFC for the diagnosis of arrhythmogenic right ventricular cardiomyopathy and other cardiomyopathy/dysplasia

1. Global or regional dysfunction and structural alterations
   - Major
   - Second echo criteria
   - Regional RV akinesia, dyskinesia, or aneurysm and one of the following measured at end-diastole
   - PLAX RVOT $\geq$32 mm or
   - PSAX RVOT $\geq$36
   - Fractional area change $\leq$33%
   - MRI criteria
   - Regional RV akinesia or dyskinesia or dyssynchronous RV contraction and one of the following
   - Ratio of RV end-diastolic volume to BSA >=110 mL/m^2 (male) or $\geq$100 mL/m^2
   - RV ejection fraction <=40%
   - RV angiography criteria
   - Regional RV akinesia, dyskinesia, or aneurysm
   - Minor
   - Second echo criteria
   - Regional RV akinesia or dyskinesia or dyssynchronous RV contraction and one of the following measured at end-diastole
   - PLAX RVOT $\geq$29 <32 mm or
   - PSAX RVOT $\geq$32 <36
   - Fractional area change >33% $\leq$40%
   - MRI criteria
   - Regional RV akinesia or dyskinesia or dyssynchronous RV contraction and one of the following
   - Ratio of RV end-diastolic volume to BSA >= 100 to <110mL/m^2 (male) or >=90 to <100 mL/m^2 (female)
   - RV ejection fraction >40% to <=45%
2. Tissue characterization of wall
   - Major
   - Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of the RV free-wall myocardium in $\geq$1 sample
   - With or without fatty replacement of tissue on endomyocardial biopsy
   - Minor
   - Residual myocytes 60–75% by morphometric analysis (or 50–65% if estimated), with fibrous replacement of the RV free-wall myocardium in $\geq$1sample
   - With or without fatty replacement of tissue on endomyocardial biopsy
3. Repolarization abnormalities
   - Major
   - Inverted T waves in right precordial leads (V1, V2, and V3) or beyond in individuals >14 years of age (in the absence of complete RBBB QRS $\geq$120 ms)
   - Minor
   - Inverted T waves in V1 and V2 in individuals >14 years of age (in the absence of complete RBBB) or in V4, V5, and V6
   - Inverted T waves in leads V1, V2, V3, and V4 in individuals >14 years of age in the presence of a complete RBBB
4. Depolarization/conduction abnormalities
   - Major
   - Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of T wave) in the right precordial leads (V1–V3)
   - Minor
   - Late potentials by SAECG in $\geq$1 of 3 parameters in the absence of a QRSd $\geq$110 ms on standard ECG
   - Filtered QRS duration (fQRS) $\geq$114 ms
   - Duration of terminal QRS <40 microV $\geq$38 ms
   - Root-mean-square voltage of terminal 40 ms $\leq$ microV
   - Terminal activation duration $\geq$55 ms measured from the nadir of the end of the QRS, including R′, in V1, V2, or V3 in the absence of complete RBBB
5. Arrhythmias
   - Major
   - Nonsustained or sustained VT of LBBB morphology with superior axis
   - Minor

Risk Stratification and Decision to Implant an ICD

The second step is the most important goal of management, and it consists in the prevention of SCD. Studies have shown that more than 50% of patients with ARVD/C have received an ICD and have appropriate device interventions during follow-up (Bhonsale et al., 2011; Piccini et al., 2005).

Bhonsale et al. (2011) evaluated 84 patients who received the ICD for primary prevention over a mean follow-up of 4.7 ± 3.4 years. ICD therapy was appropriate in 40 (48%) of 84 patients. Predictors of appropriate therapy included being the proband, demonstrating VT inducibility at electrophysiological study (EPS), having NSVT, and having >1000 PVCs in 24 h. Inducibility at EPS and Non sustained ventricular tachycardia (NSVT) remained significant predictors on multivariable analysis. They also demonstrated that more frequent ventricular ectopy was associated with progressively more frequent ICD therapy. Lastly, the incremental risk of VA and ICD therapy was observed in patients with multiple risk factors.

The management of ARVD/C poses a clinical challenge. Until more rigorous evidence is available, experts from all over the world have developed a consensus statement (Philips et al., 2013) to serve as a clinical guide for the management of this complex pathology. In this document, the authors propose risk stratifying the patients in high, intermediate, and low risk to decide whether the implantation of an ICD is necessary.

Implantation of an ICD is recommended in the high-risk group, which consists of those individuals with history of aborted SCD due to VF, sustained ventricular tachycardia, severe RV (RV EF ≤35% of RV fractional area change (FAC) of ≤17%), severe LV dysfunction (LV EF ≤35%), or both (Corrado et al., 2015).

The intermediate group is divided in two categories. In the first category, an ICD should be considered in patients with ≥1 major risk factor: syncope, NSVT, moderate RV dysfunction (RV EF between 40% and 36% or FAC between 24% and 17%), and moderate LV dysfunction (LV EF between 45% and 36%). Meanwhile, in the second category, an ICD may be considered in the presence of ≥1 minor risk factor: proband status, young age at diagnosis, male gender, compound and digenic heterozygosity of desmosomal mutations, inducibility on programmed ventricular stimulation, extent of T-wave inversion in precordial and inferior leads, amount of electroanatomic scar and electroanatomic scar-related fractionated electrograms, low QRS amplitude, and QRS fragmentation (Corrado et al., 2015).

Lastly, ICDs are not indicated in patients that are healthy gene carriers but do not have any other risk factors (Corrado et al., 2015) (**Fig. 6**).

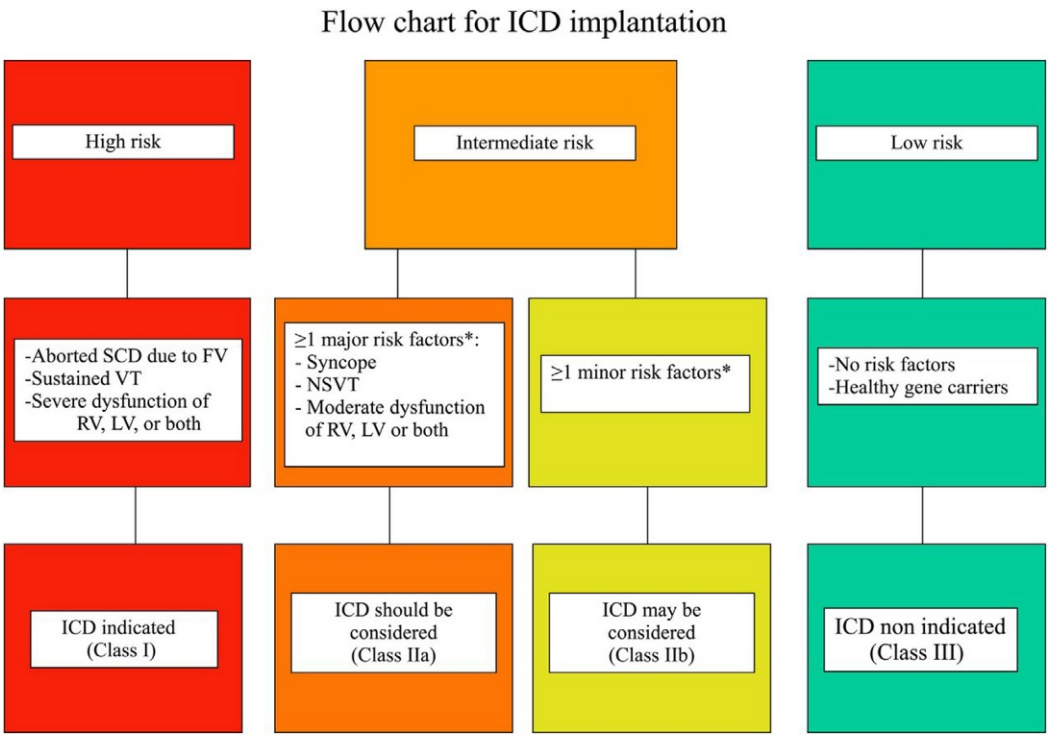

Fig. 6 Flow chart of risk stratification and indications to ICD implantation in ARVD/C. Based on the available data on annual mortality rates associated to specific risk factors, the estimated risk of major arrhythmic events in the high-risk category is 0.10% per year, in the intermediate ranges from 1 to 10% per year, and in the low-risk category is.1% per year. *SCD*, sudden cardiac death; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia; *RV*, right ventricle; *LV*, left ventricle. *See the risk stratification and decision to implant an ICD section for the distinction between major and minor risk factors. Treatment of arrhythmogenic right ventricular cardiomyopathy/dysplasia: An International Task Force Consensus Statement. *European Heart Journal*, **36**(46), 3227–3237.

Minimizing Symptoms and Preventing ICD Therapies

Pharmacological therapy

Beta-blockers. Few studies have been done to establish the efficacy and safety of pharmacological therapy in ARVD/C. Beta-blockers are used for almost all patients with the disease based on the fact that they reduce risk of SCD in patients without ARVD/C. Furthermore, high-dose isoproterenol can trigger VT in patients with the disease (Philips et al., 2013; Denis et al., 2014) and most of the arrhythmias and SCD are triggered by exercise.

In summary, beta-blocker therapy is recommended in ARVD/C patients with recurrent VT, appropriate ICD therapies, or inappropriate ICD interventions resulting from sinus tachycardia, supraventricular tachycardia, or atrial fibrillation/flutter with high ventricular rate. Beta-blocker therapy should be considered in all patients with ARVD/C irrespective of arrhythmias (Corrado et al., 2015).

Afterload reducers. ACE inhibitors are commonly used as afterload reducers in patients with ARVD/C. Even though there are no published trials in patients with ARVD/C, there are enough data supporting the use of these medications in a broader population of patients with cardiomyopathy (Calkins, 2013, 2015). Additionally, these medications should be used in patients that develop right- and/or left-sided heart failure as part of heart failure management.

Antiarrhythmic drugs. When it comes to antiarrhythmic agents, the goal is to improve quality of life by preventing symptomatic VA and ICD therapies. Although, there are no randomized control trials to compare the different antiarrhythmic drugs available, amiodarone and sotalol are commonly used.

These medications should be considered as an adjunct therapy to ICDs in patients receiving frequent appropriate discharges and to improve symptoms caused by NSVT and frequent PVCs (Corrado et al., 2015).

Antiarrhythmic drugs may also be considered as an adjunct therapy to catheter ablation in those patients with recurrent ventricular tachycardia (Corrado et al., 2015).

Catheter ablation

Catheter ablation is an option for treatment of patients with ARVD/C who have VT. However, it is important to recognize that its role is not curative but improves quality of life by decreasing the frequency of episodes of VT.

The outcomes of catheter ablation were evaluated on a cohort of 24 patients with ARVD/C who underwent 48 VT ablation procedures (Dalal et al., 2007). The study showed that there was a high rate of recurrence (40/48) of VT in ARVD/C patients undergoing radiofrequency catheter ablation (RFA). The cumulative VT-free survival rates were 75%, 50%, and 25% and at 1.5, 5, and 14 months, respectively.

Philips et al. (2012) assessed the recurrence of VT following RFA and the effect of it in VT burden. The study consisted of 87 patients who underwent a total of 175 VT ablations. The rates of freedom from VT were 47% at 1 year, 21% at 5 years, and 15% at 10 years, over a mean follow-up of 88.3 ± 66 months. After epicardial ablation, the rates of cumulative freedom of VT were significantly longer than endocardial RFV ($p = 0.02$), with 64% and 45% at 1 and 5 years, respectively. VT burden was reduced irrespectively from the type of ablation ($p < 0.001$).

Most recently, a single center experience on 30 ARVD/C patients who underwent epicardial catheter ablation of VT showed a significant reduction ($p < 0.001$) of VT burden (Philips et al., 2015). Twenty seven percent ($n = 8$) of patients had VT recurrence after epicardial RFA. Most of the VT recurrences occurred during exercise, in the first year after the procedure, had fast cycle lengths and required an ICD intervention for termination.

The current recommendations for catheter ablation are for patients with incessant VT or frequent appropriate ICD therapies despite maximal pharmacological therapy. An epicardial approach is for those who fail one or more attempts of endocardial VT ablation. Catheter ablation should also be considered in patients with incessant VT or frequent ICD therapies who have failed pharmacological therapy. A combined approach (endocardial/epicardial ablation) can be considered depending on the operator's experience. Catheter ablation may also be an alternative in those patients who do not want to be treated with pharmacological therapy. (Corrado et al., 2015)

Preventing Progression

The hypothesis that exercise is an environmental factor in the pathogenesis of this disease began with the observation that there are a disproportionate number of athletes among patients with ARVD/C although there are no studies prospectively examining the rate of progression of ARVD/C. Exercise restriction is presently considered the only effective strategy for preventing disease progression.

Evidence of the role of exercise in ARVD/C

One of the first studies to highlight the relationship between exercise and ARVD/C was done by Corrado et al. (2003)) in the region of Veneto, Italy. They found that young athletes had a fivefold risk of dying of ARVD/C compared with nonathletes.

Since then, many studies followed, and their aim has been to determine the role of exercise as a disease modifier in ARVD/C.

La Gerche et al. (2012) were one of the pioneer groups to observe that the ARVD/C phenotype can be acquired through intense exercise. They studied 47 athletes with definite or probable ARVD/C. The majority ($n = 41$) practiced endurance sports (cyclists 72%, distance runners 6%, triathletes 6%, and kayakers 2%). They identified desmosomal mutations in only six athletes, and only two patients in the group had a family history of ARVD/C. They found that the group that performed the most exercise had lower rates of

desmosomal mutations, yet many of them met diagnostic criteria for definite or probable ARVD/C. Based on these results, they concluded that high-intensity endurance exercise may be sufficient to evoke an ARVD/C phenotype, even in mutation-negative individuals.

Saberniak et al. (2014) investigated the impact of exercise on myocardial function. The study included 110 patients, 65 with ARVD/C and 45 mutation positive family members. Exercise participation was measured by metabolic equivalent (MET) minutes per week. Athletes were classified as those participating in vigorous ($\geq$6 METs) for $\geq$4 h/week. The authors found that athletes were more likely to meet diagnostic criteria; they had lower biventricular function and earlier onset of life-threatening VA when compared with nonathletes.

Ruwald et al. (2015) studied 108 probands that met TFC for ARVD/C diagnosis. They assessed the effects of competitive and recreational sports on age of onset and risk of VA or death. Patients self-reported the age at which they initiated the sport and the commonly practiced sport via a questionnaire. They found that the patients engaged in competitive exercise had an earlier presentation of the disease and also had a twofold increase in the risk of life-threatening arrhythmias and death when compared with inactive patients and those practicing recreational sports.

Posteriorly, three important manuscripts were published better defining the link between exercise in ARVD patients with and without mutations and examining the important question of a safe exercise threshold.

The first paper (James et al., 2013) studied the role of exercise in ARVD/C patients with a pathogenic desmosomal mutation. For this purpose, 87 probands and family members were interviewed to determine their exercise used for leisure/recreation, work, and transportation. Participants were classified as an endurance athlete if they performed 50 h/year or more of vigorous intensity sports with a high dynamic demand as defined by the 36th Bethesda Conference Classification of Sports (Task Force 8) (Maron and Zipes, 2005). Our study had several key findings. ARVD/C patients who were endurance athletes became symptomatic at an earlier age. Furthermore, endurance exercise and higher duration of exercise participation were both associated with increasing likelihood of developing manifest ARVD/C. Endurance exercise was also associated with worse survival from a ventricular arrhythmia and heart failure. Lastly, those individuals after presentation who continued to participate in the top quartile for hours of annual exercise had worse survival from first ventricular arrhythmia compared with individuals who reduced their exercise after presentation.

Subsequently, the role of exercise in ARVD/C patients without mutations was reported (Sawant et al., 2014). The duration and intensity of exercise participation in 43 probands without a genetic desmosomal defect were compared with that of 39 probands with desmosomal mutations all of whom met the 2010 TFC. The results show that among nondesmosomal patients, those participating in the highest quartile of MET-hours/year of exercise presented at a significantly earlier age had worse structural abnormalities on CMR and significantly poorer survival from a ventricular arrhythmia during follow-up. Also, exercise participation stratified by mutation status and family history was analyzed. It was observed that nondesmosomal ARVD/C patients had done a similar duration of annual exercise as the desmosomal carriers, but exercise in the nondesmosomal patients was more intense, and more subjects participated in endurance sports and expended greater MET-hours/year of exercise compared with desmosomal patients. Lastly, ARVD/C nondesmosomal patients with no family history performed the highest MET-hours/year exercise compared with nondesmosomal patients with a family history and desmosomal mutation carriers (Fig. 7). Since the nondesmosomal patients

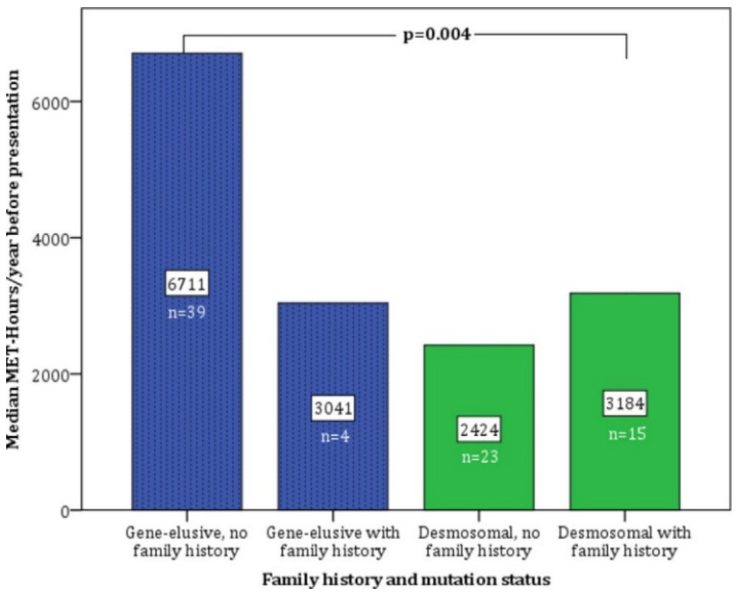

Fig. 7 Exercise intensity among patients stratified by genotype and 2010 family history task force criteria (TFC). Gene-elusive, nonfamilial patients participated in significantly higher-intensity exercise than those with family history or desmosomal mutations ($P = 0.004$, Kruskal–Wallis one-way analysis of variance). MET-hours indicate metabolic equivalent hours. Reproduced with permission from Sawant, A. C., Bhonsale, A., and Te Riele, A. S. et al. (2014). Exercise has a disproportionate role in the pathogenesis of arrhythmogenic right ventricular dysplasia/cardiomyopathy in patients without desmosomal mutations. *Journal of the American Heart Association*, **3**(6), e001471.

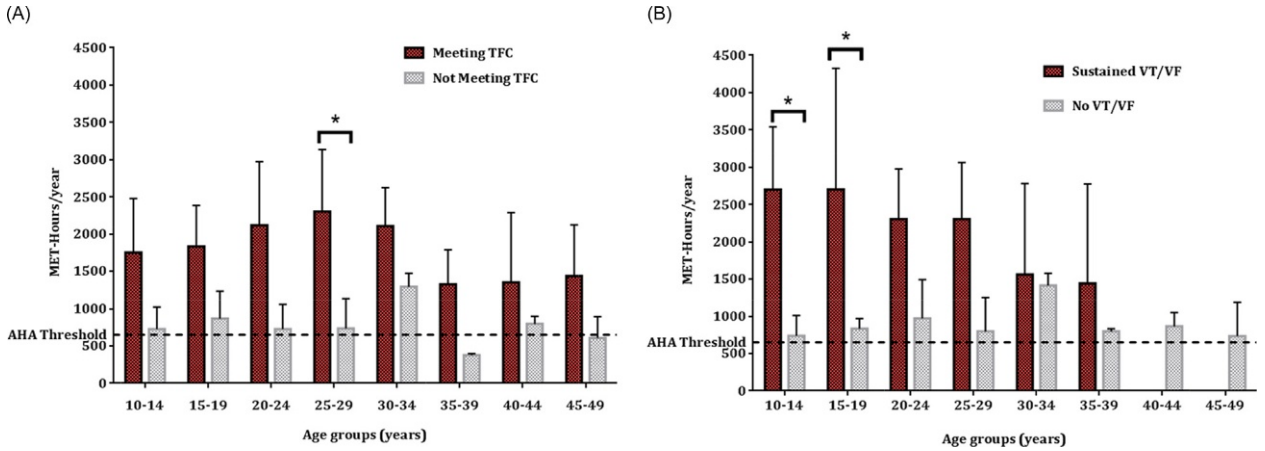

Fig. 8 Median exercise intensity (MET-hour/year) before diagnosis in 5-year age increments compared with the AHA-recommended minimum stratified by diagnosis by TFC (A) and VT/VF history (B). *Dotted black line* represents the upper bound of the American Heart Association (AHA)-recommended minimum exercise (650 MET-hour/year). Error bars depict interquartile range. *Statistically significant $P < .05$. *MET-hr*, metabolic equivalent hours; TFC 2010 task force criteria; *VT/VF*, ventricular tachycardia/ventricular fibrillation. Reproduced with permission from Sawant, A. C., Te Riele, A. S., and Tichnell, C. et al. (2015). Safety of American Heart Association-recommended minimum exercise for desmosomal mutation carriers. *Heart Rhythm*, **13**(1), 199–207.

without family history did the highest intensity exercise, they concluded that exercise may be the key environmental factor driving disease pathogenesis in that subgroup. Interestingly, when we compared annual prepresentation MET-hours and endurance exercise participation during youth (age ≤25), it was found that higher-intensity exercise during youth was associated with earlier age of presentation in both desmosomal and nondesmosomal ARVD/C patients.

The safety of the American Heart Association (AHA) minimum exercise recommendations for overall health (390–690 MET-h/year), for healthy desmosomal mutation carriers, has also been assessed (Sawant et al., 2015). Twenty-eight family members of 10 probands with a PKP2 mutation were interviewed. Probands had done more exercise than family members, and the family members that were athletic had worse outcomes. However, there was no life-threatening VA in the healthy carriers that restricted exercise at or below the upper bound of the AHA minimum exercise recommendations. Furthermore, at the time of ARVD/C diagnosis and their first ventricular arrhythmia, patients had accumulated 2.8-fold and a 3.5-fold greater MET-hour of exercise than the AHA recommendations (Fig. 8). The authors concluded that unaffected PKP2 mutation carriers should refrain from endurance and high-intensity exercise but that they may be safe practicing the minimum exercise for healthy adults recommended by the AHA, although this continues to be an area of active research.

The link between exercise and ARVD has also been demonstrated using transgenic animal models (Kirchhof et al., 2006; Cruz et al., 2015; Chelko et al., 2014; Martherus et al., 2015). These data together show that there is need for more research to evaluate what threshold of exercise triggers the onset of ARVD/C. We also need to understand the interaction of genotype and exercise and other environmental factors with the potential of triggering the disease.

In summary, exercise restriction is a key component in the management of ARVD/C. Recently, an update to the 36th Bethesda Conference Eligibility Recommendations for Competitive Athletes with Cardiovascular Abnormalities has been published by the AHA and the American College of Cardiology (Maron et al., 2015). The current recommendation is avoidance of all competitive activities for patients with probable, borderline, or definite diagnosis of ARVD/C except for sports with a low cardiovascular demand (class III and level of evidence C).

The ARVD/C treatment consensus statement, published by Corrado et al. (2015), concluded that patients with a definite diagnosis of ARVD/C should not participate in competitive or endurance sports with the possible exception of recreational low-intensity sports. Restriction from competitive sports may be considered in ARVD/C family members that are healthy gene carriers and those that have an unknown genotype.

Cardiac transplantation

ARVD/C patients rarely require cardiac transplantation (Tedford et al., 2012), but among 18 ARVD/C transplants, the age of first symptoms averaged 24 ± 13 years, and the age at cardiac transplantation averaged 40 ± 14 years, suggesting early onset of disease in those ultimately requiring transplantation.

Introduction

Physical exercise is dependent on the ability of the cardiovascular system to provide oxygenated blood to the critical organs and to remove deoxygenated blood from tissues and the lungs ability to clear carbon dioxide. With exercise a greater proportion of the oxygen is required in the tissue and is extracted from the blood. Athlete's heart or athletic heart syndrome refers to cardiac adaptations that occur from repetitive strenuous physical exercise.

Assessment of gas exchange at rest and with exercise can be performed with cardiopulmonary stress testing. With exercise, there is increasing oxygen demand and oxygen uptake by the tissues. In time physiologic adaptations seen with exercise include a lower blood pressure, lower heart rate, enhanced ventricular contraction, and relaxation. Cardiac output, the product of stroke volume and heart rate, increases with exercise in which a majority this augmentation is due to the increase in heart rate. Other physiologic changes such as peripheral vascular resistance vary depending on the type of exercise performed.

The hemodynamic effects of strenuous training cause differing cardiac adaptations depending on the type of exercise, so-called sport-specific cardiac remodeling. Morganroth and colleagues were first to classify the hemodynamic effects of exercise into two main groups resulting from either endurance (dynamic) and strength (static) exercise (Morganroth et al., 1975).

Isotonic exercise as seen with endurance athletes leads to sustained elevations in cardiac output with a normal to reduced peripheral vascular resistance. This sustained elevation in cardiac output causes a volume challenge to all heart chambers and the aorta which may lead to dilatation. Examples of isotonic exercises include long distance running and swimming. Individuals exposed to endurance training demonstrate left ventricular (LV) enlargement with balanced increases in LV cavity size and wall thickness (Gilbert et al., 1977; Utomi et al., 2013).

Conversely, isometric exercise as seen with strength training or short burst exercises causes a brief but potentially marked elevation in systolic blood pressure and LV afterload. This predominant pressure elevation may lead to cardiac remodeling including concentric LV remodeling and hypertrophy. Examples of isometric exercises include weight lifting and track and field throwing.

Morganroth's original hypothesis did not address cardiac remodeling that may be influenced by ethnicity, age, gender, duration of training and genetics (Maron, 1986). When training, athletes usually focus on exercises that will strengthen specific muscles related to their sport and a combination of both isometric and isotonic exercises is common. Frequently combined isometric and isotonic training (cycling and rowing) result in both volume and pressure load to the heart. This may make it difficult to differentiate pathology from cardiac adaptation to strenuous exercise. Pathologic states such as hypertrophic cardiomyopathy (HCM) usually have asymmetric hypertrophy.

Most amateur athletes have normal chamber dimensions; however LV dilation may occur (**Figs. 1, 2**). In a large series of athletes, LV end diastolic diameter exceeded normal in 40% of patients but only 14% of highly trained athletes had LV chamber dimensions of >60 mm (Pelliccia et al., 1999). Chamber enlargement can be accompanied by a relatively mild increase in absolute LV wall thickness (from 13 to 15 mm) (Pelliccia et al., 1991) and should reverse after cessation of exercise. Hypertrophy greater than 16 mm should raise concern for HCM. LV systolic function in athletes remains normal or low normal with no wall motion abnormalities and preservation right ventricular (RV) contractile function with exercise.

Remodeling of the left atrium (LA) is a physiological adaptation present in highly trained endurance athletes (Pelliccia et al., 2005). Increased anterior–posterior LA dimension (≥ 40 mm) occurs in 20% of athletes where larger dimensions (≥ 45 mm) occur in approximately 2% of athletes (Maron and Pelliccia, 2006). Although there is a quantitative increase in LA size, the overall proportion of the LA should remain proportional to the LV cavity size. Atrial arrhythmias such as atrial fibrillation are also increased in endurance athletes (Mont et al., 2009; Furlanello et al., 1998).

Understanding the aforementioned cardiac adaptations to training is important as these findings will help differentiate cardiac adaptations from pathology. Exercising with an underlying cardiomyopathy may increase the risk of adverse events including arrhythmia and sudden cardiac death. The United States National Registry analyzed 842 athletes over 31 years with autopsy-confirmed cardiovascular diagnoses after sudden cardiac death and found that men had a 6.5 fold higher incidence of disease compared to women and adverse events were also more frequent in nonwhites (Maron et al., 2016). In that series, HCM was the leading cause of sudden cardiac death in athletes.

HCM is a well recognized cause of exercise-related sudden cardiac death among athletes. The prevalence of the disease is approximately 1 in 500 and over 1500 mutations have been associated with the disease (Maron et al., 1995; Maron et al., 2012). Individuals with HCM have characteristic myofibrillar disarray on histologic inspection and gross analysis of the ventricle

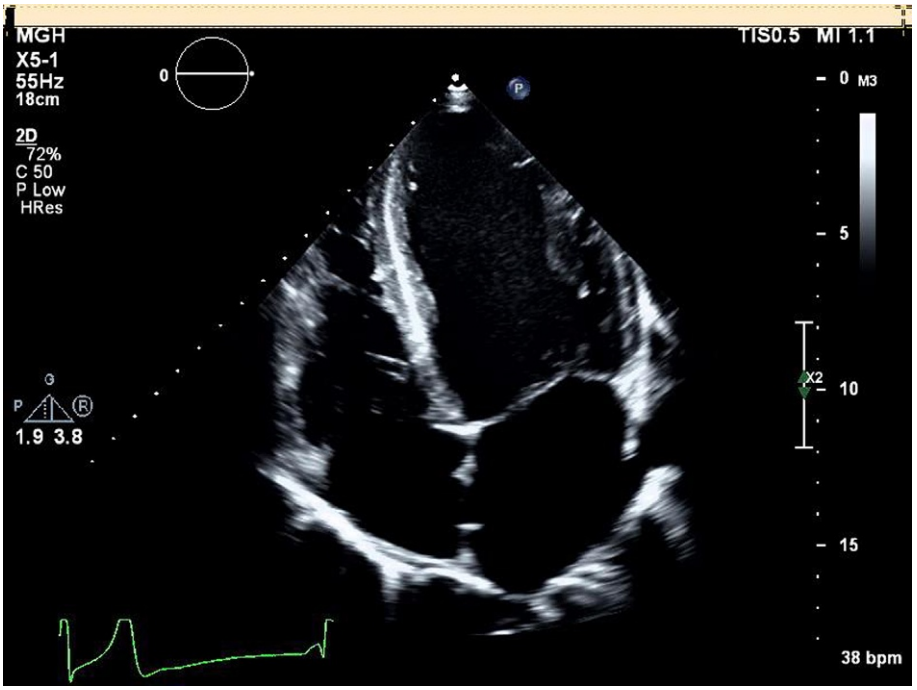

Fig. 2 Transthoracic echocardiographic imaging of an elite athlete showing left ventricular and left atrial enlargement but preservation of overall chamber ratios.

demonstrates LV hypertrophy with increased ventricular wall thickness in either symmetric or asymmetric distribution (Fig. 3). This myocardial hypertrophy can cause LV outflow obstruction and systolic anterior motion (SAM) of the anterior mitral valve leaflet leading to mitral regurgitation (Figs. 4, 5).

The presence of underlying HCM may trigger exercise-induced arrhythmias and patients may present with syncope, lightheadedness with exertion, palpitations or even with sudden cardiac death. The underlying substrate for exercise-induced arrhythmias is unpredictable and athletes with clinical expression of HCM should limit athletic participation to low-intensity

sports (Levine et al., 2015). For patients who are genotype positive but have no phenotypic expression of the disease, participation in competitive athletics is reasonable.

Echocardiography is the preferred initial imaging modality for the diagnosis of HCM. An LV wall thickness of greater than 16 mm is suggestive of HCM. Differentiating LV hypertrophy secondary to exercise remodeling from HCM may be challenging, especially in those individuals whose LV myocardium measures 13–15 mm. Pelliccia and colleagues performed echocardiographic assessments of LV wall thicknesses in 947 elite athletes and found that 1.7% of athletes have LV wall thickness greater than 13 mm

and all those patients had concomitant LV cavity dilation, a combination not typically found among individuals with HCM (Pelliccia et al., 1991).

Diastolic function of the LV can also be helpful in differentiating between the two diagnoses. The diastolic pulsed tissue Doppler velocities of athletes are usually normal or increased whereas usually reduced in patients with HCM (**Fig. 6**) (Caselli et al., 2014; Cardim et al., 2003). In athletes and transmitral *E*/*A* ratios are often >2 with low *A* velocities. This differs from HCM patients where *E*/*A* is <1 and the *E* velocity deceleration time is increased (D'Andrea et al., 2015).

Left ventricular noncompaction (LVNC) is a rare cardiomyopathy thought to occur due to failure of myocardial compaction during embryological development. LVNC is characterized by increased LV trabeculations, intertrabecular recesses often referred to as "crypts," and thin layer of compacted myocardium. Usually the recesses are located at the LV apex, mid-inferior and lateral walls of the left ventricle and less likely to be seen on the septal wall. Coronary circulation is usually normal although global ventricular function may be depressed and thrombi may form within the crypts. Familial and sporadic cases have been identified.

The natural history of LVNC has not been well defined. Patient presentation of LVNC varies from asymptomatic to presentation with heart failure, thromboembolic events, arrhythmias, or sudden cardiac death. Patient's are managed medically with a focus on associated complications of LVNC and may include arrhythmia ablation procedures, ICD placement, or cardiac transplant in advanced disease.

To help guide the diagnosis, along with a through history and physical, imaging is usually ordered. Echocardiography is usually the first imaging modality ordered to evaluate for LVNC for both the index patient and family members. 2D-echocardiography can identify increased trabeculations in the left ventricle (**Figs. 7,8**). Also, color Doppler and echocardiographic contrast can be used to show blood flow into the crypts thereby decreasing the likelihood of thrombi. A ratio of noncompacted myocardium to compacted myocardium of 2:1 on echocardiography was suggested to help guide the diagnosis of LVNC (Jenni et al., 2001; Ritter et al., 1997). Cardiac magnetic resonance (CMR) is better able to distinguish the border of compacted and noncompacted myocardium. A ratio of noncompacted to compacted myocardium on CMR of >2.3 was suggested for diagnosis of LVNC (Patersen et al., 2005). CMR is also able to comment on the presence of fibrosis and to evaluate ventricular function.

In athletes, the LV remodels and dilates causing the appearance of increased trabeculations in the left ventricle. Caution should be made to not diagnose LVNC in those athletes whose ventricles have remodeled and do not necessarily carry the disease. The presence of increased trabeculations has also been reported in African–American athletes (Gati et al., 2013). Patients with confirmed LVNC with LV systolic dysfunction or tachyarrhythmias should not participate in competitive sports.

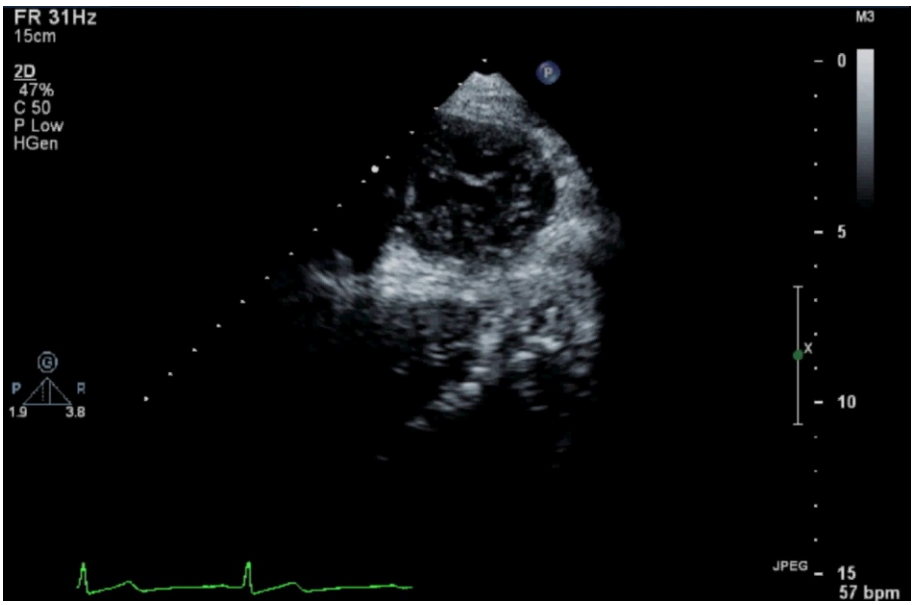

Fig. 8 A zoomed-in echocardiographic image of the left ventricular apex showing increased trabeculations in a patient with LVNC.

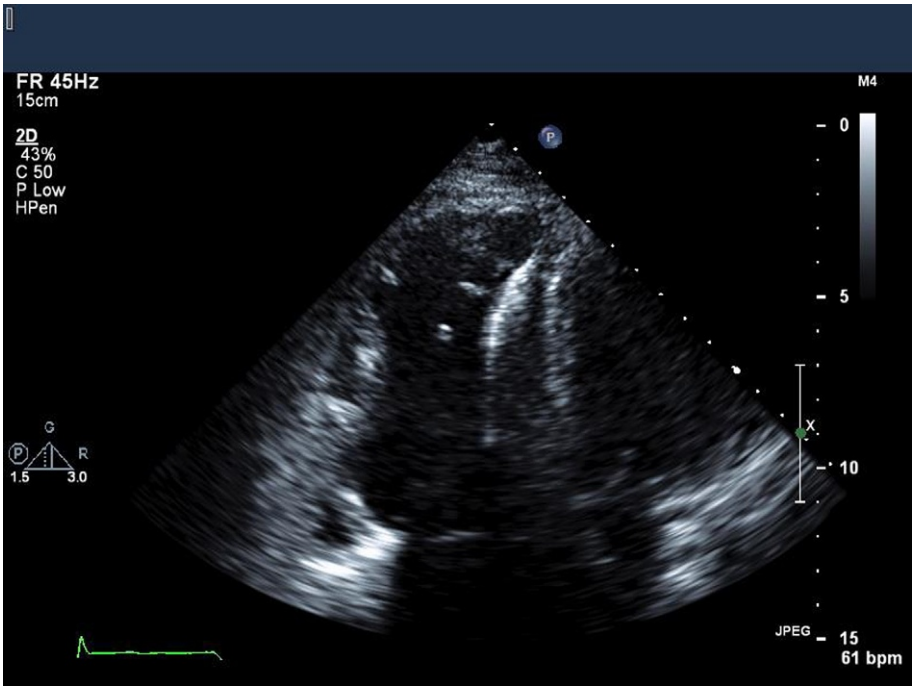

Fig. 9 RV focused view on a patient with ARVD showing a dilated right ventricle with thinned walls. Also seen is an ICD wire in the RV cavity.

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also known as arrhythmogenic right ventricular dysplasia (ARVD), is a rare cardiomyopathy characterized by progressive replacement of the RV myocardium with fibrofatty tissue. The RV outflow tract, RV apex, and infundibulum are usual places of disease involvement. ARVC is an autosomal dominant disorder with variable penetrance. The genetic defect leads to desmosome dysfunction (which work with cell–cell adhesion) causing a "defective glue." The natural history of ARVC includes progressive RV dysfunction and electrical instability (Hubot et al., 2004). Most patients usually present before the age of 40 with right heart arrhythmias although presentation with right-sided heart failure is not uncommon.

Imaging modalities used for the assessment and diagnoses include electrocardiogram, echocardiography and CMR. On electrocardiogram, T wave inversions in precordial leads (V1–V3), epsilon waves, and tachyarrhythmias with left bundle branch pattern may be seen. On echocardiography, the right ventricle is dilated, hypokinetic, with possible aneurysm formation (**Fig. 9**). A thickened or hyperreflective moderator band has also been reported (Bauce et al., 2010). Quantitative measures of RV function such as RV fractional change may be decreased. Fatty infiltration of the RV myocardium can be seen with CMR. A thinned and dilated right ventricle may be seen with computed tomography (**Fig. 10**). The gold standard for diagnosis of ARVD is an endomyocardial biopsy that shows fibrofatty tissue replacement of the RV myocytes and a thinned RV wall.

In endurance athletes, RV dilation may occur (Baggish et al., 2008). This cardiac remodeling and ventricular dilatation in athletes may make the normal trabeculations of the RV more prominent in appearance and difficult to differentiate from pathology. If arrhythmia is found, specifically paroxysmal ventricular tachycardia originating from the right heart, in an otherwise healthy athlete, ARVD should be excluded. Patients with ARVC should avoid competitive sports with the exception of low-intensity class 1A sports.

Screening and Athletic Competition

A comprehensive history and physical examination is recommended prior to athletic competition in order to detect congenital cardiovascular abnormalities. Currently, routine ECG screening for athletes is not recommended by the American Heart Association however may be considered in small cohorts along with the history and physical with awareness that false positives may occur.

Conclusions

Athletic heart syndrome refers to the cardiac remodeling that occurs in response to the hemodynamic challenges of repetitive strenuous exercise. Sport-specific remodeling occurs and it is important to be able to recognize these changes and differentiate them from pathology.

Introduction

Atrial tachycardias represent a subset of the supraventricular tachycardias. They are characterized by their need only for atrial tissue, not requiring the sinus node, presence of an accessory pathway, or ventricular tissue, for their initiation and perpetuation. They can be further divided into subcategories based on the underlying mechanism of arrhythmia, including atrial flutter—typical and atypical, focal atrial tachycardia, sinus node reentry, and multifocal atrial tachycardia (MAT). We will consider each subcategory separately.

Atrial Flutter

Background

Atrial flutters represent a class of macroreentrant tachycardias within one or both atria. They share features with atrial fibrillation, particularly in terms of anticoagulation and morbidity, but, in many cases, are extremely treatable via catheter-based approaches. They fall under two large categories: the more common typical or isthmus-dependent flutters, and the less common, and often more difficult to treat, atypical or nonisthmus-dependent flutters.

Definition

Unfortunately, the definition of atrial flutter can be confusing. There is an electrocardiographic one which describes flutter as an organized atrial rhythm usually between 250 and 300 beats/min. There is also a mechanistic one which defines flutter as a macroreentrant rhythm, with less concern about rate. As the mechanistic definition makes understanding of the physiology, pathophysiology, and therapeutic alternatives easier to grasp, it is the one that most electrophysiologists prefer.

 https://doi.org/10.1016/B978-0-12-809657-4.99781-3

Isthmus-dependent atrial flutter is one that uses the cavotricuspid isthmus as an essential part of its circuit, regardless of whether it travels through the isthmus in a clockwise or counterclockwise fashion. Any other macroreentrant tachycardia is termed an atypical flutter (i.e., not dependent on the cavotricuspid isthmus for its perpetuation).

Typical and atypical flutters share the same general characteristics with the major difference being that the former are easy targets of ablation, while the latter can be quite challenging. The following discussion will discuss both of them as a unit except where they differ in significant fashion.

Incidence

It has been difficult to determine the incidence of atrial flutter as it typically has been grouped with atrial fibrillation, or often miscategorized as atrial fibrillation or atrial tachycardia. The Marshfield Epidemiological Study Area reported an overall incidence of 88/100,000 person-years. Incidence rates ranged from 5/100,000 in those <50 years old to 587/100,000 in subjects older than 80. Atrial flutter was 2.5 times more common in men ($P < 0.001$). The risk of developing atrial flutter increased 3.5 times ($P < 0.001$) in subjects with heart failure and 1.9 times ($P < 0.001$) for subjects with chronic obstructive pulmonary disease. Among those with atrial flutter 16% were attributable to heart failure and 12% to chronic obstructive lung disease (Granada et al., 2000). This translates, assuming one can extrapolate to whole of the US population, to an incidence of 200,000 cases of atrial flutter per year. It accounts for about 15% of supraventricular arrhythmias.

Characteristics

Typical flutter

The right atrium is a very complex structure composed of venous orifices, embryological remnants, ridges, and trabeculations. The anterolateral portion, which is trabeculated and includes the right atrial appendage, is separated from the smooth portion of the right atrium which originated embryologically from the sinus venosus. These embryologically distinct portions are separated by the crista terminalis laterally and the Eustachian ridge inferiorly. The crista terminalis is an electrophysiologically important structure as it acts as a line of block to conduction. It runs from just below the origin of the superior vena cava down to just above of the inferior vena cava, where it is extended by the Eustachian ridge along the floor of the right atrium to the os of the coronary sinus. These structures provide anatomical barriers which allow atrial flutter to exist in a protected circuit, which is necessary for perpetuation of reentry. The bottleneck for the circuit is the cavotricuspid isthmus, which is the portion of right atrium between the inferior portion of the tricuspid annulus and the orifice of the inferior vena cava. Because of its dependency on this protected isthmus, the electrocardiographic characteristics are very distinctive and reproducible between individuals.

Typical atrial flutter, which may be referred to as type I flutter by electrocardiographers, has atrial rates that are usually 250–350 bpm, with 300 bpm being the most common. Since the AV node in most individuals cannot conduct atrial rates that high in 1:1 fashion, there is usually 2:1 conduction, but it may be slower. In situations where antiarrhythmic drugs are used which result in slowing of the flutter rate, in very large atria where the circuit length is increased or in very young individuals or individuals with accessory pathways, atrial flutter can conduct 1:1. This latter situation is usually very poorly tolerated and can result in hemodynamic collapse. It may also result in misdiagnosis of the rhythm as a supraventricular tachycardia or a ventricular tachycardia, particularly as the QRS may be widened at these rates in the setting of aberrancy, preexcitation, pseudowidening of the QRS by superimposition of the QRS on the flutter wave or antiarrhythmic drug effect.

On ECG, the flutter waves are regular, recurring, and identical resulting in the classical "saw tooth pattern" with continuous atrial activation (i.e., lack of an isoelectric portion on the ECG). This pattern is most often demonstrated in the inferior leads (II, III, aVf). If the QRS is widened for any reason, it may be difficult to spot these saw tooth waves when 2:1 conduction or faster is present. In these situations, Valsalva maneuver, adenosine, or carotid sinus massage may help in establishing the diagnosis by slowing AV-node conduction, decreasing ventricular rate, and thus unmasking typical flutter waves. These waves are negative in the inferior leads in the case of counterclockwise flutter (referring to how the circuit travels relative to the tricuspid valve in the left anterior oblique projection), but will be positive in the less common clockwise atrial flutter(Bochoeyer et al., 2003) (**Fig. 1**).

Flutter may be paroxysmal, particularly in individuals with structurally normal hearts. In those with larger atria, it may be sustained and very stable, often presenting as tachycardia-induced cardiomyopathy. Although often a primary arrhythmia, it may accompany thoracic surgery, pericarditis, myocarditis, myocardial ischemia, or exacerbations of pulmonary disease.

Clinical presentation is very variable and depends on rate, underlying heart disease and age. Range of presentations include asymptomatic individuals in which it is discovered as an incidental finding, palpitations, fatigue, exercise intolerance, lightheadedness, dyspnea, and in the cases of 1:1 conduction, may present as syncope or hemodynamic collapse. Untreated flutter is a predictor of several poor outcomes, as evidenced by the Framingham Heart Study(Rahman et al., 2016).

Atypical flutter

Atypical flutters can occur anywhere within the atria and as such, do not have a typical electrocardiographic appearance unlike typical flutters(Bochoeyer et al., 2003; Gerstenfeld et al., 2007). They are defined as having the same range of rates as with typical flutter (250–350) and also share the characteristic lack of isoelectric segment on the ECG. Unlike typical flutters, they tend to not occur in structurally normal hearts as they usually require an anatomical focus for reentry, such as an atriotomy scar or prior

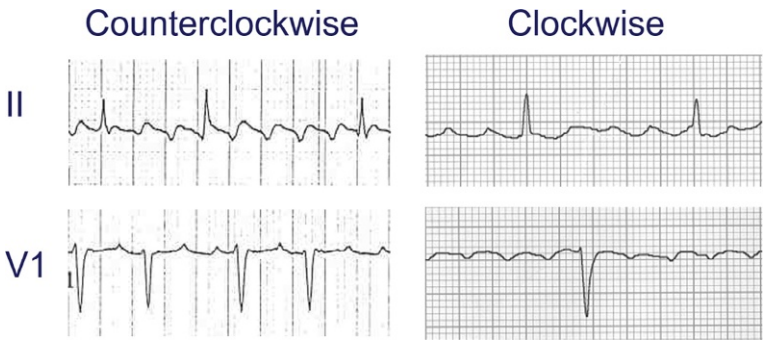

Fig. 1 Representative leads II and V1 demonstrating common appearance of flutter waves for each of counterclockwise and clockwise atrial flutter. With counterclockwise atrial flutter, classical "saw tooth pattern" is seen in lead II and positive flutter waves in lead V1. For clockwise atrial flutter, positive flutter waves are seen in lead II and negative waves in lead V1.

surgeries or ablations. That having been said, they can occur due to functional reentry in the setting of favorable pulmonary vein anatomy or as a proarrhythmic response to antiarrhythmic drugs, most commonly Ic agents such as flecainide and propafenone. The circuits may be very large, or relatively small. In the latter situation, the line between flutters with small reentrant circuits and atrial tachycardia becomes blurred.

Clinical presentations are as variable as with atrial flutter, but they tend to be more sustained.

Mechanisms

Typical atrial flutter represents the quintessential macroreentrant rhythm. In order to have reentry, several elements need to be present:

- A protected isthmus (in this case the cavotricuspid isthmus) which can only be entered on either end (like an insulated electrical cable).
- Unidirectional block in one limb of the circuit. If this is not present, the circuit will terminate as wave fronts coming from opposite directions in the isthmus will collide. A premature atrial contraction will enter the isthmus and block in one direction but conduct in the other. However, the conduction needs to be slow enough to allow recovery of the tissue from the previous depolarization, otherwise, the wave front will encounter refractory tissue and terminate. This brings up the final requirement for reentry:
- Slow conduction required for both initiation and perpetuation. This can be due to medications, particularly sodium channel blockers, which cause slowing of wave front propagation: a classic proarrhythmia of this class of drugs. More frequent causes are enlarged atria which, while not directly causing slow conduction, allow a larger circuit and therefore longer transit time. Fibrosis in the annulus, from pacemaker of ICD leads, prior ablations, valve surgeries, or inflammatory conditions are another predisposing factor(Waldo, 1995; Waldo et al., 1997).

The concept of anisotropic conduction also needs to be understood to understand the mechanisms of reentry. Anisotropic conduction occurs due to increased longitudinal distribution of gap junctions, as opposed to transverse. Therefore, longitudinal conduction can occur much more rapidly than transverse conduction. This is the case with the crista terminalis, for example, which thus creates an effective barrier to conduction in one direction. The crista terminalis linked on either end to the ostia of the vena cavae offer a posterior barrier to reentry with the tricuspid annulus providing the anterior barrier. This anisotropic conduction partially explains why counterclockwise flutter is more common than the clockwise variant as fiber geometry in the annulus appears to favor unidirectional block in one direction over another(Waldo, 1995; Waki et al., 2000).

Many textbooks illustrate typical flutter as a two-dimensional circle around the tricuspid valve. In actual fact, a better way to visualize the circuit is as an upside-down basket where the handle represents the isthmus between the tricuspid annulus and the inferior vena cava. The handle then fans out to the basket proper representing the right atrial septum, the roof of the right atrium and the lateral wall joining up again on the other side. The left atrium is activated passively via the coronary sinus and Bachman's bundle in the roof of the interatrial septum (Fig. 2).

Management

Rate control

Beta-blockers and nondihydropyridine calcium channel blockers can be used for rate control. Digoxin can be added as an adjunctive agent, but is very unlikely to provide adequate rate control on its own. Digoxin used for rate control for atrial flutter should be done cautiously due to the often high doses required to achieve rate control. Because digoxin shortens the atrial action potentials, it may result in conversion of atrial flutter to atrial fibrillation. While this generally results in improved rate control, digitalis toxicity should

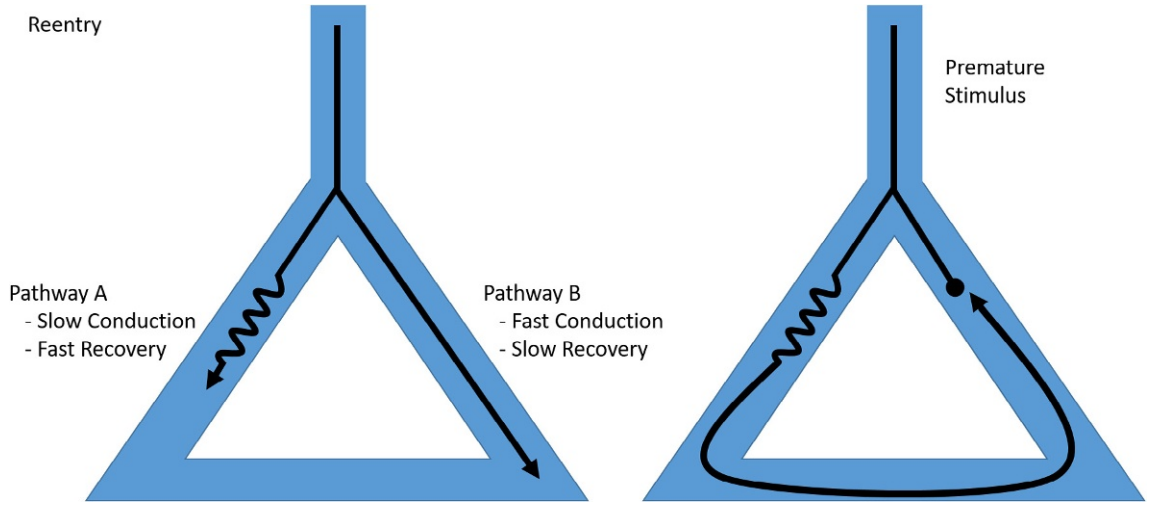

Fig. 2 Concept of reentry is depicted here. In the left panel, a stimulus that comes in at a normal timing interval will conduct down pathway B faster than pathway A. However, if an appropriately timed, premature stimulus is delivered (right panel), the stimulus will find pathway B refractory and conduct only down pathway A. As this conduction is slow, it will arrive back at pathway B, and find that it has recovered, then conduct in a retrograde fashion up pathway B. In similar fashion, pathway A has now recovered and reentry then ensues.

be suspected when this is observed. Nondihydropyridine calcium channel blockers should be avoided in patients with decreased ejection fractions due to their powerful negative inotropic effects. Atrial flutter is usually more difficult to rate control than atrial fibrillation; the reason for this is that conduction in flutter is usually 2:1, 3:1, 4:1, etc. For an atrial rate of 300 bpm, this amounts to ventricular rates of 150 bpm, 100 bpm, 75 bpm, etc., as opposed to the more linear dose-to-ventricular response curve that is possible in atrial fibrillation. Thus, the amount of medication required to slow a ventricular response in atrial flutter from 150 to 100 bpm tends to be much higher than for an equivalent decrease in ventricular rate in atrial fibrillation. Even when rate control is accomplished, the high dose of medications required usually causes side effects, such as fatigue, decreased exercise tolerance and lightheadedness as well other side effects specific to the medications used. Patients in flutter typically have very little heart rate variability which can result in chronotropic incompetence when rate control is excessive.

Adenosine will cause transient atrioventricular block and can be useful to unmask the flutter waves when there is 2:1 conduction and the QRS is wider, therefore making the flutter waves difficult to see. However, because flutter is not AV-node dependent, adenosine will not terminate the rhythm. Judiciously applied carotid sinus massage can accomplish the same effect as adenosine administration.

Because of the difficulties and limitations of the rate control strategy, it should not be considered a great long-term strategy in most cases. It should be seen as a bridge to more definitive care, such as a cardioversion or ablation (**Fig. 3**).

Amiodarone can also be used as a rate control agent in patients who do not tolerate beta-blockade or calcium channel blockers due to hypotension. Intravenous amiodarone will have a hypotensive effect due to the diluents, so has to be administered cautiously. Intravenous amiodarone functions predominantly as a noncompetitive calcium channel- and beta-blocker, but gets metabolized by the liver to *N*-desethylamiodarone, which has sodium and potassium channel-blocking properties. This metabolite starts having significant effect 24–36 h after continuous infusion, so conversion to sinus rhythm is possible. Therefore, care must be taken to ensure that risk of embolization is minimized in the event of conversion.

Anticoagulation

Due to the presence of organized atrial activity on the ECG, it was long felt that atrial flutter presented a lower stroke risk than atrial fibrillation. Due to the fact that atrial fibrillation often coexists in these patients, in addition to most large population studies failing to separate the two rhythms, the actual incidence of stroke prevention in atrial flutter is not truly known. In the Canadian Registry of Atrial Fibrillation database, there was no difference in stroke risk between atrial flutter and atrial fibrillation(Lelorier et al., 2004). Currently, guidelines recommend no distinction between atrial fibrillation and flutter In terms of long-term anticoagulation and periprocedurally for cardioversions(Page et al., 2016). More problematic is how long to continue anticoagulation after the flutter is ablated since many such patients go on to develop atrial fibrillation, which is often asymptomatic after a successful flutter ablation(Chinitz et al., 2007). A definite answer is not available at this time and, like all decisions regarding anticoagulation, will necessitate joint decision-making with an informed patient.

Cardioversion

Due to the difficulties of rate-controlling atrial flutter, cardioversion is an attractive early option. Just like in atrial fibrillation, if the patient is not chronically anticoagulated and the duration of the flutter cannot be firmly established to be less than 24 h, then a

Fig. 3 Analagous representation of right atrial flutter circuit is demonstrated with an upside-down basket. The handle represents the critical isthmus between the inferior vena cava and tricuspid annulus. The basket proper represents the right atrium, with activation propagating out from the isthmus, joining on the other side anterior to the crista terminalis.

transesophageal echocardiogram needs to be performed prior to restoring sinus rhythm to exclude the presence of a left atrial appendage thrombus.

Cardioversion can be performed with a synchronized shock. Generally, low energies are required, in the order of 50–100 J. In individuals with large body habitus, these lower energies may induce atrial fibrillation, which would then require higher energy levels to cardiovert. This is the preferred method because it is expeditious, safe, and not associated with proarrhythmia. However, deep sedation is often required as energy delivery is painful. The inability to give sedation, most commonly due to patient not being in a fasting state, may require pharmacological means for cardioversion.

In the United States, antiarrhythmic drugs that are available intravenously are limited. The most commonly used for atrial flutter would be ibutilide and procainamide. Ibutilide is a potassium channel blocker that has an approximately 60%–90% conversion rate for atrial flutter after one dose. Because the drug can cause QT prolongation and torsades, it needs to be administered in a setting where continuous monitoring, defibrillation and, occasionally, back-up pacing can be delivered. Procainamide has a slower rate of administration and longer half-life and tends to cause more hypotension during its administration usually limiting its administration to ICU-type settings.

Pace termination

Because flutter is a macroreentrant rhythm, introducing a competing wave front of atrial depolarization that can enter the circuit, collide with the flutter wave front and terminate the rhythm is a possible treatment. However, the only time this is a practical solution is when the patient has an atrial lead from an implantable cardiac device, or temporary epicardial pacing wires after cardiac surgery. Placement of an esophageal pacing lead to stimulate the left atrium is rarely used because it is cumbersome and uncomfortable for the patient. Rapid atrial pacing through any mechanism can sometimes terminate flutter, but, more commonly, results in transforming the rhythm to atrial fibrillation, which is often better tolerated and easier to rate control, so this is not an undesirable outcome.

Antiarrhythmic drugs

Unless there is a well-delineated reversible condition (such as pericarditis, postcardiac surgery, thyrotoxicosis), the recurrence rate of atrial flutter is very high. Therefore, recurrence should be expected. One way to reduce the recurrence rate is to administer chronic antiarrhythmic drugs. Class III drugs are generally preferred, such as sotalol, dofetilide, dronedarone, or amiodarone. Class I drugs, particularly the Ic drugs such as flecainide and propafenone can slow the atrial flutter rate sufficiently to allow 1:1 conduction in the AV node. These rhythms are typically over 200 bpm and poorly tolerated. Therefore, good AV nodal blockade should be ensured when using antiarrhythmic medications for atrial flutter, other than amiodarone and sotalol which have intrinsic AV nodal-blocking properties. It should be noted that typical atrial flutter can be cured with a high degree of success and low complication rate with a procedure that is relatively easy to perform for adequately trained physicians. Because of this, there is little reason to subject patients to long-term antiarrhythmic drugs for this condition, unless ablation risk or complexity would be prohibitive due to anatomical or comorbid conditions.

Atypical flutters are usually difficult to treat with antiarrhythmics but can present more of a challenge as the target for ablation is more variable and can be difficult to identify. Because of this, long-term therapy with antiarrhythmic drugs is a more viable long-term strategy than with typical flutters.

Ablation

Ablation of typical atrial flutter is usually straightforward. The critical isthmus between the tricuspid annulus and the inferior vena cava is very easy to reach with a femoral access. The ablation catheter is advanced into the right atrium and flexed into the proximal right ventricle. It is then pulled back from the point where one first sees atrial electrograms to the inferior vena cava, at which point atrial electrograms will disappear. Termination of the atrial flutter proves that the flutter was isthmus-dependent, but the end-point of the procedure is bidirectional block. The radiofrequency lesions result in thermal injury which causes edema initially and is followed by scar formation. As scar consists of collagen, it does not support electrical conduction. Bidirectional block is proven when electrical impulses are no longer able to travel along the isthmus in either direction as determined by pacing from either end of the isthmus. The procedure has low morbidity and low incidence of complications. While acute success is virtually 100%, recurrences can occur months or years later(Waldo, 1995; Morady, 2004) (**Figs. 4–6**).

Ablation of atypical flutter is generally more challenging as the circuits may be due to functional reentry, rather than anatomical, and can occur in either or both atria as well as structures such as the superior vena cava, pulmonary veins, atrial appendages, and coronary sinus. When it is due to a clear anatomical substrate, such as an atriotomy scar, success rates can be quite high. However, when they result from extensive ablations of the atria, such as from ablations or surgeries for atrial fibrillation, the reentrant circuits can be quite complex and targeting a vulnerable isthmus may be difficult. In addition, high recurrence rates make these among the most challenging arrhythmias that the electrophysiologist must contend with.

Focal Atrial Tachycardia

Definition

Focal atrial tachycardia is a specific type of supraventricular tachycardia, characterized by the presence of discrete P waves on surface EKG. Atrial activation begins at a localized site, with subsequent atrial activation spreading centrifugally outward to the remainder of atrial tissue. There is usually an isoelectric segment between P waves, in distinction to atrial flutter, where at any point in time, a portion of the atrial tissue will be depolarized. An analogy would be to consider the wave front generated by dropping a pebble into a pool of standing water.

Incidence

Focal atrial tachycardias are among the least common of the paroxysmal supraventricular tachycardias. The overall prevalence is difficult to establish. However, data from EKG review in both symptomatic and asymptomatic young men has suggested an overall prevalence of 0.34%–0.46% (Poutiainen et al., 1999). Data from the Marshfield study epidemiologic study area demonstrated an overall prevalence of paroxysmal supraventricular tachycardia to be 0.23%(Orejarena et al., 1998). Among patients referred for

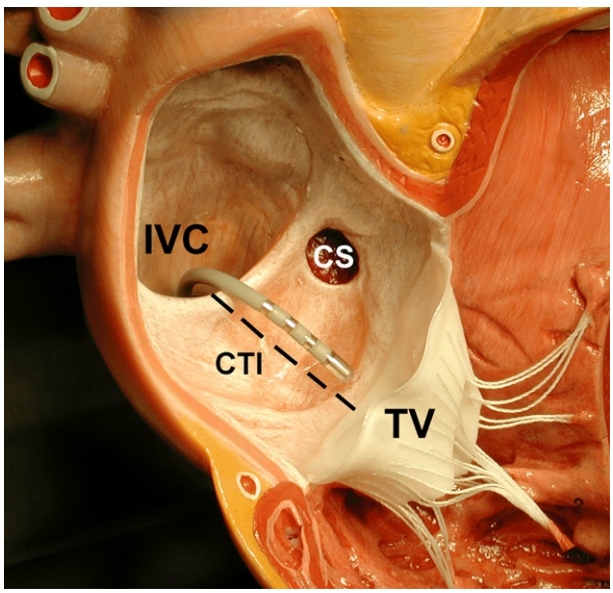

Fig. 4 Depiction of positioning of ablation catheter along the cavotricuspid isthmus in a 3D heart model (IVC = Inferior vena cava, CTI = cavotricuspid isthmus, TV = tricuspid valve, CS = coronary sinus).

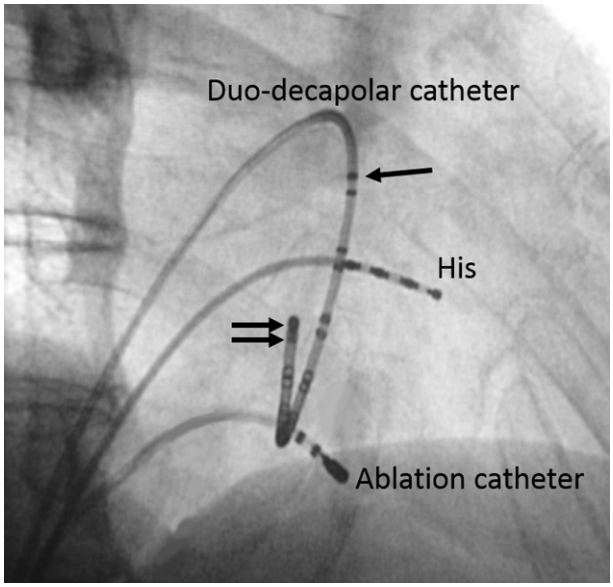

Fig. 5 Fluoroscopic image of catheter positioning during ablation of the cavotricuspid isthmus for typical atrial flutter. The image is in the right-anterior oblique (RAO) projection, such that right ventricle is toward the right of the image and the coronary sinus is in a plane perpendicular to the image. The duodecapolar catheter is positioned such that the distal end is in the coronary sinus (*double arrows*) and the proximal end is near the roof of the right atrium (*single arrow*). A catheter is positioned at the region of the His bundle for reference. The ablation catheter is positioned along the cavotricuspid isthmus, near the tricuspid annulus.

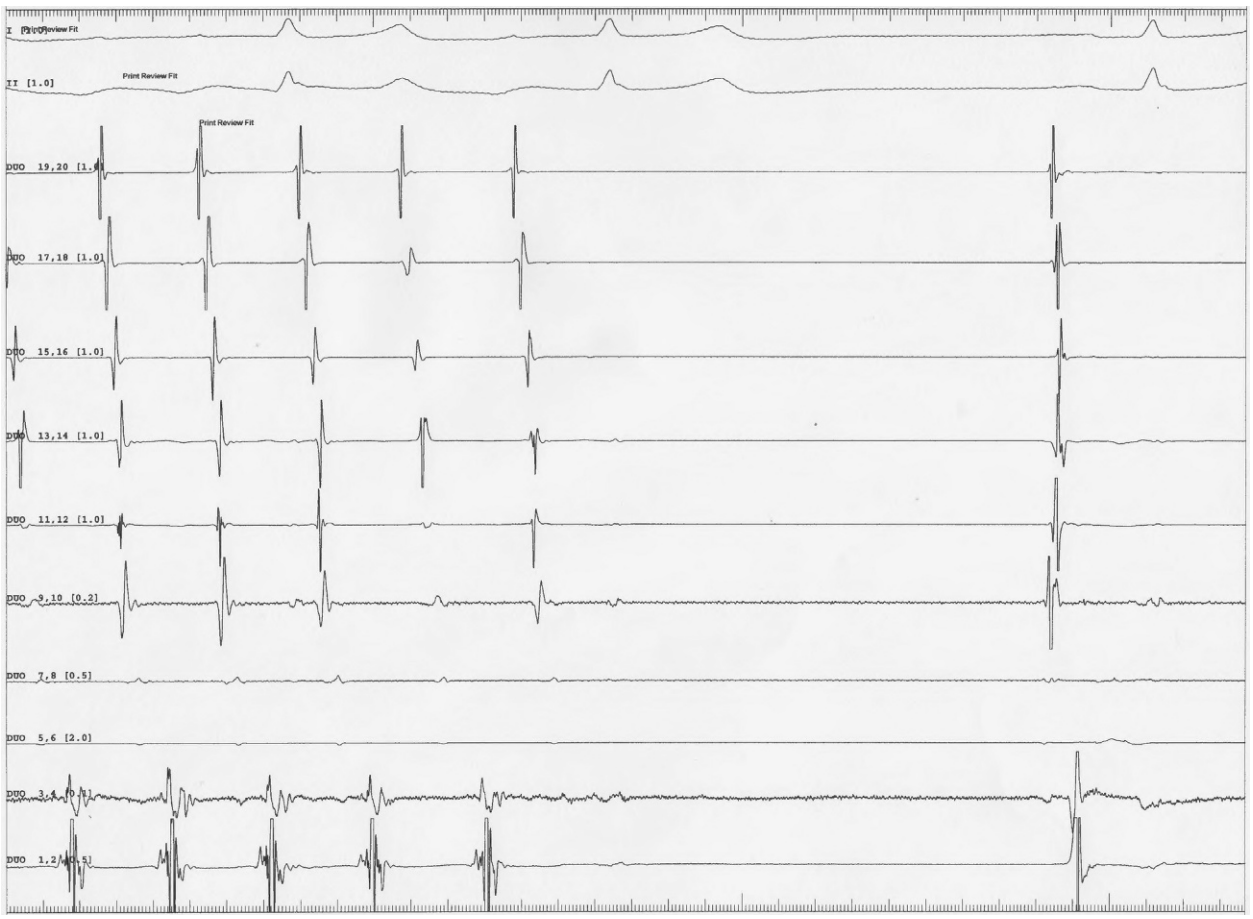

Fig. 6 Intracardiac electrogram during radiofrequency ablation of the cavotricuspid isthmus is shown. There is counterclockwise activation of the right atrium, in that the first signal observed is at the superior aspect of the right atrium (Duo 19,20) with subsequent activation inferiorly (Duo 19,20 to Duo 9,10) and then into the left atrium (Duo 3,4 to 1,2). Poles 7 and 8 are positioned along the isthmus. The first five beats represent atrial flutter. At this point, the flutter terminates as no atrial signal is observed in the coronary sinus. Thereafter, a pause is seen, followed by a junctional escape beat.

electrophysiology study for paroxysmal SVT, the incidence of focal tachycardia is between 3% and 17%(Pedrote et al., 2016; Porter et al., 2004). These data also suggest that patients with atrial tachycardia more often tend to be women.

Characteristics

The rate of atrial tachycardia is usually between 100 and 250 bpm. Episodes may be nonsustained or sustained. Atrial tachycardia may demonstrate a "warm-up" period, in which the tachycardia rate may gradually increase at the onset of tachycardia and "warm-down" at termination. Clinical symptoms can include the sensation of a rapid heart rate, accompanied by dyspnea, chest pressure, lightheadedness, or syncope. In patients with a structurally normal heart, this diagnosis usually carries a benign prognosis. Frequent episodes of atrial tachycardia may be associated with developing atrial fibrillation in the future. There is little evidence to suggest treatment of atrial tachycardia will change the long-term outcome, however.

Surface EKG can provide valuable clues to distinguish atrial tachycardia from other supraventricular tachycardias. Usually, focal atrial tachycardias fall under the category of "long RP" tachycardia—that is the segment from the R wave to onset of P wave is longer in duration than the PR interval. This is neither a sensitive, nor a specific finding, however. Although a tachycardia may demonstrate a short RP interval, this may still represent a focal atrial tachycardia, in that the P wave is conducting to the subsequent R wave, rather than relating to the preceding one.

It is estimated that approximately 75% of focal atrial tachycardia arise from the right atrium. The most common sites of origination in the right atrium include the crista terminalis (31%), tricuspid annulus (22%), perinodal/para-Hisian region (11%), and ostium of the coronary sinus (8%). The most common site in the left atrium is from within the pulmonary veins (19%). Other less common sites of origination include the intraatrial septum, body of the coronary sinus, mitral annulus, and the right and left atrial appendages(Kistler et al., 2006).

The P wave morphology may help with localization, with lead V_1 being the most useful in helping to differentiate a right from a left atrial origin. A negative or biphasic (+/−) P wave in lead V_1 is highly specific for right atrial tachycardia, while a positive or biphasic (−/+) is more suggestive of left atrial tachycardia. A P wave that is positive in the inferior leads (II, III, aVF) suggests a superior location of the tachycardia. Algorithms have been proposed to focally predict and identify origin with some success, however, there is significant overlap and therefore limited sensitivity and specificity. For example, a tachycardia that arises from the right upper pulmonary vein, which anatomically is positioned posterior to the right atrium and the sinus node, may appear similar to a sinus P wave(Kistler et al., 2006).

Focal atrial tachycardia, if arising from near the sinus node, in the region of the superior crista terminalis, or posteriorly from the right upper pulmonary vein, must be distinguished from arrhythmias related to the sinus node, including sinus tachycardia, sinus node reentry, and inappropriate sinus tachycardia. Sinus tachycardia may be appropriate, if there is an underlying physiologic cause, or inappropriate, if there is not. Usually, sinus tachycardia demonstrates a gradual increase in heart rate from normal, which can be discerned on cardiac ambulatory monitoring. While focal atrial tachycardia may demonstrate a "warm-up" period over a few beats, onset is usually abrupt. Identification of P wave morphology may help to distinguish from a focal AT (**Figs. 7–12**).

Sinus node reentry is a less common form of focal atrial tachycardia. It involves microreentry within the sinus node that results in a P wave morphology identical to that of the sinus P wave. Onset is usually abrupt, but rates rarely exceed 150 bpm. An electrophysiologic study is necessary to make this diagnosis and differentiate from focal AT originating from the crista terminalis.

Lastly, inappropriate sinus tachycardia is a condition which is characterized by sinus tachycardia without an apparent, underlying physiological explanation. Periods of sinus tachycardia are observed at rest or with minimal exertion. A constellation of other symptoms, including profound weakness and palpitations may be present. There is a loosely understood relationship and overlap with autonomic dysfunction and postural orthostatic tachycardia syndrome. All secondary causes of sinus tachycardia must be excluded(Page et al., 2016).

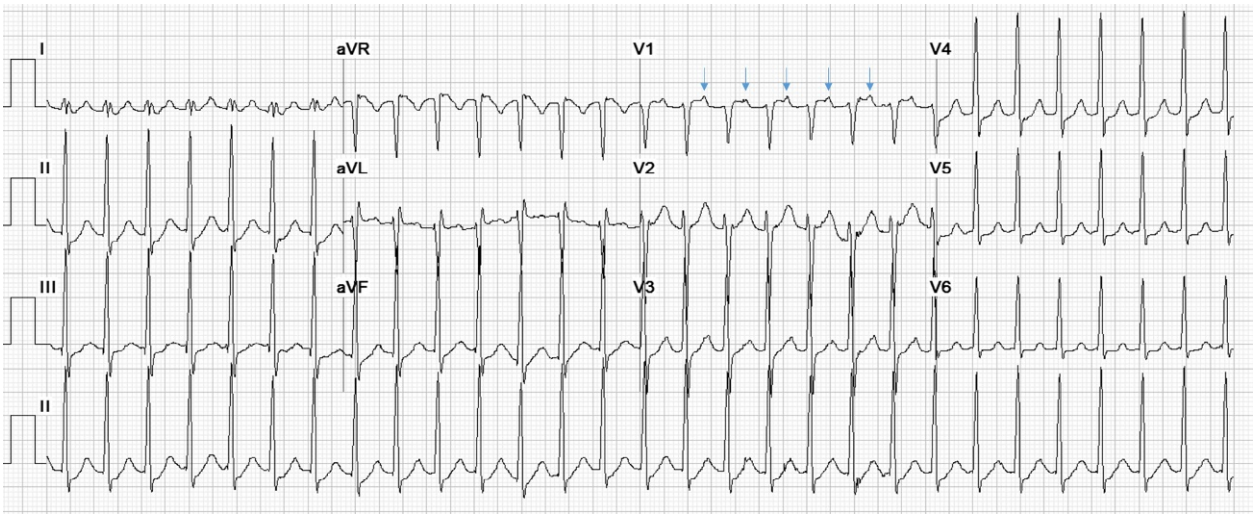

Fig. 7 EKG of focal atrial tachycardia, which was later mapped to the right lower pulmonary vein, where radiofrequency ablation was performed focally, with termination of the arrhythmia. P waves are denoted with *arrows*.

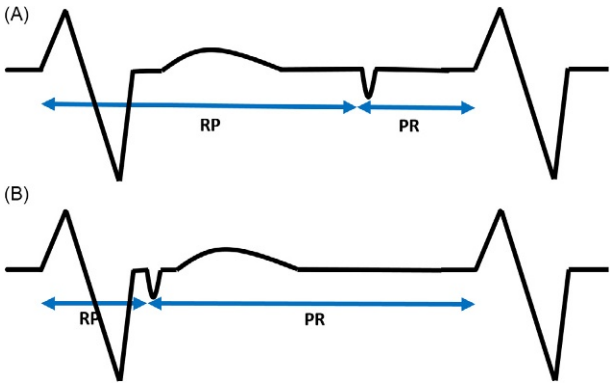

Fig. 8 In the top panel, A, a long RP rhythm is shown (RP segment >PR). Conversely, in the bottom panel, B, the RP relationship is shorter than the PR. Both may occur with atrial tachycardia.

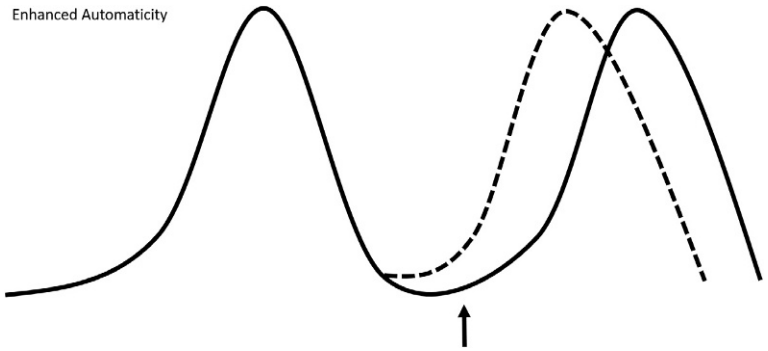

Fig. 9 The *arrow* denotes phase 4 depolarization. The *dotted line* shows an increased slope of phase 4 depolarization, possibly due to decreased I_{k1} or enhanced I_f currents. This will lead to a faster rate of automaticity.

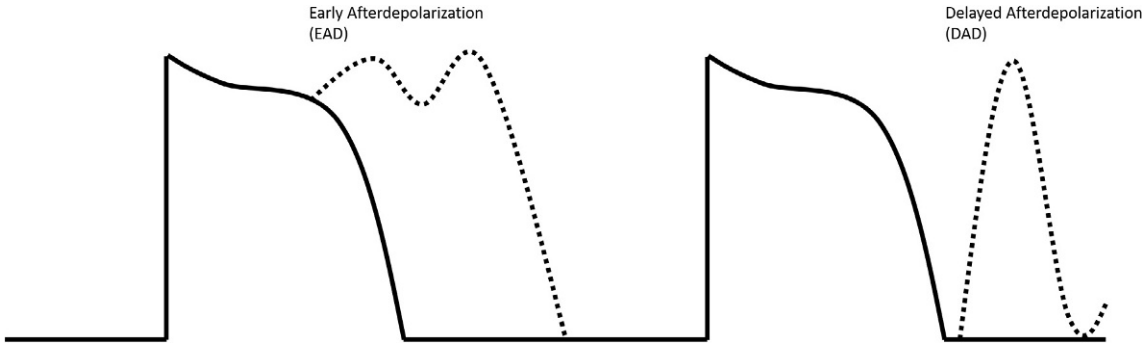

Fig. 10 Early afterdepolarizations occur during phase 2 or phase 3 of the cardiac action potential (left), due to I_{ca} reactivation that may occur in the setting of prolonged repolarization. Delayed afterdepolarizations (right) occur during phase 4, due to Ca^{2+} overload.

Focal atrial tachycardia may contribute to a tachycardia-mediated cardiomyopathy. The overall incidence of this is 10%. Incessant or highly frequent tachycardia is a risk factor for this phenomenon. Abolition of the tachycardia, frequently with catheter ablation, will restore sinus rhythm, with likely improvement in systolic function(Medi et al., 2009).

Mechanisms

The mechanism of focal atrial tachycardia can be due to enhanced automaticity, triggered activity, or microreentry. Understanding these mechanisms will help to understand treatment strategies and use of various diagnostic maneuvers to identify etiologies of undifferentiated narrow complex tachycardias.

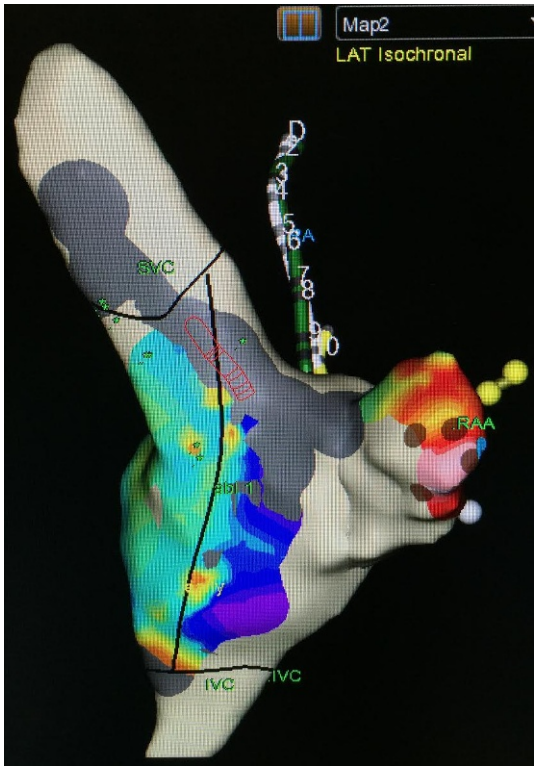

Fig. 11 A 3D electroanatomic activation map is created during focal atrial tachycardia. The *red* area corresponds to earliest activation within the right atrial appendage. Areas of *blue* and *purple* represent later areas of activation. Radiofrequency ablation was carefully performed within the right atrial appendage, without complication, and with termination of the tachycardia.

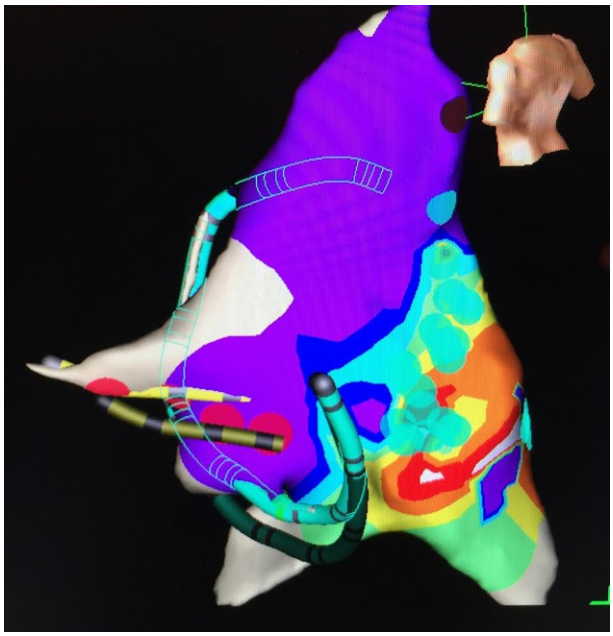

Fig. 12 Similarly, a 3D electroanatomic activation map, created during focal atrial tachycardia, is shown with earliest areas mapped to the interatrial septum in the right atrium (*red* and *white* areas).

- The concept of reentry has previously been discussed in the section discussing atrial flutter. *Microreentry* refers to the same concept applied to a smaller circuit—some have defined this as <2 cm and others as an area that is smaller than the spatial resolution afforded by current 3D mapping systems.
- *Enhanced automaticity* will occur with increased slope of phase 4 depolarization, resulting in an increased firing rate. This is usually fastest in the sinus node, but if abnormal automaticity occurs in other tissue, ectopic atrial activity will be seen. Focal atrial tachycardia, when secondary to enhanced automaticity, may demonstrate a "warm-up" period.
- *Triggered activity* refers to impulse formation that results in afterdepolarizations that occurs during or after the repolarization phases of the cardiac action potential. An early afterdepolarization occurs in phase 3 while a delayed afterdepolarization (DAD) occurs after repolarization has completed (phase 4). Atrial tachycardia with AV block may be seen with digoxin toxicity. The likely mechanism is related to triggered activity, secondary to DADs that may occur in the SA node(Gaztanaga et al., 2012).
- *Macro reentrant* atrial tachycardia refers to atrial flutter, both typical and atypical, which was previously discussed.

Pacing maneuvers during an electrophysiology study can be used to define the mechanism of arrhythmia.

Bedside maneuvers and administration of certain drugs can also be useful in distinguishing the underlying mechanism and distinguishing focal AT from atrial flutter. Adenosine decreases L-type calcium currents via inhibition of intracellular cAMP generation. Via this effect, adenosine may terminate focal ATs that arise due to triggered activity. Additionally, adenosine may activate adenosine-sensitive potassium currents (I_{kAdo}), leading to hyperpolarization and suppress enhanced automaticity. Adenosine does not have an effect on atrial flutter or microreentrant AT(Markowitz et al., 2007). Valsalva maneuvers may terminate a small subset of focal atrial tachycardias that are related to triggered activity. However, the vast majority of focal atrial tachycardias cannot be terminated in this manner. With Valsalva, usually transient AV block is noted, with continuation of atrial activity without conduction to the ventricle.

Acute management

In the acute setting, as for any hemodynamically unstable rhythm, direct current cardioversion may be necessary. This is considered a temporizing measure and, unless a clear precipitant of the arrhythmia is identified and corrected, should not be considered the ultimate therapy.

If the patient is stable, administration of intravenous medications or vagal maneuvers can be useful. Intravenous beta-blockers, diltiazem, or verapamil are generally considered first-line therapy in the treatment of focal atrial tachycardia in a hemodynamically stable patient. Intravenous amiodarone or ibutilide can also be considered in a hemodynamically stable patient(Page et al., 2016). There is no prospective clinical data on the utility of each of these agents.

As discussed previously, adenosine may be useful for termination if the underlying mechanism of the focal atrial tachycardia is triggered activity. If the underlying mechanism is enhanced automaticity, transient suppression of the arrhythmia may be seen. Adenosine may be useful as a diagnostic maneuver: if AV block is achieved with continuation of atrial activity, this eliminates supraventricular tachycardias that are dependent on the AV node for maintenance, such as AV node reentry and atrioventricular reentry (discussed elsewhere). Vagal maneuvers, including carotid sinus massage or Valsalva, may result in the same effect as adenosine and may help in diagnosis of the etiology the supraventricular tachycardia.

Long-Term Management

Pharmacologic

Options for long-term pharmacotherapy include oral beta-blockers, diltiazem, or verapamil. Class IC antiarrhythmic drugs (flecainide or propafenone) as well as the class III agents, sotalol or amiodarone, can also be effective in suppressing focal atrial tachycardia. However, in a symptomatic patient, pharmacotherapy is considered second-line after catheter ablation.

Ablation

Over the past 20 years, the safety and success of catheter ablation for focal atrial tachycardia has markedly improved. The hallmark of electrophysiology study first involves induction of the tachycardia, which, depending on the underlying mechanism of the arrhythmia, can be accomplished with incremental atrial pacing, or programmed stimulation, with or without the use of a beta-agonist, such as isoproteronol. Mapping can be performed either with a contact or noncontact mapping catheter. With contact mapping, a roving catheter is manipulated across the surface of the atrium, attempting to find an early site of activation relative to a fixed reference, usually the surface P wave. This can be done in conjunction with an impedance-based navigation system, which can provide visualization of the catheter within a 3D electroanatomic model of the chamber. A noncontact mapping catheter uses a multielectrode catheter positioned within the chamber, not actually in contact with tissue, and generating a map of earliest activation. This form of mapping may be useful in cases where the arrhythmia is frequently changing, is nonsustained, or is not clinically tolerated by the patient. 3D mapping systems help to significantly increase precision of catheter movement and increase success rates for ablation procedures. If performed in experienced centers, success rates are in excess of 85% with complications rates of ~2%(Pedrote et al., 2016). Major complications occur in 0.3% of cases, which include cardiac perforation, tamponade, or AV block, depending on the location of the tachycardia.

Anticoagulation

In the absence of atrial flutter or fibrillation, there is low thromboembolic risk. Therefore, oral anticoagulation is not indicated.

Multifocal Atrial Tachycardia

MAT is characterized by a rapid (>100 bpm), irregular rhythm with at least three P wave morphologies. MAT is associated with medical comorbidities, including chronic obstructive pulmonary disease, pulmonary hypertension, and valvular heart disease. In general, management of this arrhythmia is focused on treating the underlying medical conditions. Nondihydropyridine calcium channel blockers can be used to slow conduction in the AV node. Verapamil is usually preferred but diltiazem can also be used. In the acute setting, there may some benefit to using intravenous magnesium. Intravenous verapamil is safe and effective for controlling heart rate. Beta-blockers should be used with caution with concurrent pulmonary disease. Amiodarone can be considered. Cardioversion is not useful for MAT, as the rhythm will almost certainly resume. Catheter ablation is also not a treatment option for this arrhythmia(Page et al., 2016).

Introduction

Atrioventricular node reentrant tachycardia (AVNRT) is the most common regular supraventricular tachycardia observed in clinical practice. The reentrant circuit, located in the atrioventricular (AV) node, consists of at least two pathways with different electrophysiological properties, called fast and SPs in allusion to their conduction times. In this article we review the mechanisms that lead to the different types of AVNRT, as well as, their clinical and varies electrocardiographic presentations. We provide a simplified algorithm that may allow readers to quickly identify this arrhythmia. Also, we discuss the electrophysiological mechanisms and maneuvers that enable distinguishing AVNRT from other supraventricular tachycardias. Finally, we highlight its acute and long-term management with particular emphasis in current transcatheter mapping and ablation techniques.

Pathophysiology

The Atrioventricular Node

Background and function

The AV node is an integral part of the AV conduction axis within the heart. The atria and the ventricles are separated by a fibrous insulating plane. At the most basic level, the AV node is the link between the conduction system of the atria and the subnodal His-Purkinje conduction system of the intraventricular septum and the ventricles. It allows impulses generated at the sinoatrial (SA) node to propagate from the atria to the ventricles each cardiac cycle. The AV node also accounts for the largest component of the delay in the AV transmission. The delay of the impulses arriving from the atria is fundamental in the overall cardiac cycle, allowing sufficient time in diastole for the ventricles to fill. This atrio-His (AH) delay is broad during normal sinus rhythm with an AH range between 60 and 125 ms (Josephson, 2008). This is largely attributed to the sensitivity of the AV node conduction velocity and refractoriness to changes in autonomic nervous system afferents.

 https://doi.org/10.1016/B978-0-12-809657-4.99780-1

Apart from its role in the regular cardiac cycle, the AV node has an important survival mechanism which allows impulses to be delayed during periods of rapid atrial activity. A phenomenon known as decremental conduction ensures that as the time intervals between stimulation of the AV node from the atria decrease, the refractoriness of the AV node increases (Patterson and Scherlag, 2002). Decremental conduction is of paramount importance in protecting the ventricles from rapid rates of atrial arrhythmias.

Although it serves as an important protective mechanism for the ventricles during periods of rapid atrial activity, the heterogeneity within the AV node can lead to the generation of arrhythmia on its own. Discussed later are the important anatomic and electrophysiologic properties of the AV node, and their relation to mechanisms of arrhythmia.

AV node anatomy

Tawara was the first to prove the physical existence of the AV node in the early 1900s (Tawara, 1905). Until then, it had been hypothesized that there was an anatomic unit responsible for the connection between the atria and the ventricles and of importance in the conduction and modulation of impulses between these two units. Further histopathological and electrophysiological evaluations of the AV node reveal that it is far from a homogenous structure. In fact, it is remarkably heterogenous, both anatomically and electrically.

An important anatomical landmark when discussing the anatomy of the AV node is the Triangle of Koch (**Fig. 1**). The Triangle of Koch accounts for a significant component of the septal portion of the right atrium on the endocardial surface. It is delimited anteriorly by the insertion of the septal leaflet of the tricuspid valve. The most posterior border is the fibrous strand continuation of the valve of the inferior cava vein: the tendon of Todaro. At the apex of the triangle of Koch, just below the right atrial endocardium, lies the compact AV node. Here, the AV conduction system penetrates the insulating plane at the AV junction. Located superiorly and anteriorly to this site lies the bundle of His (HB) (Anderson and Cook, 2007).

Histopathology and electrophysiologic properties

The AV node is made up of different types of cells that can be broadly categorized based on the region within the AV node that they arise. The compact zone is more homogeneous and less similar to the surrounding myocytes. It is enveloped by the transitional zone, made up of transitional cells. This is a more histologically heterogeneous group of cells that is the result of the merging of surrounding myocytes to the AV node proper. Functionally, action potential characteristics recorded using microelectrodes recordings in the rabbit AV junction have been used to classify the AV node into distinct electrophysiological "regions": atrionodal (AN), nodal (N), and nodal-His (NH). These distinct regions have both unique histopathologic and electrophysiologic characteristics (Anderson and Cook, 2007).

AN region

The AN region corresponds anatomically to the area called the transitional zone. It is the less compact and most inferior portion of the AV node. Atrial cells group into bands and gradually merge into the more compact AV node. The cells are histologically distinct from atrial myocytes and cells in the compact AV node. Two AV node inputs can be observed forming bridges from atrial tissue to

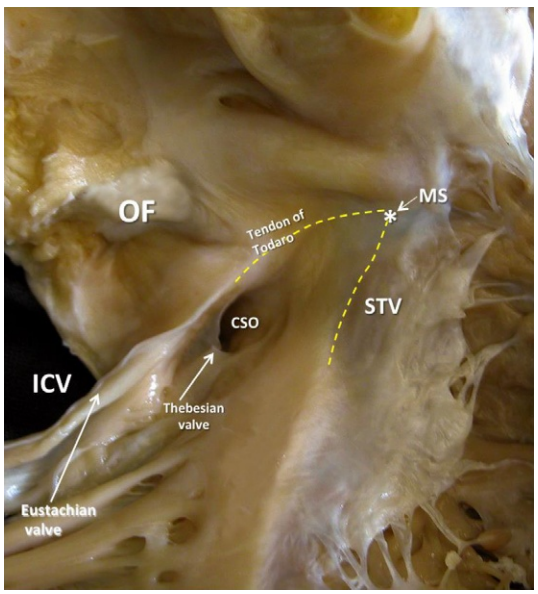

Fig. 1 Simulated right anterior oblique view of the right atrium showing the anatomical landmarks of the triangle of Koch. The apex of the triangle points superiorly whereas the coronary sinus ostium (CSO) is located inferior. The posterior border is given by the tendon of Todaro, and the anterior border by the septal leaflet of the tricuspid valve (STV). The AV node is located in the superior margin of the triangle between the tendon of Todaro, the membranous septum (MS), and the hinge of the septal leaflet of the tricuspid valve. *OF*, oval fossa; *ICV*, inferior cava vein. Courtesy Dr Damian Sanchez-Quintana.

the AV node. The anterior (superior) approach connects the anterior limbus of the fossa ovalis to the AV node close to the triangle of Koch. The posterior (inferior) approach connects the coronary sinus ostium to the AV node close to the interior septal RA. An additional approach has more recently been described connecting the AV node to the septum and the left atrium (Lockwood et al., 2009; Racker and Kadish, 2000; Mazgalev, 2009; Basso et al., 2008).

N region

The N region represents the compact AV node. The compact node is 5–7 mm length, 3–4 mm width (Mani and Pavri, 2014). Here, the transitional cells merge with the mid-nodal cells. The N cells are responsible for the majority of conduction delay within the AV node. This is due to several factors relating to the histopathology of the N cells. The depolarization rates are slower due to a paucity of sodium channels and the action potential in this region is largely mediated by inward L-type calcium channels. Additionally, there are fewer gap junctions in the area, which translates into less intracellular connections and slower propagation of depolarization waves (Tawara, 1905; Mani and Pavri, 2014).

NH region

The NH region corresponds to the cells merging with the HB, which penetrates the insulating AV plane in a leftward direction, away from the right atrial endocardium and toward the ventricular septum. These are closer in appearance to the rapidly conducting cells of the HB.

When traced inferiorly, toward the base of the triangle of Koch, the compact AV node area separates into two extensions. These extensions bifurcate toward the CS ostium and tricuspid annulus (right posterior extension) and the mitral annulus (left posterior extension). The right posterior nodal extension has been classically marked as the SP involved in the AVNRT circuit. The fast pathway (FP) is less well defined from an anatomical point of view and has been classically described in an anterior (superior) location in the Koch's triangle. Nevertheless, the concept of the AV node as having anterior (superior) and posterior (inferior) inputs is a simple theoretical framework that allows the clinician to confront most cases (Issa et al., 2012). Reentry occurring along these pathways is the core mechanism for various subtypes of AVNRT (slow–fast and fast–slow).

In patients with this anatomic characteristic, the depolarizing wave-fronts from the atria arrive at the compact AV node via those two distinct pathways. The anteriorly located pathway conducts impulses faster but has a long refractory period. In contrast, the posteriorly located pathway conducts more slowly but has a short refractory period. This has led to specific observations regarding the electrophysiologic characteristics of the AV node known as the "dual AV nodal pathways physiology." This can be observed under normal physiologic states, but is of great important in abnormal states, such as nodal-dependent arrhythmias. The definition of dual pathways in the cardiac electrophysiology lab (EP lab) depends on the response of the AV node to programmed premature atrial stimuli that demonstrates discontinuous propagation of anterograde impulses through the AV node.

The dual nodal physiology, as well as the phenomenon of decremental conduction, has been demonstrated in both animal (Zhuang et al., 2002) and human (Schauerte et al., 2001) models using programmed atrial stimulation. At normal heart rates, conduction occurs via the FP, so the normal PR interval lasts between 120 and 200 milliseconds (ms). During programmed atrial stimulation, a train of atrial impulses is delivered to the AV node at a fixed cycle length (CL) followed by a single atrial premature stimulus. As the prematurity of the extrastimulus is increased, the conduction time of the earlier atrial impulse to the His signal is prolonged (decremental conduction). The AH prolongation is progressive, adding no more than 50 ms to the previous AH values at each 10 ms decrease in the extrastimulus CL, until the impulse block in the AV node (AV node effective refractory period (ERP)) (**Fig. 2**). The so-called dual nodal physiology consists of an abrupt AH prolongation more than 50 ms. This abrupt prolongation reflects the FP ERP and the "jump" on the impulse conduction from one pathway to the other. Now the impulse is conducted through the SP, named "slow" as it takes at least 50 ms more than the previous impulse to arrive at the HB (Moe et al., 1956). In summary, an AH jump is defined as an increase in the length of the AH interval $\geq$50 ms, caused by a decrease in the coupling interval of an atrial extrastimulus (A1A2) of 10 ms.

Another manifestation of a dual physiology are (1) the presence of two different PR intervals during sinus rhythm in the same patient; (2) a PR interval longer than the RR interval during rapid atrial pacing; (3) two QRS for only one P wave or a "double ventricular response" (Josephson, 2008).

Tachycardia Circuit

Dual AV nodal physiology is the underlying substrate for AVNRT. In other words, AVNRT only occurs in patients with dual AVN physiology; however, this physiology is present in almost half of the population, and only a few of them will develop AVNRT. As in any reentrant tachycardia, the substrate is essential, but other conditions are required for the creation and maintenance of a reentrant arrhythmia (Josephson, 2008):

1. Two anatomically or functionally different pathways that connect proximally and distally forming a closed-loop system.
2. Unidirectional block in one of these pathways (longer ERP) due to a premature beat.
3. Slow conduction down the unblocked pathway (shorter ERP) allowing the previously blocked pathway sufficient time to recover excitability. In other words, the conduction time down the unblocked pathway must exceed the refractory period of the pathway initially blocked to allow a closed-loop conduction system to form. Because the unblocked pathway has a shorter refractory period and recovers faster, it will be ready to receive the incoming activation, maintaining the tachycardia.

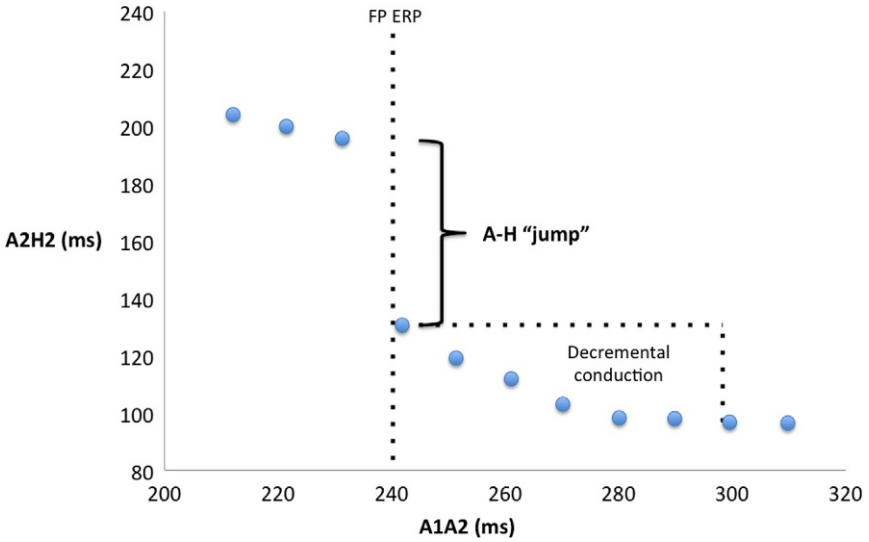

Fig. 2 The model of dual AV nodal pathways on the antegrade conduction curve is shown. The *X* axis represents the time interval between the last beat of the drive train and the premature atrial impulse. The *Y* axis represents the time interval between the premature atrial impulse and the resulting His bundle. With increasingly premature atrial complexes (decreasing A1A2), the effective refractory period of the fast pathway is reached (FP ERP), and the impulse can now only conduct down the slow pathway. At this level, an abrupt increase in the length of the AH interval is seen ($\geq$50 ms); this is called "AH jump."

The AVNRT circuit is limited to the compact AV node and does not involve the ventricles. Whether the circuit involves atrial myocardium (perinodal) is controversial. Other controversial concepts are the presence of upper and lower common pathways. These concepts are referred to additional AV nodal tissue extrinsic to the tachycardia circuit to explain various electrophysiological phenomena observed during AVNRT (Miller et al., 1987). There is real evidence that the distal junction of the slow and fast pathways is located in the AV node, with the existence of a region of AV tissue extending between the distal junction of the two pathways and the HB (the lower common pathway), at least in some patients. The concept of a lower common pathway has been used to explain some unusual situations as the presence of AV block without recording of a His signal during AVNRT (Otomo et al., 2006).

Current evidence supports the role of perinodal tissue and suggests that the fast and slow pathways involved in the reentrant circuit of AVNRT represent conduction over different atrio-nodal connections, thus making at least a small amount of atrial tissue a necessary part of the reentrant circuit (Issa et al., 2012).

In AVNRT, the pathway that has a faster conduction time takes longer to recover to the point where it can accept an incoming activation (longer refractory period). The slower pathway recovers quicker (shorter refractory period) and can accept a new signal earlier than the pathway that conducts faster. If a premature beat occurs in the time period when the FP is not ready to receive a new signal, but the SP is, then the early signal will travel down the SP only prolonging the AH interval and PR interval. When the early signal reaches the lower connection between both pathways, it is possible that the faster is now ready to conduct. If this happens, the early signal will split with part of it traveling down into the ventricles along the normal conduction system. The other part of the signal will return backward, or retrograde, up the FP to the atrium. As the FP conducts faster than the SP, makes the upward conduction so fast that the ventricles and atria are activated almost at the same time. This first beat of reentry, when a retrograde P wave is visualized very close to the QRS, is called echo beat. When this signal reaches the top of the node where the upper connection between the two pathways is located, if the SP is recovered, the impulse will not only activate the atria but also it will travel down the SP. The circuit is now in a loop that will continue until the electrophysiology properties in some of the pathways changes, and the circuit is interrupted (**Fig. 3**).

Anatomic and physiologic relationships mentioned above are related to the typical slow–fast AVNRT, where the activation travels anterogradely using the SP and retrogradely using the already recovered FP. This type accounts for 90% of all AVNRTs encountered in clinical practice, but in some cases, this circuit could be inverted with the first anterograde activation arriving fast usually at different levels in the coronary sinus before reaching back the atrium through the SP (type fast–slow). Also, multiple SPs have been described in up to 14% of the patients with AVNRT (Issa et al., 2012). These pathways would be involved in more rare forms of AVNRT with similar slow conduction between both pathways (type slow–slow).

Epidemiology

AVNRT represents the most common form of paroxysmal supraventricular tachycardia (PSVT) in humans, accounting for more than 50% of all PSVT cases in adults (Josephson and Wellens, 1997).

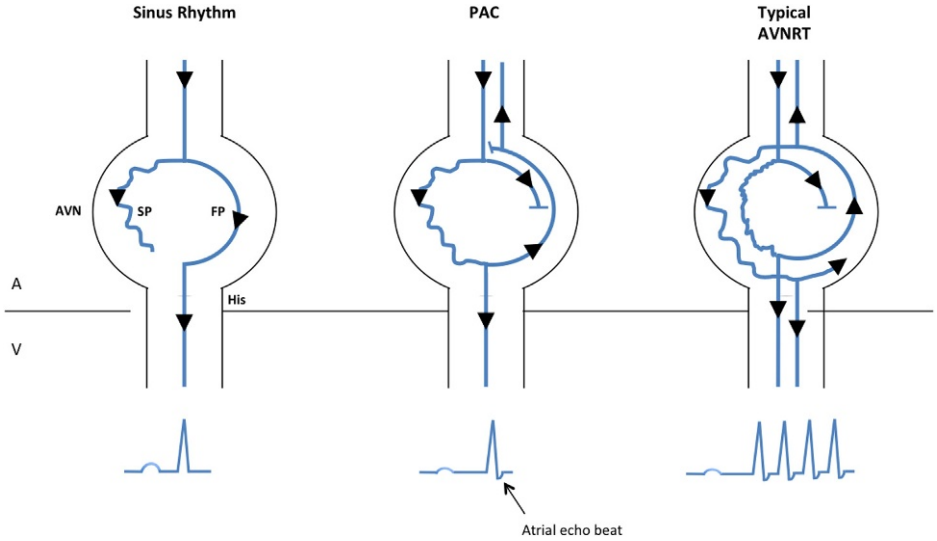

Fig. 3 Prototype of dual AV nodal pathways physiology in sinus rhythm, with a premature atrial complex (PAC) which trigger a typical "slow–fast" AVNRT. See text for details. *SP*, slow pathway; *FP*, fast pathway.

The number of patients with AVNRT increases with age. The mean age of onset is about 30 years old and is unusual in children less than five years old. In contrast, atrioventricular reentrant tachycardia (AVRT) manifests earlier. This pattern may be related to the natural evolution of AV nodal physiology over the first two decades of life, as well as age-related changes in atrial and nodal physiology observed in later decades. AVNRT is more common in women with a 2:1 predominance (Porter et al., 2004; Scheinman and Huang, 2000). The reason may be related to gender differences in the anterograde and retrograde electrophysiological properties (Suenari et al., 2010).

Clinical Presentation

The clinical presentation depends on heart rate, but the most common symptoms are palpitations of abrupt onset and termination. The faster the heart rate and/or the older the patient, palpitations are poorly tolerated, and other hypoperfusion symptoms may be present as dizziness, dyspnea, angina, or syncope.

In some cases and especially in a young woman without ECG documentation, recurrent episodes can be misdiagnosed as a panic attack.

Due to the atria and ventricles contracting at the same time during typical AVNRT, in about half of the patients, palpitations are felt in the neck. Canon A-waves in the jugular venous waveform result from the simultaneous contraction of the atria and ventricles against closed AV valves, causing a reflux of blood into the neck veins. The characteristic flapping or bulging appearance of the neck veins is also described as the "frog sign" (Contreras-Valdes and Josephson, 2016). Although neck palpitations it can be present during AVRT, it is less common. Moreover, neck palpitations have been postulated as the only clinical predictor of AVNRT when positive ECG findings were lacking (González-Torrecilla et al., 2009).

In summary, a woman with palpitations of abrupt onset and termination felt at the neck and first episode after 20 years of age are variables more related with AVNRT than another type of PSVT.

ECG Identification

AVNRT is typically a narrow complex tachycardia (QRS duration <120 ms), with the same QRS morphology as in sinus rhythm. The QRS duration could be prolonged if aberrant conduction (most likely right bundle-branch type) or previous conduction defect exists (Lockwood et al., 2009). The rates of AVNRT vary widely, ranging from 100 to 280 beats per minute (bpm) with an average of 170 bpm. Slower rates use to be seen in older patients (Josephson, 2008).

In typical (slow–fast) AVNRT, the RP interval is very short (RP/RR <0.5) (usually RP <80 ms) and abnormal P-waves are indiscernible or very close to the QRS complex because of the simultaneous atrial and ventricular activation. Thus, the P-wave can distort the initial portion of the QRS ("pseudo" q-wave in inferior leads), it can be masked by the QRS, or distort the terminal part of the QRS ("pseudo" s-wave in inferior leads and "pseudo" r'-wave in lead V1). In atypical AVNRT (fast–slow and slow–slow), P-waves are visible after the QRS (RP/RR >0.5) (usually RP >80 ms) (Issa et al., 2012). When visible, the retrograde atrial activation is seen as negative P-waves in leads II, III, AVF and positive in lead V1 (Fig. 4).

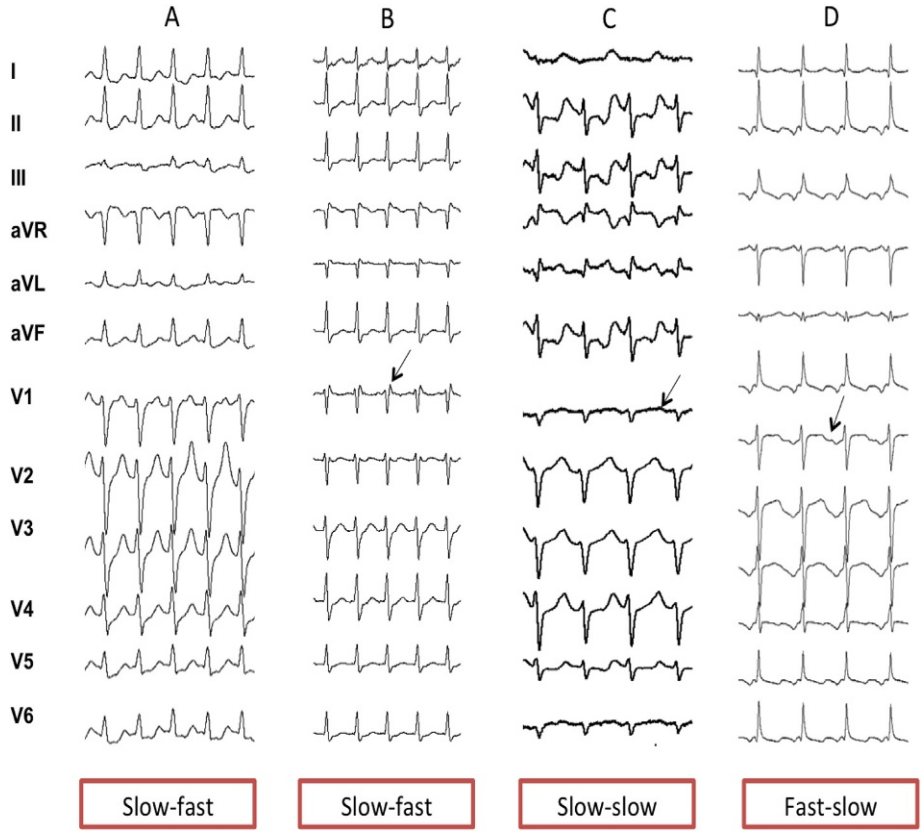

Fig. 4 Different types of AVNRT showing different surface ECG presentation. In all types of AVNRT, the P wave is relatively narrow, negative in inferior leads, and positive in V1. In typical (slow–fast) AVNRT, the retrograde P wave may lie within the QRS (A) or deform the terminal portion of the QRS, "pseudo" r wave in V1 (B). In slow–slow AVNRT the P-waves lies in the ST-T segment (C). In fast–slow AVNRT, the P wave presents before the QRS with a long RP interval (D). *Arrows* mark the positive P-waves in lead V1.

Usually, the P/QRS ratio during AVNRT is 1, however, 2:1 AV block can be present if the level of block occurs below the reentry circuit (in the lower common pathway or below HB). If so, retrograde P-waves are inscribed exactly between QRS complexes.

Electrocardiographic Differential Diagnosis of Narrow-Complex Tachycardia

Narrow-complex tachycardias denote all tachyarrhythmias that originate from the supraventricular tissue. In an acute setting, the quick and correct interpretation of the ECG is paramount since the management may differ between some arrhythmias (Fig. 5).

The proposed algorithm from Queen's University is a simplification of the multiple possibilities for the diagnosis of narrow-complex tachycardias in order to facilitate its clinical use. It is intended to help the physician in the rapid recognition of the most common forms seen in adults (Nadeau-Routhier and Baranchuk, 2016).

During a narrow-complex tachycardia, the first step is to classify the arrhythmia according to whether there is a regular or irregular ventricular rate. An irregular RR interval suggests atrial fibrillation (most likely), multifocal atrial tachycardia (AT) or atrial flutter with variable conduction. If the atrial wave is clearly identified and the rate is greater than the ventricular rate, then atrial flutter ("saw-tooth pattern") or AT is usually present.

If the tachycardia is regular, the next step is to identify the location of the P-waves. If no P-waves are visible, then typical AVNRT (slow–fast) is the most likely diagnose. If the P-waves are visible (negative) after the QRS, analysis of the RP interval is paramount. The differential diagnosis of "short RP" tachycardias includes typical AVNRT and orthodromic AVRT. In "long RP" tachycardias the most likely diagnoses are atypical AVNRT ("fast–slow") and ATs originating in the lower aspect of the atria (i.e., ostium of the coronary sinus).

If the P-wave is visible just before the QRS, then we should review its morphology in the inferior leads. The main differential diagnoses includes sinus tachycardia (positive P-waves), low AT (negative P-waves), or atrial flutter ("saw-tooth" P-waves appearance).

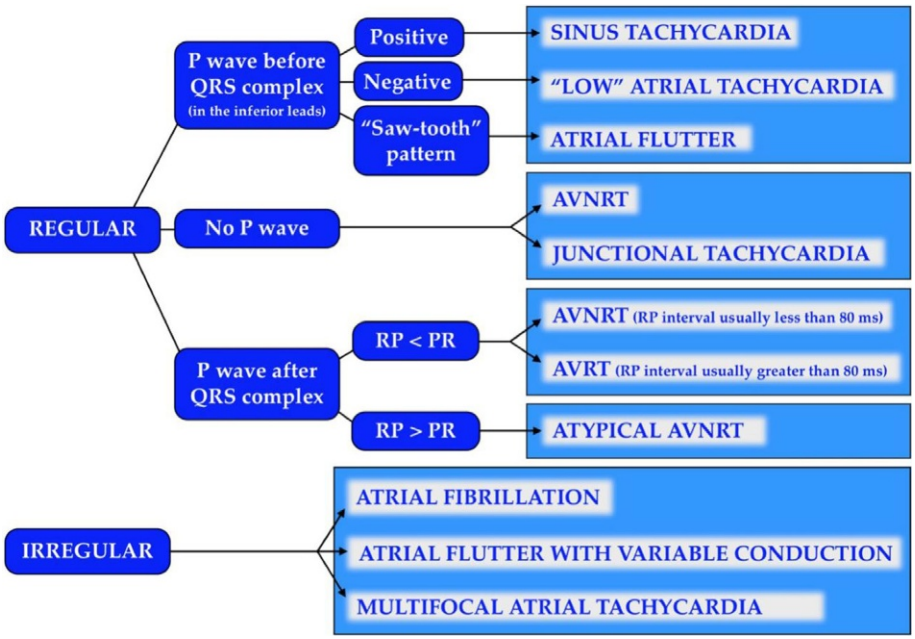

Fig. 5 Electrocardiographic approach to the most common tachycardias with narrow-complex QRS in adults. From Nadeau-Routhier, C. and Baranchuk, A. (2016). In Nadeau-Routhier, C. and Baranchuk, A. (eds.) Electrocardiography in practice: What to do? pp 123–140. Accessed October 2016: https://itunes.apple.com/us/book/electrocardiography-in-practice/id1120119530?mt=13.

Electrophysiological Classification of AVNRT

Depending on which type of pathway the stimulus utilizes as anterograde and retrograde limb of the circuit, three major types of AVNRT exist: typical slow–fast AVNRT, atypical fast–slow, and slow–slow AVNRT. Different methodologies have been used by the investigator during the electrophysiology studies to classify between typical and atypical AVNRT: pattern of earliest retrograde atrial activation (EARA), absolute values of Atrial-His (AH) and His-Atrial (HA) intervals, AH/HA ratios (Heidbüchel and Jackman, 2004; Willems et al., 2004; Otomo et al., 2007; Yamabe et al., 2007; Fujiki et al., 2008).

The facts that AVNRT may present with atypical retrograde activation, and different forms of AVNRT may be seen in the same patient have made the diagnosis intricated (Heinroth et al., 2002). Therefore, appropriate classification is necessary to avoid misdiagnosis and subsequently prolonged procedures during catheter ablation.

Typical AVNRT (Slow–Fast)

Typical slow–fast AVNRT is the most common type of AVNRT (>90%) and the circuit uses the SP anterogradely and the FP retrogradely. In this type of AVNRT, induction is dependent on achieving a critical AH interval. It means that the antegrade conduction down the SP should be slow enough that allows for recovery of the FP to conduct retrogradely (**Fig. 3**). In the EP lab, this can be achieved with atrial extrastimuli testing or atrial burst pacing near the Wenckebach CL (**Fig. 6**). If this cannot be achieved, stimulation under infusion with isoproterenol may be required.

During tachycardia, the EARA (via FP) is usually localized in the anterior septum which is recorded by the electrodes at the HB. However, posterior or even left sided EARA may occur in up to 8% of the patients (**Fig. 7**) (Chen et al., 2004; Nam et al., 2006).

The EARA appears slightly before, at the onset, or just after the QRS complex thus maintaining AH/HA ratio >1. Most important, the HA interval is typically <70 ms, measured from earliest deflection of the HB activation to the earliest rapid deflection of the atrial activation in the HB electrodes. When the HB cannot be recorded during tachycardia, the VA interval is also a useful criterion. The VA interval, measured from the onset of ventricular activation on surface ECG to the earliest atrial activation on the HB electrodes, is <60 ms (**Fig. 8**).

Spontaneous termination of typical AVNRT occurs because of a block on the slow or fast pathway and appears to be "time-related." When the block takes place on the slow antegrade conduction, there is a prolongation of the AH interval (Mobitz type I block) which occur only after an initial period of stable tachycardia intervals. This mechanism is consistent with an underlying concealed fatigue phenomenon. Interruption of the reentry in the retrograde direction (FP) would also be a "time-related" event but developed suddenly without AH interval prolongation (Mobitz type II block) (Chiale et al., 2015).

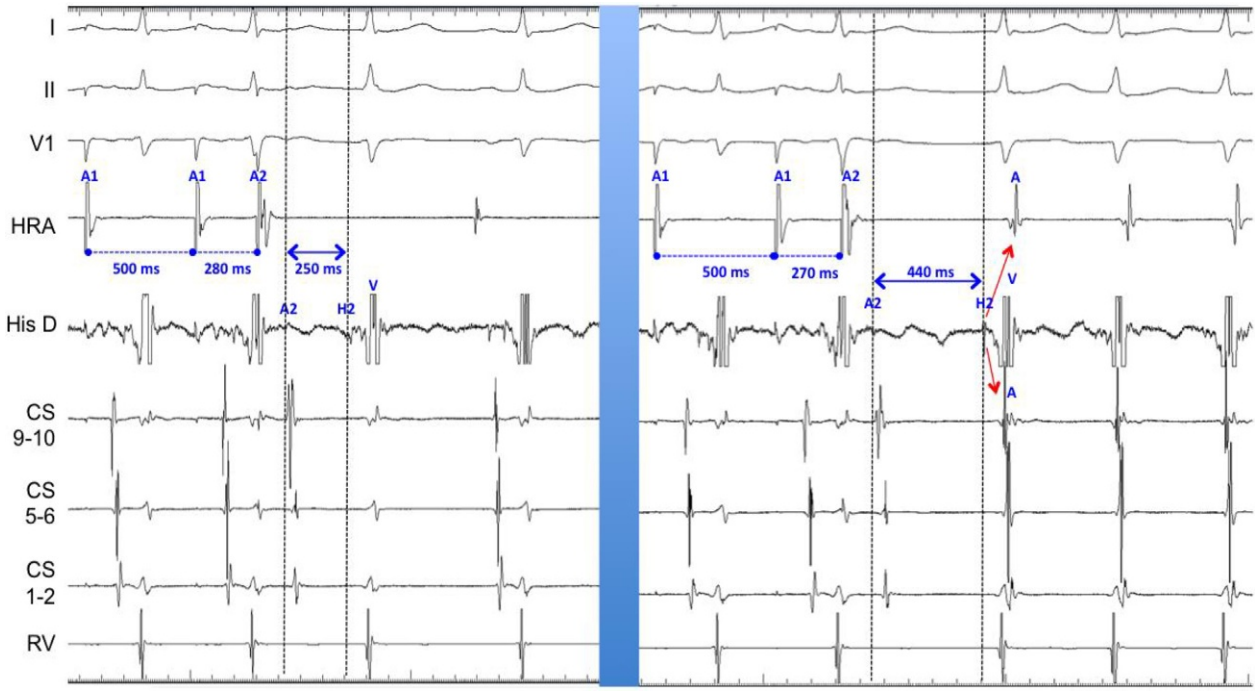

Fig. 6 Demonstration of dual AV nodal physiology and induction of typical AVNRT. Single extrastimulus (A2) of progressively shorter coupling intervals were delivered from the high right atrial (HRA) at a basic drive of 500 ms (A1). A jump or sudden increase of the AH interval from 250 ms (Left) to 440 ms (Right) occurs after shortening of the atrial extrastimulus from 280 to 270 ms. The atrial extrastimulus conducts through the slow AV nodal pathway, followed by retrograde conduction through the fast AV nodal pathway to activate the atrium (*red arrows*) starting a typical AVNRT (Right).

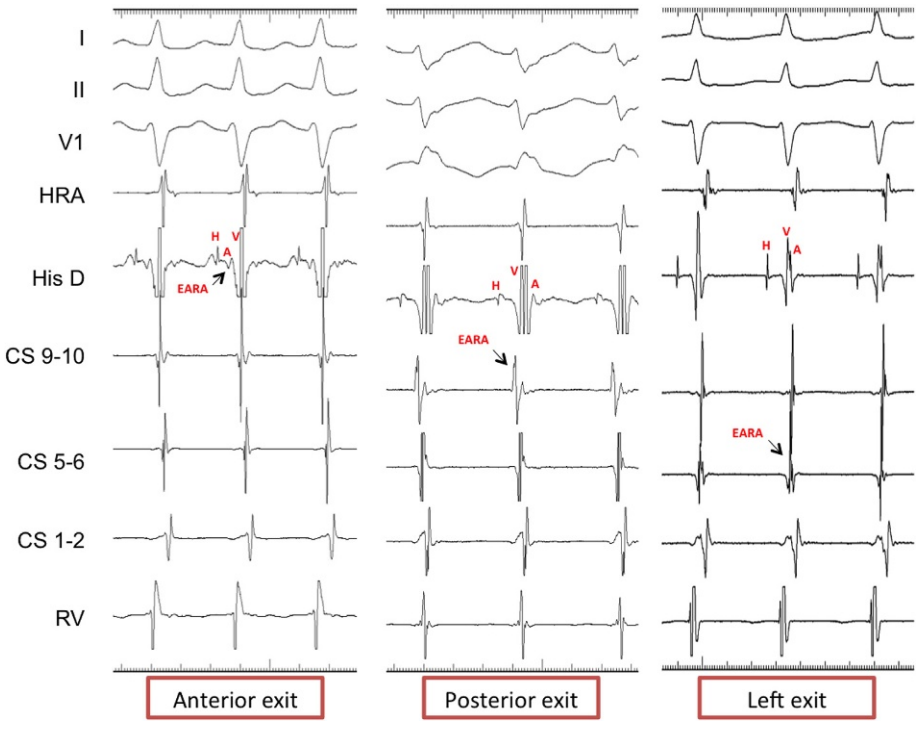

Fig. 7 The figure shows the different location of the earlier retrograde atrial activation (EARA) during typical AVNRT. In the anterior atrial "exit," the ERAA is recorded by the His electrode. In the posterior "exit," ERAA is recorded by the proximal CS electrode. In the left "exit," EARA is recorded in mid or distal CS electrode. *HRA*, high right atrium; *CS*, coronary sinus; *RV*, right ventricle.

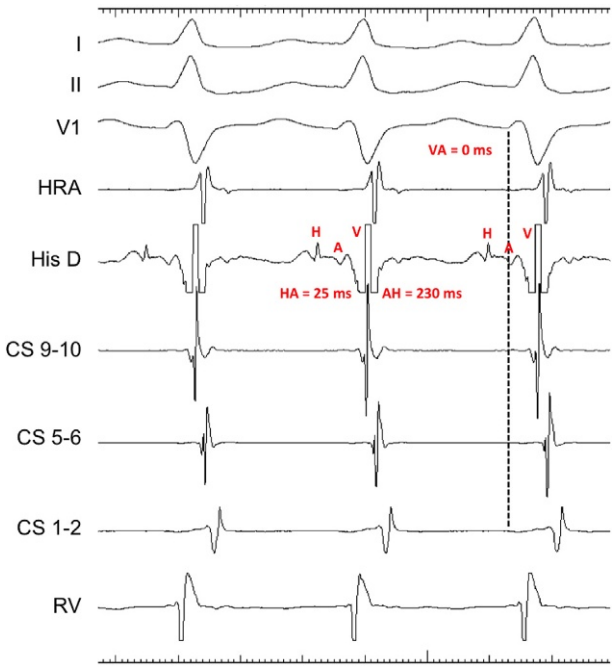

Fig. 8 Intracardiac electrograms in typical AVNRT (AH > HA, HA <70 ms, VA ≤60 ms). Note earliest atrial activation at the His bundle and the simultaneous atrial and ventricular activation. *Dash line* points the VA time. AH, atrial to His interval; HA, His to atrial interval measured from earliest deflection of the His bundle activation to the earliest rapid deflection of the atrial activation in the His bundle electrogram; VA, ventricle to atrial interval measured from the onset of ventricular activation on surface ECG to the earliest deflection of the atrial activation on the His bundle electrograms.

Atypical AVNRT (Fast–Slow and Slow–Slow)

The prevalence of atypical forms of AVNRT has been described around 10%. However, recent studies have reported a lower prevalence 4%–6%. It is possible that the reason for higher prevalence previously reported was due to the characterization as slow–slow atypical AVNRT what were actually typical AVNRT cases (Katritsis and Josephson, 2013). During the tachycardia induction, a critical AH interval is less obvious and sometimes antegrade dual AV nodal physiology is not demonstrable. Both types, fast–slow and slow–slow, can be induced by atrial or ventricular stimulation and frequently required the administration of isoproterenol. Conversely to typical AVNRT, in some patients tachycardia is induced only by ventricular stimulation (Heidbüchel and Jackman, 2004).

In the fast–slow variant, the reentrant circuit occurs in the opposite way than the typical AVNRT: the FP conducts anterogradely and the SP retrogradely. Although it is thought of using the same circuit as typical AVNRT in the reverse direction, the fast–slow form of AVNRT may do not utilize the same limb for FP conduction (Katritsis et al., 2015a,b). Since the retrograde conduction is slower than the anterograde conduction, the AH/HA ratio is <1. Also, as the retrograde activation uses the SP, the retrograde atrial electrograms are recorded after the ventricular activation. The HA interval is ≥70 ms, and the VA interval is ≥60 ms (**Fig. 9**).

In the slow–slow variant, the reentrant circuit uses a slow or an intermediate pathway anterogradely and a second SP retrogradely. This type has the same HA and VA interval cutoff than the fast–slow type, but the AH/HA ratio is usually ≥1.

In both types of atypical AVNRT, the EARA uses an SP and it was traditionally reported in the posterior septum, near the coronary sinus ostium. Several authors have indicated that EARA can also occur at the anterior septum (His bundle electrode) and the left atrium (distal CS electrode) (Chen et al., 2004; Hwang et al., 1997). Therefore, EARA would not be useful to elucidate between the different types of AVNRT (Katritsis and Josephson, 2013).

There are some tachycardias with a relatively prolonged AH interval but an AH/HA ratio <1 that cannot be classified as either fast–slow or slow–slow. Therefore, some authors propose only the HA interval (or VA interval) as a criterion for the diagnosis of typical or atypical AVNRT (**Fig. 10**). Further classification into fast–slow or slow–slow forms would be arbitrary and would not been yet validated (Katritsis et al., 2015a,b).

Electrophysiological Study: Exclusion of Other Mechanisms of Tachycardia

The diagnosis of AVNRT requires the exclusion of other mechanisms as AVRT using a septal retrograde accessory pathway, AT, and junctional tachycardia (JT). Due to the risk of AV block associated with catheter ablation of AVNRT, a correct diagnosis is desired. Even more, successful ablation of AT or AVRT using a septal accessory pathway requires mapping to the earliest atrial electrogram, while in AVNRT the SP is targeted.

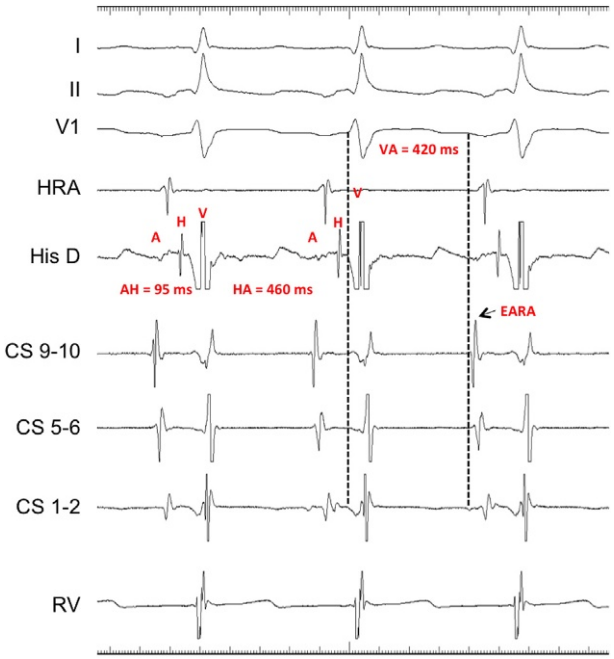

Fig. 9 Intracardiac electrograms in atypical AVNRT. The form is defined as type "fast–slow": AH 70 ms, VA >60 ms. The earliest atrial activation (EARA) is recorded at the proximal CS electrode. *Dash lines* point the VA time.

	HA	VA	AH/HA	Expected ERAA
Typical AVNRT	≤70 ms	≤60 ms	>1	His
Atypical AVNRT	>70 ms	>60 ms	Variable*	Cs ostium

Fig. 10 Electrophysiological classification of AVNRT. *In atypical "fast–slow" type the AH/HA ratio is commonly 1, and in "slow–slow" >1.

It is also noteworthy that there is no electrophysiologic finding that "per se" is diagnostic of AVNRT, often the correct diagnosis is performed after the observation of some tachycardia features like presence of dual AV nodal physiology, EARA, AH–HA–VA intervals, tachycardia induction-termination; in combination with pacing maneuvers. Fig. 11 depicts a simplified algorithm for rapid diagnosis of PSVT used in our EP lab.

In typical AVNRT, by far the most frequent presentation is with a concentric atrial retrograde activation and a VA time ≤60 ms. If this is the case, we should consider two differential diagnoses: septal AT or JT. AVRT is ruled out as the VA time is always longer than 60 ms.

Overdrive pacing from the right ventricle at a CL 10–40 ms shorter than the tachycardia CL is our first tool to rule out AT. To use this maneuver, it is required that the atrial CL be accelerated to the pacing CL and the tachycardia continues after pacing is discontinued. If the postpacing returning activation sequence is atrial–atrial–ventricular ("AAV") rules in AT, whiles an atrial–ventricular ("AV") response indicates that a reentrant mechanism is implied, ruling out AT (Fig. 12) (Knight et al., 1999). Importantly, the last atrial electrogram accelerated to the pacing CL is the first atrial electrogram counted in the interpretation of this response.

Differentiation of JT from slow–fast AVNRT may be a challenge since they share a short HA conduction time with EARA near the apex of the triangle of Koch (His electrode). JT can be differentiated from AVNRT using the maneuver described by Padanilam et al., which consists of analyzing the response to premature atrial contractions (PACs) introduced during or before HB refractoriness (Padanilam et al., 2008). A PAC introduced during HB refractoriness cannot penetrate to the automatic focus and therefore cannot alter the tachycardia. By contrast, in AVNRT, the PAC may advance the next beat of tachycardia by conduction in the SP (Fig. 13). Early PACs introduced before His refractoriness may advance the following beat and continue a JT but should terminate AVNRT because of collision of the antegrade PAC wavefront and retrograde tachycardia wavefront in the FP.

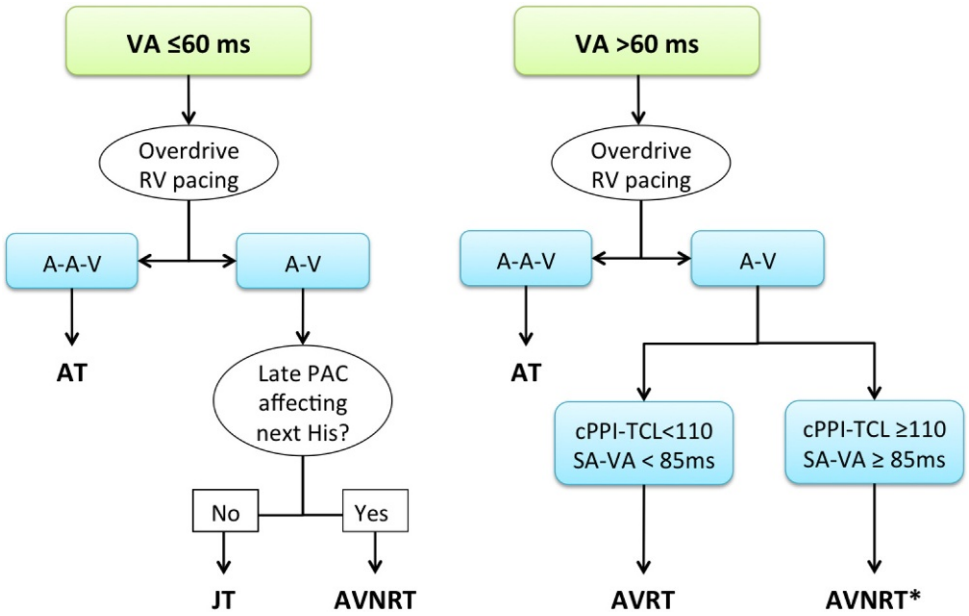

Fig. 11 Algorithm employed in the EP lab for rapid diagnosis of sustained PSVT with 1:1 AV relationship. See text for details. *Even though AVNRT is the most likely diagnosis, AVRT with a decremental pathway should be investigated.

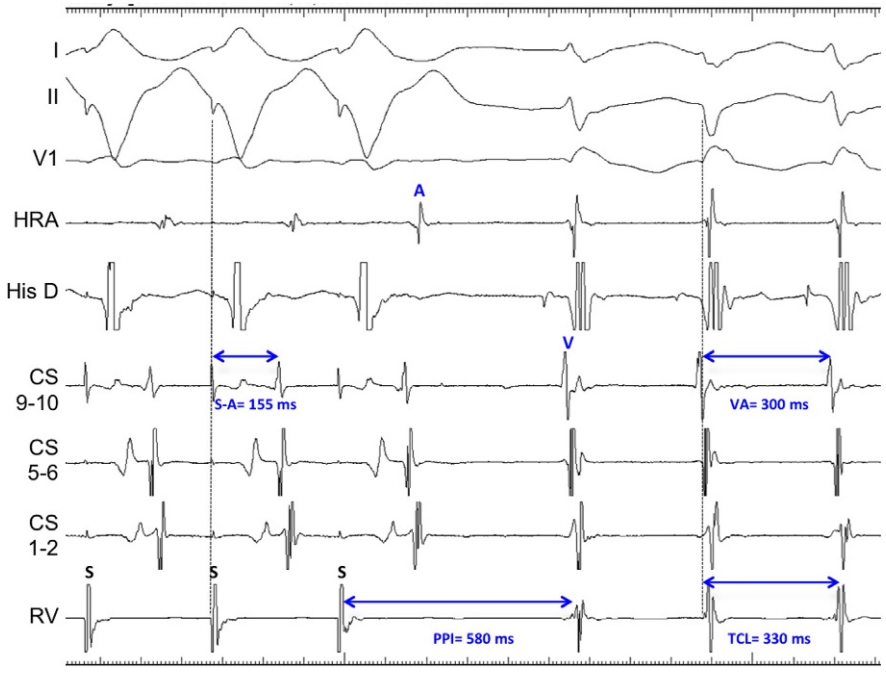

Fig. 12 Response to cessation of overdrive ventricular pacing (310 ms) in a typical AVNRT (CL 330). The atrial CL was accelerated to the ventricular CL and the response after pacing (S) is stopped is A–V, ruling out AT. The PPI–TCL difference is 145 ms (300–155 ms) and the SA–VA interval difference is 250 ms (580–330 ms), both measurements rule out AVRT. The PPI is measured from the pacing stimulus to the first return ventricular electrogram recorded by the pacing channel. The SA interval is measured from the pacing stimulus to the earliest atrial electrogram. The VA interval is measured from the beginning of the earliest QRS complex in SVT to the same atrial electrogram that was used to measure the SA interval.

In atypical AVNRT the VA time is >60 ms or the HA >70 ms with a most common EARA at proximal CS. JT is ruled out since the HA is <70 ms and the EARA occurs at the His electrode. Therefore, we should consider two differential diagnoses: AT and AVRT. Again, overdrive RV pacing is our first maneuver of choice to rule out AT after an "AV" response is obtained. Using the same maneuver, we can also differentiate AVNRT from AVRT. In response to ventricular overdrive pacing, orthodromic AVRT also produces an "AV" response; however, the differences in VA times between pacing and tachycardia are <85 ms (Michaud et al., 2001). During AVNRT the ventricle and atrium are activated in parallel, while during entrainment of AVNRT by ventricular

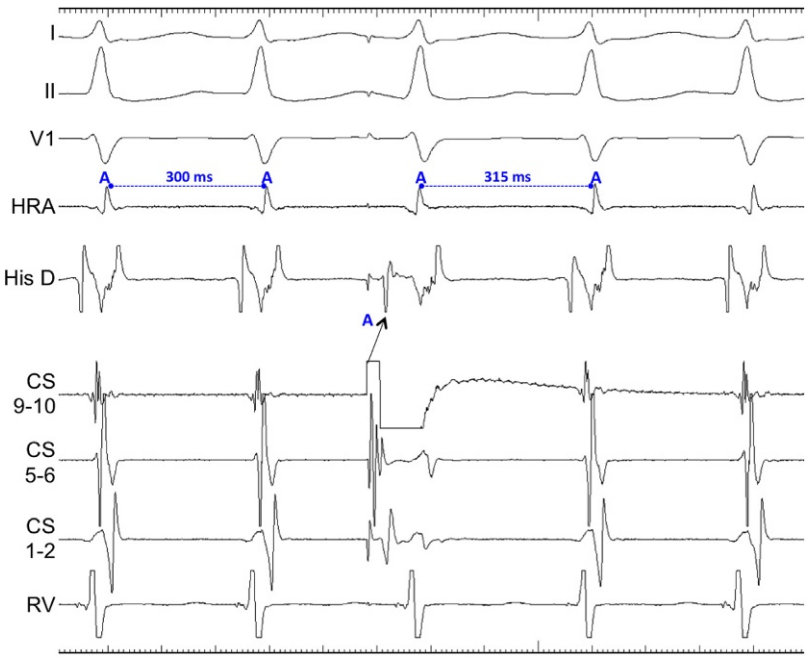

Fig. 13 Late PAC response in AVNRT. During supraventricular tachycardia with a cycle length of 300 ms and simultaneous atrial and ventricular activation, a PAC is delivered by electrodes at the ostium of the coronary sinus (CS 9–10) timed to His refractoriness. The *arrow points* to the local atrial activation at the His channel. Delay of the subsequent atrial activation by 15 ms indicates a diagnosis AVNRT where the PAC prematurely activated the slow pathway, delaying the subsequent beat due to decremental conduction.

overdrive pacing, their activation is in series. In contrast, during orthodromic AVRT and entrainment of orthodromic AVRT, the ventricle and atrium are activated in series. Accordingly, the difference between the VA interval during entrainment and SVT should be longer for AVNRT than for AVRT (**Fig. 12**).

Keeping in mind the same concept, in AVRT the postpacing interval—tachycardia CL difference (PPI–TCL) is <115 ms. A long return AH interval may invalidate this maneuver unless a correction is applied. PPI will increase if overdrive pacing (rate dependent) causes decremental conduction in the AV node. During entrainment of AVRT by RV pacing, the atria are accelerated to the pacing CL. Thus, the input to the AV node is also accelerated and subsequently AV node conduction time will increase (decremental properties) prolonging the AH interval and the PPI. Therefore in AVNRT, the first AH interval after entrainment (last accelerated beat) is often prolonged compared to the AH interval during AVRT. The PPI can be corrected by subtracting the increase in the AH interval on the first return beat compared to the AH interval during spontaneous AVRT from the PPI–TCL difference. A corrected PPI–TCL (cPPI–TCL) <110 ms is diagnostic of AVRT (Gonzalez-Torrecilla et al., 2006).

If overdrive pacing cannot be performed (lack of sustained and regular tachycardia) or interpreted (tachycardia stop during pacing), other maneuvers can be helpful to differentiate AVNRT from AVRT (Hirao et al., 1996; Martinez-Alday et al., 1994). A simple maneuver consists in delivering premature ventricular complexes (PVCs) when the HB is refractory (Josephson, 2008). PVCs that occur during SVT at a time when the stimulated wavefront would be expected to collide with the SVT wavefront in the His-Purkinje network or the ventricular myocardium cannot affect the atrial timing during AVNRT. Therefore, if such PVC affects the atrial timing implies the presence of another pathway (AVRT) connecting the ventricles with the atria (**Fig. 14**) (Veenhuyzen et al., 2012).

Prognosis

AVNRT is not a life-threatening arrhythmia and does not influence survival. In most patients, the episodes are self-terminated or respond acutely to vagal maneuvers or adenosine. Complications as syncope, angina, or heart failure are usually seen in patients with structural heart disease.

Treatment

Acute Management

Any maneuver or drugs that slow AV node conduction can be used to terminate the tachycardia. Vagal maneuvers, including Valsalva or carotid sinus massage, are recommended as the first-line intervention to terminate AVNRT (Class I) (Page et al., 2015).

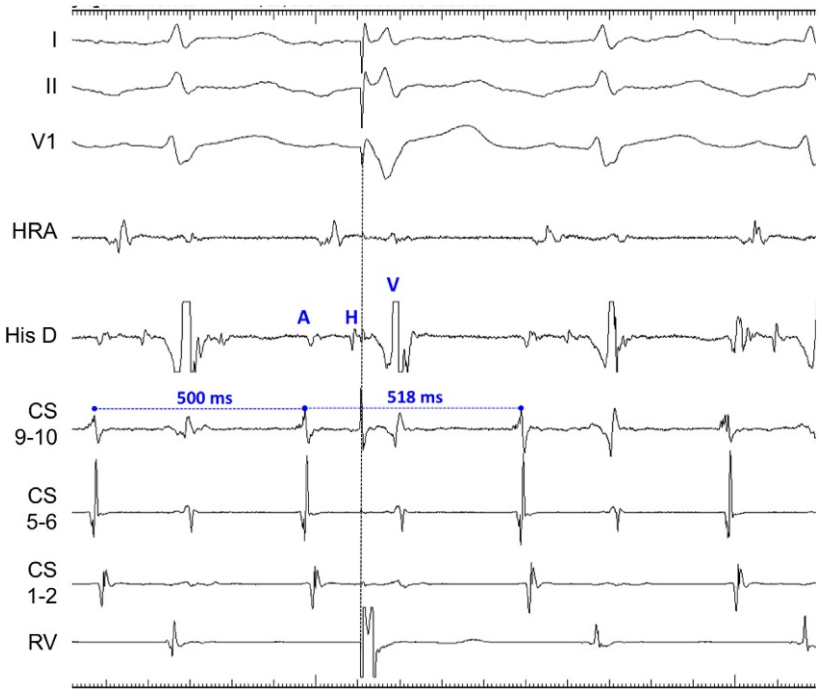

Fig. 14 Delay of atrial activation by a His refractory PVC. During an SVT with a CL of 500 ms and long RP interval (VA >60 ms), a PVC is delivered when the His is refractory and the subsequent atrial activation is delayed by 18 ms. The delayed of atrial activation without a change in the atrial activation sequence indicates that an accessory pathway with decremental conduction is present and participating in orthodromic AVRT.

These maneuvers have shown to be effective in at least one-third of the patients (Lim et al., 1998; Walker and Cutting, 2010). If these interventions fail, termination can be achieved with AV node blocking agents. Adenosine is the drug of choice as it is effective in approximately 95% of cases (Class I) (DiMarco et al., 1990; Cairns and Niemann, 1991; Glatter et al., 1999). Usually starting with 6 mg and going up in increasing dose boluses. Also, intravenous beta blockers, verapamil (10 mg in bolus), or diltiazem (5–25 mg in bolus) can be used (Class IIa) (Amsterdam et al., 1991; Waxman et al., 1981; Dougherty et al., 1992). Importantly, verapamil and diltiazem should be avoided in hemodynamically unstable patients or those with suspected systolic heart failure.

For resistant cases, a second or a third bolus of adenosine, verapamil, or diltiazem is often effective. Finally, in rare occasions that AVNRT cannot be terminated or in hemodynamically unstable patients, synchronized cardioversion with low energy (10–50 J) can always be used (Class I) (Reisinger et al., 2010).

Chronic Management

Because the prognosis of AVNRT is benign, the indication for its treatment relates to the impact on patient's quality of life. Factors to take into consideration during the therapeutic decision include the tolerance of symptoms, the frequency and duration of tachycardia, and the presence of concomitant structural heart disease. In a prospective study of patients who were followed for 15 years, almost half of minimally symptomatic patients who received no therapy became asymptomatic over time (D'Este et al., 2007). Thus, a patient who presents minimally symptomatic episodes of AVNRT that terminate spontaneously or with vagal maneuvers may be followed clinically (Class IIa).

Once we have opted to initiate therapy for preventing recurrences of AVNRT, the question arises whether we should choose catheter ablation or antiarrhythmic drugs.

Transcatheter ablation

Because of its high efficacy (>95%) and low complication risk, catheter ablation is recommended as first-line of therapy in symptomatic patients (Class I) (Jackman et al., 1992; Hindricks, 1996). Usually, the procedure is curative, and chronic pharmacological therapy is not needed. In the past, the target of catheter ablation was the FP located around the anterosuperior aspect of the triangle of Koch ("anterior approach"). However, as the FP is located close to the compact AV node, this approach was linked with high rates of AV block and was consequently abandoned. Nowadays, the target is the SP ("posterior approach") located between the CS ostium and the tricuspid annulus. The "posterior approach" has been proved at least as effective as the "anterior approach" with significantly less rate of AV block (Mitrani et al., 1993).

Radiofrequency ablation technique

The number of vein access and catheters placed for catheter ablation varies center to center. In general, a decapolar catheter is placed in the CS and three quadripolar catheters are placed in the right ventricle, HB, and high right atrium.

Once the diagnosis of AVNRT is confirmed and with the patient in sinus rhythm, the ablation catheter is advanced and positioned anterior to the CS ostium using the right anterior oblique (RAO) view. The angle of RAO should be adjusted so that the His catheter is perpendicular to the fluoroscopic plane. This view is especially helpful because it best displays Koch's triangle (**Fig. 15A**). The initial target zone for SP ablation is the tissue located between the tricuspid valve annulus and the CS ostium. The ablation catheter is advanced into the RV, moved inferiorly, so it lies anterior to the ostium of the CS, and then withdrawn toward the tricuspid annulus until the distal pair of electrodes records a small atrial deflection in addition to a large ventricular deflection (**Fig. 15B**). Clockwise torque will move the catheter toward the septum, confirmed in left anterior oblique view. The optimal A/V ratio in the distal electrode of the ablation catheter may range from 1:2 to 1:5. Also, the atrial electrogram at successful location usually has multiples components (**Fig. 16**). Before delivery energy, the absence of His signal in the distal electrodes has to be confirmed, to prevent FP damage and AV block. As the catheter tends to move with respiration and heartbeats, a long sheath is sometimes needed to enhance catheter stability.

In our laboratory, radiofrequency (RF) energy is delivered using a 3.5 mm nonirrigated catheter, in the temperature mode with a target temperature of 55–60°C for 60 s. During RF delivery, the most reliable marker of effective energy delivery is the continuous monitoring of impedance because a significant drop in impedance indicates better tissue contact compared to tip electrode temperature. We usually delivery RF energy for about 15–20 s waiting for the presence of accelerated junctional rhythm, which suggests effective SP ablation site (**Fig. 16**). If so, ablation is continued until reaching 60 s. In the case of lack of junctional rhythm, the catheter is moved to a new spot by micromovements. In few cases, successful ablation can be achieved in the absence of junctional beats during RF application (Hsieh et al., 1998).

Importantly, energy delivery must be immediately interrupted if fast junctional rhythm or changes in the AV or VA relationship are noticed because they may reflect damage to the compact AVN (**Table 1**) (Hintringer et al., 1995; Tebbenjohanns et al., 1995).

Cryoablation technique

Cryoenergy is an alternative source of energy to RF for catheter ablation procedures. In the recent past, cryoablation has been well studied in patients with AVNRT. This technology has shown a high acute success rate (95%) comparable with RF energy. However, the long-term recurrence rate is higher with cryoablation (9% vs. 4.5%) (Santangeli et al., 2014). The main benefit of cryoablation lies in the low rate of permanent AV block (0% vs. 1%). This is due to at least two specific features of this technology. Firstly, cryomapping makes possible the assessment of functional effects on the AV node before permanent lesion. Secondly, during cryoablation the catheter tip adheres to the tissue because of ice formation. This cytoadherence prevents dislodgement of the catheter avoiding lesions on the AV node.

In summary, cryoablation is particularly useful, as an alternative to RF in high-risk patients. For instance, in those patients where RF is attempted and AVNRT is still inducible. Thus, we need to move the catheter to closer areas in the vicinity of the compact AV node.

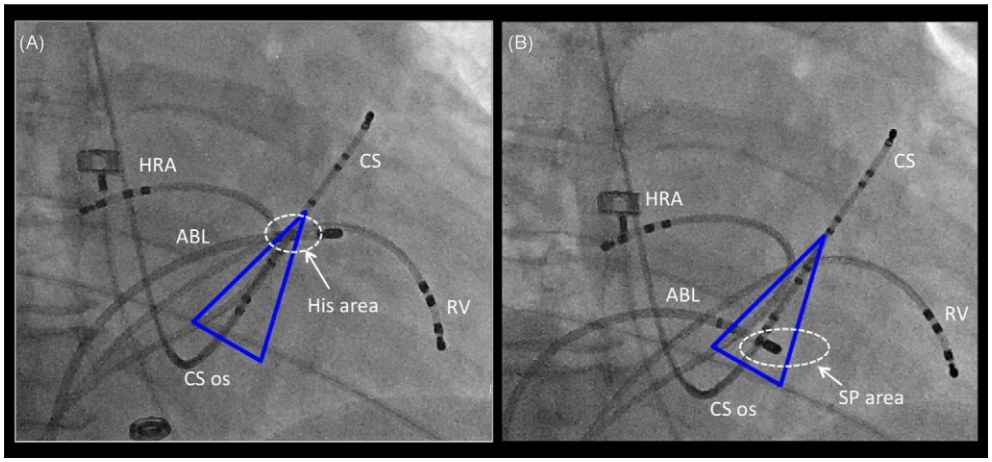

Fig. 15 Right anterior oblique view of catheter positions for anatomically guided slow pathway (SP) ablation. Triangle of Koch is delimited in *blue lines*. The ablation catheter is located close to the His bundle area. AV nodal injury should be expected with ablation at this site (A). Then, the ablation catheter is moved inferiorly and toward the septum to reach the SP area. This is the safest and most effective region for slow pathway ablation (B). *HRA*, high right atrium catheter; *ABL*, ablation catheter; *CS*, coronary sinus catheter; *CS os*, coronary sinus ostium; *RV*, right ventricle catheter.

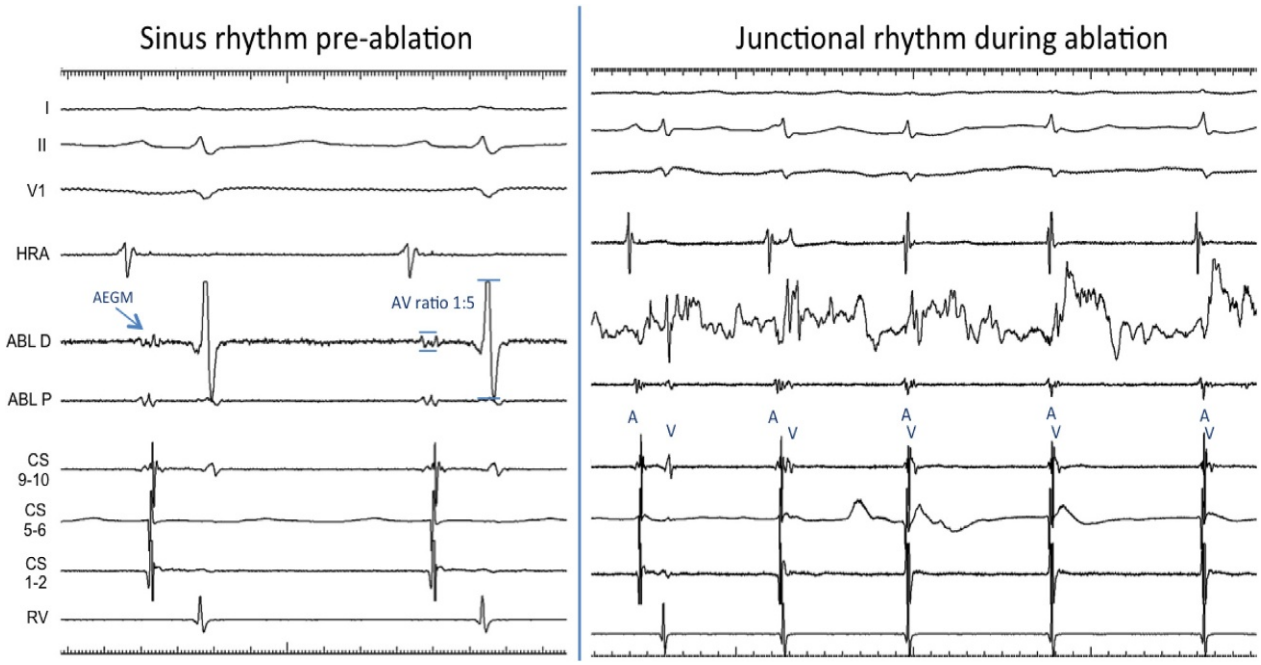

Fig. 16 Ablation catheter at the site of successful slow pathway ablation. The atrial electrograms (AEGM) has multiple components and the A/V ratio is 1:5 (left). At that site, radiofrequency is delivery and junctional rhythm is induced which indicate appropriated slow pathway injury (right).

Table 1 Predictors of AV block during RF ablation

Mapping	His signal in the distal electrode
	Interval <20 ms between the ablation atrial EGM and the His-Atrial EGM
Ablation	Fast junctional rhythm (<350 ms)
	VA block during junctional rhythm
	Non-conducted atrial EGM

The initial part of the procedure is similar to that described above for RF ablation. Cryoablation is performed with either an 8-mm-tip or 6-mm-tip catheter.

There are two commonly used techniques for positioning of the cryoablation catheter in the target tissue. Some operators perform it like RF ablation by first entering the right ventricle, withdrawing the catheter while deflecting the tip caudally. Usually, an A/V ratio of about 1:1 to 1:2 is searched. Other operators start by positioning the tip of the cryoablation catheter one-third of the distance from the level of the CS ostium to the level of the HB catheter in the left anterior oblique view. Once in the target zone, use of cryomapping at −30°C is performed to test safety. If damaging of the AV node is seen, the cryomap is stopped, and the lesion will be reverted. Otherwise, the application is continued to freeze at −70 to −80°C to obtain a permanent lesion. Each application takes between 4 and 5 min, allowing to monitor inducibility during applications. Also, the AH interval is carefully monitored. Sometimes the AH interval progressively increases to the point of complete AV block. Cryoablation is rapidly discontinued when the AH prolongation increases more than 200 ms, or high-grade AV block is achieved. Usually, the AH interval return to normal after the cessation of cryoablation, and permanent AV block is very rare using cryoenergy. In contrast to RF ablation, junctional rhythm is rarely seen during cryoablation. Usually, delivery of several cryoapplications is required to eliminate the SP completely (Wang and Chentg, 2013).

Endpoints of ablation

The "perfect" endpoint for SP ablation is the elimination of dual AVN physiology/SP conduction without impairing the FP (Table 2). Having said that, abolition of all sign of SP conduction is not a sine qua non-requirement for a successful ablation procedure. Therefore, the non-inducibility of AVNRT with residual signs of dual AV node pathways (AH jump) and single AVN echo, is an acceptable endpoint. However, double AV nodal echoes predict inducibility of AVNRT and late recurrence (McElderry and Kay, 2006).

Table 2 End points for catheter ablation

Tachycardia rendered noninducible with/without isoproterenol
Elimination of slow pathway function
● Elimination of 1:1 antegrade conduction over slow pathway
● Elimination of AH interval jumps
Modification of slow pathway function
● AH interval jump with single echoes only (previously inducible)

Antiarrhythmic drugs

Long-term pharmacological therapy is recommended for patients who are not candidates for or prefer not to undergo, catheter ablation. In general, any pharmacological agent that depress the AV node conduction can be used. However, the efficacy preventing recurrences of AVNRT is low (30%–50%) (Lockwood et al., 2009). Both verapamil and diltiazem have been well studied and are an effective alternative to ablation (Mauritson et al., 1982). Evidence for beta blockers is limited. One small randomized clinical trial compared digoxin, verapamil, and propranolol in patients with AVNRT and AVRT. The recurrences and duration of tachyarrhythmia were similar among the three drugs (Winniford et al., 1984). Beta blockers should be chosen over calcium blockers in patients with systolic dysfunction.

If those drugs are ineffective or contraindicated, flecainide or propafenone is the reasonable option in patients without structural heart disease (Class IIa).

Lastly, in patients with infrequent but prolonged episodes of tachycardia refractory to vagal maneuvers, a "pill in the pocket" approach could be considered (Class IIB). This approach consists in the use of a single dose of a drug that has a short onset of action (diltiazem or flecainide) alone or in combination with propranolol to terminate the tachycardia (Yeh et al., 1985).

Conclusions

AVNRT is a common arrhythmia in clinical practice. The full understanding of its electrophysiological mechanisms allows designing the most appropriate therapeutical approach. Adequate ECG interpretation and differential diagnosis with other supraventricular arrhythmias are paramount.

Introduction

Amyloidoses are a set of systemic diseases whereby misfolded proteins form insoluble aggregates known as amyloid fibrils. These fibrils deposit in the extracellular space of various organs leading to their dysfunction. Cardiac amyloidosis is an infiltrative cardiomyopathy caused by the accumulation of amyloid fibrils in the extracellular space of the myocardium and often leads to diastolic and systolic dysfunction, conduction disease, and death (Ruberg and Berk, 2012; Gertz et al., 2015; Falk et al., 2016). The classification of amyloidosis depends upon which precursor protein leads to the pathologic aggregates; there are dozens reported (Sipe et al., 2016). The predominant causes of cardiac infiltration are immunoglobulin light-chain (AL) amyloidosis and transthyretin amyloidosis (ATTR). This article focuses on the pathophysiology, epidemiology, diagnosis, prognosis, and treatment of ATTR.

Transthyretin (TTR) is a 56-kDa protein, formerly called prealbumin, that is predominantly synthesized in the liver with smaller contributions (<5%) from the choroid plexus and retinal pigment epithelium (Ruberg and Berk, 2012; Gertz et al., 2015). The protein's name is derived from its primary function, *trans*porting *thy*roxine and *retin*ol (Vitamin A) (Gertz et al., 2015; Falk et al., 2016), but it also has a multitude of roles in neuronal growth and neuronal pathways (Vieira and Saraiva, 2014). In its functional form TTR exists as a homotetramer, but monomers are prone to dissociate and misfold into insoluble beta-pleated sheets (Brunjes et al., 2016). In ATTR, it is these misfolded, insoluble proteins that deposit in target organs as amyloid fibrils. ATTR can result from the deposition of normal, or wild-type, TTR (ATTRwt) or from the deposition of genetically abnormal, or mutant, TTR (ATTRm). These distinct processes have varying clinical manifestations and treatments, and both disease entities will be discussed at length in this article.

Pathogenesis

As described earlier, the principle pathophysiologic mechanism uniting all forms of amyloidosis is interstitial deposition of misfolded, insoluble amyloid proteins leading to multiorgan dysfunction and eventually failure.

AL amyloidosis is a disease of the plasma cell, similar but distinct from multiple myeloma, whereby immunoglobulin light chains (lambda and/or kappa) are overproduced. Aggregates of these light chains deposit in target organs causing disease. The kidney is the most commonly affected organ, leading to nephrotic syndrome and eventual chronic kidney disease (Falk et al., 2016).

 https://doi.org/10.1016/B978-0-12-809657-4.10983-4

The heart is the next most commonly affected organ, but amyloid deposition and clinical sequelae thereof can be found in multiple other organs as well: nerve involvement can result in peripheral neuropathy and postural hypotension, depositions in the tongue can result in macroglossia, microvascular disease can lead to pronounced periorbital bruising, hepatic involvement can lead to a firm and nonpulsatile liver (though usually not frank liver failure) (Falk et al., 2016). There is also some emerging evidence that pathologic circulating amyloid light chains play a role in cardiac dysfunction independent of infiltrative disease (Liao et al., 2001; Brenner et al., 2004).

ATTRwt, formerly called senile cardiac amyloidosis, occurs with the myocardial deposition of misfolded, but genetically normal, TTR. The incidence of ATTRwt increases profoundly with age but the exact mechanism of age-related TTR misfolding and the predilection for clinical disease, especially in men is unclear. Some authors have suggested that age-related biochemical changes to either the native protein or one of its chaperone proteins results in a propensity for TTR to disaggregate and/or impairs the cell's ability to clear the misfolded protein (Ruberg and Berk, 2012; Buxbaum et al., 2012). In contrast, in ATTRm amyloid deposition occurs due to a mutation in the TTR gene that hastens misfolding and aggregation (Ruberg and Berk, 2012). ATTRwt has a significant association with carpal tunnel syndrome (Sekijima et al., 2011) and, depending on the exact mutation, ATTRm often affects peripheral nerves and kidneys in addition to the heart. In both forms of ATTR though, cardiac dysfunction takes the form of an infiltrative and restrictive cardiomyopathy. Amyloid fibrils infiltrate the myocardium and cause increased ventricular wall thickness and impaired lusitropy, resulting in elevated filling pressures and eventually heart failure with preserved ejection fraction (HFpEF). Amyloid infiltration also leads to conduction disease, specifically atrioventricular block and atrial fibrillation or flutter. Progression to systolic dysfunction is a late finding (Gertz et al., 2015).

Epidemiology and Genetics

ATTRwt is sporadic but is overwhelmingly a disease of older, white men (Maurer et al., 2016). Greater than 90% of those diagnosed are older than 60 years, and autopsy studies have shown upward of 25% of all-comers older than 80 years have evidence of cardiac ATTRwt, many of which did not have clinical evidence of heart failure (Ruberg and Berk, 2012; Tanskanen et al., 2008). The true prevalence of ATTRwt is unknown, but there is general consensus that it is under diagnosed and this will bear out in clinical practice with improvements in diagnostic technology (outlined later). A single center study showed that 13% of all patients hospitalized with HFpEF and ventricular wall thickness >12 mm were newly diagnosed with ATTRwt via technetium scintigraphy (González-López et al., 2015).

Epidemiology of ATTRm depends greatly on the specific disease-causing mutation, and there are over 80 disease-causing TTR mutations described today (Benson and Kincaid, 2007). All follow an autosomal-dominant inheritance pattern, but penetrance is variable. The most common pathogenic mutation worldwide and second most common in the United States is V30M (Maurer et al., 2016). The V30M mutation predominantly affects patients with Portuguese, Swedish, Japanese, or Brazilian heritage and has a prevalence around 1:1000 (Ruberg and Berk, 2012; Gertz et al., 2015). The V30M mutation has widely variable clinical penetrance, but peripheral neuropathy is nearly universal (95%), while only 43% have diagnosed cardiomyopathy (Swiecicki et al., 2015). The V122I mutation originates in West Africa and is present in 3%–4% of the US black population, making it the most common ATTR-associated mutation in the United States. The clinical importance of a genetic carrier of V122I is not entirely clear. Studies have shown that mortality is not significantly increased (Quarta et al., 2015), but heart failure outcomes in general are worse for those who carry V122I even in the absence of diagnosed amyloidosis (Buxbaum et al., 2006). The T60A mutation originated in County Donegal in the northwest region of Ireland where it still has a 1% prevalence (Ruberg and Berk, 2012). There is a T60A cadre in the United States as well, where the disease was formerly called Appalachian amyloidosis. In one study, 82% of T60A carriers were diagnosed with cardiomyopathy and 65% were diagnosed with peripheral neuropathy (Swiecicki et al., 2015).

Relative incidence and prevalence data is helpful but not perfectly clear. In the United States the annual incidence of AL amyloidosis is a little more defined than ATTR and has historically been quoted around 1–2 per million patient-years (Kyle et al., 1992). An older (1995) US study of 100 consecutive patients referred for cardiac biopsy for presumed amyloidosis demonstrated that 74% had AL amyloidosis versus 22% ATTRwt and 6% ATTRm (Crotty et al., 1995). A 2010 German study of 101 consecutive patients with previously diagnosed cardiac amyloidosis found higher rates of ATTR, with AL amyloidosis being found in 54% versus 37% ATTRwt and 5% ATTRm (Kieninger et al., 2010). It is also worth remembering that ATTR (particularly ATTRwt) is generally considered to be under diagnosed.

Clinical Features and Diagnosis

Clinical Manifestations

The first clues to establishing the presence of cardiac amyloidosis are clinical. The diagnosis should be considered for any patient being evaluated for heart failure with preserved systolic function (HFpEF), especially when extracardiac manifestations are present. Peripheral neuropathy is common, particularly in ATTRm, and in fact an historical name for heritable forms of ATTR was familial amyloid polyneuropathy. ATTR-associated neuropathy is classically a progressive, symmetric, length-dependent, axonal process. It can affect all nerve types, which can help distinguish this neuropathy from other more common neuropathies (e.g., the small fiber neuropathy associated with diabetes). Neurologic symptoms typically start in the lower limbs and progress to upper limbs.

Autonomic involvement is also common (Gertz et al., 2015). Approximately 95% of V30M, 65% of T60A, and 30% of V122I carriers are diagnosed with peripheral neuropathy. ATTRwt does not typically demonstrate the same discrete polyneuropathy, but approximately 50% of those going on to be diagnosed with ATTRwt will have a preceding diagnosis of carpal tunnel syndrome owing to amyloid infiltration of the connective tissue of the carpal tunnel itself (Sekijima et al., 2011). Nephrotic syndrome is a common presentation for AL amyloidosis (Falk et al., 2016), and renal dysfunction is demonstrated in approximately 15% of those with ATTRwt (probably tracking with age) (Maurer et al., 2016). Prevalence and degree of renal dysfunction in ATTRm depends on the specific mutation (Falk et al., 2016; Maurer et al., 2016)—a study of patients with V30M ATTR showed rates of nephropathy and ESRD approaching 40% and 10%, respectively (Lobato et al., 2004).

The most marked clinical cardiac manifestation of amyloidosis is an infiltrative cardiomyopathy and consequently impaired diastolic function and HFpEF. Symptoms of right-sided heart failure tend to be more common early, but clinical evidence of biventricular failure is not uncommon and frank systolic dysfunction (right or left-sided) is a late finding (Patel et al., 1997).

ECG

Echocardiography reliably shows left ventricular free wall and septal thickening (± right ventricular thickening), but ECG generally fails to show evidence of left ventricular hypertrophy (LVH) (Gertz et al., 2015). The classic association for cardiac amyloidosis is LVH by echocardiography with paradoxically low voltage on ECG; however, previous reports have demonstrated low voltage in only around half of those with AL amyloidosis and 25% of those with ATTR (Rapezzi et al., 2009; Cyrille et al., 2014). A "pseudoinfarct" pattern of pathologic Q-waves, ST-T changes, and/or poor R-wave progression is more a sensitive marker seen in nearly 70% of those with both AL amyloidosis and ATTR (**Fig. 1**).

In addition to these diagnostic ECG clues, frank conduction disturbances are common in cardiac amyloidosis (Maurer et al., 2016; Pinney et al., 2013). In a study of 200 patients with all three forms of cardiac amyloidosis, atrial fibrillation was most common in ATTRwt (38% vs. 17% for ATTRm and 6% for AL) (Cyrille et al., 2014). First degree AV block was common in all groups—45% for ATTRwt, 33% for ATTRm, and 26% for AL—but, second degree AV block was only seen in those with ATTRwt (10% vs. none for ATTRmt and AL). Cardiac biomarkers (troponin I/T and BNP/NT-pro-BNP) are frequently elevated in cardiac amyloidosis and have some role in prognosis, but their utility in diagnosis is limited. Biomarkers will be discussed further in the "**Prognosis**" section of this article. Other simple lab tests crucial to the initial work-up include serum and urine protein electrophoresis (SPEP and UPEP) and specifically immunofixation and a serum-free light-chain assay. This testing should suggest monoclonal gammopathy in patients with AL amyloidosis and should be negative in those with ATTR although the false positive rate approaches 20% in the aged ATTR population (Gillmore et al., 2016).

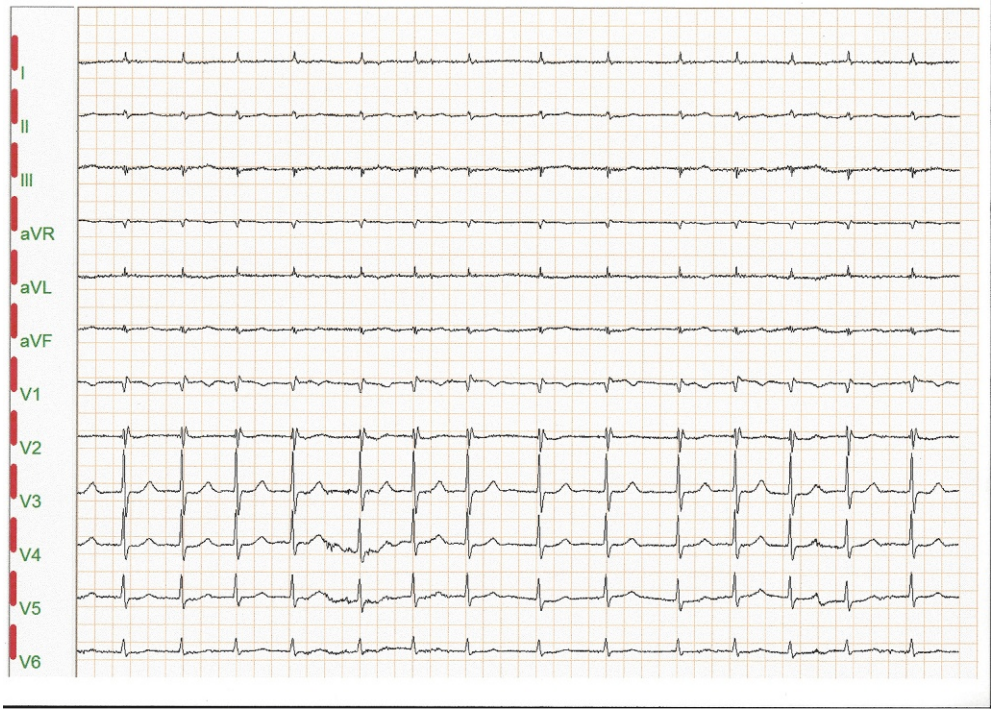

Fig. 1 Twelve lead ECG showing atrial fibrillation and low voltage, especially in the limb leads. Incomplete right bundle branch block and nonspecific STT changes.

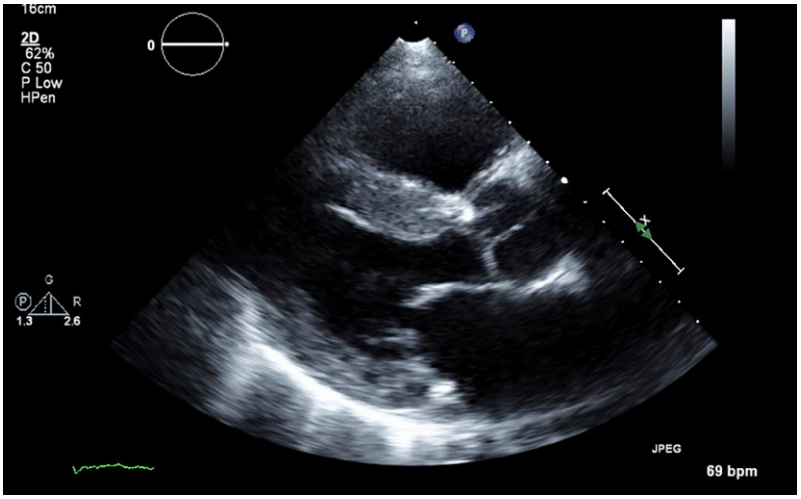

Fig. 2 Parasternal long-axis view demonstrating left ventricular hypertrophy with a "speckled" pattern. Left atrial enlargement is also noted.

Echocardiography

Echocardiography is the most widely available and most well-studied imaging modality for identifying and following patients with cardiac amyloidosis. As has been mentioned, the classic echocardiographic findings include thickened left ventricular wall and septum, small LV chamber volume, and atrial enlargement (Ruberg and Berk, 2012). Ventricular septal thickness is of particular importance. In those with known AL amyloidosis, ventricular septal thickness >12 mm (without concomitant hypertension or aortic valve pathology) defines cardiac involvement of the disease. Degree of ventricular thickness is not, however, uniform across the various cardiac amyloidoses. ATTRwt consistently demonstrates increased LV wall thickness over ATTRm and AL amyloid (Rapezzi et al., 2009; Quarta et al., 2014; Ng et al., 2005), and Cyrille et al. showed a nonsignificant increase in estimated LV mass in those with ATTRwt (355 g) versus ATTRm (333 g) and AL (266 g) (Cyrille et al., 2014). This may reflect a later diagnosis and longer survival of ATTRwt relative ATTRm and AL amyloidosis. At the time of diagnosis, left enlargement (mean 49.5 mm in ATTRwt and 43.1 mm in ATTRm) is characteristic, and pericardial effusion is common (80% in ATTRwt and 59% in ATTRm) (Rapezzi et al., 2009) (**Fig. 2**).

The distinguishing features of an infiltrative cardiomyopathy include findings of LVH by echocardiography without clinical evidence of long-standing hypertension or hypertrophic cardiomyopathy (HCM). While both hypertensive cardiomyopathy and HCM should demonstrate ECG evidence of LVH, there are limitations to overreliance on ECG findings as outlined in the previous paragraph. Other echocardiographic parameters that can be seen in cardiac amyloidosis such as thickening of the atrial septum and/or RV wall should not be seen in hypertensive cardiomyopathy or HCM (Rapezzi et al., 2010; Jacobson et al., 2011). Additionally, speckle tracking and Doppler longitudinal strain can demonstrate even early cardiac amyloid involvement (Koyama and Falk, 2010; Sun et al., 2009) (**Fig. 3**). In a cohort of 45 patients with cardiac AL amyloidosis and 48 with cardiac ATTR, Cappelli et al. showed that LV longitudinal strain was impaired in both AL and ATTR relative to a control group with noncardiac AL amyloidosis (Cappelli et al., 2015). More to the point, Phelan, et al, demonstrated that a longitudinal strain pattern with relative "apical sparing" reliably predicted cardiac amyloidosis relative controls with LVH due to hypertension or aortic stenosis (Phelan et al., 2012). This phenomenon is easily visualized by the "bull's-eye" pattern seen on polar plot diagram (**Fig. 4**).

Cardiac MRI

The advent of cardiac MRI (CMR) has greatly increased the clinician's ability to recognize cardiac amyloidosis and, particularly, to distinguish it from the primary echocardiographic differential of HCM and LVH secondary to hypertension. The distinctive finding for amyloidosis on CMR is global subendocardial late gadolinium enhancement (LGE). Gadolinium is the contrast agent commonly used in MRI. It is an extracellular agent which enters the interstitial space with predictable kinetics allowing for a uniform signal in normal myocardium. With the infiltration of amyloid deposits that characterizes cardiac amyloidosis, the interstitial space is perturbed and gadolinium accumulates in a diffuse pattern (as opposed to a more focal pattern of LGE like that seen in myocardial infarction) (Ruberg and Berk, 2012) (**Figs. 5** and **6**). In a study of 33 consecutive patients with restrictive cardiomyopathy and clinical concern for cardiac amyloidosis sent for both endomyocardial biopsy (EMB) and CMR, Vogelsberg et al. showed that 12 of the 15 patients with biopsy-proven cardiac amyloidosis demonstrated this pattern of LGE (Vogelsberg et al., 2008). This gave a positive predictive value of 92% and a negative predictive value of 85% for global subendocardial LGE in cardiac amyloidosis. There is also some evidence that CMR with more diffuse LGE can differentiate between cardiac amyloidosis and LVH caused by HCM or hypertension where LGE tends to be more focal (Takeda et al., 2013). While it was initially thought that CMR

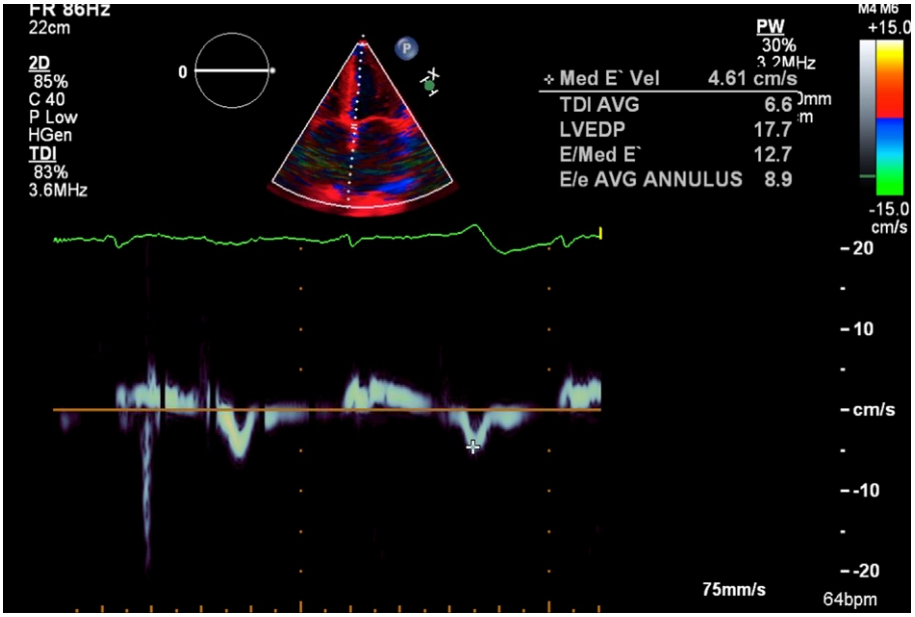

Fig. 3 Tissue Doppler assessment of the septal annulus demonstrates a markedly reduced early diastolic velocity of 4.6 cm/s (+). Normal is greater than 7 cm/s.

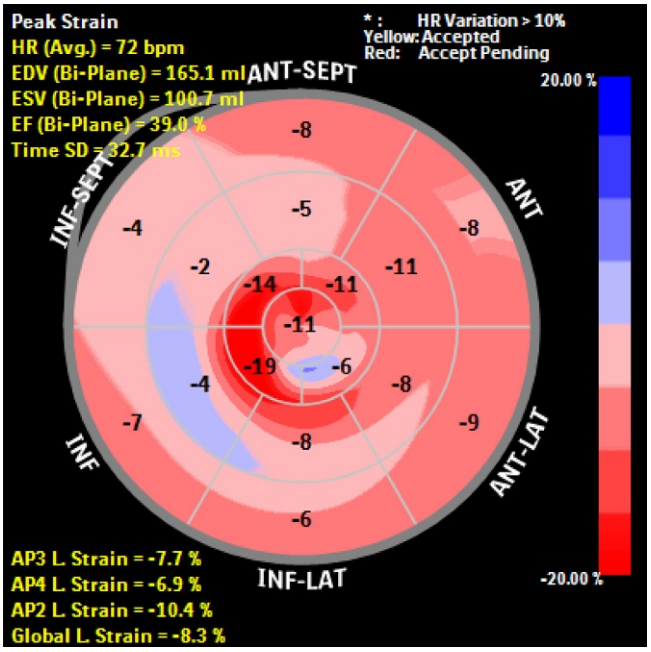

Fig. 4 Typical "bull's-eye" pattern seen on polar plot diagram indicative of longitudinal strain pattern with relative apical sparing.

findings, specifically LGE patterns, were similar between AL amyloidosis and ATTR (Ruberg and Berk, 2012), investigators recently reported that 90% of their patients with ATTR demonstrated transmural LGE as opposed to only 37% of those with AL (Dungu et al., 2014).

Furthermore, difficulty with nulling the images is a typical MRI characteristic in cardiac amyloid (Maceira et al., 2005). It is believed that faster than usual gadolinium washout from the blood and higher myocardial uptake is the cause of this phenomenon.

In addition to LGE, assessment of the extracellular volume fraction through the technique of T1 mapping has also proven successful in identifying cardiac amyloidosis with a high correlation with LGE in these patients (Mongeon et al., 2012). Compared to gadolinium administration, noncontrast T1 mapping technique can be performed throughout all ranges of renal function.

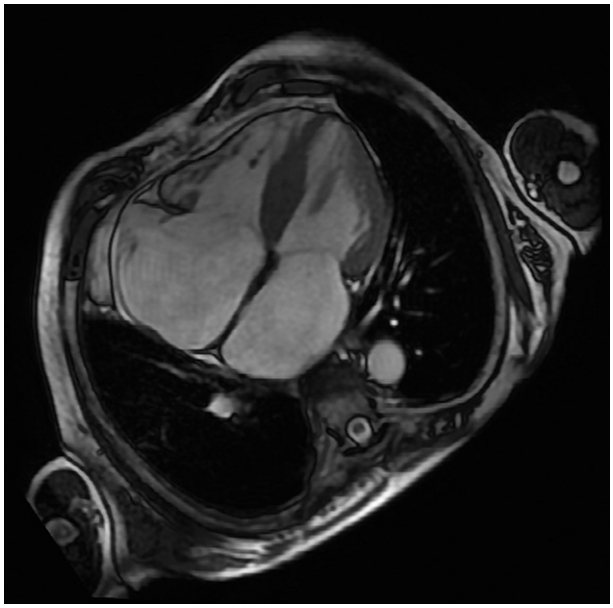

Fig. 5 Four-chamber view showing increased wall thickness and severe biatrial enlargement.

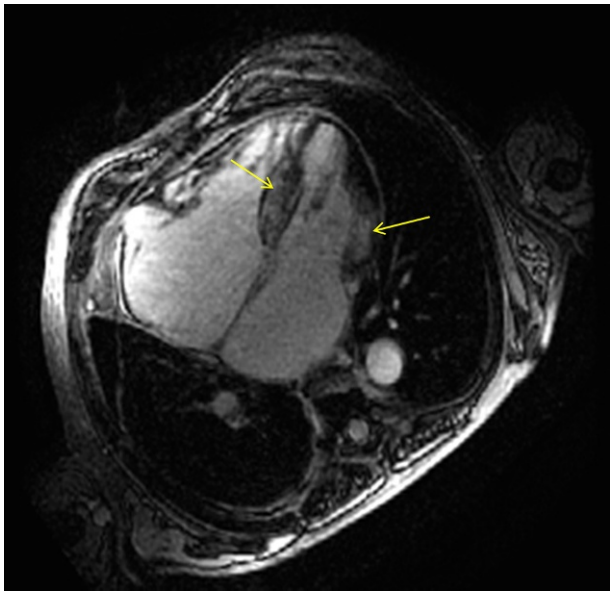

Fig. 6 Corresponding four-chamber view demonstrating late gadolinium enhancement involving the septum and lateral wall.

There is emerging evidence that those with AL cardiac amyloidosis have evidence of strain impairment on CMR even prior to developing LGE (Kuetting et al., 2017). To our knowledge this is yet to be confirmed in ATTR, but this represents yet another promising avenue for early identification of cardiac involvement.

Biopsy

EMB with Congo red staining of amyloid deposits has long been the gold standard for establishing the diagnosis of cardiac amyloidosis. However, with a consistent clinical picture and characteristic imaging findings, a biopsy of affected noncardiac tissue can suffice. AL amyloidosis will often have tongue, skin, or kidney involvement, and these sites are more easily accessible for biopsy, but these organs are rarely involved in ATTR to a degree that biopsy is fruitful (Ruberg and Berk, 2012). For these reasons, diagnosis via noncardiac biopsy has generally been less common in ATTR than AL amyloidosis (Gertz et al., 2015). Fine et al. showed that in 286 patients with ATTR (186 with ATTRm and 100 with ATTRwt), 94% of those with ATTRm were able to be diagnosed without an

EMB versus only 35% of those with ATTRwt (Fine et al., 2014). Nerve biopsy is possible in both AL and ATTR if there is significant neuropathy, though this is rarely the case is ATTRwt. In the Fine et al. study sural nerve biopsy was performed in 29% of the ATTRm subjects and was positive in 83% of those (none were attempted in ATTRwt); rectal biopsy (also looking for nerve involvement) was performed in 28% of those with ATTRm and 4% of ATTRwt and was positive in 81% and 50%, respectively. Abdominal fat aspirate is a simple outpatient or office-based procedure that has been studied in ATTR (Jacobson et al., 2011). In the Fine et al study, 76% of those with ATTRm and 84% of those with ATTRwt underwent abdominal fat aspirate with positive results in 67% of ATTRm versus only 14% of ATTRwt. In a patient with suspected ATTR and no extracardiac symptoms, abdominal fat aspirate is reasonable, but its sensitivity is low in the setting of ATTRwt, and the majority of these patients go on to EMB if tissue diagnosis is required.

Historically, biopsy samples of affected tissue underwent immunohistochemical staining for light chains and TTR. Immunoperoxidase and immunogold stains for TTR have the potential for false positives (Satoskar et al., 2011), but the addition of mass spectroscopy analysis to immunohistochemical staining has been shown to improve diagnostic accuracy from 76% to 94% with regard to differentiating AL amyloidosis from ATTR (Gilbertson et al., 2015). The process of genotyping ATTR can be accomplished via isoelectric focusing (electrophoresis), but more recently polymerase chain reaction and gene sequencing using a simple blood sample has simplified the process and provides more definitive diagnosis.

Radionuclide Imaging

Radionuclide imaging is an evolving modality in the world of cardiac amyloidosis and in some cases establishes a diagnosis without a biopsy at all. Several commonly used tracers bind avidly to TTR (both mutant and wild-type) and have the potential to establish the diagnosis of cardiac ATTR or distinguish ATTR from AL when the diagnosis of amyloidosis is known or strongly suspected. Three of the most commonly used radiotracers are ^{99m}Technetium-3,3-diphosphono-1,2-propanodicarboxylic acid (Tc-DPD), ^{99m}Technetium-pyrophosphate (Tc-PYP), and ^{99m}Technetium-hydroxymethylene diphosphonate (Tc-HMDP). An initial study of Tc-DPD in Italy showed that in 25 patients with cardiac amyloidosis (15 with ATTR and 10 with AL), there was robust cardiac uptake in all of the ATTR patients and none of the AL patients (Perugini et al., 2005). However, a larger follow-up study by the same authors demonstrated 100% uptake in the ATTR group but weak uptake in almost a third of the AL group, thus weakening the specificity for this agent (Rapezzi et al., 2011). Tc-PYP is more widely available in the United States, and a study by Bokhari et al. of 45 patients with cardiac amyloidosis (16 with ATTRwt, 17 with ATTRm, 12 with AL) demonstrated a 97% specificity and 100% sensitivity for this tracer in the detection of ATTR (Bokhari et al., 2013). Tc-HMDP is the newest of these agents and in a study of patients with known TTR amyloidosis, this tracer showed cardiac uptake in all those with echocardiographic evidence of amyloidosis and in 8/19 without echocardiographic evidence of cardiac amyloid infiltration (Glaudemans et al., 2014). This suggests that Tc-HMDP may be even more sensitive than echocardiography in detecting early cardiac involvement in those with ATTR. In a study of 121 patients with suspected cardiac amyloidosis, Tc-HMDP scintigraphy demonstrated uptake in 100% of patients with ATTRwt ($n = 21$), 97% of those with ATTRm ($n = 34$), but 7% of those with AL amyloidosis ($n = 14$) (Galat et al., 2015). In total, these studies suggest that robust cardiac uptake is suggestive of ATTR, while lack of cardiac radiotracer uptake virtually eliminates the possibility of cardiac ATTR.

Genotyping and Role for Nonbiopsy Diagnosis

Given the substantial differences in management among the various types of cardiac amyloidosis, prompt diagnosis with identification of the specific amyloidogenic precursor protein is crucial. As outlined previously, amyloid genotyping used to absolutely require a sample of affected tissue, but now TTR gene sequencing with a peripheral blood sample has greatly simplified the task of genotyping once the diagnosis of ATTR is established. In fact, new data suggests that ATTR can be reliably diagnosed without a biopsy of any kind. In a study of 1217 patients with suspected cardiac amyloidosis referred to specialized amyloid centers in the United States and Europe, the absence of monoclonal gammopathy (on SPEP/UPEP, immunofixation, and serum-free light chains) combined with robust myocardial uptake (grade 2 or 3) on technetium scanning had a positive predictive value of 100% for cardiac ATTR (Gillmore et al., 2016). It is worth noting that the pretest probability for cardiac amyloidosis was extremely high in these patients given their referral to a specialized amyloid center. This will likely result in a substantially lower specificity in actual clinical practice; nonetheless, this study has altered the work up for cardiac amyloidosis, and it has given a clear path for the nonbiopsy diagnosis of ATTR. **Diagram 1** outlines our suggested diagnostic algorithm for those patients in whom suspicion of cardiac amyloidosis is high on the basis of the clinical features and imaging characteristics we have described; in particular it highlights the possibility of a nonbiopsy diagnosis.

Natural History

The natural history for all three forms of cardiac amyloidosis involve worsening heart failure and eventual death from pump failure and/or arrhythmia, but there is considerable heterogeneity in any individual's course, and there are varying contributions from noncardiac manifestations depending upon the specific disease entity. ATTRwt has the most delayed diagnosis and the most indolent course of the three. Patients with ATTRwt are typically older (diagnosed in their mid-70s), have the largest ventricular wall thickness, and are more likely to have systolic dysfunction compared to those with ATTRm and AL amyloidosis (Rapezzi et al., 2009;

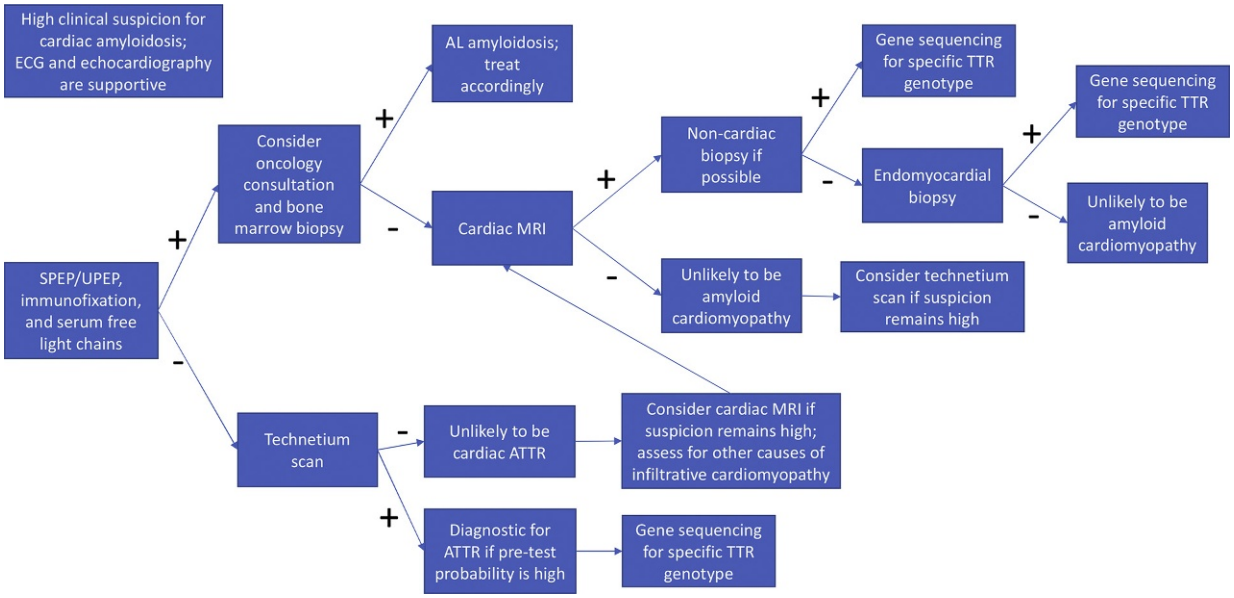

Diagram 1 Diagnostic algorithm for patients with high clinical suspicion for cardiac amyloidosis.

Ng et al., 2005). This likely reflects delayed diagnosis of these patients due to both underrecognition and relative lack of noncardiac manifestations. Despite thicker ventricular walls and advanced age, ATTRwt is associated with a relatively longer survival. A study of 18 consecutive patients diagnosed with ATTRwt compared with 18 randomly selected AL amyloid controls demonstrated median survival of 6 years in ATTRwt versus only 11 months in the AL controls (Ng et al., 2005). Additionally, a 2009 study comparing the clinical course of 233 patients with cardiac amyloidosis (AL $n = 157$; ATTRm $n = 61$; ATTRwt $n = 15$) not only showed that ATTR had prolonged survival over AL, but that ATTRwt specifically had a higher rate of MACE-free survival (77% at 2 years vs. only 51% for AL) (Rapezzi et al., 2009).

As outlined in the "**Pathogenesis**" section of this article, the course for ATTRm is more likely to be complicated by extracardiac manifestations in addition to infiltrative cardiomyopathy, but clinical course varies by mutation and previous therapy (specifically organ transplantation). In a UK/Canadian study of 60 consecutive patients with T60A ATTRm, the median age of symptom onset was 63 years and the median time from diagnosis to death was 41 months (Sattianayagam et al., 2012). For patients with V122I, the commonest ATTR-associated mutation in the United States, two studies of patients with cardiac involvement referred to an amyloid center have demonstrated a median age of 70 years at diagnosis and a median survival of 27 and 25.6 months, respectively (Connors et al., 2009; Ruberg et al., 2012). Only around 40% of carriers of the V30M mutation go on to develop clinically significant cardiomyopathy, but because of the near-universal development of neuropathy, these patients tend to be diagnosed younger (mean age 41 years (Lobato et al., 2004)), and authors have quoted older data demonstrating overall survival around 10-15 years postdiagnosis (Lobato et al., 2004; Andersson, 1976; Ericzon et al., 2015). This mutation also has a particularly high rate of renal dysfunction; around 10% of carriers progress to dialysis-dependent ESRD (Lobato et al., 2004). In one study, these patients had a 2-year survival of only 38% after initiating dialysis.

Taken together, these data suggest that diagnosis is often delayed in those with ATTRwt relative ATTRm (and certainly relative AL amyloidosis), but the course of ATTRwt is generally more indolent and extracardiac manifestations are less common. Among the common mutations associated with ATTRm, those with V30M tend to be diagnosed earliest but die the youngest, owing mostly to the extracardiac manifestations of their disease.

Prognosis

Clinical/Laboratory

There is a robust literature base supporting the link between elevated troponin and BNP or pro-BNP and inferior outcomes in AL amyloidosis (Dispenzieri et al., 2003; Kumar et al., 2012; Palladini et al., 2003). A 2012 study out of the Mayo Clinic using seven different parameters to create and validate an AL severity scoring system showed that only troponin T, NT pro-BNP, and a variable known as free light-chain difference (the difference between involved and uninvolved light chains) were independently predictive of survival (Kumar et al., 2012). The role for biomarkers in ATTR is less definitive but evolving. A Swedish study of 29 patients with ATTRm (mostly V30M) showed low positivity overall for troponin (10% for troponin T and 21% for troponin I), but elevated BNP was found in 76% of these patients and this correlated with ventricular septal thickness and impaired strain pattern on echocardiography (Suhr et al., 2008). In a Japanese study of 27 patients with ATTR (14 with ATTRm and 13 with ATTRwt), the log BNP

correlated with increased left ventricular wall thickness and impaired echocardiographic parameters of diastology (E/e') (Usuku et al., 2013). A 2013 study of 99 patients with ATTRwt demonstrated that NYHA class, need for pacemaker placement, and positive troponin T (but not NT pro-BNP) were all predictive of increased mortality (Pinney et al., 2013). More recently, Grogan and colleagues found that advanced age, presence of pericardial effusion, impaired ejection fraction, and elevations of NT pro-BNP and troponin T were all associated with increased mortality in their cohort of 360 ATTRwt patients (Grogan et al., 2016). Additionally, they developed a staging system based only on threshold elevations of NT pro-BNP (above 3000 pg/mL) and troponin T (above 0.05 ng/mL). Patients negative for both (stage I) or positive for one of the two (stage II) had 4-year survival rates of 57% and 42%, respectively. Those positive for both (stage III) had a 4-year survival of only 18%—a hazard ratio of 3.6 relative to stage I.

Imaging

RV dilatation has been associated with shorter survival in the AL amyloidosis population (Patel et al., 1997). In a cohort of 82 cardiac amyloidosis patients (AL = 26, ATTRm = 37, ATTRwt = 19), NYHA class and tricuspid annular plane systolic excursion less than 14 mm were independent predictors of MACE (Bodez et al., 2016), but not specifically mortality. The diagnostic role for nuclear imaging with technetium was discussed in the last section; however, a recent study of 602 patients with cardiac ATTR (ATTRm = 225 and ATTRwt = 377) failed to demonstrate the prognostic utility of Tc-DPD (Hutt et al., 2017). Tc-PYP demonstrating a quantitative uptake heart to contralateral (H/CL) ratio greater than 1.6 was shown in one study to be associated with poorer 5-year survival in patients with all forms of ATTR (Castano et al., 2016). Serial Tc-PYP scanning as a modality for monitoring disease progression in those with known ATTR was not shown to be beneficial in a recent study of 20 patients (ATTRwt = 10 and ATTRm = 10) (Castaño et al., 2016). While not having a role in diagnosis, assessment of cardiac sympathetic denervation with ^{123}-meta-iodobenzylguanidine (MIBG) scanning has been shown to have prognostic value in ATTRm. In a study of 143 patients with V30M mutation, those with late heart-to-mediastinum uptake ratio below the lower limit of normal (<1.60) were shown to have an increased mortality at 5.5 years with a hazard ratio of 7.19 (Coutinho et al., 2013). Cardiac dysautonomia as assessed by myocardial MIBG uptake and heart rate response to atropine was similarly shown to have prognostic value in ATTRm patient postliver transplantation (Algalarrondo et al., 2016). The diagnostic utility of LGE on CMR was discussed in the previous section, but LGE pattern has prognostic value as well. Raina and colleagues pooled data from seven studies of patients with cardiac amyloidosis undergoing CMR (AL = 275 and ATTR = 146) and found that the presence of LGE was associated with increased mortality at the mean study duration of 25 months with an odds ratio of 4.96 (Raina et al., 2016).

Treatment

Supportive Care

The first and most important step in treating any amyloidosis is to initiate the appropriate supportive care for the sequelae wrought by amyloid deposition. From a cardiac perspective that means addressing symptoms of heart failure and/or arrhythmia. While diuresis is certainly important for control of excessive volume and associated dyspnea and peripheral edema, the restrictive cardiomyopathy characteristic of ATTR often leaves patients in a preload dependent state and those patients do not tolerate aggressive diuresis; loop diuretics should be used with caution (Ruberg and Berk, 2012; Gertz et al., 2015). Spironolactone is often better tolerated (Ruberg and Berk, 2012), and there is some data to suggest a benefit to aldosterone antagonism in HFpEF more broadly (Lewis et al., 2016; Gu et al., 2016; Kosmala et al., 2016; Pfeffer et al., 2015). Older studies have shown less favorable outcomes in AL amyloidosis treated with calcium channel blockers and/or digoxin as these agents can bind to amyloid fibrils and lead to toxicity (Grogan and Dispenzieri, 2015; Rubinow et al., 1981). Cautious afterload reduction with ACE inhibitors or angiotensin receptor blockers has been suggested by some authors as a way to improve forward flow (Ruberg and Berk, 2012) but this has been discouraged by other authors (Gertz et al., 2015; Grogan and Dispenzieri, 2015). Tachycardia is often a compensatory mechanism to maintain cardiac output in these patients, and for this reason beta blockade (or any negative chronotropy) is generally poorly tolerated and considered contraindicated (Ruberg and Berk, 2012; Gertz et al., 2015; Grogan and Dispenzieri, 2015). Left ventricular assist devices (LVAD) have been used in patients with severe cardiomyopathy secondary to ATTR, generally as a bridge to transplantation. As may be expected, mortality is high in these patients that are not able to undergo transplantation (Grupper et al., 2015; Swiecicki et al., 2013). Some authors have suggested that thickened ventricular walls and the relatively small ventricular cavity size characteristic of ATTR poses a technical challenge for VAD over a more traditional dilated cardiomyopathy (Gertz et al., 2015). There are also concerns about high comorbid RV dysfunction in this group and thus inability to tolerate high venous return. Though trials are scarce, there is literature out of the Mayo Clinic suggesting that LVAD placement is feasible as both bridge to transplant and destination therapy in patients with an otherwise poor prognosis and that it prolongs survival over medical therapy alone, even with the bulk of patients having at least moderate RV dysfunction (Grupper et al., 2015; Swiecicki et al., 2013). In 28 total patients followed for approximately 15 months, preoperative LV end diastolic diameter less than 46 mm was associated with increased mortality.

Atrial fibrillation is the most common dysrhythmia associated with ATTR. A study by Cyrille et al. that was previously discussed in this article quoted prevalence of 38% in ATTRwt and 17% in ATTRm (Cyrille et al., 2014). Given the degree of atrial dilatation and amyloid infiltration, cardioversion and other rhythm control strategies are often unsuccessful in this patient group (Ruberg and Berk, 2012). As mentioned, low-dose beta blockade can be attempted for rate control but is often poorly tolerated. Amiodarone has

been used as a rate control agent as well. Though data are relatively sparse, radiofrequency ablation for atrial fibrillation in the setting of cardiac amyloidosis (both AL and ATTR) has been described and has demonstrated symptomatic benefit (Tan et al., 2016). Some authors have suggested that ablation for atrial fibrillation tends to have a lower success rate but is more promising in ATTR patients with a typical flutter circuit (Ruberg and Berk, 2012). In those patients who cannot be rate controlled or cannot tolerate attempts at rate control, there is a role for AV nodal ablation (Tan et al., 2016) and subsequent pacemaker placement. High degree or symptomatic AV block is an indication for pacemaker placement as well (Algalarrondo et al., 2012; Epstein et al., 2008). It is uncertain if dual chamber pacemaker placement with chronic right ventricular pacing in the setting of cardiac amyloidosis poses an additional risk of progressive left ventricular failure. The role of upfront cardiac resynchronization therapy with biventricular pacing in this setting make sense physiologically and has been described in the literature (Zizek et al., 2013), but its benefits have not been studied in a trial setting.

Due to the risk of arrhythmia and sudden cardiac death, prophylactic ICDs have been placed in patients with ATTR, though there is a relative paucity of data supporting their benefit. In one study of ICD placement in 33 patients with AL amyloidosis and 19 with ATTR (10 ATTRwt and 9 ATTRm), ICD firing was much more common in those with AL and appropriate shocks were more common in those patients that had had their ICD placed as secondary rather than primary prevention (Lin et al., 2013). While it seems reasonable to pursue ICD placement in ATTR, particularly for secondary prevention, ultimately no study has shown a survival benefit in this patient population (Lin et al., 2013; Kristen et al., 2008; Varr et al., 2014; Hamon et al., 2016).

Organ Transplantation

Given TTR is primarily synthesized in the liver; orthotopic liver transplantation should be considered for definitive disease-modifying treatment in those with ATTRm. By removing the hepatic source of mutant TTR and replacing this with a source of wild-type TTR there is attenuation of progressive organ dysfunction from continued mutant amyloid deposition. While transplantations are performed all over the world, including the United States, the majority have been done in Europe and Brazil on patients with V30M mutations. Outcomes data for these patients comes from the Familial Amyloid Polyneuropathy World Transplant Registry (FAPWTR), and the 20-year experience was published in 2014 (Ericzon et al., 2015). Greater than 90% of transplanted patients carried the V30M mutation, and 20-year survival for all-comers was 55%. The authors note that this is a substantial improvement to the mean time from diagnosis to death of 10–15 years that is classically attributed to V30M. Independent risk factors for poorer survival included elevated BMI, age at transplant >50 years, time of disease duration prior to transplant, and mutation other than V30M. In fact, patients with V30M transplanted at <50 years had a 10-year survival approaching 80%. Cardiovascular cause of death was reported in 22% of their fatalities which, the authors note, was substantially higher than the 9% rate reported by European Liver Transplant Registry (representing patients with all indications for liver transplantation). Cardiac dysautonomia postliver transplant as assessed by myocardial MIBG uptake and heart rate response to atropine has prognostic value, as was discussed in the previous section (Algalarrondo et al., 2016).

Though liver transplantation has seemingly prolonged survival in patients with ATTRm due to the V30M mutation, liver transplantation is not a panacea for patients with ATTR. A Dutch study of nine patients with ATTRm followed for at least 4 years postliver transplantation showed a decreased health-related quality of life relative a control group of liver transplant recipients (Drent et al., 2009). In particular, six of the nine ATTRm patients reported worse cardiovascular health at 4 years. In fact, worsening cardiac function in ATTRm patients postliver transplant is not uncommon. Several studies have shown progressive infiltrative cardiomyopathy even postliver transplantation (Okamoto et al., 2011; Olofsson et al., 2002). The reason for this seems not to be related to any recurrence of mutant TTR, but rather an accelerated codeposition of wild-type TTR on top of the existing mutant TTR fibrillar matrix. An autopsy study of three patients with ATTRm postliver transplant compared with a control group of seven ATTRm patients who did not undergo liver transplant demonstrated that the relative composition of cardiac amyloid deposition in nontransplanted patients was 60% mutant TTR and 40% wild-type, versus only 25% mutant TTR and 75% wild-type in those who had undergone transplantation (Liepnieks and Benson, 2007). This phenomenon of accelerated deposition of wild-type TTR has also been shown to cause progressive neuropathy in ATTRm patients postliver transplantation (Liepnieks et al., 2010).

This concept of accelerated wild-type TTR deposition worsening cardiomyopathy postliver transplantation has prompted combined heart and liver transplantation, with the premise being that one removes and replaces first the nidus for clinically significant amyloid deposition (the heart) and then the source of amyloidogenic protein (the liver) (Ericzon et al., 2015; Nelson et al., 2013; Sack et al., 2008). In a Danish study of seven patients undergoing heart and liver transplantation due to ATTRm (Leu111Met mutation) and severe cardiomyopathy, two died in the first year while the other five survived to the study's mean follow up of 55 months without recurrence of their infiltrative cardiomyopathy (Nelson et al., 2013). Isolated heart transplant has been reported in ATTR (Davis et al., 2015; Hamour et al., 2008; Thenappan et al., 2014) and seems to be most effective and practical in patients with the V122I mutation who tend to present later in life and have a more indolent course with less frequent extracardiac disease.

Pharmacologic Therapy

There are some disease-modifying pharmacologic treatments available and they are of emerging importance. Pharmacotherapies for ATTR can be divided into stabilizers, degraders, and silencers based on their mechanism of action.

Stabilizers

Diflunisal is an FDA approved nonsteroidal antiinflammatory that has been shown in ATTR patients to impair TTR tetramer dissociation and thus misfolding into amyloid fibrils (Sekijima et al., 2006; Tojo et al., 2006). In an open-label study of 13 patients with compensated heart failure due to ATTR (7 ATTRwt and 6 ATTRm), diflunisal was generally well tolerated but did not impact any cardiac parameters after 1 year of follow-up (Castaño et al., 2012). In an international randomized trial of 130 patients with ATTRm (55% were V30M), diflunisal slowed the progression of neuropathy and improved quality of life; those with heart failure (NYHA <IV) were included in the study but cardiac outcomes were not specifically addressed (Berk et al., 2013). Diflunisal at a dose of 250 mg twice per day is reasonable in patients with ATTR and significant polyneuropathy and/or compensated heart failure and no contraindications to NSAIDs; however, data demonstrating tangible cardiac benefits are lacking.

Tafamidis is another disease-modifying agent that is available in Europe but not currently in the United States. Like diflunisal, tafamidis stabilizes the TTR tetramer and prevents dissociation and resultant fibril formation (Bulawa et al., 2012). Initial studies have shown that tafamidis slows progression of neuropathy in ATTRm patients and that it is well tolerated over a period of years (Coelho et al., 2013a; Coelho and Maia, 2012). In an open label study of 21 patients with non-V30M ATTRm, treatment with tafamidis 20 mg daily for 1 year resulted in biochemical evidence of TTR tetramer stabilization and no deterioration in ventricular wall thickness, left atrial size, or NT pro-BNP (Merlini et al., 2013). In another open label study of 31 patients with ATTRwt and NYHA class <3, tafamidis (20 mg daily for 1 year) was generally well tolerated and resulted in stabilization of both TTR tetramers and NT pro-BNP levels (Maurer et al., 2015). Two patients (6.5%) died and seven (23%) were hospitalized for cardiovascular causes during the study period; 65% showed no worsening of NYHA class throughout the study. There is an ongoing US trial studying the longer-term effects of tafamidis, specifically in those with ATTR cardiomyopathy (NCT 02791230).

Degraders

The tetracycline antibiotic, doxycycline, has been shown in vitro to disrupt existing amyloid fibrils, and tauroursodeoxycholic acid (TUDCA), a bile acid derivative, has been shown to decrease prefibrillary TTR aggregates in a mice (Cardoso et al., 2003). In a mouse model of ATTRm, the combination of these two drugs decreased the overall burden of amyloid deposition (Cardoso et al., 2010). An open label human trial testing doxycline 100 mg twice per day and TUDCA 250 mg three times per day in patients with ATTR and NYHA <4 has been completed and results are forthcoming. Published preliminary data from that trial showed that with 7 patients completing 12 months of therapy and 10 patients completing 6 months of therapy, the treatment was well tolerated and no patients demonstrated progression of their underlying neuropathy or cardiomyopathy (Obici et al., 2012).

Other compounds that have shown promise in halting the progression of cardiac ATTR include green tea extract (specifically epigallocacatechin-3-gallate) and a red wine derivative, resveratrol. In one study, 19 patients with compensated heart failure due to ATTR (10 ATTRm and 9 ATTRwt) were treated with either tablets of 300 mg green-tea extract or the equivalent 1.5–2 L of brewed green tea per day for 1 year. Fourteen patients completed the study and none demonstrated increased ventricular thickness or progression of their cardiomyopathy as assessed by echo and/or CMR (Kristen et al., 2012). Resveratrol has been shown in cardiac myocytes in vitro to both stabilize TTR tetramers and promote association of TTR monomers into tetramers, thus preventing formation of TTR amyloidogenic aggregates (Bourgault et al., 2011). In vivo human studies, though, have focused more on Alzheimer's disease than cardiac ATTR (Pasinetti et al., 2015).

Silencers

The newest disease-modifying therapies being studied are the small molecules—small interfering RNAs (siRNAs) or antisense oligonucleotides. An siRNA is an exogenous RNA molecule that mediates, epigenetically, the suppression of its target mRNA and thus the transcription of its target protein, in this case TTR. Proof-of-concept phase I trial results for two different delivery formulations of a TTR-targeted siRNA (ALN-TTR01 and ALN-TTR02) demonstrated biochemical evidence of reduction in TTR in both patients with ATTR (NYHA <3) and healthy controls (Coelho et al., 2013b). Patisirin (Alnylam Pharmaceuticals) is the trade-name for ALN-TTR02, and it is currently being studied in a phase III trial (NCT01960348), as is another siRNA, revusiran (ALN-TTRsc; Alnylam Pharmaceuticals; NCT02319005). The concept behind antisense oligonucleotides is similar to siRNA, except these molecules are perfect complements that bind directly to their target mRNA mediating its destruction and thus suppression of target protein transcription. IONIS-TTRrx (Ionis Pharmaceuticals) is an antisense oligonucleotide targeting TTR and is currently being studied in a phase III trial (NCT01737398). Interim data from this trial showed a dose-dependent reduction in serum TTR levels (Ackermann et al., 2012). Small molecules are emerging therapies for a variety of diseases, but they are particularly promising for the future pharmacologic treatment of ATTR which thus far has a paucity of convenient, safe, and effective disease-modifying therapies.

Summary

Cardiac ATTR is a progressive and lethal infiltrative cardiomyopathy and is comprised of two distinct disease entities, mutant and wild-type. ATTR, particularly ATTRwt, is more common than previously thought and should be included in the differential diagnosis for any patient with HFpEF. The classic association of thick-walled ventricles on echocardiography and low voltage on

ECG can be a clue for the diagnosis of cardiac amyloidosis, but it is not particularly sensitive. EMB has long been the gold standard for diagnosis of cardiac amyloidosis, and indeed a tissue sample is generally required to diagnose ATTR. However, with CMR and technetium imaging suggestive of ATTR and a positive noncardiac biopsy (generally peripheral nerve or abdominal fat aspirate), the diagnosis of ATTR can be made without an EMB. Once tissue is obtained, isoelectric focusing and/or polymerase chain reaction can differentiate ATTRm from ATTRwt and usually yield a specific mutation. The chief cardiac manifestations of ATTR are HFpEF, atrial fibrillation, and AV block, and supportive care addressing these issues is paramount. Liver transplantation has been considered definitive therapy for those ATTRm patients in whom it is feasible; however, long-term follow-up has shown progression of cardiomyopathy due to acceleration of TTRwt deposition, and this has prompted consideration of combined heart and liver transplantation. Disease-modifying pharmacologic therapies are available as well with diflunisal, tafamidis, and doxycycline/TUFDA, but these are unproven to date. Small-molecule TTR inhibitors—siRNAs and antisense oligonucleotides—are currently being studied and offer promise for halting progression of this lethal disease.

Acknowledgments

The authors would like to thank and acknowledge Dr Sanjeev Francis for his analysis and edits of the MRI section of this review.

Introduction

Poor diet and insufficient exercise drive cardiovascular disease in the United States and globally. Any serious attempt to cure cardiovascular disease will have to focus on these risk factors at the individual and population level.

The data are sobering. Nearly two-third of Americans are overweight or obese, and half of adults have one preventable, noncommunicable disease like hypertension or diabetes that predisposes them to chronic poor health and early death.

Ischemic heart disease is the cause of death in one in five Americans. Stroke and diabetes follow close behind and are driven by the same risk factors as frank heart disease.

Diet is the largest factor leading to cardiovascular disease and death (Marczak et al., 2016). While diet is a modifiable risk factor, and therefore of particular interest from a public health standpoint, there remains a vast web of food and socioeconomic policies in addition to individual and social behaviors that influence dietary patterns. Lack of exercise also places a tremendous stress on the body and is a modifiable risk factor. Physicians are undertrained to address these risk factors and often feel that they cannot influence patient behavior. Evidence clearly demonstrates that this is false. Appropriate diet and exercise counseling does have a meaningful impact on patient behaviors. It is more useful, on an individual and population basis, than many of the medicines and interventions designed to treat or relieve symptoms of disease caused by poor diet and exercise habits.

The Biochemical Consequence of a High Fat Diet

Poor dietary habits such as excess caloric intake and over consumption of certain nutrients such as saturated fats and carbohydrates found in processed, packaged meats and fast foods contribute to cardiovascular risk (Mozaffarian and Ludwig, 2010).

Increased dietary consumption of saturated fats elevates low-density lipoprotein (LDL) cholesterol secondary to inhibiting LDL receptor activity. Increased carbohydrate intake results in increased carbohydrate storage in the form of triglycerides. These triglycerides are subsequently stored in the liver (Siri-Tarino et al., 2015a). The presence of higher triglycerides in the liver influences the content of lipoproteins that are made in and secreted from the liver. The result is an increase in small LDL particles and a decrease in high-density lipoproteins (HDL) (Siri-Tarino et al., 2010). Small LDL particles are the most atherogenic type that causes coronary artery disease.

Elevated LDL and elevated triglycerides lead to endothelial dysfunction through a multistep process. LDL undergoes oxidation. Oxidized LDL (oxLDL) causes direct damage to vascular endothelial cells. It also activates monocytes and platelets, leading to the formation of lipid laden macrophage foam cells. Foam cells destabilize coronary plaques and predispose them to rupture and subsequently myocardial infarction.

Additionally, the vascular smooth muscle cells (VSMCs) within the vessels are affected by oxidative injury and proinflammatory cytokines secreted by LDL. VSMCs exposed to oxLDL lose some of their contractile and connective properties. When exposed to oxidized LDL the cells become proliferative and migratory. This change allows the cells to migrate to the intima. The interaction of LDL with cells in the innermost layers of the vasculature is the nidus for plaque formation (Helkin et al., 2016).

Saturated fats also dysregulate the dynamics of insulin use. In the setting of increased free fatty acids, by-products of fatty acid metabolism like diacylglycerol (DAG) and ceramide collect within skeletal muscle cells. The presence of DAG and ceramide induces activation of serine/threonine kinases that phosphorylate insulin-receptor substrate (IRS). This results in reduced glucose sensitivity (Snel et al., 2012a). Likewise, accumulation of DAG within hepatocytes activates protein kinase C. This compels a cascade of metabolic dysregulation that results in increased glucose production and decreased glucose uptake by the liver (Snel et al., 2012b).

The macroscopic consequence of these microscopic changes is diabetes, obesity, and cardiovascular disease.

Obesity and sequelae as a consequence of excess calories

Overtime, a positive energy balance secondary to increased caloric intake and decreased physical exercise leads to increase in the number and size of adipocytes (Tchkonia et al., 2013a) as well as deposition of lipids, mostly triglycerides, in adipose tissue throughout the body (Heymsfield and Wadden, 2017a). Adipose tissue is not simply a storage tank; it has immune, mechanical, and endocrine functions. In states of obesity and lipid storage dysregulation, there is increased adipose deposition in ectopic locations, direct toxicity related to excess fat, and activation of the sympathetic nervous system and renin–angiotensin–aldosterone systems. Such changes to the fat mass result in subsequent release of cytokines (adipokines) from adipocytes and macrophages. This leads to a state of systemic inflammation which further propagates metabolic dysregulation and compels fat deposition, (Heymsfield and Wadden, 2017b; Tchkonia et al., 2013b).

Visceral adipose deposition triggers a series of changes that impact systemic health. The most pronounced of these is chronic activation of the sympathetic nervous system. This results in hypertension and dysregulation of multiple endocrine homeostatic mechanisms.

Furthermore, visceral adipose deposition around the kidneys plays a direct role in the genesis of hypertension. The mechanical compression of the kidney from fat stimulates the renal–angiotension–aldosterone system and sympathetic nervous system (SNS). In addition, adipose deposition around the pharynx can lead to obstructive sleep apnea. Sleep apnea is known to be associated with a loss of diurnal variation in blood pressure and the development of heart failure.

Obesity is the ultimate multisystem disease. Health care systems need to attack the roots of this illness from multiple angles. Physician education, patient education, and policy changes are essential to reversing the epidemic of obesity that is driving the vast majority of illness in our country.

What should our patients eat, and how much will it matter?

Reducing saturated fat intake has been the cornerstone of cardiovascular disease prevention. Modern science has revealed that a more nuanced approach is necessary. It is not adequate to simply replace saturated fat; what this nutrient is replaced with will influence the overall cardiovascular benefit of a shift away from saturated fats. Additionally, the source of the saturated fat matters, as dairy can overall have a neutral to beneficial cardiovascular effect, while red meat consumption clearly increases cardiovascular risk.

The concept of a balanced diet has appropriately shifted from an individual nutrient emphasis to an emphasis on whole foods. There is increasing recognition that valuable nutrients are not well absorbed in isolation, or as a "supplement"; the body will extract what it needs most effectively when presented with healthy foods that naturally complex nutrients with molecules like fiber that are further beneficial to health. The most valuable guidance we can give is for patients to eat fruits and vegetables, in addition to fish, nuts, and whole grains, legumes, unsaturated oils, low-fat dairy, and poultry, while limiting highly processed red meats and sugars., (Obbagy and Essery, 2014a; Siri-Tarino et al., 2015b; Part D, 2015a).

Two diet patterns have been shown to reduce cardiovascular risk. Both the Dietary Approaches to Stop Hypertension (DASH) and Mediterranean diet have been shown to decrease cardiovascular risk (Part D, 2015a). The DASH diet emphasizes fruits, vegetables, dairy, whole grains, fish, poultry, beans, seeds, and nuts, while decreasing sodium, sugar, and red meat intake (Heart and Blood Institute, 2015). The Mediterranean diet similarly encourages fruit, nuts, vegetables, cereals, and olive oil (monounsaturated oil); with moderate fish, poultry; and low dairy, red and processed meats, and sugar (Estruch et al., 2013). Other diets such as vegetarianism, lacto-ovo-vegetarian, and veganism have less evidence in support of cardiovascular endpoints such as death from ischemic heart disease, (Obbagy and Essery, 2014b; Part D, 2015b) but have been shown to have some cardiovascular benefit and to be effective in weight reduction (Jensen et al., 2013).

Overall, reduced calorie intake is an essential part of restoring energy balance and reducing weight. This is a challenge due to the profound influence of the processed foods industry, food marketing, and the asymmetrical distribution of healthy food purchase points, particularly in rural and urban areas.

The food environment

If you ask a person, "how many food decisions do you make in a day?" the average answer will be 15. In fact, the average person makes over 220 food-related decisions per day (Wansink and Sobol, 2007). The food environment plays a central role in dietary decisions. To begin at address cardiovascular disease at a population level, physicians and policymakers need to be acquainted with the practical realities of securing healthy food. One example of a challenge is the pervasiveness of food deserts throughout our urban and rural landscapes.

A food desert is a census tract that is both low income and in which 33% of residents live more than one mile (or more than 10 miles in a rural area) from a supermarket or large grocery store (Block and Subramanian, 2015). Disparities in access to nutritious food have contributed to the widespread rates of obesity, seen in rural areas and in neighborhoods that are racially and

socioeconomically clustered (Hilmers et al., 2012). Lower income areas, often with higher populations of African Americans versus White Americans, have fewer supermarkets than higher income areas, which is a barrier for those with limited transportation (Drewnowski et al., 2012). This means that in certain communities, access to fruits, vegetables, whole grains, and dairy products are limited. These neighborhoods often have more convenience stores and smaller grocery stores where nutritious food is not stocked, prices for the limited selection of healthy foods are higher, and there is increased availability of cheap, high calorie, low-nutrition processed food (Krukowski et al., 2010).

In addition to proximity, the price and type of supermarket plays a role in obesity. Shopping at a lower-priced grocery store is associated with a higher likelihood of being obese. Consumers with lower income and less education are more likely to shop at lower-priced grocery stores, even if they are further away from where they live. The food environment of higher-priced supermarkets tends to promote fresh produce; whereas, junk food and nonnutritious food is often cheaper, sold in bulk, and more prominently displayed and marketed at lower-priced grocery stores (Ghosh-Dastidar et al., 2014).

There is an opportunity to erase food deserts. The public health and medicine community are challenged to develop public–private partnerships that eliminate this disparity and connect low income consumers to healthy food at a reasonable price. Projects like the Virtual Supermarket (https://www.baltimarket.org/virtual-supermarket/), in Baltimore, Maryland, and the food prescription projects of Wholesome Wave (www.wholesomewave.org) are crafting creative solutions to this persistent problem.

Additionally, agricultural policies, subsidies, and taxes affect which foods are affordable. Food-marketing policies such as labeling, menu options, and incentive advertising of junk food items affect individual food choices. Communities can promote zoning for grocery stores and farmer's markets and limit fast food restaurants near and within schools (Healthy food environment, 2017).

The challenge of caloric restriction in already obese individuals

Physicians often hear from patients that they "hardly eat" but are unable to lose weight. Furthermore, if they do lose weight, most patients regain it. Approximately 80% of people regain all the weight they lose through a range of efforts. This occurs primarily because of adaptive thermogenesis. Effectively, the body gets more efficient, resulting in the need for fewer calories. More specifically, the body gets more efficient during nonresting energy expenditure (exercise). There is a 20% increase in skeletal muscle efficiency and a decreased sympathetic tone. This results in a relatively hypometabolic state. A 10% reduction in body weight results in a 20%–25% decline in 24 h energy expenditure. As a result, a formerly obese person will need 300–400 fewer calories per day to maintain the same body weight as a person who was never obese.

As physicians, our primary counsel should be that calorie restriction is paramount to weight loss, and that the caloric restriction is the lynchpin of keeping weight off (Keranen et al., 2009). Keeping even 5%–10% of weight loss over an extended period of time is a great achievement (LeCheminant et al., 2005). Exercise is an important component of weight maintenance, but patients should not expect to lose substantial weight with just exercise alone.

Exercise and cardiovascular disease risk reduction

The beneficial effects of physical fitness on cardiovascular health have been well established in multiple observational and randomized controlled trials. There are direct links between increased exercise and reduced risk of cardiovascular disease. It is well known that people who exercise are 50% less likely to develop hypertension. Furthermore, people with hypertension who exercise have a 40%–60% lower risk of dying than hypertensive patients who do not exercise. Exercise has also been linked to increased HDL levels and lower triglyceride levels. Exercise has a neutral effect on LDL levels. These impacts are larger than many pharmacologic interventions, but only 13% of doctors routinely give any advice regarding exercise. The PACE/INSURE studies demonstrate that physician counseling can result in 7%–10% of patients beginning to exercise (Physical Activity and Health, 1996).

In the United States, less than 5% of the total population participates in more than 30 min of exercise daily. Many people quote a lack of time, other commitments, lack of means, or simply a general disinterest in pursuing physical activity. Those who are less educated and have lower incomes are generally less likely to exercise. Women are generally less physically active than men. Minorities in the United States are less likely to exercise. There is even a disparity geographically, with adults in the north-central and western United States more likely to be physically active than those in the south and northeast.

In discussing the impacts of exercise on the cardiovascular system, a delineation between physical *activity* and physical *fitness* must be made. Physical activity, in basic terms, is any bodily movement made by skeletal muscles that causes energy expenditure. Physical fitness, in relation, is defined as set of attributes, unique to an individual, that includes muscle endurance, muscle strength, body composition, and flexibility. These are achieved through regular and regimented physical activity (Physical Activity Guidelines Advisory Committee, 2008).

Broadly, there are two main kinds of exercise: aerobic and anaerobic. Aerobic exercise is a type of physical activity that promotes increased heart rate and promotes increased oxygen uptake from the cardiorespiratory system and trains the skeletal muscles in more efficient oxygen uptake. Aerobic exercise includes activities such as long-distance running, walking, cycling, and other so-called endurance activities. The ultimate goal of aerobic exercise is to develop the cardiovascular system to better and more efficiently regulate oxygen uptake and distribution to the muscle.

In contrast, anaerobic training is a static type of exercise in which muscle metabolism occurs at a rate that overcomes cardiovascular effort, leading to an oxygen debt. This typically occurs in strength exercise training, which typically uses resistance, such as heavy weights, to build overall maximum strength of a muscle and increase muscle size.

Physiologically, physical activity that targets aerobic development increases the body's demand for oxygen and increases the cardiovascular system's ability to provide it. This ability is termed the ventilatory oxygen uptake, or VO_2. VO_2 is derived from the Fick equation and can generally be understood as the product of cardiac output multiplied by the difference of arterial minus venous oxygen content. Ultimately, the purpose of developing aerobic fitness is to increase the stroke volume (thus increasing cardiac output) and also increase the maximal difference between arterial and venous O2 content, meaning that the muscles extract more oxygen. This "maximal" exercise capacity is known as the VO_2 max. As VO_2 max improves with aerobic exercise the body is able to do more physical work with less demand on the cardiovascular system.

Aerobic exercise has been proven to reduce mortality by approximately 30% (Thompson et al., 2003). There is a general decrease in cardiovascular event risk with a specified exercise time of 40 min per session 3 to 4 times per week. The association between *anaerobic* exercise and decreased risk factors is not as well established. There does not appear to be consensus in metaanalyses for anaerobic exercising causing a decrease in blood pressure, though some studies do show that blood pressure is in fact also reduced by anaerobic exercise, and regular anaerobic exercise decreases insulin resistance, which can help offset the features of type 2 diabetes mellitus. However, this is not to the same degree that is found in aerobic exercise (Chaudhary et al., 2010 Dec).

Overall, the AHA/ACC strongly endorses aerobic exercise; resistance exercise can be added to an exercise regimen, but aerobic exercise is preferred over anaerobic exercise for cardiovascular disease risk reduction.

Exercise is also beneficial for people with heart failure, coronary disease, and atrial fibrillation. In those with coronary artery disease, exercise training has been proven to increase exercise capacity, reduce ischemia, delay angina pectoris, and improve endothelial function (Bateman et al., 2011). This can be accomplished either through a supervised cardiac rehabilitation program or through encouragement of physical activity similar to the type recommended by the ACC/AHA for primary prevention of coronary artery disease.

Per AHA/ACC official guidelines, patients with coronary disease should be encouraged to perform their exercise at a moderate intensity, related to their level of physical fitness. Goal heart rate at this intensity of exercise should be 70%–85% of the peak heart rate, calculated by the difference of 220 minus age. Patients can use the "talk test" to determine the strenuousness of their exercise—in true "moderate" exercise, the performer should be breathing at a faster rate than at rest or at light exercise, but still able to talk in full sentences.

In the setting of heart failure, the HF-ACTION study, a large, case-controlled study involving patients across the spectrum of heart failure severity, recommended physical exercise in those with stable, systolic heart failure, noting a decrease in all-cause mortality and rehospitalizations. This was achieved with following the AHA/ACC recommendation of at least 30 min of moderate-intensity exercise three to four times a week. This is a departure from the previously established recommendation that recommended rest and avoidance of physical activity (O'Connor, 2009). Ongoing studies continue to demonstrate the exercise is essential for improving outcomes in patients with atrial fibrillation.

Most people are aware that moderate physical activity is good primary prevention for coronary artery disease, and also for reducing the severity of risk factors. There are multiple electronic exercise measuring tools that people use, such as the "Fitbit" device. These devices allow the regular person to keep track of their fitness levels, amount of physical activity, and they can also measure exercise basics such as heart rate and the amount of calories that are being used during exercise. Studies have been done to determine if these tools change outcomes, especially in regard to weight, BMI, fitness, physical activity, and dietary intake.

The IDEA study, which looked at younger adults, indicated that wearable technology do result in some weight loss benefits as far out as 6 months after implementation of this technology but did not result in sustained weight loss at 2 years. Another study which recruited older, obese, and more sedentary patients did show evidence that wearable technology with feedback and tracking abilities did show some utility in enhancing lifestyle changes that promoted weight loss and reduced waist circumference (Shuger et al., 2011).

However, many of the studies that analyze the utility of these technologies are very small, observational studies, and only look at the effects of these interventions on how they affect overall physical activity levels and weight change; these studies are limited in the respect that they do not have results on how digital technologies affect such things as resting heart rate, VO_2 max, or other more specific physiologic measurements. The specific information that is recorded by these exercise technologies is very limited and usually confined to measuring heart rate and amount of steps taken, or miles exercised. There is a substantial error rate with these devices; up to 92% error has been recorded for estimating moderate to vigorous activity, while up to 65% error rates have been recorded on estimates of sedentary behavior (Rosenberger et al., 2016). App-based technologies have improved accuracy when compared to wearables in clinical trials, but there is still substantial variation. Mobile technologies are digital health tools that have a tremendous drop off rate; the majority drop-out of use after 3 months and only 3% of users become long-term users (Helander et al., 2014).

Medical providers can play an instrumental role in helping to get patients increase their physical activity and physical fitness level. Most physicians are aware of the general benefits of moderate exercise in cardiovascular health, mental health, and pain reduction. However, by one study, nearly 47% of physicians do not talk to patients about exercise as part of a treatment plan, and in the same study, only 13% of the patients polled had any recollection of being counseled on exercise as part of their general health (Sallis and Hovell, 1990).Many physicians are not highly skilled in exercise counseling. However, even simply mentioning the topic is useful to patients. It is further impactful for physicians to write an exercise prescription. Exercise prescriptions have been shown to increase long-term patient compliance in an exercise program (Leijon et al., 2010).

The Challenge of Prevention in Modern Medicine

Over 70% of cardiovascular disease is related to poor diet and reduced exercise. Patients are increasingly looking beyond their medical providers to find counsel and guidance on these important issues. Unsustainable healthcare costs related to cardiovascular disease may be what ultimately alters the landscape from a focus on treatment of disease toward upstream solutions that lay diet and exercise as the cornerstones of modern medical treatment.

Introduction

Bicuspid aortic valve (BAV) is a common congenital cardiac disease, usually asymptomatic for a long time. The incidence of BAV is around 0.9%–2% in the general population (Fedak et al., 2002) as well in competitive athletes (Stefani et al., 2008) with main prevalence in male (Basso et al., 2004; Stefani et al., 2008). BAV can be often found in association with other minor congenital cardiopathies as mitral valve prolapsed, interventricular septal defect, patent ductus arteriosus (Duran et al., 1995). All these conditions do not normally represent a real obstacle to practice sports activity, also in competitive athlets. An accurate clinical approach is on the contrary necessary when aortic tract dilatation (Keane et al., 2000; Roberts, 1970a) or coarctation (Nistri et al., 1999a) is present and particular attention is necessary when they are potentially evolving in acute dissection (Ward, 2000). Regular athletic training can induce an hemodynamic load during exercise and particularly pressure overload during strength training may also lead to aortic remodeling (Zeppilli et al., 2006).

BAV is commonly studied for the valve dysfunction. It can show a mobility dysfunction often represented by aortic regurgitaion or stenosis, often evident in a mixed form. A mild aortic valve dysfunction is tollerate in competitive sports activity; however the aortic valve insufficiency can induce a left ventricle (LV) systolic and diastolic enlargment, as well aortic stenosis can determine a progressive LV chamber modification. All these conditions are associated with the LV mass increase. In addition the cardiac adaptations to different forms of athletic conditioning tend to produce disparate morphological forms of the athlete's heart. For this reason, more recently, the LV's morphology and structure is an emerging interested aspect in BAV. The myocardial remodeling due to regular sports activity, so-called athlete's heart, can be therefore partially overlapped to the LV mild enlargement as consequence of both the causes. This aspect, studied either in general population as in athletes needs to be considered for a correct interpretation of the natural history of BAV (Beroukim et al., 2006). The impact of different sports activity in athletes with BAV is in fact not yet completely clarified in sports medicine and therefore an appropriate follow-up and surveillance is often mandatory. The progressive effect of sports training could be an additional factor for heart workload and therefore decisive for the eventual evolution of the disease. The echocardiographic exam is in this population of athletes, necessary at least one in a life before to start with a regular training and potentially suggested as a correct follow-up for a long-time surveillance. A more complete echocardiographic assessment during physical ergometric test, called echostress test, is determinant for a aortic valve and LV performance evaluation.

History and General Implications

The first description of BAV has been attributed to Leonardo da Vinci 400 years ago, anyway several other authors (Osler, 1886) have described the presence of BAV during infective endocarditis or aortic dissection findings (Wauchope, 1928).

The possible association with other cardiac congenital disease, the potential complications in BAV, and also their clinical implications are frequently investigated.

Congenital BAV has been described since 1927 to have a ninefold grater risk disease for aortic dissection (Acierno, 1994). This aspect has contributed to highlight the interest to a possible enhancement of sudden death.

Sports eligibility protocol, mainly in the Italian context, but also in Europe has induced the sports physicians to perform an initial and accurate staging of the BAV, taking into account hemodynamic factors, aortic complications, and other significant cardiovascular anomalies.

The progressive development of the echocardiographic imaging has improved the definition and the incidence of the BAV in general population and also in athletes. The use of 2D ecocardiographic traditional and not traditional (strain) parameters has increased the definition of the myocardial performance and the risk of the complications. The rising interest is nowadays due to the large series of ages represented among the subjects with BAV that are engaged in physical activities and in sports at different levels of intensity.

Sports medicine eligibility is now open to a large context of general population where also the master athletes are involved in competitive sports activity. This is an emerging and new field of interest where some other variables like eventual comorbidities association need to be considered

Embriology and Morphology of BAV

The aortic cups derive from the mesenchymal cardiac cushions situated along the ventricular outflow of the primary heart tube. Among the possible etiologies of BAV, the anomalous behavior of the neural crest cells seems to be one of the most reliable etiologies (Fernandez et al., 1996; Roberts, 1970b). Some researchers have verified the frequent association of BAV with others congenital malformations of the aortic arch in addition to the involvement of the neural crest cells during the semilunar valves growth (Sumida et al., 1989). Others researchers have suggested the possible impairment in the extra cellular matrix and deficit of metalloproteases system as causes of abnormal valvulogenesis particularly in the differentiation and the formation of this one (Fedak et al., 2003). The anatomy of BAV shows often an unequal size of the cusps, the raphe usually appears in the middle of the larger cusp as expression of the site of fusion and therefore without valve tissue.

Respect of normal tricuspid aortic valve (TAV), where the asymmetry of the valve is unusual, BAV shows an eccentric closure normally well evaluated with the bidimensional echocardiographic exam in long-axis view.

The two images in short-axis view (obtained by ESAOTE-My lab echocardiography) show the different position of raphe as expression of cusps fusion and diverse valve closure (**Figs. 1** and **2**).

The BAV can be often associated with a mild aortic valve insufficiency, with eccentric jet (**Fig. 3**).

The long-axis color image shows the eccentric aortic valve coresponding to the aortic mild regurgitation.

Literature reports some different morphological patterns of BAV. The most common origin of the BAV is the fusion of the "left and the right" valve cushions (Pattern A), but the exact mechanism triggering remains unclear. The fusion of right with noncoronary leaflet (Pattern B) is not so common as the pattern "A." Pattern B is on the contrary more frequently associated with aortic stenosis and regurgitation mainly in pediatrics series (Stefani et al., 2014a). The least common variant in BAV is the fusion of left and

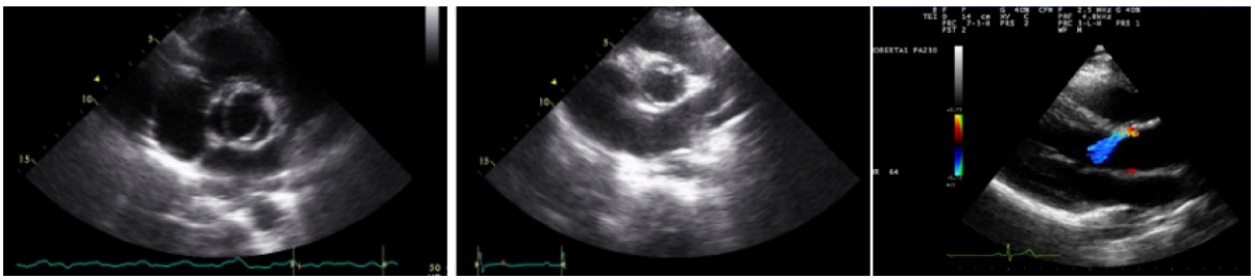

Fig. 1 The two images in short axis view (obtained by ESAOTE-My lab echocardiography) show the different position of raphe as expression of cusps fusion and diverse valve closure. The BAV can be often associated to a mild aortic valve insuficiency, with eccentric jet. The long axis color image shows the eccentric aortic valve corresponding to the aortic mild regurgitation.

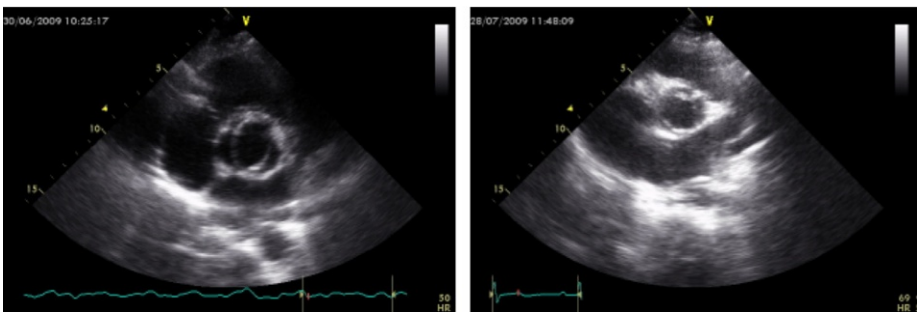

Fig. 2 BAV from 2D short-axis view at echocardiographic exam. Images in short axis view show the different position of raphe as expression of diverse valve closure.

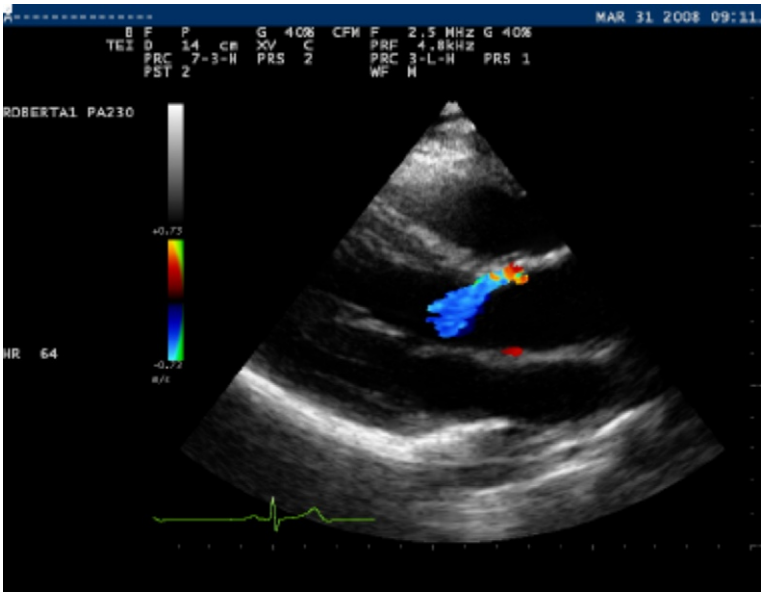

Fig. 3 2D echocardiographic long-axis view of BAV.

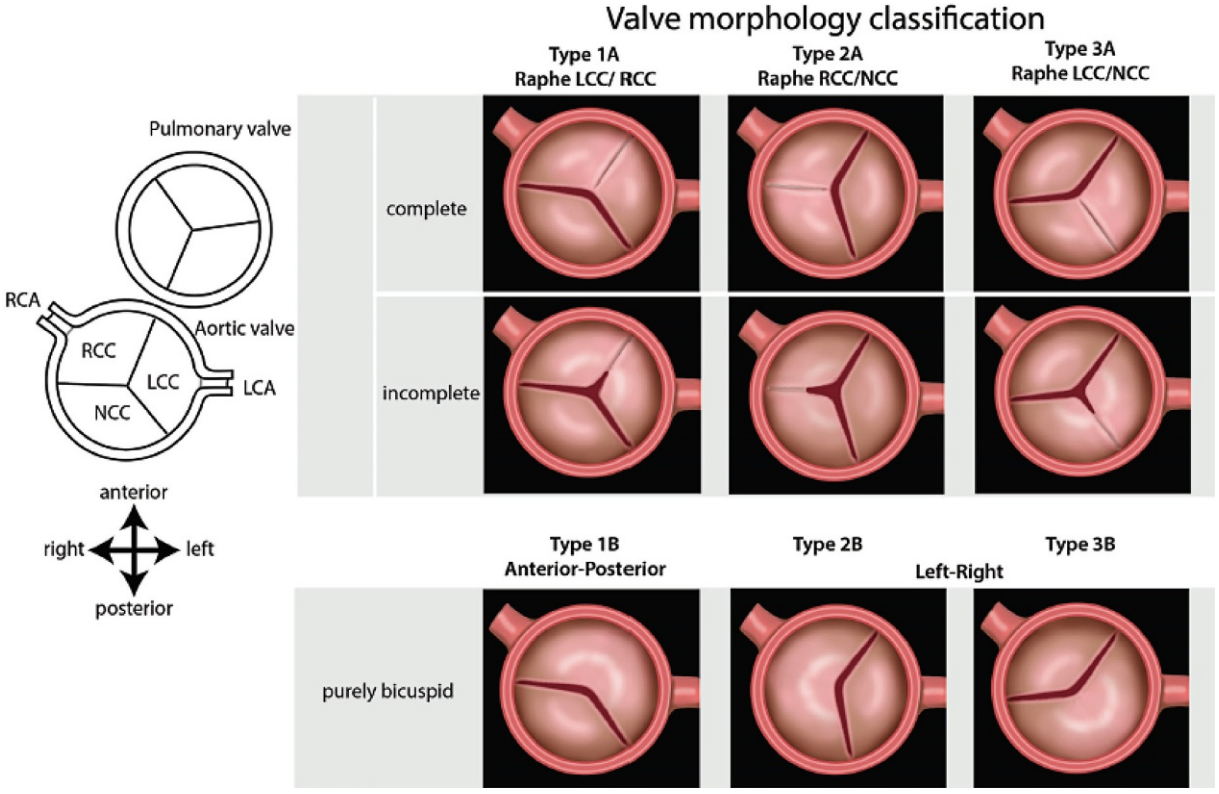

Fig. 4 BAV morphological classification.

noncoronary cusps (Pattern C). These different patterns of fusion determine inevitably a diverse position of the valve commissure and different kind of closure: for example, horizontal, vertical, or oblique with complete and incomplete raphe.

Fig. 4 shows the different morphological pattern and different raphe orientation as consequence of the cusps fusion.

These morphologies of BAV, normally used to classify the type of the valve, have been considered in deep for the correct interpretation of the potential role in the possible various evolution to a different levels of aortic valve dysfunction. It has been also hypothesized a different impact toward the LV involvement and damage, especially in athletes (Stefani et al., 2014a).

The investigation has demonstrated that in any case, the different patterns of BAV do not affect the long-term LV performance in athletes regularly trained, when the valve dysfunction is not severe.

Genetic

Several studies describe BAV as a consequence of an underlying genetic abnormality. A wide group of investigations, conducted among the relatives of subjects affected by BAV, have reported a prevalence of 14.6% in the major of the family studies (Brown et al., 2002; Emmanel et al., 1978). In several familiar clustering the prevalence of BAV is compatible with an high heritability of the disease, while in other studies the number of subjects affected seems to be asymmetric and compatible with an autosomal inheritance patter with reduced penetrance (Huntington et al., 1997). This particular aspect is likely due to mutations in diverse genes with dissimilar inheritance patterns in families. Starting from this background echocardiographic family's screening is recommended, especially for first-degree relatives of subjects affected by BAVs. In addition, considering the frequent involvement of the aortic tract among BAV athletes, a sort of overlapping in genetic pattern (involving the Cr 15), between BAV and ascending aortic aneurysm, has been studied (Glic and Roberts, 1994). Any eventual responsibility of the human gene in the pathogenesis of BAV will need further studies.

BAV and Associated Congenital Cardiovascular Lesions

In the 5% of cases, BAV can be associated with additional cardiovascular malformation.

One of the most common is aortic coarctation that can be present in a "simple" form, when isolated, or "complex" if associated with other intracardiac defects. Literature reports a frequent association of aortic coarctation with BAV where right and left cusps (type A) are fused. In some reports it is present in 15% or 18% of the series analyzed (Goh et al., 2002).

The BAV subjects with associated aortic coarctation are often addressed to a surgical intervention where valve or the vessel is involved. In many cases, subjects submitted to a surgical treatment for the aorta in first line are often reconsidered in second session for the valve replacement (Attenhofer Jost et al., 2002; Coehn et al., 1989; Larson and Edwards, 1984). A particular investigation (Acierno, 1994) in a wide group of athletes involving 2273 competitive and nonelite subjects, evaluated since 1 Jan. 2000 to 31 Dec. 2004, has showed anyway a low prevalence of aortic coarctation in them. In this study only two cases diagnosed among the 356 cases of structural heart disease have been reported. Nonetheless athletes in general do not seem to be less affected by aortic coarctation than general population. However it is relevant to consider that athletes are a selected population, where the preparticipation protocol in order to obtain the eligibility, especially in Italian context, tends to exclude subject with aortic coarctation unless they are operated.

Regarding the other eventual congenital cardiovascular diseases potentially associated to BAV, the most frequently defects found are the patent foramen ovale (PFO), atrial sepal defect, interventricular septal defect, mitral valve prolapsed. They are normally present in same prevalence of general population. All of these cardiac minor congenital cardiac diseases need to be periodically followed, especially in case of regular sports activity. They do not normally represent an obstacle to allow sports activity.

It needs to pay particular attention either in general population or in athletes, to the coexistence of eventual congenital coronary artery anomalies in BAV. The increased incidence of coronary abnormalities origin, described as case report (Fiorella, et al. 2010) and in few cases in BAV, may have clinical relevance, with negative impact during exercise, especially if at maximal exertion up to a sudden death occurrence.

Clinical Symptoms

Although the BAV may remain asymptomatic and without clinical consequences for a lifetime, it may be responsible for severe complications such as aortic stenosis, aortic insufficiency, endocarditis, and aortic dilation/dissection, sometimes requiring surgery. In general population as well a in athletes, the initial diagnosis is often suspected in the presence of "systolic click" and "ejection murmur" at the aortic valve opening.

The murmur is usually noted during the physical examination. The ejection sound is referred to the valve leaflet mobility and it diminishes when the valve becomes more immobile. In young where the valve regurgitation is more frequent than stenosis, this acoustic report is more common. During the clinical examination the "early peck systolic flow murmur" is normally heard after the systolic click sound. In consequence of these few clinical symptoms, the possibility to early discover the presence of BAV is reasonable lower than expected.

Particularly in sports medicine context, considering that in Europe and also in the United States the evaluation to obtain the eligibility does not normally include the echocardiographic exam, the diagnosis of BAV is therefore partially limited.

The finding and morphological definition of the valve depends, therefore principally, on the echoexamination. Ejection fraction (EF) appears normal for several years after the diagnosis. Nevertheless the symptoms related to the eventual heart failure, characterized by a reduced exercise tolerance, as a consequence of the prolonged impact of the aortic regurgitation to the LV chamber plays a relevant role in the clinical features and symptoms. This aspect remains in any case the crucial points in athletes with BAV even if excluded from the eligibility.

BAV athletes need to be early addressed toward a clinical and instrumental approach in order to discover a possible valve and myocardial worsening in them. Many morphological aspects are investigated at rest conditions, but the most important features are evaluated by the physical echostress exam where the valve functioning and its behavior during the exercise are tested.

With respect to the normal aortic valve function, the main parameters observed are the eventual reduction of the opening of the valve during the life and also the eventual worsening of the valve insufficiency during the physical exercise or regular training.

Myocardial contractility is an other relevant aspect tested during stress echo. A progressive increase of the EF without any substantial modifications of the segmental contraction is important characteristics in BAV athletes. The eventual presence of ventricular or supraventricular extrasystolia is also determinant to decide to allow the sports eligibility. The extrasystolia induced by physical exercise can in fact represent a contraindication to allow the sports activity.

Echocardiographic Exam in BAV

The standard 2D echocardiographyc exam is the principal noninvasive tool to ascertain the presence of BAV, to define its morphological characteristics, to verify the presence of other cardiovascular abnormalities eventually associated, and also to follow up the subjects affected by BAV. The echo exam is normally performed following the current AHA guidelines (Cheitilin et al., 2003).

Starting from the long-axis view, the eccentric valve closure and the doming systolic aspect of the cusps are often well evaluated. This feature is confirmed by the presence of two only cusps showed in short-axis view. Sometimes the presence of raphe can make a confusion and address to an incorrect diagnosis in consequence of the possible identification of this one with the anatomical valve commeasure. In this case, the possibility to mistake the trileaflet valve with a bicuspid one could be elevated. Despite the well-known limits due to the sonographer's experience and to the quality of the images obtained, several authors report an high accuracy of the echoexam with a sensibility of 78% and specificity of 96% for the diagnosis (Picano, 2004) in BAV. The apical five chamber view, with the addition of the color and Doppler analysis, is often used to evaluate the degree of the valve failure. The presence of the aortic insufficiency is normally estimated from 0 to 4 degree following a color grade scale from + to ++++, while the aortic flow velocity evaluated by continuous wave (CW) Doppler analysis is directly related to the degree of the valve stenosis. The score of the valve stenosis, BAV in athletes normally accepted to allow the eligibility, is referred to a value not higher than 20 mmHg at rest.

During physical stress test, where the hemodynamical circumstances of the exercise are reproduced, a value of the aortic valve velocity higher than the 3–4 msec and corresponding to a gradient more than 55 mmHg, at the peak of the effort, needs to be evaluated in the context of the specific sport eligibility, kind of sports, and therefore cardiovascular impact. In any case the eventual fast reduction of the aortic valve gradient, in the immediate time after the maximal effort, can be considered as a not pathological event and therefore not an obstacle to practice sports activity. The rate of the clinical examination needs to be established carefully. The aortic valve regurgitation is often found in the adolescent and in young adults, while the aortic stenosis is more frequent in older. Doppler analysis contributes to correctly define the degree of the aortic valve insufficiency. The pressure-half-time measurement (PHT) is the parameter used to classify the degree of the regurgitation as "low, moderate, or severe" (500 ms found at PHT measure is the cut-off value to distinguish moderate from severe). The recognition of a physiological reduction of the aortic valve regurgitation during the physical exercise is the most important aspect to follow up the valve dysfunction.

The complete cardiological assessment of BAV includes the echocardiographic measurement of the aortic tract at four levels (aortic root, valsava sinus, sino tubular junction, proximal ascending aorta).

This is particularly helpful to obtain information regarding the potential progression in dimensions of the first aortic tract, predominantly involving the sinotubular junction of BAV. This aspect is mainly relevant in consideration of the incidence of aortic dissection that in BAV occurs also in the absence of histmic coarctation or hypertension.

The autoptic study reports as this complication is present in approximately in 7%–9% of patients (Coehn et al., 1989).

Especially in young athletes with BAV the aortic root dimension is therefore an important evaluation, as expressly demonstrated in literature (Picano, 2004). The progressive enlargement of the first aortic tract seems to be a peculiar marker of the BAV and therefore independent from the aortic root disease itself. It has been demonstrated as the aortic roots are found larger than normal with the mean rate of progression of 0.5 mm/year at the sinuses of Valsalva and 0.9 mm in the ascending aorta (Gurvitz et al., 2004).

BAV is in fact considered as a congenital defect of the heart or great vessel (Ferencik and Pape, 2003) commonly associated with abnormalities of the ascending aortic tract like dilatation, aneurysm, dissection, and coarctation (Dwards et al., 1978; Niwa et al., 1999). Several echocardiographic and histological studies have suggested an independent association between BAV and aortic dilatation (Hahn et al., 1992; Keane et al., 2000; Nistri et al., 1999b; Pachulski et al., 1991). More recently some of these morphological aspects, evaluated in the general population and also in athletes, have showed concordant and helpful results in terms of management of BAV athletes.

One of the most interesting feature actually emerging is the possibility to find anyway a sort of relationship between BAV and aortic vessel just in particular community or geographic zone (Duran et al., 1995). There is a biologic rationale and data supporting the hypothesis of an intrinsic aortic disease in the presence of BAV. The aortic cusps, the outflow tract, the aortic arc are embryologically linked. They originate from the neural crest and they are often implicated in the arterial dissection of the cervico–cefalic tract.

Among the pathogenetic causes, some specific aspects are recognized as factors inducing this progression.

The NO_2 synthesis defect has been identified to induce a premature apoptosis of the medial layers smooth muscle cells. This deficiency has an high incidence in BAV (42%) respect of controls (Nkomo et al., 2003). Literature has also investigated the role and the contribution of the hemodynamic component as consequence of the severity of the aortic valve failure, in the progressive enlargement of the aortic tract. It has been demonstrated that the proximal aortic dilatation is beyond the implications associated with the valvular lesions (Schmid et al., 2003). Subjects with BAV with associated valve stenosis show an aortic dilatation at all the levels which are not found in subjects with normal TAV and same valvular lesion. This interesting feature has been investigated also in athletes population with BAV and mild aortic regurgitation (Keane et al., 2000; Pachulski et al., 1991), where the poor hemodynamic component of the valve's failure did not represent an obstacle for the regular training or sports activity. The results obtained, during a period of 5 years, support the hypothesis of any additional negative impact of the sport activity on the aortic tract at least in presence of mild regurgitation (Hahn et al., 1992).

Other investigations support this thesis showing that the degree of the aortic dilatation in BAV with stenosis is similar to the subjects with moderate or severe regurgitation and therefore no association between the eventual aortic valve failure and the dilatation of the aortic vessel, as consequence of the BAV presence is actually evident or demonstrated (Galanti et al., 2010).

Several authors have explored the aortic root pathology showing that it consists of a process similar to "cystic medial necrosis," and it is characterized primarily by an extensive loss of elastic elements with the media (Roberts and Ko, 2005a). For this peculiar characteristic composed by an intrinsic abnormality of the proximal aortic tract, the similarities with Marfan syndrome are very strong (McKusick, 1972). However, at present the progression and the involvement of the aortic tract have to be more clearly defined.

The similar enlargement of the first aortic tract dimensions has been described also in athlete's population in particular (Stefani et al., 2008). The yearly enlargement is approximately 0.78 mm/year for the aortic root; 0.61 mm/year for valsalva sinus; 0.81 mm/year sinus tubular junction; 0.98 mm/year proximal ascending per year with the major involvement of the sinus tubular junction tract.

In an other investigation where the possible sport activity impact on aortic tract has been evaluated (Hahn et al., 1992), the results are also in agreement with the data obtained in general population.

In conclusion, nowadays the aortic dimensions in BAV athletes, regularly trained, seem to be in complete overlapping to the general population not skilled (Dwards et al., 1978). No additional negative impact of sports activity in aortic enlargement has been demonstrated.

Echocardiography is consequently considered an helpful tool particularly for athletes where the best decision-making to guarantee the eligibility despite the presence of BAV.

LV Chamber in BAV Athletes

Despite the BAV has been normally considered exclusively an aortic tract disease, more recently a new aspect regarding the possible participation of the intrinsic contractile properties of the LV chamber is growing on.

The standard 2D echo-exam normally includes also the evaluation of the LV chamber calculating end-systolic and end-diastolic dimensions, the interventricular septum and posterior wall thickness and the diastolic parameters derived from the transmitral flow pattern. This approach is normally performed as similar procedure for both, general and athlete population. The attention to a possible development of the LV dimensions in BAV athletes is an additional specific aspect especially in those trained subjects where the eventual overlapping with the athlete's heart modifications can create a confusion for a correct interpretation of the consequence of the regular training. Recent study, during at least a 5-year follow-up (Hahn et al., 1992), has described in BAV athletes an yearly progressive enlargement of the LV chamber that anyway maintains the values within the normal range. This investigation is based on the recent knowledge demonstrating a different expression of the metalloprotease system (MPS) in BAV compared to TAV subjects. The study was conducted to verify any eventual difference in a long period.

The role of this mechanism has been however investigated in the blood vessel tissue but not yet in the myocardial segments (Kornbluth et al., 1999; Le Marie et al., 2005a). The major of research regarding the pathogenesis of the ascending aortic dilatation and based on this hypothesis has in fact focused on aneurysms caused by Marfan syndrome. The molecular mechanism responsible for aneurysm in patients with BAV remains anyway poorly understood. On the other hand, more current information is available on "ascending aortic aneurysms" where BAV disease exhibits an increase of MPS expression respect of TAV (Kornbluth et al., 1999).

In any case, starting from this background and taking care of the progressive enlargement of the LV chamber in BAV respect of controls, often associated with a decrease of the myocardial contractile property during their life, a presence of universal pathological mechanisms underlining the myocardium walls failure has been recently proposed (Le Marie et al., 2005b). This hypothesis is in fact going to be valorized and extended to a more large interpretation and to a new version of the pathogenesis of BAV disease. Authors are now working in evaluating this aspect as a possible cause related with a reduction of the contractile properties of the myocardium described.

Particularly in athletes, where the LV performance is normally evaluated by EF, the necessity to verify the persistence of this parameter during training has to be maximally considered in order to early decide the necessity to avoid any possible further heart impairments due to the additional effects of sport activity in them. However in the absence of currently advanced biological techniques dedicated to a direct and easy evaluation of the intrinsic contractile properties of the myocardial cells, two noninvasive methods are now available in echocardiography: physical echostress and the study of deformation parameters like strain.

The Complementary Information by Speckle Tracking Analysis on LV Performance

In echocardiography the deformation parameters (strain in different components, rotation, and torsion) are often involved to investigate the segmental and global myocardial function. Literature reports several studies in sports medicine to evaluate the LV performance in the presence of cardiac congenital disease or in the presence of valvular disease like aortic stenosis or insufficiency (Lewin and Otto, 2005; Souterland et al., 2004).

Particularly for the longitudinal component of strain LPSS (longitudinal peak systolic strain) it has been shown relevant data with clinical implications. The LPSS plays a recognized predictive role in the initial LV dysfunction of heart valve diseases such as aortic regurgitation or stenosis (Faber et al., 2007; Lewin and Otto, 2005). There is some evidence that, despite normal EF, strain of the LV can be depressed in subjects with aortic valve lesions (Onishi et al., 2007). These lower values of strain of the LV have been used as an indication for early surgery in such patients. In this context particularly in BAV athletes, some studies have been focused focusing to early discover an eventual initial LV failure in them (Poulsen et al., 2007). This kind of investigation has been completed in BAV athletes by using of a more sophisticated program dedicated to the 3D strain evaluation (Stefani et al., 2014b),(Stefani et al., 2009) where the LV contraction and the synergic activation of endocardial and epicardial fibers are more in deep studied. The results in athletes with BAV show values of LPSS within the normal and validated range confirming the normal function of the LV chamber and therefore in agreement with the EF.

From these data it is reasonable to suggest the addition of the deformation parameters in the instrumental evaluation of the BAV athletes in order to obtain a further confirmation of the normal function in them especially in case of high transvalvular gradient. The ST method, now validated, produces results with an high reproducibility and specificity and so it can be proposed, particularly for its easy application, as a routinely employment mainly in subjects where the other parameters are normal. The clinical implication of the gradient alone will need further studies involving a larger group of subjects analyzed: nowadays it cannot be excluded a peculiar utilization in athletes only.

Fig. 5 shows the representation of principal strain direction at the end-systole computed from the deformation at the subendocardial level in three groups of subjects: Control; TAV and BAV, respectively. The strain lines are colored to emphasize the positive angle of endocardial right-handed helical fibers with clockwise movement from base to apex.

Sports Activity in BAV Athletes

The natural history of BAV is usually addressed to the calcification of the cusps in the almost the totally of subjects affected: more than 50% of adults with severe aortic stenosis have a BAV (Köstner and Meinertz, 2007; Roberts and Ko, 2005b).

Nonetheless, one of the most important and crucial points is anyway to verify if BAV is loaded of an incidence of mortality higher respect of normal subjects. Frequent association with complications like endocarditis (Lamas and Eyhyn, 2000), the progression to valve stenosis especially in men (Gaudiani et al., 2004), or worsening of regurgitation requiring the valve replacement in addition to a frequent susceptibility to aneurism formation of aorta (Barndeburg et al., 2004) are not sufficient to clarify the prognostic consequences in terms of mortality. This problem is current not yet completing clarified manly in athletes where additional factors related to the intensity and kind of sports are present. Theoretically the regular training could favorite an early deterioration of the BAV even if the positive general impact of sport activity in men and women are well noted.

In addition to this, in athletes heart is often hard to differentiate the physiological adaptation due to sport from the pathological modification in consequence of valve disease. In case of BAV with preexisting aortic dilatation, intensive exercise, often isometric, can address to an high incidence of aortic rupture. Several recommendations for athletes are therefore referred to the ESC and AHA guidelines (Bonow et al., 1998) but all they do not anyway include the echocardiographic exam in first line. The high prevalence of

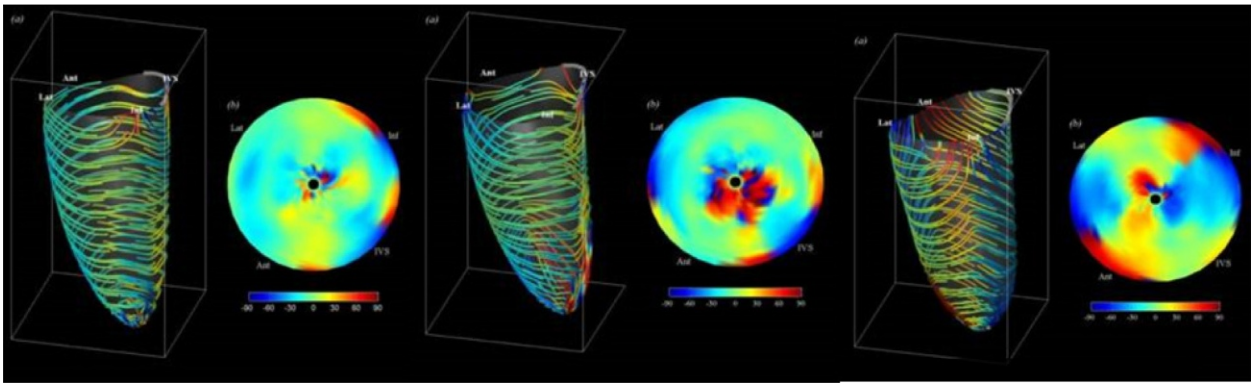

Fig. 5 Representation of principal strain direction at the end- systole computed from the deformation at the sub-endocardial level in three groups of subjects: Control; TAV and BAV respectively. The strain lines are colored to emphasize the positive angle of endocardial right- handed helical fibers with clockwise movement from base to apex.

this congenital cardiac disease and the same prevalence in general population and in athletes are strongly suggestive for a necessity of an early diagnosis potentially helpful. An echo exam at least one in a life could be proposed. This aspect might be considered mainly in the children and adolescent often invited to practice sport after the execution of a general check up or ECG only. For this aspect, both athletes and general population could be considered within in the same investigating model.

Some hemodynamical aspects of the impact of the prolonged physical exercise in athletes have to be considered. Aerobic exercise produces a physiological increase in heart's overloading, involving both the right and the LV; however the chronic intensive LV contraction induces an increase in myocardial performance that can be followed by echocardiographic exam. No substantial differences have been reported in case of resistance exercise with respect to aerobic one especially incase of BAV.

In order to take any decision about sports eligibility, sports physicians should perform an initial accurate staging of the BAV, taking into account hemodynamic factors, aortic complications, and associated significant cardiovascular anomalies.

No peculiar limits for specific sports are evident in literature in case of abnormal BAV function. The eventual contraindications to practice sports are related to the severe aortic valve failure and the LV chamber dysfunction (Köstner and Meinertz, 2007). Physiological adaptations of the heart have to be differentiated from pathological adaptations, and it is important to take into account the adverse consequences that regular training can have on subjects with BAV through different mechanisms. In athletes with BAV and associated aortic regurgitation, a preexisting pathological adaptation caused from a slightly elevated volume load due to the aortic regurgitation, it has to be taken into account and can have negative effect when the athlete is engaged in regular training.

In endurance exercise, the development of eccentric hypertrophy and ventricular dilatation may have consequences on this preexisting pathological adaptation. In athletes involved in mainly static or isometric exercise, the pressure's overload from/to the high systemic arterial pressure found in this type of exercise will cause a chronically elevated aortic wall tension, and consequently aortic dilatation and regurgitation. In the case of BAV with a preexisting aortic dilation, intensive and competitive exercise carries high risk for aortic dissection or rupture, which is even higher in isometric exercise. In fact, during competition, often phases of high intensities occur, inducing relevant increases in arterial blood pressure which would facilitate an aortic rupture. Those rare patients with BAVs associated with an anomalous origin of the coronary arteries have an increased risk of sudden cardiac death (SCD) during exercise. Although seldom recognized and often unappreciated, coronary artery aberrancies and anomalies account for up to 20% of cases of SCD in young athletes. Most types produce few, if any, symptoms, but some pose a much more substantial risk. Anatomical coronary abnormalities can imply a potential risk of coronary artery compression, especially following exercise. These consequences predispose to myocardial ischemia, syncope, or decompensated heart failure, and likely to account for most cases of SCD. Since coronary artery disease is often asymptomatic and most patients have not revealed physical examination, their detection can be quite difficult. Although echocardiography and echostress can be proposed in first line to reduce the risk of SCD in them.

Sports Medicine Indications in BAV athletes

Athletes with BAV who develop valve insufficiency or stenosis may require restrictions from strenuous competitive sports. Particularly subjects with aortic valve insufficiency and aortic dilatation should avoid strenuous sporting activity, as consequence of the eventual increased risk of aortic rupture. A general judgment in athletes with BAV about their ability for competitive sports is not possible, and therefore the eligibility for participation and the ability to continue to practice competitive sports needs to be individualized. It depends on age, severity of lesions, and the type of sport.

The *Guidelines of Bethesda Conference* No. 36 offer the recommendations to continue to participate in sports activity or to avoid (temporarily or permanently) to practice every sports. Some indications are dedicated to the suggest the eventual recreational athletic activities and to support the normal lifestyle for those athletes who are disqualified from competitive sports. However further studies are needed to better understand the genetics of BAV, to know the natural history and the impact of regular training in athletes with BAV especially if competitive.The natural course of BAV is not yet completely known.

In Italy, the competitive sports practice has several legal implications. The sports medicine check up is a complex evaluation based on the complete cardiovascular assessment by ergometric test and it includes also the urine exam. In case of BAV discovery the echocardiographic exam is mandatory. The impairment of the aortic valve and the progressive enlargement of the aortic tract or of the LV diameters may frequently determine the discontinuing of sport activity in BAV. Despite the presence of asymptomatic conditions, a regular yearly clinical and instrumental follow up is generally performed so as to discover as early as possible any signs of myocardial dysfunction.

The current suggestions are to perform a strict echo surveillance in BAV primarily if asymptomatic than symptomatic.

Introduction

Cardiovascular diseases (CVD) are diseases involving the heart and blood vessels, with one of the major pathologies being atherosclerosis, or the narrowing and hardening of blood vessels. Major CVD such as coronary artery disease (CAD), myocardial infarction (MI), and stroke, are the leading causes of mortality worldwide (Mensah et al., 2014), and less deadly CVD such as peripheral vascular disease (PVD) also contribute significantly to the morbidity of CVD. To enable effective prevention and therapy, enormous efforts have been dedicated in the past decades to improve our understanding of the etiology of CVD. These efforts have led to gratifying discoveries on disease mechanisms and subsequently the development of highly effective cholesterol-lowering

medications that have contributed significantly to the recent decreases in the death toll of CVD. However, despite the reductions in death rate, global prevalence of CVD has been increasing and we still face enormous challenges in preventing and reducing the occurrence of CVD and achieving more effective treatments (Mozaffarian et al., 2015; Heidenreich et al., 2011; World Health Organization, 2014).

One of the major hurdles towards eradicating CVD is the lack of comprehensive understanding of the molecular mechanisms. Before the arrival of high throughput technologies, CVD was primarily investigated using classic reductionist approaches that focus on single elements, one at a time, in confined contexts. For instance, if a gene is suspected to play a role in CVD development, perturbation experiments can be conducted in in vivo or in vitro systems to examine and elucidate the function and role of the candidate gene. Such studies have undoubtedly shed light on numerous molecules and regulatory pathways that are involved in CVD. Successful examples of reductionist approaches include the illustration of the cholesterol biosynthetic pathway and the low density lipoprotein receptor pathway, leading to the discovery of numerous lipid lowering drugs including highly effective statins and new classes of PCSK9 inhibitors. However, accumulating evidence, especially that from recent genetic studies, supports that CVD is far more complex than individual genes or pathways at play and the disease complexity is difficult to be fully captured with reductionist approaches (MacLellan et al., 2012). First, CVD is clearly the result of convoluted interaction of numerous genetic and environmental pathogenic factors. Second, CVD involves systems-level changes in diverse cell types, tissues, and organs. Third, multidimensional molecular entities and their interactions determine the complex paths leading to CVD development. Effective prevention and therapeutic strategies can only be achieved through a systems-level holistic view of CVD pathogenesis.

The revolutionary technological advances in the past decade have enabled cost-effective, high throughput profiling of multiomics molecular entities including genomics, epigenomics, transcriptomics, proteomics, metablomics, and microbiomics, paving the way towards a systems-level characterization of CVD pathogenesis (MacLellan et al., 2012; Meng et al., 2013; Civelek and Lusis, 2014). Notably, comprehensive molecular profiles have the capacity to capture the complexity of CVD by reflecting on the initiating genetic and environmental insults and the subsequent multitissue and multidimensional molecular perturbations that lead to the development of CVD. This capacity is further enhanced by the growth of public data repositories such as Gene Expression Omnibus (GEO) (Clough and Barrett, 2016), ArrayExpress (Parkinson et al., 2011), and dbGAP (Tryka et al., 2014), as well as coordinated national data generation efforts such as the Encyclopedia of DNA Elements (ENCODE) (Encode Project Consortium et al., 2007) and the Gene by Tissue Expression (GTEx) projects (G. TEx Consortium, 2013).

In response to the explosion of high throughput data, the field of bioinformatics has also seen significant development. Bioinformatics is a scientific discipline that aims to catalog, store, process, analyze, and interpret the biological significance of a variety of data by combining the tools and techniques of mathematics, statistics, computer science, and biology (Benton, 1996). Scores of bioinformatics tools are now readily available to researchers and are rapidly enabling novel discoveries in all major biological fields. In this review, we first introduce the characteristics of CVD that make big data research a necessity, next we delineate the basic bioinformatics principles applicable to the CVD field and the representative bioinformatics tools and applications. We mainly focus on major omics data types involved in CVD research and the corresponding bioinformatics principles, tools, and applications. We also highlight the importance and fundamentals of systems-level multidimensional data integration that represents the future of bioinformatics investigation on CVD.

Why CVD Requires Data-Rich Approaches?—Multilevel Complexity

A consensus has been reached that CVD are highly complex diseases. The complexity is reflected at several levels: multifactorial risks, multitissue pathologies, and multidimensional molecular perturbations (**Fig. 1**), as detailed below.

Multifactorial Risks

CVD originates from the collective contribution of a complex genetic architecture and its interaction with numerous environmental risk factors (Hunter, 2005; Kathiresan and Srivastava, 2012). CVD are highly heritable diseases, and the heritability estimates are 40–60% for CAD, 16–40% for stroke, and 21–58% for PVD (McPherson and Tybjaerg-Hansen, 2016; Bevan et al., 2012; Leeper et al., 2012), Numerous genetic studies via both candidate approaches and more recently, genome-wide association studies (GWAS), have uncovered hundreds of genetic loci for CVD (Kessler et al., 2016; McPherson and Tybjaerg-Hansen, 2016). In addition to the numerous genetic risks, many environmental factors (the exposome) have also been highlighted as major contributors to CVD. The most notable environmental risks include smoking, alcohol intake, low physical activity, high caloric diets rich in fat, cholesterol, and sugar, infections, environmental chemicals and pollutants, and stress (Cosselman et al., 2015). These environmental risks have been shown to have profound capacity to influence major organ systems critical for the maintenance of vessel and heart functions and likely contribute to the globalization and the soaring prevalence of CVD in the past few decades. Other environmentally linked diseases such as obesity, diabetes, and infectious diseases are also strong risk factors of CVD. Besides the large numbers of individual genetic and environmental risk factors that make CVD complex, growing evidence also supports gene-gene (McPherson and Tybjaerg-Hansen, 2016) and gene-environment interactions (Joseph et al., 2013; Ordovas, 2006; Corella and Ordovas, 2009). For example, interactions between the *COL4A1*/*COL4A2* locus and the *SMAD3* locus have been observed in CAD (Turner et al., 2015), and diet has been shown to modify the association strength of 9p21, one of the strongest genetic predictors for CAD (Schunkert et al., 2008; Samani et al., 2007; Do et al., 2011).

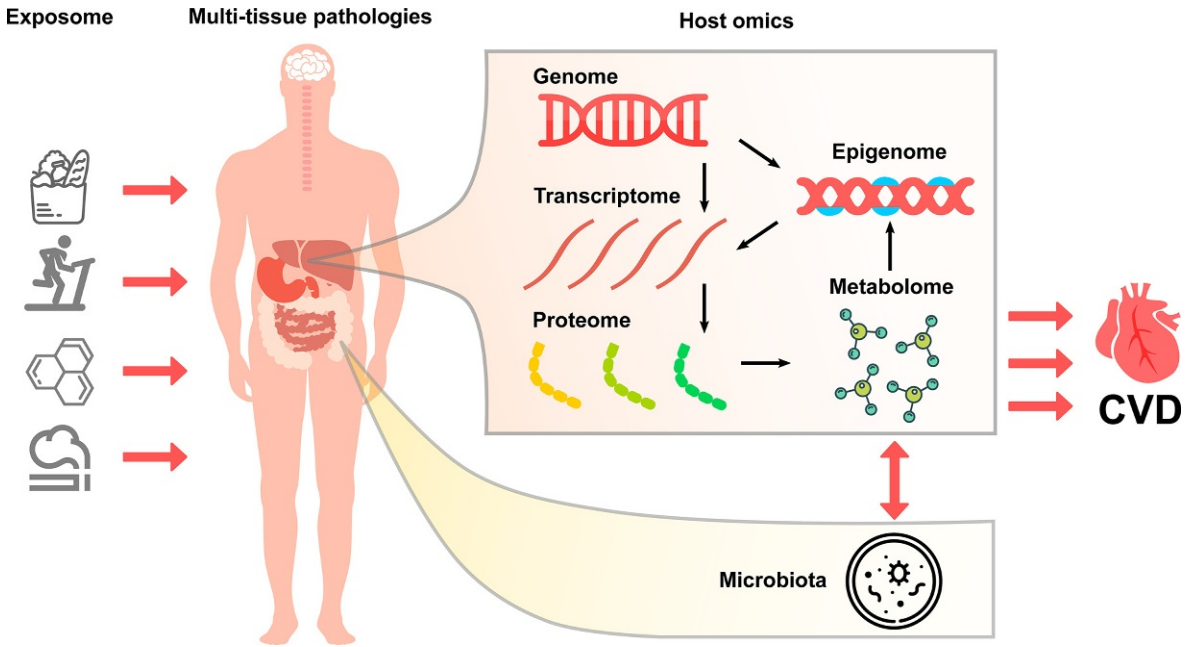

Fig. 1 Multilevel complexity of CVD. The complexity of CVD is reflected as (1) diverse environmental factors related to diet, behaviors, and chemical exposure which interact with genetic determinants to confer risk to CVD; (2) convoluted etiology that involves systemic perturbation in multiple tissues; (3) multidimensional perturbations at different molecular scales and the intricate interactions between the different scales.

Multi-tissue Pathologies

To further complicate the issue, CVD pathogenesis is highly systemic. Although CVD can originate from endogenous defects within the blood vessels or cardiomyocytes, systems-level studies have demonstrated that pathogenic factors from remote sites such as metabolic tissues (liver, adipose tissue), the immune and coagulation systems, and the central nervous system were all implicated in CVD development (Talukdar et al., 2016; Franzen et al., 2016; MacLellan et al., 2012; Malpas, 2010). More importantly, between-tissue communications and interactions are critical for the maintenance and dysregulation of cardiovascular system. Therefore, without a clear understanding of the roles of individual cells, tissues, and organs as well as the interactions among them, it is difficult if not impossible to fully understand CVD.

Multidimensional Molecular Perturbations

Within each cell or tissue involved in CVD, multidimensional molecular events connect and transmit genetic and environmental risk exposures to observable clinical outcomes (Fig. 1). According to the central dogma, genetic variations in the genome control the transcriptome and in turn affect the proteome. On top of this classic information flow, environmental risks factors can interact with the genome and perturb the epigenome such as DNA methylome, histone modifications, and chromatin structure to modulate the transcriptome and proteome. Additionally, the metabolome, either as products downstream of host proteome or products from gut microbiota, can also contribute to epigenomic modifications and subsequently transcriptional and translational alterations. Indeed, studies examining molecular changes in CVD at each of these dimensions have revealed extensive pathogenic perturbations.

In summary, the multilevel complexity described above substantiates the necessity to gather rich data that systematically measures all molecular entities in individual CVD-relevant cells or tissues under diverse risk conditions to describe CVD from a holistic perspective. Such efforts will help better illustrate the complex mechanisms of CVD in a tissue-specific and risk-specific fashion, thus facilitating mechanism-supported disease subtyping and precision medicine.

Bioinformatics Principles and Tools for CVD

With the advances of genomic technologies, the volume of omics-level datasets such as genome sequencing nearly doubles every year (Marx, 2013) and the complexity of data types and structures is also increasing. Consequently, the bottleneck of research output is gradually shifting from data acquisition to data analysis and interpretation. To accommodate the ever-growing size and complexity of the data, bioinformatics has seen dramatic advances in recent years, with new algorithms and tools published every day.

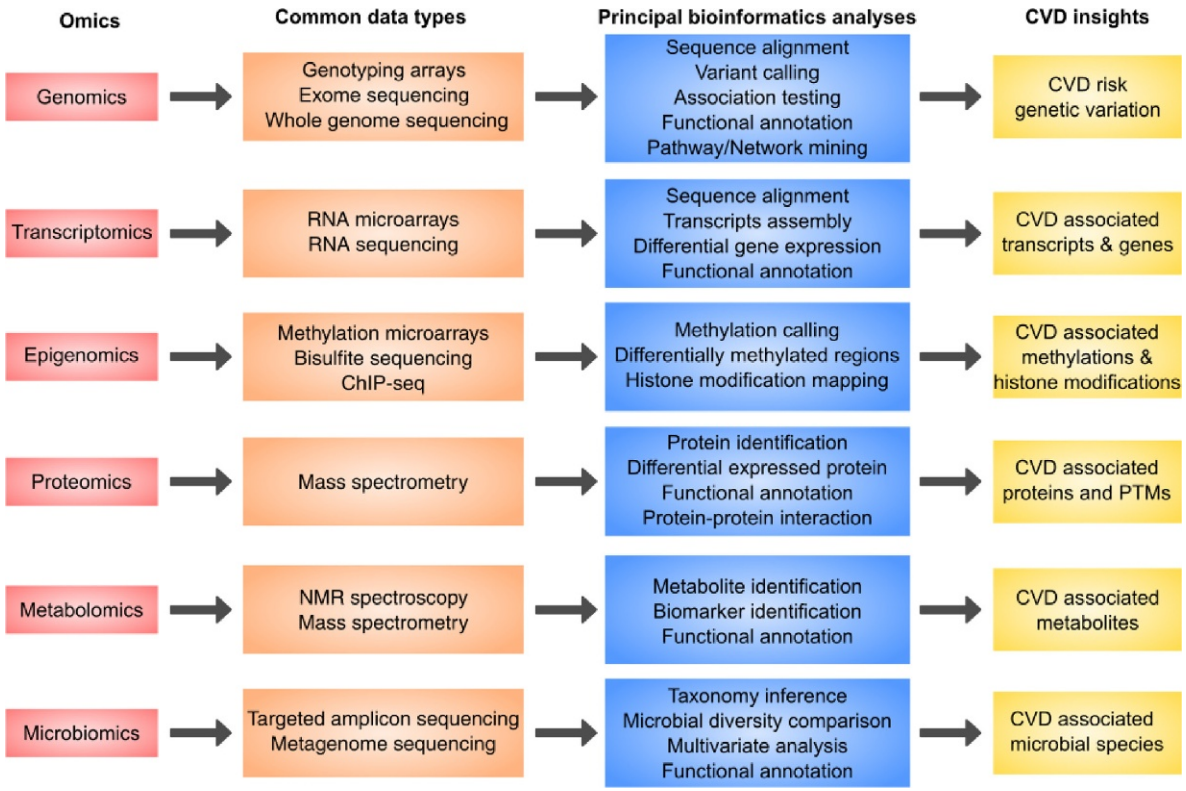

Fig. 2 Principal applications of bioinformatics on omics data for CVD.

Bioinformatics is a highly diversified field encompassing structured data storage, computing platforms, resource databases, and analytical algorithms and tools. We focus the current review on the principles and algorithms of bioinformatics tools for big data analysis, which are usually highly tailored to individual data types. Herein we introduce core bioinformatics principles and tools for commonly encountered data types in CVD studies (Fig. 2), including genomics (genotyping arrays, exome, and whole genome sequencing (WGS)), transcriptomics (microarrays, RNA sequencing), epigenomics (methylation microarrays, bisulfite sequencing, chromatin immunoprecipitation (ChIP-seq)), metabolomics (mass spectrometry (MS)), proteomics (nuclear magnetic resonance (NMR) spectroscopy, MS), and microbiota profiling (16S rDNA sequencing, metagenomics).

Genomics

Genomics measures DNA sequence variations that are heritable. The goal of CVD genomics is to identify heritable genetic risks of CVD, i.e., genetic variants that are associated with and likely causal for CVD development, through genetic association studies either in the form of linkage or genome-wide association analysis. Classic linkage analysis is powerful for Mendelian diseases or traits in which a single genetic locus of strong effect is involved but this methodology has limited power for complex diseases like CVD where a large number of genetic loci of moderate effect size are at play. Therefore, GWAS studies that screen for associations at dense genetic variants at genome scale have become a routine practice. In principle, genomics analysis involves the following steps: variant identification from either array-based genotyping or next-generation DNA sequencing platforms, genome-wide analysis of variant-disease associations, in silico functional annotation of disease-associated variants, and pathway analysis, as detailed below.

Variant identification

Genetic variations manifest in various forms including single nucleotide polymorphisms (SNPs) and structural variations including insertions and deletions (indels), inversions, and copy number variations (CNVs). Detailed catalogs of these variations can be found at bioinformatics databases such as dbSNP (http://www.ncbi.nlm.nih.gov/projects/SNP/) for SNPs and The Database of Genomic Variants (http://dgv.tcag.ca/dgv/app/home) for structural variations. Among these, SNPs are the most common form (>10 million in the human genome) and hence the most studied type of DNA variation in GWAS of CVD.

High density genotyping arrays from Affymatrix and Illumina have been the dominant technologies to capture SNPs and CNVs. These arrays utilize the complementary hybridization properties of DNA sequences to design nucleotide probes specific for known SNPs and CNVs. Numerous algorithms and tools have been developed for different genotyping platforms to generate accurate genotype calls, as discussed in detail by LaFramboise (LaFramboise, 2009). For Affymetrix genotyping arrays, each generation has been tailored with specific algorithms (e.g., BirdSeed for the Affymetrix Human SNP Array 6.0), whereas for Illumina arrays, the

algorithm has been relatively stable and is implemented in the Illumina GenomeStudio software. The basic principle underlying the various algorithms and tools is to normalize and model the probe hybridization intensity measures for each SNP or CNV to estimate the most likely call for the allele and genotype of a SNP or the copy number of a CNV for a given sample.

More recently, as genome-scale sequencing has become affordable, whole exome sequencing (WES) that focuses on the protein-coding sequences and WGS that can additionally capture important noncoding regulatory regions like promoters and enhancers (Sims et al., 2014), have become increasingly adopted to detect all forms of genetic variations, both common and rare. The Exome Sequencing Project sponsored by the National Institutes of Health, Heart, Lung, and Blood has generated an invaluable WES resource called the Exome Variant Server (http://evs.gs.washington.edu/EVS/). A large number of variant calling pipelines have been developed, as discussed in detail by Pabinger et al. (Pabinger et al., 2014) and Hwang et al. (Hwang et al., 2015). The basic workflow underlying sequencing-based variant detection is to first align sequencing reads to reference sequences using aligners such as BWA (Li and Durbin, 2009), Bowtie2 (Langmead and Salzberg, 2012), and Novoalign (http://novocraft.com/), followed by variant calling using tools such as the Genome Analysis Tool Kit (DePristo et al., 2011; McKenna et al., 2010), Samtools mpileup (Li et al., 2009), and Freebayes (Garrison and Marth, 2012). The performance of the various pipelines differs by sequencing platforms (e.g., Illumina vs. Ion Torrent) and the types of variants being called (e.g., SNPs vs. indels). Therefore, it is important to follow the best practices recommended for different genotyping or sequencing platforms or to employ and compare multiple tools for variant detection. Following variant calling, various quality control steps are usually taken to detect and remove sex inconsistency, relatedness, batch effects, and population substructure, and to calculate variant and sample call rates to assess quality and remove outliers. These quality control steps can be performed using a robust and popular tool called PLINK (Purcell et al., 2007).

Genetic association testing

To model the association between SNPs or other genetic variations with CVD susceptibility, it is important to first consider the study design (e.g., case-control or population study) and the data type of the phenotype (e.g., categorical or quantitative), because the statistical tests for association analysis are highly dependent on these factors (Cordell and Clayton, 2005). For instance, when comparing CAD cases vs. control individuals, Chi-square test and logistic regression can be used to test the differences in allele or genotype frequencies of individual SNPs between the two populations using the disease status as the categorical endpoint; whereas for population studies of quantitative traits such as cholesterol levels, the parametric linear statistical analysis is one of the most commonly used methods due to its theoretical robustness and ease of implementation using software packages like R, Matlab and SAS. PLINK represents a specialized tool that implements an array of statistical tests suitable for different study designs (Chang et al., 2015; Purcell et al., 2007). Additionally, linear mixed model based tools such as EMMA (Kang et al., 2008) and GEMMA (Zhou and Stephens, 2012) can efficiently account for population structure in genetic association tests.

Association testing of individual variants works well for common variants, but it is severely underpowered for rare variants due to the low frequency of each variant and high abundance of rare variants. To resolve this issue, gene or region-based tests which evaluate the aggregated effect of multiple markers, such as burden tests (Li and Leal, 2008), variance-component tests (Wu et al., 2011), and exponentially combined tests (Chen et al., 2012), have been developed.

Annotation and exploration of functional implications of CVD variants

The most intuitive steps following a GWAS study are to identify the true causal variants and subsequently capture the causal genes. Although the linkage disequilibrium structure helps to significantly reduce the number of candidate variants, there are often tens to hundreds of variants remaining at each risk locus (Yang et al., 2012). Sophisticated statistical framework can be applied to further refine the association signals and quantify the posterior probability of each variant being causal by jointly modeling the association statistics of all variants in a given locus (Hormozdiari et al., 2014). Functional annotation can also be achieved based on knowledge-driven information using tools such as GRAIL (Raychaudhuri et al., 2009) and DEPICT (Pers et al., 2015), as demonstrated in the investigation of CAD loci by (Braenne et al., 2015). In addition, ANNOVAR (Wang et al., 2010), fgwas (Pickrell, 2014), and PAINTOR (Kichaev et al., 2014) stand as popular tools that evaluate the functional importance of variants using functional genomic information derived from resources like ENCODE (Encode Project Consortium et al., 2007; Encode Project Consortium, 2012). Variants that affect the coded amino acids, gene expression, and splicing are more likely to be causal.

Functional genomics studies that identify intermediate quantitative trait loci can also serve as the fundamental basis of functional annotation of genetic variants (Yang, 2012; Meng et al., 2013). Genetics of gene expression studies that identify expression quantitative trait loci (eQTLs) (Schadt et al., 2008) can be especially useful to reveal candidate causal genes for CVD (Folkersen et al., 2010; Braenne et al., 2015; Yang, 2012). The GTEx study also provides an eQTL browser for quick eQTL-gene mapping (Lonsdale et al., 2013). Advanced tools based on Mendelian randomization can also integrate summary-level GWAS data and eQTLs to identify CVD associated genes (Zhu et al., 2016).

Pathway analysis

Complementary to single-variant functional analysis, GWAS-based pathway analysis has been widely used to derive biological pathways that are enriched for disease associated variants (Segre et al., 2010; Shu et al., 2016; Zhong et al., 2010). Popular tools include MAGENTA (Segre et al., 2010), iGSEA4GWAS (Zhang et al., 2010), GSA-SNP (Nam et al., 2010), and GSEA-SNP (Holden et al., 2008). We have also recently implemented a Marker Set Enrichment Analysis that incorporates functional information such as eQTLs into the pathway analysis (Shu et al., 2016). Despite differences in confounder correction and enrichment statistics, the conceptual basis of GWAS-based pathway analysis tools is similar, which is to evaluate the disease relevance of a pathway based on

the overall association strengths of variants assigned to the genes in the given pathway. The primary advantage of such methods is that they can fully utilize the whole spectrum of association information provided by a GWAS, thus substantially improving the statistical power to reveal hidden biology not captured by a few top variants.

Application of genomics in CVD

In recent years, painstaking efforts have been devoted to GWAS to perform genome-wide screening of common variants. Such efforts have identified significant associations of numerous common DNA variations with CVD and related traits (Nikpay et al., 2015; CARDIoGRAMplusC4D Consortium et al., 2013; McPherson and Tybjaerg-Hansen, 2016; Kessler et al., 2016). For instance, the most recent GWAS catalog (https://www.ebi.ac.uk/gwas/; accessed in September 2016) has documents 71 loci for CAD, 13 for MI, 43 for stroke, and 5 for PVD. Several interesting observations have emerged from the genome-scale discovery studies. First, the GWAS loci not only captured well-known risk pathways such as cholesterol and lipid metabolism, immune response, and inflammation, but also unraveled under-appreciated risk processes such as mitochondrial respiration, TGF-beta signaling, and actin networks (Nikpay et al., 2015). Second, the majority of the discovered loci only moderately alter the susceptibility of CVD and are located in noncoding regions. Third, the total heritability explained by the top loci is far below the estimated genetic heritability of individual CVD.

These common-variant-focused GWAS have been recently supplemented by WES and WGS studies that enhance our ability to capture association of rare variants with CVD phenotypes (Galmiche et al., 2011; Ghezzi et al., 2012; McPherson and Tybjaerg-Hansen, 2016; Kessler et al., 2016). For example, recent WES studies have identified rare variants in the coding regions of genes in lipoprotein metabolism to be significantly associated with CAD (Myocardial Infarction Genetics Consortium et al., 2014; Crosby et al., 2014; Do et al., 2015). Successful application of pathway analysis on CVD GWAS has led to novel biological insights that are otherwise difficult to capture (C. ARDIoGRAMplusC4D Consortium et al., 2013; Makinen et al., 2014; Ghosh et al., 2015).

Transcriptomics

Transcriptomics reflects the immediate transcriptional consequences of genetic level perturbations and has the potential to bridge the gap between genetics and other omics layers or CVD traits. Transcriptomic studies on CVD can help identify important transcripts and genes that either contribute to the pathogenesis of CVD or serve as biomarkers of CVD pathology. Gene expression microarrays and high-throughput RNA sequencing (RNA-seq) are the most common technological platforms for transcriptomic profiling. Microarrays are designed based on known transcripts or genes. Compared to microarrays, RNA-seq has higher sensitivity, dynamic range, and the ability to capture novel transcripts or splicing events (Wang et al., 2009). Due to these advantages, RNA-seq has received increased popularity and application. More recently, parallel single cell RNA-seq technologies such as Fluidigm and Drop-seq offer tremendous value in learning the molecular circuits in individual cells of heterogeneous tissues (Hashimshony et al., 2012; Macosko et al., 2015). Here we introduce the fundamental bioinformatics concept and tools for microarrays and RNA-seq analyses.

Analysis of gene expression microarrays data

Microarrays on different RNA species such as mRNA (Hwang et al., 2002), microRNA (van Rooij et al., 2008; Kuwabara et al., 2011) and long-noncoding RNA (Li et al., 2013; Ounzain et al., 2015) have helped identify novel biomarkers and mechanistic insights of CVD, although technically noncoding RNAs belong to the epigenome which we will discuss in the next section. Common platforms are from Affymatrix and Ilumina, although Agilent arrays were also used in earlier studies. Bioinformatics toolkits for microarrays have matured over the past decades, with a wide array of commercial and open-source computational libraries available to effectively handle the workflow of microarray analytical pipelines, including preprocessing data from different platforms to derive measurements of gene or transcript expression levels, data normalization, quality control, differential expression (DE) analysis, and result visualization (www.agilent.com) (Ritchie et al., 2015; Du et al., 2008). Normalization and DE analysis are usually the steps that require the most attention. Technical guidance about the selection of normalization methods has been discussed in detail previously (Quackenbush, 2002; Smyth and Speed, 2003). Although there are numerous variations for DE analysis, *t*-test, and linear model are typically the core underlying elements of different methods (Cui and Churchill, 2003). For Affymatrix microarrays, the affy and limma R Bioconductor packages are widely used. For Illumina microarrays, the GenomeStudio software by Illumina and the lumi R Bioconductor package are popular choices.

Analysis of next-generation RNA sequencing data

Compared to the maturity of microarray analysis methodologies, tools for RNA-seq analysis are currently undergoing rapid development. The basic steps of RNA-seq data analysis include sequence read alignment, read assembly and quantification of gene abundance at gene, transcript, exon levels, DE analysis, and alternative splicing detection. At each analysis step, numerous methods and tools have been developed. For read alignment, the widely used tools are BWA (Li and Durbin, 2009), Bowtie2 (Langmead and Salzberg, 2012), and Novoalign (http://novocraft.com/). More recently HISAT (Kim et al., 2015) has been introduced as a more efficient aligner. For read assembly and transcripts abundance quantification, Cufflinks (Trapnell et al., 2010; Trapnell et al., 2012), StringTie (Pertea et al., 2015) and Ballgown (Frazee et al., 2015) are available. For DE analysis, EdgeR (Robinson et al., 2010), DESeq (Anders and Huber, 2010), Voom (Ritchie et al., 2015), and Ballgown (Frazee et al., 2015) are widely adopted. In terms of alternative splicing identification, popular tools include Cufflinks (Trapnell et al., 2013), GSNAP

(Wu and Nacu, 2010), DEXSeq (Anders et al., 2012), and rMATS (Shen et al., 2014). In addition to these individual methods, computational pipelines that assemble various tools in a sequential manner also exist to facilitate streamlined analysis of RNA-seq data, among which the most notable are TopHat, Cufflinks, and Cuffdiff pipeline (Trapnell et al., 2012), and a more recent HISAT, StringTie, and Ballgown pipeline (Pertea et al., 2016). Importantly, no consensus has yet been reached about the best practices for RNA-seq analysis, and different tools have highly variable behaviors under different study designs, sample sizes, data heterogeneity, as well as the metrics used for performance evaluation (Seyednasrollah et al., 2015).

Functional annotation of gene signature

A transcriptome study typically generates a large number of signature genes that are associated with a disease and it is important to extract biologically meaningful insights from this data. Therefore, categorizing the disease signature genes into molecular pathways can help interpret the transcriptome data. A wide spectrum of pathway analysis tools have been released, each with its own unique advantages and disadvantages (Khatri et al., 2012). One particular web-based tool, DAVID (Huang et al., 2009), offers a user-friendly solution that allows users to flexibly upload lists of genes and easily retrieve the enriched pathways in the gene lists. However, focusing on limited numbers of top signature genes can often lead to the loss of valuable information on genes with subtle but biologically meaningful changes. Tools like gene-set enrichment analysis (GSEA) have been developed to overcome this challenge (Subramanian et al., 2005). The core concept of GSEA is to evaluate the enrichment of differentially expressed genes at the level of gene sets, which can be common biological functions, pathways, chromosomal regions, or regulatory targets. GSEA is able to take advantage of both the expression abundance data and rich knowledge-driven annotation databases like GO (Ashburner et al., 2000), KEGG (Kanehisa and Goto, 2000), and Reactome (Schmidt et al., 2006), to extract gene sets whose member genes show coordinated patterns of up or downregulation without the need to predefine a statistical cutoff to determine the DE of individual genes.

Application of transcriptomics in CVD

Transcriptomics is the most widely used omics approach to study CVD and there are numerous applications of gene expression microarrays and more recently RNA-seq in CVD research. As a result, numerous tissue-specific transcriptomics datasets and signatures have been generated by the CVD community over the past decades and we will not review in detail but only exemplify with a few studies here. In the Framingham Heart Study, (Joehanes et al., 2013) and (Huan et al., 2013; Huan et al., 2015a) have detected blood gene signatures of CVD and blood pressure by comparing the gene expression patterns measured with microarrays. In another example, (Yang et al., 2010) identified aorta gene expression signatures from microarray analysis of atherosclerosis development in both $Apoe^{-/-}$ and $Ldlr^{-/-}$ mouse models. Using RNA-seq, Liu et al. identified gene signatures in different heart failure subtypes and used these signatures to accurately classify heart failure status in a patient population (Liu et al., 2015). In another study, Lee et al. performed a comprehensive characterization of transcriptome in murine hearts by identifying novel exons and transcript clusters (Lee et al., 2011).

Epigenomics

Epigenomics measures various DNA modifications and gene regulatory mechanisms that do not involve DNA sequence changes or genetic variations. The types of epigenetic mechanisms include DNA methylation, histone modifications (methylation, acetylation, phosphorylation, DP-ribosylation, and ubiquitination), chromatin modification, and ncRNAs (microRNAs, long noncoding RNAs or lncRNAs, small interfering RNAs). The epigenome plays a pivotal role in the dynamic regulation of gene expression and is a critical mediator of the influence from environmental factors. Therefore, alterations of the epigenome could help to explain gene by environment interactions that are hypothesized as one of the major contributors to CVD. Indeed, various epigenetic changes have been associated with CVD events and related risk factors (Ordovas and Smith, 2010; Baccarelli et al., 2010; Zhong et al., 2016).

To measure the epigenome, a number of approaches have been developed. Methods for DNA methylome measurements include restriction enzyme-enriched sequencing techniques, affinity-enrichment-based sequencing techniques, DNA methylation arrays, reduced representation bisulfite sequencing, and whole-genome bisulfite sequencing, each with its unique advantages and disadvantages (Heyn and Esteller, 2012; Laird, 2010). For histone modifications and chromatin organization, various sequencing-based methods, such as ChIP-seq, FAIRE-seq, and DNase-seq have become readily available, as reviewed in detail by others (Morozova and Marra, 2008; Telese et al., 2013). For ncRNA profiling, RNA-seq can be used with modifications in the sample processing and RNA extraction steps (Pritchard et al., 2012). Here we introduce the bioinformatics principles and tools for a few commonly used epigenomic platforms.

DNA methylation arrays

Microarray-based methylation profiling is the most commonly used method to retrieve genome-wide methylation profiling, and has contributed to the generation of first-hand evidence linking global methylation perturbations to CVD events (Sharma et al., 2008; Sharma et al., 2014; Zaina et al., 2014; Kim et al., 2010). DNA methylation typically occurs at the cytosine of CpG dinucleotide sites. The Illumina platform is a popular technical solution for methylation profiling at single CpG site resolution and comes in two common sizes which profile 27 k and 450 k CpGs respectively (Bibikova et al., 2011). Additionally, smaller, custom, targeted methylation arrays are available from 48 to 384 loci (that is VeraCode GoldenGate arrays). Similar to gene expression microarrays, mature computation pipelines Methylumi (Davis et al., 2012) and minfi (Aryee et al., 2014)) are available

to handle critical analytical processes of methylation data including quality control, normalization, and differentially methylated region identification. Minfi also provides advanced analytical functions including methylation block finding and subset-quantile within-array normalization that reduce the within- and between-array technical variation (Maksimovic et al., 2012).

Bisulfite sequencing

Bisulfite sequencing is used for profiling of DNA methylation. Bisulfite sequencing leverages the fact that methylated cytosine remains unaffected under bisulfite treatment, whereas unmethylated cytosine will be converted to uracil. Whole genome bisulfite sequencing (WGBS) is enabled by the advance in next-generation sequencing technologies to analyze genome-wide DNA methylation at single-nucleotide resolution. As a variant of WGBS, reduced representation bisulfite sequencing (RRBS) is a method that first enriches for the genome regions with high CpG content using methylation-sensitive restriction enzymes, thus avoiding the high cost associated with WGBS (Meissner et al., 2005). Similar to RNA-seq discussed earlier, the analysis of RRBS and WGBS involves alignment of sequence reads to a reference genome, followed by the estimation of the methylation percentages at individual CpG sites. Common algorithms for WGBS and RRBS reads mapping include "wild card" (allowing either Cs or Ts to map to Cs) and "three letter" aligning (all Cs are converted to Ts), which are supported by numerous tools like BS Seeker (Guo et al., 2013) and Bismark (Krueger and Andrews, 2011). Performance comparison of different mapping tools has been discussed previously (Kunde-Ramamoorthy et al., 2014). Methylation percentages at each cytosine can be computed and compared between groups to detect differentially methylated CpG regions (DMRs) using tools such as methylKit (Akalin et al., 2012), DMAP (Stockwell et al., 2014), MOABS (Sun et al., 2014), and metilene packages (Juhling et al., 2016). The statistics underlying DMR detection can be Fisher's exact test (Akalin et al., 2012), logistic regression (Akalin et al., 2012) or *t*-tests (Hansen et al., 2012).

ChIP-seq

For epigenomics, ChIP-seq has been mainly utilized to characterize histone modifications, DNA methylation, and nucleosome positioning (O'Geen et al., 2011; Furey, 2012; Landt et al., 2012). In ChIP-seq, antibodies are first used to immunoprecipitate different types of chemical modifications or DNA binding proteins along with cross-linked DNA to enrich the genomic DNA sites of interest such as specific types of histone modification sites. The enriched genomic DNA is then sequenced. Technical challenges involved in ChIP-seq experiments include antibody quality, obtaining large numbers of required cells, and previous knowledge of a histone modification or DNA-binding protein location (Furey, 2012). Similar to RNA-seq and RRBS, ChIP-seq reads need to be mapped to the reference genome using aligners, as described previously. Once reads have been aligned, the next step involves determining "peaks" where binding signals are enriched. There are a number of popular strategies for peak calling including MACS (Zhang et al., 2008), PeakSeq (Rozowsky et al., 2009), and ZINBA (Rashid et al., 2011). Among these methodologies, MACS is the most simplistic, fitting the data to a Poisson distribution; whereas both PeakSeq and ZINBA take into account the mappability of genomic regions where significant peaks are determined against a null random background distribution. Once these peaks have been called, individual peaks can be compared between samples using tools that are traditionally used in differential gene expression like EdgeR (Robinson et al., 2010) and DESeq (Anders and Huber, 2010). Both methods have similar underlying methodologies where they call differential peaks by modeling the data as having a negative binomial distribution and use a modified Fisher's exact test (Robinson and Smyth, 2008). Histone modification signals are generally diffused and lack well-defined peaks, posing unique technical challenges to map epigenetic states from ChIP-seq data (Wang et al., 2008). Therefore, new algorithms have been developed based on spatial clustering (Zang et al., 2009) or hidden Markov models (Song and Smith, 2011) to improve the signal-to-noise ratio. The chromatin landscape can be further correlated to transcriptional regulation elements like enhancers to better clarify the whole regulatory circuitry (Wamstad et al., 2012).

Application of epigenomics in CVD

The relationship between CVD and each type of epigenetic marker measured with various technological platforms has been under intensive investigation, and the involvement of all types of epigenomic mechanisms ranging from DNA methylation and histone modification, to noncoding RNAs is strongly supported. For example, RRBS has been used to link global methylation events with CVD (Sharma et al., 2008; Zaina et al., 2014), revealing a hypermethylation pattern in the atherosclerotic lesions that connects to pathways related to endothelial and smooth muscle functions. ChIP-seq has also been used to reveal differential histone methylation profiles associated with heart failure (Movassagh et al., 2011). The role of noncoding RNAs in CVD has been supported by a number of studies of microRNAs and lncRNAs (Wu et al., 2014; Kataoka and Wang, 2014; Uchida and Dimmeler, 2015; Huan et al., 2015b;Klattenhoff et al., 2013).

Proteomics

Proteomics is the large-scale investigation of proteins, the vital functional unit of living organisms. Importantly, despite being the translational product of mRNA, transcriptomic level expression is poorly correlated with protein levels, making it difficult to predict protein expression from transcriptome profiling (McGregor and Dunn, 2006). Proteomics can help comprehensively characterize protein alterations in the process of CVD and capture posttranslation modifications (PTMs), thereby facilitating the identification of protein level biomarkers, regulatory mechanisms, and potential therapeutic targets. A number of proteomics technologies have been developed, including one- and two-dimensional gel electrophoresis (2D-GE), protein chip, high-performance liquid chromatography, and MS (Breker and Schuldiner, 2014). The protein identification step is highly dependent on the technological

platforms and has been discussed in detail by other reviews (Altelaar et al., 2013; Larance and Lamond, 2015). Here we focus on the bioinformatics tools in the differential and functional analyses.

Differential protein expression

Similar to the other omics fields, comparison of protein levels under different conditions can help prioritize important proteins in pathogenesis. Although statistical and computational frameworks discussed for transcriptomics studies may also be applied in proteomics, there are challenges unique to proteomics (Langley et al., 2013). First, label-free protein expression data usually contains missing values for proteins with low abundance, which could break the normality assumption of statistical tests like *t*-test, ANOVA, and linear regression. In addition, most proteomics studies involve small sample sizes due to the relatively low throughput of proteomics technologies and therefore could suffer from high noise-to-signal ratio. For MS, this challenge can be alleviated by methods like (1) normalized spectral index (Griffin et al., 2010) which combines multiple abundance features and eliminates variance between MS measurements, and (2) hybrid-based approach (Wang et al., 2012) that combines the advantages of intensity-based and presence/absence-based protein quantification.

Functional annotation

The previously mentioned pathway and functional gene set databases used for annotating transcriptomic data can also be applied to proteomic data, in combination with gene set enrichment analysis tools like GSEA (Isserlin et al., 2010). In addition, protein-specific annotation resources like Protein Analysis Through Evolutionary Relationships (PANTHER) which performs comprehensive evolutionary and functional classification using a webserver (Mi et al., 2016), are also available. Protein-protein interactions (PPI) are also important determinants of protein functions and are critical for biological processes (Stelzl et al., 2005). There are a number of public PPI repositories that vary by data source and method of construction and organizing interactions, like the Human Protein Reference Database (Prasad et al., 2009) and STRING (Szklarczyk et al., 2015), as detailed elsewhere (Lage, 2014).

Application of proteomics in CVD

Wide-spread proteomic alterations have been captured in CVD (Sharma et al., 2013; Lindsey et al., 2015). In addition, proteomics studies have been carried out in multiple CVD related cell types including arterial smooth muscle cells (Dupont et al., 2005), cardiomyocytes (Stastna et al., 2010), and pro-angiogenic cells (Urbich et al., 2011), as well as subcellular regions such as the mitochondrial proteome (Taylor et al., 2003) and the extracellular matrix (Barallobre-Barreiro et al., 2012). Moreover, these efforts have been pooled into public proteomics data repositories such as the Human Proteome Map (Kim et al., 2014) and the Proteomics Identification Databases (Vizcaino et al., 2013), allowing for efficient protein identification and quantification for future proteomics studies. In CVD, PPI information is usually contextualized in the form of networks that bear additional structural and functional relationships through the topological layouts. The networks can be used to interrogate novel functional complexes and regulatory hubs for CVD (Li et al., 2014a; Ren and Liu, 2013; Magger et al., 2012).

Metabolomics

Metabolomics platforms and tools

Metabolomics focuses on metabolites that are traditionally considered the final stops of biological information flow, reflecting perturbations in the genome, epigenome, transcriptome, and proteome, although metabolites can also feedback to the gene regulation process by modulating the epigenome. Typically, a metabolomics study can take a targeted approach to specifically measure predesignated metabolites involved in certain pathways or biological functions, or an untargeted approach, where no prior knowledge of metabolites selection is needed (Kordalewska and Markuszewski, 2015). Advances in MS and NMR spectroscopy have made it possible to perform rapid identification and quantification of hundreds of metabolites in signaling, receptor binding, translocation, and biochemical reaction pathways (German et al., 2005). Each platform has inherent advantages and disadvantages, such as the high reproducibility but a low sensitivity in NMR-based techniques compared with MS-based techniques (Gibbons et al., 2015; Gika et al., 2014).

Bioinformatics is applied in the data processing and analysis steps in metabolomics studies (Johnson et al., 2016). The data processing workflow typically involves data conversion, feature detection, data set alignment, normalization, metabolite identification, and quality control (Sugimoto et al., 2012). Pipelines like MetaboAnalyst offer step-wise functional modules to complete the whole processing workflow (Xia et al., 2012). The accurate identification of metabolites is further powered by metabolite annotation databases like The Human Metabolome Database (Wishart et al., 2009). In addition, functional analysis can be performed by comparing lists of metabolites with predefined functional groups like KEGG metabolic pathways (Xia et al., 2015; Xia and Wishart, 2010b; Xia and Wishart, 2010a), where metabolites can be related to each other and provide targets for downstream mechanistic studies.

Application of metabolomics in CVD

Metabolomics studies have successfully contributed to the identification of metabolite biomarkers associated with atherosclerosis (Wurtz et al., 2012), CAD (Laborde et al., 2014), MI (Mohamad et al., 2015), and CVD (Wang et al., 2011). The association between the plasma concentration of choline, betaine, and trimethylamine-N-oxide (TMAO) with the increased risk of CVD is probably the most prominent and robustly validated metabolomics discovery in the field (Koeth et al., 2013; Wang et al., 2011;

Tang et al., 2013), and has led to the encouraging establishment of new CVD therapy (Wang et al., 2015). Metabolomics has also been integrated with GWAS to establish functional link between genetic variants, intermediate metabolic traits, and CVD relevant endpoints (Suhre et al., 2011).

Microbiota

The intestinal microbiota consists of trillions of commensal microorganisms that mediate the effect of diet, the primary environmental determinant of CVD. As the major processing station for food, microbiota are closely involved in the homeostasis of metabolites, thus establishing a link with the metabolome (Wikoff et al., 2009). Microbiota can be classified into various taxa including kingdoms, phyla, classes, orders, families, genera, and species based on sequence similarity and phylogenetic information. Here we focus on bioinformatics for microbial DNA assessed by two approaches: (1) targeted amplicon analysis which only focuses on a few selected marker DNA sequences that can differentiate bacterial species and (2) metagenomics in which the whole microbiota DNA sequence is interrogated.

Targeted amplicon profiling

Bacteria carry unique DNA sequences that are absent in eukaryotes and can reflect bacterial speciation. One such bacterial DNA sequence, the 16S rDNA, encodes the 16S ribosomal RNA and is the most widely used amplicon for microbiota profiling because the gene sequence is highly conserved within bacteria of the same genus and species but different between genera and species (Woo et al., 2008; Janda and Abbott, 2007). Briefly, whole DNA from gut microbiota is isolated and 16S rDNA is amplified and then sequenced. The 16S rDNA sequence data is clustered into operational taxonomic units (OTUs, microorganisms grouped by the similarity of their DNA sequences), either with or without reference information of known taxa. Reference based OTU clustering is getting more and more favorable due to the increasing aggregation of microbiota sequences in public repositories (Turnbaugh et al., 2007; Caporaso et al., 2010). Simultaneously, the phylogenetic relationships among sequences can also be inferred using the UniFrac method or phylogenetic diversity measurement (Lozupone and Knight, 2005; Faith and Baker, 2006). In addition to OTUs and phylogenetic trees, microbial diversity can be further dissected and visualized using analyses such as rarefaction curves (for within-community diversity) and principal coordinates analysis (PCoA, for across community diversity) (Kuczynski et al., 2012). The streamlined pipelines QIIME (Caporaso et al., 2010) and Mothur (Schloss et al., 2009) are available to conduct the above mentioned analyses.

Metagenomic profiling

Metagenome of human microbiota consists of a vast number of nonredundant genes with highly diversified functional composition (Li et al., 2014b). Unlike amplicon-based profiling that focuses on the determination of phylogeny from selected genes, metagenomics sequencing has the capacity to produce the whole sequences of all bacteria in a given biological sample and shed light upon the functional potential of the microbial community. However, the overwhelming volume, complexity, and lack of annotation resources of metagenomics data pose unique challenges to bioinformatics (Thomas et al., 2012). First of all, for metagenome assembly, classical reference-based methods are less favorable due to the enormous gap between microbial diversity and the coverage of reference database. As a result, numerous de novo metagenome assembly algorithms have been developed, such as the de Bruijn graph-based approach (Chaisson and Pevzner, 2008) and coabundance based segregation of metagenome (Nielsen et al., 2014).

The next critical step after assembly is to perform functional annotation of metagenomics data, where sequences can be mapped to known orthologous groups with well-documented functional descriptions that are deposited in various large annotation databases such as eggnog, KEGG, and COG (Huerta-Cepas et al., 2016; Kotera et al., 2015; Galperin et al., 2015). Both local software such as SmashCommunity (Arumugam et al., 2010) and webservers such as RAST and IMG/M (Meyer et al., 2008; Markowitz et al., 2012) are available for this task.

Lastly, to maximize clinical relevance, metagenomics studies typically aim to identify difference of features (organisms, clades, OTUs, genes, or functions) between samples or disease states. This can be a daunting task due to the large number of species and functional groups under investigation, and the high intersubject variability of microbial communities. Various advanced statistical models have been developed to address this need. For example, Metastats utilizes an extended *t*-test to detect differential features from the count data (White et al., 2009). On top of that, LEfSe (Linear discriminant analysis effect size) allows for the capture of differential features consistent with biologically meaningful categories (Segata et al., 2011). And MetaPath can further identify finer-level metabolic subnetworks by adopting a statistical framework to aggregate the sequence-level differences into biological pathways (Liu and Pop, 2011).

Application of microbiota profiling in CVD

Mounting evidence has suggested that microbiota is related to a wide spectrum of metabolic, immune response, and signaling events that are fundamental in cardiometabolic disease pathogenesis (Nicholson et al., 2012; Turnbaugh et al., 2006; Vijay-Kumar et al., 2010; Hansen et al., 2015). One exemplary piece of direct evidence connecting gut microbiota with CVD is from the studies on TMAO, which is generated by the microbial metabolism of choline (Griffin et al., 2015). The association of elevated plasma TMAO concentration and increased atherosclerosis and CVD risk has been found to be dependent on gut microbiota (Wang et al., 2011; Koeth et al., 2013). However, direct evidences linking specific microbiota alteration to CVD are still limited, with only a few genera suggested to be involved by small cross-sectional studies (Karlsson et al., 2012; Hansen et al., 2015).

Multiomics Data Integration

The above discussions are mainly focused on the bioinformatics aspects at individual omics levels. However, to fully disentangle the molecular underpinnings of CVD that connect pathogenic perturbations to the ultimate phenotypic manifestation, it is essential to holistically investigate the flow of biological information starting from the genetic perturbations to different intermediate components. We have comprehensively reviewed the principles and applications of systems-level data integration (Meng et al., 2013) and will only briefly summarize the principles here (**Fig. 3A**). First, multiomics integration typically requires coherent collection of various types of omics datasets from a study population under well-controlled conditions. When comprehensive datasets are not available from the same biological samples, it is also possible to integrate multidimensional omics data across studies. Omics data can be partitioned into three broad categories: genetics which carries causal information, intermediate omics (e.g., epigenomics, metabolomics, proteomics), and disease phenotypes. Next, pair-wise relationships within and between data types are analyzed. Within the same omic level, relationships between molecular entities such as protein-protein correlations and gene coexpression patterns are retrieved. This is typically performed using network modeling approaches such as the weighted gene coexpression network analysis (Langfelder and Horvath, 2008) and directional network construction. Such networks form the organizational maps among molecular entities and inform on functional relationship between molecules. Between omics dimensions, pair-wise associations are calculated, such as GWAS between genetic markers and disease phenotypes, genetics of gene expression or eQTLs analysis between genetic markers and gene expression, or correlations between microbiota and metabolites. Thirdly, causality modeling between intermediate markers and a disease phenotype can be performed using genetic markers as the causal anchor to

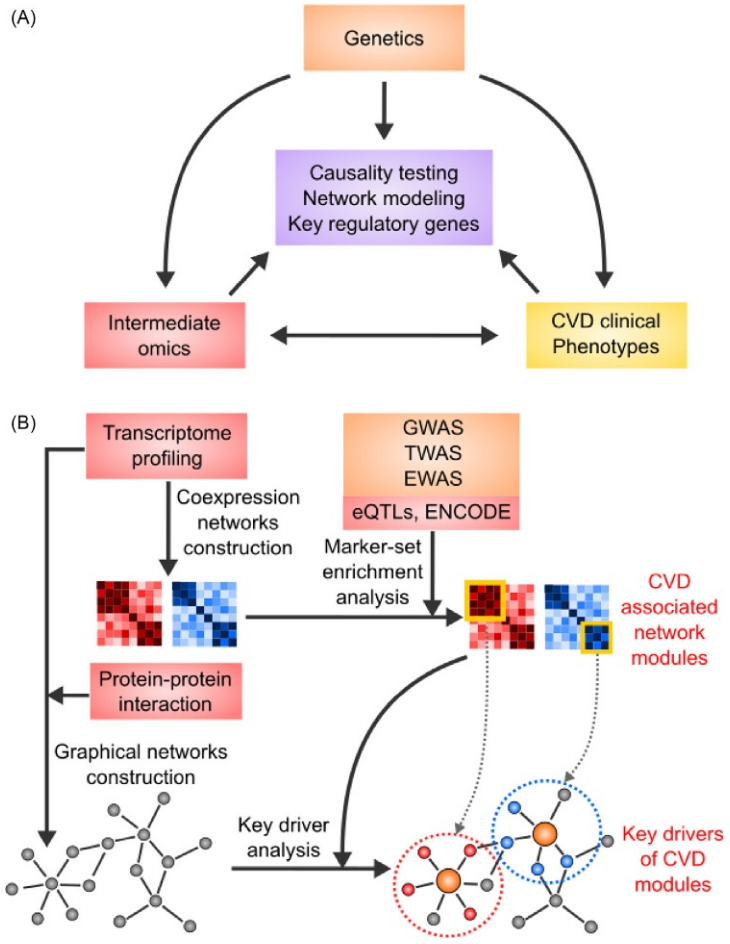

Fig. 3 Fundamentals of multiomics data integration for CVD. (A) A systems biology strategy that integrates different layers of big data relevant to CVD. Genetics causally drives the changes in intermediate omics (e.g., epigenome, microbiome, proteome, etc.) and CVD clinical phenotypes. Pairwise relationship between different data types can be retrieved. This information can further enable systems-level integration through approaches such as causality testing, network modeling, and identification of key regulatory genes. (B) Mergeomics, a multiomics data integration framework to study CVD. First, transcriptomic profiling data is used to construct CVD-related coexpression networks. This can lead to the identification of CVD associated network modules by leveraging different types of omics-wide association, eQTLs, and ENCODE data using the Marker-set Enrichment Analysis. On the other hand, transcripts and protein level interaction data can be used to generate biologically relevant graphical networks. Interrogating networks using the Key Driver Analysis helps reveal key drivers of CVD modules that serve as candidates for downstream investigation. *GWAS*, genome-wide association study; *TWAS*, transcriptome-wide association study; *EWAS*, epigenome-wide association study.

determine which intermediate markers are likely causal for the disease. Lastly, biological pathways and molecular networks that are informed by the multiomics datasets are retrieved and differentiated into causal and reactive pathways and networks based on genetic information and causal inference. The causal pathways and networks can be further analyzed to retrieve key regulatory genes that are central and connect with a large number of disease genes in the network organization. These predicted regulatory genes, once mechanistically tested and validated, may serve as more effective drug targets. The advantage of this integrative framework not only utilizes data patterns but also explicitly considers the intrinsic biological relationships between omics data types.

Multiomics integration tools

Although methods and tools for individual components of the above described workflow have been developed, convenient pipelines or tools for multiomics integration are sparse at present. The limited number of multiomics integration tools mostly target cancer research, such as iCluster. iCluster implements a joint latent variable model to facilitate clustering of different types of data and it has been applied to integrating mutation, CNV, DNA methylation, and gene expression data to determine tumor subtypes in glioblastoma (Shen et al., 2012). This type of tool mainly uses data patterns and does not consider the intrinsic biological relationships between data types and may limit mechanistic discoveries. To facilitate more general applications of multiomics integration in various disease areas and enable mechanistic insights, we have recently developed a flexible and convenient computational pipeline Mergeomics, both as an R package (Shu et al., 2016) and as a user-friendly web server (Arneson et al., 2016), to implement the integration workflow described above and to identify disease networks, pathways, and key regulators that are informed by multiomics data sets (**Fig. 3B**). Mergeomics takes as input (1) summary level marker-disease association information from genome-, transcriptome-, epigenome-, proteome-, and metabolome-wise association analysis, (2) functional relationship or causal information between omics markers and genes, (3) membership of genes in pathways or molecular networks, and (4) molecular network topology information. The outputs include pathways and networks associated with a disease and a list of prioritized potential regulatory genes; when genetic information is given, the genes, pathways, and networks are putatively causal.

Application of multiomics data integration in CVD

A number of pioneering studies published in recent years have exploited the power of multidimensional data integration in understanding the etiology of CVD. Earlier multiomics studies in CVD were mainly conducted in mouse F2 crosses with genomics and transcriptomics as the main data types (Wang et al., 2007; Yang et al., 2010). More recently the data types have been expanded to epigenomics, metabolomics, proteomics, and microbiota in the hybrid mouse diversity panel (HMDP) comprised of ~100 inbred and recombinant inbred mouse strains (Bennett et al., 2010; Parks et al., 2013; Bennett et al., 2015). Multiomics studies in human populations are also emerging (Huan et al., 2015b; Inouye et al., 2010; Inouye et al., 2012; Talukdar et al., 2016; Franzen et al., 2016). For example, taking advantage of genetic and gene expression data from relevant tissue samples of CAD patients, the Björkegren group (Franzen et al., 2016; Talukdar et al., 2016) constructed regulatory gene networks and identified both CAD-causal subnetworks and key drivers. The relationship between key drivers and CAD related phenotypes was further prioritized and validated using HMDP and siRNA knockdown. They also revealed a tissue-specific expression pattern that is dependent on the CAD genetic susceptibility of participants.

As direct access to internal tissues relevant to CVD is not always possible in human studies, integration of multidimensional omics data across studies and species has also been extensively explored over the past years (Makinen et al., 2014; Zhao et al., 2016). For example, using CAD GWAS from the CARDIoGRAM study and tissue-specific transcriptomics, eQTLs, and gene networks from a multitude of studies, Makinen et al. captured an array of CAD associated pathways and networks (Makinen et al., 2014). These pathways/modules are projected onto tissue-specific Bayesian networks to identify novel CAD key regulators. In another study by Zhao et al., CAD GWAS, transcriptomic profiling in CAD patients and controls, and network modeling were used to unravel tissue-specific relations among the CAD candidate genes at top CAD loci (Zhao et al., 2016).

Considerations, Challenges and Remaining Gaps

Special Statistical and Computational Considerations of Omics Data

Multiple testing correction

One key feature common to all omics platforms is the large number of variables measured (e.g., millions of SNPs in genomics and tens of thousands of genes in transcriptomics). Consequently, the number of statistical tests performed within each omics level is large, which dramatically increases the random chance for spurious positive results. This phenomenon is called "multiple testing," and correcting for multiple testing is critical for determining the appropriate statistical cutoffs that minimize false discoveries. A number of statistical methods have been developed for multiple testing correction. Among these, the most convenient approach is Bonferroni correction, which is simply the desired p value cutoff (e.g., $p<0.05$) divided by the number of tests. For instance, $p<5\times10^{-8}$ is usually the cutoff used in GWAS to determine genome-wide significance of genetic loci, which is calculated by 0.05/(1 million tests). However, Bonferroni correction is likely too stringent as it assumes all performed statistical tests are independent, which ignores the intrinsic nonindependent relationships between molecular markers. Popular alternatives include the Benjamini-Hochberg false discovery rate (Benjamini and Hochberg, 1995), q-value (Storey and Tibshirani, 2003) and permutation test.

Data dimension reduction

Another consideration that is related to the large numbers of testable features and the multiple testing issue is to leverage dimension reduction techniques to reduce high dimensional data comprised of hundreds, thousands, or even millions of features into fewer dimensions based on coordinated behaviors of groups of molecular features. Principal component analysis (PCA) is the most commonly used approach for easy visual identification of outliers and batch effects and summarizing group behaviors (Nyamundanda et al., 2010). PCA is conducted by projecting features onto a set of orthogonal components which are arranged in decreasing order of variance explained using an eigenvalue decomposition. However, it can often be difficult to visualize all relevant combinations of principal components as only two dimensions can be visualized at once. The t-distributed stochastic neighbor embedding (*t*-SNE) is another useful dimensionality reduction technique which leverages the Kullback-Leibler divergence when only two dimensions are desired for visualization (van der Maaten and Hinton, 2008). As an alternative to PCA, partial least squares regression (Helland, 1988; Höskuldsson, 1988) is a supervised method based on correlation that fits a regression model to the features which have been projected to a new space and generates weights for each of the features. Other unsupervised learning methods, like hierarchical clustering, can leverage a "bottom up" or "top down" approach to decide whether clusters should be joined or split based on the chosen distance metric to find related features (Johnson, 1967). However, if the goal is not to group related features, random forests method (Breiman, 2001) allows for the most informative features to be selected for a particular attribute of interest. Therefore, these dimension reduction methods can not only detect and partition features that are statistically or functionally related, but can help detect data irregularities and alleviate the multiple testing burden.

Challenges and Remaining Gaps

As of September 2016, searching "CVD" in GEO returns ~350 unique datasets involving more than 30,000 samples and 200 platforms. Despite the rapid advances of bioinformatics, there are still challenges and gaps in tackling the formidable amount and complexity of CVD data. First, due to the imbalance of data availability of different omics types, most mature tools with robust performance were designed for genomics and array-based transcriptomics analyses. For the other data types, the availability and performance of methods and tools are highly variable. Therefore, better performing algorithms and methods are still in great need for newer data types such as RNA-seq. Second, while novel data analytic and mining approaches are being released on a daily basis, few of them adequately take intrinsic biological properties of data into consideration when designing algorithms. This could lead to false discoveries and artifacts even if the technical implementation is valid. Third, current bioinformatics efforts still mainly focus on methodologies specific to individual types of data, and analytical frameworks and tools that could effectively incorporate different data types and perform multiomics data integration are still limited. Fourth, algorithms and tools that can examine between-tissue interactions and conduct dynamic modeling of big data are lacking. Lastly, while the CVD community has collectively generated rich data and numerous published studies, this information is scattered and there is currently no comprehensive bioinformatics database that curates CVD-related multiomics datasets or platforms that summarize the biological findings from bioinformatics studies of CVD to allow queries of the valuable biological insights. More coordinated efforts are needed from the CVD research community to collectively improve the bioinformatics implementation in this promising area.

Conclusions and Future Directions

Owning to the rapid advances of modern molecular technologies, we are now moving towards realizing a systems-level understanding of CVD. Bioinformatics has played an indispensable role in this process. First of all, bioinformatics has proven to be invaluable in quality assessment and preprocessing of large-scale omics data into reliable and analyzable molecular profiles with majority of the quality issues, artifacts, and confounders removed or corrected. In addition, bioinformatics employs sophisticated statistical, mathematical, and computational modeling algorithms and techniques to reduce the complexity of data and retrieve biologically relevant molecular patterns at each omics level. Furthermore, given the systemic nature of CVD, bioinformatics enables sophisticated modeling frameworks that integrate different levels of omics data in a tissue-specific and biologically meaningful manner for comprehensive and novel mechanistic insights. Ultimately, whether researchers can effectively and properly utilize bioinformatics methods will determine how much hidden value can be eventually realized from multimillion dollar datasets.

For the CVD field, a main future direction of bioinformatics lies in facilitating the translation of the basic understanding of CVD into clinically relevant applications to improve the precision of diagnostics and therapeutics. In this regard, bioinformatics can disseminate both mechanistic insights and molecular biomarkers obtained from the omics studies through well-designed databases or query systems. This type of effort can enable more effective utilization of available data and avoid a waste of resources. Bioinformatics can also facilitate the design of diagnostic biomarker panels based on molecular patterns of CVD subtypes to improve diagnostic accuracy and enable personalized medicine. Moreover, bioinformatics can help predict novel drugs or drug targets and reposition existing drugs based on matching molecular patterns or mechanisms between CVD and drugs. Despite these promises, it is important to note that bioinformatics findings can be easily questioned for their robustness and accuracy. Thus it is imperative to push for more in-depth multidisciplinary collaborations between bioinformaticians and researchers on the bench and clinical sides, in order to speed up the validation and translation processes and fully realize the potential of bioinformatics in mechanistic discovery and translational medicine for CVD.

Introduction

Heart failure (HF) is defined as a "complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood" (Yancy et al., 2013). HF remains a growing epidemic and currently affects greater than 5 million people in the United States alone. Greater than 650,000 cases are diagnosed each year, and the incidence increases with advancing age. Furthermore, mortality remains high with 50% passing away within 5 years of diagnosis (Yancy et al., 2013). HF can be classified as HF with reduced ejection fraction (HFrEF) in patients who have an EF of $\leq$40% and HF with preserved ejection fraction (HFpEF) in those with an EF of $\geq$50%; those with EF values in between are considered to have borderline HFpEF (Yancy et al., 2013). Although HFrEF has multiple, evidence-based treatment options, therapies for HFpEF are still lacking.

Given this significant burden of disease as well as the complexity of the syndrome of HF, instruments to supplement the information ascertained from clinical history and physical exam are warranted. Biomarkers are useful tools to assist with diagnosis, risk stratification, and management of HF, and recently there has been an explosion in the discovery of new biomarkers as well as the volume of biomarker research (Januzzi and Felker, 2013). **Fig. 1** shows various established and emerging biomarkers.

Criteria for what constitutes a useful biomarker have been proposed by Morrow and de Lemos and are as follows: (a) to provide accurate and repeated measurements with short turnaround times, (b) to provide additional information beyond what can be ascertained from a thorough clinical assessment, and (c) to use results to aid in making clinical decisions (Morrow and de Lemos, 2007). Subsequent to these, Januzzi and van Kimmenade recommended the following criteria specific for HF biomarkers: (a) have been evaluated in a wide range of patients characteristic of the diagnosis with rigorous statistical methods; (b) can be easily, quickly, and accurately measured with defined biological variability and low analytical imprecision of the assay; (c) demonstrate an important component of HF pathophysiology, if extracardiac independently useful information for diagnosis, prognosis, disease progression, or therapy should be contributed; and (d) provide clinically useful information for caregivers and patients to assist in diagnosis, risk stratification, and management by adding to what can already be determined by standard clinical and laboratory data (van Kimmenade and Januzzi, 2012).

To date, only the natriuretic peptides (NP) fulfill the aforementioned criteria, and they remain the gold standard HF biomarker; however, there are multiple emerging biomarkers that are also gaining relevance. This article serves to review the use of the NPs as well as other promising biomarkers in the diagnosis, risk stratification, and management in patients with HF.

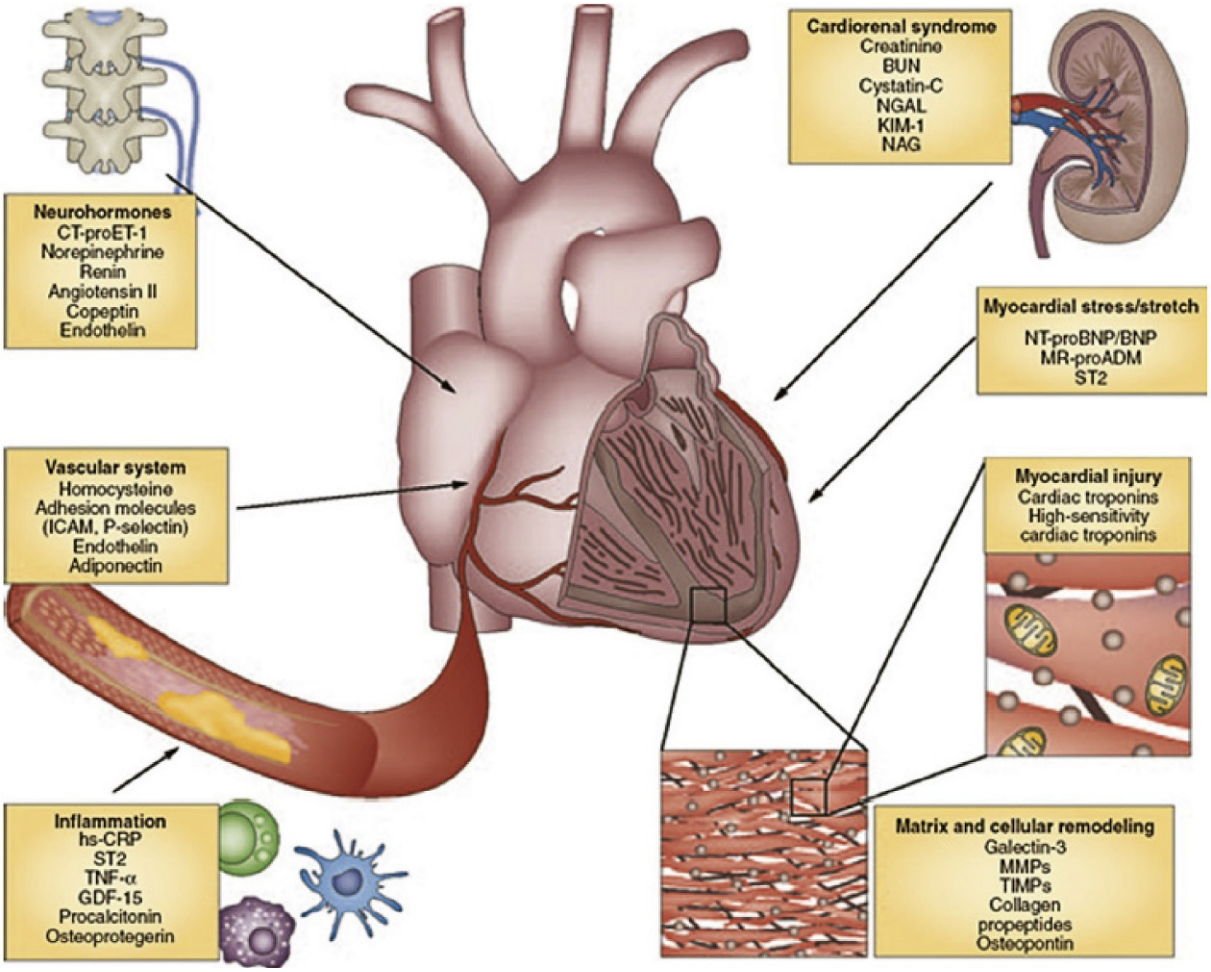

Fig. 1 Pathophysiologic representation of the multiple established and emerging biomarkers in heart failure. Reproduced with permission Gandhi, P. U., Testani, J. M., Ahmad, T. (2015). The current and potential relevance of heart failure biomarkers. *Current Heart Failure Reports* **12**, 318–327.

Natriuretic Peptides

Discovery and Biology

The NPs were first discovered in 1981 when de Bold identified a substance, which was later identified to be atrial natriuretic peptide (ANP), from rat atrial tissue that resulted in an increase in urine volume, excretion of sodium, potassium, and chloride, as well as reduction in arterial blood pressure (de Bold et al., 1981). Subsequently in 1988, B-type natriuretic peptide (BNP) was isolated from porcine neural tissue and was found to have similar physiologic effects (Sudoh et al., 1988). BNP was later discovered in both atrial and ventricular myocytes, identifying the heart as its primary source.

The primary trigger for release of both ANP and BNP is myocardial wall stress, but the hormones differ in how they are stored and secreted. ANP is produced predominantly in atrial cardiomyocytes and is stored as a prohormone that is subsequently cleaved to produce a biologically inert fragment and active ANP. The latter has a very short half-life, and therefore it is difficult to measure clinically (Munagala et al., 2004). Small amounts of BNP are stored in both atrial and ventricular myocytes, but the majority of BNP is produced by ventricular myocytes due to their greater mass. After gene activation, initially a 134 amino acid prepropetide is produced; this prepropetide is cleaved into $proBNP_{1\text{-}108}$ and a 26-amino acid signal peptide. At the time of secretion, $proBNP_{1\text{-}108}$ is subsequently further cleaved by corin into BNP and amino-terminal proBNP (NT-proBNP) (Munagala et al., 2004).

Although synthesized by the same pathway, BNP and NT-proBNP have important differences. Notably, BNP is biologically active, exerting multiple systemic effects such as vasodilation, diuresis, natriuresis, increased renal perfusion, as well as antifibrotic effects on the myocardium, whereas NT-proBNP is biologically inert. Additionally, the half-life of BNP is 22 min, whereas the half-life of NT-proBNP is 120 min (Motiwala and Januzzi, 2013). There are also significant differences in their numerical concentrations with NT-proBNP typically five to eight times higher than BNP, though there is no direct conversion (Heil and Tang, 2015).

Diagnosis

The application of BNP for the diagnosis of acutely decompensated HF (ADHF) was established in the landmark Breathing Not Properly trial. Approximately 1500 patients presenting to the emergency department with dyspnea were included in the study and BNP measurement was obtained upon presentation. The diagnosis of ADHF was subsequently evaluated by two cardiologists, who were blinded to the BNP results; 47% of the patients were determined to have dyspnea secondary to ADHF. Taking into consideration multiple historical and physical exam findings, a BNP concentration of $\geq$100 pg/mL was the most accurate characteristic for diagnosing HF with an odds ratio (OR) of 29.6 ($P<0.001$), sensitivity of 90%, and specificity of 73% (Maisel et al., 2002).

Similarly, the use of NT-proBNP in the assessment of dyspnea in 599 patients was examined in the ProBNP Investigation of Dyspnea in the Emergency Department (PRIDE) study. An NT-proBNP concentration <300 pg/mL had a 99% negative predictive value for ruling out the diagnosis of ADHF. Additionally, elevated NT-proBNP concentration was the strongest independent predictor of the diagnosis of HF with a sensitivity of 90%, specificity of 85%, and an OR of 44 ($P<0.0001$) (Januzzi et al., 2005). An NT-proBNP cut-point of 900 pg/mL was comparable to a BNP cut-point of 100 pg/mL, but an age-stratified approach improved the positive predictive value of NT-proBNP; therefore, the following cut-points for NT-proBNP were established for use in ADHF: 450 pg/mL for age <50 years, 900 pg/mL for age 50–75 years, and 1800 pg/mL for age >75 years (Januzzi et al., 2006b). **Table 1** shows the various cut-points for diagnosis of HF using both single and multiple cut-point strategies (Januzzi et al., 2006b; Kim and Januzzi, 2011).

Although the NPs hold strong diagnostic value, use of biomarkers to diagnose HF should always be used in conjunction with clinical findings, similar to application of any other diagnostic tool. A significant pitfall of the NPs is their lack of specificity, as there are several other conditions that can also increase or decrease their concentrations (**Table 2**) (Daniels and Maisel, 2007; Yancy et al., 2013). Many of these conditions are often comorbidities associated with HF, further complicating interpretation. Therefore, it is of utmost importance to use biomarkers as another tool in our armamentarium to supplement clinical information and assist with diagnosis. Concentrations may also fall in between the cut-points for ruling out and ruling in HF or the "gray zone," as shown in **Table 1**. This occurs in approximately 20 percent of patients presenting to the emergency department, and in these patients clinical correlation is even more important to determine the underlying etiology of elevated NP concentration and arrive at the correct diagnosis (van Kimmenade et al., 2008).

Although the NPs are most frequently used to aid in the diagnosis of ADHF, they have also been investigated to assist with diagnosis of chronic HF in the ambulatory setting. In the outpatient setting, their negative predictive value to exclude the diagnosis of HF has been the most widely studied application for both BNP and NT-proBNP. Values to exclude HF are considerably lower in this patient population given that they are not as acutely ill as those with ADHF. In an asymptomatic patient, the cut-point of BNP is <20 pg/mL and in a symptomatic patient the cut-point is <40 pg/mL. For NT-proBNP, the cut-points remain age-stratified, as shown in **Table 1** (Hildebrandt and Collinson, 2008; Rehman and Januzzi, 2008). If concentrations above these cut-points are resulted, a cardiac work-up should be initiated.

Based on these data, the NPs have significant diagnostic value in HF when measured in patients presenting with dyspnea, and they have been assigned a Class I, level of evidence A recommendation by the ACC/AHA for use in the diagnosis of HF (Yancy et al., 2017).

Table 1 Cut-points for B-type natriuretic peptide (BNP) and amino-terminal pro-B-type natriuretic peptide (NT-proBNP) (Hildebrandt and Collinson, 2008; Januzzi et al., 2006; Kim and Januzzi, 2011; Rehman and Januzzi, 2008).

"Rule Out" acutely decompensated heart failure	
BNP	<30–50 pg/mL
NT-proBNP	<300 pg/mL
"Rule In" acutely decompensated heart failure	
Single cut-point strategy	
BNP	<100 pg/mL
NT-proBNP	<900 pg/mL
Multiple cut-point strategy	
BNP, gray zone approach	<100 pg/mL to exclude, 100–400 pg/mL "gray zone," >400 pg/mL to rule in
NT-proBNP, age-stratified approach	<450 pg/mL for age <50 years, <900 pg/mL for age 50–75 years, <1800 pg/mL for age >75 years
Ambulatory care	
BNP	20 pg/mL (asymptomatic) or 40 pg/mL (symptomatic)
NT-proBNP	<125 pg/mL for age <75 years or <450 pg/mL for age >75 years OR <50 pg/mL for age <50 years, <75 pg/mL for age 50–75 years, and <250 pg/mL for age >75 years

Table 2 Causes of elevated and reduced natriuretic peptide concentrations (Daniels and Maisel, 2007; Yancy et al., 2013).

Elevated concentrations	*Reduced concentrations*
Cardiac	
Heart failure, involving right or left ventricle	Heart failure occurring anatomically upstream from the left ventricle
Acute coronary syndrome	Flash pulmonary edema
Atrial fibrillation or flutter	Pericardial constriction
Valvular heart disease	Pericardial tamponade
Myocarditis	
Cardiac surgery	
Cardioversion	
Noncardiac conditions	
High-output conditions	Obesity
Critical illness	
Anemia	
Older age	
Renal Failure	
Pulmonary disease (cor pulmonale, acute respiratory distress syndrome)	
Pulmonary embolism	

Prognosis

In addition to their use in the diagnosis of HF, the NPs possess substantial prognostic value. In patients with ADHF, a BNP concentration of >200 pg/mL was found to be predictive of future HF events and mortality over 90 days when compared to those with a BNP <200 pg/mL (29% versus 9%; $P=0.006$) (Maisel et al., 2004). NT-proBNP is similarly prognostic in those with ADHF. Data from the PRIDE study revealed that an NT-proBNP concentration >986 pg/mL upon presentation to the emergency department was the strongest predictor of mortality at 1 year with a hazard ratio of 2.88 in adjusted analysis (Januzzi et al., 2006a). Gray zone concentrations are also prognostic, and it is important to note that patients with NP concentrations in this range have a worse prognosis than those who have truly negative NP concentrations (van Kimmenade et al., 2008).

Although baseline NP concentrations have established prognostic merit in ADHF, subsequent studies have demonstrated even greater prognostic value for follow-up measurements, particularly those measurements obtained prior to discharge (Kociol et al., 2011). A predischarge BNP concentration of <350 pg/mL was associated with significantly reduced rates of HF readmission or death over 180 days of follow-up (Logeart et al., 2004). Other studies have examined a percent reduction in NT-proBNP over the course of hospitalization and have found that variation in NT-proBNP concentration is a significant predictor of future HF admission and death (Bettencourt et al., 2004). Furthermore, a less than 50% reduction in NT-proBNP concentration is associated with a 57% increase in risk of readmission or death compared with those who have a greater than 50% reduction in a multivariable analysis (Michtalik et al., 2011). The ACC/AHA guidelines have recently assigned a class IIa recommendation to obtain a predischarge NP value to establish post-discharge prognosis (Yancy et al., 2017).

NPs also are considerably prognostic in the chronic HF setting. In a systematic review, each 100 pg/mL increase was associated with a 35% increase in the relative risk of mortality (Doust et al., 2005). There have also been multiple studies that portray the significance of serial measurements over time in patients with chronic HF. In patients with HFrEF who were symptomatic but stable from the Val-HeFT study, changes in BNP concentrations over 12 months revealed that those who had concentrations in the lowest quartile (relative to a median BNP concentration of 97 pg/mL) had the best prognosis, followed closely by those who began with high concentrations that decreased to the low range. Those who either had concentrations in the highest quartile over the entire 12-month period or those who had low concentrations that increased from the lowest to the highest quartile over the 12 months had the worst prognosis (Latini et al., 2006). Similar results were found with NT-proBNP (Masson et al., 2008). Therefore, the ACC/AHA guidelines have given a class I, level of evidence A recommendation for use of NPs in prognostication of HF or to establish disease severity in chronic HF (Yancy et al., 2017).

Management

Treatment of HF is complex and multifaceted including pharmacologic, device-based, and lifestyle-based therapies. The NPs have an established role in the diagnosis and risk stratification of patients with HF, raising the consideration that their concentrations may be useful in managing HF as well. Furthermore, multiple established HF therapies have been shown to reduce NP concentrations with improved effects on clinical characteristics including hemodynamics and filling pressures (Motiwala and Januzzi, 2013).

These therapies include loop diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, aldosterone antagonists, and even nonpharmacologic therapies such as cardiac resynchronization therapy and exercise (Motiwala and Januzzi, 2013).

In patients with ADHF, the mainstay of therapy is decongestion with use of diuretic therapy. While diuretics result in a decrease in NP concentrations, it is unclear whether using NP concentrations would assist in specifically guiding therapy. Studies have been conducted to evaluate this question (Stienen et al., 2014) but have not yet been published. Therefore, evidence is currently insufficient to recommend use of NP-guided therapy in the inpatient setting (Yancy et al., 2013). However, use of NP concentrations in the diagnosis of HF has been shown to improve triage, reduced cost, and shorten intensive care unit stays (Boldanova et al., 2010; Moe et al., 2007).

Use of NPs to guide therapy in ambulatory HF has been studied dating back to 2000 with the seminal study by Troughton et al. which demonstrated a significant improvement in outcomes when a goal of lowering NP concentrations was used in addition to standard of care compared to standard care alone (Troughton et al., 2000). Since then, approximately 10 studies including a total of ~2500 patients have been conducted to further investigate this concept, but the results have been variable primarily due to heterogeneous study design, differences in follow-up and medication titration between study arms, and variability in both selection and achievement of an NP target. Positive studies were more likely to demonstrate significant treatment differences between study arms and achieve lower NP concentrations when compared to studies that were negative or neutral (Troughton et al., 2014a).

While current evidence is limited due to the aforementioned caveats, the trials that revealed a significant benefit with a biomarker-guided approach have demonstrated important advantages including uptitration of guideline-based neurohormonal therapies (Motiwala and Januzzi, 2013), enhanced quality of life (Bhardwaj et al., 2012), and reduction in left ventricular size with improved left ventricular function (Weiner et al., 2013). This strategy has also been found to be cost-effective (Sanders-van Wijk et al., 2013) and safe (Gandhi et al., 2015b). Furthermore, meta-analyses have been conducted which have shown an approximate mortality benefit of 25%–30% with the application of NP-guided HF management (Felker et al., 2009; Porapakkham et al., 2010; Savarese et al., 2013). More recently, an individual patient meta-analysis was conducted, revealing approximately a 40% reduction in all-cause mortality in those younger than 75 years of age; however, no significant benefit was found in those over the age of 75 (Troughton et al., 2014b). In order to definitively investigate the strategy of NP-guided management of ambulatory HF, a large, multicenter, randomized, controlled trial (Guiding Evidence-Based Therapy Using Biomarker Intensified Treatment in HF, GUIDE-IT, NCT#01685840) was conducted (Felker et al., 2014). However, this study was terminated early due to lack of difference in the primary outcome between treatment arms. The results have not yet been published, but are likely to be informative. Substudy analyses are currently underway. (Chow et al., 2017)

In addition to using NPs to guide therapy in patients with established HF, there has been recent interest in employing NP concentrations to assist with managing patients at risk for HF with the goal of prevention. One study demonstrated a substantial reduction in the development of clinical HF or left ventricular dysfunction with intensified diagnostic testing and treatment in patients with a BNP >50 pg/mL (Ledwidge et al., 2013).

Finally, the concept of using biomarkers to create novel therapies has also been exemplified by the NPs with the development of the medication valsartan/sacubitril (LCZ696), which is a combination of the angiotensin receptor blocker valsartan and a neprilysin inhibitor sacubitril. Neprilysin is a neutral endopeptidase that degrades multiple proteins including the NPs. Inhibition of neprilysin subsequently increases the concentrations of these beneficial proteins, counteracting vasoconstriction, sodium retention, and remodeling induced by other neurohormones (McMurray et al., 2014). The PARADIGM-HF trial demonstrated a reduction in mortality and HF hospitalization in patients with symptomatic ambulatory HFrEF who were receiving LCZ696 compared with those who received the angiotensin-converting enzyme inhibitor enalapril (McMurray et al., 2014).

Preserved EF

Patients with HFpEF tend to have lower NP concentrations compared to patients with HFrEF (van Veldhuisen et al., 2013). Although there have been some data to suggest that the sensitivity may be slightly reduced for both BNP and NT-proBNP to assist with diagnosing HF (Maisel et al., 2003; O'Donoghue et al., 2005), the concentrations do retain similar prognostic value regardless of ejection fraction (van Veldhuisen et al., 2013). Additionally, in patients with an ejection fraction of >45%, NT-proBNP was found to be one of the strongest independent variables for all-cause mortality (Komajda et al., 2011). Use of NPs to guide management in patients with HFpEF remains uncertain, as only a small percentage of patients with HFpEF were included in clinical trials (Troughton et al., 2014b) and guideline-based therapies for HFpEF are yet to be established.

Troponin

Biology

The troponins are proteins that help regulate contraction of both cardiac and skeletal muscle. The cardiac troponin unit is composed of troponin I, troponin T, and troponin C. Troponin I and troponin T are found in two locations in the cardiomyocyte: a small percentage can be found in the cytoplasmic pool, but the majority is located in the contractile apparatus. Troponin is most commonly used to detect cardiomyocte injury in the setting of suspected acute coronary syndrome, for which it is highly sensitive and specific (Thygesen et al., 2012). The sensitivity of troponin assays continues to increase and the most current generation of

high-sensitivity assays are employed in multiple parts of the world, and have recently been approved in the United States. In addition to their application for acute coronary syndrome, elevated troponin concentrations can also be found in HF for which multiple proposed etiologies exist, including cardiomyocyte necrosis due to increased wall stress, epicardial coronary artery disease, or even direct injury from neurohormones and inflammatory markers (Januzzi et al., 2012; Kociol et al., 2010).

Diagnosis

Troponin is not used to diagnose HF, but acutely decompensated HF can be present in the setting of an acute coronary syndrome. If an elevated troponin concentration is found, it is imperative to determine the etiology as it may drastically change management, particularly if the elevated concentration is due to a type I myocardial infarction involving plaque rupture (Januzzi et al., 2012).

Prognosis

Although troponin does not possess a significant role for diagnosis of HF, troponin measurement has established utility for prognosis. The ACC/AHA guidelines have assigned a class I recommendation in acutely decompensated HF and class IIb for chronic HF for the purpose of prognostication (Yancy et al., 2017). In patients hospitalized with acutely decompensated HF from the Acute Decompensated HF National Registry (ADHERE) database, 6.2% were found to have a troponin concentration that was deemed positive by a conventional assay. Those with an elevated concentration had a significantly higher rate of in-hospital mortality compared to those without an elevated concentration (8.0% versus 2.7%, $P < 0.001$) (Peacock et al., 2008). With high-sensitivity assays, nearly all patients with acute HF have measurable concentrations (Pascual-Figal et al., 2012), and higher concentrations are independently associated with worse prognosis, including cardiovascular mortality or death from HF (Felker et al., 2015).

In patients with chronic HF from the Valsartan HF Trial (Val-HeFT), troponin was detected in 10.4% and 92% of the patients using both a conventional and highly sensitive assay, respectively. Elevated concentrations were found to be predictive of mortality and HF hospitalization; moreover, addition of highly sensitive troponin improved prognostication in risk prediction models (Latini et al., 2007). Finally, serial measurements of high-sensitivity troponin were also examined for prognostic value, and increasing concentrations over time were associated with an increase in all-cause mortality (Masson et al., 2012).

Management

To date, no studies have specifically investigated the use of troponin to manage HF. However, troponin concentrations have been measured in various therapy trials and have found increased concentrations with use of omecamtiv mecarbil (Teerlink et al., 2016) and decreased concentrations with serelaxin (Metra et al., 2013) and valsartan/sacubitril (LCZ696) (Packer et al., 2015), but the significance of these changes remains unclear until further investigations are undertaken.

Preserved EF

Similar to the NPs, concentrations of troponin tend to be lower in those with preserved EF compared to those with reduced EF (Santhanakrishnan et al., 2012), and troponin concentrations appear to have similar prognostic value in both types of HF (Sanders-van Wijk et al., 2015). Furthermore, in patients admitted with acutely decompensated HFpEF, troponin elevation was recently found to be independently associated with worse in-hospital and postdischarge outcomes (Pandey et al., 2016). With regard to treatment, valsartan/sacubitril (LCZ696) was also shown to reduce high-sensitivity troponin concentration in patients with HFpEF (Jhund et al., 2014).

ST2 and Galectin-3

Biology

Suppression of tumorigenicity 2 (ST2) and galectin-3 are emerging HF biomarkers. ST2 is a member of the IL-1 receptor family, and it has multiple forms including a transmembrane ligand (ST2L) and a soluble form (sST2) (Weinberg et al., 2002). It is a marker of myocardial strain (Weinberg et al., 2003), fibrosis, and remodeling (Sanada et al., 2007), and expression of the ST2 gene is triggered in response to myocyte and fibroblast strain (Weinberg et al., 2002). Galectin-3 is a member of the β-galactoside-binding lectin family that is found in macrophages and fibroblasts. It is associated with fibrosis of many organs, including the heart (Sharma et al., 2004).

Diagnosis

ST2 and galectin-3 are not useful to assist with diagnosis of HF.

Prognosis

Both sST2 and galetcin-3 have been investigated for risk stratification in acute and chronic HF. In patients presenting with shortness of breath in the PRIDE study, sST2 was significantly elevated in those with acutely decompensated HF compared to those with

shortness of breath from other causes. Additionally, elevated sST2 was associated with an increased risk of mortality in adjusted analyses. Combination of sST2 with NT-proBNP identified subjects with the highest mortality risk (Januzzi et al., 2007). Another study examined multiple biomarkers in over 5000 patients with acutely decompensated HF, and sST2 was found to be among the strongest predictors of mortality when combined with clinical factors of risk prediction (Lassus et al., 2013).

Galectin-3 has also been investigated for prognosis in acutely decompensated HF. In data from a recent pooled analysis of three studies examining patients with acutely decompensated HF, elevated galectin-3 concentrations were associated with increased rehospitalization and mortality at 30, 60, 90, and 120 days after discharge. After adjustment for relevant clinical factors and NP concentrations, galectin-3 remained a useful predictor of HF rehospitalization (Meijers et al., 2014).

The prognostic utility of both sST2 and galectin-3 has also been investigated in patients presenting with chronic HF. Soluble ST2 was investigated in 1,114 patients with ambulatory HF, and patients with sST2 concentrations in the highest tertile had an increased risk of adverse events (adjusted HR 1.9, $P=0.002$) compared to those in the lowest tertile. When combined with NT-proBNP and added to a conventional risk model (Seattle Heart Failure Model), 15% of patients were reclassified into different risk categories (Ky et al., 2011). Serial sST2 concentrations were found to possess even stronger prognostic merit when compared to other markers, including NT-proBNP and high-sensitivity troponin T (Gaggin et al., 2014).

Multiple studies have investigated the utility of galectin-3 for risk stratification in chronic HF. In a substudy of the HF: A Controlled Trial Investigating Outcomes of Exercise TraiNing (HF-ACTION) trial, elevated galectin-3 concentrations were associated with reduced HF hospitalization-free survival, but its prognostic value was not retained when adjusted for other clinical factors, particularly with inclusion of NP concentrations (Felker et al., 2012). Similar results have been found with other studies, and subsequently a head-to-head trial was conducted comparing sST2 with galectin-3 which demonstrated its modest prognostic value when compared to sST2 (Bayes-Genis et al., 2014). However, a recent meta-analysis that investigated patients with both acute and chronic HF revealed that a 1% increase in circulating galectin-3 concentrations was associated with a 28% increase in all-cause mortality and a 59% increase in cardiovascular mortality in models including both renal function and NT-proBNP (Chen et al., 2015). The ACC/AHA guidelines have assigned a class IIb recommendation for measurement in acutely decompensated HF and symptomatic chronic HF to assist with prognosis for both sST2 and galectin-3 (Yancy et al., 2017).

Management

Although there have been no prospective studies examining sST2 or galectin-3 to guide management, there have been a number of important retrospective observations. There appears to be a reduction in sST2 concentrations with use of beta-blocker therapy (Gaggin et al., 2013) as well as with the angiotensin receptor blocker valsartan (Anand et al., 2014). Additionally, another study found an interaction between elevated sST2 concentrations and mineralocorticoid receptor antagonist therapy (Maisel et al., 2014). Similar observations have been found for galectin-3, but interestingly those with lower (rather than elevated) galectin-3 concentrations seem to benefit from treatment with rosuvastatin (Gullestad et al., 2012) or valsartan (Anand et al., 2013). Although experimental models have suggested a potential relationship between galectin-3-mediated fibrosis and aldosterone (Calvier et al., 2013), clinical studies have not found a significant therapeutic interaction (Gandhi et al., 2015a). Finally, targeted anti-galectin therapies are also being investigated in experimental models and have demonstrated attenuation of fibrosis (Yu et al., 2013). At this time, more evidence is needed before sST2 or galectin-3 can be applied to guide HF management.

Preserved EF

Data regarding sST2 in HFpEF appear to be conflicting. One study investigating patients with acutely decompensated HF and preserved EF did not show predictive value with regard to outcomes at 6 months (Frioes et al., 2015), whereas another study showed sST2 was an independent predictor of mortality in patients with acutely decompensated HF regardless of EF (Manzano-Fernandez et al., 2011). Galectin-3 has also been examined in patients with HFpEF, and it was found to be independently prognostic in this patient population for mortality and HF hospitalization (de Boer et al., 2011). Furthermore, the aforementioned pooled analysis included subjects with HFpEF and also showed elevated galectin-3 concentrations were associated with risk of short-term hospitalization in these subjects as well (Meijers et al., 2014).

Future Directions

The number of biomarkers that are being investigated continues to rapidly expand (Januzzi and Felker, 2013) raising questions regarding the optimal method to investigate and apply biomarkers to patient care. To date, the NPs remain the gold standard and have truly exemplified how a biomarker can aid in diagnosis, prognosis, management, and development of novel therapies. Given that each biomarker provides a different window into the pathophysiology of HF, it is possible that a multimarker strategy may be the most optimal approach (Allen and Felker, 2010). One study examined a multimarker panel (BNP, high-sensitivity C-reactive protein, myeloperoxidase, soluble fms-like tyrosine kinase receptor-1, troponin I, soluble toll-like receptor 2, creatinine, and uric acid) incorporating a variety of biological pathways in 1513 patients with HFrEF for risk stratification and found that addition of this panel to the Seattle HF model resulted in a significant improvement in prognostication (Ky et al., 2012). Prior to clinical adaptation of a multimarker strategy, demonstration of incremental benefit beyond existing clinical information and risk prediction models, therapeutic implication, and cost-effectiveness is imperative (Allen and Felker, 2010).

Conclusion

The use of biomarkers in HF is a rapidly expanding area of interest. The NPs remain at the forefront of this field with troponin, sST2, and galectin-3 rapidly approaching. Future studies will assist in clarifying the appropriate use of both established and emerging markers for assisting in diagnosis, risk stratification, and management of this complex condition.

Introduction

Ischemic heart disease (IHD) is one of the most important cardiac diseases and defined by an inadequate oxygen supply of the myocardial cells (Task Force Members et al., 2013). The mismatch of demand and supply can be caused by various conditions including plaque-related obstruction of coronary arteries, microvascular dysfunction or vasospasm. Coronary artery disease (CAD) is one of the most important factors leading to IHD. It is an ongoing chronic process, which is based on accumulation of foam cells in the intima, followed by plaque formation and possible plaque-rupture. Stable IHD is defined by either stable symptoms (angina or dyspnea), which are thought to be related to CAD, or asymptomatic patients with prior-diagnosed CAD. An acute worsening or new onset of symptoms is defined as acute coronary syndrome (ACS). It includes acute myocardial infarction (AMI), which is caused by myocardial ischemia, or unstable angina (Roffi et al., 2016).

Cardiovascular disease and especially IHD remains one of the most important causes of death accounting for up to 30% of all deaths worldwide in 2012 (World Health Organization, 2017). Within the past decades medical treatment with statins, antiplatelet-drugs, and ACE-inhibitors, as well as revascularization have substantially improved the outcome of patients with IHD. The assessment of CAD in the population is difficult, as clinical information and imaging results are required. The prevalence of angina has been reported in the general population and is highly variable, as it ranges from 5% in younger women up to 14% in older men (Task Force Members et al., 2013). Therefore, the individual risk assessment in patients with suspected or diagnosed IHD remains an ongoing challenge. In clinical routine two important goals for patients with IHD include (1) the identification of individuals at high risk for future cardiovascular events and (2) the early diagnosis or rule-out of AMI in the acute setting. For risk prediction, several scores (e.g., Framingham Risk Score or ESC Score) have been established. They can identify high-risk individuals based on classical cardiovascular risk factors (Task Force Members et al., 2016a; D'Agostino et al., 2008). In patients with suspected AMI the use of biomarkers is well established and cardiac troponin is the gold-standard in clinical routine.

In the past years, numerous novel biomarkers were discovered and evaluated with regard to their predictive and diagnostic ability in IHD. This article will provide an overview on established and novel biomarker applications in patients with IHD.

General Considerations

Many biomarkers have been evaluated with regard to their diagnostic and predictive ability in patients with cardiovascular diseases and especially IHD. The most promising biomarkers are summarized in the following (Fig. 1). However, so far only few biomarkers are routinely used in the clinical setting.

When investigating new biomarkers several aspects should be kept in mind by researchers and physicians:

(1) At first, a robust test is required to allow reproducible results with a low variation. This is particularly important, when comparing results from different groups or laboratories.
(2) The new biomarker should be compared to other clinical risk markers or biomarkers and improve risk stratification. As an example, a biomarker might be compared to the Framingham risk score, which is an established and validated model for risk prediction. The improvement could be investigated by comparing the c-statistics or the net reclassification. This approach investigates, whether individuals are more likely to be assigned into the correct risk category when adding the biomarker.
(3) The results should be tested and validated in independent samples.
(4) Finally, the biomarker should ideally be cost-effective and improve patient management and outcome.

Metabolic and Renal Biomarkers

Metabolic processes play a central role in the pathogenesis of atherosclerosis. In particular, dyslipidemia was identified as one of the most important risk factors more than half a century ago. The determination of total cholesterol, low-density-lipoprotein (LDL) cholesterol, and high-density-lipoprotein (HDL) cholesterol has been clinical standard for decades (Task Force Members et al., 2013; Piepoli et al., 2016). These biomarkers are also included in established risk score (e.g., Framingham or ESC Score) and are therefore included as the gold-standard, when comparing novel biomarkers for their ability of risk prediction in statistical analyses. For LDL cholesterol, numerous studies provided strong evidence of a causal role in the pathogenesis of atherosclerotic disease. This is different for HDL cholesterol, which is inversely correlated with IHD, but so far could not be related to disease in a direct causal pathway (Voight et al., 2012). Statin-treatment is one of the most effective strategies in secondary prevention and can reduce the LDL cholesterol substantially. This effect is associated with a strong reduction of the relative risk. Furthermore statins are even able to decrease the diameter of coronary plaques (Baigent et al., 2005; Ballantyne et al., 2008). The use of statin therapy is widely established in patients with relevant IHD nowadays. As a consequence, in well-treated IHD patients LDL concentrations lose their predictive ability for mortality (Ndrepepa et al., 2014). Current ESC guidelines recommend annual measurements of LDL cholesterol and aim for a concentration below 70 mg/dL (or a 50% reduction of the baseline concentration) for patients with prior history of CAD (Task Force Members et al., 2013).

Lipoprotein A (Lp(a)) is a protein, which consists of the apolipoproteins B-100 and A (Malaguarnera et al., 2013). It is similar to LDL cholesterol and involved in the development of atherosclerotic disease. The plasma concentrations of Lp(a) are determined by

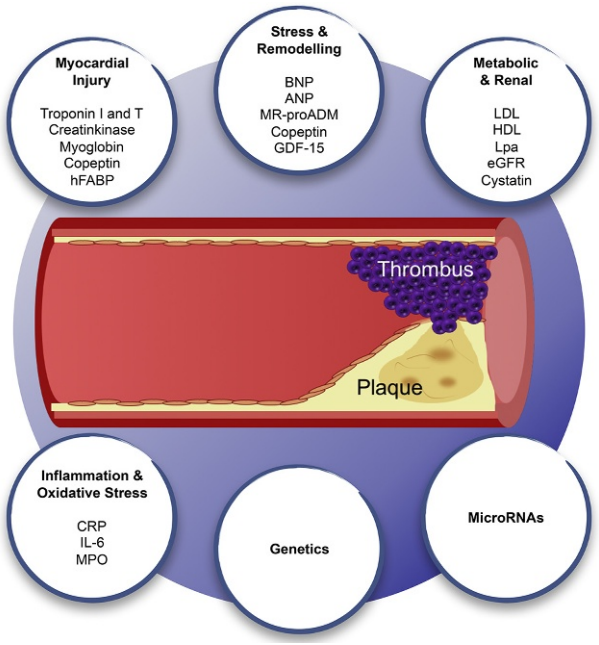

Fig. 1 Overview on selected biomarkers in patients with IHD.

genetic factors and appear to be stable over the lifespan (Nordestgaard et al., 2010). Treatment with niacin or fibrates was able to reduce Lp(a) concentrations, but so far, no clinical benefit was shown for a reduction of Lp(a). Therefore current ESC guidelines do not recommend general testing, while Lp(a) should be measured in patients with high cardiovascular risk or with a strong family history of IHD (Task Force Members et al., 2016b).

Impaired renal function is closely associated with IHD and poor outcome (Go et al., 2004). This is explained by accumulation of risk factors, but also by pathophysiological pathways including increased inflammation and aldosterone activity among others (Mule et al., 2015). In clinical routine the measurement of creatinine and the calculation of the estimated glomerular filtration rate (eGFR) are well established and validated. In a huge population of more than one billion individuals, decreased eGFR was associated with mortality and cardiovascular events (Go et al., 2004). Cystatin C has been investigated as an alternative biomarker for patients with renal impairment. It is thought to be less affected by confounding factors (e.g., age and muscle mass) and might be superior for detection of minor changes in renal function at early stages of renal impairment (Shlipak et al., 2013). In patients with IHD, cystatin C was associated with mortality. The cystatin C-based eGFR appears to be superior compared to the creatinine-based formula (Keller et al., 2009; Waldeyer et al., 2016). However, cystatin C-based IHD risk estimation has not been introduced widely in clinical routine and annual determination of creatinine and eGFR is recommended (Task Force Members et al., 2013).

Biomarkers of Myocardial Injury

Patients with suspected AMI are one of the most important populations, who profit from rapid decision-making based on biomarkers. While patients with ST-elevation AMI can be identified using the electrocardiogram, the diagnosis of non-ST-elevation AMI (NSTEMI) relies on biomarkers and their dynamic changes (Thygesen et al., 2012a). In AMI patients timing is crucial and early diagnostic approaches are needed in the emergency department. On the one hand, high-risk patients with NSTEMI due to obstructive CAD, who receive an early invasive treatment, have an improved outcome, compared to delayed treatment (Mehta et al., 2009; Milosevic et al., 2016). On the other hand, emergency departments are usually crowded and an early discharge of low-risk patients is required. In the past decades, several diagnostic biomarkers and approaches have been evaluated for patients with suspected AMI and are presented in the following. Improved diagnostic accuracy rendered them ideal, also for risk prediction.

Creatine Kinase and Myoglobin

Among the first biomarkers applied in clinical routine for the detection of myocardial necrosis were creatine kinase myocardial band (CK-MB) and myoglobin (Duma and Siegel, 1965; Rosano et al., 1977). Due to a rather slow dynamic change, CK-MB is of secondary importance for acute decision-making. However, an increase of CK-MB remains an important biomarker for patients with diagnosed AMI. Here, the increase of CK-MB is associated with the infarct size (Costa et al., 2008). Furthermore, current ESC guidelines recommend CK-MB as the preferred biomarker for patients who present early after prior AMI, as CK-MB shows a fast decrease after AMI (Roffi et al., 2016). Myoglobin shows an early increase after myocardial necrosis, but is less cardiac-specific and expressed in myocardial as well as skeletal muscle cells. Therefore, myoglobin is not recommended for clinical use anymore (Thygesen et al., 2012b).

Cardiac Troponin

Cardiac troponin is a protein complex, which has a central role in myocyte contraction. The three subcomplexes troponin C, I, and T are bound to tropomyosin and interact with the actin filament (Takeda et al., 2003). Troponin T and I are expressed exclusively in the myocyte and are released after myocardial necrosis (Parmacek and Solaro, 2004). The detection of troponin was first developed in 1987 using a radioimmunoassay (Cummins et al., 1987) and the first clinical application was presented in 1992, as troponin T positive patients with unstable angina had a poor outcome (Hamm et al., 1992). After introduction of troponin in clinical routine, elevated troponin concentrations were used as a diagnostic marker for patients with AMI (Alpert et al., 2000; Task Force Members et al., 2007). Ever since assays detecting troponin T and I underwent a rapid improvement in terms of sensitivity and accuracy. In the past years, numerous newer troponin assays were developed and used in clinical routine. These assays have a much higher sensitivity and can detect troponin concentrations not only in patients with AMI, but even in the general population. Furthermore, the accuracy, measured by the coefficient of variation at the 99th percentile, was improved impressively. Recently, the term of "high-sensitivity" troponin (hs-Tn) assay was introduced for assays with a 10% coefficient of variation, which is below the 99th percentile and that are detectable in at least 50% of the general population. In **Fig. 2** currently available troponin assays together with the specific limit of detection and the percentage detectable in the general population is displayed.

Diagnosis of AMI

Troponin is the best established and most widely used biomarker in patients with suspected AMI. International guidelines for patients with NSTEMI recommended a troponin cutoff concentration at the 99th percentile (determined in the general population) to rule-out AMI (Task Force Members et al., 2007; Amsterdam et al., 2014). Using less sensitive assays at that time, serial sampling was recommended after six or twelve hours in order to assess dynamic changes. After introduction of more sensitive or even high-sensitivity troponin assays a shorter time period of only three hours was suggested and recommended in the 2011 ESC guidelines

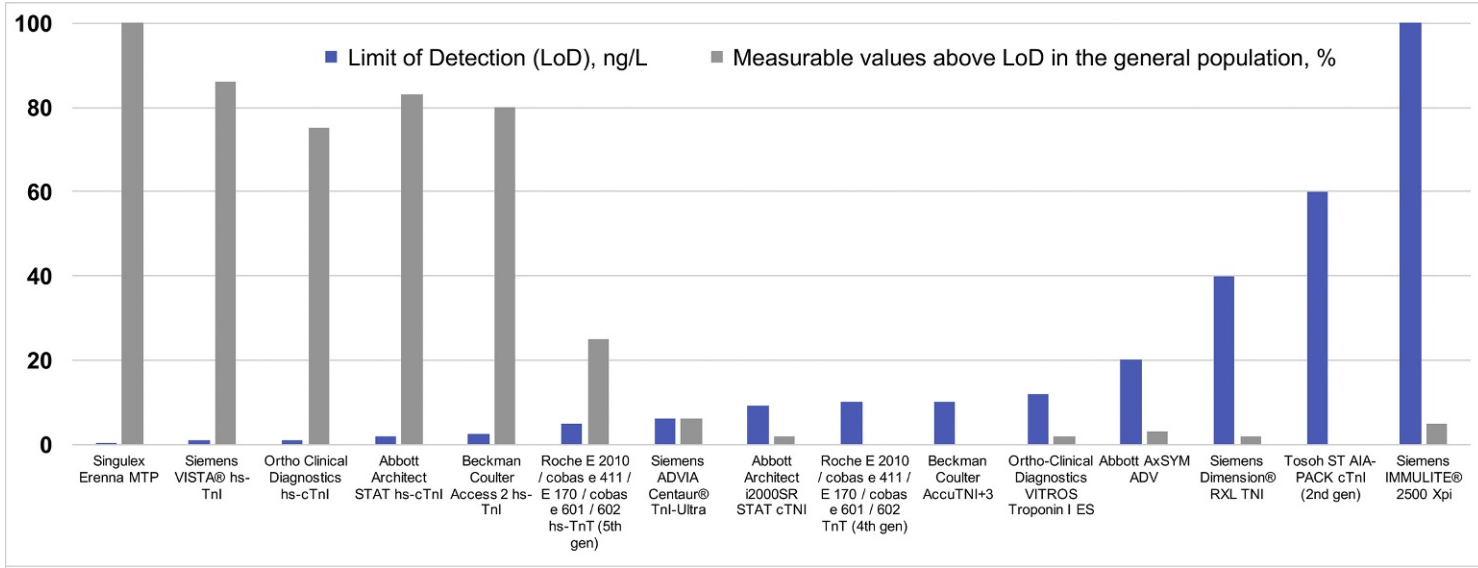

Fig. 2 Overview on selected currently available troponin assays, their limit of detection and rate detectable in the general population. Adapted from Westermann, D., Neumann, J. T., Soerensen, N. and Blankenberg, S. (2017). High-sensitivity assays for troponin in patients with cardiac disease. *Nature Reviews Cardiology*. https://doi.org/10.1038/nrcardio.2017.4.

(Ridker et al., 2008; Reichlin et al., 2009; Keller et al., 2011; Hamm et al., 2011). The ESC working group on Acute Cardiac Care recommended a baseline cutoff concentration at the 99th percentile and a >50% increase after three hours, when the baseline concentration was below the 99th percentile, or a >20% increase of the initial value, when the baseline concentration was above the 99th percentile in order to rule-out or to diagnose AMI. An optional measurement after six hours was recommended.

High-sensitivity assays

Using newer high-sensitivity troponin T and I assays the application of much lower cutoff concentrations became feasible and was investigated in several large cohorts of patients with suspected AMI (e.g., ADAPT, APACE, BACC, High-STEACS, and TRAPID-AMI cohorts). The ADAPT cohort was the first one to reduce the duration of serial sampling to two hours and measured hs-TnI (Than et al., 2012). A combined diagnostic approach based on the 99th hs-TnI percentile, the TIMI risk score, the ECG and history or symptoms, revealed a high diagnostic accuracy to rule-out AMI. A shorter timeframe of only one hour was evaluated in the APACE, BACC, and TRAPID-AMI cohorts (Mueller et al., 2016; Neumann et al., 2016a; Rubini Gimenez et al., 2015). In summary, all cohorts reported a high negative predictive value (NPV) to rule-out AMI based on very low hs-Tn concentrations at baseline (around 3 ng/L for hs-TnT and 2–6 ng/L for hs-TnI) and a low change after one hour (around 12 ng/L for hs-TnT and 5–6 ng/L for hs-TnI). On the other hand, the positive predictive value (PPV) was high, when the baseline concentration was high (52 ng/L for hs-TnT and hs-TnI) or delta change after one hour was high (around 5–6 ng/L for hs-TnT and hs-TnI). Importantly, these concentrations were significantly lower compared to the 99th percentile, which has been described at 27 ng/L (Zeller et al., 2014a).

Baseline troponin concentration

One step further, a single hs-TnI concentration directly at admission was tested to rule-out AMI. The High-STEACS cohort suggested a low cutoff of 5 ng/L and rule-out AMI in 61% of all patients with a NPV of 99.6% (Shah et al., 2015a). The BACC cohort aimed for a NPV of 100%, which was reached at a hs-TnI concentration of 3 ng/L in combination with a low-risk ECG without ischemic signs (Neumann et al., 2016b). This performance was validated independently in the ADAPT and Stenocardia cohorts. Finally, the first US cohort UTROPIA suggested a cutoff concentration at the limit of detection at 1.9 ng/L and described a NPV of 99.6% (Sandoval et al., 2017).

Current clinical practice

The improvements of troponin assay sensitivity enabled earlier decision-making in patients with suspected AMI. The 0/1 h approach has been incorporated in the 2015 ESC guidelines as an alternative to the three hours algorithm (Roffi et al., 2016). The suggested 0/1 h concept is based on assay-specific cutoff concentrations, which are provided in the guidelines. The general concept of early rule-out and rule-in is displayed in **Fig. 3**. Importantly, troponin concentrations are only one part of the decision-making process. Accurate evaluation of symptoms, patient history, physical examination, imaging results, and differential diagnoses is mandatory. Several aspects of the new biomarker algorithms have been discussed controversially (Crea et al., 2016). As an example, it has been argued, if sex-specific cutoff concentrations should be used (Cullen and Mills, 2016; Giannitsis, 2016; Rubini Gimenez et al., 2016; Shah et al., 2015b). Women tend to have lower troponin concentrations in general, which is reflected by a lower 99th percentile. However, currently available data on sex-specific cutoffs is limited and no general recommendation possible. Furthermore, data on patients who present early after symptom onset (e.g., less than three hours) is limited. In these patients, a troponin change might not yet be visible, even using hs-Tn assays. Therefore, the guidelines recommended the baseline rule-out of AMI only for those patients with symptom duration of more than three hours.

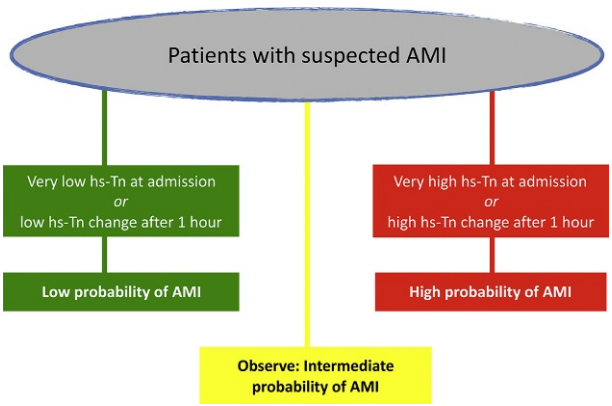

Fig. 3 Summary of the general concept of the ESC guideline 0/1 h approach. The exact cutoff concentrations are assay-specific. The baseline rule-out of AMI is only recommended for patients with symptom duration of more than 3 h.

In the past years hs-Tn assays were used worldwide, excluding the US. Therefore, the current AHA/ACC guidelines still recommend three to six hours troponin serial sampling (Amsterdam et al., 2014). This might change in the future, as the first hs-TnT assay was approved by the FDA in the beginning of 2017 (FDA, 2017). This approval will have major impact on the clinical routine within the US, as application of faster diagnostic protocols will become available.

Risk prediction

The improvement in assay sensitivity opened the venue for a much broader use of the biomarker troponin. Besides acute diagnostic application, the troponin-based risk prediction was investigated in study samples with cardiac disease. In 3679 patients from the PEACE study, which included patients with stable CAD, higher troponin T and I concentrations were associated with mortality and heart failure (Omland et al., 2009, 2013). In the BARI 2D study patients with stable CAD and prior-diagnosed diabetes were included and here hs-TnT concentrations above the 99th percentile were observed in 39% of the study population. Again, troponin concentrations were associated with mortality and future cardiovascular events (Everett et al., 2015a). Serial troponin sampling was performed in the LIPID study, which included patients with a history of AMI or unstable angina in combination with elevated LDL cholesterol (White et al., 2014). Patients were randomized to receive either placebo or pravastatin and followed for at least 1 year. Interestingly, a decrease of troponin was associated with risk reduction for future cardiovascular events and vice versa.

Due to higher sensitivity, hs-Tn concentrations were evaluated for their ability of risk prediction in the community (de Lemos et al., 2010; Saunders et al., 2010). In the FINRISK population, three troponin assays with different sensitivity were compared with regard to their prediction of future cardiovascular events. Interestingly, the most sensitive assay showed the best predictive performance (Neumann et al., 2014). In the large BiomarCaRE consortium hs-TnI was determined in 70,000 individuals from several European cohorts (Blankenberg et al., 2016). Here, hs-TnI concentrations above 5.9 ng/L were strongly associated with incidence of cardiovascular disease within the long-term follow-up period of 20 years. Finally, the use of hs-Tn for risk prediction in primary prevention was evaluated. The JUPITER trial randomized patients with elevated hs-CRP, but without cardiovascular disease, to receive either placebo or rosuvastatin (Everett et al., 2015b). Again hs-TnI was impressively associated with cardiovascular events within the follow-up time of 2.5 years. The WOSCOPS trial included patients with elevated LDL cholesterol, but without cardiovascular disease and randomized them to receive either placebo or statin-treatment (Ford et al., 2016). Patients receiving statins had a high relative risk reduction, especially when their hs-TnI was high. These findings are interesting and promising, but do not qualify for guideline recommendations yet. Further studies are needed to provide more insight to a more personalized medicine. In future troponin will be an important tool for risk assessment of patients with IHD.

Copeptin

Copeptin is a peptide, which is cleaved from the neurohypophysial hormone prepro-vasopressin and secreted in the blood during procession to vasopressin (Keller et al., 2010). It is released during stress and shows a rapid increasing kinetic. Therefore, several studies investigated the use of copeptin as a biomarker in patients with suspected AMI. Due to a low specificity, elevated copeptin concentrations can be observed in various conditions including sepsis, trauma, and shock. On the other hand, a negative copeptin results showed a high NPV for the diagnosis of AMI. When compared to sensitive troponin assays the additional use of a negative copeptin result increased the area under the curve (AUC) (Maisel et al., 2013). However, when using hs-Tn assays this effect does not appear relevant anymore (Mockel et al., 2015).

Heart-Type-Fatty-Acid-Binding-Protein

The heart-type-Fatty-Acid-Binding-Protein (hFABP) is a protein, which is involved in intracellular myocardial transport (Bruins Slot et al., 2010; Reiter et al., 2013). After myocardial necrosis hFABP is rapidly released into the blood stream and was therefore investigated as a biomarker for AMI. However, due to low sensitivity and specificity hFABP has not been proven useful, compared to the diagnostic performance of hs-Tn assays (Bruins Slot et al., 2010; Reiter et al., 2013).

MicroRNAs

In the past years microRNAs have been investigated as potential biomarkers in various diseases (Schulte and Zeller, 2015). MicroRNAs are small, circulating noncoding RNA molecules, which modulate the gene regulation. Up to date more than 2500 microRNAs have been described. MicroRNAs seem to be involved in the development of atherosclerosis and different microRNAs have been found in different stages of coronary plaque stages (Jovanovic et al., 2014). In patients with chest pain a combination set of eight microRNAs (miR-19a, miR-19b, miR-132, miR-140-3p, miR-142-5p, miR-150, miR-186, and miR-210) was able to discriminate patients with unstable angina from other patients (Zeller et al., 2014b). These eight microRNAs were further investigated in a large cohort of patients with CAD (stable and instable) (Karakas et al., 2016). Here, especially miR-132, miR-140-3p, and miR-210 were associated with cardiovascular death within the follow-up of 4 years. In summary, current data on the use of microRNAs is limited and comparison with established biomarkers is needed. In the future, sets of microRNAs might be helpful to improve individual risk stratification.

Biomarkers for Cardiac Stress and Remodeling

B-Type Natriuretic Peptide

Among cardiac biomarkers, the b-type natriuretic peptide (BNP) and the n-terminal fragment (NT-proBNP) are extremely well established. BNP is released from the ventricle during myocardial stress and can be detected in the blood using immunoassays. In the current guidelines for the diagnosis of heart failure, BNP is one of the most important cornerstones to diagnoses or to rule-out heart failure (Ponikowski et al., 2016). There is some substantial overlap of patients with heart failure and IHD, which makes BNP an important biomarker in this population as well.

Already in 2001 BNP was shown to be a strong predictor for mortality in patients with acute coronary syndrome (de Lemos et al., 2001). Furthermore, in patients with suspected CAD undergoing angiography NT-proBNP was a strong predictor for mortality (Kragelund et al., 2005). In stable CAD patients from the PEACE study BNP and NT-proBNP were measured and significantly associated with cardiovascular mortality, heart failure, and stroke (Omland et al., 2007). Importantly, both biomarkers provided incremental value to established risk stratification tools. The HOPE study, which included high-risk individuals, identified NT-proBNP as the most important predictor for cardiovascular events, besides classical risk factors (Blankenberg et al., 2006). Finally, in a multibiomarker approach from the MORGAM project in the general population, NT-proBNP, troponin I, and CRP were the strongest predictors for cardiovascular events and improved the reclassification (Blankenberg et al., 2010). BNP-guided therapy in patients with heart failure has been intensively discussed and might improve patient care. It is currently recommended by the US, but not the ESC guidelines (Ponikowski et al., 2016; Troughton et al., 2014).

Atrial-Natriuretic Peptide and Adrenomedullin

Similar to BNP, the atrial-natriuretic peptide (ANP) or its stable flanking protein MR-proANP, is released from the atrial myocytes during increased myocardial stress or pressure overload (Levin et al., 1998). Adrenomedullin (ADM) is a vasodilatory peptide, which is released in various acute and nonacute conditions. The mid-regional prohormone (MR-proADM) is more stable and can be measured using an immunoassay. It has been studied in patients with heart failure, hypertension, infections, and IHD (Peacock, 2014). Both biomarkers have been investigated in several studies and showed to further improve the risk stratification. In a population of patients with suspected AMI, MR-proANP, and MR-proADM were able to predict mortality or AMI and improved the reclassification, when compared to the GRACE score (Tzikas et al., 2013). Similar results were reported in the PEACE cohort, as both biomarkers were associated with mortality and incident heart failure. In the general population, MR-proADM was associated with subclinical and clinical cardiovascular disease (Neumann et al., 2013). However, the clinical use of these biomarkers is still limited.

Growth-Differentiation Factor 15

The growth-differentiation factor 15 (GDF-15) is a biomarker from the transforming growth factor-beta cytokine family (Wollert et al., 2017). It is increased after tissue damage, apoptosis, inflammation, and oxidative stress. GDF-15 has been evaluated in various cardiovascular disease cohorts where it predicted adverse outcome. In a large sample of patients with IHD, GDF-15 concentrations were associated with mortality, stroke, and AMI (Hagstrom et al., 2017). The AtheroGene study included patients with stabile angina undergoing angiography. In this cohort GDF-15 predicted coronary mortality (Kempf et al., 2009). GDF-15 concentrations were also investigated in the setting of patients with acute coronary syndrome, myocardial infarction, or cardiogenic shock. Here, GDF-15 was also a strong predictor for adverse events (Hagstrom et al., 2016; Fuernau et al., 2014; Eitel et al., 2011). In addition, GDF-15 was a predictor for major bleeding after ACS in the PLATO study (Hagstrom et al., 2016). Finally, the highest GDF-15 concentrations have been observed in patients with acute heart failure (Anand et al., 2010). In the community GDF-15 was a predictor for all-cause mortality (Rohatgi et al., 2012; Wang et al., 2012). These findings render GDF-15 a promising biomarker for risk prediction. However, current data indicates GDF-15 to be less specific for IHD, but rather a more general biomarker.

Biomarkers for Oxidative Stress and Inflammation

Inflammatory processes and oxidative stress are directly involved in development and progress of atherosclerotic disease. Local inflammation is one of the important factors leading to plaque formation, while oxidative stress is a potent inductor of endothelial dysfunction and especially present in the acute setting of plaque disruption (Hansson et al., 2015). Therefore, biomarkers of these pathophysiological pathways have gained attention within the past years.

C-Reactive Protein

The c-reactive protein (CRP) is one of the mostly used biomarkers worldwide to diagnose acute infections. CRP is released from the liver after stimulation by cytokines (e.g., interleukin-6 (IL-6) or tumor-necrosis-factor-alpha) and can be easily measured in blood. CRP concentrations are highly elevated in response to bacterial infections, but are also related to chronic inflammatory processes. Using newer high-sensitivity CRP (hs-CRP) assays lower concentrations can be detected, which makes this a promising biomarker to

identify individuals at risk. In the PEACE study, patients with IHD and elevated hs-CRP above 1 mg/L were at higher risk for future events (mortality, stroke, AMI), even after multiple adjustment (Sabatine et al., 2007). In the ATHEROREMO study the relation of CAD plaque burden and hs-CRP was recently investigated. Interestingly, hs-CRP was associated with plaque burden and incident MACE within the follow-up, but not with thin-cap fibroatheroma (Cheng et al., 2014). These results indicate, that CRP is a more general marker of atherosclerosis and not specific for heart diseases. In contrast to that a large study, which investigated genetic variations resulting in increased CRP concentrations, did not find an association of these polymorphisms with cardiovascular events (Zacho et al., 2008). The JUITER trial was the first study to base treatment decisions on hs-CRP concentrations (Ridker et al., 2008). Patients with hs-CRP above 2 mg/L and LDL cholesterol below 130 mg/dL were randomized to receive placebo or rosuvastatin. The study reported an impressive risk reduction by statin therapy within the complete study population. Interestingly, this effect was most prominent in those individuals with a hs-CRP reduction below 1 mg/L in the follow-up period. In summary, the use of CRP in risk prediction remains an interesting topic, but the clinical implications are not clear yet.

Other Markers

While CRP is the most prominent one, also other biomarkers have been investigated that represent inflammation and oxidative stress. The concentration of IL-6, a cytokine centrally involved in inflammation, is correlated with CRP which is explained by the inflammatory cascade since IL-6 stimulated CRP production and release. It has been shown to be associated with incident AMI or mortality (Fisman et al., 2006). Myeloperoxidase (MPO) is a product of neutrophil granulocytes and related to oxidative stress. With regard to IHD, higher MPO concentrations have been associated with cardiovascular events in patients after ACS (Baldus et al., 2003). In stable patients with CAD, MPO was also a prognostic marker (Tang et al., 2011). Furthermore, the lipoprotein-associated phospholipase A2, the pregnancy-associated plasma protein, and the phospholipase A2 have been discussed (Omland and White, 2017).

Multibiomarker Approach

More recently, a multibiomarker approach has been suggested to improve risk prediction and diagnosis of CAD. The concept of a biomarker-score, which combines the pathological results of different markers, reflects the multifactorial background of atherosclerotic disease. In the Framingham Heart Study, a general population setting, the biomarkers BNP, CRP, urinary albumin-to-creatinine ratio, homocysteine, and renin were associated with a first cardiovascular event (Wang et al., 2006). The combination of 30 cardiovascular biomarkers improved risk assessment for long-term cardiovascular disease incidence (Blankenberg et al., 2010). In another multiplex approach, more than 100 biomarkers were investigated in a cohort of patients undergoing angiography (Ibrahim et al., 2017). The four biomarkers adiponectin, apo C-I, KIM-1, and midkine were selected and combined in a predicting model. These new biomarkers combine the different pathophysiological backgrounds including inflammation (midkine), metabolic status (adiponectin and apo C-1), and renal dysfunction (KIM-1) and resulted in an AUC of 0.87 for the diagnosis of CAD. To date, multimarker approaches have shown that natriuretic peptides and inflammatory biomarkers range among the strongest predictors of CAD. However, the efficiency of multimarker testing in clinical practice has not been proven to be efficient.

Omics and Genetics

Most of the established biomarkers have been identified by classical, hypothesis-driven research. However, over the past years a novel tool for identification of potential biomarkers came up. By the term "omics" the comprehensive measurement evaluation of different biological steps from genome to transcriptome, proteome, and metabolome are summarized. Using mass array measurements huge amounts of data can be generated to detect potential target pathways. This approach requires large and well-characterized samples and novel statistical methods to identify potential biomarkers that may be clinically relevant. Most advanced are genomics with the identification of numerous genetic loci that are associated with disease risk by genome-wide association studies of common genetic polymorphisms and increasingly sequencing information (Abraham et al., 2016; Myocardial Infarction et al., 2016; Nikpay et al., 2015). Within the past 15 years the rapidly evolving field of genome-wide association studies (GWAS) and increasing sequencing data has provided fundamental insights into the genetics of IHD (Pjanic et al., 2016). These large studies aim to discover hitherto unknown pathophysiological pathways of the disease. They are well-suited for this purpose because the approach is largely hypothesis-free and associates specific genetic loci with IHD. With regard to IHD, several large-scale studies have been performed (Samani et al., 2007). In a recently published metaanalysis including 185,000 individuals, 58 loci were identified to be associated with CAD (Nikpay et al., 2015). In the future, these studies will have major impact on our understanding of disease pathophysiology and potential treatment approaches. Genetics remain stable over a lifetime and genetic risk scores improve risk prediction beyond classical risk factors (Abraham et al., 2016). However, clinical use is still limited.

Summary and Outlook

Biomarkers in patients with IHD are well established and used in clinical routine. Cholesterol subfractions are true risk factors as their treatment results in modification of IHD risk. Cardiac troponin is one cornerstone for the diagnosis of AMI that is well established in clinical routine. Development of newer, high-sensitivity troponin assays enabled the detection of much lower concentrations, which are far below the routinely used 99th percentile. This improvement resulted in lower cutoff concentrations and rule-in or rule-out of AMI after only one hour after admission for many patients. Furthermore, high-sensitivity troponin assays are also used for risk prediction in diseased cohorts, e.g., with stable CAD or even the general population. Several other biomarkers are on the horizon and are evaluated in clinical studies. The most promising ones include microRNAs that have been proven to be modifiable and genetics that will help to gain deeper insights into the pathophysiology of IHD development and manifestation.

Introduction

Despite significant advances in the field of cardiology and an overall reduction in age-standardized rates of death attributable to cardiovascular disease (Wang et al., 2016), heart failure (HF) is becoming an increasingly prevalent chronic condition. In fact, HF is the most common admitting diagnosis in hospitals located in high-income countries for patients aged 65 years and older, accounting for approximately one million hospital admissions in the United States alone (Braunwald, 2015).

While both medical and device-based therapies for HF have made significant inroads, survival after HF diagnosis still remains poor. The OPTIMIZE-HF (Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure) study demonstrated greater than 8% mortality within 90 days of discharge following a hospitalization for HF exacerbation; the combined endpoint of death or repeat hospitalization was 36% (Fonarow et al., 2008). Some studies estimate survival at 50% at 5 years, and as low as 10% at 10 years following diagnosis of HF (Roger, 2013). These studies illustrate the importance of continued improvements in our understanding of disease progression, management, and disease prevention.

This review will examine the clinical utility of circulating biomarkers in disease management, and potential prevention strategies. Since the introduction of B-type natriuretic peptide (BNP) to guide HF diagnosis, management, and prognosis in 2001 (Maisel, 2009), there has been intense interest in novel biomarker discovery in heart failure, as evidenced by an exponential increase in publications on the topic (van Kimmenade and Januzzi, 2011). However, beyond natriuretic peptides, the clinical utility of biomarkers in HF remains unclear (Wilson Tang et al., 2007). In this review, we will (1) summarize current guidelines for the use of biomarkers in HF; (2) highlight general principles to evaluate clinical utility of novel biomarkers; (3) review existing studies to support the role of select biomarkers to guide prognosis, management, and risk prediction of HF; and (4) identify current knowledge gaps and future directions whereby biomarkers may inform clinical decision-making.

Current Guidelines for Biomarkers in Heart Failure

Many recommendations outlining the use of biomarkers to guide diagnosis and management of HF are available, including practice guidelines from groups such as the American College of Cardiology Foundation (ACCF), American Heart Association (AHA), Heart Failure Society of America (HFSA), and the European Society of Cardiology (ESC). Though these guidelines were developed independently, one commonality has emerged: confirmation of the utility of measuring natriuretic peptides in patients with HF, as summarized in **Table 1**.

All three society guidelines support the use of natriuretic peptides to aid diagnosis of HF in patients suspected of having HF (Ponikowski et al., 2016; America, 2010; Yancy et al., 2013). The ESC guidelines specifically point out the high negative predictive value of natriuretic peptides at specified thresholds and comment on their use to rule out HF but not necessarily to establish the diagnosis (Ponikowski et al., 2016). While useful in symptomatic individuals, the use of natriuretic peptides as a screening test in the absence of symptoms is not recommended by the HFSA guidelines. Once HF diagnosis has been established, ACC/AHA guidelines support a class I recommendation for the use of natriuretic peptides to aid in prognostication, whereas ESC supports a class IIa recommendation for initial assessment in newly diagnosed HF. Beyond aiding in HF diagnosis and prognosis, the ACCF/AHA guidelines also support Class IIa and Class IIb recommendations for the use of natriuretic peptides in guiding medical therapy

Table 1 Summary of major society recommendations for the use of biomarkers in heart failure

Biomarker	*Society**	*Class*	*Setting*
Natriuretic peptides	ACC/AHA	I	Diagnosis: ambulatory, acute
		I	Prognosis: ambulatory, acute
		IIa	Ambulatory HF: achieve guideline-directed medical therapy
		IIb	Acute HF: guide medical therapy
	ESC		Diagnosis: rule out HF
		IIa	Initial assessment in newly diagnosed HF
	HFSA	Recommended	Diagnosis: when HF is suspected
		Not recommended	Routine screening in asymptomatic individuals
Myocardial injury	ACC/AHA	I	Prognosis: ambulatory, acute
Myocardial fibrosis	ACC/AHA	IIb	Additive risk stratification: ambulatory, acute

*Guideline recommendations pertaining to heart failure from ACC/AHA 2013, ESC 2016, and HFSA 2010 documents.

in chronic HF and in acutely decompensated HF, respectively. By contrast, neither the ESC nor the HFSA guidelines remark on the utility of natriuretic peptides in the management of previously diagnosed HF.

Beyond natriuretic peptides, however, the clinical applicability of other biomarkers in routine medical practice is less clear. The ACCF/AHA guidelines also support the use of cardiac troponins in establishing disease severity and prognosis in acute decompensated HF (Class I), and the use of biomarkers of myocardial fibrosis for additive risk stratification, with specific mention of soluble ST2 and galectin-3 (Class IIb). By contrast, the ESC guidelines state that there is no definite evidence supporting the use of other biomarkers in routine clinical practice. Lastly, the HFSA guidelines do not mention additional biomarkers beyond natriuretic peptides. Motivated by these differences, we will examine general principles used to evaluate biomarker studies and summarize key studies supporting current guidelines below.

What Defines Potential Clinical Utility of Biomarkers in HF?

A number of objective criteria have been put forth in order to appraise the potential relevance of biomarkers to clinical practice. The AHA suggests six phases of evaluation for any new biomarker: proof of concept, prospective validation, incremental value, clinical utility, clinical outcomes, and cost-effectiveness (Hlatky et al., 2009). Others have specified three criteria to evaluate the utility of biomarkers: the biomarker must be measurable, informative, and actionable (Morrow and de Lemos, 2007). Specific to the field of HF, the National Academy of Clinical Biochemistry has elucidated similar goals for biomarkers specifically in the setting of HF; in this definition, biomarkers should be able to identify underlying causes of HF, confirm presence of HF syndrome, estimate severity of disease, and predict the risk of disease progression (Wilson Tang et al., 2007).

Beyond assay-specific qualities such as reproducibility, accuracy, and cost, a given biomarker must first associate strongly with the disease in question. The additive value of a biomarker with respect to risk prediction can then be evaluated using metrics of discrimination, reclassification, and calibration. Discrimination indicates the ability of a biomarker to differentiate between an event and a nonevent (Ahmad et al., 2014). Often, the incremental discriminatory value of a biomarker when added to a clinical model is assessed by the change (or improvement) in the C-statistic. Given inherent limitations in the C-statistic, reclassification metrics have also been used (Pencina et al., 2008). The net reclassification improvement (NRI) metric evaluates whether a biomarker is able to assign higher risk to individuals who eventually develop the outcome of interest, while assigning lower risk to those who do not develop events (Pencina et al., 2011). Lastly, calibration is a measure of how frequently a predictive model matches the outcome in reality (Ahmad et al., 2014).

While assessment of discrimination and reclassification help refine our understanding of biomarkers in risk prediction, it is important to note existing limitations. Despite strong associations with HF, the majority of biomarker studies have demonstrated only modest increments in C-statistics and NRI with respect to HF risk prediction (Wang, 2011). It may be that clinical predictors already result in a "high" C-statistic, above which an added improvement with any biomarker is much more difficult to demonstrate (Pencina et al., 2008). It is important to acknowledge that no accepted risk categories exist for HF, making the NRI somewhat more difficult to interpret. Lastly, studies of HF risk prediction have largely combined the categories of HF with preserved ejection fraction and HF with reduced ejection fraction, despite distinct underlying pathophysiology and therapies among the two HF subtypes (Echouffo-Tcheugui et al., 2015; Yancy et al., 2013). This amalgam reduces the specificity of existing risk prediction models.

Selected Biomarkers: What Do We Know?

There has been intense interest in elucidating the role of biomarkers in HF, with studies focused on risk prediction of future HF, as well as prognostication among patients with acute and chronic HF as summarized in **Table 2**. Below we summarize key studies for selected biomarkers.

Table 2 Existing studies examining biomarkers relevant to the ACC/AHA clinical stages of heart failure

Biomarker	*Stage A Risk factors*	*Stage B LV remodeling*	*Stage C/D Symptomatic HF*		
Characteristic	*Prediction of incident HF*		*Diagnosis*	*Prognosis*	*Guide therapy*

B-Type Natriuretic Peptide & N-Terminal Pro-B Type Natriuretic Peptide

In the early 1990s, BNP was found to be secreted from the ventricular myocardium in response to pressure overload, in many cases itself a byproduct of volume expansion (Daniels and Maisel, 2007). Downstream effects of the binding of BNP to its receptor include natriuresis, vasodilation, inhibition of the renin–angiotensin–aldosterone system (RAAS), and increased myocardial relaxation (Kim and Januzzi, 2010). Studies focused on tailoring HF management to serum levels of natriuretic peptides began just a few years later, in the late 1990s (Murdoch et al., 1999; Troughton et al., 2000). These studies provided initial evidence that BNP-tailored management may improve clinical outcomes.

Other studies from that time demonstrated that measurement of BNP could rapidly confirm the diagnosis of HF (Dao et al., 2001; Maisel et al., 2002). In a 2002 study known as the Breathing Not Properly Multinational Study, BNP levels alone were found to be more accurate than any other component of the history, physical exam, or additional laboratory values in determining the cause of a patient's dyspnea (Maisel et al., 2002). The PRIDE (Pro-Brain Natriuretic Peptide Investigation of Dyspnea in the Emergency Department) study, a similar study measuring NT-proBNP levels in the Emergency Department, provided further evidence that natriuretic peptide measurements could facilitate diagnosis of HF (Januzzi et al., 2005).

A 2003 follow-up study to the Breathing Not Properly Multinational Study with 6 months of monitoring revealed that BNP levels were also highly predictive of cardiac events (Harrison et al., 2002). In an analysis of the Framingham Offspring Study, BNP levels were found to be independently predictive of the risk of death, heart failure, stroke, and atrial fibrillation, even after statistical adjustment for traditional risk factors (Wang et al., 2004). Larger, more recent studies have corroborated these early studies; BNP and NT-proBNP have been proven to be strongly associated with cardiovascular events and mortality in both symptomatic and asymptomatic patients (Doust et al., 2005; Di Angelantonio et al., 2009). However, more data are needed from low- and intermediate-risk populations before testing in the general population can be recommended without reservation (Di Angelantonio et al., 2009). There is some evidence that measurement of NT-proBNP levels in a healthy population may not offer reliable predictions regarding cardiovascular outcomes, though prognostic value was added with its measurement in patients with Stage A/B HF, a finding consistent with prior studies (McKie et al., 2010).

Current research in this field is focused on the role of monitoring natriuretic peptide levels both in the inpatient and outpatient settings. During acute HF exacerbations requiring hospitalization, general consensus argues for measurement of BNP levels at time of admission and prior to discharge (Pang et al., 2012). Many studies have shown that a substantial decrease in BNP levels during hospitalization portends good outcomes, while patients with relatively stable or increased BNP levels were more likely to experience hospital readmissions or increased mortality rates (Van Cheng et al., 2001; Bettencourt, 2004; Michtalik et al., 2011). A number of studies have further examined the potential utility of natriuretic peptides in guiding medical therapy in the acute and chronic setting and are summarized under "Future Directions" later in this article. Outpatient monitoring of BNP levels remains controversial (Januzzi and Troughton, 2013; Desai, 2013), in no small part due to the fact that the intraindividual biological variability of BNP and NT-proBNP levels is quite high (O'Hanlon et al., 2007). For this reason, some support the establishment of a baseline or "steady-state" BNP level; recognizing a patient's normal BNP level allows for clinical decision-making based on variation from that mean (Daniels and Maisel, 2007).

Lastly, the utility of BNP in screening approaches for the prevention of HF has also been recently examined and is summarized under "Future Directions." Though there is no single perfect biomarker in HF, the utility of measuring BNP and NT-proBNP has been proven in many different studies, and its current use in establishing diagnosis and risk stratification of patients with HF is widespread. Future studies may further define BNP-guided management strategies and a potential role in screening and HF prevention. Significant value may also be gained from a multimarker approach in the context of several other biomarkers, as described later.

Highly Sensitive Troponin-I (hsTnI) & Highly Sensitive Troponin-T (hsTnT)

The measurement of cardiac proteins troponin-I and troponin-T is a mainstay for diagnosis and evaluation of patients with acute coronary syndrome. However, cardiac troponins have also been found to be elevated in patients with HF (Gaggin and Januzzi, 2013). As biomarker assays become more refined, highly sensitive troponin (hsTn) assays will be increasingly utilized. One benefit of the hsTn assays is that troponin values are measurable in the majority of patients, and therefore elevated levels may represent better discrimination when compared to traditional, low-sensitivity troponin assays.

The measurement of hsTnI in patients with acute decompensated HF has been shown to have prognostic value. This is particularly notable because troponin proteins are often measured in patients with acute decompensated HF on presentation in order to rule out myocardial infarction as a cause of their acute symptoms. In a study of patients hospitalized with decompensated heart failure, Xue et al. (2014) showed that even small changes in troponin values during a HF exacerbation are associated with increased 90-day mortality and hospital readmission; moreover, increasing levels of hsTnI in admitted patients suggest higher mortality than patients in whom hsTnI levels are stable or decreasing. Increased levels of hsTn have also been seen in patients with chronic and symptomatic HF in proportion to the severity of disease (Latini et al., 2007). Notably, the prognostic value of hsTn may improve when evaluated in combination with other markers, such as NT-proBNP and soluble ST2 (Pascual-Figal et al., 2014). Lastly, hsTn concentrations predict incident HF among population-based studies (Wang et al., 2012; deFilippi et al., 2010). As more clinical centers adopt hsTn assays as part of routine medical care, the utility of hsTn measurements in HF will become clearer.

Soluble ST2

ST2, a member of the IL-1 receptor family, is a protein with transmembrane (ST2L) and soluble (sST2) isoforms (Sanada et al., 2007). Soluble ST2 acts as a decoy receptor for the ligand IL-33, which has been shown to be antifibrotic and antihypertrophic (Sanada et al., 2007). Therefore, the cardioprotective effects of the IL-33/ST2L interaction, shown in experimental models to reduce apoptosis and to improve myocardial function, are inhibited by sST2 (Pascual-Figal and Januzzi, 2015).

Similar to BNP and NT-proBNP, ST2 is a protein induced by mechanical strain in cardiac myocytes; it has been found to be significantly higher in patients with severe HF when compared to patients without HF (Weinberg, 2003). Elevations in ST2 indicate a worse prognosis in patients with chronic HF and increases in ST2 levels over a 2-week period have proven to be an independent predictor of mortality or transplantation; notably, dynamic changes in BNP in this study were not shown to predict adverse outcome, suggesting that ST2 may be even more sensitive than natriuretic peptide levels (Weinberg, 2003). A subanalysis of PRIDE, a prospective study of more than 500 patients who presented to the Emergency Department with acute shortness of breath, demonstrated that ST2 levels were as predictive of mortality at 1 year as NT-proBNP (Januzzi et al., 2007). Importantly, elevations of both NT-proBNP and ST2 were associated with the highest 1-year mortality in the cohort, arguing there may be a role for clinical prediction using multiple HF biomarkers simultaneously (Januzzi et al., 2007). This finding has been confirmed in multiple additional studies (Bayes-Genis et al., 2014; Pascual-Figal et al., 2014). Some studies suggest that ST2 may be reliable even in elderly patients with ischemic disease, a population in which natriuretic peptide levels have been shown to be less useful (Broch et al., 2014).

Outpatient monitoring of ST2 is not yet standard of care in clinical practice; however, some studies have demonstrated the utility of its measurement. An analysis of over 3000 patients in the Framingham Heart Study revealed the prognostic value of elevated ST2 levels in a community-based cohort. Patients in the Framingham Heart Study with elevated ST2 levels, only a small percentage of whom had prevalent cardiovascular disease, were more likely to experience adverse outcomes, including incident HF (Wang et al., 2012).

At this point, there does not seem to be utility to serial measurements of ST2 obtained in an effort to guide therapy. However, a single measurement of ST2 might be useful in helping clinicians to make management decisions. One study, though limited by a small sample size, suggests that eplerenone may attenuate left ventricular remodeling in patients with high levels of ST2 following acute myocardial infarction (Weir et al., 2010). The ability of ST2 to reflect ventricular remodeling provides information beyond what can be determined by measuring natriuretic peptides alone. Further, unlike other biomarkers, ST2 levels do not appear to be affected by weight or kidney function, which allows for more standardized measurements across populations (Karayannis et al., 2013).

Galectin-3

Galectin-3 is a β-galactoside-binding lectin that is overexpressed in cardiac macrophages of failure-prone hearts even before overt clinical HF can be diagnosed (Sharma, 2004). Further supporting the idea that galectin-3 is related to cardiac dysfunction is evidence that intrapericardial delivery of exogenous galectin-3 leads to collagen deposition and fibrosis (Sharma, 2004). In fact, murine models showed that the level of galectin-3 associated strongly with the severity of future cardiac fibrosis (Sharma, 2004). It also plays a significant role in fibrosis of other organs, including the liver and kidney (Henderson et al., 2006, 2008).

The aforementioned PRIDE study also identified galectin-3 as a possible biomarker for patients with acute decompensated heart failure. In that study, galectin-3 was found to be a better prognostic marker for 60-day mortality compared to NT-proBNP (Januzzi et al., 2005). Perhaps more importantly, the combination of biomarkers improved prognostic capability (van Kimmenade et al., 2006). A subset of these patients had a longer follow-up period; galectin-3 levels were associated with both 1- and 4-year mortality

(Shah et al., 2014). Further, galectin-3 levels showed an association with echocardiographic markers of LV filling, diastolic function, valvular regurgitation, and RV function (Shah et al., 2014), suggesting that galectin-3 may associate strongly with HF with preserved ejection fraction. Other studies have also shown that the predictive value of galectin-3 may be greater in patients with preserved systolic function (de Boer et al., 2010).

Additional research has demonstrated the value of galectin-3 as a biomarker in patients with chronic heart failure. The DEAL-HF study confirmed galectin-3 as an independent predictor of mortality in patients with moderate-to-advanced chronic HF (Lok et al., 2010). A study of patients with severe HF requiring mechanical circulatory support showed that galectin-3 levels were significantly higher in patients with HF than controls and that HF patients who did not survive ventricular assist device support had higher galectin-3 levels than those that were able to successfully undergo heart transplantation (Milting et al., 2008).

Prospective studies to see whether galectin-3 might be used to guide therapy do not exist. However, multiple studies have shown that increasing galectin-3 levels increase the risk of repeat hospitalization for HF and the risk of death (van der Velde et al., 2013). Other studies have shown that therapies for HF may be more effective in patients with low galectin-3 levels at baseline. Val-HeFT, a study of the effect of valsartan in patients with heart failure demonstrated a reduction in repeat HF hospitalizations for patients with low galectin-3 levels; this finding was not seen in patients with high galectin-3 levels (Anand et al., 2014). Similarly, a *post hoc* analysis of the CORONA (Controlled Rosuvastatin Multinational Trial in Heart Failure) study appeared to show benefit with rosuvastatin therapy in patients with systolic HF and low levels of galectin-3 (Gullestad et al., 2012), despite a lack of evidence for statin therapy for all patients with heart failure.

Lastly, galectin-3 was shown to predict incident HF among community-dwelling adults (Ho et al., 2012). While not yet shown to be a valuable diagnostic marker in heart failure, galectin-3 has been shown to contribute to cardiac fibrosis and ventricular remodeling; its role in the development and progression of HF may lead to significant advancements in disease treatment in the future. At the present time, however, it remains a useful biomarker with prognostic value in both acute and chronic heart failure.

Growth Differentiation Factor-15 (GDF-15)

Growth differentiation factor-15 (GDF-15), a member of the transforming growth factor β (TGF- β) family of cytokines, has been shown to have antiapoptotic, antihypertrophic, and antiinflammatory in cardiovascular disease models (Wollert and Kempf, 2012). Wang et al. (2012) have shown that GDF-15 concentrations were strongly associated with risk of HF and with mortality. A 2007 study showed that GDF-15 levels were significantly increased in patients with HF and that there was a graded relationship between the level of GDF-15 at time of study entry and the risk of death during study follow-up (Kempf et al., 2007). The Val-HeFT study demonstrated similar findings; GDF-15 was again found to be an independent predictor of death. In this study, repeat measurement of GDF-15 12 months after first measurement provided additional information. Changes in GDF-15 levels over time were independent associated with risk of mortality. Further, it was found that the intraindividual variation between GDF-15 levels in patients with stable chronic HF were lower than with other common biomarkers (Anand et al., 2010), suggesting that repeat measurements of GDF-15 may be useful in biomarker-guided therapy.

Future Directions

Biomarker-Guided HF Management

Prior studies examining the use of natriuretic peptides in biomarker-guided care have demonstrated mixed results (Lainchbury et al., 2009; Pfisterer et al., 2009; Januzzi et al., 2011). This heterogeneity in results appears to be related to whether or not the active arm achieved lower natriuretic peptide levels through the trial, in addition to the population being studied, with younger patients and those with heart failure with reduced ejection fraction deriving the most benefit (Yancy et al., 2013). In the Pro-BNP Outpatient Tailored Chronic Heart Failure (PROTECT) study, targeting an NT-proBNP level of 1000 pg/mL or lower resulted in a reduction in cardiovascular events in the active vs standard of care groups (Januzzi et al., 2011). A substudy provided echocardiographic evidence that left ventricular volumes and function improved with lower NT-proBNP levels, irrespective of treatment allocation within the study (Weiner et al., 2014). Multiple other studies have supported improvements in clinical HF outcomes with NT-proBNP-guided therapy (Felker et al., 2009; Porapakkham et al., 2010; Pfisterer et al., 2009). However, the largest prospective, randomized trial to date, the Guiding Evidence-Based Therapy Using Biomarker Intensified Treatment (GUIDE-IT) trial, was recently halted by the Data Safety Monitoring Board 18 months prior to planned study completion in light of an interval analysis demonstrating no difference in the primary outcome between NT-proBNP-guided management and usual care. While the formal publication of GUIDE-IT results is still pending at this time, the future of biomarker-guided therapy remains very much unclear.

Improving Risk Prediction

While single biomarker studies may demonstrate relatively modest effects with respect to discrimination and reclassification metrics, several biomarkers representing distinct physiologic pathways, when combined in a multimarker approach may improve upon current risk prediction models. In the MOCA (Multinational Observational Cohort on Acute heart failure) study, multiple biomarkers showed incremental value above and beyond clinical risk factors in patients with acute decompensated heart failure. The combination of CRP and MR-proADM predicted 30-day mortality, with an NRI of 36.8%, and CRP and soluble ST2 predicted

1-year mortality with an NRI of 20.3% (Mebazaa et al., 2015). Multimarker models have also improved upon risk prediction of future HF in community-based populations. Among Framingham Heart Study participants, the combination of natriuretic peptides, soluble ST2, GDF-15, hsTnI, and hsCRP improved clinical prediction of incident HF with an NRI of 39% (Wang et al., 2012). With the emergence of large-scale mass spectrometry and newer aptamer-based technology (Ganz et al., 2016), the ability to rapidly ascertain a large number of known and novel biomarkers will continue to refine current HF risk prediction models in the future. Lastly, it is important to acknowledge that current HF risk prediction models are focused on overall HF and group together HF with preserved and reduced ejection fraction, despite distinct pathophysiologic drivers and therapies. To this end, future studies examining biomarkers in relation to specific HF subtypes are needed.

Biomarkers in Prevention of Heart Failure

Two recent studies have examined the utility of natriuretic peptides in guiding preventive efforts in HF. The St Vincent's Screening to Prevent Heart Failure (STOP-HF) trial randomized 1374 participants with cardiovascular risk factors free of HF to BNP screening versus usual care. Participants in the BNP screening arm who had elevated BNP levels of 50 pg/mL or higher underwent echocardiography and collaborative subspecialty care. Investigators found that BNP-based screenng reduced incident left ventricular dysfunction and HF and appeared cost-effective (Ledwidge et al., 2013). Similarly, in the PONTIAC (NT-proBNP Selected PreventiOn of cardiac eveNts in a populaTion of dIabetic patients without A history of Cardiac disease) study, 300 patients with elevated NT-proBNP >125 pg/mL were randomized to "intensified" treatment in a cardiac clinic focused on uptitration of medical therapy versus usual care. PONTIAC demonstrated accelerated uptitration of renin angiotensin system antagonists and beta-blockers in the "intensified" group, with a significant reduction in cardiac events after 2 years compared to the usual care group (Huelsmann et al., 2013). These studies suggest that biomarkers may help identify at-risk individuals and have the potential to guide preventive strategies in the future.

Conclusion

Despite the widespread use of natriuretic peptides and hsTn in the diagnosis and management of HF, the clinical utility of the myriad of other cardiovascular biomarkers that have been associated with HF alone or in combination remains unclear. The field of biomarkers in HF is at an exciting inflection point with the emergence of large-scale metabolomic and proteomic platforms now allowing for rapid assessment of existing and novel circulating biomarkers. Future studies will be necessary to refine current risk prediction models using multimarker approaches and HF subtypes, with the ultimate goal of assisting clinicians in risk stratifying and treating their patients with HF.

What is a Biomarker?

A biomarker is a reflection of a biological, physiological, or pathological process or a pharmacologic response to a therapeutic intervention that can be measured objectively, accurately, and reproducibly (adopted from Strimbu and Tavel (2010) and Biomarkers Definitions Working Group (2001)). Thus, a broad spectrum of measures can be considered as biomarkers, including markers measured in various biosamples (e.g., blood, urine, stool, or tissue), imaging tests (e.g., echocardiography, magnetic resonance imaging, or computed tomography), and (electro-)physiological measures (e.g., blood pressure, electrocardiography) (Vasan, 2006). In recent years, also complex molecular markers and marker profiles are being increasingly evaluated as potential cardiovascular biomarkers, including genetic, metabolomic, and proteomic markers (Vasan, 2006; Ussher et al., 2016). In terms of their temporal relation to disease processes and their clinical application, biomarkers can be classified, for example, as markers that identify individuals at high risk of disease, before the disease has developed (antecedent biomarkers), as biomarkers that detect subclinical changes, for example, of the heart or the vascular system (screening biomarkers), or markers that detect clinically overt disease (diagnostic biomarkers) (Biomarkers Definitions Working Group, 2001; Vasan, 2006). Among patients with established disease, biomarkers can inform treatment strategies (e.g., by predicting the response to and efficacy of a given therapy; predictive biomarkers) and help in assessing disease severity (staging biomarkers) and prognosis of patients (e.g., by predicting the future course of disease; prognostic biomarkers) (Biomarkers Definitions Working Group, 2001; Vasan, 2006).

Key Requirements and Features of a Good Biomarker

In order to be applicable in clinical practice, risk stratification, or population screening, biomarkers should meet several requirements, as outlined, for example, by the American Heart Association (AHA) (Hlatky et al., 2009). First, biomarkers need to be accurately and reproducibly measurable (Manolio, 2003). Additionally, one of the most basic requirements for a novel risk marker is a strong statistically significant association with the outcome of interest, independently of other risk factors (Hlatky et al., 2009). Furthermore, the biomarker should explain a reasonable proportion of the interindividual variation of the disease outcome of interest, and improve risk prediction models beyond established risk factors (please see below for

details) (Hlatky et al., 2009; Manolio, 2003). Some characteristics of biomarkers vary with their intended use (e.g., screening, diagnosis, prognosis) (LaBaer, 2005). For example, in clinical settings, biomarker measurements need to be acceptable to the patient, be easy to interpret by clinicians, and should be linked to patient management (Manolio, 2003), in the sense that measuring the biomarker should impact clinical decision making, and ultimately improve patient outcomes. The present article aims to focus on biomarkers in the context of risk stratification and population screening. Important basic concepts for risk stratification and population screening are the estimation of absolute disease risks and the performance of risk prediction models, both of which are detailed in the next paragraph.

Assessment of Absolute Disease Risk and Principles of Risk Prediction

The cardiovascular disease (CVD) risk of a given individual is determined by a complex interplay of multiple risk factors over the life course. To reflect the multifactorial nature of CVD, risk scores have been developed that incorporate information from multiple risk factors to generate estimates of absolute disease risk. Commonly used scores include, for example, the American College of Cardiology (ACC)/AHA 2013 risk score (Goff et al., 2014), the Framingham Risk Score (FRS) (Wilson et al., 1998), the Reynolds Risk Score (Ridker et al., 2007), or the SCORE of the European Society of Cardiology (ESC) (Conroy et al., 2003).

To evaluate the performance of risk scores and prediction models and to assess the incremental value of biomarkers when added to these models, different metrices have been developed, including discrimination, calibration, and reclassification.

Discrimination refers to the ability of a risk prediction model to distinguish individuals who do not develop the outcome of interest over a given follow-up period from those who develop the disease of interest (Greenland et al., 2010). A common measure of discrimination is the C statistic which is equivalent to the area under the receiver operating characteristic (ROC) curve (Hanley and McNeil, 1982). The C statistic incorporates the sensitivity and specificity of a screening or diagnostic test and predicts the probability that in two randomly paired individuals, one with and one without the disease, a given model correctly identifies the one who is diseased from the one who is not. Values for the ROC or C statistic range from 0.5 (uninformative model) to 1.0 (perfect discrimination) (Wang, 2011). As an example, the FRS, which is based on traditional cardiovascular risk factors, yields a C statistic of ~0.75 (Wang et al., 2006).

Calibration quantifies the agreement between predicted and observed risks, that is, the disease risk as predicted by the score on the one hand, and the risk that is actually observed in a given prospective cohort on the other hand (Wang, 2011). It is usually assessed in quantiles of baseline risk and tested using the Hosmer–Lemeshow test. The observed number of events within a given time horizon is compared to the expected number of events, as predicted by the score. Importantly, when transferred to other populations, risk prediction models may have to be recalibrated, in order to account for different mean risk factor levels and differences in the incidence rates of the outcome of interest between populations (Vasan, 2006; Wilson et al., 1998).

A third performance measure, *reclassification*, refers to the ability of a (modified) score to reclassify individuals between defined risk categories. Individuals can be assigned, for example, to low risk, intermediate risk, and high risk, based on their absolute disease risk estimates. When a given score is modified (e.g., by adding a new biomarker to the model), some individuals will shift between risk categories because the predicted risk in the baseline model belonged to a different risk category than their risk based on the modified score. Reclassification refers to the proportion of individuals that is correctly assigned to a new risk category, once additional information is added to the risk prediction model, for example, by including information from a new biomarker (Hlatky et al., 2009). Reclassification of intermediate-risk individuals to the low- or high-risk category might be particularly helpful because for intermediate-risk individuals, treatment decisions are usually less clear as compared to low- and high-risk individuals (Helfand et al., 2009). However, simply quantifying the proportion of individuals that are being reclassified might be misleading, because down-classifying individuals who actually develop an event is inappropriate as is upward-classification of individuals who remain free of CVD. The net reclassification improvement (NRI) (Pencina et al., 2008) subtracts incorrectly reclassified individuals from the number of individuals who are correctly reclassified (in the right direction (upward-classification of individuals with an event during follow-up; downward-classification of individuals free of an event during follow-up). As an orientation, changes in the C statistic of >0.01 and an NRI $>10\%$ indicate meaningful improvement in risk prediction when adding a new biomarker to a traditional model (Folsom, 2013). More recently, Pencina et al. (2011) presented a modified version of the NRI, the continuous or category-free NRI, that counts the direction of change in an extended risk prediction model for every person rather than the crossing of a threshold (Pickering and Endre, 2012). In scenarios where no established categories of risk exist (or risk categories have no clinical/practical consequences), it might be more appropriate to use the continuous NRI (Pencina et al., 2011).

As outlined by the AHA, novel biomarkers should improve the performance of risk prediction models beyond established risk factors (Greenland et al., 2010), including the reclassification of individuals in more appropriate risk strata, and the identification of particularly vulnerable people.

Biomarkers in Population Screening

One of the main purposes of screening biomarkers in the general population is to identify individuals who are at high risk of future CVD but who are currently free of clinical CVD and who might benefit from some sort of intervention (lifestyle modification or pharmacological treatment) to prevent clinically overt disease. In order to serve this purpose, it is important that such biomarkers capture the disease process at an early stage and, for example, detect subclinical changes of the vascular or cardiac system that might

predispose to overt CVD (Vasan, 2006; Naghavi et al., 2003) but that are potentially reversible or whose progression could be slowed down upon appropriate intervention. As an important hallmark, screening markers should have good discriminative abilities. Thus, they should be able to distinguish between individuals with future CVD and individuals who will remain free of CVD. One fundamental basis for such discrimination abilities is a very strong association between the biomarker level and future disease risk (Wald et al., 1999). In this context, it is worth noting that most causal risk factors (including high blood pressure and LDL-cholesterol) do not represent good screening tools because the distribution of risk factor levels in individuals with versus without the disease may substantially overlap leading to a low discrimination of these markers (Wald et al., 1999).

In primary prevention settings, high specificity of a biomarker is particularly important because mislabeling a healthy individual (predicting disease when it is likely to be absent) can cause unnecessary anxiety, medical follow-up examinations (with associated costs), and treatment and may outweigh the consequences of missing a rare condition (Piepoli et al., 2016). However, extensive community screening in people at relatively low risk of CVD is uncertain to be effective in reducing the risk of cardiovascular events. The costs of such screening are high, and it is conceivable that these resources may be more efficiently used in people with higher baseline CVD risk (Piepoli et al., 2016).

Official recommendations: Thus, the ESC does not recommend general systematic CVD risk assessment in men <40 years of age and in women <50 years of age without known risk factors (Piepoli et al., 2016). Still, systematic CVD risk assessment may be considered in adult men >40 years of age and in women >50 years of age or in postmenopausal women without known risk factors. Additionally, the ESC recommends a regular repetition of risk assessment, for example, every 5 years (Piepoli et al., 2016). Similarly, the ACC/AHA guidelines recommend the estimation of absolute 10-year CVD risk beginning at the age of 40 years. The estimation of long-term or lifetime risk is recommended for individuals between 20 and 39 years of age and for those between 40 and 59 years of age who are determined to be at low 10-year risk (<7.5%). For these low-risk persons, the ACC/AHA guidelines recommend a repetition of risk assessment every 4–6 years (Goff et al., 2014).

Risk Stratification

Traditional risk factors form the basis of established prediction models in order to estimate absolute disease risks, which can then be used to stratify a given population, for example, in individuals of low, intermediate, and high CVD risk. Even though the exact cutpoints might differ, this stratification has potential therapeutic/clinical consequences, for example, with respect to the initiation or intensity of risk factor treatment (Greenland et al., 2010).

Biomarkers could potentially help to improve the prediction of absolute disease risk and in identifying those individuals at particularly high risk for CVD (through a more accurate estimation of the absolute disease risk) and through subsequent more accurate reclassification into a more appropriate risk category. Thus, reclassification might be a suitable measure for the usefulness of a new biomarker in improving risk stratification.

Different Types of Biomarkers

Since CVD conditions evolve over the life course, overt CVD is typically preceded by a long period of cumulative exposure to elevated risk factor levels and subclinical alterations of the heart or the vascular system (Gibbons and Dzau, 1994; Cohn et al., 2000). Imaging biomarkers are best suited to detect the presence of subclinical CVD, genetic markers could capture a certain predisposition for a disease of interest, but since most DNA sequence information does not change over the life course, genetic markers are unlikely to capture progressive changes of a disease process or disease activity. Circulating biomarkers could theoretically capture all stages along the disease continuum, including subclinical disease, and changes in circulating biomarker levels could parallel changes in disease activity (Wang, 2011). The following paragraph summarizes recent evidence regarding defined circulating, genetic, and imaging biomarkers.

Circulating Biomarkers

C-reactive protein

C-reactive protein (CRP) is the most established marker of chronic systemic inflammation and has been consistently associated with future CVD in multiple epidemiological studies (Danesh et al., 2004; Buckley et al., 2009). In a large 2012 metaanalysis of 52 prospective studies including 246,669 participants, the addition of CRP to a prognostic model for CVD increased the C statistic only modestly by 0.0039 ($p < 0.001$) and yielded a NRI of 1.52% (Emerging Risk Factors Collaboration et al., 2012). In individual studies ($n = 6502$, $n = 6814$, $n = 3006$, respectively), increments in the C statistic from 0.697 to 0.701 ($p = 0.26$) (Seven et al., 2015), from 0.623 to 0.640 ($p = 0.03$) (Yeboah et al., 2012), and from 0.795 to 0.799 (Wilson et al., 2008) and NRIs of 3.9% (Seven et al., 2015), 7.9% (Yeboah et al., 2012), and 5.6% (Wilson et al., 2008) after adding CRP to FRS risk factors have been reported.

Official recommendations: According to the ACC/AHA guidelines, measurement of CRP for screening purposes may be reasonable for cardiovascular risk assessment in asymptomatic intermediate-risk men ≤50 years of age or women ≤60 years of age (Class IIb recommendation). But CRP measurement is not recommended for risk assessment in asymptomatic high-risk adults, or in low-risk men ≤50 years of age or women ≤60 years of age (Class III recommendation) (Goff et al., 2014; Greenland et al., 2010).

B-type natriuretic peptide

B-type natriuretic peptide (BNP) is synthesized and released from the myocardium as a response to blood pressure and volume overload. It has been recognized as a sensitive marker of acute heart failure (HF) and levels of BNP and of N-terminal prohormone of B-type natriuretic peptide (NT-proBNP), a precursor of BNP, were elevated in individuals with established CVD (Panagopoulou et al., 2013). Furthermore, BNP as well as NT-proBNP levels have also been investigated in community-based samples, and variations within the normal range were found to predict incident CVD in the general population. A metaanalysis of 40 cohort studies reported a summary RR of 2.82 (95% CI: 2.40–3.33) for incident CVD in those with a BNP level in the highest versus lowest tertile. The improvements in risk discrimination (C statistic) were modest, generally ranging from 0.01 to 0.1 (Di Angelantonio et al., 2009). Similarly, in several cohort studies in primary prevention settings, BNP and NT-pro BNP led to relatively minor increments in the C statistic (from 0.01 to 0.03) (Zethelius et al., 2008; Melander et al., 2009; Olsen et al., 2007). In two studies, reclassification was assessed and found to be statistically nonsignificant for cardiovascular events (Melander et al., 2009) or cardiovascular mortality (Zethelius et al., 2008). In another individual-participant-data metaanalysis of 95,716 participants, the addition of NT-proBNP to a model containing conventional risk factors increased the C statistic by 0.012 and 0.019 and yielded NRIs of 2.7% and 2.8%, for two different combinations of endpoints, respectively (Natriuretic Peptides Studies Collaboration et al., 2016). In two United Kingdom-based cohort studies using two different risk scores, NT-proBNP was associated with increased CVD risk and resulted in an increase in the C statistic by 0.017 ($p=0.005$) for one of the risk scores but did not improve the C statistic of the other risk score. However, NT-proBNP yielded NRIs of 5.9% and 4.7% (Welsh et al., 2016). Interestingly, in studies that compared BNP (or NT-proBNP) with CRP, BNP/NT-proBNP have demonstrated consistently stronger associations with vascular events and a higher predictive value for cardiovascular and coronary events than CRP (Zethelius et al., 2008; Olsen et al., 2007; Blankenberg et al., 2006; Wang et al., 2004).

Official recommendations: The ACC/AHA 2010 guidelines note that we do not expect a benefit from measurement of natriuretic peptides for CVD risk assessment in asymptomatic adults at the moment due to uncertain discrimination and reclassification values and thus do not recommend this approach for screening in the general population (Class III recommendation) (Greenland et al., 2010).

Lipoprotein-associated phospholipase A2

A newer biomarker in the field of risk prediction is Lipoprotein-Associated Phospholipase A2 ($LpPLA_2$). This enzyme is expressed by inflammatory cells and is bound to lipoproteins, primarily LDL. $LpPLA_2$ leads to the production of proinflammatory factors (Zalewski and Macphee, 2005). A metaanalysis of 32 prospective studies revealed a linear relation between $LpPLA_2$ activity and mass and vascular risk in individuals with and without CVD (Thompson et al., 2010). However, there are only few data concerning the ability of $LpPLA_2$ to improve risk discrimination, calibration, or reclassification. Two studies reported a significant increment in the area under the ROC curve although the increments were relatively small (0.006 and 0.022, respectively) (Daniels et al., 2008; Folsom et al., 2006). In another study of 765 participants, $LpPLA_2$ resulted also in a moderate statistically nonsignificant increase in the area under the ROC curve (0.02, $p=0.31$) and was associated with a statistically nonsignificant NRI of 9.5% (Tsimikas et al., 2009). However, in a Multiethnic cohort of 1821 female CVD patients and a matched subcohort of 1992 women, the association between $LpPLA_2$ and CVD risk disappeared after adjusting for traditional cardiovascular risk factors. The addition of $LpPLA_2$ to two predictive models improved the C statistic by only 0.005 and 0.006 and resulted in a small NRI of 2.7% and 3.5%, respectively (Cook et al., 2012).

Official recommendations: The ACC/AHA guidelines indicate that $LpPLA_2$ might be reasonable for cardiovascular risk assessment in asymptomatic adults with intermediate risk (Class IIb recommendation) (Greenland et al., 2010).

Troponin

Cardiac troponins are released in response to cardiomyocyte necrosis, reflect myocardial cell damage, and are mainly measured in clinical settings in patients for the diagnosis of acute myocardial infarction (MI) (Cahill et al., 2015). Recently, new techniques have been developed that are sensitive enough for detecting low concentrations of circulating troponin and, thus, are usable to measure troponin in general population samples (Cahill et al., 2015). Within the BiomarCaRE project (Blankenberg et al., 2016), a large consortium of multiple clinical and community-based prospective cohort studies across Europe, troponin I emerged as an independent predictor for CVD, cardiovascular mortality, and total mortality in the general population (total sample size, $n=74{,}738$). In moderate to large individual studies (AGES, $n=5764$; the Scottish Heart Health Extended Cohort, $n=15{,}340$; ARIC, $n=9698$), troponin was consistently associated with CVD, coronary heart disease (CHD), or related endpoints (Thorsteinsdottir et al., 2016; Zeller et al., 2014a; Saunders et al., 2011). Adding troponin I to standard prediction models led to increments in the C-statistic ranging from 0.0044 (Zeller et al., 2014a) to 1.4 (Thorsteinsdottir et al., 2016) and NRIs were between 3.2% (Zeller et al., 2014a) and 4.8% (Blankenberg et al., 2016).

Official recommendations: So far, there are no official recommendations regarding the use of troponin for screening and risk prediction for CVD in asymptomatic individuals or the general population.

In summary, existing circulating biomarkers lead to relatively modest improvements in risk prediction. Their clinical utility, cost-effectiveness, and potential ability to change patient management and outcome need to be further evaluated. Two of the most comprehensively studied circulating biomarkers for CVD risk are CRP and BNP/NT-proBNP. While both biomarkers are clearly positively associated with CVD in various settings, improvements in discrimination and risk reclassification are generally only moderate.

Genetic, Metabolomic, and Proteomic Biomarkers

Genetics

In the past decade, multiple common genetic variants have been identified that are reproducibly associated with clinical CVD events, particularly with coronary artery disease (CAD) (Lieb and Vasan, 2013). By contrast, genome-wide association studies for subclinical disease traits revealed substantially fewer associated SNPs (Vasan et al., 2009). One of the most consistently associated loci is the 9p21 locus, which has been associated with CAD as well as with coronary artery calcification and MI (O'Donnell et al., 2011). Since most of these loci were discovered in large consortia with large samples, effect sizes were typically rather small, ranging from 10% to 30% increased risk per copy of the risk allele, despite the statistically significant associations between genetic variants and MI risk. These effects are expected to result in only modest improvements, if any, in risk discrimination or calibration (Samani et al., 2007; McPherson et al., 2007; Kathiresan et al., 2009). More recently, also low-frequency and rare genetic variants are being evaluated in the context of subclinical and clinical CVD. For example, an exome-wide study revealed modest associations of coronary artery calcium and carotid intima-media thickness with APOB and APOE variants, respectively (Natarajan et al., 2016) and comprehensive genotyping and sequencing efforts revealed rare mutations in ANGPTL4, LPL, and SVEP1 to be associated with CVD risk (Myocardial Infarction Genetics et al., 2016).

Furthermore, combinations of genetic variants (genetic risk scores) have been evaluated in the context of clinical and subclinical CVD. For example, in two observational studies ($n = 1154$ and $n = 4392$), a polygenic risk score was significantly associated with a greater risk of coronary artery calcification and carotid plaque, respectively (Natarajan et al., 2017). And in a joint investigation of five prospective population cohorts, a genomic risk score was associated with incident CHD. In two of these five studies a fixed-effects metaanalysis was performed and revealed that addition of this score to traditional risk factors significantly improved the C statistic (by 0.016) and yielded a NRI of 10% (Abraham et al., 2016). Similarly, in a study using data of nine prospective European cohorts, two different genetic risk scores improved net reclassification over the FRS for coronary risk prediction and one of the scores also improved discrimination (Hughes et al., 2012). A review on the clinical usefulness of genetic tests for atherosclerosis reported additive effects of a high genetic risk score (including 50 genetic variants) and self-reported family history with respect to the prediction of incident CHD (Paynter et al., 2016). Another recent study demonstrated that genetic risk scores and lifestyle factors interact in their association with CAD (Khera et al., 2016). Cross-classifying individuals based on their genetic risk and their adherence to a favorable lifestyle revealed that a more favorable lifestyle was associated with lower risk of coronary events, regardless of the genetic risk category (Khera et al., 2016). Finally, genetic risk scores might help identifying individuals that might benefit from statin therapy in primary prevention settings, in the sense that statin therapy leads to a greater reduction in relative risk in those with a high genetic risk score (Natarajan et al., 2017).

Official recommendations: Because of small odds ratios and small incremental risk information of individual genetic polymorphisms, the ACC/AHA and the ESC do not recommend genotype testing for CHD risk assessment in asymptomatic adults (Class III recommendation) (Greenland et al., 2010; Piepoli et al., 2016).

Metabolomics and proteomics

Metabolites are small biochemicals and end-products of complex regulatory pathways that provide information about metabolic processes. In a prospective study of three population-based cohorts, a panel of 68 lipids and metabolites was evaluated in relation to incident CVD and revealed that, after adjusting for several CVD risk factors, higher serum phenylalanine and monounsaturated fatty acid levels were associated with increased CVD risk, whereas higher omega-6 fatty acids and docosahexaenoic acid levels were associated with lower risk (Wurtz et al., 2015). A risk score including these four biomarkers yielded a NRI of 7.6% and 5.3%, respectively, with the majority of individuals being reclassified belonging to the intermediate risk group (Wurtz et al., 2015). In analyses of metabolite profiles and their association with prevalent and incident atrial fibrillation in 2458 Framingham Heart Study participants (Ko et al., 2016), none of the examined amino acids, organic acids, lipids, and other plasma metabolites was significantly associated with the risk of future atrial fibrillation. In this analysis, previous results that demonstrated a relation between metabolites and atrial fibrillation could not be replicated (Ko et al., 2016). In a mass spectrometry-based nontargeted metabolomics approach, four metabolites (lysophosphatidycholine 18:1, lysophosphatidycholine 18:2, monoglyceride 18:2, sphingomyelin) were associated with incident CHD in multivariable-adjusted models and, in combination, led to moderate improvements in discrimination (C statistic: 0.76 vs. 0.75) and reclassification (NRI: 9.2%) (Ganna et al., 2014). In people with established CVD, a large panel of circulating protein markers ($n = 1130$) has been evaluated and revealed that a set of nine proteins is associated with cardiovascular outcomes and improves discrimination by 0.05–0.09 after addition to the Framingham secondary event risk model (Ganz et al., 2016).

Imaging Biomarkers

Coronary artery calcium

A number of observational studies have reported strong associations between coronary artery calcification (CAC) and the risk of incident cardiovascular events (Helfand et al., 2009; Pletcher et al., 2004; Greenland et al., 2007; Hoffmann et al., 2016). Most reports indicated a RR of coronary events of ≥ 2 for those with any CAC compared with those with no CAC, a RR of >4 for those with CAC scores >100, and a RR of >10 for persons with a score of >1000 (Pletcher et al., 2004; Greenland et al., 2007). Available evidence also suggests that CAC scores may improve discrimination. In the MESA and the Rotterdam Studies, CAC scores

were strong predictors of cardiovascular and coronary events and raised the C statistic from 0.77 (with traditional risk factors) to 0.81 (plus CAC score) and from 0.72 to 0.76, respectively (Elias-Smale et al., 2010; Folsom et al., 2008). There is also increasing evidence that CAC scores improve reclassification, particularly for individuals at intermediate risk. In the MESA cohort, 23% of individuals with events were correctly classified upward and 13% without events were correctly classified downward (Polonsky et al., 2010). Analyses in the Framingham Heart Study (n=3486) revealed similar results, displaying consistent association of CAC with incident major CHD and CVD in multivariable-adjusted statistical models. CAC significantly improved discrimination beyond traditional risk factors for CHD (C statistics, 0.78–0.82), but not for CVD, and provided substantial reclassification for CVD and CHD where two-thirds of the intermediate-risk population were reclassified accurately (Hoffmann et al., 2016).

In the MESA cohort, the impact of 13 negative risk markers has been evaluated and revealed that among all negative CVD risk markers analyzed, a CAC score of 0 resulted in the largest proportion of correctly downward reclassified individuals (Blaha et al., 2016). In a separate report from the MESA cohort, a CAC score >100 had a significant HR of 4.6 for CHD in low lifetime risk individuals. Adding CAC to traditional risk factors increased the area under the ROC curve from 0.775 to 0.806, though this difference was not statistically significant (Joshi et al., 2016).

It has to be kept in mind, though, that CAC scanning goes along with exposure to ionizing radiation. This is particularly relevant when considering CAC scanning for broad applications on the population level. Thus, the health consequences associated with exposure to ionizing radiation have to be weight against the potential benefits with respect to cardiovascular prevention on the population level (Lauer, 2009).

Official recommendations: The ACC and AHA consider the measurement of CAC as reasonable for cardiovascular risk assessment in asymptomatic adults at intermediate risk (10%–20% 10-year risk) (Class IIa recommendation), and it may also be reasonable in persons at low to intermediate risk (6%–10% 10-year risk) (Class IIb recommendation). Due to the radiation exposure and general low prevalence of calcification in individuals with no or few other risk factors, persons at low risk (<6% 10-year risk) should not undergo CAC scan for cardiovascular risk assessment (Class III recommendation) (Goff et al., 2014; Greenland et al., 2010). The ESC released similar recommendations (Piepoli et al., 2016).

Carotid intima-media thickness

Another established technology for assessing subclinical atherosclerosis is ultrasound of the carotid artery (Nezu et al., 2016). Multiple epidemiological studies and a recent metaanalysis have reported an independent association of carotid intima-media thickness (IMT) with cardiovascular events although estimates of effect vary widely. However, Folsom and colleagues reported that carotid IMT led to a small increase in the C statistic (0.77–0.78) for predicting cardiovascular or coronary events (Folsom et al., 2008). In the ARIC study, the addition of information on carotid IMT and plaque led to an improvement in the area under the ROC from 0.742 to 0.755 and to a NRI of ~9.9% among intermediate-risk individuals (10%–20% 10-year risk) (Nambi et al., 2010). A metaanalysis, based on 15 population-based cohorts, reported a consistent association, but only moderate and statistically nonsignificant ($p=0.8$) increments in the C statistics from 0.726 (model with traditional CVD risk factors only) to 0.729 with addition of carotid IMT (van den Oord et al., 2013). In 2965 members of the Framingham Offspring Study cohort, the addition of IMT of the internal carotid artery to the FRS increased the C statistic modestly but statistically significantly by 0.009 and reached a statistically significant NRI of 7.6%, whereas the IMT of the common carotid artery did not significantly improve discrimination and reclassification (Polak et al., 2011). Recently published data from the MESA study indicate that IMT confers incremental information beyond the traditional FRS (increase in the area under the ROC curve from 0.721 to 0.7396 ($p=0.0008$)) and beyond a model including traditional risk factors and CAC (increment in the C statistics from 0.7627 to 0.7714 ($p=0.02$)) (Polak et al., 2017). By contrast, a recent metaanalysis could not show any added value of IMT compared with the FRS for the prediction of future CVD (Den Ruijter et al., 2012).

In epidemiological and clinical trial settings, carotid IMT is usually assessed using highly standardized procedures and specifically trained personnel and centralized reading centers (Greenland et al., 2010). It is uncertain whether a comparable level of standardization can be achieved and whether subtle differences in IMT between individuals with different cardiovascular risk were detectable, if IMT measurements were broadly used as screening tools in the population (Wang, 2011). In this context, the difficulty of standardization of the definition and measurement of IMT, its high variability and low intraindividual reproducibility have raised concerns (Piepoli et al., 2016).

Official recommendations: Thus, the ACC and AHA and the ESC do not recommend the routine measurement and systematic use of carotid ultrasound IMT in clinical practice for risk assessment (Class III recommendation) (Goff et al., 2014; Piepoli et al., 2016).

Flow-mediated dilation

Flow-mediated dilation (FMD) is an important marker of vascular function and can be assessed with the use of ultrasound of the brachial artery. Impaired FMD has been associated with an adverse cardiovascular risk profile, including hypertension and hyperlipidemia, and was found to predict clinical CVD events in the community (Greenland et al., 2010; Brevetti et al., 2003; Yeboah et al., 2009). However, in the MESA cohort, FMD did not improve the C statistic and inappropriately down-reclassified 23% of individuals who experienced events (Yeboah et al., 2009). A study, comparing the predictive value of different risk markers for cardiovascular risk assessment, revealed no association of FMD with incident CHD and FMD led to the lowest improvement in the area under the ROC curve (0.016) compared to other biomarkers and also yielded only a small NRI of 2.4% (Yeboah et al., 2012). In a 2014 published study of 618 subjects, individuals above the median of FMD (>11.3%) had a statistically significant OR of 2.78

for cardiovascular events compared with individuals at or below the median. However, alterations in discrimination and reclassification were not reported in that study (Shechter et al., 2014).

Furthermore, brachial ultrasound might not be suitable for broad application as a screening tool, since its standardized performance requires substantial training (Wang, 2011).

Official recommendations: The ACC and AHA do not recommend peripheral arterial FMD for cardiovascular risk assessment in asymptomatic adults (Class III recommendation) (Greenland et al., 2010).

Ankle–Brachial index

The ankle–brachial index (ABI) is a simple and noninvasive measure for the presence of peripheral arterial disease (PAD; indicated by a value of <0.9) (Greenland et al., 2010). ABI values also show a graded relation with the risk for other CVD events and mortality beyond traditional risk factors, for example, in a large metaanalysis including 24,955 men and 23,399 women free of CHD at baseline (Fowkes et al., 2008). In that analysis, discrimination was improved, with the area under the ROC curve increasing from 0.646 to 0.655 in men and from 0.605 to 0.658 in women, after adding the ABI to the FRS. Reclassification occurred in 19% of men and in 36% of women (Fowkes et al., 2008). Associations with stroke have also been reported (Gronewold et al., 2014). However, in that study (n=4299), the C-statistic increased only slightly and nonsignificantly (from 0.751 to 0.767) and the NRI was only 1.5% (Gronewold et al., 2014).

Official recommendations: The ACC and AHA and the ESC state that the measurement of ABI may be considered for cardiovascular risk assessment in asymptomatic adults at intermediate risk (Class IIa-IIb recommendation) (Goff et al., 2014; Greenland et al., 2010).

Left ventricular structure and function

Alterations in cardiac structure and function are important precursors of CVD, particularly of HF in the community (Greenland et al., 2010). Left ventricular mass (LVM) (Levy et al., 1990) and left ventricular hypertrophy (LVH) (Okwuosa et al., 2015), as well as change in both parameters over time (Lieb et al., 2014; Fox et al., 2015), have consistently been associated with incident CVD events. On a parallel note, slight impairments of cardiac function are intermediate phenotypes predicting incident HF (Wang et al., 2003). Since LVM, LVH, and impaired systolic function represent subclinical changes of the cardiovascular system with clear associations to clinical endpoints, such alterations represent potentially interesting candidate phenotypes for population screening. However, their ability to improve risk prediction models is only modest. In the ARIC cohort (n=14489 participants), electrocardiography (ECG)-determined LVH was associated with CVD and CHD events but did not significantly reclassify or improve the C statistic compared with FRS alone (Okwuosa et al., 2015). In the elderly (aged $\geq$65 years), LVH determined by both echocardiography and ECG was predictive of HF and increased the C statistic equally when added to traditional risk factors (Almahmoud et al., 2015). Similar observations of a comparable association of ECG- and echocardiography-assessed LVH was reported in another analysis with stroke in the same cohort (O'Neal et al., 2015).

Alterations in cardiac structure and function can be assessed by imaging technologies (including ultrasound and MRI); specific ECG changes are also indicative of changes in cardiac structure. Vasan and colleagues tested the hypothesis, whether serum markers of neurohormonal activation correlate with and could potentially be used to screen for alterations in cardiac structure and function in the community. BNP and N-terminal proatrial natriuretic peptide (NT-ANP) were positively associated with elevated LVM and left ventricular systolic dysfunction in the Framingham cohort. However, the area under the ROC curve for both outcomes was at or below 0.75 for both peptides, respectively, and increased only moderately (0.02-0.03) when added to clinical risk factors. Thus, the improvements in discrimination were moderate suggesting suboptimal/limited performance as screening tools as screening tool for elevated LVM and left ventricular systolic dysfunction in the community (Vasan et al., 2002).

Official recommendations: Because the methodology for LVH measurement by echocardiography can vary widely between studies, the ACC and AHA recommend the use of methodology and cut-points as defined by the American Society of Echocardiography (Greenland et al., 2010; Nagueh et al., 2016). Due to the lack of convincing evidence that echocardiography improves cardiovascular risk classification, and because of the logistical challenges in performing it, the ESC does not recommend echocardiography for CVD risk prediction (Class III recommendation) (Piepoli et al., 2016). The ACC and AHA do recommend consideration of echocardiography to detect LVH for cardiovascular risk assessment only in asymptomatic adults with hypertension (Class IIb recommendation), but not for asymptomatic individuals without hypertension (Class III recommendation). According to the ACC and AHA 2010 guidelines, resting ECG is reasonable for cardiovascular risk assessment in asymptomatic adults with hypertension or diabetes (Class IIa recommendation) and may be considered for cardiovascular risk assessment in asymptomatic adults without hypertension or diabetes (Class IIb recommendation) (Greenland et al., 2010).

In summary, several imaging biomarkers display consistent associations with CVD and imaging biomarkers are particularly suitable to detect existing subclinical disease. Given that subclinical changes are important precursors of clinical events and indicate structural or functional alterations of the cardiovascular system, these markers are potentially interesting for screening purposes to identify individuals at high risk of clinical events (Wang, 2011). However, the overall evidence for most imaging biomarkers in terms of improving risk prediction and risk stratification is still uncertain and needs to be further studied. The best predictive performance of imaging biomarkers has been observed for CAC, CAC, which can detect prevalent atherosclerosis at the coronary arteries. However, potential risks associated with a population-wide application of CAC scanning have to be taken into consideration (Wang, 2011).

Combination of Multiple Biomarkers (Risk Scores)

Due to the relatively modest performance of individual biomarkers for risk prediction, multimarker scores, including information from multiple biomarkers, have been generated in order to predict disease risks and patient outcomes more accurately (Wang, 2011; Bodi et al., 2005; Newby et al., 2001; Sabatine et al., 2002). Multimarker approaches can, for example, include either several circulating biomarkers (Wang et al., 2006) or multiple genetic markers (Kathiresan et al., 2008). Some multimarker scores also include imaging markers (Cao et al., 2007). One of the first multimarker paper focused on 10 circulating biomarkers, reflecting different pathways, to predict incident CVD in the Framingham Offspring Study ($n = 3209$ individuals) and revealed that the urinary albumin-to-creatinine ratio and BNP levels displayed the strongest associations with CVD among the markers evaluated. However, the addition of these biomarkers led only to small increases in discrimination when added to conventional risk factors (Wang et al., 2006). In 5067 individuals from the Malmo Diet and Cancer Study, six biomarkers were assessed and tested for association with coronary and cardiovascular events. The C statistic was raised by only ~0.01 and reclassifications did not improve (NRI = 0%) (Melander et al., 2009). In 2010, a panel of 30 biomarkers was evaluated in the MORGAM study. None of the biomarkers alone improved discrimination significantly, however, an optimal combination of NT-proBNP, CRP, and troponin I reached a statistically significant improvement of the C statistic by 0.03. The NRI was 11% (Blankenberg et al., 2010). And in participants with dysglycemia, a set of 15 (out of 237 evaluated) cardiometabolic biomarkers were independent determinants of cardiovascular outcomes or death. The C statistic increased from 0.64 to 0.68 (combined endpoints: MI, stroke, cardiovascular death, HF hospitalization, revascularization), from 0.64 to 0.71 (combined endpoints: MI, stroke, cardiovascular death), and from 0.64 to 0.75 (endpoint: all-cause death) (Gerstein et al., 2015).

The use of imaging markers (Carotid IMT and plaque) combined with circulating biomarkers (CRP) was tested, for example, in the Cardiovascular Health Study (n=5888 elderly individuals; mean age, 73 years). Interestingly, elevated CRP predicted cardiovascular events only in individuals with carotid plaque, whereas carotid plaque predicted events independently from baseline CRP. The C statistic was raised by ~0.02 with the addition of carotid measures to traditional risk factors and by <0.01 with the addition of CRP. Reclassification was not assessed (Cao et al., 2007).

The Malmo Diet and Cancer Study tested a combination of multiple genetic markers. A score including nine lipid-associated SNPs was incorporated into risk models and proved to be a significant predictor of cardiovascular events even after adjustment for measured lipid levels. This score did not improve the C statistic but was associated with a moderate improvement in classification (NRI = 6.2%) (Kathiresan et al., 2008). In 6041 Danes, a constructed genetic risk score consisting of 45 genetic risk variants was tested for its ability to estimate the risk of incident MI and CAD. The genetic risk score was significantly associated with the risk of MI but not with CAD, and it did not improve either discrimination or NRI after addition to the European SCORE (Krarup et al., 2015).

When multimarker scores are used, several factors have to be taken into consideration: Biomarkers that have been measured on the same set of individuals and at the same time or belong to the same pathway are likely to have an inherent correlation, and therefore, with the number of biomarkers in a score increasing the C statistic will not automatically increase equally (Wang, 2011; DeLong et al., 1988). Furthermore, multimarker algorithms may need to weigh individual biomarkers differentially depending on the endpoint being predicted (Morrow and Braunwald, 2003).

Summary and Perspectives

Identifying individuals with elevated risk of incident CVD is an important public health priority. Thus, a range of promising biomarkers for CVD risk prediction have been evaluated in the past decades. Many markers have been reported that display strong and consistent associations with CVD endpoints. However, the added value beyond traditional risk factors of most novel biomarkers is limited in most scenarios. Only a minority of markers is, therefore, recommended for screening purposes or to improve risk stratification in the community. For example, one of these biomarkers is CAC that has been shown to improve discrimination and risk reclassification and is considered reasonable for cardiovascular risk assessment in asymptomatic adults at intermediate risk (Class IIa recommendation).

Novel biomarkers are constantly being studied, for example, within the international BiomarCaRE consortium (Blankenberg et al., 2016; Zeller et al., 2014b). It has to be kept in mind, though, that a broad application of screening biomarkers might require specific training programs for physicians to enable them to adequately interpret the results of complex marker profiles (Vasan, 2006). Furthermore, ethical and regulatory issues, e.g. in the context of genetic biomarkers, need to be addressed appropriately (Vasan, 2006; Hook et al., 2004; Hackett and Gutman, 2005).

Therefore, the value of novel biomarkers for screening and risk prediction issues has to be further analyzed and weight against potential clinical, practical, and ethical disadvantages and challenges.

Introduction

Cardiac arrhythmias remain a significant clinical problem. Despite advances in pharmacologic management, many patients are left with refractory arrhythmias due to clinical inefficacy, or experience significant cardiac and noncardiac toxicities (such as proarrhythmia, heart failure, or organ toxicity) (Fuster et al., 2006; Roy et al., 2000; Singh et al., 2003; Nademanee et al., 2008; Corley et al., 2004). Given the limitations of pharmacologic therapies, alternate approaches were sought for the treatment of cardiac arrhythmias when drugs have been ineffective or cannot be tolerated. The development and evolution of percutaneous catheter ablation for the treatment of cardiac arrhythmias represents a major accomplishment in the field of cardiology.

The clinical use of catheter ablation for the treatment of cardiac arrhythmias is approximately 35 years old, having been first used clinically in the early 1980s as an alternative to technically difficult surgical ablation (Scheinman et al., 1982; Gallagher et al., 1982; Borggrefe et al., 1989). Employing the use of high- and low-energy direct current shocks, initial studies concentrated the use of this technique on reasonably well-understood focal arrhythmia substrates such as the atrioventricular junction or His-Bundle (i.e., complete or total atrioventricular node ablation), AV reentrant tachyarrhythmias (i.e., AV node reentry or accessory AV pathways), and ischemic ventricular tachycardia (i.e., diastolic pathway or VT exit site) (Scheinman et al., 1982; Gallagher et al., 1982; Borggrefe et al., 1989; Newman et al., 1989; Lemery et al., 1989, 1992). Unfortunately, these early ablation procedures were long (>4–8 h), complicated, and associated with a significant potential for complications (myocardial perforation, unintended AV block, venous thrombosis, myocardial depression, proarrhythmia, and sudden death), which largely limited them to patients with malignant arrhythmias or severe comorbidities.

Technological advancements in the late 1980s led to the development of catheters capable of delivering continuous-wave, unmodulated radiofrequency (RF) energy. More recently, novel catheter designs and ablation energy modalities have been sought in an effort to address the perceived limitations associated with RF ablation. This article will focus on the background and lesion science associated with the two dominant energy modalities: (1) RF and (2) cryothermal ablation. An enhanced understanding of lesion science can result in more optimal ablation procedures and improved patient outcomes.

RF Ablation

The shift from direct current to RF ablation represented a major advance in the field of invasive cardiac electrophysiology. Compared to direct current shocks, RF ablation offered the advantages of: (1) minimal discomfort during energy delivery (allowing the procedure to be performed in conscious patients), (2) no skeletal- and cardiac-muscle stimulation, (3) relatively discrete ablation lesions without barotrauma, and (4) the potential for the premature termination of ablation in an effort to avoid impending complications (Morady, 1999). As such, RF energy provided a reasonably low-risk treatment option and led to the rapid and widespread adoption of percutaneous catheter ablation for the treatment of supraventricular and ventricular arrhythmias.

RF Lesion Formation

The RF ablation circuit consists of an RF generator, the ablation catheter, and the indifferent electrode (Fig. 1). Current is delivered via the catheter electrode and passes through the tissue (and patient) before returning to the generator by the indifferent electrode. It is important to note that the patient represents an important part of the ablation circuit. As current flows through the rest of the patient there is a loss of approximately 30%–40% of total delivered power, particularly in the area near the indifferent electrode patch.

Lesion formation with RF results from the combination of direct *resistive heating* at the catheter electrode interface, and *conductive heating* to the surrounding myocardium (Fig. 2). Resistive heating is the process of generating heat by passing an electric current through a resistive material, which dissipates power in that material. In the case of RF ablation, the catheter electrode delivers high-frequency (usually ~500 kHz) alternating electrical current between the catheter tip and indifferent electrode. This passage of alternating current from the low electrical resistance catheter electrode to the high electrical resistance body tissue results in acceleration of ions in the cardiac cells generating heat. The rise in tissue temperature interrupts the transmission of myocardial signals and results in a lesion.

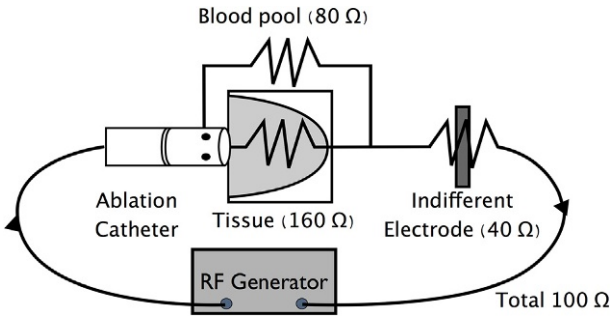

Fig. 1 The RF ablation circuit consists of an RF generator, the ablation catheter, and the indifferent electrode. Current is delivered via the catheter electrode, passes through the tissue (and patient) before returning to the generator by the indifferent electrode. The myocardial tissue and blood pool represent resistance circuits in parallel, with the indifferent electrode and patients body representing resistance circuits in series. In this theoretical example the total resistance is 100 Ω.

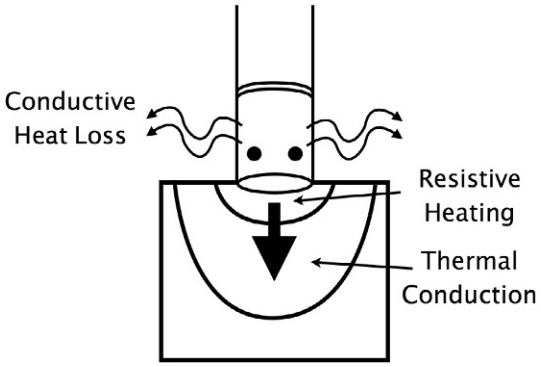

Fig. 2 Lesion formation with RF ablation. Lesion formation with RF results from the combination of direct *resistive heating* at the catheter electrode interface, and *conductive heating* to the surrounding myocardium. In general the effects of RF ablation are reversible up to a tissue temperature of ~50°C. Up to 50°C there is a decreasing action potential duration and amplitude, with progressive cellular depolarisation associated with increase in intracellular calcium. Beyond 50°C there is an irreversible loss in excitability, associated with hyperthermia-induced changes in ionic transport, cytoskeleton collapse, sarcolemmal disruption, and mitochondrial dysfunction.

Recall that current density rapidly decreases with the fourth power of distance from the RF current source. As such the majority (~90%) of delivered power is quickly absorbed into only a small volume of tissue (~2 mm) in close opposition with the catheter electrode tip. The heating of this rim of tissue is quick, with a monoexponential temperature rise to reach steady state in a few seconds (t½ 5–10 s). However, the resistive heating emanates and spreads in a radial fashion to the deeper, cooler tissue layers through microscopic collisions of particles. This transfer of thermal energy (thermal conduction) accounts for the majority of the lesion volume generated by RF ablation. However, the lesion expansion is relatively slow, taking 1–2 min to reach the point of stabilization (i.e., the point where the energy entering the tissue from the thermal source equals the amount of energy that is being dissipated, or "thermal equilibrium"). It is important to note that the extent of lesion penetration will be balanced by conductive heat loss to contiguous tissue as well as convective heat loss to both the circulating blood pool and the intramyocardial circulation.

Temperature and Lesion Formation With RF

RF lesion formation requires achieving tissue temperatures >50°C or higher to result in tissue desiccation, blood coagulation, and protein denaturation. In practice RF lesion size increases linearly with tissue temperature up to the point of plasma coagulation at the catheter–tissue interface (~100°C). These denatured serum proteins form an electrically insulating coagulum along the electrode interface, with the subsequent rise in impedance limiting the penetration of ablation energy into the tissue. Moreover, high tissue temperatures are associated with the buildup of intramural gases with resultant risk of perforation (e.g., carbonization due to excessive heating resulting in a "steam pop") (Nath et al., 1993).

Unfortunately, the relationship between lesion size and electrode tip temperature is variable. This is because the ablation electrode tip temperature (provided to the operator on the RF generator) is not a true a reflection of tissue temperatures (Hogh Petersen et al., 1999). Specifically, the ablation electrode itself does not "heat up" when delivering RF. The temperature rise occurs directly in the tissue and is then conducted back to the tip of the catheter electrode where it is recorded. As such the actual myocardial temperature is usually significantly higher than measured electrode temperature. From a practical perspective this concept is best illustrated by the contrasting lesion dimensions and electrode temperatures observed with nonirrigated RF ablation in a "wedged" state (high electrode temperature with small myocardial lesion) versus irrigated ablation (low electrode temperature with large myocardial lesion). Therefore, the difference in myocardial temperature and electrode temperature must be considered in order to minimize the risk of thrombus formation or the occurrence of a steam pop.

Other Factors Affecting Lesion Formation

While lesion size is directly proportional to tissue heating, the size of an ablation lesion created is ultimately dependent on a multitude of factors including RF power level, duration of RF delivery, convective cooling (e.g., passive blood flow over the electrode–tissue interface, or active cooling with catheter electrode irrigation), electrode size, electrode orientation, and electrode tip/tissue contact.

RF Power, Energy, and Current

Experimental models have demonstrated that RF lesion size increases linearly with RF energy (J), power (W), and current (mA) delivery (**Fig. 3**) (Nath et al., 1993; Hindricks et al., 1989). This is because the use of higher power will result in a combination of: (1) increased source temperature and (2) increasing the radius of heated tissue, which in turn increases the size of the heat source (i.e., zone of resistive heating). However, it is important to realize that in vivo only a fraction of "delivered" energy (or power) is used for lesion formation, with the balance of "useful" energy (i.e., delivered to the tissue and used for lesion created) to "wasted" energy (i.e., in the blood pool and rest of the patient) being determined by a combination of: (1) the degree of electrode surface

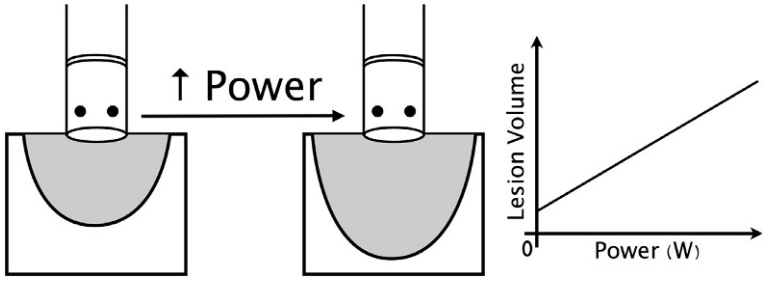

Fig. 3 The effect of increasing power on lesion volume during RF ablation. In general there is a linear relationship between increasing power and lesion volume, with increasing power resulting in deeper penetration of heat. However very high power is limited by emergence of complications such as plasma coagulation at the catheter–tissue interface (which serves as an insulator and prevents heat transfer to the tissue), as well as the buildup of intramural gases (steam pop) (Nath et al., 1993).

contact relative to the target tissue and surrounding blood pool and (2) the relative electrical conductivity of the blood compared to the target tissue (approximately two-fold greater for blood than that of tissue).

Consider the following. In a typical circumstance, approximately 25% of the ablation catheter electrode surface will be in reasonable contact with the target tissue (note: this is highly variable depending on electrode size, orientation, and patient anatomy; however even in ideal circumstances it is highly unlikely that the electrode is ever in >50% contact with the target tissue). As such, with 25% electrode–tissue contact the remaining 75% of the electrode surface will be in contact with blood pool. Thus, when coupled with the two times greater conductivity of blood, this 25% tissue contact will result in a transfer of power to tissue that is roughly six times lower than that delivered to blood pool. Adding in the loss of power to the indifferent electrode (see below) it would be expected that only 8.5% of the total power (or 4.3 W of delivered 50 W) will reach the target endocardial tissue (i.e., 40% loss to patient via indifferent electrode, meaning the remaining 60% of the total power is divided 6:1 between blood and tissue).

While increasing overall power delivery can overcome some of the limitations associated with the power loss to blood pool, excess heating of the electrode tip may result in the formation of thrombus/coagulum which can further impede the flow of electrical current by increasing impedance.

Ablation Circuit Impedance

For unipolar RF ablation the power dissipated throughout the circuit is proportional to the impedance and voltage drop of each component within the circuit. In practice most of the delivered power is shunted through the lower-resistance blood pool (the myocardial tissue and blood pool represent resistive circuits in parallel), with power loss in the return path (the patients body and indifferent electrode patch in series). As such it is important to consider that the return path (patient) plays a significant role in the ablation circuit, accounting for a loss of approximately 30%–40% of the delivered power.

As such, strategies to limit this loss near the indifferent electrode patch, particularly by reducing the indifferent electrode resistance, can result in an increase in lesion size. Returning to our previous example, reducing indifferent electrode resistance from 40% to 20% of the total resistance will result in a significant increase in the power deposited into the myocardial tissue (5.4 W vs. 4.3 W of the 50 W delivered to the catheter). Practically this is accomplished by the positioning of the indifferent electrode closer to the ablation site (i.e., on the trunk rather than the thigh), or using two dispersive electrodes in cases of high baseline impedance.

RF Frequency

RF energy is delivered as alternating electrical current at a frequency of 350–750 kHz in order to accelerate the electrons in the cardiac cells generating heat. While low-frequency alternating current is able to induce similar tissue injury its use is limited by cardiac and skeletal muscle stimulation (resulting in pain and/or arrhythmia induction). Conversely the use of higher RF frequencies (i.e., in the megahertz range) changes the mode of injury from resistive heating to dielectric heating, which is associated with reduced efficiency of heating and a lessened rise in tissue temperature.

Ablation Electrode Material

While platinum is the most widely utilized ablation electrode material, gold electrodes have four times the thermal conductivity resulting in increased effective energy transfer to tissues. In temperature control mode the improved heat dissipation will result in the creation of deeper lesions for a given temperature and impedance (Lewalter et al., 2005).

RF Ablation Duration

The lesions created by RF ablation form over time as a function of heat transfer from the electrode tip to the deeper tissue. This transfer, which is based on the degree of RF energy delivered and rate of thermal conduction, follows a "monoexponential relationship" (Wittkampf et al., 1989) (**Fig. 4**). In other words, the majority of a lesion is created within the first 5–10 s of energy

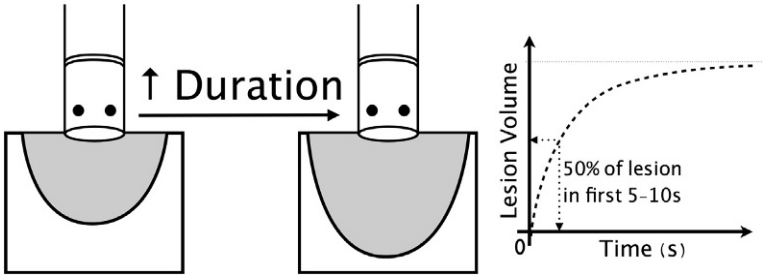

Fig. 4 The effect of increasing ablation duration on lesion volume during RF ablation. For nonirrigated RF ablation the majority of the lesion is created within the first 5–10 s, prior to the lesion volume reaching a plateau at about 45–60 s. For irrigated RF ablation the plateau in lesion volume is delayed to closer to 2 min.

delivery due to the rapidity by which the superficial tissue close to the electrode tip is affected by resistive heating. The remainder of the lesion is generated by the slow thermal energy transfer to deeper tissue layers. This process continues until steady state is reached, meaning that the amount of energy entering the tissue at the thermal source (i.e., heat generated within the lesion) equals the amount of energy being dissipated at the tissue margins beyond the lesion border (i.e., heat transferred away from the lesion). This equilibrium occurs after approximately 60 s for standard RF ablation but can be significantly delayed (i.e., >2 min) for ablation with irrigated RF.

Ablation Mode

Nonirrigated RF ablation is typically performed in power control mode, or temperature control mode. Under power control mode the power output is constant, with a temperature cutoff set only for safety purposes (i.e., the generator will shut off if the temperature limit is reached). This mode is an appropriate for focal ablation in thin myocardium (e.g., focal atrial tachycardia, accessory pathways, and AV nodal substrates); however its use is limited by complications related to the use of high-power settings and/or high target temperatures when performing more extensive ablation in thicker tissues (i.e., the ventricle) or in areas with limited blood flow (e.g., trabeculated tissues with impaired convective cooling). In response, temperature-limited ablation was developed. Under temperature control, RF power delivery is regulated to maintain a constant electrode temperature (typically between 50°C and 60°C). This allows for titration of power (e.g., the delivery of higher power) in order to facilitate creation of the largest possible lesion volume while leveraging the ambient cooling of the electrode by the surrounding blood flow to prevent the electrode–tissue interface temperature from increasing to the point of coagulum formation and/or steam "pop." However, it is important to recall that the tissue temperature may be 10–30°C higher than the electrode temperature, meaning that the risk thrombus formation and/or steam pop may still occur during temperature-limited ablation.

Convective Cooling and Blood Flow

Recall that lesion size increases linearly with tissue temperature, which is a function of the amount of RF energy that is delivered and converted to energy in the tissue. The heat produced by resistive heating is transferred into the deeper tissues by thermal conduction resulting in lesion formation. However, at the same time this generated heat is also conducted back to the electrode tip and the circulating blood pool. Given its characteristics of high heat capacity as well as a relatively high rate of flow the circulating blood pool is a major factor working in opposition of effective heat transfer to the deeper tissue. As such the convective cooling by surrounding blood flow has a significant influence on the amount of RF energy that can be delivered to the tissues and thus lesion formation. This is most relevant in the case of power control mode, where the amount of power delivered is stable and thus an increase in convective cooling will result in a reduction in lesion size by removing heat from the tissue.

However, it is important to recognize that convective cooling can be leveraged to improve lesion formation. In temperature control mode increased convective cooling can facilitate increased lesion size through the delivery of higher power, and thus the achievement of higher tissue temperatures. Conversely, in states of low surrounding blood flow the reduced convective electrode cooling will cause the ablation electrode to reach the target temperature at a lower power level. In these circumstances increasing the electrode temperature to 65°C or 70°C only minimally increases RF power at the expense of a significant increase in the risk of thrombus formation and impedance rise. Passive convective cooling can be facilitated through the use of larger ablation electrodes and electrode orientation.

Catheter Tip Size

In power control mode, the use of a larger ablation catheter electrode results in smaller lesions in comparison to a smaller electrode when ablation is performed at the same power (**Fig. 5**) (Langberg et al., 1990). This is due to the increased surface area associated with the larger electrode size (e.g., an 8-mm electrode has almost twice the surface area of a 4-mm electrode, for a similar radius)

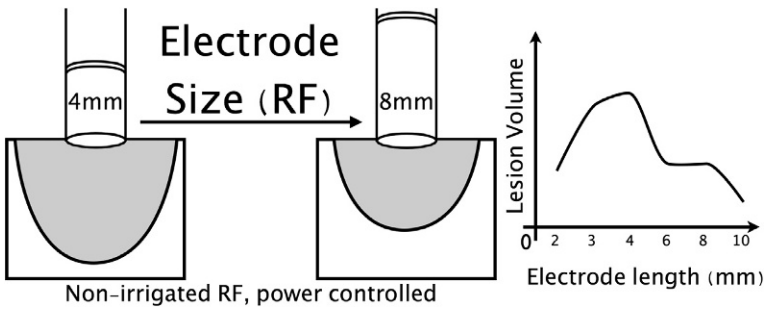

Fig. 5 The effect of increasing electrode size on lesion volume during power controlled RF ablation. The lesion volume increases with electrode tip size up to 4 mm but then decreases substantially as electrode size increases (Langberg et al., 1990).

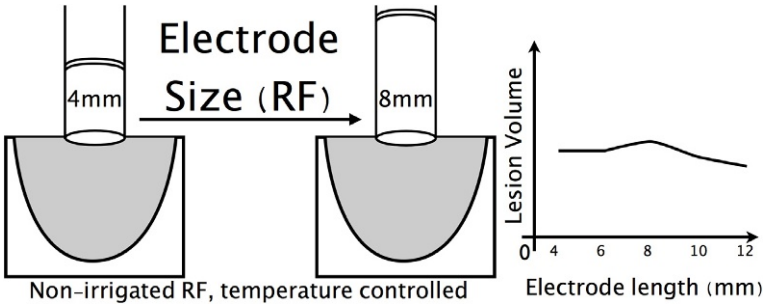

Fig. 6 The effect of increasing electrode size on lesion volume during temperature-controlled RF ablation. With increasing lesion tip size the volume of the lesion is relatively unchanged (Chugh et al., 1999).

resulting in a reduction in the interface impedance between blood and tissue, without altering the impedance through the rest of the patient. As such larger ablation electrodes result in an increasing proportion of current being shunted to blood pool, reducing the efficiency of power transfer, or current density, available to the tissue (Langberg et al., 1990). Specifically, the doubling in electrode tip size (e.g., from 4 to 8 mm) would necessitate a doubling in power (e.g., from 50 to 100 W) to maintain the same density of current provided to tissue. Unfortunately, despite doubling the power the lesion created with a larger ablation tip remains smaller than that with a smaller tip due to the combination of: (1) the increased surface area reducing the interface impedance with blood and tissue (e.g., from 120 to 100 Ω) without altering the impedance through the rest of the patient (e.g., 45 Ω). This further reduces the relative power available near the electrode tip (e.g., 55% with 8 mm vs. 63% with 4 mm, which is then further subdivided between tissue and blood pool based on contact). Lastly, the larger electrode size makes the degree of contact more unpredictable, with variable contact across the electrode resulting in unreliable energy delivery and potential for greater losses of energy transfer to blood pool. As such, due to the reduced efficiency of the larger electrode, a doubling of electrode size may require as much as 1.5–5 times more power to achieve the same tissue temperature and lesion volume (Wittkampf and Nakagawa, 2006).

In temperature control mode, a greater amount of power is delivered as the larger electrode surface area (i.e., increased electrode circumference and length) is more easily cooled by the surrounding blood flow (Chugh et al., 1999). This ambient cooling facilitates the delivery of a greater amount of power for the same degree of blood flow, which results in an increase in lesion volume with the larger ablation electrodes compared to the smaller electrodes (**Fig. 6**).

Catheter Tip Orientation

Catheter electrode–tissue contact surface area is heavily influenced by catheter orientation. With perpendicular orientation and good tissue contact it would be expected that approximately 25% of a 4-mm electrode would be in contact with the target tissue (as the rounded distal end of the electrode represents approximately 25% of total electrode surface). Taking the same 4-mm electrode into a parallel orientation will result in roughly the same amount of the electrode surface being in contact with the tissue (largely owning to limitations with translating significant pressure via the catheter shaft with the electrode in this orientation). As such, the lesion created with the 4 mm tip electrode in both parallel and perpendicular orientation would be expected to be similar when ablation is performed at the same power.

However, the use of larger electrode tips may demonstrate a difference in lesion size between the parallel and perpendicular orientation due to a greater relative difference in electrode–tissue contact (**Fig. 7**). Specifically, the distal end of an 8-mm electrode represents approximately only 12% of the total electrode surface, meaning 88% of the electrode remains in contact with blood pool. This effectively drops the delivered power from 8.5% (or 4.25 W of 50 W) to 3.3% (1.65 W of 50 W) when utilized in power control mode. However, the use of a perpendicular orientation should maintain an approximate 25% contact, which would maintain a power delivery to tissue of approximately 8.5% in power control mode. As such, in power control mode the perpendicular orientation with a larger ablation electrode would result in a smaller lesion owing to proportionately less contact at the electrode–tissue interface.

In temperature control mode a differing result is observed owing to the effect of convective cooling of these larger electrodes (**Fig. 8**) (Chugh et al., 1999). Specifically, a parallel orientation facilitates increased power delivery and results in larger lesions owing to beneficial relationship between tissue contact and convective cooling. While this effect may be observed for smaller electrode sizes (e.g., 4 mm) the relative benefit of parallel electrode orientation on lesion size is more marked for larger electrode tips (e.g., 8 mm).

Catheter Tip Irrigation

The use of active cooling (closed- or open-loop irrigation) enables the creation of larger lesions by providing adequate environmental cooling to facilitate the delivery of more RF energy (**Fig. 9**) (Nakagawa et al., 1995). This active electrode cooling of the results in a lower electrode tip–tissue interface temperature, reducing char and thrombus, as well as facilitating the creation of

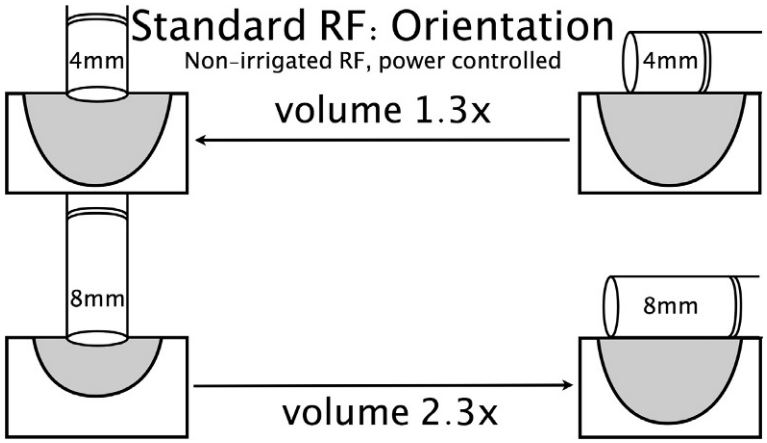

Fig. 7 The effect of catheter orientation on lesion volume during power-controlled RF ablation. For the 4-mm tip catheter the lesion volume is slightly greater in the perpendicular orientation owing to a slight increase in lesion length. For the 8-mm tip catheter the lesion volume is significantly larger in the parallel orientation owing to the reduced current density associated with a perpendicular orientation.

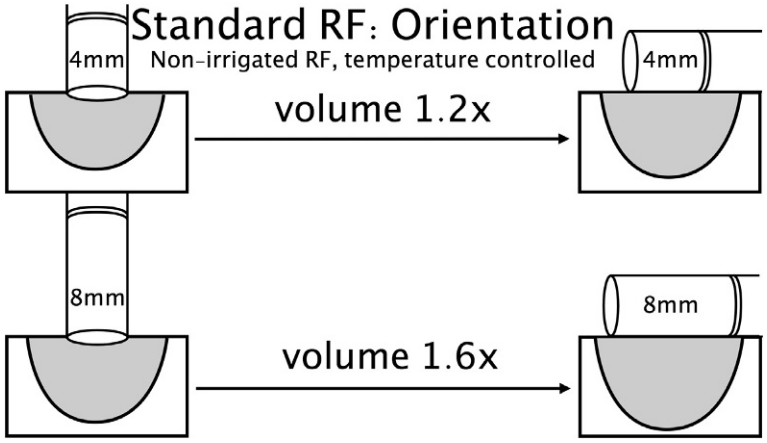

Fig. 8 The effect of catheter orientation on lesion volume during temperature-controlled RF ablation. For both the 4-mm tip catheter and the 8-mm tip catheter the lesion volume is larger in the parallel orientation owing to the ability to deliver increased power although the relative increase in volume is greater with the larger tip catheter (Chugh et al., 1999).

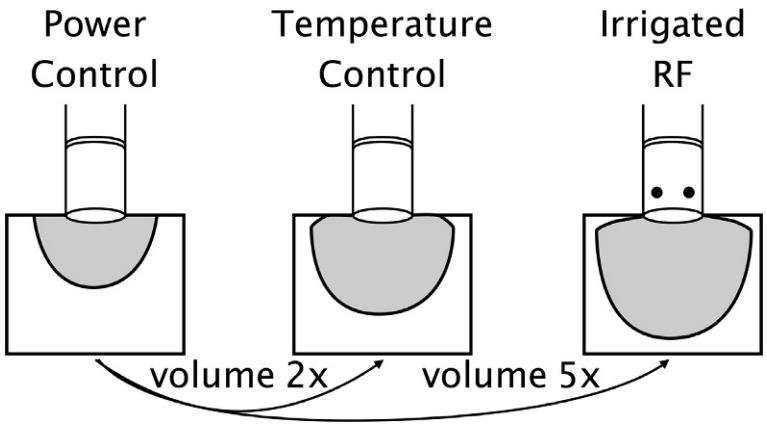

Fig. 9 Comparison of lesion volume generation with power-controlled RF ablation, temperature-controlled RF ablation, and open-irrigated RF ablation (Nakagawa et al., 1995). The use of temperature control and active electrode cooling facilitates larger lesion volume through the delivery of increased RF power, and thus a greater heat transfer to the deeper tissues.

deeper lesions by sustaining adequate RF power even at sites with low blood flow (i.e., the ablation process is no longer limited by an electrode temperature rise). As a result the use of irrigated RF ablation catheters has become the standard of care for ablation in the systemic circulation (such as atrial fibrillation) (Macle et al., 2002) or in thicker myocardial substrates (such as the ventricle) (Reddy et al., 2003).

Closed Versus Open Irrigation

Irrigated RF catheters circulate continuous electrode irrigation fluid either within the electrode (closed loop) or by flushing saline through small openings in the distal ablation electrode (open irrigation). This results in differences in the effect of cooling on the electrode–tissue interface, as well as the lesion itself (**Fig. 10**) (Yokoyama et al., 2006). The closed-loop irrigation focuses the effect of cooling on the interface between the ablation electrode and tissue with minimal effect on the surface area or depth of the lesion. Conversely open irrigation cools the electrode, and it is direct environment (the tissue surface, and the blood pool around the electrode) resulting in a minimally reduced lesion surface area, with the maximum lesion diameter being found slightly deeper into the tissue. In either case it is important to note that irrigation itself does not increase lesion size but merely facilitates the delivery of RF energy in environments limited by temperature.

However, a key difference between open- and closed-loop irrigation is the observation that closed-loop irrigation is associated with a higher electrode–tissue interface temperature despite low electrode temperatures. This electrode–tissue interface temperature frequently exceeded 80°C and was associated with thrombus formation, steam pops, and impedance rises. Conversely open-loop irrigation is associated with lower interface temperatures, and lower risk of thrombus and steam pop (Yokoyama et al., 2006).

Irrigation Flow Rate

For open-irrigated catheters the rate of irrigation flow will affect the size of the lesion produced (**Fig. 11**) (Squara et al., 2014; Gonzalez-Suarez et al., 2016). At the same power level an increase in the irrigation flow rate will result in a smaller lesion due to increased power loss, and increased cooling of the electrode and the adjacent tissue. Conversely a decrease in irrigation flow rate will

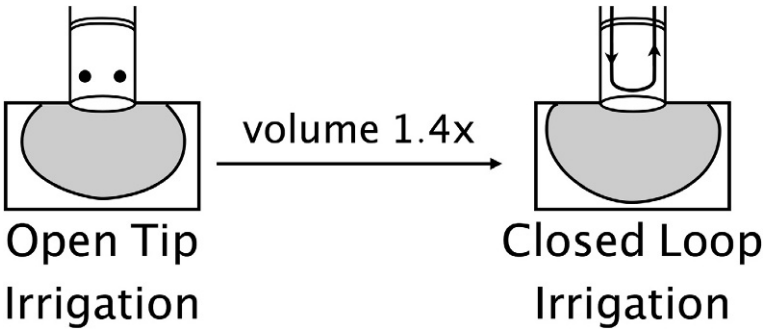

Fig. 10 Comparison of lesion volume generated by open tip and closed-loop saline irrigation (Yokoyama et al., 2006). In general the surface diameter and maximum diameter was slightly smaller with open irrigation, with comparable lesion depths. This led to a slightly smaller overall lesion volume with open tip irrigation compared to closed-loop irrigation. However closed-loop irrigation is associated with higher catheter–tissue interface temperatures, as well as a higher incidence of thrombus formation and "steam pop."

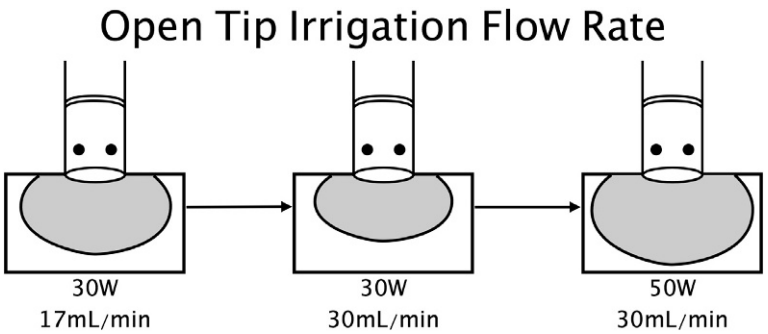

Fig. 11 The effect of irrigation flow rate on lesion volume (Squara et al., 2014; Gonzalez-Suarez et al., 2016). At constant power an increase in irrigation flow rate will result in a smaller lesion volume owing to greater cooling at the tissue interface limiting heat transfer to the deeper tissues. However, in the presence of constant irrigation flow rate increasing power will result in an increased lesion volume.

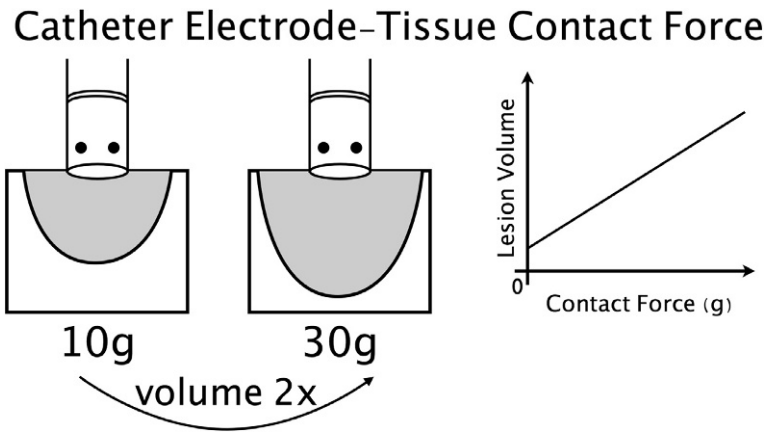

Fig. 12 The effect catheter electrode–tissue contact force on lesion volume. With increasing contact force there is an increase in lesion volume (linear relationship) (Yokoyama et al., 2008).

result in a larger lesion due to less power loss, and less cooling of the electrode and adjacent tissue. As such, the main benefit of an increase in irrigation flow rate is the ability to safely increase power delivery, resulting in increases in lesion size while avoiding complications.

Catheter Tip–Tissue Contact Force

With increasing catheter electrode–tissue contact force there is an increased contact area and more efficient energy transfer (i.e., power delivery) to the myocardium, effectively resulting in lesion creation at a much lower power level (**Fig. 12**) (Yokoyama et al., 2008). Preclinical studies have demonstrated a strong relationship between lesion volume and contact force. Weiss and colleagues performed irrigated-tip ablation using an ovine thigh model using constant power (30 W) but varying contact force (5, 10, 30, and 50 g). They found that lesion width was unaffected by the degree of contact force; however lesion depth and consequently lesion volume did increase with increasing contact force (5.5–9 mm for perpendicular catheter orientation) (Weiss et al., 2002). Similarly, FTI (force time integral, or area under the contact force curve) has been showed to correlate with lesion volume with intermittent contact (characterized by a lower FTI) producing smaller lesions than variable contact with a higher FTI, and with the largest lesions being produced in conditions with the highest FTI (e.g., constant contact) (Shah et al., 2010). Clinically an average CF of <10 g and an average FTI of <500 g/s were associated with higher rates of AF recurrence at 12 months compared to an average CF >20 g (100% vs. 20% recurrence; $P=0.01$) and an average FTI >1000 g/s (75% vs. 31% recurrence; $P=0.03$) (Reddy et al., 2012).

However, it is important to consider that, while increasing contact force is associated with significantly larger lesions it is also associated with a higher incidence of complications, with a clear dose–response relationship that parallels that observed with increasing power (Thiagalingam et al., 2010). As such it has been suggested that "moderate" catheter contact force (20 g) with low power ablation (impedance control and fixed power 20 W) offers the best compromise between safety and efficacy (low risk of popping with a reasonable lesion size, ~ 8.5 mm wide $\times$ 5.5 mm deep). In the event of "light" catheter contact (<20 g) then higher power (30 W) appears to create similar sized lesions compared to lower power ablation with moderate contact; however this is with a small risk of popping.

Cryothermal Ablation

While RF ablation remains the standard of care for the treatment of the majority of arrhythmias, novel ablation energy modalities have been sought in an effort to address some of its limitations. Of these novel energies, cryothermal ablation is the most advanced and thus the most routinely used in clinical practice.

Cryotherapy, or the therapeutic use of freezing temperatures, has a long history of use in medicine. In contrast to RF energy, cryothermal ablation results in cold-induced tissue injury through a combination of direct cellular damage (ice crystal formation during hypothermia) and ischemic cell death (microcirculatory failure and subsequent vascular stasis during thawing). When compared to RF energy, cryoenergy offers the potential advantages of: (1) improved catheter stability, (2) the creation of an ablation lesion that is less arrhythmogenic, (3) reversible tissue suppression (which allows for active electrophysiologic evaluation of potential ablation sites during mapping and/or ablation), (4) a lower risk of damage to collateral structures, and (5) a lesser degree of endothelial disruption and platelet activation (Herrera Siklody et al., 2011; Gaita et al., 2011).

Preceded by a near half-decade of experimentation, the modern era of cryosurgery was initiated by Cooper and Lee in 1961 when vacuum-insulated cryosurgical probes cooled by liquid nitrogen (-196°C) were introduced (Cooper and Lee, 1961). Novel cryoprobes were subsequently developed using thermoelectric cooling (Peltier effect) and later modified for cooling using the

Joule–Thomson effect (i.e., from the expansion of a highly compressed nonideal gas into a region of low pressure). While the thermoelectric method (cooling by the passage a direct current through dissimilar metal junctions) offered limited thermal efficiency, the Joule–Thomson effect was relatively efficacious. Although the core tenets of its design have remained largely unchanged, the transvenous cryoablation catheter has evolved from a 9-French focal cryoablation catheter with slow cooling and a temperature limit of −50°C to the modern 7-French version with rapid cooling and achievable temperatures below −80°C.

Lesion Formation

The lesion is created with cryothermal ablation is through convective cooling, whereby the cryorefrigerant absorbs heat from the surrounding tissue before returning to the console. This results in cold-induced cellular and tissue injury is due to a combination of: (1) direct cellular damage due to the deleterious effects of ice crystal formation during hypothermia and (2) ischemic cell death due to microcirculatory failure and subsequent vascular stasis during thawing (Gage and Baust, 1998). These complex mechanisms occur in the sequence of: (1) freezing, (2) thawing, (3) hemorrhage and inflammation, and (4) replacement fibrosis (Khairy and Dubuc, 2008).

During the first phase, progressive hypothermia results in a slowing of cellular metabolism, whereby ion pumps progressively lose their transport capabilities and the intracellular pH becomes more acidic (Baust et al., 1997). In general, these early effects are transient if the duration of cooling is limited. Thereafter, progressive cooling is associated with the formation of ice crystals, predominantly in the extracellular space (at tissue temperatures below −15°C); however intracellular ice can occur with temperatures below −40°C (Budman et al., 1995). The formation of extracellular ice results in relative hypertonia, with the compensatory egress of water from the intracellular to the extracellular space in an effort to reestablish osmotic equilibrium resulting in cellular shrinkage (Mazur, 1970; Meryman, 1956; Whittaker, 1984). The newly established osmotic gradient precipitates a diffusion gradient between extracellular and intracellular spaces, resulting in biochemical injury (cellular protein damage, enzyme system impairment, and adverse effects on lipoprotein components of the plasma membrane) due to a further reduction in intracellular pH (Whittaker, 1984; Gill et al., 1968).

Upon completion of the freezing phase, the tissue passively returns to body temperature, inducing cellular damage through a combination of: (1) recrystallization and coalescence of intra- and extracellular ice crystals which increase the osmotic damage and generate shear forces, further disrupting tissue architecture (Meryman, 1956; Gage et al., 1985) and (2) restoration of microcirculatory function is associated with a hyperemic vascular response characterized by hemorrhage and inflammation (Baust et al., 1997; Budman et al., 1995; Mazur, 1970). As these blood vessel walls become porous there is increased capillary permeability leading to interstitial edema. This vascular congestion, combined with endothelial injury-induced platelet aggregation and microthrombi formation, culminates in vascular obliteration and ischemic cellular necrosis. As such, while the central region subjected to the coldest freezing temperatures undergoes direct cellular damage, the thawing effect results in the extension of tissue destruction through surrounding microvascular injury.

The final phase of cryoinjury begins concurrent to thawing and is characterized by reactive inflammation, followed by tissue repair and replacement fibrosis. Over the subsequent weeks, these processes culminate in the generation of a mature lesion, which has a distinct, well-circumscribed central region of dense fibrosis surrounded by a narrow border zone of variable cellular death (due to microvascular injury and apoptosis) (Khairy et al., 2003).

Temperature, Duration, Blood Flow, and Lesion Formation With Cryothermy

Factors influencing cryolesion size are fundamentally similar to those observed with RF ablation with some notable exceptions. While tissue temperature and ablation duration are important for both cryothermal ablation and RF ablation, the relationship is slightly more pronounced for cryoablation. Recall that a period of reversible tissue inhibition necessarily precedes irreversible tissue destruction with cryoablation. This factor is more pronounced at the periphery of the lesion where the degree of permanent cellular damage with relatively warmer tissue temperatures (−10°C to −25°C) is directly related to duration of freezing (Khairy and Dubuc, 2008; Gage et al., 1985). In these areas permanent tissue injury requires maintaining a tissue temperature of −20°C for 3–4 min (probe temperature −75 to −80°C). In contrast RF ablation is able to induce permanent tissue injury with shorter ablation durations.

The second major difference in lesion size is the more proportional relationship between electrode size and lesion formation. In contrast to power-controlled RF ablation the use of larger cryoablation catheter tips were associated with significantly larger lesions volumes (approximate doubling in lesion volume with 8 mm catheter compared to 4 mm catheter in perpendicular orientation, but up to 5× increase in volume with parallel orientation—**Figs. 13** and **14**) (Wood et al., 2007, 2009).

For cryoablation the convective warming that accompanies increasing blood flow results in a decrease in lesion volume by approximately 50% (**Fig. 15**). For the 4 mm catheter tip the reduction in lesion volume in high flow states is irrespective of catheter orientation owing to relatively similar contact areas. For the 8 mm tip electrode the parallel orientation is associated with a lesser reduction in lesion volume in high flow states due to relatively reduced convective warming. Specifically, the larger electrode is associated with a greater surface area in contact with the tissue, and thus a smaller portion of the electrode being exposed to blood pool.

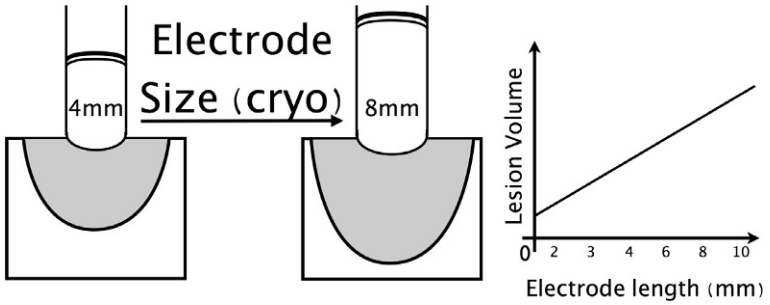

Fig. 13 The effect of increasing electrode size on lesion volume during cryoablation. With cryoablation there is an almost linear increase in lesion volume with increasing electrode tip size (Wood et al., 2007).

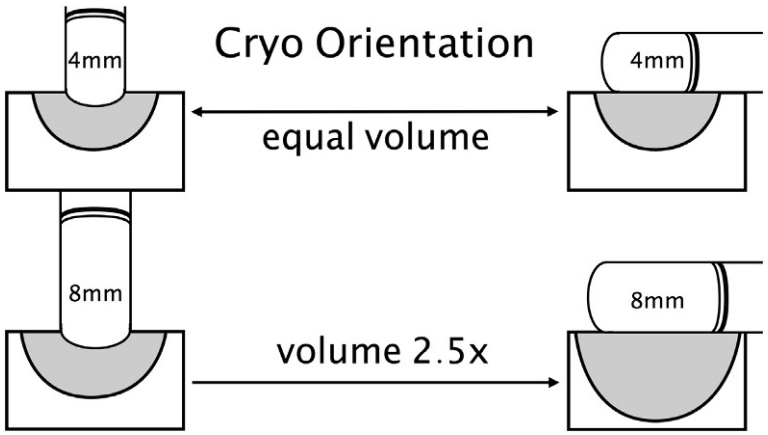

Fig. 14 The effect of catheter orientation on lesion volume during cryoablation. For the 4-mm tip catheter the lesion volume is comparable in parallel and perpendicular orientation. For the 8-mm tip catheter the lesion volume is markedly larger in the parallel orientation (Wood et al., 2007, 2009).

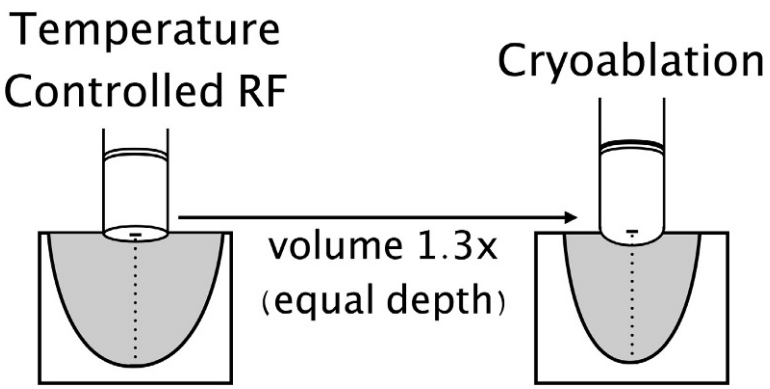

Fig. 15 Comparison of ablation lesions created with a 4-mm tip temperature-controlled radiofrequency (RF) ablation catheter and a 4-mm tip cryoablation catheter. While the depths of the two lesions are comparable, the RF lesion has a greater surface area ($P=0.002$) and thus a greater volume ($P=0.059$). Reproduced with permission from Khairy et al (Khairy et al., 2003).

Comparing Cryoablation to RF

RF energy and cryothermal ablation have both proven to be highly effective in the treatment of arrhythmias with a reasonably low complication rate. However, as the mechanism of cellular injury differs between the two modalities, important relative benefits and drawbacks must be considered.

Reversible Suppression

Both RF ablation and cryothermal ablation are associated with the potential for the premature termination of ablation in an effort to avoid impending complications.

For cryothermal ablation this translates into the ability to dynamically and prospectively assess the safety and efficacy of a potential ablation lesion site. Recall that a period of reversible tissue inhibition obligatorily precedes irreversible tissue destruction as the hypothermic wavefront spreads centrifugally from the catheter tip to the surrounding tissue (Gage and Baust, 1998; Khairy and Dubuc, 2008; Gage et al., 1985). Thus while extreme freezing (i.e., tissue temperatures colder than −50°C) results in near instantaneous permanent tissue injury, the degree of permanent cellular damage with relatively warmer tissue temperatures (−10°C to −25°C) is directly related to duration of freezing (Khairy and Dubuc, 2008; Gage et al., 1985). Thus, the use of milder freezing temperatures and/or shorter ablation times facilitates the assessment of clinical effect at the target lesion site (so-called efficacy mapping), and confirmation that a target site does not result in adverse clinical outcomes (so-called safety mapping).

In the case of RF ablation, the practical benefit of "reversibility" is limited by the inability to assess the effect of heating the tissue at a certain site in the heart without creating an irreversible effect, as well as thermal latency. Recall that the tissue injury occurs as a result of resistive heating and subsequent thermal conduction. After 30–60 s of ablation a state of thermal equilibrium has been reached, in other words the local tissue temperatures have reached their maximum value (i.e., there is a steady flow of heat from the electrode to its environment). If ablation is terminated at the point of thermal equilibrium there will be a direct but gradual drop in tissue temperatures. However, if ablation is terminated prior to the attainment of thermal equilibrium the heat generated from the resistive heating will continue to dissipate to the deeper tissues despite the cessation of RF current flow. This is particularly important during the ablation of structures in close proximity to the AV node, whereby early ablation termination in response to inadvertent affect (i.e., AV block) may still result in further tissue penetration and subsequent injury.

Catheter Adhesion

During RF ablation the catheter remains free-floating during ablation, and active manipulation is required to maintain a stable catheter position at the desired site. Conversely, cryothermal ablation is associated with freeze-mediated catheter adhesion to the target tissue. This catheter–tissue attachment provides several advantages. First, freeze-mediated catheter stability facilitates the efficacious ablation of technically challenging regions, such as sites where contact is difficult to maintain. Second, cryoadhesion eliminates the "brushing effect," whereby RF energy is applied to the target and surrounding nontarget tissue due to cardiac and respiratory motion. It can be expected that increased catheter stability would result in less collateral damage to nearby critical structures, such as the conduction system (Khairy and Dubuc, 2008). Conversely, the lack of brushing effect with cryothermal ablation requires that lesion placement be more precise (especially taking into account the cryocatheter movement prior to adhesion). Lastly, catheter adhesion allows for the dynamic assessment of lesion efficacy. Specifically, the ablation can be performed during ongoing arrhythmia, or programmed electrical stimulation, as there is no risk of catheter dislodgement with arrhythmia termination.

Lesion Characteristics, Endothelial Integrity, and Thrombosis

In comparison to RF, lesions associated with focal cryothermal ablation have a smaller surface area due, in part, to cryoadhesion-induced loss of the brushing effect, with no difference in lesion depth (Khairy et al., 2003). However, when applied to immature myocardium, the rate of expansion of cryoablation lesions with growth is similar to RF (**Fig. 16**) (Khairy et al., 2011).

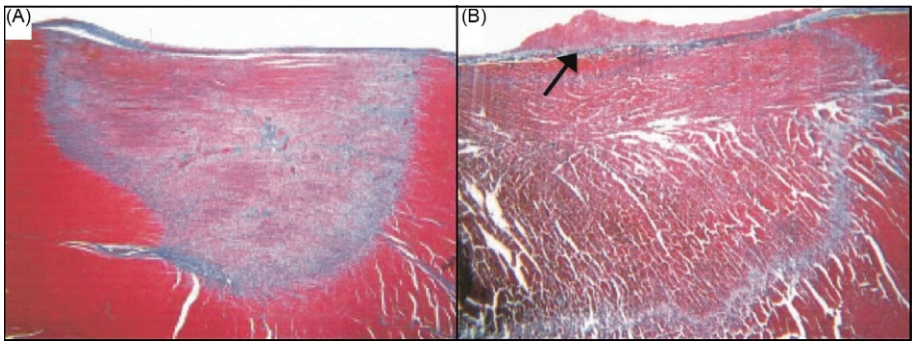

Fig. 16 Histology of lesions generated by cryothermal ablation (A; −75°C x 4 min) and temperature-controlled RF ablation (B; +70°C, 50 W, 60 s). Stained with Masson's trichrome and magnified 16-fold. Note more homogeneous nature of cryolesion, with a smoother, sharper demarcation from normal myocardium (A). In contrast, RF lesion is less well circumscribed, with serrated edges (B). *Arrow* indicates endocardial thrombus formation overlying the ablation site. Reproduced with permission from Khairy et al (Khairy et al., 2003).

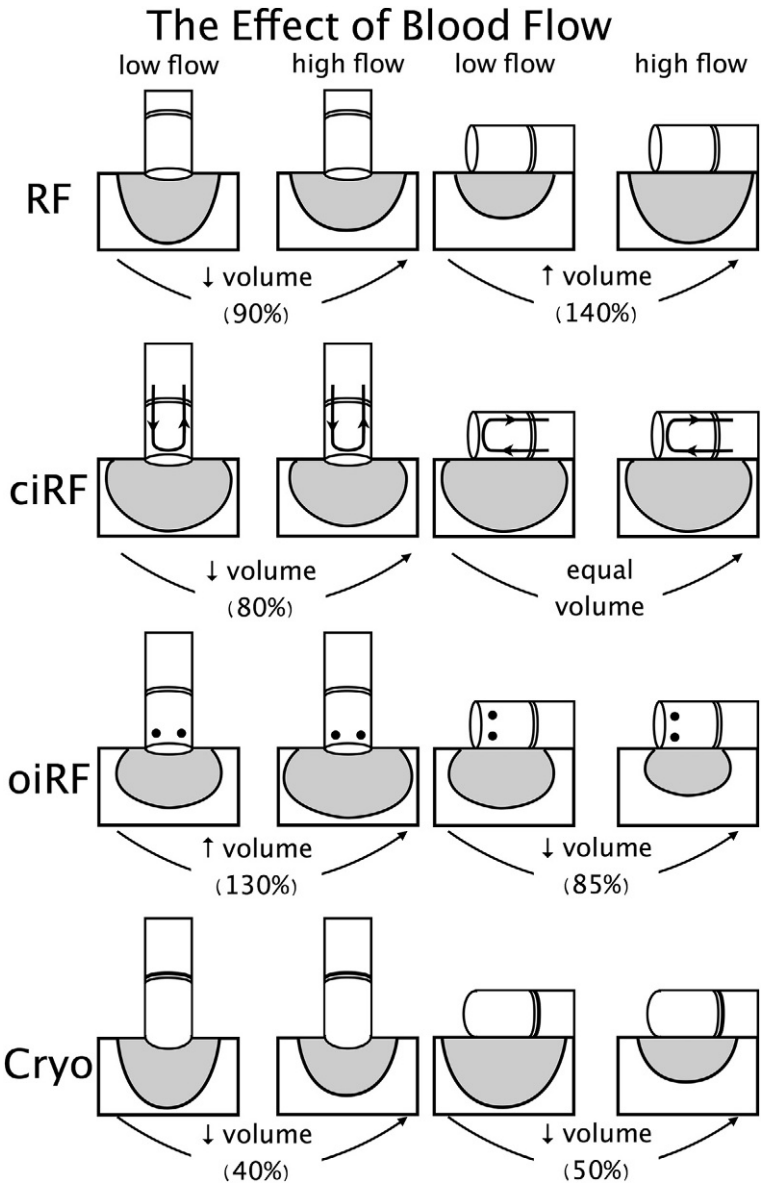

Fig. 17 The effect of ambient blood flow on lesion size, as influenced by catheter orientation (Wood et al., 2007). Low blood flow pictured to the left, and high blood flow pictured to the right. *RF*, temperature-controlled radiofrequency ablation; *ciRF*, closed-loop irrigated RF; *oiRF*, open-irrigated RF; *Cryo*, cryothermal ablation.

Histologically, cryothermy results in a dense, homogenous fibrosis that is well demarcated from normal myocardium (**Fig. 17**) (Gage et al., 1985; Khairy et al., 2003; Klein et al., 1979). In contrast, the hyperthermic injury induced by RF results in diffuse cellular destruction characterized by intralesional hemorrhage and ragged edges less clearly demarcated from underlying normal myocardium (Klein et al., 1979). It may be speculated that lesions produced with cryoablation should be less arrhythmogenic (given that distinct border zones are less susceptible to spontaneous depolarization, **Table 1**).

Although devitalized, cryoablation lesions are associated with preservation of ultrastructural integrity, an observation that is attributed to the remarkable resilience of fibroblasts and collagen fibers to hypothermia (Shepherd and Dawber, 1984). In contrast RF energy denatures the extracellular tissue matrix which has the potential to weaken the ablated tissue, predisposing to myocardial perforation and damage of adjacent structures. With cryoablation the preservation of tissue ultrastructural integrity should theoretically result in a lower incidence of venous or arterial stenosis (given the minimal tissue contraction observed with lesion healing) (Khairy and Dubuc, 2008; Gage et al., 1985; Khairy et al., 2003; Klein et al., 1979; Feld et al., 2003).

Cryothermal ablation lesions are associated with a lesser degree of endothelial surface disruption, as well as a lesser degree of platelet activation and the coagulation cascade activation when compared to RF (Khairy et al., 2003; Hochholzer et al., 2007; Sarabanda et al., 2005). Preclinical studies have demonstrated a significantly lower incidence of overlying thrombus (30.1% vs. 75.8% despite the use of ASA and heparin), and a lesser thrombus volume with cryothermal ablation compared to RF (Khairy et al.,

Table 1 Factors that influence lesion size

Variables	*Modifiers*	*Effect on lesion size*
Tissue	Scar and fat	Smaller
Power	RF	Increases (linearly)
Tissue temperature	RF	Increases (linear: warmer = larger)
	CRYO	Decreases (linear: colder = larger)
Tip temperature	Power control	Increases (variable relationship)
	Temperature control	Increases (variable relationship)
	Irrigated tip	Unrelated
	CRYO	Decreases (linear: colder = larger)
Ablation duration	Power control	Increases (plateau 45–60 s)
	Irrigated-tip	Increases (plateau after ~2 min)
	CRYO	Increases (plateau after ~60 s)
Cooling (convective)	Power control	Smaller
	Temperature control	Larger
	Active (irrigated RF)	Larger (if unrestricted power)
		Smaller (if constant power)
	CRYO	Smaller
Intramyocardial blood flow	RF and CRYO	Smaller
Electrode size (increasing)	Power control	Smaller
	Temperature control	Larger
	CRYO	Larger
Electrode Orientation	Power control	Parallel = larger
	Temperature control	Parallel = smaller
	Active (irrigated RF)	Parallel = smaller
	CRYO	Parallel = larger
Contact force		Increases

2003; Sarabanda et al., 2005). Moreover, in contrast to RF lesions where the extent of hyperthermic tissue injury was positively correlated with thrombus bulk, cryoablation lesion dimensions were not predictive of overlying thrombus volume. Taken together, these effects suggest a possible pathophysiologic mechanism as to why cryoablation is less thrombogenic than RF, which may have important safety implications, particularly for procedures in the systemic circulation (Herrera Siklody et al., 2011; Gaita et al., 2011; Khairy et al., 2003; Hochholzer et al., 2007; Sarabanda et al., 2005).

Conclusion

RF ablation and cryothermal ablation are effective treatment modalities for the invasive management of multiple arrhythmic substrates. Significant tissue injury can be obtained using both technologies in a safe and effective manner. An enhanced understanding of lesion science can result in more optimal ablation procedures and improved patient outcomes.

Introduction

Blood pressure variability has been considered a physiological marker of autonomic nervous system control, with short- and long-term fluctuations from intricate interactions among behavioral, environmental, neural central or reflex influences, along with other potential contributing factors.

Current indexes of blood pressure variability raise methodological issues related to their poor reproducibility, their interdependence, and their association with the level of blood pressure. Besides methodological problems, the progn ostic significance of blood pressure variability remains controversial. Some studies reported association of end-organ damage (Parati et al., 1987a; Tatasciore et al., 2007; Matsui et al., 2011), cardiovascular events (Kikuya et al., 2000; Rothwell et al., 2010a,b; Rothwell, 2010; Webb et al., 2010; Johansson et al., 2012; Shimbo et al., 2012), or mortality (Muntner et al., 2011) with blood pressure variability, whereas others failed to find any association or found variability to be inferior to the level of blood pressure (Pierdomenico et al., 2006; Hansen et al., 2010; Schutte et al., 2012). This review addressed to what extent blood pressure variability and blood pressure level contribute to risk stratification.

Indexes of Blood Pressure Variability

A major problem in many reports is that they assessed target organ damage or the incidence of events as a function of blood pressure variability indexes that are highly dependent on blood pressure level. In the early 1970s, Clement and coworkers (1979) assessed blood pressure variability from the standard deviation (SD) and the coefficient of variation (CV) of blood pressure measurements obtained every 5 min for 3 h in 70 untreated hypertensive patients. Sympathetic activity correlated with level and SD of blood pressure, but not with CV, a measure of variability that is less dependent on level than the SD (Clement et al., 1979). In the 1980s, Mancia and coworker analyzed 24 h continuous intra-arterial recordings and showed that SD correlated positively with blood pressure level and fell with antihypertensive drug treatment, whereas CV was independent of level irrespective of drug intervention (Mancia et al., 1980). Notwithstanding these initial findings, the same group used SD rather than CV to estimate the association of blood pressure variability and target organ damage on the incidence of cardiovascular complications (Parati et al., 1987b; Frattola et al., 1993), and many investigators continue using the SD as the index of blood pressure variability.

Other measures of variability, such as the weighted SD (Bilo et al., 2007), the difference between the maximum minus minimum blood pressure level (MMD), and average real variability (ARV) (Mena et al., 2005) also remain highly dependent on blood pressure level. The weighted SD is the mean of day and night SD values weighted for the number of hours covered by these two periods during ambulatory monitoring. ARV is calculated using the following formula:

$$ARV = \frac{1}{\sum w_k} \sum_{k=1}^{n-1} w_k \times BP_{k+1} - BP_k$$

where n is the number of blood pressure readings, k ranges from 1 to $n-1$, and w_k is the time interval between BP_k and BP_{k+1}. ARV therefore accounts for the order of the measurements and weighs each value according to the measurement interval.

 https://doi.org/10.1016/B978-0-12-809657-4.99591-7

More recently, Rothwell and colleagues (2010a,b) proposed blood pressure variability independent of the mean (VIM) as a new index. VIM (Rothwell et al., 2010a,b) is the within-subject SD divided by the within-subject mean blood pressure level to the power x and multiplied by the population mean blood pressure level to the power x. The power x is obtained by fitting a curve through a plot of SD against mean blood pressure level, using the model $SD = a \times \text{mean}^x$, where x is derived by nonlinear regression. The correlation of VIM with the other indexes of blood pressure variability is high (Levitan et al., 2013), but VIM does not correlate with the blood pressure level (Rothwell et al., 2010a,b). VIM therefore allows assessing association of outcome with blood pressure variability with little confounding by blood pressure level (Rothwell et al., 2010a,b). However, VIM is tied to the population being examined and cannot be compared across population, because it is derived from the distribution of the blood pressure values in each population.

Recent Evidence on Prognostic Significance

Blood pressure may be recorded over different time intervals: beat-to-beat (very short-term), over 24 h (short-term), and day-by-day or visit-to-visit (long-term). The techniques of measurement include continuous beat-to-beat recordings, usual office blood pressure measurement, 24 h ambulatory blood pressure monitoring, or home blood pressure monitoring.

Beat-to-Beat Blood Pressure Variability

Beat-to-beat recordings allow capturing blood pressure variability, even over short time intervals (Wei et al., 2014). In 256 untreated Chinese patients referred to a hypertension clinic, we assessed the association of target organ damage with VIM, MMD, and ARV, determined from 10 min beat-to-beat, 24 h ambulatory, and 7-day home blood pressure recordings (Wei et al., 2014). Effect sizes (standardized β) were computed using multivariable regression models. In beat-to-beat recordings, left ventricular mass index ($n = 128$) was not ($P \geq 0.18$) associated with systolic blood pressure level but increased with all three systolic variability indexes (+2.97–3.53 g/m^2; $P < 0.04$). The urinary albumin-to-creatinine ratio increased ($P \leq 0.03$) with systolic blood pressure level (+1.14–1.17 mg/mmol, according to the model) and MMD (+1.18 mg/mmol). Aortic pulse wave velocity increased with systolic blood pressure level (+0.69 m/s; $P < 0.001$). In 24-h recordings, all three indexes of organ damage increased ($P < 0.03$) with systolic blood pressure level, whereas the associations with systolic blood pressure variability were nonsignificant ($P \geq 0.15$) except for an increase in aortic pulse wave velocity ($P < 0.05$) with VIM (+0.16 m/s) and MMD (+0.17 m/s). In home blood pressure recordings, the urinary albumin-to-creatinine ratio (+1.27–1.30 mg/mmol) and aortic pulse wave velocity (+0.36–0.40 m/s) increased ($P < 0.05$) with systolic blood pressure level, whereas all associations of target organ damage with the variability indexes were nonsignificant ($P \geq 0.07$). In summary, while accounting for systolic blood pressure level, associations of target organ damage with systolic blood pressure variability were readily detectable in beat-to-beat recordings and least noticeable in home recordings, with 24 h ambulatory monitoring being informative only for aortic pulse wave velocity (Wei et al., 2014).

Reading-to-Reading Blood Pressure Variability

Palatini and associates analyzed 7112 untreated hypertensive participants (43.8% women; mean age, 50.8 years) with daytime and nighttime ambulatory blood pressure enrolled in six prospective cohorts (Palatini et al., 2014). During a median follow-up of 5.5 years, 130 fatal and 455 nonfatal cardiovascular events occurred. In a multivariable-adjusted Cox model, the SD of the nighttime systolic blood pressure predicted cardiovascular mortality (hazard ratio (HR), 1.48; confidence interval (CI), 1.20–1.84) and morbidity (HR, 1.83; CI, 1.17–2.86), whereas SD of daytime systolic blood pressure did not ($P \geq 0.096$). These researchers proposed optimal cutoff limits for the nighttime SD 12.2 mm Hg systolic and 7.9 mm Hg diastolic. Participants above these arbitrary thresholds had a 41–132% higher risk of a composite cardiovascular end point than those below these cutoff limits ($P \leq 0.028$). As outlined in the preceding text, SD as index of blood pressure variability is closely correlated with blood pressure level (Palatini et al., 2014).

Hansen and colleagues (2010) assessed blood pressure variability from the SD and ARV (**Fig. 1**) in 24-h ambulatory recordings in the International Database on Ambulatory blood pressure monitoring in relation to Cardiovascular Outcome (IDACO) population. Higher diastolic ARV in 24 h ambulatory blood pressure recordings predicted ($P \leq 0.03$) total (HR, 1.13; CI, 1.07–1.19) and cardiovascular (HR, 1.21; CI, 1.12–1.31) mortality and all types of fatal combined with nonfatal end points (HR, ≥ 1.07) with the exception of cardiac and coronary events (HR, ≤ 1.02; $P \geq 0.58$). Similarly, higher systolic ARV in 24 h ambulatory recordings predicted ($P < 0.05$) total (HR, 1.11; CI, 1.04–1.18) and cardiovascular (HR, 1.17; CI, 1.07–1.28) mortality and all fatal combined with nonfatal end points (HR, ≥ 1.07), with the exception of cardiac and coronary events (HR, ≤ 1.03; $P \geq 0.54$). SD predicted only total and cardiovascular mortality. The incremental cardiovascular risk explained by adding ARV to models already including 24 h ambulatory blood pressure level and other covariables was less than 1%. This report established that reading-to-reading blood pressure variability is an independent risk factor, significant in a statistical but not in a clinically meaningful manner. It highlighted that the level of the 24 h blood pressure remains the primary blood pressure-related risk factor to account for in clinical practice (Hansen et al., 2010).

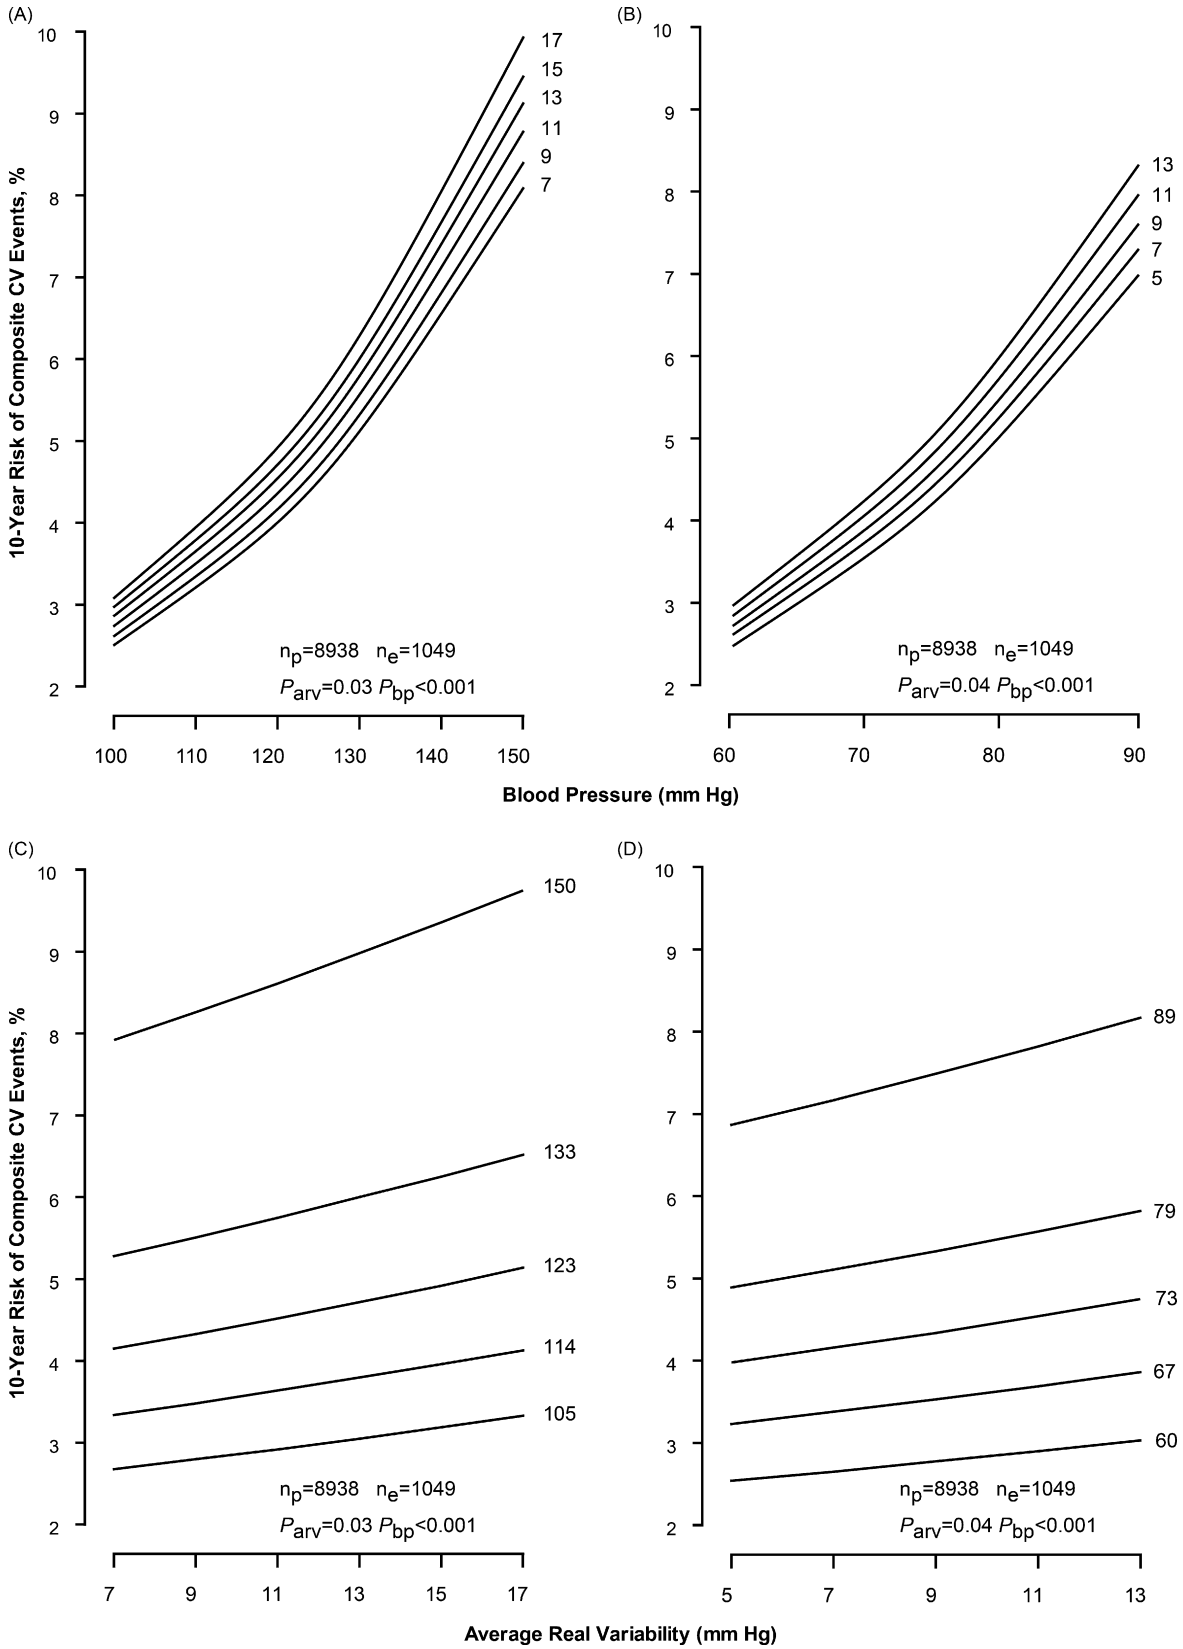

Fig. 1 Ten-year absolute risk of combined cardiovascular events in relation to 24 h blood pressure (A and B) at different levels of systolic and diastolic average real variability (ARV_{24}) and in relation to ARV_{24} (C and D) at different levels of 24 h systolic and diastolic blood pressure. The analyses were standardized to the distributions (mean or ratio) of cohort, sex, age, 24 h heart rate, body mass index, smoking and drinking, serum cholesterol, history of cardiovascular disease, diabetes mellitus, and treatment with antihypertensive drugs. In panels (A) and (B), the risk functions span the 5th–95th percentile interval of the 24 h blood pressure and correspond to the 5th, 25th, 50th, 75th, and 95th percentiles of ARV_{24}. In panels (C) and (D), the risk functions span the 5th–95th percentile interval of ARV_{24} and correspond to the 5th, 25th, 50th, 75th, and 95th percentiles of the 24 h blood pressure. *P*-values are for the independent effect of ARV_{24} (P_{arv}) and 24 h blood pressure (P_{bp}). n_p and n_e indicate the number of participants at risk and the number of events. ARV_{24} denotes average real variability over 24 h. (Reproduced with permission from Hansen, T. A., for the International Database on Ambulatory Blood Pressure in Relation to Cardiovascular Outcome Investigators. (2010). Prognostic value of reading-to-reading blood pressure variability over 24 hours in 8938 subjects from 11 populations. *Hypertension* **55**, 1049–1057. Wolters Kluwer Health, Inc.)

Variability of Self-Measured Home Blood Pressure

The prognostic significance of self-measured home blood pressure variability was first assessed in the Ohasama population, using the within-participant SD of the morning systolic blood pressure over 26 days (median) (Kikuya et al., 2008). In multivariable-adjusted Cox models also including blood pressure level, the SD was associated with higher risk of total mortality (HR per 1-SD increase of within-participant SD, 1.18; CI, 1.07–1.31), cardiovascular mortality (HR, 1.20; CI, 1.02–1.40), noncardiovascular mortality (HR, 1.18; CI, 1.04–1.34), stroke mortality (HR, 1.38; CI, 1.12–1.72), but not cardiac mortality (HR, 1.02; CI, 0.89–1.29). The Finn-Home investigators assessed the day-to-day variability of the self-measured systolic blood pressure in the morning. The within-participant SD over 7 days predicted total mortality and cardiovascular events (Johansson et al., 2012). The HRs expressing the incremental risk for a 1-SD increment in variability (3.93 mm Hg) were 1.17 (CI, 1.00–1.30; $P=0.03$) and 1.21 (CI, 1.08–1.40; $P=0.006$), respectively (Johansson et al., 2012). Day-to-day variability in the evening systolic blood pressure was not predictive ($P\geq 0.11$) (Johansson et al., 2012).

Asayama and colleagues (2013) explored whether fatal and nonfatal outcomes were associated with the new indexes of blood pressure variability, VIM, ARV, and MMD, derived from the self-measured home blood pressure. They analyzed mortality and stroke risk in 2421 Ohasama residents after excluding high-risk participants with a history of stroke. Participants were asked to record their self-measured home blood pressure for 4 weeks after at least 2 min of rest in the morning within 1 h after awakening and before taking any blood pressure-lowering drugs and in the evening before going to bed. Over a median follow-up of 12 years, 412 participants died, 139 of cardiovascular causes, and 223 had a stroke. In multivariable-adjusted Cox models including morning systolic pressure, VIM and ARV predicted total and cardiovascular mortality in all participants ($P\leq 0.044$), while VIM predicted cardiovascular mortality in treated ($P=0.014$), but not in untreated ($P=0.23$) participants. Morning MMD did not predict any end point ($P\geq 0.085$). In models already including evening systolic pressure, only VIM predicted cardiovascular mortality in all and in untreated participants ($P\leq 0.046$). When these researchers calculated multivariable-adjusted 10-year risk of cardiovascular mortality and stroke incidence in relation to the mean level and VIM (Fig. 2 in all of the participants), both morning and evening systolic blood pressure were consistent predictors ($P\leq 0.032$) with the exception of cardiovascular mortality in treated participants for morning systolic pressure ($P=0.082$). Being on antihypertensive drug treatment seemed to be the main driver of the significant associations between cardiovascular mortality and blood pressure variability (Asayama et al., 2013), whereas the new indexes of blood pressure variability, VIM derived from self-measured home blood pressure, did not incrementally predict outcome over and beyond mean systolic pressure level.

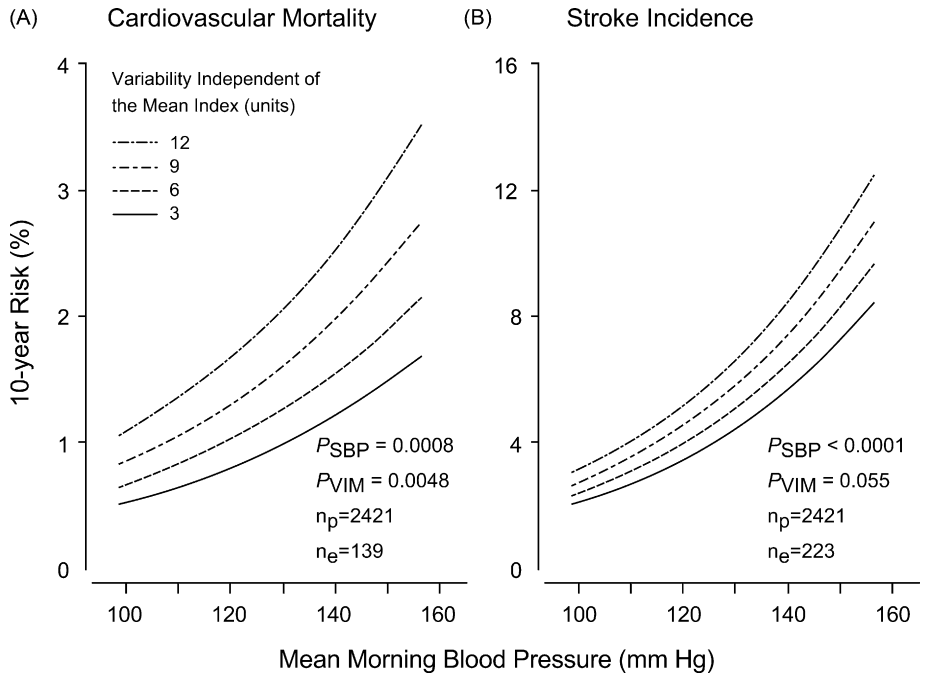

Fig. 2 Absolute 10-year risk of cardiovascular mortality (A) and stroke incidence (B) in relation to the mean level of systolic blood pressure measured at home in the morning in 2421 participants. The analyses were standardized to the distributions (mean or ratio) of sex, age, body mass index, heart rate, smoking and drinking, total cholesterol, diabetes mellitus, history of cardiovascular diseases, and treatment with antihypertensive drugs. Four continuous lines represent the risk independently associated with blood pressure variability independent of the mean (VIM) equal to 3, 6, 9, and 12 units. *P*-values are for the independent effect of SBP (P_{SBP}) and VIM (P_{VIM}). n_p and n_e indicate the number of participants at risk and the number of events. (Reproduced with permission from Asayama, K., Kikuya, M., Schutte, R., Thijs, L., Hosaka, M., Satoh, M., Obara, T., Inoue, R., Metoki, H., Hoshi, H., Ohkubo, T., Staessen, J.A., Imai, Y. (2013). Home blood pressure variability as cardiovascular risk factor in the population of Ohasama. *Hypertension* **61**, 61–69. Wolters Kluwer Health, Inc.)

Within-Visit and Between-Visit Blood Pressure Variability

Results from randomized clinical trials constitute the strongest evidence for the role and reversibility of any cardiovascular risk factor. In the Systolic Hypertension in Europe (Syst-Eur) trial, Hara and colleagues (2014) investigated whether systolic blood pressure variability determines prognosis over and beyond level. Using a double-blind design, 4695 patients ($\geq$60 years) with isolated systolic hypertension (160–219/<95 mm Hg) were randomly allocated to active treatment or matching placebo. Active treatment consisted of nitrendipine (10–40 mg/day) with possible addition of enalapril (5–20 mg/day) and/or hydrochlorothiazide (12.5–25.0 mg/day) (Staessen et al., 1997, 1999). We assessed whether on-treatment systolic blood pressure level, visit-to-visit VIM, or within-visit variability (WVV) predicted total ($n=286$) or cardiovascular ($n=150$) mortality or cardiovascular ($n=347$), cerebrovascular ($n=133$), or cardiac ($n=217$) end points (Hara et al., 2014). At 2 years (median follow-up), in analyses dichotomized by the median, patients with low versus high VIM had similar event rates ($P\geq0.14$). Low versus high WVV was not associated with event rates ($P\geq0.095$), except for total and cardiovascular mortality on active treatment, which were higher with low WVV ($P\leq0.0003$). In multivariable-adjusted Cox models, systolic blood pressure level predicted all end points ($P\leq0.0043$), whereas VIM did not predict any adverse outcome ($P\geq0.058$). Except for an inverse association with total mortality ($P=0.042$), WVV was not predictive ($P\geq0.15$). The double-blind placebo-controlled Syst-Eur trial irrefutably demonstrated that blood pressure-lowering treatment reduces cardiovascular complications by decreasing systolic blood pressure level, but not systolic variability, and that higher systolic blood pressure level predicted risk without material contribution of variability.

In a randomly recruited Flemish population sample ($n=2944$; 50.7% women; mean age, 44.9 years), Schutte and colleagues (2012) computed VIM, MMD, and ARV for WVV, between-visit variability, and overall—within-visit combined with between-visit—variability. Over a median follow-up of 12 years, 401 deaths occurred, and 311 participants experienced a fatal or nonfatal cardiovascular event. Overall (10 readings over two visits), systolic blood pressure variability averaged (SD) 5.45 (2.82) units for VIM, 15.9 (8.4) mm Hg for MMD, and 4.08 (2.05) mm Hg for ARV. In multivariable-adjusted analyses, overall and within- and between-visit blood pressure variability did not predict total or cardiovascular mortality or the composite of any fatal plus nonfatal cardiovascular end point. For instance, the HRs for all cardiovascular events combined in relation to overall variability as captured by VIM, MMD, and ARV were 1.05 (CI, 0.96–1.15), 1.06 (CI, 0.96–1.16), and 1.08 (CI, 0.98–1.19), respectively. By contrast, mean systolic blood pressure level was a significant predictor of all end points under study, independent of blood pressure variability (Schutte et al., 2012). These findings suggest that, in the general population, within-subject blood pressure variability does not have any prognostic significance over and beyond systolic blood pressure level (Schutte et al., 2012).

Conclusion

Methodological issues that might have confounded previous publications on the prognostic value of blood pressure variability as compared with blood pressure level include categorization of continuous variability indexes that are dependent on blood pressure level and the limitation of end points to mortality. While addressing these issues in the aforementioned population studies (Hansen et al., 2010; Schutte et al., 2012), we were never able to identify blood pressure variability as a clinically meaningful cardiovascular risk factor. In particular, our Syst-Eur analysis in line with current recommendations is strong evidence supporting the idea that blood pressure level, not variability, remains centerfold in the primary and secondary prevention of blood pressure-related cardiovascular complications. Although this does not preclude that blood pressure variability remains a target in clinical categorization research, in particular if captured by beat-to-beat recordings (Wei et al., 2014), the current large international population studies and the Syst-Eur randomized clinical trial (Hara et al., 2014) do not support blood pressure variability as prime target in the management of hypertension in clinical practice.

Introduction

Brugada syndrome (BrS) represents one extreme of the clinical manifestation of the J wave syndromes, which are known to be associated with vulnerability to development of polymorphic ventricular tachycardia (VT) and ventricular fibrillation (VF) leading to sudden cardiac death (SCD) in young adults with no apparent structural heart disease (Brugada and Brugada, 1992; Antzelevitch and Yan, 2010; Nam et al., 2008; Haissaguerre et al., 2008) and occasionally to sudden infant death syndrome (Kanter et al., 2012; Antzelevitch, 2001a; Wedekind et al., 2001). The region of the heart most affected in BrS is the anterior right ventricular outflow tract; whereas in other forms of the J wave syndromes such as early repolarization syndrome (ERS), it is the inferior region of the left ventricle (LV) (Haissaguerre et al., 2008; Nagase et al., 2002; Nakagawa et al., 2014; Rosso et al., 2008a; Koncz et al., 2014; Antzelevitch, 2006; Coronel et al., 2005). Accordingly, BrS is characterized by accentuated J waves, appearing as a coved-type ST segment elevation in the right precordial leads, V1–V3, whereas ERS is characterized by J waves, J_o elevation, notch or slur of the terminal part of the QRS and ST segment or J_t elevation in the lateral (type I), infero-lateral (type II) or in infero-lateral + anterior or right ventricular leads (type III) (Antzelevitch and Yan, 2010).

Prevalence

The prevalence of BrS with a type 1 ECG in adults is higher in Asian countries, such as Japan (0.15%–0.27%) (Sakabe et al., 2003; Tsuji et al., 2008), the Philippines (0.18%) (Gervacio-Domingo et al., 2008), as well as among Japanese-Americans in North America (0.15%) (Ito et al., 2006) than in Western countries, including Europe (0%–0.017%) (Letsas et al., 2010; Gallagher et al., 2008; Pecini et al., 2010) or North America (0.005%–0.1%) (Patel et al., 2009; Lee et al., 2005)

Diagnostic Criteria

Fig. 1 illustrates three types of ST segment elevation. Only a Type I coved ST segment elevation is diagnostic of BrS. According to the most recent consensus document (Antzelevitch et al., 2016a,b), BrS is characterized by ST segment elevation ≥ 2 mm (0.2 mV) in ≥ 1 right precordial leads (V1–V3) positioned in the 4th, 3rd, or 2nd intercostal space. When a Type 1 ST segment elevation is unmasked using sodium channel blockers, diagnosis of BrS requires that the patient also presents with one of the following: documented VF or polymorphic ventricular tachycardia (pVT), syncope of probable arrhythmic cause, a family history of sudden cardiac death at <45 years old with negative autopsy, coved-type ECGs in family members, or nocturnal agonal respiration. Inducibility of VT/VF with one or two premature supports the diagnosis of BrS under these circumstances (Sroubek et al., 2016). Table 1 presents the recently proposed scoring system for the diagnosis of BrS.

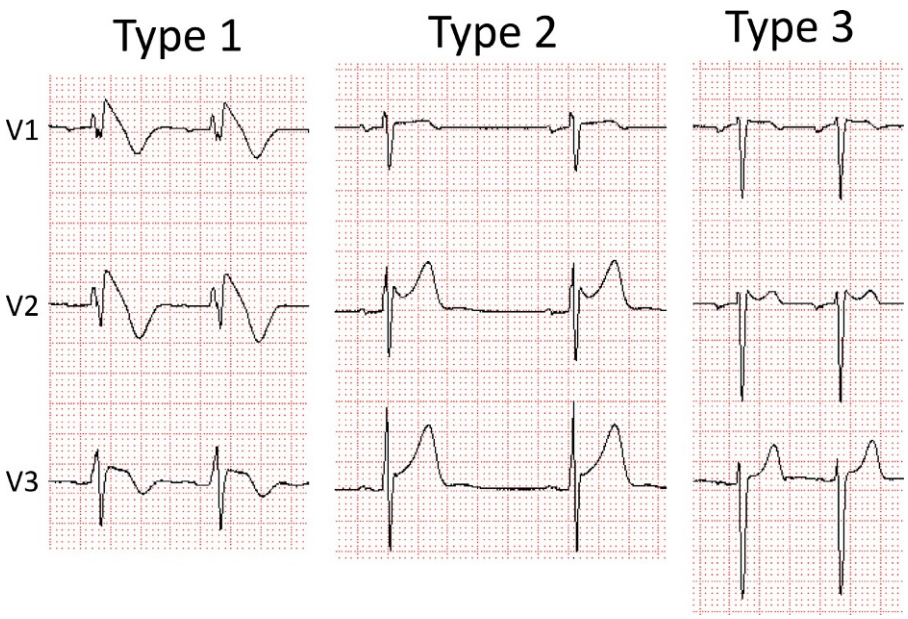

Fig. 1 Three types of ST segment elevation associated with Brugada syndrome. Type I is characterized by a coved-type ST segment elevation of $\geq$2 mm. Only type 1 is diagnostic of BrS. Type 2 is characterized by ST segment elevation of $\geq$0.5 mm (generally $\geq$2 mm in V2) in $\geq$1 right precordial lead (V1–V3), followed by a convex ST. The ST segment is followed by a positive T wave in V2 and variable morphology V1. Type 3 is characterized by either a saddleback or coved appearance with an ST segment elevation of $<$1 mm. Table 1 Proposed Shanghai score system for diagnosis of Brugada syndrome

	Points
I. ECG (12-lead/ambulatory)	
(A) Spontaneous type 1 Brugada ECG pattern at nominal or high leads	3.5
(B) Fever-induced type 1 Brugada ECG pattern at nominal or high leads	3
(C) Type 2 or 3 Brugada ECG pattern that converts w/ provocative drug challenge	2
Note: Only award points once for highest score within this category. One item from this category must apply.	
II. Clinical history	
(A) Unexplained cardiac arrest or documented VF/polymorphic VT	3
(B) Nocturnal agonal respirations	2
(C) Suspected arrhythmic syncope	2
(D) Syncope of unclear mechanism/unclear etiology	1
(E) Atrial flutter/fibrillation in patients $<$30 years without alternative etiology	0.5
Note: Only award points once for highest score within this category	
III. Family history	
(A) 1st or 2nd degree relative with definite BrS	2
(B) Suspicious SCD (fever, nocturnal, Brugada aggravating drugs) in a 1st or 2nd degree relative	1
(C) Unexplained SCD $<$45 years in first/second degree relative with negative autopsy	0.5
Note: Only award points once for highest score within this category	
IV. Genetic test result	
(A) Probable pathogenic mutation in BrS-susceptibility gene	0.5
SCORE (requires at least 1 ECG finding)	
$\geq$3.5 points—probable/definite BrS	
2–3 points—possible BrS	
$<$2 points—nondiagnostic

B., Sacher, F., Shimizu, W., Viskin, S., Wilde, A. A. (2016). J-Wave syndromes expert consensus conference report: Emerging concepts and gaps in knowledge. *Heart Rhythm* 32(5), 315–339, with permission.

Diagnostic Tools

When BrS is suspected in the absence of spontaneous type 1 ST segment elevation, a pharmacological challenge using a sodium channel blocker is recommended. A list of agents used for this purpose are presented in **Table 2** (also see www.brugadadrugs.org). The test is considered positive when a type 1 ST segment elevation is recorded. Drug infusion should be discontinued in case of frequent ventricular extrasystoles or other arrhythmias, or widening of the QRS >130% over the baseline value (Antzelevitch et al., 2005). Alternatively, ECGs can be recorded before and after a large meal, taking advantage of increased vagal tone associated with a "full stomach." The use of in superior positions for V1 and V2 leads increases the sensitivity of recording spontaneous type I ST segment elevation at night or after heavy meals (Shimeno et al., 2009).

Differential Diagnosis

Table 3A presents a list of other causes of ST segment elevation that need to be excluded before establishing the diagnosis of BrS. Conditions that produce a Type 1 Brugada-like ECG include right bundle branch block, pectus excavatum, arrhythmogenic right ventricular cardiomyopathy (ARVC), as well as occlusion of the left anterior descendent artery or the conus branch of the right coronary artery, which supplies the right ventricular outflow tract (RVOT).

Although debate continues as to the extent to which structural abnormalities are present in BrS, most investigators consider BrS to be a channelopathy. Concealed structural abnormalities, such as histologic myocardial fibrosis of the RVOT, which may not become evident using conventional imaging techniques have been proposed to account for or contribute to delayed conduction and ventricular arrhythmias in BrS. MRI and electron beam computed tomography studies of BrS patients consistently show subtle abnormalities, including wall motion abnormalities and reduced contractile function of the right ventricle (RV) and to a lesser extent of the LV, and dilatation of the RVOT (Papavassiliu et al., 2004, 2010; Takagi et al., 2003; Catalano et al., 2009). Antzelevitch

Table 2 Drugs used to unmask the Brugada electrocardiogram

Drug	*Dose*	*Administration*
Ajmaline	1 mg/kg over 10 min	Intravenous
Flecainide	2 mg/kg over 10 min	Intravenous
	200–300 mg	Oral (>1 h)
Procainamide	10 mg/kg over 10 min	Intravenous
Pilsicainide	1 mg/kg over 10 min	Intravenous

Table 3 Differential diagnosis and modulating factors in Brugada syndrome

A. Differential diagnosis	*B. Modulating factors*
● Atypical right bundle branch block	● Electrolyte abnormalities:
● Ventricular hypertrophy	● Hyperkalemia
● Early repolarization (especially in athletes)	● Hypokalemia
● Acute pericarditis/myocarditis	● Hypercalcemia
● Acute myocardial ischemia or infarction (especially of the right ventricle)	● Hyponatremia
● Pulmonary thromboembolism	● Temperature: hyperthermia (fever), hypothermia
● Prinzmetal angina	● Hypertestosteronemia
● Dissecting aortic aneurism	● Treatment with:
● Central and autonomic nervous systems abnormalities	● Antiarrhythmic drugs: sodium channel blockers (class IC, class IA), calcium antagonists, beta-blockers
● Duchenne's muscular dystrophy	● Antianginal drugs: calcium antagonists, nitrates, potassium channel openers.
● Friedreich's ataxia	● Psychotropic drugs: tricyclic/tetracyclic antidepressants, phenothiazines, selective serotonin reuptake inhibitor, lithium, benzodiazepines
● Spinobulbar muscular atrophy	● Anesthetics/analgesics: propofol, bupivacaine, procaine
● Myotonic dystrophy	● Others: histamine H1 antagonist, alcohol intoxication, cocaine, cannabis, ergonovine
● Arrhythmogenic right ventricular dysplasia	
● Mechanical compression of the right ventricular outflow tract (for instance, pectus excavatum, mediastinal tumor, hemopericardium, etc.)	
● Hypothermia	
● Postdefibrillation ECG	

Modified from Antzelevitch, C., Yan, G. X., Ackerman, M. J., Borggrefe, M., Corrado, D., Guo, J., Gussak, I., Hasdemir, C., Horie, M., Huikuri, H., Ma, C., Morita, H., Nam, G. B., Sacher, F., Shimizu, W., Viskin, S., Wilde, A. A. (2016). and coworkers have suggested an alternative explanation (Antzelevitch, 2002, 2006; Antzelevitch et al., 1999) pointing out that dilatation of the RVOT may be due to loss of the action potential dome in this region of the heart, which also creates the arrhythmogenic electrical substrate.

In contrast to BrS, imaging techniques in ARVC clearly display morphological and functional changes (e.g., fibro-fatty infiltration, dilatation, bulging/aneurysms, and wall motion abnormalities). ARVC is an inherited cardiac disease resulting from genetically defective desmosomal (DS) proteins (Corrado and Thiene, 2006; Corrado et al., 2011), characterized by fibro-fatty myocardial replacement predisposing to scar-related ventricular arrhythmias which may lead to SCD, mostly in young people and athletes (Thiene et al., 1988). Life-threatening ventricular arrhythmias may occur early, during the "concealed phase" of the disease, prior to overt structural changes (Corrado and Thiene, 2006; Corrado et al., 2011; Delmar and McKenna, 2010). Recent experimental studies demonstrated that loss of expression of DS proteins may induce electrical ventricular instability by causing sodium channel loss of function, predisposing to the development of BrS (Delmar and McKenna, 2010; Delmar and Makita, 2012; Cerrone et al., 2012, 2014; Corrado et al., 2001). These findings support the hypothesis that DS-gene mutations involved in the pathogenesis of ARVC can lead to a decreased depolarization reserve that can manifest as J-wave/BrSs.

Modulating Factors

Sympathetic and parasympathetic influences, hormones, metabolic factors, and pharmacological agents are known to modulate the electrocardiographic and arrhythmic manifestations of BrS (**Table 3B**) (Postema et al., 2009).

Acquired Brugada Pattern

The Brugada ECG is often concealed and can be unmasked with a wide variety of drugs and conditions, including a febrile state, vagotonic agents and maneuvers, α adrenergic agonists, β adrenergic blockers, Class I antiarrhythmic drugs, tricyclic or tetracyclic antidepressants, hyperkalemia, hypokalemia, hypercalcemia, as well as by alcohol and cocaine toxicity (Shimizu, 2005; Brugada et al., 2000a,b; Miyazaki et al., 1996; Babaliaros and Hurst, 2002; Goldgran-Toledano et al., 2002; Tada et al., 2001; Ortega-Carnicer et al., 2001; Nogami et al., 2003; Araki et al., 2003; Pastor et al., 2001). An up-to-date list of agents known to unmask the Brugada ECG and that should be avoided by patients with BrS can be found at www.brugadadrugs.org (Postema et al., 2009).

Genetics

BrS has been associated with variants in 19 different genes (**Table 4**). Genetic defects in *SCN5A* are the most prevalent. To date more than 300 BrS-related variants in *SCN5A* have been described (Antzelevitch, 2012, 2013; Kapplinger et al., 2010; Ackerman et al., 2011). **Fig. 2** shows the overlap between Brugada and other inherited cardiac arrhythmia syndromes attributable to genetic defects in sodium, calcium, and potassium channel defects. The available evidence suggests that the presence of a prominent I_{to} determines whether loss-of-function mutations resulting in a reduction in I_{Na} will manifest as BrS/ERS or as conduction disease (Park et al., 2015; Antzelevitch and Yan, 2015; Szel and Antzelevitch, 2014; Patocskai et al., 2014).

New susceptibility genes proposed and awaiting confirmation include the Transient Receptor Potential Melastatin Protein 4 gene (*TRPM4*) (Liu et al., 2013) and the *KCND2* gene. Variants in *KCNH2*, *KCNE5*, *SEMA3A*, although not causative, have been identified as capable of modulating the substrate for the development of BrS (Verkerk et al., 2005; Wilders and Verkerk, 2010; Ohno et al., 2011; Boczek et al., 2014). Loss-of-function mutations in *HCN4* causing a reduction in pacemaker current, I_f, can unmask BrS by reducing heart rate (Ueda et al., 2004).

Only a small fraction of identified genetic variants in the genes associated with BrS have been examined using functional expression studies to ascertain causality and establish their pathogenicity. Very few have been studied in genetically engineered mouse models, in native cardiac cells, or in induced pluripotent stem cell-derived cardiac myocytes isolated from BrS patients. In silico tools developed to predict the functional consequences of mutations are helpful, but these methods have not been rigorously tested. The lack of functional or biological validation of mutation effects remains the most severe limitation of genetic test interpretation as recently highlighted by Schwartz et al. (2013).

The presence of variants associated with BrS in large public databases of genetic variation such as the 1000 genomes, the National Heart Lung and Blood Institute Exome Sequencing Project (ESP), and the Exome Aggregation Consortium (ExAC) has challenged the view that BrS is a monogenic autosomal dominant inherited syndrome (Refsgaard et al., 2012; Kapa et al., 2009; Andreasen et al., 2013; Alfares et al., 2015; Le Scouarnec et al., 2015; Behr et al., 2015; Veeramah et al., 2014; Risgaard et al., 2013). The absence of genotype–phenotype correlation in some large BrS families with *SCN5A* mutations has also raised concerns (Probst et al., 2009). Collectively, these and other recent studies suggest the possibility that in the individual patient BrS and the susceptibility to VF and SCD may not be due to a single mutation (classical Mendelian view), but rather to inheritance of multiple BrS-susceptibility variants (oligogenic) acting in concert through one or more mechanistic pathways (Bezzina et al., 2013). Moreover, expressivity of the syndrome may be multifactorial in that the genetic predisposition can be modulated by hormonal (testosterone (Matsuo et al., 2003; Antzelevitch, 2003), thyroxine (Korte et al., 2015)), and other environmental factors, as well as

Table 4 Gene defects associated with the Brugada syndrome

Genetic Defects Associated with BrS

	Locus	*Gene/protein*	*Ion channel*	*% of probands*
BrS1	3p21	*SCN5A*, $Na_v1.5$	↓ I_{Na}	11%–28%

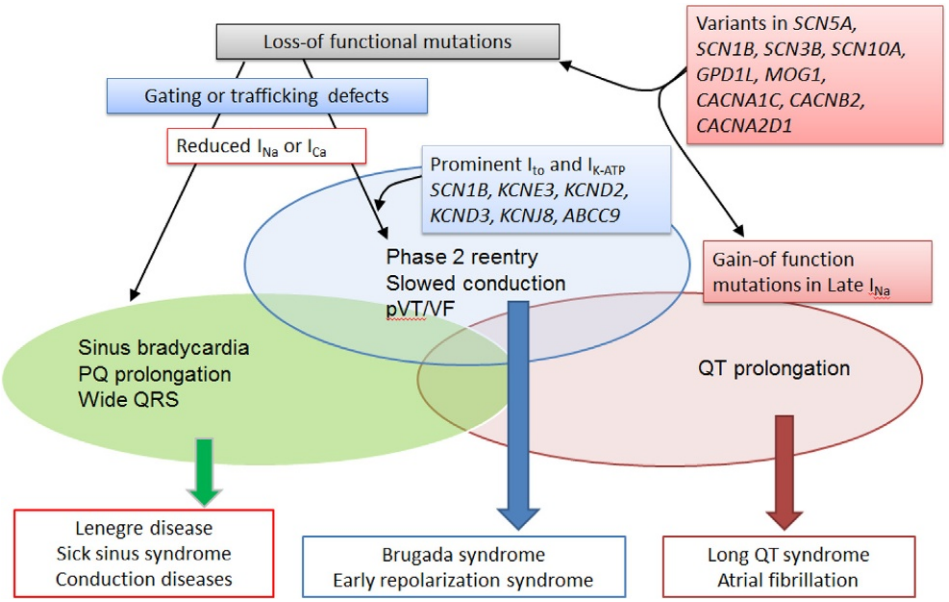

Fig. 2 Schematic showing overlap between Brugada and other inherited cardiac arrhythmia syndromes resulting from genetic defects secondary to loss of function of sodium (I_{Na}) and/or calcium (I_{Ca}) channel current. In the absence of prominent I_{to} or $I_{K\text{-}ATP}$, loss-of-function mutations in the inward currents result in various manifestations of conduction disease. In the presence of prominent I_{to} or $I_{K\text{-}ATP}$, loss-of-function mutations in inward currents cause conduction disease as well as the J wave syndromes (Brugada and Early repolarization syndromes). Early repolarization syndrome is believed to be caused by loss-of-function mutations of inward current in the presence of prominent I_{to} in certain regions of the LV, particularly the inferior wall of the LV. The genetic defects that contribute to BrS and ERS can also contribute to the development of long QT and conduction system disease, in some cases causing multiple expression of these overlap syndromes. In some cases, structural defects contribute to the phenotype. Modified from Antzelevitch, C., Yan, G. X., Ackerman, M. J., Borggrefe, M., Corrado, D., Guo, J., Gussak, I., Hasdemir, C., Horie, M., Huikuri, H., Ma, C., Morita, H., Nam, G. B., Sacher, F., Shimizu, W., Viskin, S., Wilde, A. A. (2016). morphological changes (fibrosis) (Nademanee et al., 2015). Genetic testing, although helpful in the identification of family members possibly at risk, is generally not used for risk stratification or prognosis purposes (Antzelevitch et al., 2016b; Gray and Behr, 2016).

Ionic and Cellular Mechanisms Underlying BrS

The cellular mechanisms underlying BrS have long been a matter of debate (Wilde et al., 2010; Morita et al., 2009a). Two principal hypotheses have been advanced: (1) The *repolarization hypothesis* (**Fig. 3**) asserts that an outward shift in the balance of currents in right ventricular epicardium can lead to repolarization abnormalities resulting in the development of the substrate for reentrant activity as well as the development of phase 2 reentry, which generates closely coupled premature beats capable of precipitating VT/VF; (2) The *depolarization hypothesis* suggests that slow conduction in the RVOT, secondary to fibrosis, reduced Cx43 leading to

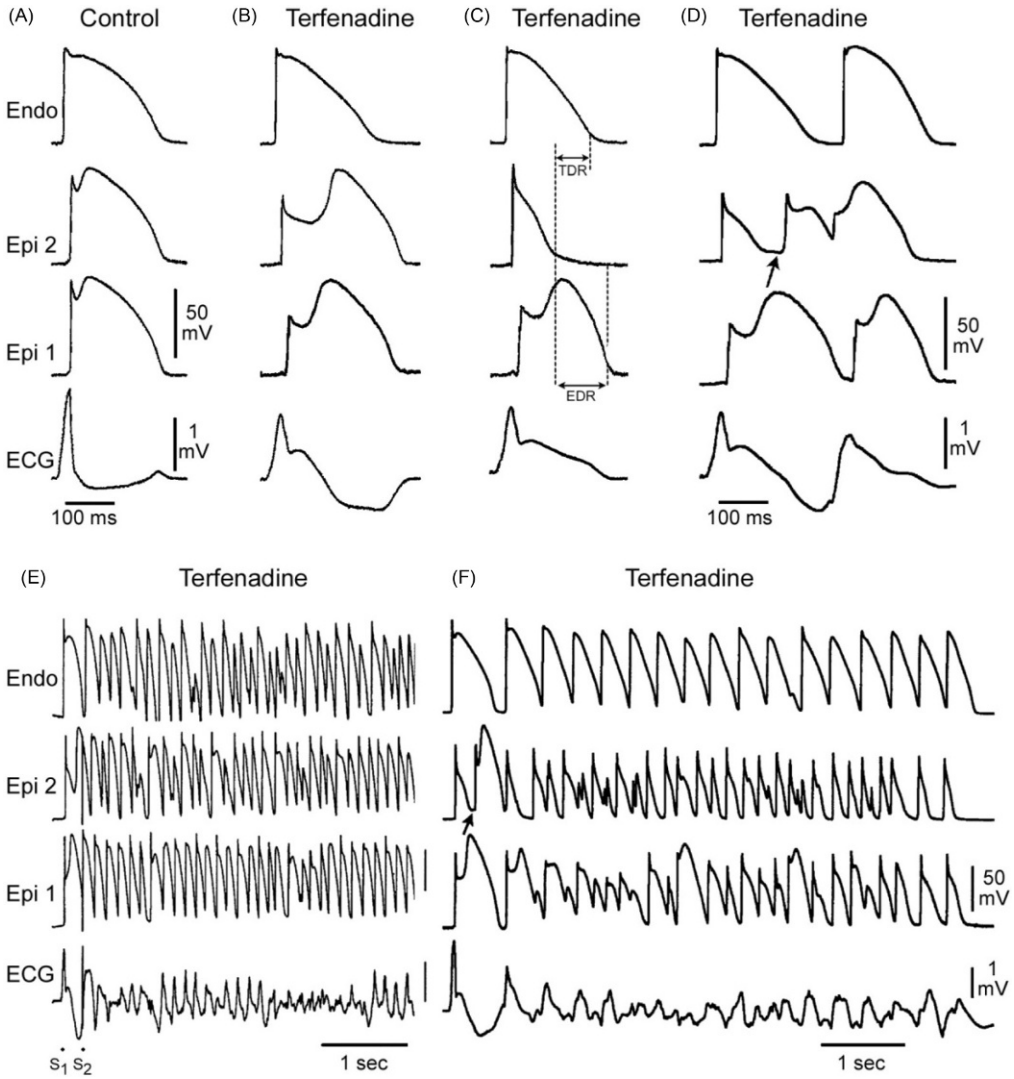

Fig. 3 Cellular basis for electrocardiographic and arrhythmic manifestation of BrS. Each panel shows transmembrane action potentials from one endocardial (top) and two epicardial sites together with a transmural ECG recorded from a canine coronary-perfused right ventricular wedge preparation. (A) Control (Basic cycle length (BCL) 400 ms). (B) Combined sodium and calcium channel block with terfenadine (5 μM) accentuates the epicardial action potential notch creating a transmural voltage gradient that manifests as an ST segment elevation or exaggerated J wave in the ECG. (C) Continued exposure to terfenadine results in all-or-none repolarization at the end of phase 1 at some epicardial sites but not others, creating a local epicardial dispersion of repolarization (EDR) as well as a transmural dispersion of repolarization (TDR). (D) Phase 2 reentry occurs when the epicardial action potential dome propagates from a site where it is maintained to regions where it has been lost giving rise to a closely coupled extrasystole. (E) Extrastimulus (S1–S2 = 250 ms) applied to epicardium triggers a polymorphic VT. (F) Phase 2 reentrant extrasystole triggers a brief episode of polymorphic VT. Modified from reference Fish, J. M, Antzelevitch, C. (2004). Role of sodium and calcium channel block in unmasking the Brugada syndrome. *Heart Rhythm* 1, 210–217, with permission.

discontinuities in conduction and plays a primary role in the development of the electrocardiographic and arrhythmic manifestations of the syndrome. Conduction slowing is not necessarily limited to the RVOT area.

Presumed evidence in support of the depolarization hypothesis was advanced by Nademanee et al. (2011) showing that radiofrequency (RF) ablation of epicardial sites displaying fractionated bipolar electrograms (EGs) and late potentials in the RVOT of patients with BrS suppresses the electrocardiographic and arrhythmic manifestations of BrS. These authors concluded that the late potential (LP) and fractionated electrogram activity are both due to conduction delays within the RVOT (Nademanee et al., 2011; Sacher et al., 2014; Brugada et al., 2015). Similar conclusions were arrived at by Brugada et al. (2015) and Sacher et al. (2014). These authors were of the opinion that ablation of the sites of slow conduction is the basis for the ameliorative effect of ablation therapy. Szel and Antzelevitch (2014) provided a direct test of this hypothesis and showed using an experimental model of BrS that the electrophysiologic manifestation is due to a repolarization defect rather than a depolarization or conduction defect. They showed that low-voltage fractionated electrogram activity similar to that observed in the RVOT of BrS patients develops secondary to heterogeneous appearance of the second action potential upstroke, due to accentuation of the epicardial AP notch and not to slow or delayed conduction (**Fig. 4**). They further showed that high-frequency late potentials develop in RV epicardium due to delayed phase 2 upstroke and to concealed phase 2 reentry. Slow or delayed conduction of the primary beat was never observed in a wide variety of BrS models created by exposing canine right ventricular wedge preparations to drugs mimicking the different genetic defects that have been associated with BrS (Szel and Antzelevitch, 2014). These findings revealed that in the setting of BrS fractionated electrograms and late potentials are due to repolarization rather than conduction defects.

Why then is ablation of regions of the RVOT exhibiting fractionated electrogram activity and late potentials effective in diminishing the ECG and arrhythmic manifestations of BrS? Patocskai et al. tested the hypothesis that ablation ameliorates the BrS phenotype by destroying sites of abnormal conduction. Epicardial regions displaying fractionated electrograms and late

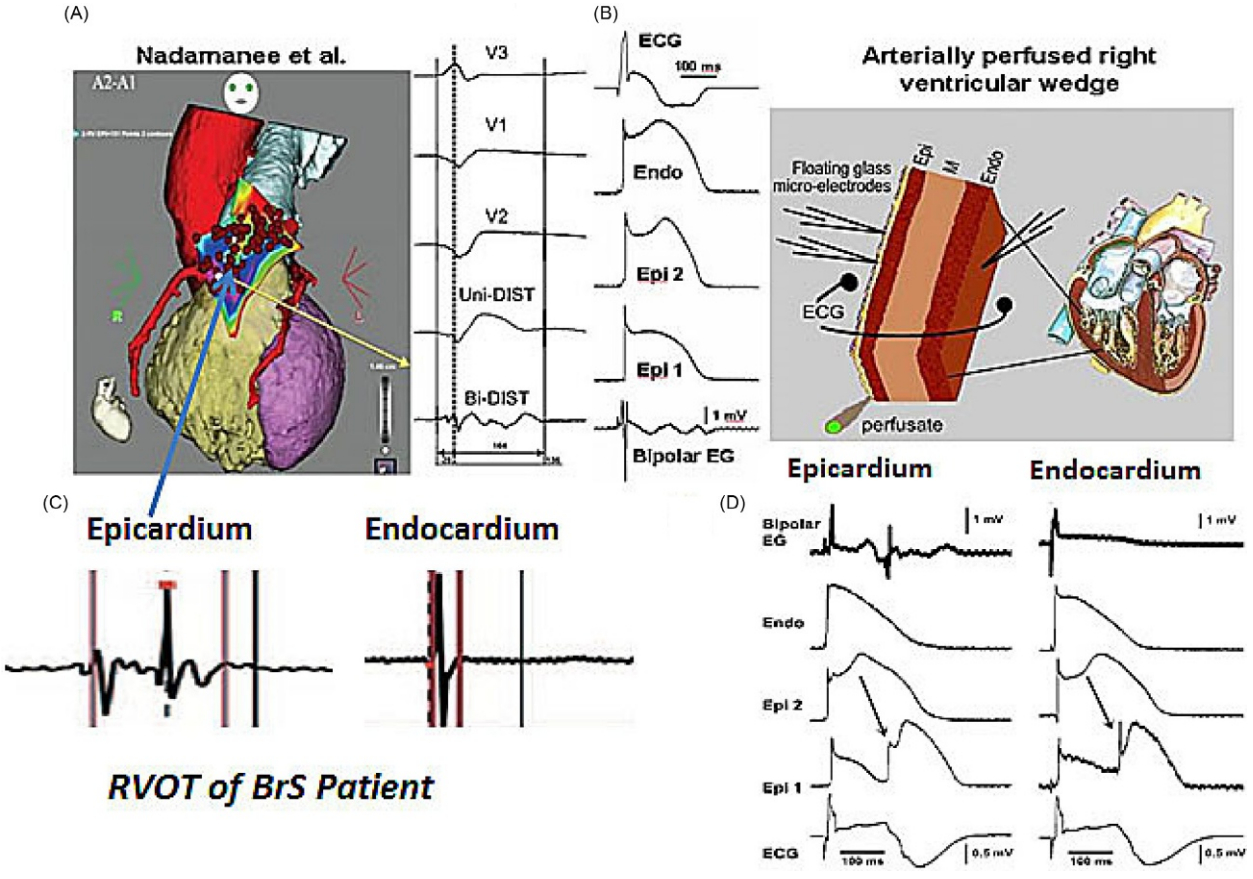

Fig. 4 New interpretation of fractionated electrogram activity and late potentials. Desynchrony in the appearance of the epicardial action potential second upstroke gives rise to fractionated epicardial electrogram (EG) activity and concealed phase 2 reentry gives rise to high-frequency late potentials in the setting of Brugada syndrome (BrS). (A) Shown are right precordial lead recordings, unipolar and bipolar EGs from the right ventricular outflow tract of a BrS patient. (B) ECG, action potentials from endocardium (Endo) and two epicardial (Epi) sites, and a bipolar epicardial EG (Bipolar EG) all simultaneously recorded from a coronary-perfused right ventricular wedge preparation treated with the I_{to} agonist NS5806 (5 μM) and the calcium channel blocker verapamil (2 μM) to induce the Brugada phenotype. Basic cycle length = 1000 ms. (C) Bipolar EGs recorded from the epicardial and endocardial surfaces of the RVOT in a patient with BrS. The epicardial EG displays fractionated electrogram activity as well as a high-frequency late potential late potential (130 ms delay). (D) Bipolar electrograms recorded from the epicardium and endocardium of a coronary-perfused wedge model of BrS, together with AP recordings from an endocardial and two epicardial sites and a transmural ECG. Slow or delayed conduction was never observed (Patocskai and Antzelevitch, 2015b). The clinical data are from Nademanee et al. (2011) and the experimental data are from Szel and Antzelevitch (2014), with permission.

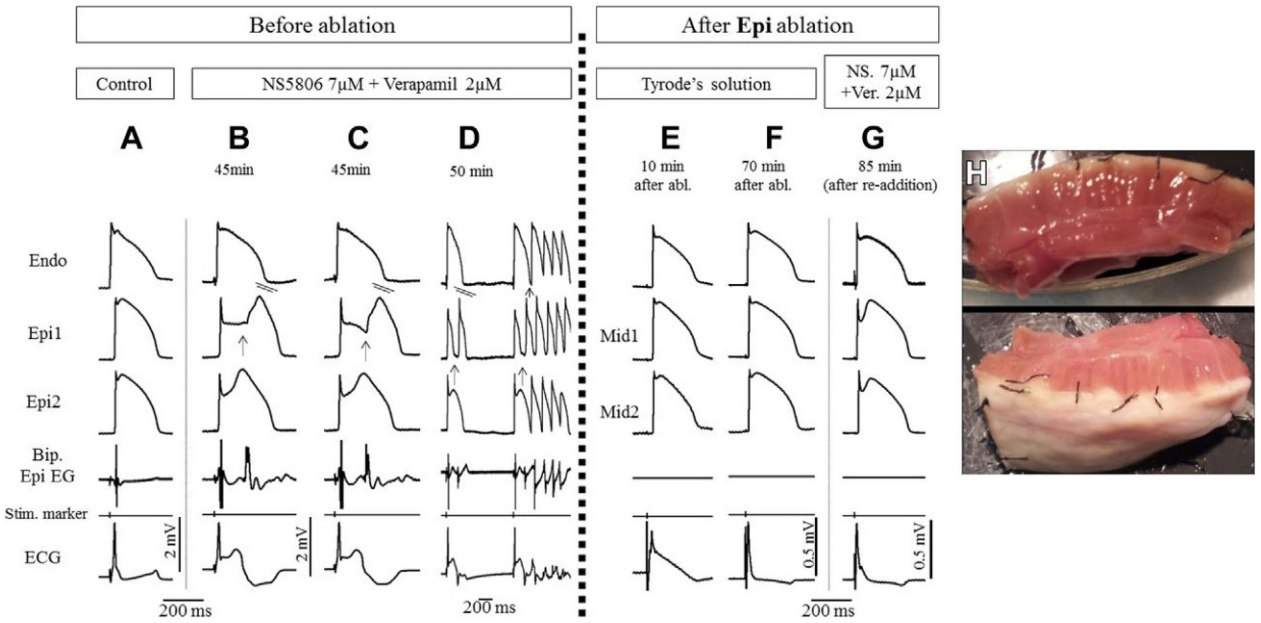

Fig. 5 Radiofrequency ablation of *epicardium* (Epi) suppresses the electrocardiographic and arrhythmic manifestations of Brugada syndrome in coronary-perfused canine RV wedge model generated using a combination of the I_{to} agonist *NS5806* and calcium channel blocker *verapamil*. Each column shows action potentials (AP) simultaneously recorded from an endocardial (Endo) and 2 epicardial (Epi1 and Epi2) sites together with a bipolar epicardial electrogram (Bipol. Epi EG) and an ECG recorded accross the bath. (A) Control. (B, C, D) The addition of NS5806 7 μM and verapamil 2 μM to the perfusate induced pronounced J waves and phase 2 reentry depicting as abnormal electrogram activity when concealed, and giving rise to ventricular fibrillation when it succeeds in propagating out. (E, F) Recovery period of the preparation after epicardial ablation. Note the normalization of ST-elevation after 70 min. Action potential recordings were obtained from midmyocardial (Mid) and subepicardial layers due to inactivation of the epicardium. (G) With superficially ablated epicardium, the readministration of the provocative agents (in the same concentration as before) did not produce pronounced J waves or arrhythmic activity. (H) Photo of wedge preparation after epicardial ablation to a depth of 1–2 mm, taken at the end of the experiment. Reproduced from Patocskai, B., Yoon, N., Antzelevitch C. (2017). Mechanisms underlying epicardial radiofrequency ablation to suppress arrhythmogenesis in experimental models of Brugada syndrome. *JACC: Clinical Electrophysiology*, with permission.

potentials in the experimental models of BrS were ablated. Once again, these electrophysiologic manifestations were shown to be due to repolarization abnormalities and concealed phase 2 reentry rather than conduction abnormalities (Fig. 5). Ablation of the RV epicardium suppressed the manifestation of J waves and ST segment elevation and abolished all arrhythmic activity, a result identical to that obtained by the clinical investigators. These findings provided direct evidence in support of the hypothesis that radiofrequency ablation (RFA) exerts an ameliorative effect by destroying the cells with the most prominent AP notch, thus eliminating the source of repolarization abnormalities responsible for phase 2 reentry and VT/VF (Patocskai et al., 2017).

Further support for the repolarization hypothesis derives from the demonstration that monophasic APs (MAPs) recorded from the endocardial and epicardial surfaces of the RVOT of a patient with BrS were nearly identical to transmembrane APs recorded from the endocardial and epicardial surfaces of the wedge model of BrS (Antzelevitch et al., 2002; Kurita et al., 2002) and from the demonstration that minipigs genetically engineered to heterozygously express a nonsense mutation in SCN5A (E558X) originally identified in a child with BrS (Park et al., 2015) develop conduction defects but not the BrS phenotype. These observations are expected owing to the lack of I_{to} in the pig, which is a prerequisite for the development of the repolarization abnormalities (outward shift imbalance) associated with BrS.

The congruence between BrS and ERS with respect to clinical manifestations and response to therapy provide further support for the repolarization hypothesis. Koncz et al. (2014) developed experimental models of ERS using canine coronary-perfused left ventricular wedge preparations and provided evidence in support of the hypothesis that, similar to the mechanism operative in BrS, an accentuation of transmural gradients in the LV wall is responsible for the repolarization abnormalities underlying ERS. Using ECG Imaging (ECGI), Rudy and coworkers provided additional evidence in support of the repolarization abnormalities by identifying abnormally short activation–recovery intervals (ARI) in the inferior and lateral regions of LV and a marked dispersion of repolarization (Ghosh et al., 2010).

Similarities and Difference Between BrS and ERS

BrS and ERS display several clinical similarities, suggesting similar pathophysiology. Table 5 summarizes the similarities and differences between the two J wave syndromes and mechanisms thought to be involved (Antzelevitch, 2013; Nam, 2012; Yan and Antzelevitch, 1996; Yan and Antzelevitch, 1999; McIntyre et al., 2012).

Table 5 Similarities and differences between Brugada and early repolarization syndromes and possible underlying mechanisms

	BrS	*ERS*	*Possible mechanism(s)*
Similarities between BrS and ERS			
Male predominance	Yes (>75%)	Yes (>80%)	Testosterone modulation of ion currents underlying the epicardial AP notch
Average age of first event	30–50	30–50	
Associated with mutations or rare variants in *KCNJ8*, *CACNA1C*, *CACNB2*, *CACNA2D*, *SCN5A*, *ABCC9*, *SCN10A*	Yes	Yes	Gain of function in outward currents ($I_{K\text{-}ATP}$) or loss of function in inward currents (I_{Ca} or I_{Na})
Relatively short QT intervals in subjects with Ca channel mutations	Yes	Yes	Loss of function of I_{Ca}
Dynamicity of ECG	High	High	Autonomic modulation of ion channel currents underlying early phases of the epicardial AP
VF often occurs during sleep or at a low level of physical activity	Yes	Yes	Higher level of vagal tone and higher levels of I_{to} at the slower heart rates.
VT/VF trigger	Short-coupled PVC	Short-coupled PVC	Phase 2 reentry
Ameliorative response to quinidine and bepridil	Yes	Yes	Inhibition of I_{to} and possible vagolytic effect
Ameliorative response to Isoproterenol denopamine and milrinone	Yes	Yes	Increased I_{Ca} and faster heart rate
Ameliorative response to cilostazol	Yes	Yes	Increased I_{Ca}, reduced I_{to} and faster heart rate
Ameliorative response to pacing	Yes	Yes	Reduced availability of I_{to} due to slow recovery from inactivation
Vagally-mediated accentuation of ECG pattern	Yes	Yes	Direct effect to inhibit I_{Ca} and indirect effect to increase I_{to} (due to slowing of heart rate)
Effect of sodium channel blockers on unipolar epicardial electrogram	Augmented J waves	Augmented J wave	Outward shift of balance of current in the early phases of the epicardial action potential
Fever	Augmented J waves	Augmented J waves (rare)	Accelerated inactivation of I_{Na} and accelerated recovery of I_{to} from inactivation
Hypothermia	Augmented J waves mimicking BrS	Augmented J waves	Slowed activation of I_{Ca}, leaving I_{to} unopposed. Increased phase 2 reentry, but reduced pVT due to prolongation of APD (Morita et al., 2007)
Differences between BrS and ERS			
Region most involved	RVOT	Inferior LV wall	Higher levels of I_{to} and/or differences in conduction
Leads affected	V1–V3	II, IIa, VF, V4, V5, V6; I, aVL, both: infero-lateral	
Regional difference in prevalence			Europe: BrS = ERS Asia: BrS > ERS
Incidence of late potential in SAECG	Higher	Lower	
Prevalence of atrial fibrillation	Higher	Lower	
Effect of sodium channel blockers on the surface ECG	Increased J wave manifestation	Reduced J wave Manifestation	Reduction of J wave in the setting of ER is thought to be due largely to prolongation of QRS. Accentuation of repolarization defects predominates in BrS, whereas accentuation of depolarization defects predominates in ERS
Structural changes—including mild fibrosis and reduced expression of Cx43 in RVOT or fibro-fatty infiltration in cases of ARVC. Imaging studies have also revealed wall motion abnormalities and mild dilatation in the region of the RVOT	Higher in some forms of the syndrome	Unknown	Some have hypothesized that some of these changes may be the result of rather than the cause of the BrS substrate, which may create a hibernation-like state due to loss of contractility in the RVOT secondary to loss of the AP dome

RVOT, right ventricular outflow tract; *AP*, action potential; *PVC*, premature ventricular contraction.

Risk Stratification

Risk assessment of the factors contributing to development of life-threatening arrhythmias in BrS and ERS has been a high priority in recent years (Brugada and Brugada, 1992; Osher and Wolff, 1953). **Fig. 6** presents a graphic representation of the prevalence and arrhythmic risk associated with the appearance of electrocardiographic J waves and clinical manifestations of BrS and ERS.

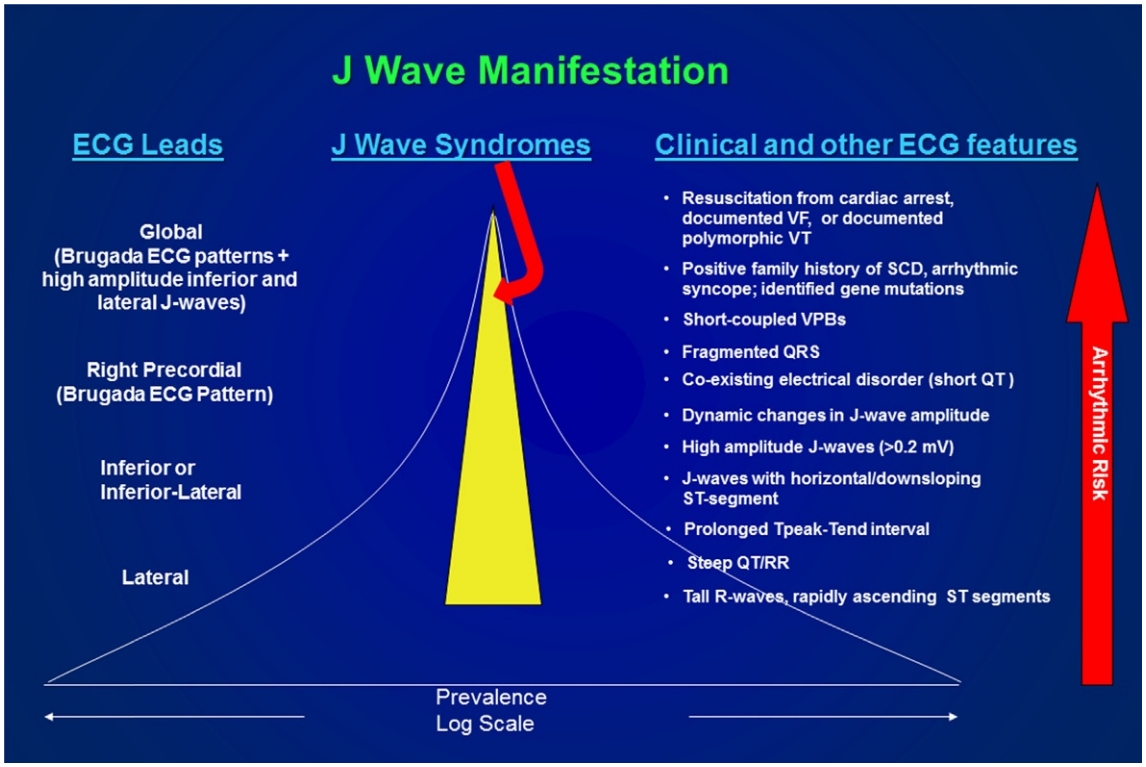

Fig. 6 Prevalence and arrhythmic risk associated with the appearance of ECG J waves and clinical manifestations of Brugada and Early Repolarization syndromes. The yellow highlighted region estimates the prevalence of the J wave syndromes. J waves in the lateral ECG leads have a high prevalence but are associated with a very low arrhythmic risk in a relatively small fraction of the cohort of individuals displaying J waves. On the other extreme, J waves appearing globally in the ECG have a very low prevalence but are associated with a very high level of arrhythmic risk in a large fraction of the cohort presenting with J waves. Likewise, individuals displaying rapidly ascending ST segment elevation have a high prevalence but low risk, whereas subjects resuscitated from cardiac arrest have a very low prevalence by the highest level of arrhythmic risk. Reproduced from Antzelevitch, C., Yan, G. X., Ackerman, M. J., Borggrefe, M., Corrado, D., Guo, J., Gussak, I., Hasdemir, C., Horie, M., Huikuri, H., Ma, C., Morita, H., Nam, G. B., Sacher, F., Shimizu, W., Viskin, S., Wilde, A. A. (2016). J-Wave syndromes expert consensus conference report: Emerging concepts and gaps in knowledge. *Heart Rhythm* 32(5), 315–339, with permission.

Clinical presentation is the strongest predictor of risk in BrS, overshadowing all other risk factors. The risk of recurrent VF among patients presenting with cardiac arrest is considerable: ≈35% at 4 years (Probst et al., 2010; Kamakura et al., 2009), 44% at 7 years (Conte et al., 2015), and 48% at 10 years (Sacher et al., 2013). One-third of BrS cases present with syncope nowdays (Probst et al., 2010). Their risk of arrhythmic events during follow-up is intermediate: approximately four times higher than the risk of asymptomatic patients (Probst et al., 2010; Priori et al., 2012a,b) but four times lower than that of patients diagnosed postcardiac arrest (Probst et al., 2010), probably due to inclusion of subjects with vagal syncope, which is associated with a relatively good prognosis.

Asymptomatic patients represent approximately 63% of newly diagnosed Brugada patients today (Probst et al., 2010; Kamakura et al., 2009). Their risk of developing symptoms is relatively low (0.5% per year) (Probst et al., 2010; Kamakura et al., 2009). Unfortunately, for most of these patients the first symptom is cardiac arrest or sudden cardiac death. Risk stratification of asymptomatic patients is therefore of utmost importance, and strategies for doing so are discussed later.

Age and gender: The mean age at the time of cardiac arrest in BrS patients is 39–48 (Probst et al., 2010; Kamakura et al., 2009; Conte et al., 2015). BrS in children is rare, but sudden death in this population is reported (Priori et al., 2000; Conte et al., 2014; Probst et al., 2007). Males are at increased risk of displaying a spontaneous type I Brugada ECG and of SCD (Kamakura et al., 2009; Benito et al., 2008).

Spontaneous versus drug-induced type I Brugada pattern: Patients displaying a spontaneous type I ECG at time of diagnosis are at much grater risk of developing arrhythmic events than patients who develop a type I ST segment elevation *only* when challenged with a sodium channel blocker (Probst et al., 2010; Delise et al., 2011) and is an independent predictor of arrhythmic events. Placing the right precordial leads over the 2nd and 3rd intercostal space, in addition to the standard 4th intercostal space, increases the sensitivity for detecting the coved ST segment elevation of the type I Brugada pattern (Miyamoto et al., 2007; Okamura et al., 2015; Govindan et al., 2010).

Electrophysiologic (EP) testing with programmed electrical stimulation: The role of programmed electrical stimulation has long been a matter of intense debate (Brugada et al., 2011; Wilde and Viskin, 2011; Viskin and Rogowski, 2007). The key question is whether the

prognostic information provided by VF inducibility is robust enough for clinical decision-making. Some studies suggest this to be the case (Delise et al., 2011; Brugada et al., 2005; Sieira et al., 2015), whereas others do not (Kamakura et al., 2009; Conte et al., 2015; Priori et al., 2012b). Using a pooled analysis of prospective observational studies of BrS patients undergoing EP study, Sroubek et al. reported that induction with 2 or less extrastimuli was indeed associated with higher risk for development of arrhythmic events and that failure to induce does not necessarily portend low ventricular arrhythmia risk particularly in patients with high-risk clinical features (Sroubek et al., 2016).

Approach to Therapy

Fig. 7 presents recommendations for the management of BrS from the recent expert consensus conference (Antzelevitch et al., 2016b).

ICD and Ablation

The only proven effective therapy for the prevention of SCD in high-risk BrS patients is an implantable cardioverter defibrillator (ICD) (Brugada et al., 2000c; Nademanee et al., 2003). Arrhythmic events and sudden cardiac death in BrS generally occur during sleep or at slow heart rates. These observations notwithstanding a potential therapeutic role for cardiac pacing remains largely unexplored (van Den Berg et al., 2001). A few case reports are available (Bertomeu-Gonzalez et al., 2006; Lee et al., 2000). Nademanee et al. (2011) showed that radiofrequency ablation (RFA) of the epicardium of the RVOT of BrS patients can significantly reduces arrhythmia-vulnerability as well as the ECG-manifestation of the disease and renders VT/VF noninducible. Additional evidence in support of the effectiveness of epicardial substrate ablation was provided by Sacher et al. (2014) and Shah et al. (2011), and Brugada et al. (2015). It is noteworthy that the use of radiofrequency ablation to prevent arrhythmogenesis in the setting of BrS was demonstrated by Morita and coworkers in 2009 using an experimental model of BrS (Morita et al., 2009b).

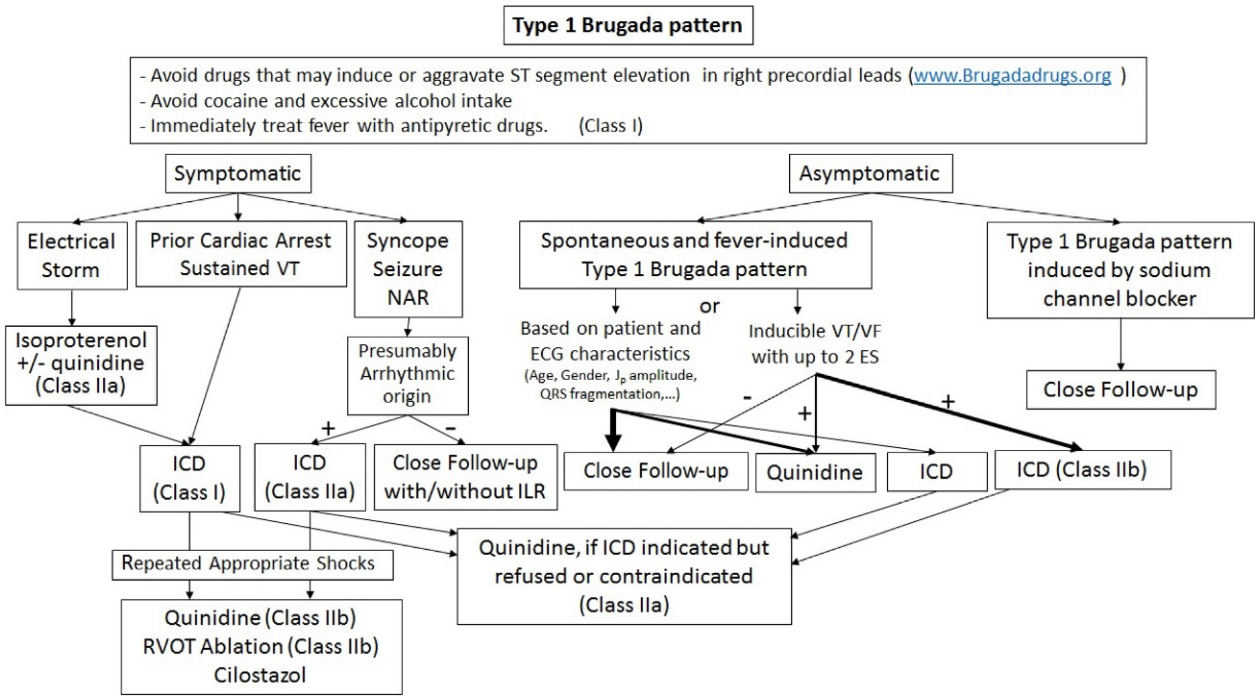

Fig. 7 Indications for therapy of patients with Brugada syndrome. *ES*, extrastimuli at RV apex; *ICD*, implantable cardioverter defibrillator; *ILR*, implantable loop recorder; *NAR*, nocturnal agonal respiration; *pVT*, polymorphic VT; *SCD*, sudden cardiac death; *VT*, ventricular tachycardia. Pharmacologic Approaches to Therapy

Because the BrS substrate develops as a consequence of an outward shift in the balance of current during the early phases of the epicardial action potential, the principal goal of therapy involves the induction of an inward shift in the balance of current. This can be accomplished either by boosting inward calcium current using β-adrenergic agent or phosphodiesterase III inhibitors or by reducing outward currents including the transient outward current (I_{to}) using agents such as quinidine (Patocskai and Antzelevitch, 2015a).

Because a prominent I_{to} is a prerequisite for the development of both BrS and ERS, partial inhibition of this current is thought to be effective regardless of the ionic or genetic basis for the disease. Unfortunately, cardio-selective and I_{to}-specific blockers are not available. The only agent available in the United States and around the world with significant I_{to} blocking properties is quinidine (Antzelevitch et al., 1999; Yan and Antzelevitch, 1999). Experimental studies have shown that quinidine is effective in restoring the epicardial action potential dome, thus normalizing the ST segment and preventing phase 2 reentry and polymorphic VT in a variety of different experimental models of BrS (Szel and Antzelevitch, 2014; Yan and Antzelevitch, 1999; Minoura et al., 2012; Minoura et al., 2013; Johnson et al., 1960). A recent experimental study suggests that quinidine, owing to its effect to block I_{to}, can also exert a protective effect against hypothermia-induced VT/VF in a J wave syndrome model (Gurabi et al., 2014).

Clinical evidence for the effectiveness of quinidine in normalizing ST segment elevation and or preventing arrhythmic events in patients with BrS has been reported in numerous studies and case reports (Belhassen et al., 2004; Belhassen et al., 1987; Belhassen et al., 2002; Alings et al., 2001; Belhassen and Viskin, 2004; Viskin et al., 2009; Belhassen et al., 2009; Marquez et al., 2013; Pellegrino et al., 2013; Probst et al., 2006; Schweizer et al., 2010; Hasegawa et al., 2014; Marquez et al., 2005; Viskin et al., 2007; Ohgo et al., 2007; Rosso et al., 2008b; Hermida et al., 2004; Mok et al., 2004). A prospective registry of empiric quinidine for asymptomatic BrS can be accessed at http://clinicaltrials.gov/ct2/show/NCT00789165?term_brugada&rank_2. Doses between 600 and 900 mg were recommended, if tolerated (Viskin et al., 2009).

Quinidine may be considered (Class IIb indication) in BrS patients who present with electrical storms and in patients implanted with an ICD who experience repeated appropriate shocks. Quinidine can also be useful in asymptomatic BrS patients displaying a spontaneous Type I ECG, if they qualify for an ICD, and the device is refused or is contraindicated (Class IIa recommendation).

Agents that augment the L-type calcium channel current, including β adrenergic agents like isoproterenol, denopamine, or orciprenaline, have proved usefull (Yan and Antzelevitch, 1999; Schweizer et al., 2010; Ohgo et al., 2007; Antzelevitch, 2001b; Tsuchiya et al., 2002; Kyriazis et al., 2009). Isoproterenol, at times in combination with quinidine, has been utilized successfully to control VF storms and normalizing ST elevation particularly in children (Miyazaki et al., 1996; Belhassen et al., 2002; Alings et al., 2001; Pellegrino et al., 2013; Ohgo et al., 2007; Mok et al., 2004; Maury et al., 2004, 2005; Jongman et al., 2007; Watanabe et al., 2006; Furniss, 2012; Shimizu et al., 2000; Suzuki et al., 2000; Tanaka et al., 2001; Shimizu and Kamakura, 2001; Sharif-Kazemi et al., 2011; Roten et al., 2012; Kaneko et al., 2014). Administration of isoprotereonol is a Class IIa recommendation for BrS patients presenting with electrical storms (Priori et al., 2013).

Phosphodiesterase III inhibitors such as cilostazol (Ohgo et al., 2007; Tsuchiya et al., 2002; Agac et al., 2013) normalize ST segment, elevation in BrS by augmenting calcium current (I_{Ca}) as well as by reducing I_{to} secondary to an increase in cAMP, and heart rate (Kanlop et al., 2011). Milrinone is another phosphodiesterase III inhibitor recently identified in an experimental model of BrS as a more potent alternative to cilostazol in suppressing ST elevation and arrhythmogenesis (Szel and Antzelevitch, 2014; Szel et al., 2013). No clinical reports are available as yet.

Wenxin Keli, a traditional Chinese medicine, has recently been shown to inhibit I_{to} and thus to suppress polymorphic VT in experimental models of BrS when combined with low concentrations of quinidine (5 μM) (Minoura et al., 2013).

Agents that augment peak and late I_{Na}, including bepridil and dimethyl lithospermate B (dmLSB), are suggested to be of value in BrS. Bepridil has been reported to suppress VT/VF in several studies of patients with BrS (Ohgo et al., 2007; Sugao et al., 2005; Murakami et al., 2010; Aizawa et al., 2013). The drug's action is thought to be mediated by: (1) inhibition of I_{to}, (2) augmentation of I_{Na} via upregulation of the sodium channels (Kang et al., 2009), and (3) prolongation of QT interval at slow rates thus increasing the QT/RR slope (Sugao et al., 2005; Aizawa et al., 2013).

Participation in Sports

Because malignant ventricular arrhythmias are infrequent in asymptomatic patients with BrS (Probst et al., 2010) and usually unrelated to physical activity, the presence of these patterns does not contraindicate participation in sports, although insufficient data are currently available to make definitive recommendations for participation in sports.

Introduction

The heart is the fundamental blood supply pump of the body, generating the pressure and flow to deliver oxygen and nutrients to all of the body's tissues. It is an intricate four-chambered organ with many unique anatomic and physiological features. Its normal function is dependent upon a myriad of factors including, but not limited to, development, hemodynamics, autonomic nervous system regulation, and hormonal regulation from both the central blood supply and local metabolites. In this chapter, we provide a general overview of cardiac and coronary anatomy, physiology, and pathophysiology.

Cardiac Anatomy

Cardiac Macroscopic Structure and Route of Blood Flow

Cardiac anatomy, coronary blood supply, and cardiac cellular and subcellular structure and function are all critical to cardiac function and physiology. As detailed cardiac anatomy can be found in many anatomical textbooks (Netter, 2010; Moore et al., 2014), we provide here only a brief description of cardiac anatomy to lay the foundation for understanding the physiology of the cardiac cycle. The heart is composed of a series of inflow collecting chambers (atria) and outflow pumping chambers (ventricles) as shown in **Fig. 1**. The atrioventricular valves, the tricuspid and mitral valves, connect the atria to the ventricles and the semilunar valves, the aortic and pulmonary valves, connect the ventricles to the outflow tract (the aorta and pulmonary arteries, respectively). These valves serve to restrict blood flow to one direction under normal circumstances. The heart is separated into a right and left side with the interatrial septum (IAS) and interventricular septum (IVS) separating the right and left atria and right and left ventricles, respectively (**Fig. 1A and B**) (Netter, 2010; Moore et al., 2014).

Deoxygenated red blood cells enter the heart at the right atrium (RA) via the superior vena cava from above and the inferior vena cava from below. The RA is identified by the presence of pectinate muscles, a broad thumb-like right atrial appendage, and a smooth ridge in the superior portion of the RA called the crista terminalis, which divides the right atrial appendage and muscular portion of the RA from the smooth portion of the RA. The wall of the RA is relatively thin and is highly compliant, expanding with blood as it

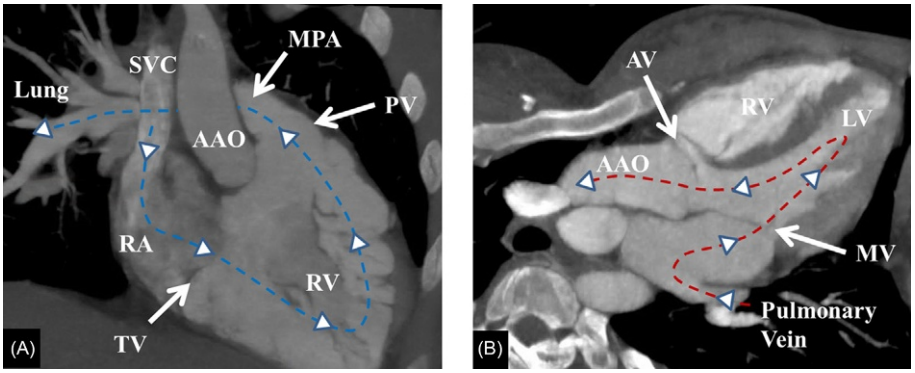

Fig. 1 Cardiac anatomy and route of blood flow tracing the course of (A) systemic deoxygenated blood from the SVC to the lungs (*blue lines*) and (B) oxygenated blood from the lungs to the pulmonary veins to the aorta (*red lines*).

fills during atrial diastole; thus the RA pressure is normally very low (≤5 mmHg, varying with respiration). After filling, the RA pumps deoxygenated blood into the right ventricle (RV) through the tricuspid valve, aided by spontaneous RA contraction at the end of the atrial contraction phase (atrial systole) or ventricular diastole. The tricuspid valve is situated between the RA and the RV and is characterized by its multiple attachments to the ventricular septum by being more apically positioned than the mitral valve. The tricuspid valve has three leaflets: the septal, posterior, and anterior. The tricuspid valve opens during ventricular diastole to allow the RV to fill and closes during ventricular systole to prevent blood from leaking back into the RA from the RV (**Fig. 1A**) (Netter, 2010; Moore et al., 2014).

The RV is identified by its association with the tricuspid valve, its triangular shape, and trabeculated appearance, as well as the moderator band (also known as trabeculae septomarginalis or septomarginal trabeculations), which separates the apical portion of the RV from the rest of the RV. The RV pressure is typically low (systolic ≤25 mmHg and diastolic ≤5 mmHg) and is typically ≤25% of that of the left ventricle (LV). The function of the RV is to pump deoxygenated blood through the pulmonary valve into the pulmonary artery and to the lungs. The pulmonary valve is a semilunar valve situated between the RV and pulmonary artery, has three leaflets, and arises from the infundibulum of the RV. The pulmonary valve is separated from the tricuspid valve by the RV infundibular musculature that forms the right ventricular outflow tract. The pulmonary valve controls blood flow through the pulmonary artery to the lung by opening during RV contraction (systole) and closing during RV filling (diastole), thus preventing regurgitation of blood back into the RV (**Fig. 1A**).

Deoxygenated blood enters the main pulmonary artery and then flows through right and left branch pulmonary arteries on its way to the lung where it passes through a complex network of capillaries and adjacent alveoli to become oxygenated before returning to the left atrium (LA). Like the RV, the pressure in the main pulmonary artery and branch pulmonary arteries are low, typically less than 25% of systemic blood pressure (systolic ≤25 mmHg and diastolic ≤10 mmHg) (Mukharji et al., 1990; Anderson et al., 2004; Partridge and Anderson, 2009; Gavaghan, 1998; Crick et al., 1998). Once oxygenated, blood returns to the LA via four pulmonary veins, which typically enter the posterior aspect of the LA (**Fig. 1A and B**).

The LA is typically identified as lacking significant pectinate muscle and having a thin, finger-like left atrial appendage. Like the RA, the LA has a pulmonary venous component as well as a vestibule and septal surface; unlike the RA, however, the LA has a large body component that connects these other parts together. Similar to its RA counterpart, the wall of the LA is relatively thin and highly compliant, expanding with blood as it fills during atrial diastole. Because of this the LA pressure, though higher than that of the RA, is normally low (≤10 mmHg). The function of the LA is to pump oxygenated blood into the LV through the mitral valve, aided by spontaneous LA contraction at the end of the atrial filling phase (atrial systole) or ventricular diastole.

The mitral valve is situated between the LA and the LV and is identified by its papillary muscle attachments to the free wall of the LV and none to the ventricular septum. The mitral valve is comprised of an anterior leaflet, which is attached to the anterolateral papillary muscle, and a posterior leaflet, which is attached to the posteromedial papillary muscle via fibrous strands of chordae tendineae. During ventricular diastole the mitral valve opens, allowing the LV to fill; during ventricular systole the mitral valve closes, preventing blood from leaking back into the LA from the LV.

The LV is identified by its association with the mitral valve, its cone-like shape, and its numerous dense trabeculations, giving the LV wall a smooth appearance. Similar to its RV counterpart, the LV has an inlet, as well as apical trabecular and outlet components. Unlike the RV, however, the LV chamber is thick-walled, and the pressure generated by the LV at rest is much higher than that of the RV (systolic ≤120 mmHg and diastolic ≤10 mmHg). The function of the LV is to pump oxygenated red blood cells across the aortic valve and through the aorta to bring oxygen to both the upper and lower body via the arterial system. The aortic valve is a semilunar valve with three separate leaflets that is situated between the LV and ascending aorta. The aortic valve controls blood flow by opening during LV contraction (systole), allowing oxygenated blood to enter the ascending aorta on its way to the body, and closing during LV filling (diastole) to prevent regurgitation of blood back into the LV. The pressure in the ascending aorta is typically slightly lower than the LV pressure (systolic ≤120 mmHg and diastolic ≤80 mmHg) at rest, thus allowing forward flow. Oxygenated blood

entering the ascending aorta is then dispersed through a series of arterial branches to supply tissues of the upper and lower body (Holt et al., 1968; Kowalski et al., 1954; Lamers et al., 1992; Paraskevas et al., 2017).

Coronary Anatomy and Supply

The coronary vascular system is comprised of arteries, arterioles, capillaries, venules, and veins and originates as the right and left main coronary arteries just above the AV at the level of the aortic root or sinus of Valsava between the aortic annulus and sinotubular junction (Kini et al., 2007; Schaper et al., 1972). The right coronary ostium is situated at the right (anterior) cusp of the AV and gives rise to the right coronary artery system that feeds the RV. The left coronary ostium is situated at the left (posterior) coronary cusp of the AV and gives rise to the left coronary artery system that feeds the LV. The coronary arteries course over the surface of the heart and divide into smaller branches as they traverse away from the aorta, penetrating the epicardium to supply the remainder of the myocardium. The smaller coronary arteries branch into arterioles, which further branch into large numbers of capillaries, through which the oxygenated blood cells release oxygen to adjacent tissue exchanging it for carbon dioxide. Deoxygenated blood cells then flow back to the RA through the venules, which then coalesce into larger cardiac veins, with blood ultimately returning to the RA through the coronary sinus. The control and function of the coronary circulation has been nicely reviewed (Kern, 2000; van de Hoef et al., 2012, 2015).

The function of the right coronary artery system is to supply nutrient-rich oxygenated blood to the right heart and its electrical conduction system. Shortly after arising from the right coronary cusp, the right coronary artery branches to the conus arteriosus, which supplies the RV outflow tract, and an atrial branch that gives rise to the sinoatrial node artery (in 50%–75% of cases). This runs anteriorly along the RA to the superior vena cava to supply the sinoatrial node. The remainder of the right coronary artery system courses into the right atrioventricular groove posteriorly and downward into the interventricular sulcus and, on its way, gives rise to a variable number of smaller branches into the RA and RV, the most prominent of which is the right marginal coronary artery branch that supplies the right margin of the RV. Further downward on the posterior surface of the RV, 2–3 additional branches arise. The most important of these is the atrioventricular node artery that supplies the atrioventricular node (in 50%–60% of cases), the proximal part of the bundles of His, and portions of the posterior interventricular septum (Netter, 2010; Moore et al., 2014; Kini et al., 2007).

Like the right coronary artery system, the function of the left coronary artery system is to supply nutrient-rich oxygenated blood to the left heart and its electrical conduction system. The main left coronary artery, after arising from the left coronary cusp, courses between the main pulmonary artery trunk and the left atrial appendage, then branches to the left anterior descending and the left circumflex coronary arteries. The left anterior descending artery, which appears to be a continuation of the left coronary artery at the left circumflex branch, then courses along the interventricular groove toward the ventricular apex. It gives rise to the anterior septal perforating arteries that enter the septum of the myocardium and supply blood to two-thirds of the interventricular septum (in 90% of cases), while other branches supply the anterior, lateral, and apical wall of the LV in addition to most of the right and left bundle branches. The left circumflex branch, after arising from the left coronary artery, courses along the left atrioventricular groove and supplies most the LA, the posterior and lateral free walls of the LV, and part of the anterolateral papillary muscle (Netter, 2010; Moore et al., 2014; Kini et al., 2007).

Microscopic Cardiac Anatomy

The macroscopic cardiac anatomy as described earlier is composed of different chambers of the heart, valves, and vessels that make up the cardiovascular system. However, to better understand cardiovascular physiology, one must dive deeper into the microscopic cardiac anatomy. The supporting structure (cardiac skeleton) of the microscopic cardiac anatomy is composed of dense fibrous collagenous connective tissue and the cardiac fibroblasts that are largely responsible for their formation. Within this supporting structure, the cardiac muscle fibers of the atria, ventricles, and heart valves are inserted (Jarvis and Stephenson, 2013).

Cardiac muscle is formed by cells called cardiomyocytes. The most basic unit of cardiomyocytes is the sarcomere, which under microscopy appears striated with alternating dark and light bands. These sarcomeres are connected to the plasma membrane (sarcolemma) by transverse tubules (t-tubules) that facilitate coordinated sarcomeric contraction. The two most important contractile proteins in the sarcomeres are myosin and actin. While myosin forms a thick and flexible filament, its counterpart actin forms a thin more rigid filament. The contractile protein myosin has a long tail and somewhat globular head that binds to actin as well as to adenosine triphosphate (ATP) needed for muscle movement. The contractile protein actin molecules are bound to the Z-disc, forming the borders of the sarcomere. These two contractile proteins (myosin and actin) form myofibrils that are the repeating molecular structures of the sarcomere required for muscle contraction. Contraction occurs when ATP binds to myosin, causing it to separate from the actin component of the myofibril. Cardiac muscle contraction, a complex process which is regulated by calcium influx and stimulus from electrical impulses, will be detailed in the cardiac physiology section (Skwarek-Maruszewska et al., 2009; Severs, 1995, 2000).

Contraction between cardiomyocytes is coordinated by the presence of intercalated discs, which connect individual cardiomyocytes into a functional syncytium. It is this syncytium that supports the rapid spread of action potentials to synchronize the contraction of the myocardium as a whole (Paraskevas et al., 2017). Under light microscopy, intercalated discs appear as thin lines dividing adjacent cardiac muscles and run perpendicular to the direction of the muscle fibers. Adheres junctions (anchor actin filaments to the cytoplasm of cardiomyocytes), gap junctions (connect the cytoplasms of adjacent cells and transmit action

potentials between these cells, and desmosomes (bind adhesion proteins to the cytoskeleton further connecting cells), are all components of the intercalated disc. These components work together within the cardiomyocyte syncytium to coordinate the transmission of action potentials and calcium flux during cardiac muscle contraction (Martini et al., 2012).

Cardiac Physiology

Normal cardiac function is complex and influenced by many factors, including local and systemic hormones, the autonomic nervous system, the inherent load on the cardiac chambers, and the coronary circulation that supplies nutrients and oxygen to this metabolically active tissue. In this section, we describe and integrate these important functions.

The Origin of the Heartbeat–Cardiac Electrophysiology

The electrical firing of "excitable" cells is dictated largely by the electrical membrane potential for each cell type and the ion channels that comprise each cell type. That membrane potential is driven by the influx and efflux of ions (Na^+, K^+, Ca^{2+}); in the heart, specialized cells (pacemaker cells) that reside within the sinoatrial node have "leaky" Na^+ channels (Verheijck et al., 1998; Boyett et al., 2000). These leaky Na^+ channels raise the membrane potential until it reaches threshold (approximately −40 to −30 mV), at which point depolarization occurs (**Fig. 2A**). This rhythmic depolarization is known as the pacemaker potential and is responsible for the automaticity of the heart. Depolarization of pacemaker cells in the sinoatrial node propagates across the left and right atria, causing atrial contraction and activation of the atrioventricular node. Atrioventricular node activation fires the signal down the bundle of His in the interventricular septum so that the ventricles contract from apex to base in a coordinated manner.

Unlike pacemaker cells, cardiomyocytes (nonpacemaker cells) have a resting membrane potential that approximates −90 mV (**Fig. 2B**). Action potentials from neighboring cells can depolarize cardiomyocytes to threshold, triggering a rapid influx of Na^+ through fast Na^+-channels (Phase 0). This initial rapid depolarization is followed by a very brief repolarization caused by the opening of outward K^+ channels (Phase 1). This phase occurs concurrently with the slow influx of Ca^{2+} through L-type Ca^{2+} channels, causing a plateau phase (Phase 2). This plateau phase is thought to be a built-in mechanism to prevent spontaneous firing within the absolute refractory period, or period during which random depolarizations do not occur, and is aided by the continual inactivation of the fast Na^+ channels. As the L-type Ca^{2+} channels close, inward rectifying K^+ channels open (Phase 3), causing a repolarization of the cell back to resting membrane potential (Phase 4). This cycle repeats with every cardiac cycle, initiating from the electrical activities at the sinoatrial node, propagating across the atria to the atrioventricular node, and down the septal bundle of His to contract the myocardium from apex to base.

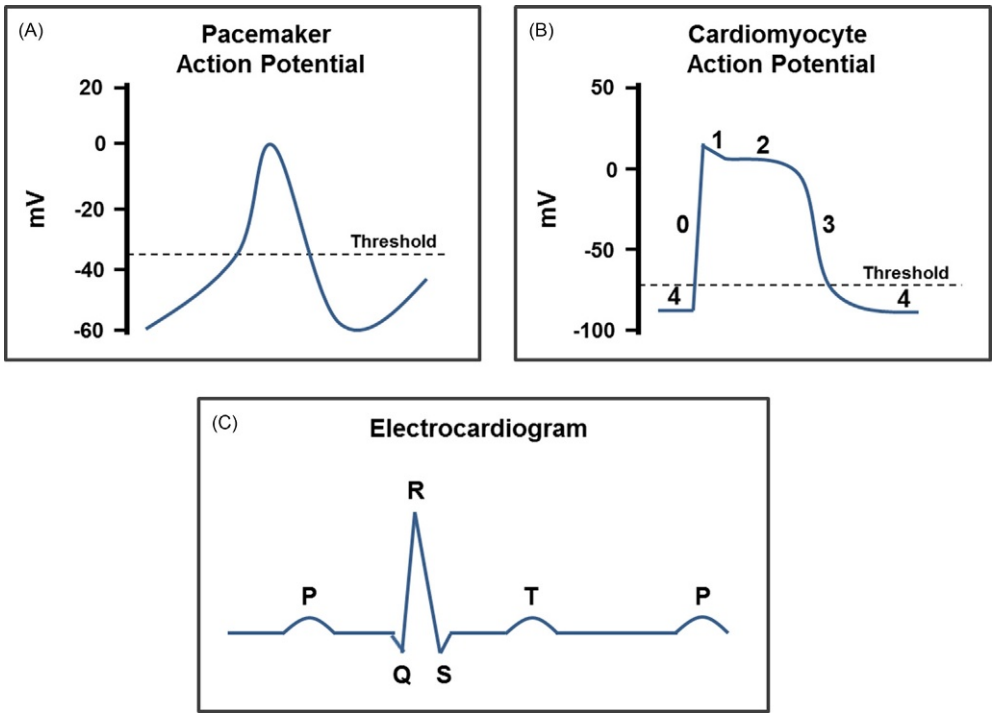

Fig. 2 Action potentials of pacemaker cells at the SA node (A) and cardiomyocytes (B), as well as the resultant normal electrocardiogram (C).

These cyclic alterations in electrical activity can be measured by the electrocardiogram (ECG, Fig. 2C). Atrial depolarization is reflected by the P wave, which is followed by the QRS complex, representing ventricular depolarization. It is important to note that the electrical magnitude of ventricular depolarization at the QRS complex masks atrial repolarization. The T wave represents ventricular repolarization, and the cycle repeats with every cardiac cycle. The duration and shape of the waves in the ECG provide important clues into cardiac arrhythmias, dysfunction, and overt heart failure, which will be discussed in later chapters.

Excitation–Contraction Coupling

The conversion of cardiomyocyte electrical depolarization via the action potential to cellular and syncytial contraction is called excitation–contraction coupling. Critical to the rapid and coordinated conduction of this signal to the interior of each cell is the existence of an intricate system of t-tubules, which are invaginations of the cardiomyocyte membrane designed to efficiently propagate the action potential. As the action potential is transmitted to each cardiomyocyte, Ca^{2+} floods the cytoplasm through L-type calcium channels during Phase 2 of the action potential. Ca^{2+} binds to ryanodine receptors on the sarcoplasmic reticulum to induce the rapid release of calcium stores to bring the intracellular Ca^{2+} concentration to approximately 10^{-7} to 10^{-5} M. Cytosolic Ca^{2+} then binds to troponin-C (TnC) on actin thin filaments to initiate myocyte contraction. Ca^{2+} binding to TnC elicits a conformational change in the troponin complex that dissociates troponin-I (TnI) from the myosin binding site on actin. The myosin head then binds to actin to induce the "power stroke" to shorten the sarcomere, resulting in systolic myocyte contraction. This power stroke uses ATP hydrolysis as its energy source. The release of contraction is caused by movement of cytosolic Ca^{2+} back into the sarcoplasmic reticulum via the sarcoplasmic reticulum calcium ATPase, or SERCA. Calcium is also removed from the cytosol to a lesser extent by the plasma membrane Na^{+}/Ca^{2+} exchange ATPase. The reduction in intracellular Ca^{2+} effectively removes it from TnC to allow rebinding of TnI to the myosin binding site on actin, resulting in the lengthening, or relaxation of the sarcomere back to its basal, noncontracted state.

The Cardiac Cycle: Systolic and Diastolic Function

The net effect of excitation–contraction coupling is the syncytial, coordinated contraction of sarcomeres in myocytes that results in ejection of blood from the heart during systolic contraction and the subsequent refilling of the cardiac chambers during diastolic relaxation. One cardiac cycle is comprised of a diastolic phase and a systolic phase, which can be represented on a pressure–volume loop (Fig. 3). During diastole, left ventricular pressure drops precipitously during isovolumic relaxation to below 5 mmHg of ventricular pressure. This drop in pressure results in passive blood flow from the atria into their respective ventricles through the atrioventricular valves. At the end of diastole, the atria contract, causing the "atrial kick" that accounts for approximately 20% of the end-diastolic volume in the ventricle prior to ventricular contraction. After the atria contract, isovolumic contraction occurs—the initial phase of contraction that continues until ventricular pressure exceeds aortic pressure across the aortic valve (for LV). Ventricular ejection (systole) occurs when the valve opens, causing a rapid reduction in ventricular volume until ventricular pressure drops below aortic pressure. After the valve closes, isovolumic relaxation begins again for the next cardiac cycle.

In addition to the cellular processes that regulate contraction and relaxation mentioned earlier, hemodynamic and neurohormonal forces play a critical role in regulating cardiac function. Central to these processes is the Frank–Starling Law of the Heart, which simplistically states that "within limits, the heart pumps all that it receives." Practically speaking, within limits, cardiac output/stroke volume increases with increased ventricular preload, or venous return (amount of blood that fills the ventricles during diastole) (Katz, 2011). This relationship is thought to be the result of optimal actin–myosin engagement until such point as

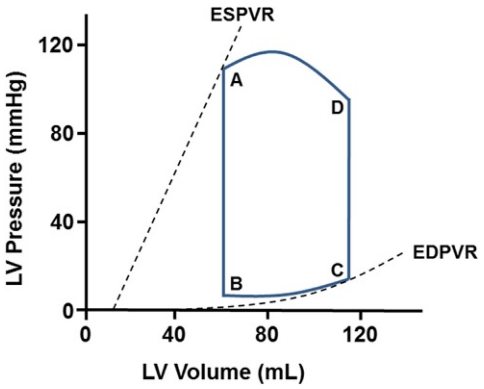

Fig. 3 Pressure–volume relationship in the left ventricle. (A to B) Isovolumic relaxation. (B to C) Passive (LV relaxation) and active (i.e., atrial kick) filling of the LV during diastole. (C to D) Isovolumic contraction—the initial phase of contraction that continues until ventricular pressure exceeds aortic pressure across the aortic valve (at point D). (D to A) Ventricular ejection, or systole, occurs when the valve opens, causing a rapid reduction in ventricular volume until ventricular pressure drops below aortic pressure (point A). After the valve closes, isovolumic relaxation begins again for the next cardiac cycle.

Table 1 Definitions of acronyms

Acronym	*Term*	*Definition*
CO	Cardiac output	The amount of blood pumped by the heart per minute
CI	Cardiac index	Cardiac output normalized to total body surface area
SV	Stroke volume	The amount of blood pumped by the heart per cardiac cycle (heart beat)
HR	Heart rate	The number of cardiac cycles (heart beats) per minute
EDV	End-diastolic volume	The volume of blood in the heart at the end of diastole (filling)
ESV	End-systolic volume	The volume of blood in the heart at the end of systole (contraction)
EF	Ejection fraction	The fraction of blood ejected from the heart with each cardiac cycle (heart beat)

the sarcomeres are stretched at high filling pressures/volumes that these interactions are no longer optimal, thus reducing ejection volume at higher preloads (Katz, 2011). The magnitude of this relationship is not only influenced by preload but also afterload, mainly the arterial pressure against which the heart has to pump blood, and cardiac inotropy, or strength of contraction. Increased afterload and/or decreased inotropy will reduce the overall cardiac output for a given venous return. Decreased afterload and/or increased inotropy will increase the overall cardiac output for a given venous return.

The efficacy of cardiac function can be determined using several physiological concepts and equations. Cardiac output (CO) is the amount of blood flow pumped by the heart per minute and is an overall readout of cardiac function. Many other readouts of cardiac function can be defined by the following equations (defined in **Table 1**):

$$\begin{aligned} CO &= SV \times HR \\ CI &= CO/\text{Body surface area} \\ SV &= EDV - ESV \\ EF &= (EDV - ESV)/EDV \end{aligned}$$

These readouts are just a start to determining how well the heart performs as a pump. There are many other factors not discussed in this section, including cardiac efficiency and cardiac work, which are beyond the scope of this chapter. Further discussion of related cardiac function concepts can be found in other chapters.

Cardiac Pathophysiology

When complex local autoregulatory control, systemic hormonal mechanisms, or both fail to work properly, the consequence is inadequate cardiac output leading to suboptimal nutrient and oxygen delivery to the heart and peripheral organ systems. Failure to maintain adequate cardiac output results in insufficient end-organ perfusion and often end-organ failure. The cardiovascular system can adapt to pathophysiological changes through remodeling in an effort to meet the demand of metabolically active tissues. In some situations, though, these compensatory mechanisms can lead to further cardiac injury, creating a vicious cycle ultimately ending in heart failure. A detailed analysis of the causes and consequences of these pathophysiological changes are outside the scope of this section, so we instead provide a brief overview of some common cardiovascular pathologies.

Congenital Heart Diseases

Congenital heart disease (CHD) (Allen, 2013; Freedom, 2004) is perhaps the most obvious cause of cardiac pathophysiology, as developmental alterations in the cardiac anatomy can affect cardiac output, oxygenation of blood, and both systemic and local blood pressure. More than 40,000 infants are born in the United States each year with CHD (Hoffman and Kaplan, 2002; van der Linde et al., 2011; van der Bom et al., 2012). CHD results in alterations in the cardiac structure in utero and results in a wide range of defects. Some of these are simple and cause minimal impact on cardiac physiology, while others are severe enough to require multiple palliative procedures, often resulting in unique and complex postoperative anatomy with abnormal blood flow. Still, others are incompatible with life, causing fetal or postnatal death, or requiring cardiac transplant either at birth or after failed palliative surgery. Many of the simple defects are small and resolve spontaneously overtime or require straightforward catheter-based interventions or simple surgical repair. Patients with complex constellations of CHD abnormalities will either require multiple cardiac surgical procedures or cardiac transplant. **Table 2** shows an overview of the most common, simple, and complex forms of CHD, which occur in approximately 8 out of every 1000 live births (Hoffman and Kaplan, 2002; van der Linde et al., 2011).

Recent advances in diagnosis and treatment of CHD have dramatically improved patient survival. In the United States alone, there are currently more than 1 million people living with CHD. With increasing numbers of survivors reaching adulthood, many require life-long evaluation for residual anatomic and hemodynamic defects. Of these, approximately 33% have minor defects, with little to no alteration in normal cardiac physiology and generally requiring minimal care. Another 33% have moderate disease, often requiring routine cardiac care, medication, or catheterization or surgical procedures. The last third of these CHD patients develop

Table 2 Overview of congenital heart disease

Septal defects
- Atrial septal defects (primum, secundum, inferior sinus venosus, superior sinus venosus)
- Ventricular septal defects (muscular, perimembranous/outlet, subpulmonary)
- Atrioventricular septal Defects (partial, transitional, intermediate, complete balance, complete unbalance)

Arterial abnormalities
- Patent ductus arteriosus
- Aortopulmonary window
- Congenital anomalies of the coronary artery (anomalous origins from the opposite cusp, anomalous origin from the pulmonary artery and single coronary artery origins)
- Vascular anomalies (vascular rings and slings)
- Aortic arch anomalies (right aortic arch, double aortic arch)
- Transposition of the great arteries
- Congenitally corrected transposition of the great arteries
- Double outlet right ventricle

Atrioventricular valve abnormalities
- Mitral regurgitation
- Mitral stenosis/mitral atresia
- Mitral valve prolapse
- Tricuspid regurgitation
- Tricuspid stenosis/atresia
- Tricuspid valve prolapse
- Ebstein's anomaly of the tricuspid valve

Right-sided congenital heart disease
- Pulmonary stenosis (subvalvar, valvar, and supravalvar)
- Pulmonary atresia with intact ventricular septum
- Pulmonary atresia with ventricular septal defect with multiple aorto-pulmonary collaterals (MAPCAs)
- Tetralogy of fallot/tetralogy of fallot with absent pulmonary valve
- Truncus arteriosus

Left-sided congenital heart disease
- Aortic valve disease (unicuspid and bicuspid aortic valve)
- Aortic stenosis (subvalvar, valvar, and supravalvar)
- Coarctation of the aorta
- Hypoplastic left heart syndrome

Venous abnormalities
- Anomalous pulmonary venous return/connection (partial and total anomalous pulmonary venous return)
- Anomalous system return/connection

Complex cardiac abnormalities
- Univentricular atrioventricular connection
- Double inlet left ventricle
- Congenital Heart disease with heterotaxy syndrome

severe or decompensated heart failure, often without palliative options or with high surgical or cardiac transplant risk, resulting in increased morbidity and early mortality (van der Bom et al., 2012; Wren and O'Sullivan, 2001; Marelli et al., 2007; Warnes et al., 2001; Morris and Menashe, 1991; Zomer et al., 2011).

Abnormal septation between the atria (atrial septal defects), ventricles (ventricular septal defects), both sets of chambers (atrioventricular septal defects), or great vessels (aortopulmonary windows and persistent truncus arteriosus) can result in miscommunication between the right and left heart and ultimately increase volume or pressure load on the right heart. Of these, atrial septal defects are the most common and result in RV volume overload. If left untreated, patients with large defects can develop Eisinmenger syndrome (pulmonary hypertension and right heart failure). Other forms of right heart CHD include tetralogy of Fallot, various forms of pulmonary stenosis, pulmonary atresia, and Ebstein's anomaly. The pathophysiology of these defects often results in increased pressure in the right heart, and in severe cases leads to cyanotic heart disease ("blue" babies) or single ventricular hearts.
