Cigarette smoking increases the risk of duodenal and gastric ulcers, delays the rate of ulcer healing, and increases the risk of relapse after ulcer treatment.[76] Smoking is also associated with esophageal reflux symptoms. Smoking produces ulcer disease by several proposed mechanisms: increasing acid secretion, reducing pancreatic bicarbonate secretion, impairing the gastric mucosal barrier (related to decreased gastric mucosal blood flow and/or inhibition of prostaglandin synthesis), reducing pyloric sphincter tone, and increasing the risk of *Helicobacter pylori* infection.[77]

Cigarette smoking is a risk factor for osteoporosis in that it reduces the peak bone mass attained in early adulthood and increases the rate of bone loss in later adulthood. Smoking antagonizes the protective effect of estrogen replacement therapy on the risk of osteoporosis in postmenopausal women.[78] Hip fractures are more common in women who smoke cigarettes. Cigarette smoking is a major cause of reproductive problems, including fetal growth restriction, preeclampsia, stillbirth, perinatal mortality, and sudden infant death syndrome.[79] Growth retardation from cigarette smoking has been termed *fetal tobacco syndrome.*[80] Cigarette smoking causes reproductive complications by causing placental ischemia mediated by the hypoxic effects of chronic carbon monoxide exposure, endothelial dysfunction, and the general increase in coagulability produced by oxidant chemicals in cigarette smoke.[81]

Other adverse effects of cigarette smoking include premature facial wrinkling, an increased risk of cataracts, age-related macular degeneration, olfactory dysfunction, and fire-related injuries. The last effect contributes significantly to the economic costs of tobacco use. Smoking reduces the secretion of thyroid hormone in women with subclinical hypothyroidism and increases the severity of clinical symptoms of hypothyroidism in women with subclinical or overt hypothyroidism, the latter effect reflecting antagonism of thyroid hormone action.[82] Cigarette smoking also potentially interacts with a variety of drugs by accelerating drug metabolism or by the pharmacologic interactions that nicotine and/or other constituents of tobacco have with other drugs (see Chapter 66).

Health Hazards of Secondhand Smoke

Considerable evidence indicates that exposure to secondhand smoke is harmful to the health of nonsmokers (Table 65.4).[83] The U.S. Environmental Protection Agency classifies secondhand smoke as a class A carcinogen, which means that it has been shown to cause cancer in humans.[84]

Secondhand smoke consists both of *sidestream* smoke generated while the cigarette is smoldering and of *mainstream* smoke exhaled by the smoker. Of the total combustion product from a cigarette, 75% or more enters the air. The constituents of secondhand tobacco smoke are qualitatively similar to those of mainstream smoke. However, some toxins, such as ammonia, formaldehyde, and nitrosamines, are present in much higher concentrations in secondhand tobacco smoke than in mainstream smoke. The Environmental Protection Agency has estimated that secondhand smoke is responsible for approximately 3000 lung cancer deaths annually in nonsmokers in the United States, is causally associated with 150,000 to 300,000 cases of lower respiratory tract infection in infants and young children up to 18 months of age, and is causally associated with the aggravation of asthma in 200,000 to 1 million children.[84] Secondhand smoke exposure promotes atherosclerosis and thrombosis by multiple mechanisms[85] and is estimated to be responsible for 40,000 cardiovascular deaths.[86] An appreciation of the hazards of secondhand tobacco smoke is important to the physician because it provides a basis for advising parents not to smoke when children are in the home,[87] insisting that child care facilities be smoke free, and recommending smoking restrictions in work sites and other public places.

TABLE 65.4 Health Hazards of Secondhand Tobacco Smoke in Nonsmokers

Children	Adults
Hospitalization for respiratory tract infection in first year of life	Lung cancer
Chronic respiratory symptoms	Myocardial infarction
Middle ear disease	Stroke
Asthma	Reduced pulmonary function
Reduced birth weight (maternal exposure)	Irritation of eyes, nasal congestion, headache
Sudden infant death syndrome	Cough

ELECTRONIC CIGARETTES

E-cigarettes, or electronic nicotine delivery devices, heat a nicotine solution to generate an aerosol that is inhaled without the combustion of tobacco and its toxic constituents. *Vaping* refers to the act of using of an e-cigarette. These devices have evolved substantially over the last decade but have in common (1) a reservoir that contains an e-liquid (propylene glycol, vegetable glycerin, nicotine, and flavorings), (2) a resistance metal coil (nickel, chromium, stainless steel, or a related alloy) that heats the e-liquid, (3) a wick (typically made of silica or cotton) that conducts the e-liquid to the coil, and (4) a battery that supplies electric current to the coil in response to airflow or a button push initiated by the user, generating a plume of small droplets (aerosol) (Table 65.5). E-cigarettes have been marketed with claims of health benefit compared with smoking cigarettes; they are marketed for use in reducing and quitting smoking, for use when a person is forbidden to smoke cigarettes, and for avoiding generating smelly and irritating secondhand smoke. The use of e-cigarettes in the United States has increased substantially since they were first marketed in 2006, with 2.8% (6.9 million) current e-cigarette users in 2017.[5] A concerning trend has been the explosive increase in e-cigarette use by young people, with 28% of high school students and 11% of middle school students reporting current e-cigarette use in 2019.[88]

As of 2020, there are thousands of e-cigarette devices on the U.S. market, and they vary with respect to size, power, coil architecture and metal type, and cartridge design. Some look like cigarettes and are disposable; others look like pens or cigars and have refillable tanks. E-cigarette liquids are sold over the Internet or in vape shops, in which the user can select the liquid, including the vehicle (varying proportions of propylene glycol and vegetable glycerin), nicotine concentration, and flavor. Over the last 3 years, pod-based devices with USB-compatible batteries, such as JUUL, have captured the majority of market share, in part because of overwhelming popularity with younger users.[88,89] Nicotine aerosolization depends on coil temperature (power), airflow, and the concentration of nicotine in the e-liquid, which ranges from 3 mg/mL or less for high-power devices to 60 mg/mL or higher for low-power devices, such as JUUL. More recently, vaping devices have been developed to aerosolize more viscous substances, such as *tetrahydrocannabinol* (THC) and cannabidiol-containing oils derived from cannabis. Vaping of THC-containing liquids has recently been implicated in an outbreak of severe acute respiratory disease (see "Cannabis" section).

TABLE 65.5 E-Cigarette Designs, Descriptions, and Brand Names*

Product	Description	Sample Brands†
Disposable e-cigarette 	Cigarette-shaped device consisting of a battery and a cartridge containing an atomizer to heat a solution (with or without nicotine). Not rechargeable or refillable and is intended to be discarded after product stops producing vapor.	NJOY, Blu, Green Smoke
Rechargeable e-cigarette 	Cigarette-shaped device consisting of a battery that connects to an atomizer used to heat a solution typically containing nicotine. Often contains an element that regulates puff duration and/or how many puffs may be taken consecutively.	V2 Cigs, Halo G6, MarkTen
Pen-style, medium-sized rechargeable e-cigarette 	Larger than a cigarette, often with a higher-capacity battery, may contain a prefilled cartridge or a refillable cartridge (often called a clearomizer). These devices often come with a manual switch allowing the smoker to regulate length and frequency of puffs.	eGo, Kanger EVOD, Halo Triton
Tank-style, large-sized rechargeable e-cigarette 	Much larger than a cigarette with a higher-capacity battery and typically contains a large, refillable cartridge. Often contains manual switches and a battery casing for customizing battery capacity. Can be easily modified.	Kanger Aerotank, Innokin iClear, Aspire Nautilus
Pod-style e-cigarette 	Low-power devices, typically USB-rechargeable; e-liquid pods typically contain a high concentration of nicotine. Some pods are refillable.	JUUL, SMOK, Aspire AVP

*E-cigarettes come in various sizes and designs. All contain a cartridge, a heating element, and a battery and provide an aerosol containing nicotine.
†Some brands may have been discontinued.
Modified from Grana R, Benowitz N, Glantz SA. Background paper on e-cigarettes (electronic nicotine delivery systems). Prepared for the 7th Meeting of the WHO Study Group on Tobacco Product Regulation. San Francisco: University of California; 2013.

PULMONARY TOXICITY

Given the relatively recent introduction of e-cigarettes, it is not surprising that their health effects are controversial and poorly characterized. Indeed, it took many decades for the toxicity of combustible cigarettes to be fully appreciated. The simpler chemical nature of e-cigarette aerosol, lacking many of the harmful components of cigarette smoke, would seem to predict less short- and long-term pulmonary toxicity, but few rigorous studies have been performed.

Population-based studies of e-cigarette users have revealed increased reports of chronic cough, sputum production,[90–92] asthma diagnoses,[93,94] and dyspnea,[94] although limitations of all of these studies include a reliance on self-reporting and frequent dual use of e-cigarettes with combustible cigarettes. Chronic smokers who are able to switch from cigarettes to e-cigarettes typically report improvements in respiratory symptoms,[95,96] but most of these studies have not rigorously compared e-cigarette use to quitting smoking without the use of e-cigarettes. A recent study from the United Kingdom randomized 886 smokers interested in cessation, using e-cigarettes or nicotine-replacement therapies as choices. The primary outcome, 1-year abstinence from cigarettes, was more frequent in the e-cigarette group (18.0 % vs. 9.9%, RR, 1.8 [CI, 1.3 to 2.6], respectively). Those randomized to e-cigarettes also had significant reductions in self-reported cough and wheeze, effects not fully accounted for by the increase in abstinence from smoking.[97]

Acutely, e-cigarette aerosol has variably been shown to cause obstructive physiology,[98–100] but whether long-term use results in persistent changes in spirometry is not yet clear. Bronchoscopic studies of healthy e-cigarette users have revealed erythematous mucosa with increased levels of inflammatory mucin proteins and damaging enzymes, including elastase, although many or most of the participants were former smokers.[101,102] Of note, the toxicity of e-cigarette aerosol is likely to be greater under high coil temperature conditions, which increase the production of toxic aldehydes and other oxidizing chemicals. A recent study in healthy young occasional cigarette smokers demonstrated impaired gas exchange after 15 minutes vaping an aerosol from a high-wattage (60-watt) device.[103] Case reports have identified several patterns of e-cigarette–associated respiratory disease, including organizing pneumonia, lipoid pneumonia, barotrauma, and hypersensitivity pneumonitis, although the incidence of these diseases and attributable risk from e-cigarettes at the population level remains unclear.[104] Experiments exposing mice to several months of e-cigarette aerosol have demonstrated major changes in surfactant and lipid metabolism, including oil-filled macrophages that stain with oil red O.[105]

E-CIGARETTES AND SMOKING CESSATION

There is currently considerable debate in the public health community about the safety and benefit of e-cigarettes. Most agree that e-cigarettes could be a health benefit if people would use e-cigarettes and stop smoking cigarettes entirely. A recent clinical trial demonstrated that e-cigarettes enhance smoking cessation with a substantially greater

benefit than nicotine medication, although 80% of those who quit smoking with e-cigarettes continued to vape at 1 year.[97] Epidemiology studies in the United States find that regular use of e-cigarettes is associated with higher rates of quitting smoking, whereas other studies find that dual use of cigarettes and e-cigarettes may be associated with lower quit rates.[106,107] Many e-cigarette users report smoking fewer cigarettes per day while using e-cigarettes, but the health benefits of such reductions are not clear.

OTHER POTENTIAL TOXICITIES OF E-CIGARETTES

In addition to pulmonary toxicity, which was discussed earlier, there are concerns that e-cigarette use may cause cardiovascular toxicity, reproductive toxicity, and possibly impair brain development in adolescents. Whereas products of combustion are thought to be the main mediators of smoking-induced cardiovascular disease, constituents of concern with e-cigarettes include oxidant chemicals, nicotine, particulates, and possibly metals.[108]

The manner in which an e-cigarette is puffed depends on the concentration of nicotine in the e-liquid,[109] the power of the device,[110] and prior cigarette use,[111] among other factors. Similarly, aerosols generated by e-cigarettes vary based on the device, power setting, e-liquid composition, and characteristics of the puff, with longer puffs resulting in higher coil temperatures and greater carbonyl production.[112] Broadly speaking, e-cigarettes produce much lower levels of oxidants than cigarettes while delivering similar levels of nicotine and particulates. The particulates in e-cigarette aerosol are similar in number and size distribution to those in cigarette smoke but are primarily liquid, rather than carbonaceous, and their toxicity is unknown. Nicotine causes sympathetic neural activation, which has some potentially deleterious effects on cardiovascular hemodynamics (increased heart rate, blood pressure, and myocardial contractility) and may impair endothelial function and promote insulin resistance; however, its effects are certainly much less than those of the combustion products in cigarette smoke. Acutely, e-cigarette use produces endothelial dysfunction similar to cigarette smoking, but when smokers switch from cigarettes to e-cigarettes, endothelial function substantially improves.[113] E-cigarette use can enhance platelet aggregation, an effect not related to nicotine, but long-term effects on coagulation are unknown.[114,115] Nicotine has neuroteratogenic effects in the fetus, but e-cigarettes are likely less toxic than smoking, which exposes the fetus not just to nicotine but also to myriad other reproductive toxins.[116] In adolescent rodents, nicotine impairs brain maturation, which has been a concern in light of the large number of young people now using e-cigarettes, but whether nicotine will impair brain maturation in people has been difficult to assess due to many social and environmental confounders.[117]

The *U.S. Food and Drug Administration* (FDA) has the authority to regulate e-cigarettes but has only very recently begun to promulgate regulations.[118] FDA regulation will be particularly useful to ensure the safety of these products, limit marketing and access to youth, and restrict use in situations where smoking is banned—both to minimize environmental pollution with e-cigarette vapor and to mitigate the renormalization of smoking behavior. Some clinicians recommend and/or support e-cigarette use in patients who have been unable to quit smoking using traditional counseling and medications, although the use of e-cigarettes in such a role is not approved by the FDA.

CANNABIS

During the past decade, many U.S. states have legalized cannabis for medical or recreational use and, although federal laws remain on the books, enforcement has declined, with nearly 9.8% of the U.S. population 12 years of age and older reporting use during the past month in 2017–18 compared to 6.4% in 2008–09.[119] Use frequency varies widely, with approximately 4 million U.S. residents estimated to have *cannabis use disorder* in 2016.[120] Furthermore, with the growth of the marketplace for cannabis and its psychoactive constituent, THC, the last several years has seen the extraordinary growth of new methods of consumption. These include the extraction of THC using butane and other solvents into waxes and oils, which are then heated and inhaled, and the development of new vape pens designed to aerosolize viscous liquids, including oils.[121] These novel methods of use have the potential to deliver concentrations of THC that exceed the use of combustible cannabis by an order of magnitude, with unknown consequences for addiction and health.[122]

PULMONARY TOXICITY

In contrast to cigarette smoke, comparatively little is known about cannabis-related pulmonary toxicity, and what is known nearly exclusively concerns traditional combustible cannabis use. Not surprisingly, cannabis smoke contains many of the same carcinogens and toxicants as cigarette smoke; perhaps surprisingly, cannabis smoking has been associated with greater increases in carboxyhemoglobin and inhaled tar per "cigarette" than cigarette smoking.[123] Typically, cannabis smoke is inhaled less frequently, but more deeply, and includes a long breath-holding time.[123] Coughing at near-total lung capacity likely explains the association of cannabis smoking with barotrauma, including pneumothorax and pneumomediastinum.[124] Most studies of chronic cannabis smoking have reported increased symptoms of upper airway irritation, including laryngitis, wheezing, and chronic cough and sputum production.[125,126]

Few high-quality studies of pulmonary function have been performed, with some showing reductions in forced expiratory volume in 1 second/forced vital capacity and reduced diffusing capacity but others showing no differences compared to control subjects.[126] Of note, two studies using high-resolution computed tomography scans have not found evidence that cannabis smoking causes emphysema.[127,128] Bronchoalveolar lavage studies have revealed increased neutrophils and alveolar macrophages,[129] with impaired responses to bacterial challenge.[130] Of importance, pulmonary fungal infections have been reported in cannabis smokers who are immunocompromised by diabetes mellitus, leukemia, and chronic steroid use.[131] Despite containing many of the same carcinogens as tobacco

smoke, cannabis smoke has not been clearly linked to lung cancer.[132] Most likely this is because cannabis smoking is generally much less frequent than cigarette smoking.

In the summer of 2019, a new syndrome of severe acute hypoxemic respiratory failure/acute respiratory distress syndrome was described, notable for the development of diffuse ground-glass opacities on computed tomography scan (frequently with subpleural sparing) in the context of gastrointestinal and constitutional symptoms.[133] Termed EVALI, this syndrome has been linked to the use of mostly illicitly produced THC-containing vape pens. At the time of this writing the etiology remains unclear, but high levels of vitamin E acetate have been found in many of the implicated devices and nearly all of the bronchoalveolar lavage samples of EVALI patients, suggesting that the toxicity may be due to vitamin E acetate.[134] Vitamin E acetate is used as a cutting agent for THC oil for resale or in the THC oil extraction process due to its similar viscosity and aerosol appearance. The Centers for Disease Control and Prevention have published recommendations for evaluating and caring for EVALI patients.[135]

CARDIOVASCULAR TOXICITY

The use of cannabis products containing THC has been associated with acute cardiovascular events, including myocardial infarction, stroke, arrhythmias, and sudden death.[136–138] The cardiovascular toxicity of marijuana smoking can be viewed as a result of one or more of these mechanisms: inhalation of combustion products (with a similar toxicity to cigarette smoking); direct sympathomimetic and other cardiovascular effects of THC; and indirect effects of THC related to extreme anxiety, hallucinations, and/or psychosis.[136] THC use acutely increases heart rate (20–100%), which can be associated with supine hypertension and increased myocardial work. Systemic catecholamine release can constrict coronary arteries and/or activate platelets. The net result can be markedly increased myocardial work and oxygen demand combined with an inadequate compensatory increase in coronary blood flow, resulting in myocardial ischemia or infarction. THC can also produce orthostatic hypotension, which poses a risk in the elderly. The cardiovascular impact of THC depends on the product (marijuana leaf vs. THC oil vs. edibles), dose consumed, route of administration, pattern of use, and degree of tolerance. Cardiovascular toxicity is likely to be greater in people with underlying cardiovascular disease.

COCAINE AND METHAMPHETAMINE

Cocaine and methamphetamine are sympathomimetic drugs that produce vasoconstriction, tachycardia, and hypertension. Cocaine hydrochloride may be inhaled nasally or injected; its free base form ("crack") can be smoked by a pipe or mixed with other substances, such as tobacco or cannabis, and smoked or vaped in an e-cigarette. Co-use of other substances with cocaine has made it challenging to discern its unique pulmonary toxicities. Smoking crack cocaine can result in hemorrhagic alveolitis and diffuse alveolar damage with a prominent eosinophilic inflammatory component.[139] Pulmonary edema may be increased due to elevated left ventricular end-diastolic pressures related to cocaine's acute vasoconstricting and hypertensive effects. Other patterns of disease reported with cocaine include acute eosinophilic pneumonia,[140] barotrauma,[141] emphysema,[142] and pulmonary hypertension.[143] Excipients (i.e., inactive materials used as the vehicle for a drug), including talc and cotton, have been associated with foreign body granulomatosis,[144] and adulterants, including levamisole, have caused systemic illness, including vasculitis[145] (see Chapter 99).

Like cocaine, methamphetamine can be taken intravenously or smoked. Its use has been associated with many of the same pulmonary diseases as cocaine, including cardiogenic pulmonary edema and diffuse alveolar damage.[146] One important difference is that methamphetamine is more frequently associated with a progressive form of pulmonary hypertension that carries a dismal prognosis.[147] Both cocaine and methamphetamine can cause acute cardiovascular injury, including myocardial infarction, stroke, and dissecting aortic aneurysm, as well as aggravate ischemia in users with underlying cardiovascular disease. For patients suffering from pulmonary toxicity from cocaine and methamphetamine, the cornerstones of management are cessation counseling and supportive care. In addition, acute eosinophilic lung disease and organizing pneumonia may respond to corticosteroid therapy.[140]

Key Points

- Tobacco use remains the leading global risk factor for disability-adjusted years of life lost.
- In addition to causing cancer and COPD, smoking increases the risk for other pulmonary diseases, including respiratory infection (including pneumococcal pneumonia and tuberculosis), asthma, interstitial lung disease, and acute respiratory distress syndrome; it also increases the incidence of cardiopulmonary complications after surgery and in critically ill patients.
- Smoking causes 20% of cardiovascular deaths and increases the risk of peptic ulcer disease, diabetes mellitus, and osteoporosis.
- Secondhand smoke causes tens of thousands of cardiovascular deaths and several thousand lung cancer deaths annually.
- Electronic cigarettes deliver nicotine in an aerosol of propylene glycol, vegetable glycerin, and flavorings, and use has increased over the last 15 years, markedly so among young people, with 28% of high school students reporting current use in a 2019 survey.
- The health risks of electronic cigarettes and potential benefits in smokers remain controversial.
- Electronic cigarette/vaping–associated lung injury is a newly described syndrome of acute respiratory distress syndrome of unclear mechanism associated with vaping THC obtained from the black market.
- Cocaine and methamphetamine have acute cardiovascular toxicity and are associated with pulmonary edema, alveolar hemorrhage, emphysema, and pulmonary hypertension.

KEY POINTS

INTRODUCTION

Pulmonologists have a highly experienced view of the burden of tobacco-related diseases, which are reviewed in Chapter 65. Unfortunately, pulmonary specialists may have little understanding of the neuropsychiatric impact of nicotine addiction and the psychological underpinning of chronic tobacco use. Consequently, many providers may not be comfortable prescribing smoking cessation medications and thus may not provide optimal tobacco cessation support. The U.S. Public Health Service Guidelines recommend that all health care providers practice the "5 A's" as the primary approach for smoking cessation: (1) ask about tobacco use, (2) advise to quit, (3) assess readiness to quit, (4) assist in connecting to tobacco treatment, and (5) arrange follow-up to review progress toward quitting.[1] Despite the clarity of this approach, only 20.9% of smokers in the United States are provided counseling, and only 7.6% receive cessation medications.[2,3] Even in the setting in which a smoker develops cancer, a 2009 survey of National Cancer Institute–designated cancer centers revealed that only 21% of patients were offered cessation treatment services, and only 62% routinely received tobacco-education materials. This core gap is now being addressed by the National Cancer Institute Moonshot program, which has launched a national Cancer Center Cessation Initiative, providing support and grants to 20 centers in the United States.[4] The Department of Health and Human Services devoted the U.S. Surgeon General's 2020 report entirely to smoking cessation, underscoring the importance of preventing tobacco-related disease.[5] With this recent background in mind, this chapter is designed to familiarize health care practitioners with currently available support options, counseling, smoking cessation medications, and trends in their use.

Medications are a key component to increase the chance a smoker will quit successfully. Spontaneous cessation with the "cold turkey" approach (without medications or counseling) yields only a 2–5% cessation rate at 1 year.[2,3] Many smokers try unsuccessfully on multiple occasions to quit with an unsupported approach before a health care provider may start to discuss tobacco use. The combination of medications and counseling/behavioral support will provide patients with the best chance of quitting successfully. The availability of *nicotine replacement therapy* (NRT) *over the counter* (OTC) is important for some patients who may not interact with a health care provider during their quit attempt.[6]

NICOTINE ADDICTION

Tobacco use is motivated primarily by the desire for nicotine. Drug addiction is defined as the compulsive use of a psychoactive substance in which the consequences are detrimental to the individual or society. Understanding addiction is useful in providing effective smoking cessation therapy.[7] Nicotine is absorbed rapidly from tobacco smoke or e-cigarette vapor into the pulmonary circulation. It then moves quickly to the brain, where it acts on nicotinic cholinergic receptors to produce its gratifying effects within 10 to 15 seconds after a puff. Chronic exposure to high levels of nicotine will cause an increased concentration of nicotinic receptors in different regions of the brain, accounting for the development of tolerance and intense withdrawal symptoms. Nicotine has a half-life of approximately 2 hours. Nicotine from smokeless tobacco is absorbed more slowly and results in less intense acute pharmacologic effects. With long-term use of tobacco, physical dependence develops, associated with an increased number of nicotinic cholinergic receptors in the brain[8,9] (Fig. 66.1). When nicotine is unavailable, even for only a few hours, withdrawal symptoms begin, including anxiety, irritability, difficulty concentrating, restlessness, hunger, craving for tobacco, disturbed sleep and, in some people, depression.

Addiction to nicotine is multifactorial, including a desire for the direct pharmacologic actions of nicotine, relief of withdrawal symptoms, and learned associations. Smokers report a variety of reasons for smoking, including pleasure, arousal, enhanced vigilance, improved performance, relief of anxiety or depression, reduced hunger, and control of body weight. Environmental cues, such as after eating a meal, drinking coffee or an alcoholic beverage, talking on the phone, or being around friends who smoke, often trigger an urge to smoke. Compared to the general population

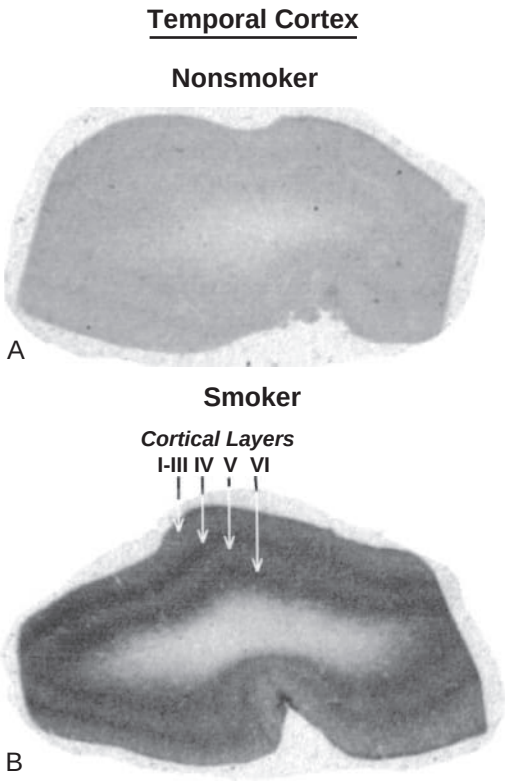

Figure 66.1 Increased nicotinic receptors in the brains of smokers. A representative autoradiographic image of radiolabeled ligand binding to nicotinic receptors in comparable sections of autopsy-derived human temporal cerebral cortex from a nonsmoker (A) and a smoker (B). In the smoker, nicotinic receptors are clearly increased throughout multiple cortical layers. (From Perry DC, Dávila-García MI, Stockmeier CA, Kellar KJ. Increased nicotinic receptors in brains from smokers: membrane binding and autoradiography studies. *J Pharmacol Exp Ther.* 1999;289:1545–1552.)

in the United States, United Kingdom, and Australia, smoking is two to three times more prevalent among people with mental illness. It is particularly high among patients with schizophrenia, bipolar disorder, posttraumatic stress disorder, and alcohol or illicit drug use disorders.[10] Smoking and depression are strongly linked. Smokers are more likely to have a history of major depression than are nonsmokers. Smokers with a history of depression are also likely to be more highly dependent on nicotine and have a lower likelihood of quitting.[11] When they do quit, depression is more apt to be a prominent withdrawal symptom.

Often tobacco use begins in childhood or adolescence.[12] Risk factors for youth smoking include peer and parental influences; behavioral problems (e.g., poor school performance); personality characteristics, such as rebelliousness or risk taking, depression, and anxiety; and genetic influences. The adolescent's desire to appear older and more sophisticated, such as by emulating more mature role models, can be another strong motivator. Environmental influences, such as advertising and smoking in movies, also contribute. Smoking rates among adults have been declining in economically advanced countries. Similarly, initiation rates for youth have gradually declined over the past 3 decades, although this is counterbalanced by the rapid increase of e-cigarette use by youth over the past 5 years. Approaches to preventing tobacco use and addiction in youth include educational activities in schools, aggressive antitobacco media campaigns, taxation of tobacco products, increasing the age for purchase from 18 to 21 years, changing the social and environmental norms (e.g., restricting indoor smoking and educating parents not to smoke around children), and deglamorizing smoking. Unfortunately, the current e-cigarette epidemic has intensified nicotine addiction in youth, and new data validate that e-cigarette use has increased cigarette use.[13]

NEUROBIOLOGIC MECHANISMS OF ADDICTION

(S)-Nicotine binds stereoselectively to *nicotinic cholinergic receptors* (nAChRs) in the brain, as well as in the autonomic ganglia, the adrenal medulla, and neuromuscular junctions. Most relevant to nicotine addiction are the receptors found throughout the brain, with the greatest number in the cortex, thalamus, and interpeduncular nucleus. There is also substantial binding in the amygdala, septum, brainstem motor nuclei, and locus coeruleus. The nAChR is a ligand-gated ion channel composed of five subunits. Most brain nAChRs are composed of α- and β-subunits. Usually, there are two α- and three β-subunits, with the α-subunits responsible for ligand binding and the β-subunits mediating other aspects of receptor function.[14] Nicotinic receptors in the brain have different chemical conductances for sodium and calcium and sensitivity to nicotinic agonists. Brain imaging studies in smokers have confirmed that smoking causes the upregulation of high-affinity nAChRs, which is maintained for up to 4 weeks after cessation of nicotine exposure.[15–17]

The various nicotinic receptors are believed to mediate different pharmacologic actions of nicotine, perhaps corresponding to the multiple effects of nicotine experienced by human smokers.[18] Adolescent nicotine exposure also appears to alter *gamma-aminobutyric acid* (GABA) signaling in the developing brain but not in the adult brain. GABA receptors are now known to alter the nicotine reward effect, which may have an impact on enhancing alcohol self-administration.[19]

Nicotinic receptor activation facilitates the release of neurotransmitters, including acetylcholine, norepinephrine, dopamine, serotonin, β-endorphin, GABA, and others.[20] Pharmacologically, nicotine is a stimulant. It enhances fast excitatory synaptic transmission, which may contribute to learning and memory.[21,22] Nicotine also releases growth hormone, prolactin, vasopressin, and adrenocorticotropic hormone. Behavioral rewards from nicotine and nicotine addiction appear to be linked largely to dopamine release[23] with an impact from GABA receptors as well.

Nicotine metabolism can vary significantly among individuals. *Cytochrome P-450* (CYP) isoenzymes impact the speed of metabolism and are categorized as poor, extensive, or ultrarapid.[24] These differences can have an impact on smoking behavior and the metabolism of nicotine replacement therapies. In addition, exposure to tobacco smoke has a wide-ranging impact on the metabolism of many drugs. Polycyclic aromatic hydrocarbons, products of combustion in cigarette smoke, upregulate certain CYP enzymes, primarily CYP1A2, and accelerate the metabolism of drugs that go through the CYP1A2 pathway. Several drugs have important pharmacokinetic interactions with smoking.

Table 66.1 Interaction Between Cigarette Smoking and Drugs

DRUGS		Interaction (Effects Compared With Nonsmokers)	Significance
Caffeine Chlorpromazine Clozapine Desmethyldiazepam Estradiol Estrone Flecainide Fluvoxamine Haloperidol	Imipramine Lidocaine Olanzapine Oxazepam Pentazocine Phenacetin Phenylbutazone Propranolol Theophylline	Accelerated metabolism	May require higher doses in smokers, reduced doses after quitting
Combined hormonal contraceptives		Enhanced thrombosis, increased risk of stroke and myocardial infarction	Do not prescribe to smokers, especially if ≥35 years old and smoke ≥15 cigarettes daily
Cimetidine and other H_2-blockers		Lower rate of ulcer healing, higher ulcer recurrence rates	Consider using mucosal protective agents
Propranolol		Less antihypertensive effect, less antianginal efficacy; more effective in reducing mortality after myocardial infarction	Consider the use of cardioselective β-blockers
Nifedipine (and probably other calcium blockers)		Less antianginal effect	May require higher doses and/or multiple-drug antianginal therapy
Diazepam, chlordiazepoxide (and possibly other sedative-hypnotics)		Less sedation	Smokers may need higher doses
Chlorpromazine (and possibly other neuroleptics)		Less sedation, possibly reduced efficacy	Smokers may need higher doses
Propoxyphene		Reduced analgesia	Smokers may need higher doses

Caffeine clearance is increased by more than 50% when a person smokes. Therefore, upon smoking cessation, it is advised that patients cut their caffeine intake by half. Nicotine in tobacco smoke also has pharmacodynamic interactions with certain drugs through antagonistic pharmacologic actions. (See Table 66.1 for pharmacokinetic and pharmacodynamic interactions with smoking.)

Nicotine causes an increase in the firing of ventral tegmental area neurons, resulting in release of dopamine in the nucleus accumbens.[23] Dopamine release is potentiated and sustained by nicotine-mediated release of glutamate.[25] Rapid dopamine release in the outer shell of the nucleus accumbens is characteristic of the effects of many addicting drugs (e.g., heroin, cocaine, and alcohol) and is thought to be an important site for drug-mediated reinforcement.[26] The addiction potential for inhaled nicotine is extremely high, in part due to the rapid attainment of the maximal concentration for nicotine achieved from an inhaled cigarette. NRT (e.g., patch, gum, and lozenge) has significantly slower and lower maximal concentration attainment and therefore has minimal addiction potential.

Acute exposure to nicotine produces stimulation of the release of dopamine from neurons in mesolimbic pathways, whereas chronic exposure to nicotine and other drugs of abuse produces other changes in mesolimbic function. Chronic nicotine exposure results in neuroadaptation, or the development of tolerance, and the absence of nicotine results in subnormal release of dopamine and other neurotransmitters. Thus, nicotine withdrawal may result in a state of deficient dopamine responses to novel stimuli in general and to a state of malaise and inability to experience pleasure. This has been termed *hedonic dysregulation* by Koob.[27] Hedonic dysregulation may explain craving, and sensitivity to drug effects may explain why even a single slip might easily result in a return to compulsive drug use.

The release of various neurotransmitters discussed previously results in behavioral arousal, sympathetic neural activation, and a number of other effects believed to be rewarding.[28,29] The release of certain neurotransmitters has been linked to the reported reinforcing effects of nicotine. For example, enhanced release of dopamine and norepinephrine may be associated with pleasure and appetite suppression, the latter of which may contribute to lower body weight. Release of acetylcholine may be associated with improved performance on behavioral tasks and improvement of memory. Release of β-endorphin may be associated with reduction of anxiety and tension. Although smokers give different explanations for their smoking, most agree that smoking produces arousal, particularly with the first cigarettes of the day, and relaxation, particularly in stressful situations, which may in part be due to the relief of nicotine withdrawal throughout the day (Fig. 66.2).

SMOKING CESSATION

Among current cigarette smokers, approximately 70% would like to quit, and about half try to quit each year.[30,31] Spontaneous quit rates (i.e., without support) are about 1% per year. Simple physician advice to quit increases the quit rate to 3%. Minimal intervention programs increase quit rates to 5–10%, whereas more intensive treatments, including smoking cessation clinics, can yield quit rates of 25–30%.[32]

The main strategies for cessation are behavioral counseling, pharmacologic intervention, or a combination of the two, which is strongly recommended. Assessing triggers

such as stress and exposure to family members or roommates who smoke is an important part of history taking before a therapeutic intervention is undertaken.

GUIDELINES

Evidence-based guidelines for the treatment of tobacco addiction emphasize identifying all tobacco users in a clinical practice setting and ascertaining each patient's intent with respect to quitting smoking (Fig. 66.3).[1,5,33,34] Identification of tobacco use is facilitated by the implementation of an office-based system so that patients are queried about tobacco use at every visit. Tobacco use should be treated as a vital sign, with reminders placed in the electronic medical record to screen patients. The practice of routinely recording a patient's tobacco use status increases the *odds ratio* (OR) for quitting by twofold.

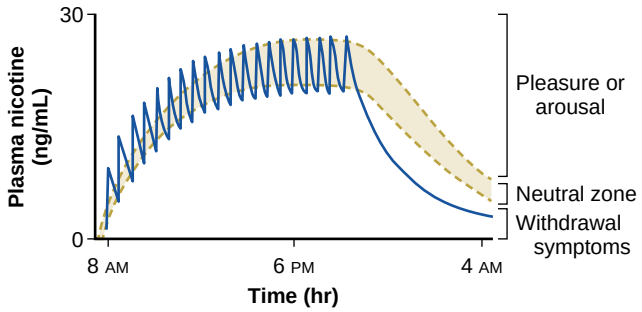

Figure 66.2 Nicotine levels in a person who smokes cigarettes. The peaks and troughs of nicotine concentrations throughout the day in a person smoking 20 cigarettes. Levels are low in the morning and drop rapidly with sleep. Smokers begin to experience withdrawal symptoms as the nicotine concentration drops below the shaded area, prompting another cigarette. The shaded area (neutral zone) represents the zone of nicotine concentrations in which the smoker is comfortable without pleasure/arousal or withdrawal symptoms. Note that the threshold levels for pleasure/arousal and withdrawal symptoms rise progressively during smoking due to development of tolerance. The magnitude of pleasure/arousal is greatest with the first cigarette of the day but becomes less intense with subsequent cigarettes. (From Benowitz NL. Cigarette smoking and nicotine addiction. *Med Clin North Am.* 1992;76:415–437.)

Brief strategies to help a patient quit, which can be implemented in as little as 3 minutes, increase cessation rates significantly. In a meta-analysis of 31 trials, brief physician advice increased quit rates by 70%.[32] Intensive behavioral treatment of tobacco dependence produces higher success rates than does brief advice (the 5 A's) and is cost-effective. However, these intensive programs are less widely available and can be challenging to provide for busy clinicians. Nevertheless, clinicians with training in intensive smoking cessation therapy should be identified as a referral source and champion for smokers who are interested.

The 2008 Public Health Service guidelines and other international guidelines recommend that all smokers trying to quit should be offered pharmacotherapy (Table 66.2).[1,34] Three types of medications have been approved by the *U.S. Food and Drug Administration* (FDA) for smoking cessation: bupropion, which was originally marketed as an antidepressant drug, NRT, and varenicline (Table 66.3). Unfortunately, smoking cessation medications are underutilized by patients and providers. It is estimated that only approximately one-third of patients use medications when

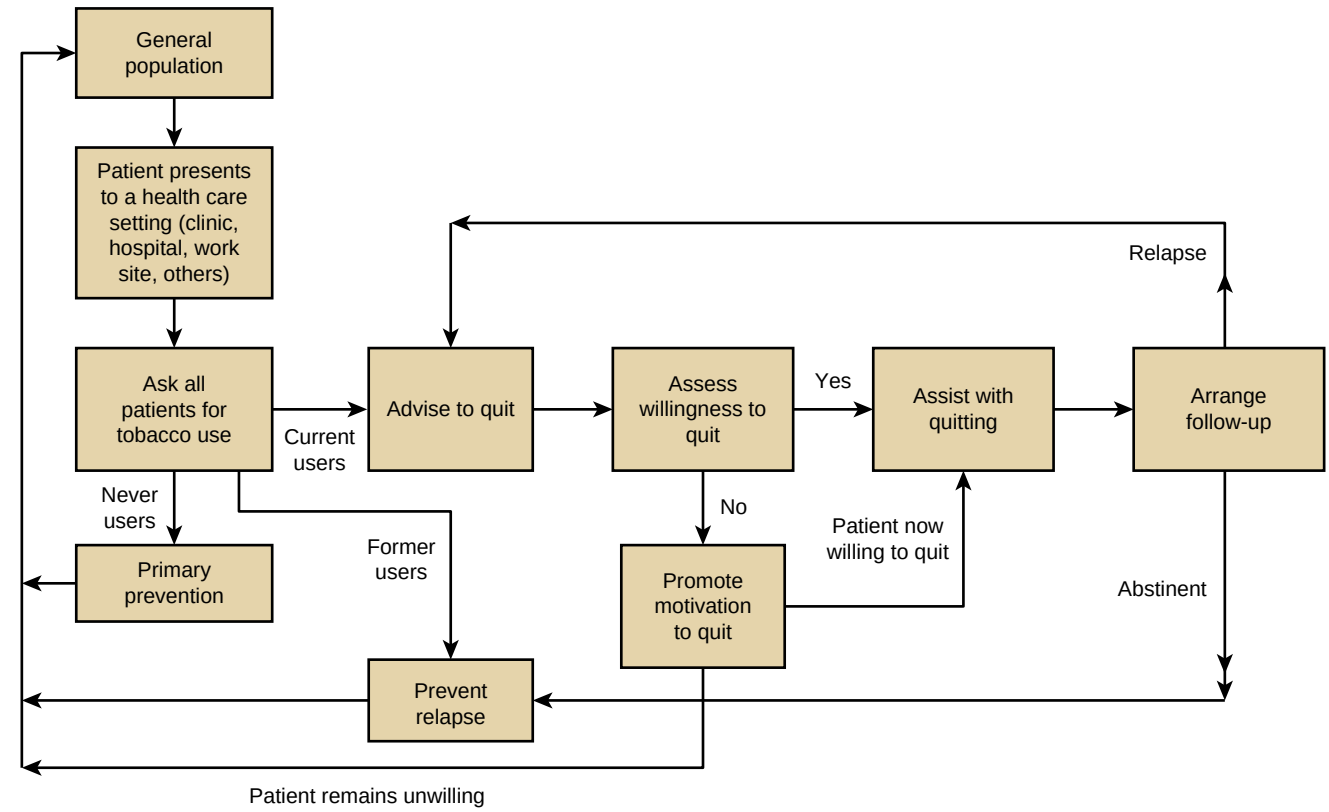

Figure 66.3 An algorithm for treating tobacco use. (From Clinical Practice Guideline Treating Tobacco Use and Dependence 2008 Update Panel, Liaisons, and Staff. A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med.* 2008;35[2]:158–176.)

Table 66.2 General Clinical Guidelines for Prescribing Pharmacotherapy for Smoking Cessation

- In general, all smokers trying to quit smoking should be offered pharmacotherapy.
- There are seven first-line smoking cessation medications—five types of *nicotine replacement therapy* (NRT), sustained-release bupropion, and varenicline. Varenicline or the combination of nicotine patch plus ad libitum short-acting nicotine products appear to be most effective. However, the choice of first-line therapy should be governed by patient preference, familiarity of the clinician with the medication, contraindications for specific patients, and prior experience of the patient with specific pharmacotherapies.
- Second-line therapies include clonidine and nortriptyline. These should be reserved for individuals with contraindications to or failure of response to first-line medications.
- Bupropion and NRT may delay but not prevent weight gain after smoking cessation. It is recommended that patients start or increase physical activity, but strict dieting is discouraged because this appears to increase the likelihood of relapse to smoking. Patients should be reassured that weight gain after quitting is self-limited and poses much less of a risk to health than smoking.
- All first-line therapies appear to be safe for patients with chronic cardiovascular disease. The over-the-counter NRT therapies (gum, lozenge, and patch) contain precautions for use if the following exist: recent (≤2 weeks) myocardial infarction, serious or underlying arrhythmias, or serious or worsening angina pectoris. This labeling is for over-the-counter use only. Bupropion and varenicline are likely to be safer than smoking in the presence of cardiovascular disease.
- In individuals with prolonged withdrawal symptoms or those who are unable to abstain in the absence of medication, extended use or long-term therapy with NRT, bupropion, or varenicline appears to be safe and effective therapy.

Modified from 2008 PHS Guideline Update Panel, Liaisons, and Staff. Treating tobacco use and dependence: 2008 update U.S. Public Health Service Clinical Practice Guideline executive summary. *Respir Care.* 2008;53:1217–1222.

trying to quit.[31] Other drugs such as nortriptyline and clonidine have been shown in clinical trials to be effective in smoking cessation but have not yet been approved by the FDA for this purpose.

SMOKING CESSATION COUNSELING

Counseling smokers about the benefits of quitting and the health consequences of tobacco should be incorporated into routine medical practice and has been shown to be an effective method to improve cessation rates. Motivational interviewing, a patient-centered values-based form of counseling, has demonstrated a clear benefit in smoking cessation.[35,36] Based on a review of 188 randomized trials, personal advice and encouragement to stop smoking provided by a physician during a routine office visit resulted in an estimated 2% of all smokers stopping and not relapsing over 1 year.[37] Although this percentage seems low, it is both cost-effective and important when considering the large population and the risk for disease. Specific patient populations may have better results: 8% of pregnant smokers, 21% of healthy men at risk for cardiovascular disease, and 36% of survivors of *myocardial infarction* (MI) will stop smoking when receiving advice and encouragement. This high success rate likely reflects the patient's inherent motivation once challenged by a condition that has been caused by or may be aggravated by cigarette smoking.

Group counseling is less cost-effective than brief advice but is a highly effective option for smokers who are not successful with less intensive therapy. A review of 16 studies comparing group counseling found increased rates of cessation compared to self-help programs (16 studies; OR, 2.0) or no intervention (six studies; OR, 2.2).[32] There is no evidence that group counseling is more effective than a similar intensity of one-on-one counseling with a clinician.[38]

Telephone counseling is also effective in promoting cessation. In a large *randomized controlled trial* (RCT) of 1973 intensively counseled callers versus 1309 control subjects, telephone counseling through a quitline nearly doubled abstinence rates.[39] The 12-month self-reported cessation rates for those who made one or more cessation attempts was 23.3% in the treatment group and 18.4% in the control group. Telephone quitlines are available at no cost in most of the United States. Thus, when clinicians are unable to provide counseling due to lack of time, they can easily refer patients to a quitline, such as 800-QUIT-NOW in the United States, for cessation counseling and support.

Counseling for smokers during hospitalization has been found to be effective for patients admitted with cardiovascular disease; this is not well studied in other populations. Molyneux[40] evaluated 274 patients in an RCT and found that NRT given with brief counseling is more effective than counseling alone or usual care. Counseling alone was not more effective than usual care, and differences between all groups disappeared at 12 months. Counseling for hospitalized patients appears to be most effective when it includes at least 1 month of supportive contact after discharge.[41]

MOTIVATING SMOKERS TO QUIT

The well-known association between cigarette use and morbidities, such as lung cancer, MI, stroke, and COPD, is often insufficient to motivate many cigarette smokers to quit. This is likely due to the significant addiction to nicotine. A telephone-based survey conducted in 1999 found that only 29% of smokers felt that they were at greater risk of MI, and only 40% felt they were at greater risk for development of cancer compared to nonsmokers.[42] This clearly indicates denial of risk and may explain why many smokers only become motivated to quit when they develop a medical condition later in life.

As described previously, many smokers depend on nicotine to cope with stressors encountered in daily life because they perceive smoking as having a stress-reducing effect. Becoming a nonsmoker requires a profound change of self-image and a discovery of personal coping skills that may have not been used previously.

Health care providers' role in the motivation process can be substantial. The message to the smoker must be consistent and inspirational (Table 66.4). Patients respect advice from their provider, and hopelessness can be allayed by describing the many options available for cessation medications and counseling. Smoking cessation is the most important health initiative many patients will ever undertake and is highly cost-effective for the health care system. It is difficult to address smoking with patients when three or four medical issues are being managed in addition to smoking cessation. For this reason, a separate planned visit focused solely on smoking cessation is recommended.

Table 66.3 First- and Second-Line Smoking Cessation Medications

Pharmacotherapy	Precautions/ Contraindications	Adverse Effects	Dosage	Duration	Availability
FIRST-LINE					
Bupropion sustained release (SR)	Current or history of seizure Current or history of eating disorders	Insomnia, dry mouth, neuropsychiatric symptoms (rare)	150 mg every morning for 3 days then 150 mg twice daily (begin treatment 1–2 wk before quit date) Allow at least 8 hr between doses Avoid bedtime dosing	7–12 wk maintenance, up to 6 mo	Prescription
Varenicline	Renal impairment	Severe nausea, trouble sleeping, abnormal or vivid/strange dreams, neuropsychiatric symptoms (rare)	0.5 mg/day for 3 days 0.5 mg twice/day for next 4 days, then 1 mg twice/day Begin treatment 1 wk before quit date	3–6 mo	Prescription
Nicotine gum	Temporomandibular joint disorder	Mouth and throat irritation, dyspepsia, hiccups	First cigarette ≥30 min after waking: 2 mg First cigarette ≤30 min after waking: 4 mg Up to 24 pieces/day	3 mo	OTC
Nicotine lozenge		Mouth and throat irritation, dyspepsia, hiccups	First cigarette ≥30 min after waking: 2 mg First cigarette ≤30 min after waking: 4 mg Up to 20 pieces/day	3 mo	OTC
Nicotine inhaler	Bronchospastic disease	Mouth and/or throat irritation	6–16 cartridges/day	3–6 mo	Prescription
Nicotine nasal spray	Chronic nasal disorders, including rhinitis, polyps, and sinusitis Severe reactive airway disease	Nasal and/or throat irritation, ocular irritation/tearing, sneezing	1 dose = 1 spray in each nostril 8–40 doses/day Maximum of 5 doses/hr or 40 doses/day	3 mo	Prescription
Nicotine patch	Skin diseases, such as atopic or eczematous dermatitis	Local skin reactions, insomnia	>10 cigarettes daily: 21 mg 14 mg 7 mg ≤10 cigarettes daily: 14 mg 7 mg	 4 wk then 2 wk then 2 wk 6 wk then 2 wk	Prescription and OTC
SECOND-LINE					
Clonidine	Rebound hypertension	Dry mouth, drowsiness, dizziness, sedation	0.15–0.75 mg/day	3–10 wk	Prescription only (oral formulation, patch)
Nortriptyline	Risk of arrhythmias	Sedation, dry mouth	75–100 mg/day	3 mo	Prescription only

Note: Tapering will vary across different medications; information is available in the package insert and the regulatory approval label.
OTC, over the counter.
Modified from 2008 PHS Guideline Update Panel, Liaisons, and Staff. Treating tobacco use and dependence: 2008 update. US Public Health Service Clinical Practice Guideline executive summary. *Respir Care*. 2008;53:1217–1222.

Motivating patients to quit needs to be more than steering them away from the health consequences of tobacco-related disease but also steering them toward greater self-control, self-expression, independence, and positive role modeling. Table 66.4 provides a few simple framing do's and don'ts to keep in mind when talking with cigarette and e-cigarette users.

Exercise during trials of smoking cessation may reduce anxiety, tension, and stress but was not found to be an independent predictor of success in a RCT.[43] Walking on a regular basis is a reasonable initial step and, in many cases, improves self-esteem and investment in health.

Other interventions for smoking cessation, such as acupuncture and hypnotherapy, are available. In many cases the interventions are either incompletely studied or have poor study methodologic quality to render a solid recommendation. Both acupuncture and hypnotherapy have significant variability in the practice of the intervention. A recent systematic review of acupuncture suggested a short-term benefit, with greater benefit when used in

Table 66.4 Key Points When Counseling Smokers

DO'S

- Determine where the person is on the spectrum of smoking cessation (precontemplation, contemplation, action, maintenance, relapse). Your focus is to move them stepwise toward action, and after cessation keep them in maintenance.
- Dose adjust nicotine replacement therapy to the maximally effective dose based on the person's cigarette use, response to medications and frequency of urges.
- Ask "Have you used any tobacco or nicotine products in the past 30 days"?

DON'TS

- Ask "Do you smoke?" People with regular tobacco use may not identify as a regular smoker and answer *no* to this question.
- Call it a habit. Cigarette smoking and nicotine addiction is an acknowledged disease with significant withdrawal symptoms.
- Do not think that talking about a tobacco-related disease like lung cancer or COPD leads to an increased motivational level. Fear can reduce energy level and lead to discouragement. Frame the benefit of cessation in a positive manner (improved breathing, greater freedom, greater control of health).

combination with counseling.[44] Hypnotherapy was systematically reviewed across 14 studies of 1926 participants. The authors concluded there was insufficient evidence to determine if hypnotherapy was more effective than other forms of behavioral support or unassisted quitting.[45] Mobile phone texting and app-based smoking cessation interventions have been studied in multiple settings. A comprehensive review of 26 studies and 33,849 participants updated in 2018 concluded that there is moderate-certainty evidence that text-based interventions result in greater quit rates than minimal support.[45a] The evidence evaluating the benefit of smartphone apps was of low certainty, clearly suggesting the need for RCTs in this area.[45a,46]

PHARMACOTHERAPY FOR SMOKING CESSATION

All types of smoking cessation medications, if used properly, double to triple smoking cessation rates compared with placebo treatments.[33]

NICOTINE REPLACEMENT THERAPY

NRT is typically started on the person's designated quit date and includes nicotine gum, transdermal nicotine patches, nicotine nasal spray, nicotine inhaler, and nicotine lozenges. Patch, gum, and lozenge formulations are available over the counter, and the nicotine nasal spray and oral inhaler are by prescription only. All have comparable efficacy when used as monotherapy. In a randomized study, adherence was greatest for the patch, lower for gum, and very low for the spray and the inhaler.[47] The use of combination therapy (nicotine patch plus a short-acting NRT used as needed for cravings) appears to be more effective.[48]

Both the nicotine gum and lozenge are available in two doses: 2 mg and 4 mg. Their dose is based on when a patient has the first cigarette upon waking. If it is within the first 30 minutes, the 4-mg dose is used; if a person waits more than 30 minutes after waking up, the 2 mg-dose is used. A person will use one piece every 1 to 2 hours while awake for the first 6 weeks, then taper over the next 6 weeks with instructions not to taper too quickly if experiencing significant urges. Optimal use of nicotine gum includes providing instructions on how to chew properly (i.e., use the chew-park-chew-park method) and to park in different areas of the mouth. A piece of gum will last about 30 minutes. Optimal use of nicotine lozenge[49] includes placing in the mouth and allowing to dissolve (it should not be chewed or swallowed) and to rotate to different areas of the mouth. A lozenge will dissolve over 20 to 30 minutes. Nicotine is absorbed across the buccal mucosa for both products. Patients should not eat or drink 15 minutes before or while using the gum or lozenge. Side effects of the gum and lozenge are primarily local and include mouth and throat irritation, upset stomach, and hiccups. The gum can also cause jaw muscle soreness.

Transdermal nicotine patches come in three strengths: 21 mg, 14 mg, and 7 mg; all deliver nicotine over a 24-hour period. A patch is applied in the morning and removed the next morning. If a patient experiences intrusive or disturbing dreams, the patch should be removed at bedtime. If a patient smokes more than 10 cigarettes a day (more than half a pack), then the 21 mg strength should be started; if a patient smokes less, then the 14-mg strength should be started (see Table 66.3 for full dosing information). It is important to rotate the sites where the patch is applied and to not use the same site for at least 1 week. The patch is generally applied to the upper body or upper outer part of the arm and to clean, dry skin (as hairless as possible) to ensure good adhesion. Although the patch provides a steady level of nicotine, the challenge becomes how to manage acute cravings; in this situation, combination NRT can be very effective, in which a short-acting NRT is used per its usual directions but on an as-needed basis.

Nicotine nasal spray is dosed one spray into each nostril and should be dosed one to two doses per hour. A patient should use at least eight doses per day for the first 6 to 8 weeks and then slowly taper over an additional 4 to 6 weeks as tolerated. It has unique side effects from the local irritation of the nasal mucosa (e.g., burning, sneezing, and watery eyes); with regular use, patients develop tolerance to these effects.

The nicotine inhaler delivers nicotine vapor across the mucosa of the mouth to the back of the throat. The nicotine is contained in a cartridge inserted into a plastic mouthpiece. A patient should use one cartridge every 1 to 2 hours, inhaling into the back of the throat or puffing in short breaths. The cartridge is depleted after 20 minutes of active puffing. Patients should not eat or drink 15 minutes before or while using the inhaler. Side effects of the inhaler are primarily local and include mouth and throat irritation, upset stomach, and hiccups. Although the labeling includes bronchospastic disease as a precaution, smoking cigarettes is likely a much greater trigger for irritation than the nicotine vapor from the inhaler.

All nicotine medications appear to be safe in patients with cardiovascular disease and can be offered to cardiovascular patients.[50–52] Although smoking cessation medications are recommended by the manufacturer for relatively short-term

use (generally 3–6 months), the use of these medications for 6 months or longer (i.e., extended use) is safe and may be helpful in smokers who fear relapse without medications.[53]

In pregnancy, the two recommended interventions are counseling and the use of NRT. The safety of other medications, such as bupropion and varenicline, has not yet been adequately studied to support a clear recommendation for use in pregnancy. Potential fetal side effects are of paramount concern, and the opportunity to quit smoking still exists in the postpartum period. Pregnancy and the parent's concerns about immediate fetal health and postpartum secondhand smoke exposure to the infant can create a highly motivated focus to stop smoking and should receive extra support and attention.[54–56] Additional high-quality research is needed to determine optimal and safe non-NRT interventions or optimal combinations of therapies.

BUPROPION

Bupropion sustained release (Wellbutrin SR, formerly available as Zyban) is a dopamine-norepinephrine reuptake inhibitor originally marketed and still widely used as an antidepressant. Bupropion was found to aid smoking cessation independent of whether a smoker was depressed.[57] In this study, Hurt demonstrated that, with a 300 mg SR dose, 44% of patients quit at 7 weeks versus 19% of control subjects. This difference was sustained at 12 months (23% vs. 12%). This study also indicated that, when smokers quit, they gained less weight while taking bupropion compared to placebo.[38] An additional randomized, placebo-controlled trial demonstrated that the combination of bupropion with nicotine patch is safe and that bupropion alone or in combination was as effective or more effective than the patch alone.[58] The combination of bupropion and nicotine patch has been approved by the FDA for smoking cessation. Bupropion used for 1 year for relapse prevention was demonstrated to be safe and effective and significantly better at promoting cessation (55%) than placebo (42%).[59] Given its antidepressant properties, bupropion is a logical choice for smokers with depression but, as mentioned previously, has clear efficacy in smokers without depression as well.

Bupropion SR is by prescription only and is dosed at 150 mg daily for 3 days, then 150 mg twice a day for 12 weeks. Bupropion should be started 1 to 2 weeks before the quit date to ensure that therapeutic levels are attained because it has a long half-life (21 hours). Dose tapering is not needed at the end of 12 weeks. Bupropion in higher doses can cause seizures and should not be used in an individual with (or a history) of seizures or with eating disorders (bulemia or anorexia). Common side effects are dry mouth and insomnia.

VARENICLINE

Varenicline (Chantix), available by prescription only, is a nicotinic receptor partial agonist that selectively binds to $\alpha 4\beta 2$ nicotinic cholinergic receptors in the brain. This receptor mediates dopamine release and is thought to be the major receptor involved in nicotine addiction. A partial agonist means that the drug activates the receptor but at a lower-level agonist activity (about 50% of that of nicotine) and also blocks the effects of other agonists (e.g., nicotine) on the receptor. It primarily works to help alleviate nicotine withdrawal symptoms. In the case of a relapse, if a person smokes, the effects of the nicotine are likely blocked by varenicline.

Varenicline is initiated in a dose of 0.5 mg daily for 3 days, then 0.5 mg twice daily for 4 days, followed by a maintenance dose of 1 mg twice daily. Varenicline generally should be started 1 week before the quit date to ensure therapeutic levels are attained because it has a long half-life (24 hours). A flexible (quit within a month) or gradual (quit within 12 weeks) quit approach can also be used after starting varenicline. Lower doses may be used if nausea is a problem at higher doses. Because varenicline is eliminated by the kidneys, dose reduction is required in the presence of severe renal disease. The treatment duration is 3 months, and an additional 3 months is possible in selected patients who have significant urges and are at high risk of relapse.

In clinical trials, varenicline treatment for 12 weeks has been shown to be more effective than bupropion SR 300 mg or placebo. Continuous abstinence rates after study medication discontinuation out to 52 weeks were 29%, 21%, and 11% for varenicline, bupropion, and placebo, respectively.[60,61] Varenicline has also been shown to be effective in preventing relapse over 6 months. In a network meta-analysis, varenicline was associated with an increased odds of quitting, with an OR of 2.9 (2.4–3.5) compared to placebo, and varenicline monotherapy was comparable to dual NRT use (OR of 2.7 vs. placebo).[48] The common side effects of varenicline are nausea and insomnia; it is important to take it with food and a full glass of water.

Both bupropion and varenicline have been associated with a variety of neuropsychiatric symptoms described in the warnings and precautions sections of their respective FDA labels. A boxed warning for severe neuropsychiatric symptoms from varenicline was removed in December 2019 as a result of the *Evaluating Adverse Events in a Global Smoking Cessation Study* (EAGLES),[62] which demonstrated that varenicline and bupropion were not associated with an increased risk of neuropsychiatric symptoms compared with NRT or placebo. The American Thoracic Society released an official clinical practice guideline on initiating cessation treatment in tobacco-dependent adults in May 2020.[63] Five "strong" recommendations (based on National Academy of Medicine criteria) were developed from an analysis of the most recent published data and included (1) using varenicline rather than a nicotine patch, (2) using varenicline rather than bupropion, (3) using varenicline rather than a nicotine patch in adults with a comorbid psychiatric condition, (4) initiating varenicline in adults even if they are unready to quit, and (5) using controller therapy (varenicline, bupropion or nicotine patch) for an extended treatment duration more than 12 weeks. Patients should be monitored for neuropsychiatric events during treatment and instructed to discontinue bupropion or varenicline and contact a health care provider if they experience adverse events.

COMBINATION THERAPY

An important consideration in smoking cessation medication strategy is the use of combination therapies. Combined

medications for smoking cessation can be more effective than individual therapies, particularly when combining long-acting medications such as nicotine patch or bupropion with short-acting NRT used at times of intense urges or cravings to smoke. Only bupropion and transdermal nicotine in combination have been approved by the FDA. However, a number of studies have looked at various combinations of medications.[63–67] Combination NRT (patch plus quick-acting NRT) is more effective than monotherapy and therefore is generally recommended over monotherapy.[48]

Combination therapies can also give people more flexibility in their plan, particularly if they start with one therapy and feel it is not fully effective and want to add a second therapy. Because there is significant individual variability in the metabolism of nicotine, some patients who rapidly metabolize nicotine may require higher doses of replacement therapy.[66] Experiencing breakthrough urges could suggest that some people are significantly underdosed by one form of NRT and that a second form or higher doses could be more effective. One prospective study found that the combination of bupropion and varenicline was more effective than varenicline alone in a specific subset of patients with a high level of dependency.[67] Published guidelines[1] have not kept pace with emerging combination data in the literature, and multiple publications have demonstrated that combinations of smoking cessation medications can be more effective than monotherapy. The safety of unapproved combination therapies is unclear and must be considered to enable an appropriate benefit versus risk assessment for an individual patient.

ELECTRONIC NICOTINE DELIVERY SYSTEMS AND E-CIGARETTES

The toxicity and side effects associated with e-cigarettes are emerging and are reviewed in Chapter 65. Several studies have begun to evaluate the use of e-cigarettes as a smoking cessation modality. However, the main concern is that this constitutes a switch from one highly addictive form of inhaled nicotine (cigarettes) to another highly addictive form of inhaled nicotine (e-cigarettes) without the intention to end nicotine addiction. The e-cigarette industry is not regulated, and there is no formal FDA-supported safety database providing accurate safety information. For these reasons, the use of e-cigarettes will remain controversial in clinical practice because their safety is unclear in comparison to health authority–approved cessation medications. Some studies have started to evaluate the use of e-cigarettes as a cessation aid. A systematic review in 2015 of the potential efficacy of e-cigarettes versus other cessation therapies revealed six RCTs and nine cohort studies of 7551 participants. Among 1242 smokers in the RCTs, 18% reported smoking cessation after using nicotine-containing e-cigarettes for a minimum duration of 6 months.[68] A separate retrospective study of 25- to 44-year-olds in the National Health Interview Survey database conducted by the Centers for Disease Control and Prevention[69] demonstrated that e-cigarette use was associated with higher quit attempts and greater smoking cessation (adjusted OR, 1.6; $P = 0.001$) in recent years compared to 2006 data. This could suggest that the new technology and media messaging associated with e-cigarettes provides an incentive to attempt quitting compared to other modalities. In contrast, a prospective cohort study from 2015–16[70] performed a random probability sample of 1284 U.S. adult smokers evaluated over 1 year. In this sample, the adjusted odds of quitting smoking were lower for those using e-cigarettes at baseline compared to those who did not use e-cigarettes (adjusted OR, 0.30). In summary, individual studies may suggest evidence for or against the potential benefit of e-cigarettes for smoking cessation but, in aggregate, in a systematic review,[71] there does not appear to be a place for their use, particularly when compared to approved smoking cessation medications.

Perhaps the most important recent trial[72] was an open-label RCT of 886 participants in the United Kingdom randomly assigned NRT (alone or combination) for 3 months versus an e-cigarette and refillable bottle of nicotine e-liquid (18 mg/mL), with all participants receiving 4 weeks of behavioral support. The 1-year abstinence from smoking was 18.0% in the e-cigarette group versus 9.9% in the NRT group (relative risk, 1.8; $P < 0.001$). Eighty percent of the participants in the e-cigarette group were using e-cigarettes at 12 months versus 9% in the NRT group. This important trial warrants significant analysis and context. Although the cessation rate was higher in the e-cigarette group at 1 year, the trial was not blinded, and the e-cigarette cessation rate was similar to rates seen with medications such as bupropion (≈20% at 1 year), varenicline (≈30% at 1 year), and a common combination of bupropion and patch (28% at 1 year[73,74]). The cessation rate of 9.9% with the convenience (multiple option) NRT treatment approach is significantly lower than a recent meta-analysis review of NRT, which yielded a 1-year point estimate of 19.8%. Of importance, as mentioned, 80% of participants in the e-cigarette group continued their use at 1 year, raising the concern about long-term safety and providing a contrast to NRT and other medications that have an intended use of approximately 3 months.

Because the health effects of e-cigarettes are only beginning to be understood, clinicians should recommend medications with a proven benefit and safety profile before considering new options. There may be a role for e-cigarettes in smokers who have a strong desire to quit smoking but refuse other cessation medications or have tried other interventions and found them to be unsuccessful. Even in this case, it is reasonable to recommend that e-cigarettes for smoking cessation should be used short term (3–6 months) because the medical goal is to end nicotine addiction.[75] Clinicians should educate patients about lung disease and other health risks that are emerging from vaping.

A recent cross-sectional analysis in the U.S. Population Assessment evaluated the risk of MI in cigarette users compared to e-cigarette users and to those with dual use. These data demonstrated that e-cigarette use and cigarette use conferred a similar risk of MI and demonstrated that dual use had an OR of 6.6 for an MI compared to never-cigarette or e-cigarette users.[76] The Forum of International Respiratory Societies has actively called for the regulation of e-cigarettes and the American College of Cardiology/American Heart Association Guidelines on the Prevention of Cardiovascular Disease (2019) recommend against the use of e-cigarettes for smoking cessation.[77] In light of the newly recognized epidemic of vaping-associated severe lung disease and associated

deaths, it appears reasonable for all physicians to discourage e-cigarette use until both the short- and long-term dangers associated with their use are understood.[78]

BENEFITS OF QUITTING

The benefits of quitting smoking are substantial for smokers of any age. A person who quits smoking before age 50 years has half the risk of dying in the next 15 years compared with a continuing smoker.[79] Smoking cessation reduces the risks of developing lung cancer, with the risk falling to half that of a continuing smoker by 10 years and one-sixth that of a smoker after 15 years' cessation. Quitting smoking in middle age substantially reduces lung cancer risk, with a 50% reduction in risk if a lifelong smoker quits at age 55 years compared with age 75 years.[80] The risk of acute MI falls rapidly after quitting smoking and approaches nonsmoking levels within 1 year of abstinence. Cigarette smoking produces a progressive loss of airway function over time characterized by an accelerated loss of *forced expiratory volume in 1 second* (FEV_1) with increasing age. Loss of FEV_1 due to cigarette smoking cannot be regained by cessation, but the rate of decline slows after smoking cessation and returns to that of nonsmokers[81] (see Fig. 64.6). Women who stop smoking during the first 3 to 4 months of pregnancy reduce the risk of having a low-birthweight infant to that of a woman who has never smoked.

After quitting, smokers gain an average of 10 pounds, which is often perceived by some smokers as undesirable and may be a barrier to quitting. Smokers tend to be thinner because nicotine increases energy expenditure and suppresses a compensatory increase in food consumption. Upon quitting, ex-smokers tend to reach the weight expected had they never smoked. Of course, the benefits of quitting far outweigh the risks associated with weight gain, and patients should be counseled accordingly.

RESOURCES FOR HEALTH CARE PROVIDERS

Most hospitals have smoking cessation services available that will enable referral of smokers if deemed necessary. Most states have free quitlines that can be accessed through a national network at 800-QUIT-NOW (800-784-8669) that provides smoking cessation information and counseling and has been shown to be effective. The American Lung Association (www.lung.org/quit-smoking) has a wealth of information and an online program called "Seven Steps to a Smoke-free Life" to which patients can be referred. The Centers for Disease Control and Prevention has information that can be downloaded for adults, youth, and Spanish-speaking patients (www.cdc.gov/tobacco/). Other web-based counseling resources include www.smokefree.gov and www.becomeanex.org. If patients do not have their own computer, the public library is a smoke-free environment where they can access computers. Patients suspected of having underlying depression, anxiety, or other substance abuse disorders may benefit from psychiatric referral to evaluate these conditions known to reduce the likelihood of smoking cessation. Finally, the Rx for Change: Clinician-Assisted Tobacco Cessation training program is available; it equips practicing clinicians and health professional students with evidence-based knowledge and skills for how to assist patients with quitting. Lectures (with downloadable PowerPoint slides) and other educational materials have been created by pharmacists and experts in smoking cessation for the medical community as a free educational and clinical resource (http://rxforchange.ucsf.edu).

Acknowledgment

Many thanks to Dr. Neal Benowitz, who as a prior contributing author to this chapter provided much of the nicotine neurobiology information still featured.

Key Points

- Nicotine is an intensely addictive chemical that causes the upregulation of nicotinic cholinergic receptors in the brain.
- Nicotine has a short half-life, and withdrawal symptoms can be severe.
- Cigarette smoking is the most important preventable cause of respiratory disease.
- Most smokers would like to quit smoking but have difficulty doing so because of nicotine addiction.
- Smoking cessation counseling and medications are extremely underutilized in the United States and many countries around the world.
- Smoking cessation medications come in two broad categories: nicotine replacement therapies and the oral medications bupropion and varenicline. Both individual therapies and combinations are effective.
- E-cigarettes represent a new and addictive technology.
- The efficacy of e-cigarettes for smoking cessation continues to be evaluated, but long-term data on safety are unknown. E-cigarettes are not recommended for smoking cessation by major medical societies.

INTRODUCTION

Cystic fibrosis (CF) is a multisystem genetic disease that affects children and young adults. CF is the most common monogenetic disease in white populations. The disease is caused by mutations in the *CF transmembrane conductance regulator* (CFTR) protein, an anion channel expressed on the epithelial surface. CF is typified by the presence of chronic upper and lower respiratory tract infection leading to bronchiectasis and end-stage lung disease. Manifestations in the pancreas, gastrointestinal tract, skin, and male reproductive tract are also prominent.

Understanding the biology and treatment strategies in CF is important for several reasons. First, CF is the most common cause of both chronic respiratory failure and pancreatic exocrine dysfunction in children and young adults. Second, it is a major cause of bronchiectasis and pansinusitis, among other sinopulmonary conditions in this age group, and therefore represents an essential consideration in the differential diagnosis of numerous clinical syndromes. Third, the pathobiology has substantial commonalities with other mucociliary disorders, thus representing common principles. Finally, advances in CF research have provided a roadmap for understanding the pathophysiology and treatment for other severe airway diseases, including COPD, asthma, and non-CF bronchiectasis. This chapter highlights the current understanding of CF pathobiology, with particular emphasis on the role of CFTR in disease pathogenesis.

HISTORICAL PERSPECTIVE

The first comprehensive description of CF as a distinct clinical entity was published in 1938 by Anderson, who named the disease "cystic fibrosis of the exocrine pancreas."[1] In 1945, Farber described the condition as a generalized *mucoviscidosis* resulting in obstruction of exocrine glands.[2,3] Also in the 1940s, clinical descriptions first linked mucoviscidosis to severe and recurrent lung infections. With the development of effective antimicrobials, new treatments to address severe pulmonary infection were applied to CF for the first time.

An extreme heat wave in the northeastern United States in the summer of 1948 led di Sant'Agnese[4] to describe high salt concentrations in the sweat of infants with CF and introduce the concept of abnormal ion transport as contributing to the disease. End-organ dysfunction in the sweat gland was among the first characteristics recognized for the disorder. Di Sant'Agnese demonstrated elevated levels of sweat sodium and chloride in greater than 98% of subjects with CF, a finding that remains a cornerstone for diagnosis today. A traditional Irish folk saying, "if your baby tastes of salt, he is not long for this world," may have presaged these fundamental scientific discoveries regarding sweat hypersalinity in CF.

Before identification of the *CFTR* gene and protein in 1989,[5–7] early observations led investigators to postulate an ion transport abnormality as a proximate cause of CF. To measure this phenomenon, Gibson and Cooke[8] developed the modern pilocarpine method of sweat chloride testing. Later, Quinton[9,10] demonstrated that sweat gland ducts in CF patients are impermeant to chloride. At the same time, a number of contributions regarding the physiology of ion transport within nasal epithelium by Knowles and colleagues[11,12] and subsequent membrane patch-clamp analysis of airway epithelial cells by Welsh and Liedtke[13] and Frizzell[14] provided conclusive evidence for defective chloride transport within plasma membranes

of epithelial cells in the upper and lower respiratory tract of patients with CF, in addition to associated abnormalities of sodium uptake.[11,12] Transformational chromosome mapping technology applied by Collins, Riordan, and Tsui[6,15,16] identified the causative gene, which they named the *cystic fibrosis transmembrane conductance regulator*. This finding set the stage for molecular cloning of the gene; independent verification that *CFTR* encoded a chloride channel protein; elucidation of the most common mutation, F508del; and definition of myriad other disease-associated variants. These studies comprise the basis for current understanding of CF pathogenesis and new therapeutics directed toward the fundamental molecular defect.[17,18]

EPIDEMIOLOGY

CF is the most common monogenetic lethal disease in white populations, found in 1 in 2500 to 3500 live births in the United States, with lower frequencies among African Americans (1:17,000). There is a varied incidence in particular ethnic groups, ranging from 1:569 in an isolated Ohio Amish population to 1:90,000 in Asian populations.[19]

CFTR mutations are most prevalent among persons descended from central and northern European populations. Non-European white populations demonstrate intermediate rates of *CFTR* mutation, and Native Americans, Asian populations, and Black Africans demonstrate the lowest rates. Proposed reasons for the selectivity of *CFTR* mutations in these populations include a heterozygote advantage in epidemic illnesses, such as cholera, tuberculosis, or plague. Cholera is of particular interest because the absence of CFTR-dependent chloride transport could confer an advantage on *cyclic 3′,5′-adenosine monophosphate* (cAMP) activation by cholera toxin.[20] Conversely, selectively lower rates of *CFTR* mutations in populations living in tropical or semitropical environments could be due to propensity for excess salt loss conferred by heterozygosity. In white populations, approximately 1 in 25 is a carrier for a *CFTR* gene mutation,[21] resulting in a carrier rate of 2–5%. CF carriers do not exhibit manifestations of CF illness, although carrier status has been proposed to increase the propensity for a wide variety of respiratory and non-respiratory disorders.[22]

GENETIC BASIS

CF is an autosomal recessive condition caused by mutations of *CFTR*, a gene located on the long arm of chromosome 7.[6,15,16] *CFTR* encodes a protein in the *adenosine triphosphate* (ATP) *binding cassette* (ABC) transporter family, sharing primary and secondary structural elements with many other proteins in this group. The approximately 190-kB *CFTR* encodes 27 exons and a full-length protein consisting of two *membrane-spanning domains* (MSDs), two *nucleotide binding domains* (NBDs), and a single *regulatory domain* (R domain). A schematic of CFTR is shown in Figure 67.1; the protein crystal structure has been solved using cryoelectron microscopy, opening the door for structural-based drug design.[23,24]

A very large number of *CFTR* mutations have been linked to clinical disease, including a current estimate of more

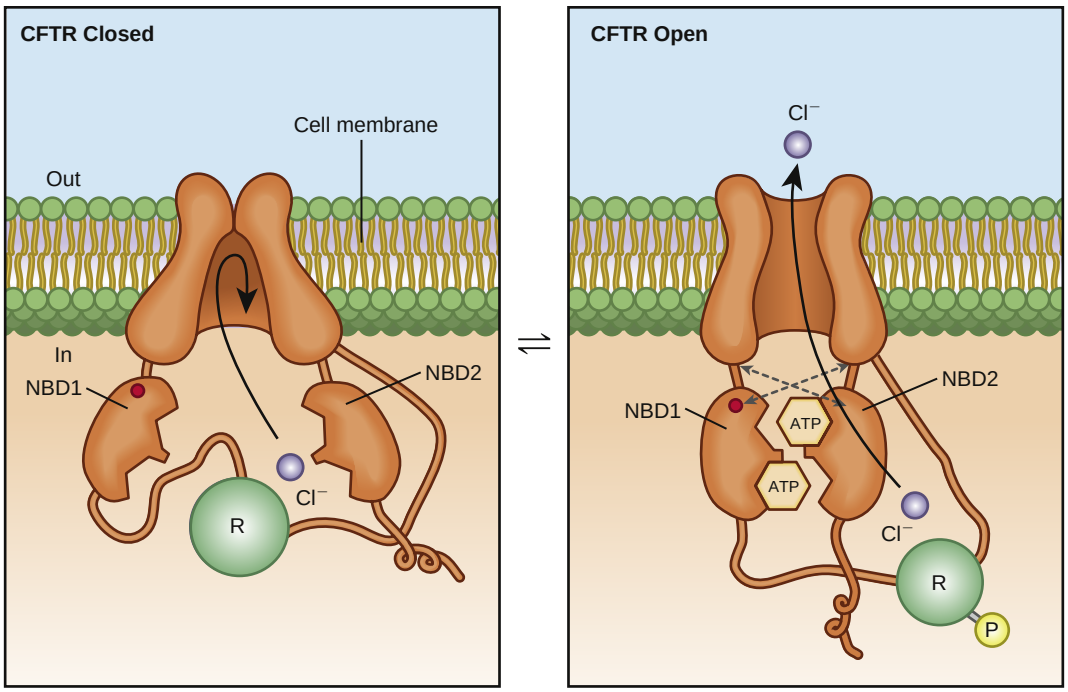

Figure 67.1 CFTR structure and domain assembly. Schematic representing the proposed structure of the *cystic fibrosis transmembrane conductance regulator* (CFTR) in its closed (*left*) and open (*right*) configurations. The two transmembrane spanning domains consist of six α-helices each and together form the channel pore. Gating of the channel is controlled by the two intracytoplasmic nucleotide binding domains (NBD1 and NBD2) as they bind and hydrolyze *adenosine triphosphate* (ATP) (*hexagons*) and a regulatory domain (R), which contains numerous sites of phosphorylation. Normal activation of the protein requires phosphorylation (P) of the regulatory domain. The NBDs bind and hydrolyze ATP, inducing channel gating by conferring opening of the pore through interfaces with the transmembrane domains via their extracellular loops (*dashed lines*), which also function to stabilize the overall protein structure. The location of the F508del mutation (*red dot*) is on the surface of NBD1, compromising its stability and interrupting interactions with the transmembrane domains.

than 1900 disease-associated variants, of which more than 350 are confirmed to cause disease.[19] That being said, a much smaller number of mutations account for the majority of disease in the CF patient population (eTable 67.1). For example, the most frequent 159 mutations account for 96% of defective CF alleles. As already stated, the most prevalent variant is F508del (c.1521_1523delCTT), which causes a three–base-pair nucleotide deletion and omission of phenylalanine at CFTR position 508. This mutation accounts for approximately 75% of CF-causing alleles, although distribution of the abnormality is heterogeneous among particular ethnic populations and as high as 86% in northern European white populations.[19]

F508del CFTR exhibits severe protein misfolding and leads to endoplasmic reticulum–associated retention and destruction of CFTR by the proteasome. The F508del defect represents a severe form of the prototypic class II variant (i.e., abnormalities resulting in premature degradation or incomplete maturation). Other less common CFTR variants fall into various mutation classes on the basis of molecular mechanism (Fig. 67.2). Additional classes include defects that confer incomplete CFTR synthesis due to premature termination codons (class I); disordered regulation and gating, causing diminished ATP binding and hydrolysis (class III), seen with the G551D mutation; defective chloride conductance (class IV); a reduced number of CFTR transcripts, such as due to a promoter or splicing abnormality (class V); and reduced protein stability at the cell surface, first reported as a defect in terminal CFTR variants that lack sequences anchoring the protein to the cell membrane (class VI). Ultimately, molecular classes reduce channel number, inhibit its function, or exhibit a combination of these effects, and the severity of these effects influences clinical outcome. Mutations in class I, II, and III tend to cause severe CFTR functional abnormalities, whereas class IV, V, and VI variants may exhibit residual function, reducing their severity (i.e., mild/variable activity) and CF phenotype. It is notable that many variants exhibit features of more than one molecular category; thus, the system is imperfect but a useful construct that has guided drug discovery efforts. For example, whereas the F508del mutation principally reduces channel number through its class II defect in processing and trafficking, it also exhibits abnormal gating (class III) and class VI (reduced channel stability) properties.[25] Understanding the molecular abnormality in each mutational class is important for addressing the defect with pharmacologic interventions such as CFTR modulators, discussed in Chapter 68.

Despite extensive knowledge concerning various mutations in *CFTR*, only approximately 90% of CF patients have both of their disease-causing alleles identified, although this number is increasing with more frequent use of full-length *CFTR* sequence analysis. Moreover, the pathogenic role of many mutations remains unknown, and knowledge in this area has dramatically improved through the CFTR2 project, which critically evaluates CFTR variants in the context of clinical phenotype on a global scale (www.CFTR2.org).[26] It has been estimated that more than 1000 *CFTR* variants are present, causing disease in fewer than five CF patients each.[18] Common nucleotide transversions, such as M470V, are designated as simple polymorphisms rather than disease-causing alleles, despite a potential (secondary) role of M470V impacting expression and/or function of F508del CFTR.[19] Other polymorphisms, such as the poly-T sequence located within intron 8, can modify CFTR expression, thus acting as important covariates of disease.[27]

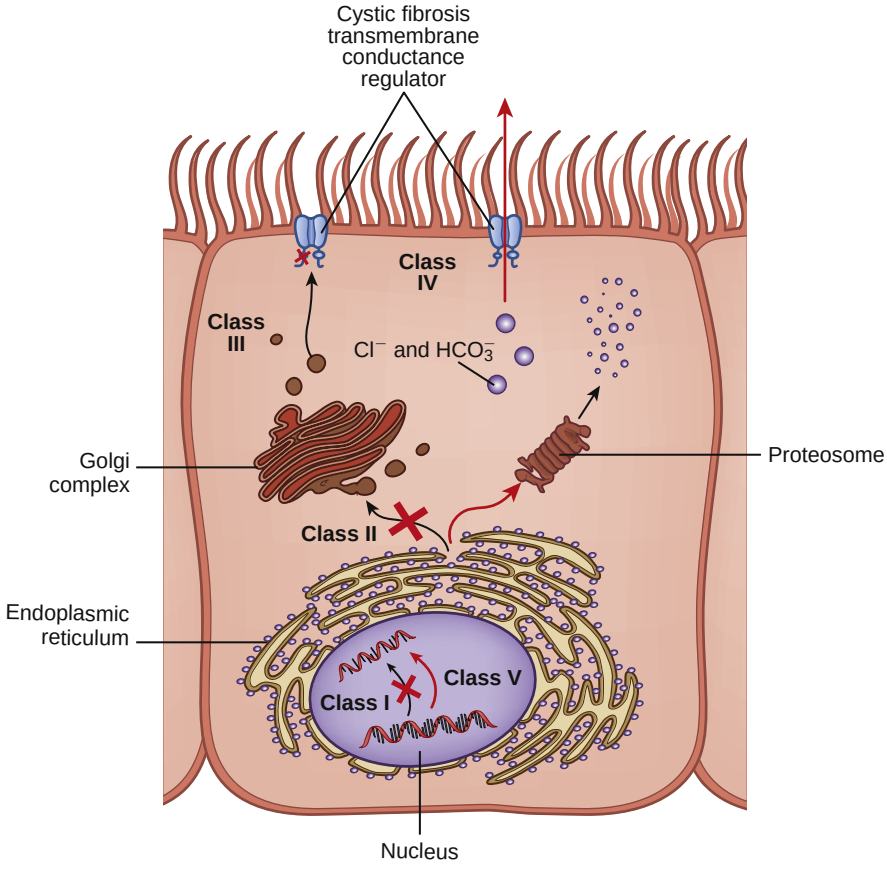

Figure 67.2 *Cystic fibrosis transmembrane conductance regulator* (*CFTR*) gene mutations and molecular consequences. Classes of defects in the CFTR gene product include the absence of synthesis (class I); defective protein maturation and premature degradation (class II); disordered regulation, such as diminished adenosine triphosphate binding and hydrolysis (class III); defective chloride conductance or channel gating (class IV); and a reduced number of CFTR transcripts due to a promoter or splicing abnormality (class V). Another class of defect has reduced protein stability at the cell surface (class VI, not shown).

The functional basis underlying specific *CFTR* mutations allows the correlation of genotype to phenotype, noting that other genetic modifiers and the environment also play prominent roles in disease expression. For example, when two severe (e.g., class I, II, or III) mutations are present, pancreatic insufficiency typically results, especially in patients homozygous for F508del. The finding of two severe mutations also confers risk for clinical manifestations, such as meconium ileus or hepatobiliary disease. On the other hand, presence of one or more mild/variable mutations may allow sufficient residual CFTR activity to diminish disease severity. CF patients with mild mutations often exhibit intermediate sweat chloride values, which correlate with pancreatic sufficiency.[19,28] When two mild/variable mutations are present, atypical forms of CF are more frequently observed, such as congenital absence of the vas deferens, "idiopathic" pancreatitis, or late-onset respiratory disease without other characteristic features of a complete CF phenotype.[27,29–31] Disease severity and expression can also be affected by non-*CFTR* genetic modifiers, which have been extensively studied. *Transforming growth factor* (TGF)-β has been shown to modify lung disease severity, specifically among subjects homozygous for F508del *CFTR*.[32,33] Other modifier loci on chromosome regions 4q35, 8p23, 11q25, and 19q13 confer increased risk of meconium ileus,[34,35] and various additional genes have been associated with acquisition of *Pseudomonas aeruginosa* infection.[36,37] Effect sizes for findings such as these have not been sufficient for routine use in the clinic, and a significant component of missing heritability may contribute to pulmonary decline in CF patients with two copies of F508del.

PATHOPHYSIOLOGY

CFTR AS AN ABC GENE

As described earlier, *CFTR* is a member of the ABC transporter or the traffic ATPase family of genes.[17,38,39] Proteins in this group are ancient and include hundreds of prokaryotic and eukaryotic polypeptides that transport nutrients, metabolites, toxins, and other small molecules across cellular membranes. All ABC proteins are characterized by two NBDs encoding canonical Walker A and B motifs (polypeptide sequences within the protein capable of binding and hydrolyzing ATP). CFTR gating, induced by ATP binding, hydrolysis, and release, confers conformational changes that allow pore opening and closing. Like other ABC proteins, CFTR encodes for two membrane-spanning domains with multiple α-helices that form highly selective passageways across lipid bilayers. Among ABC proteins, CFTR is atypical by virtue of a regulatory domain with numerous sites for *protein kinase A* (PKA)/cAMP-dependent phosphorylation, and a regulatory insertion in NBD1 shown to play an important role during channel gating[17,40,41] (see Fig. 67.1). Lasso helical structures near the CFTR amino-terminal region represent additional distinctive features of CFTR.[23,24]

STRUCTURE/ACTIVITY AND CFTR GATING MECHANISM

The CF gene product is composed of approximately 1500 amino acids and functions as a transporter of chloride ion (Cl^-) and bicarbonate ion (HCO_3^-) in numerous epithelial tissues. Site-directed mutagenesis indicates that gating is enabled by PKA/cAMP-dependent phosphorylation of the R domain. The phosphorylation step has been shown to elicit a conformational change in the regulatory insertion, leading to NBD1/NBD2 heterodimerization and structural realignments of MSD1 and MSD2, which permit opening of the ion conductive pore.[42] Key interactions between intracellular loops of the transmembrane domains and NBDs are integral to CFTR stability and interdomain assembly, as well as to transmission of forces required for channel gating (see Fig. 67.1).[43–45] NBD dimerization is greatly augmented when two ATP binding sites (at the NBD1/2 interface) are occupied; closing of CFTR is attributable to ATP hydrolysis.[46,47] It should be noted that ATP binding is not absolutely required for ion transport by CFTR; so-called ATP-independent channels can also open, for example, based on the tendency of NBDs to realign spontaneously in the open or outward-facing channel conformation.[47] Transepithelial anion flow through CFTR is governed by the electrochemical driving force, and a CFTR bioelectric signature (using membrane patch-clamp analysis or planar lipid bilayer reconstitution) describes PKA/cAMP or PKA-dependent currents through an approximately 8-picosiemen channel with linear current/voltage relationship and characteristic opening bursts. CFTR therefore uses ATP binding to enable passive ion transport, rather than subserving a function more typical of the ABC gene family (i.e., pumping of larger metabolites with stoichiometric dependence on ATP hydrolysis).

BIOGENESIS AND PROCESSING OF NATIVE CFTR

Wild-type CFTR matures and reaches the cell surface by conventional pathways that include cotranslational insertion in the *endoplasmic reticulum* (ER) membrane and post-translational modifications, such as *N*-linked glycosylation (Fig. 67.3). Subdomain folding (e.g., within NBDs) and achievement of final tertiary structure requires complex domain-binding interactions—and represents a topic of intense interest—because CFTR misfolding is a crucial mediator of clinical disease.[43,44,48–51] Wild-type CFTR processing may not be completely efficient and, in most experimental expression systems that express too much CFTR, a portion of wild-type CFTR becomes targeted for hydrolysis by *ER-associated degradation* (ERAD) and can stimulate ER stress. For CFTR advancing from the ER to the Golgi apparatus, complex glycosylation takes place at two asparagine residues. CFTR reaching the Golgi apparatus is transported to the cell surface by vesicular traffic with subsequent recycling through sorting and recycling endosomes and reinsertion in the plasma membrane or routing to the lysosome (or other cellular compartments). The cell surface apparatus governing CFTR peripheral stability (i.e., at the plasma membrane) has been well characterized and includes ubiquitin conjugation to regulate internalization.[52]

CELLULAR DEFECTS ATTRIBUTABLE TO F508del CFTR

The vast majority of F508del CFTR is retained in the ER, heavily ubiquitinated, and routed to the proteasome by ERAD.[53]

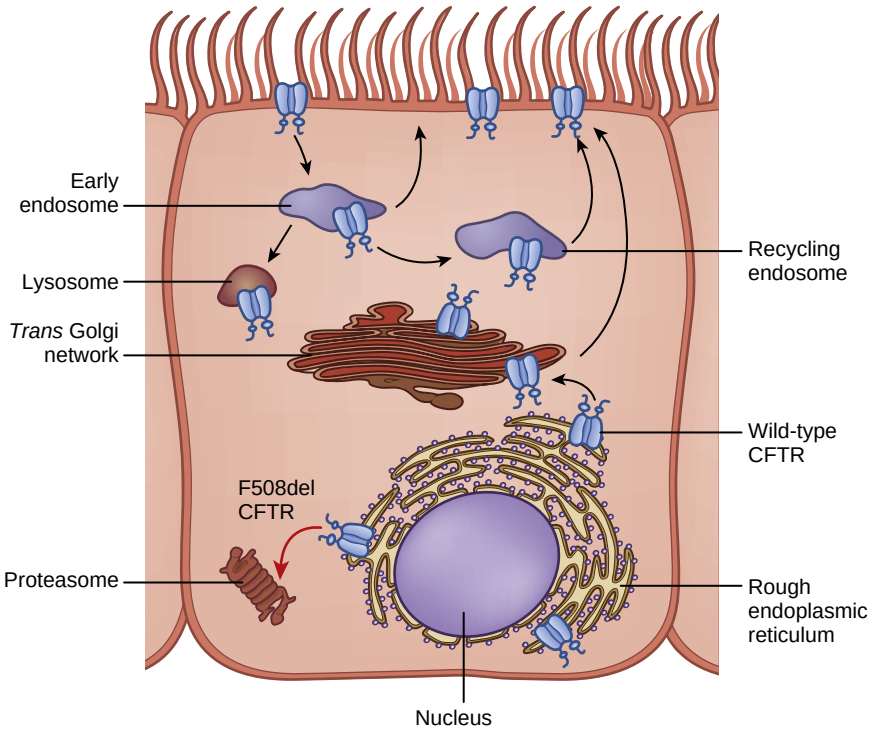

Figure 67.3 Scheme of *cystic fibrosis transmembrane conductance regulator* (CFTR) biogenesis. Biogenesis of CFTR in normal epithelial cell (*black arrows*) and F508del CF-affected epithelial cell (*red arrow*). In the normal epithelial cell, CFTR is synthesized in the rough endoplasmic reticulum, glycosylated and folded in the Golgi apparatus, and chaperoned to the cell surface. In the F508del-affected epithelial cells, the CFTR polypeptide is misfolded and tagged for premature degradation via endoplasmic reticulum–associated degradation (*red arrow*) before reaching the cell surface (class II mutation). (Modified from Ameen N, Silvis M, Bradbury NA. Endocytic trafficking of CFTR in health and disease. *J Cyst Fibros* 2007;6:1–14.)

As a consequence, F508del CFTR visualized by polyacrylamide gel electrophoresis is predominantly an ER-localized, approximately 150-kDa core glycosylated (band B) form. This is in contrast to a substantial portion of the post-ER wild-type protein, which migrates more slowly on polyacrylamide gel electrophoresis due to complex glycosylation (≈180-kDa band C). The F508del trafficking defect is temperature sensitive, and growth of epithelium at 27°C leads to measurable levels of F508del band C CFTR, with partial restoration of cell surface activity. Although likely not relevant in vivo, except perhaps at the nasal surface, this improvement in function at low temperature provided an early indication that pharmacologic intervention could diminish the cellular recognition machinery necessary for protein degradation.

Maturational processing abnormalities attributable to F508del arise from at least two distinct features.[43,44,54] Omission of F508, which is located on an externally exposed peptide loop of the first nucleotide binding domain, leads to pronounced loss of NBD1 stability as judged by thermal and isothermal calorimetry, protein aggregation, and protein yield measurements after recombinant overexpression.[43,44] In addition, F508 facilitates binding of NBD1 to a cytosolic loop from MSD2, and disruption of the NBD1/MSD2 interface (independent of NBD1 stability) leads to further impairment of F508del maturation. F508del CFTR molecules that do reach the cell surface, as shown through in vitro techniques, such as pharmacologic therapy or, alternatively, low temperature correction of cellular processing, display intrinsic channel gating abnormalities, diminished plasma membrane stability, and pronounced thermal unfolding with loss of function.[55,56] The observation of multiple distinct CFTR defects attributable to F508del presents a challenge to identifying single agents capable of restoring mutant CFTR to therapeutically relevant levels. Of note, intramolecular suppressor mutations that specifically ameliorate F508del NBD1 instability or the defective NBD1/MSD1 interface have been well characterized.[43,44] CFTR constructs encoding these suppressors provide a means to improve F508del corrective strategies and have enabled compound library screening tailored to specific CFTR folding defects (see also later).

OVERVIEW OF LUNG PATHOPHYSIOLOGY

An improved understanding of CF pathogenesis has led to better diagnostic strategies, understanding of features leading to the onset and progression of respiratory decline, and therapeutic approaches to target the underlying disease. An overview is provided in Figure 67.4 and described in further detail later. Absent or dysfunctional CFTR results in diminished protein activity, leading to deficient chloride and bicarbonate transport across airway epithelium. Several key aspects of CF pathophysiology include delayed mucociliary clearance resulting from depletion of the periciliary compartment of the *airway surface liquid* (ASL), defects involving the rheologic properties of CF mucus that contribute to mucus stasis and adhesion to the epithelial surface, predisposition to early infection because of abnormal mucosal defense, and pronounced and/or dysregulated inflammation. These processes initiate and perpetuate a cycle of destruction that ultimately results in irreversible lung injury, bronchiectasis, and respiratory failure.[17,57]

In the respiratory tract, CF manifests with infected mucus that compromises the airway lumen and contributes to obstructive pulmonary disease and reduced FEV_1 (Fig. 67.5). Respiratory damage is thought to begin in the small airways, resulting in airflow obstruction detected by spirometry midflows (i.e., $FEF_{25\%–75\%}$). Submucosal gland hyperplasia and inspissated mucus secretions emanating from the glands are also prominent in early CF

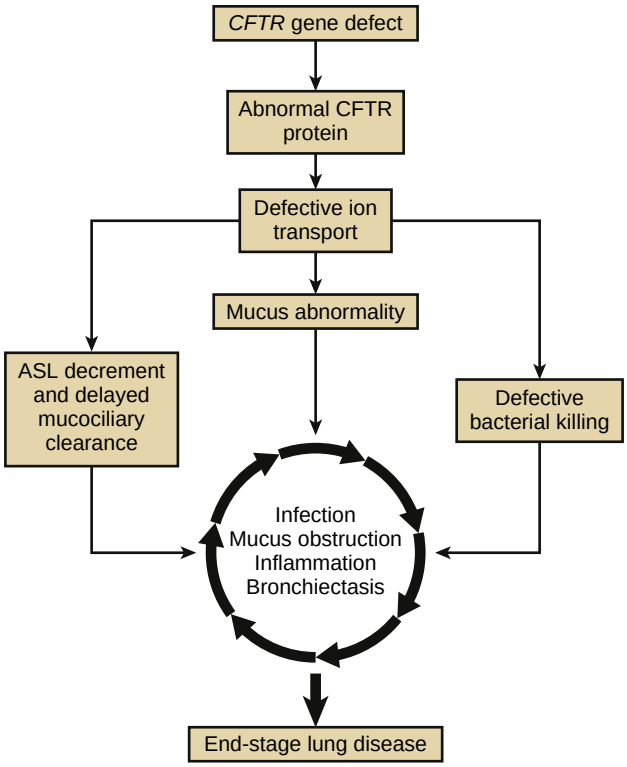

Figure 67.4 *Cystic fibrosis* (CF) pathophysiology. CF lung disease results from consequences of genetic mutations in the cystic fibrosis transmembrane conductance regulator gene (*CFTR*). Major operative pathways include reduced mucociliary clearance due to depleted airway surface liquid (ASL) hydration, abnormal mucus adhesion and viscosity, and defective bacterial killing, which each contribute to the cycle of destruction.

lungs. Radiographic changes consistent with small airway obstruction (e.g., tree-in-bud opacities) followed by bronchiectasis become apparent over time. Development of bronchiectasis leads to irreversible changes that predispose to worsening infection and accelerate disease pathogenesis.

CELLULAR FUNCTIONS OF THE *CFTR* GENE PRODUCT

The *CFTR* gene is hundreds of millions of years old on an evolutionary basis and used by diverse species, including fish, amphibians, fowl, and mammals.[58] Although best described as a chloride and bicarbonate transporter, the protein appears to regulate numerous cellular processes in addition to anion secretion (see also earlier). CFTR is situated within membrane complexes by virtue of its C-terminal anchoring sequence via a PDZ-type binding motif. CFTR is configured in close proximity to a number of integral membrane proteins, including other ion channels. By establishing electrochemical gradients, CFTR also exerts a regulatory influence on other apical ion transporters, including the *epithelial sodium channel* (ENaC), alternative chloride transporters, and bicarbonate/chloride exchangers.[59] Proteomic and transcriptome analyses demonstrate hundreds of cellular gene products that may directly bind or are impacted by CFTR.[60]

With the advent of single-cell sequencing came the surprising observation that CFTR is predominantly expressed in the airways in a minority cell type termed the *ionocyte*. The identification of the ionocyte as a major site of CFTR signaling has important implications for pathogenesis and gene therapy.[61,62] It is unknown whether the ionocyte regulates

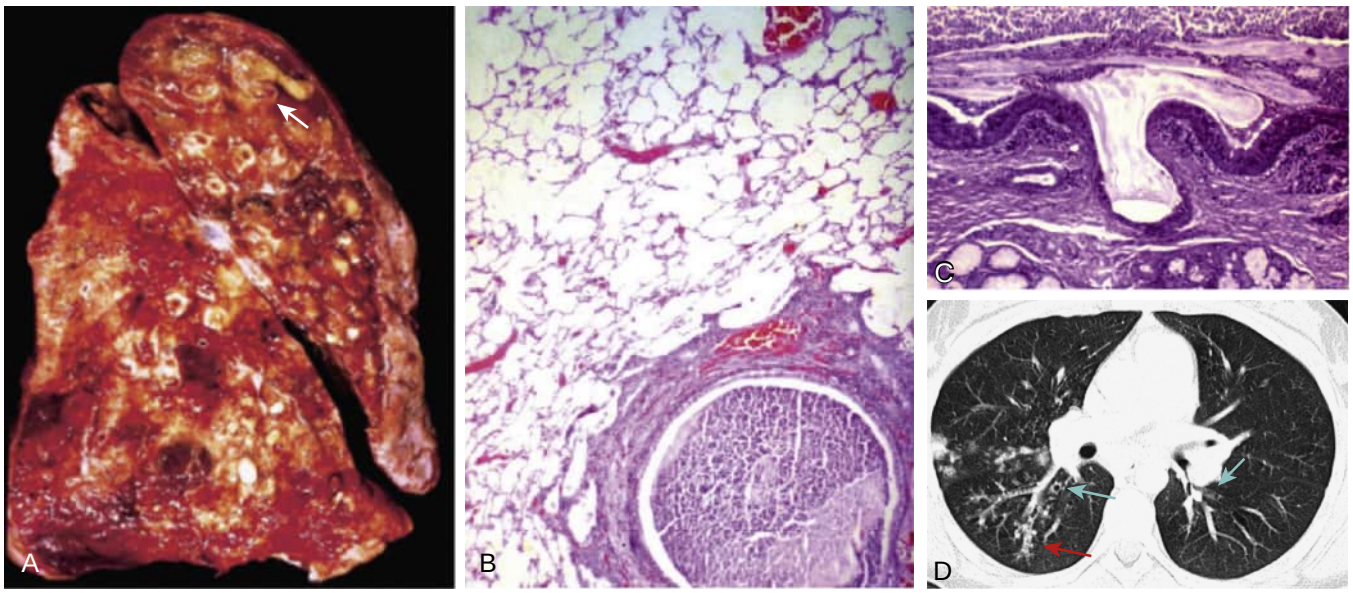

Figure 67.5 *Cystic fibrosis* (CF) pathologic and radiologic correlation. (A) Gross pathologic specimen of explanted CF lung from a patient with advanced CF. This specimen (sagittal section) shows heavy lungs characterized by ectatic bronchi (e.g., *arrow*) and numerous mucopurulent plugs. (B) Large airway pathology of CF. A large mucus plug filled with inflammatory infiltrate is seen, in addition to remodeling of the medium-size airway (hematoxylin-eosin stain). (C) Representative photomicrograph from a CF patient with end-stage lung disease is depicted. Note the thickening of the lamina propria (higher Reid index), the prominent arborized mucus plug extruding from the submucosal gland onto the airway lumen, and the hypertrophic surface epithelium (periodic acid–Schiff stain). (D) Axial high-resolution computed tomography image from a 16-year-old male patient with CF demonstrating mild to moderate multilobar bronchiectasis (*blue arrows*) and tree-in-bud opacities representing small airway mucus plugs (*red arrow*). (A–C, Courtesy Dr. David Kelly, University of Alabama, Birmingham.)

the ion transport environment of the epithelia by establishing electromotive forces or serves other unique functions yet to be discerned. This has notable implications for attempts to repair CFTR through gene therapy because it is not yet known if ionocyte repair will be a prerequisite for efficacy. In the lung, CFTR is also expressed in low numbers in surface epithelial cells and glandular epithelia, where it functions to regulate the formation and maturation of mucus.

REGULATION OF SWEAT CHLORIDE BY CFTR

The concentration of chloride in human sweat is determined by the balance of secretion and reabsorption of sodium and chloride in the sweat gland and duct. Chloride is secreted by two parallel pathways. One involves CFTR; the other uses a CFTR-independent, calcium-activated chloride channel. Because CFTR is not the only pathway by which chloride exits the apical membrane, chloride is secreted into sweat even in the absence of functional CFTR. Normally, sodium is reabsorbed along the sweat gland duct by ENaC in the apical membranes of ductular cells. Chloride follows sodium into the cell through CFTR. In CF, absent or defective CFTR significantly reduces chloride reabsorption, and the chloride content of sweat is therefore abnormally high, providing a convenient indicator of CFTR function. With differences in CFTR function either due to genetic variation or to drug therapy, sweat chloride is a dynamic and sensitive indicator of the modulation of CFTR activity.

REGULATION OF AIRWAY SURFACE LIQUID HOMEOSTASIS

The absence of apical CFTR leads to failure of chloride and bicarbonate secretion.[17,63] Because release of water into the periciliary region is driven in part by a CFTR-dependent osmotic gradient, CFTR deficiency leads to failure of mucus hydration, particularly when combined with excess mucus expression and secretion. Persistent airway fluid absorption through ENaC, which can be augmented by free nucleotides and other inflammatory stimuli, further exacerbates airway desiccation.[64–66] Hyperconcentrated mucus contributes to its elevated viscosity and correlates with disease severity across the spectrum of mucociliary diseases.[67] Osmotic forces induced by entangled mucus in the overlying mucus layer draw fluid from the periciliary layer, which normally provides the environment for appropriate ciliary function and mucus transport (Fig. 67.6). The harm caused by ASL dehydration is underscored by the therapeutic improvement among patients treated with hypertonic saline aerosols and dry powder mannitol to augment mucociliary clearance in CF lung disease by providing airway hydration, although their influence on the electrostatic environment of gel forming mucins has also been postulated.[67]

Through bicarbonate transport, CFTR serves to regulate airway pH. In people with CF and in CF pigs, the absence of the chloride bicarbonate exchanger ATP12a, present in mice, prevents compensation for airway pH abnormalities,[68] leading to an acidic airway surface. The acidic pH environment is postulated to have several effects, including a defect in bacterial killing through pH-sensitive defensins; this may be a crucial early event that initiates CF infections, particularly early in life when aspiration events are common and where fast-acting bacterial killing is highly relevant.[69] The absence of bicarbonate transport and the acidic pH environment also has consequences to the formation of mucus and its rheologic properties, as detailed later.

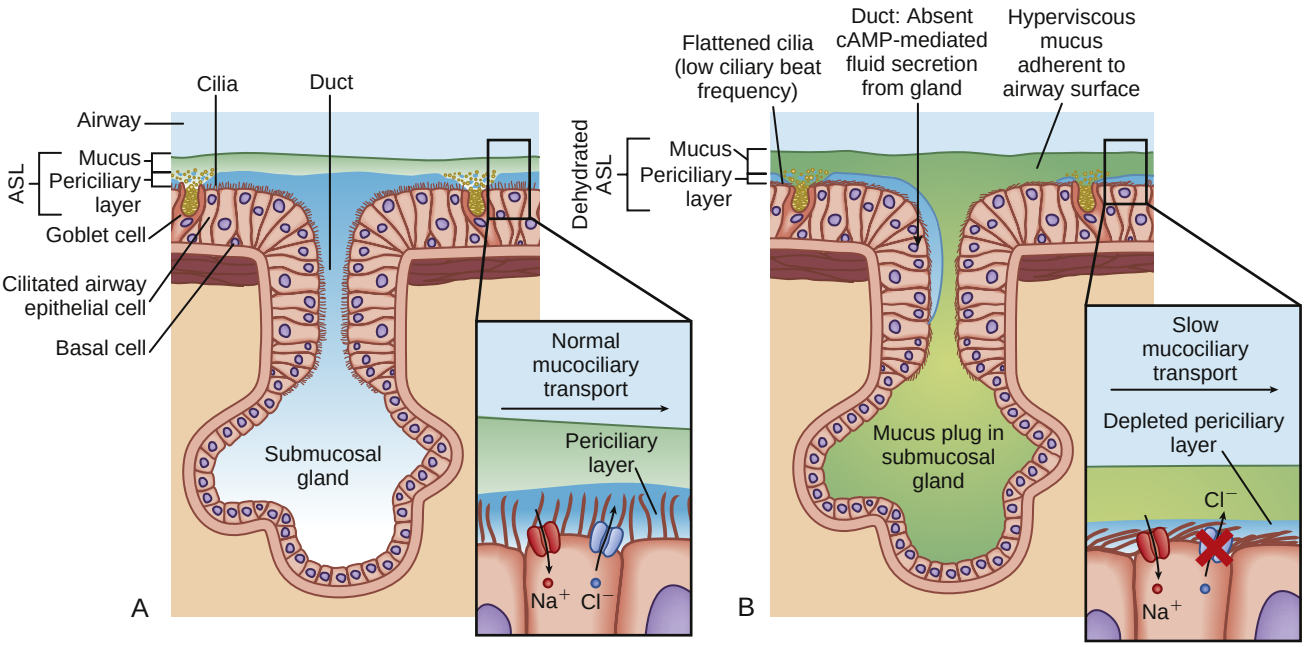

Figure 67.6 Schematic of the mucociliary transport defect in *cystic fibrosis* (CF). (A) In the healthy state, adequate airway surface homeostasis ensures effective transport of mucus extruding from airway surface goblet cells and the submucosal glands. The airway surface liquid (ASL) is maintained by fluid secretion via the cystic fibrosis transmembrane conductance regulator (CFTR) and fluid absorption via the epithelial sodium channel (ENaC) (*inset at right*) (CFTR, surface receptor in *blue*; ENaC, surface receptor in *red*). (B) In CF, the ASL is depleted through the absence of CFTR-mediated fluid secretion, accompanied by tonic fluid absorption via the ENaC. CFTR-dependent liquid dehydration decreases the depth of the ASL, including the periciliary layer, causing abnormal clearance of mucus from the epithelial cell surface in the airways. cAMP, cyclic monophosphate.

MUCUS BIOGENESIS, ADHESION, AND TRANSPORT

Hyperviscous respiratory secretions obstruct small- and medium-size airways in CF, leading to profound failure of mucociliary clearance that can be verified macroscopically by radioligand imaging[70] and direct visualization of the mucociliary transport apparatus in human nasal airways.[71] Quantitative analyses have indicated this is multifactorial, with airway dehydration and hyperviscous acidic mucus each contributing independently.[71,72] Even early in disease, before robust infection, insoluble mucus plaques (also called "flakes") can be observed in the bronchoalveolar lavage fluid of affected infants.[73] As mucus obstruction ensues, proinflammatory cytokines, such as interleukin-1β, are released, perpetuating mucus expression and exacerbating the consequences of CFTR deficiency.[73]

Specific mucins expressed in respiratory secretions include the gel-forming mucins MUC5B and MUC5AC, in addition to a complex array of extracellular proteins that participate in host defense.[74] Evidence for a primary biochemical defect in mucus composition includes the adhesion of large MUC5B strands in CF porcine airways or in those deficient in both bicarbonate and chloride transport[75] and the role of enzymatic release of mucus in the intestine.[76] Defective bicarbonate transport, in part through its effects on airway pH, contributes to mucus hyperviscosity through electrostatic forces.[77] Exocrine mucins (highly negative in charge) are produced intracellularly as compacted forms assisted by bound calcium, which shields the negative repulsive force between sulfates and other anionic groups on constituent mucins.[2] Under normal circumstances, bicarbonate secretion via CFTR, likely coordinated with mucus secretion, chelates the calcium and permits mucin expansion and a viscoelastic state compatible with physiologic clearance.[78] Failure of bicarbonate secretion results in defective mucin expansion, leading to hyperviscous secretion with abnormally adherent properties (i.e., mucus that is tightly bound to the respiratory surface and difficult to mobilize). Therapeutics in development to alter electrostatic interactions can ameliorate abnormal mucus rheology.[79] Excessive mucus adhesion that can be reversed by bicarbonate has been observed in the intestine of CF mice,[80,81] but this bicarbonate-mediated effect on mucus may not be sufficient to reverse airway mucus obstruction because CF mucus also becomes oxidized, a secondary phenomenon that also serves to increase its viscosity and may be less readily reversed. DNA strands released from dying bacteria, injured epithelial and inflammatory cells, and inflammatory secretions, such as *neutrophil extracellular trap* (NET)osis from polymorphonuclear leukocytes, represent important contributors to excess mucus viscosity and provide a rationale for the use of recombinant DNAse as an aerosolized mucolytic.

CYSTIC FIBROSIS EXOCRINE GLANDULAR EPITHELIUM

Submucosal glandular ducts filled with inspissated mucus are observed early in the course of CF pulmonary involvement. CFTR is highly expressed within epithelial cells of submucosal glands, where it functions to activate fluid and electrolyte secretion and promote release of mucus onto the airway surface.[3,82] The relative contributions of submucosal glands to overall CF respiratory pathophysiology are an area of considerable interest. Illustrating this notion, in CF rats, mucus stasis is only apparent with the development of glands as they age, even though both pH and airway dehydration are evident early in life, and is augmented by stimulation of mucus secretion.[83] Adhesive mucus at the outlet of gland ducts may further contribute to airway obstruction and provide a nidus for infection.

HOST DEFENSE AND INFECTION

CF lungs are characterized by intense neutrophilic inflammation with polymorphonuclear cells densely infiltrating airway secretions. Whether robust lung inflammation is mediated directly by CFTR, as opposed to a consequence of polymicrobial infection, is a topic of considerable debate. Sterile mucus obstruction plays an important role in experimental animals,[84] and interleukin-1β can serve as a positive feedback loop that furthers mucus stasis.[85] Neutrophil chemoattractants, such as interleukin-8, tumor necrosis factor-α, and a collagen fragment, proline-glycine-proline, are present at high levels in airway secretions, and abnormalities of CFTR-dependent macrophage function have also been implicated. Although anti-inflammatory therapies can improve lung function and slow the rate of CF respiratory decline, immune blockade also can predispose individuals to worsening lung infection, and the proper clinical balance has been difficult to achieve.[86]

Bacteria typically colonize the CF respiratory tract during infancy or early childhood. Longitudinal analysis of *P. aeruginosa* indicates sentinel infection due to a single genotype of the organism often persisting throughout the life of an individual patient.[87] The factors that lead to early colonization are not well understood. Studies have implicated acidic pH within the ASL, attributable to absent CFTR bicarbonate release, as a likely cause of the increased susceptibility to bacteria.[69] Findings such as these may, in some cases, be most relevant to early colonization events.[3]

Virulent respiratory pathogens such as *P. aeruginosa* evolve in a stereotypic fashion during the lifespan of individuals with CF and are characterized by rapid phenotypic change and hypermutability.[88] After several years of pulmonary infection, *P. aeruginosa* typically develops a mucoid phenotype in which considerable metabolic reserves are expended to synthesize and release the polyanionic protein, alginate. The appearance of mucoid *P. aeruginosa* in CF is a negative prognostic indicator. The selective advantage of alginate release has been attributed to the immunomodulating role of this exoproduct.[89,90] Studies have demonstrated the complexity of the CF microbiome, which can be altered during exacerbations by the presence of a dominant pathogen.[91] Further, co-culture studies provide evidence of synergistic interactions between bacteria that perpetuate and accelerate chronic infections.[92]

Animal Models of Cystic Fibrosis

Mouse models of CF have provided an important base of knowledge regarding the CF ion transport abnormality. A key strength of CF mice has been the ability to perform tissue-specific expression models, allowing the role of CFTR to be

explored in various tissues[93]; humanized versions of mice have also informed therapeutic evaluation. Nevertheless, CF mice have proved more limited in elucidating features of lung disease pathogenesis, unless hyperexpression of ENaC is implemented, which provides a model of airway dehydration but not other characteristic features of CF lung disease.[94] Filling the gap, porcine, ferret, and rat models of CF pulmonary disease have proved highly informative. Mice are likely protected from CF lung disease due to several features, including important differences in cell types that populate the airway, the absence of airway glands that serve as reservoirs for mucus production (see Chapter 1 for background differences between mouse and human lungs), and expression of the aforementioned ATP12a exchanger that protects mice from pH abnormalities, in addition to high expression of alternative chloride channels such as TMEM12a.[68,95] Rats, ferrets, and pigs each provide increasingly more faithful disease modeling of the airway defects and have been crucial to insights regarding lung disease pathogenesis, particularly regarding mechanisms of mucociliary clearance and CF defects in host defense. Each species exhibits elements of airway disease due to mucus obstruction and host defense abnormalities; ferrets and pigs exhibit spontaneous and progressive lung disease, whereas infection must be experimentally initiated in CF rats. These species provide informative models to assess pathophysiology, although cost, experimental complexity, and reagent availability serve as limitations that counterbalance how well they each replicate CF lung disease.

When combined with the evaluation of very young CF patients by newborn screening, animal models have provided particularly important means to clarify relationships existing among initial bacterial colonization, chronic infection, and inflammation in CF lungs. Longitudinal monitoring of CF respiratory infection in humans and transgenic animals will also facilitate a more sophisticated understanding of the complex CF microbiome and could provide new therapeutic opportunities in the future, particularly as robust models of chronic infection evolve. As gene therapy advances, animal models will also be essential to assess issues of gene delivery, tissue and cellular level expression, and correction of physiology.[96]

CFTR AND PULMONARY REMODELING

Measurements in the CF porcine model indicate a change in tracheal diameter and density of submucosal glands before the advent of hyperviscous mucus obstruction. Similar findings have been reported in human CF lungs and in CF rats (i.e., preceding the appearance of other pulmonary manifestations).[97] For tissues such as porcine and human pancreas, fibrotic damage and fatty replacement can be profound, with extensive parenchymal scarring.[98] Myofibroblast proliferation has been implicated as mediating some of these effects, and TGF-β signal transduction, which engenders myofibroblast transformation, is markedly increased throughout the CF lung.[99] TGF-β is also a well-established genetic modifier of F508del homozygous CF lung disease,[32,100] and these findings suggest that changes in TGF-β–dependent profibrotic pathways contribute to lung tissue remodeling, in addition to inflammatory responsiveness elicited by the cytokine.

Key Points

- *Cystic fibrosis* (CF) is the most common monogenic lethal disease in white populations and results from mutations in the *CF transmembrane conductance regulator* (*CFTR*) gene.
- *CFTR* genetic variants can be classified according to their molecular consequences to cell biology, which has implications for disease phenotype and for possible response to pharmacologic intervention.
- The most common *CFTR* mutation is F508del, one of more than 2000 variants, of which 350 have been confirmed to cause disease. Nearly 90% of CF individuals have one or more F508del alleles.
- CFTR is a tightly regulated anion channel of chloride and bicarbonate in the ABC transporter family. CFTR is expressed on epithelial cells and recently found on a novel cell, the ionocyte, and serves to regulate membrane potential and to influence the function of other channels.
- Absent CFTR causes delayed mucociliary clearance, abnormalities in mucus biogenesis and rheology, and host immunologic defects, which lead to chronic, progressive sinopulmonary infections and a cycle of lung destruction, bronchiectasis, and end-organ failure.
- Extrapulmonary manifestations are observed in numerous tissues that express CFTR, including the endocrine and exocrine pancreas, gastrointestinal tract, skin, bone, and male reproductive tract.

INTRODUCTION

Cystic fibrosis (CF) care has benefited from an increased understanding of CF pathobiology and from the partnership of academic and pharmaceutical research enterprises with a multinational team of care centers and the Cystic Fibrosis Foundation and other committed research entities. As a result, CF care constitutes a model for advancing treatment of chronic, life-threatening diseases through evidence-based quality improvement initiatives and comprehensive multidisciplinary care directed at multiple deleterious manifestations. It also provides a seminal example of the potential for translational medicine to deliver scientific discoveries that have transformed a universally fatal condition with targeted therapeutics addressing the underlying defect in the function of the *cystic fibrosis transmembrane conductance regulator* (CFTR). Future advances will capitalize on even more personalized therapies directed at the underlying cause of the condition and will address the potential for a genetic-based cure.

This chapter extends upon the concepts demonstrated by CF molecular pathobiology detailed in Chapter 67 to focus upon its diagnosis, prognosis, and natural history. CF therapeutics are also described, including the development of new therapies that target the basic defect.

DIAGNOSIS

OVERVIEW

The diagnosis of CF is predicated on clinical suspicion for the disease, as indicated by clinical manifestations or family history, or alternatively through newborn screening programs. Early detection through newborn screening is leading to recognition of illness before clinical findings become apparent. The first organized CF newborn screening programs were developed in the 1980s and implemented in Colorado (1987) and Australia and Europe (1980s)[1] after retrospective studies demonstrated improved clinical outcomes and decreased mortality as a result of early disease detection.[2] The number of such programs in the United States and abroad has grown in the past decade, and all states in the United States implemented newborn screening programs after a U.S. Centers for Disease Control and Prevention/Cystic Fibrosis Foundation Consensus Statement in 2004 recommended this practice.[3] The report invoked emerging prospective data that screening and early interventions in CF infants led to improved nutritional, gastrointestinal, respiratory, and cognitive functioning.[4–7]

In North America, newborns are screened using a heel prick blood test for immunoreactive trypsinogen, a byproduct of prenatal pancreatic inflammation. In most U.S. states, this test is paired with a DNA probe panel for common *CFTR* mutations. Immunoreactive trypsinogen is not a highly specific measurement due to elevated levels observed in prematurity, traumatic delivery, and other neonatal gastrointestinal disorders.[8] Because of declining immunoreactive trypsinogen levels in the first few months after birth in CF and non-CF infants,[9] this test is only useful for screening during the first few weeks postnatally. Family history or clinical suspicion based on clinical findings becomes the main impetus for diagnostic evaluation once the neonatal period has passed.

If the immunoreactive trypsinogen is elevated or in situations where CF is suspected for other reasons, a diagnosis should be confirmed by sweat chloride testing per the algorithm at a certified sweat testing lab once the newborn reaches an age where this testing may be performed accurately (usually after 10 days of age). Sweat chloride measurements are available in many clinical laboratories and have been standardized to ensure accuracy. Because of high sensitivity, sweat chloride testing has a central role in establishing the diagnosis in both the Cystic Fibrosis Foundation and European algorithms, once a positive newborn screen or compatible clinical characteristics are established.

Diagnostic Algorithms

The diagnosis of CF is based on a positive newborn screening test in newborns or CF clinical characteristics (Table 68.1). In 2017, the Cystic Fibrosis Foundation published comprehensive diagnostic guidelines for infants and adults with suspected CF[10] (Fig. 68.1) that emphasized a similar algorithmic approach for newborns, children, and adults. Similar European guidelines primarily differed only in the timing of *CFTR* mutation analysis and sweat chloride normative values.[11] There is good concordance when comparing the U.S. and European framework in terms of diagnostic accuracy.[12]

Table 68.1 Diagnostic Criteria for CF by Clinical Phenotypic and CFTR Functional Abnormalities

DIAGNOSIS OF CF CONFIRMED BY THE PRESENCE OF APPROPRIATE PHENOTYPIC CLINICAL FEATURES (ANY OF):
Chronic sinopulmonary disease ■ Chronic cough and sputum production ■ Persistent infection with characteristic pathogens (*Staphylococcus aureus, Pseudomonas aeruginosa,* other gram-negative organisms) ■ Airflow obstruction ■ Chronic chest radiographic abnormalities ■ Sinus disease; nasal polyposis
Gastrointestinal and nutritional abnormalities ■ Exocrine pancreatic insufficiency ■ Recurrent pancreatitis ■ Fat-soluble vitamin deficiency ■ Meconium ileus; DIOS
Obstructive azoospermia in males
***PLUS* LABORATORY EVIDENCE OF CFTR ABNORMALITY (ONE OR MORE OF FOLLOWING):**
Elevated sweat chloride
Disease-causing mutation in *CFTR* gene in both alleles
Characteristic bioelectric abnormalities (potential difference) in nasal epithelium
Abnormal ex vivo intestinal short-circuit current measurement

CF, cystic fibrosis; CFTR, cystic fibrosis transmembrane conductance regulator; DIOS, distal intestinal obstruction syndrome.

In the new approach, a low sweat chloride concentration (≤29 mmol/L) effectively rules out CF, whereas a high sweat chloride concentration (≥60 mmol/L) definitively establishes the diagnosis. In the case of clinical suspicion with an intermediate sweat chloride concentration (30 to 59 mmol/L), guidelines recommend performing *CFTR* sequencing or high-sensitivity DNA probe testing to establish the presence of *CFTR* mutations, usually coordinated through specialized commercial laboratories or via coordination and referral to a CF center for evaluation. Genetic confirmation by commercial *CFTR* sequencing in certified laboratories is recommended to confirm the diagnosis and to guide mutation-specific treatments, independent of the diagnostic yield of sweat chloride testing. Worldwide catalogs of CF phenotypic information by genotype are housed in the CFTR-2 repository (www.cftr2.org) and can help provide guidance about expected severity based on sequence information.

If two *CFTR* mutations are found, the diagnosis of CF is established. If one or zero mutations are present, then repeat sweat chloride testing is recommended. It should be noted that standard genetic panels (i.e., panels that test fewer than 40 mutations) are not sufficient in patients with elevated sweat chloride and atypical manifestations, because rare, partial function mutations are common in these cases and may not be detected by limited panels;

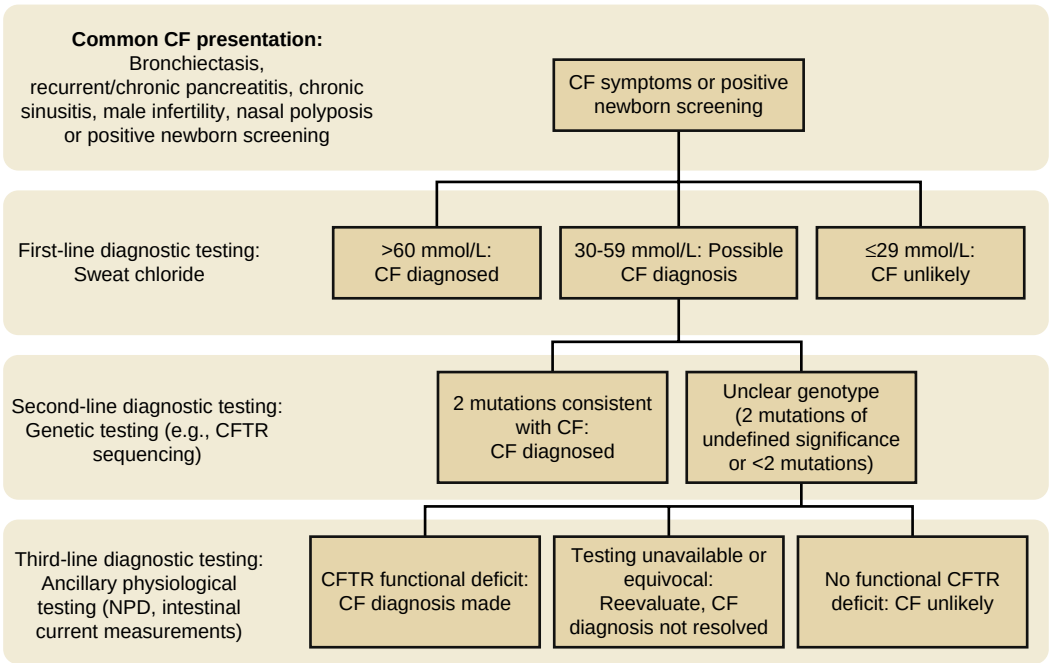

Figure 68.1 Diagnostic algorithm for *cystic fibrosis* (CF). Schematic depiction of algorithm for the diagnosis of CF in newborns through adults emphasizing sweat chloride as the cornerstone for diagnosis. Genetic testing for intermediate probability cases should trigger *cystic fibrosis transmembrane conductance regulator* (CFTR) sequencing because analysis for only a limited number of mutations can result in false-negative evaluations in this disease category. NPD, nasal potential difference. (Modified from Farrell PM, White TB, Ren CL, et al. Diagnosis of cystic fibrosis: Consensus guidelines from the Cystic Fibrosis Foundation. *J Pediatr.* 2017;181S:S4-S15.e1.)

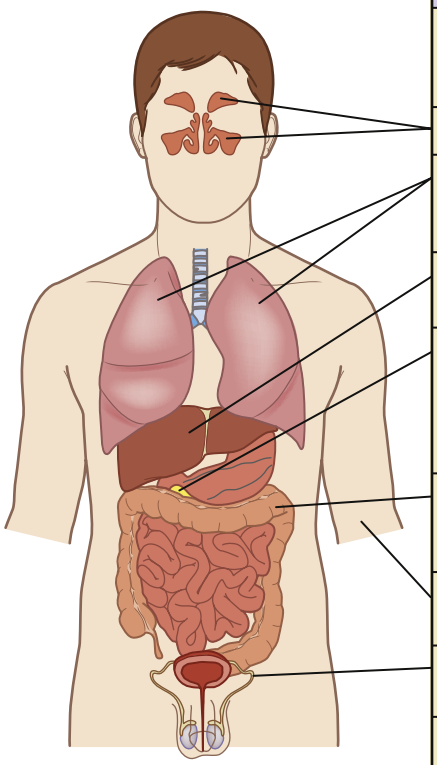
they are also biased towards mutations prevalent in those of Caucasian descent. Some patients exhibit CF-like disease even in the absence of *CFTR* mutations, a finding that might be caused by changes in genes encoding other proteins that can mimic mutations in *CFTR* (i.e., mutations in the epithelial sodium channel) or in other noncoding regions of the *CFTR* gene itself.[13]

If clinical suspicion remains and sweat chloride is in the intermediate range, there are several alternatives to confirm CFTR functional deficits. *Nasal potential difference* (NPD) testing, available at many CF research centers, can be an acceptable alternative in cases of inconclusive sweat chloride or inadequate genetic analysis. Alternatively, intestinal current measurements to estimate CFTR activity require a biopsy of rectal mucosa but the test is only available at a few centers worldwide.[14,15] Other measures of pancreatic function, such as fecal elastase, may also help support a diagnosis in this setting.

It is increasingly recognized that CFTR-related disorders represent a spectrum of disease, with pancreatic-insufficient CF as the most severe form and borderline CF-like syndromes representing the other extreme (Fig. 68.2). It is notable that functional assessments of CFTR reflect this diversity, although the relationship between genotype and CFTR functional decrements can vary on an individual level and on the tissues affected. Functional CFTR assays can help distinguish between mild and severe phenotypes by measuring the decrement in CFTR function along this continuum and can be informative beyond genotype information alone.[16] These tests are done at specialized centers throughout North America and usually are coordinated through CF referral centers. Cell-based assays are increasingly used to help resolve the functional implications of cryptic or ultra-rare mutations.

With widespread acceptance of newborn screening programs in the United States, it is now typical to diagnose CF before the onset of respiratory disease. A high index of suspicion must be maintained to ensure correct diagnosis in the event of screening failure or among individuals born before the initiation of newborn screening programs. Screening programs have led to the detection of CFTR-related dysfunction, as demonstrated by indeterminate range sweat chloride values in subjects without phenotypic CF. These individuals should be designated as having CFTR-related metabolic syndrome or, synonymously, a CF screen–positive inconclusive diagnosis. Current recommendations are that these individuals be followed annually by experienced CF providers because many have been reported to develop phenotypic CF later in life.[17] A significant number of CF patients may therefore present in adulthood because symptoms are unusual, subtle, or even absent early in life,



Organ System	CF-Pancreatic Insufficient	CF-Pancreatic Sufficient	CFTR-Related Disorder*
Typical genotype	Two severe mutations	At least one mild/variable mutation	Two mild mutations or heterozygous
Sinus	Chronic sinusitis	Chronic sinusitis	Chronic sinusitis
Airways	Severe chronic bacterial infection	Chronic bacterial infection, later onset, variable	Chronic bacterial infection, mild, later onset, variable
Liver	Severe hepatobiliary disease (5-10%)	Usually absent	Absent
Pancreas	Exocrine insufficiency	Adequate exocrine function until late in life, pancreatitis (pancreatitis in minority)	Adequate exocrine function, pancreatitis (can be presenting symptom)
Bowel	Risk of meconium ileus, DIOS	Nonspecific bowel complaints, low risk of DIOS	Nonspecific bowel complaints
Sweat chloride	90-110 mmol/L	60-90 mmol/L	40-60 mmol/L
Vas deferens	Obstructive azoospermia	Obstructive azoospermia	Normal, CUAVD, or CBAVD
Endocrine Pancreas	High risk of CF-related diabetes mellitus	Low risk of CF-related diabetes mellitus	Minimal risk of CF-related diabetes mellitus

Figure 68.2 Spectrum of cystic fibrosis disorders. A comparison between findings in severe *cystic fibrosis* (CF) and milder forms of the disease is shown. Although manifestations are variable, severity in each organ system is generally consistent with degree of *cystic fibrosis transmembrane conductance regulator* (CFTR) dysfunction conferred by genotype. CBAVD, congenital bilateral absence of the vas deferens; CUAVD, congenital unilateral absence of the vas deferens; DIOS, distal intestinal obstruction syndrome. *Refers to CFTR-related metabolic syndrome or CFTR-related disorders.

resulting in a delayed presentation. Oftentimes these CFTR-related metabolic syndrome–associated presentations are due to partially active *CFTR* alleles or other ameliorating mutations or factors resulting in milder CFTR functional defects (e.g., sweat chloride in the 30 to 59 mmol/L range or NPD in the intermediate severity range).[18] Recognition of the variable manifestations of CF is required to detect CF after early childhood.

Finally, the diagnosis of CFTR-related syndrome is usually made in older children and adults presenting with single-organ CF involvement (e.g., isolated bronchiectasis, sinusitis, pancreatitis, or congenital absence of the vas deferens) with inconclusive CFTR functional testing and genotype. The complexity of inconclusive diagnostic scenarios is outlined in eTable 68.1.

CLINICAL MANIFESTATIONS

CF has historically presented with protean manifestations and symptoms that may mimic or resemble other diseases. Usual presentations include early onset of respiratory tract findings, particularly persistent cough and recurrent or refractory chest radiographic changes. Gastrointestinal presentations are also prominent and include meconium ileus (in approximately 15% of patients) and failure to thrive with steatorrhea due to pancreatic insufficiency. A list of unusual presentations is compiled in Table 68.2. Clinical severity can vary widely; less severe disease states can be initially misdiagnosed as other more common respiratory conditions.

LOWER RESPIRATORY TRACT DISEASE

Progressive obstructive lung disease leading to bronchiectasis and respiratory failure accounts for the vast majority of mortality among individuals with the disease. Even seemingly healthy infants with CF often have significant subclinical lung findings, including inflammation often disproportionate to the degree of infection.[19,20] The most common manifestation of lung disease is cough in association with bronchitis. Early in life, symptoms are often intermittent and exacerbated by episodes of acute respiratory tract infection that tend to exhibit a protracted course. With time, cough becomes a daily event. It is often more pronounced at night and on rising in the morning. With progression or during exacerbations of lung disease, cough typically becomes productive with tenacious, mucopurulent sputum secondary to chronic bacterial infection and neutrophilic inflammation, especially after the onset of chronic infection.

Hyperinflation of the lungs is common and often observed early in the progression of CF lung disease.[21] Asthmatic or bronchiolitic-type wheezing is often observed during the first 2 years of life but may be encountered at any age. Wheezing is noted in up to one-third of infants and may be present with or without evidence of atopy.[22] Early in life, CF can mimic the clinical manifestations of asthma and/or coexist with asthma, leading to delayed recognition if newborn screening is not definitive for a diagnosis.

Lung sounds are typically unremarkable at presentation; the first detectable abnormalities may be subtle retractions, diminished intensity of breath sounds, or prolongation of the expiratory phase. Once CF lung disease becomes clinically apparent, adventitious lung sounds are usually first noted in the upper lobes. CF patients may have only mild bronchitic findings for long periods during the time lung homeostasis is maintained but still manifest exacerbation of symptoms such as increased cough intensity and sputum production. Respiratory exacerbations often present as tachypnea, shortness of breath, malaise, anorexia, and weight loss. Viral respiratory tract infection is a frequent trigger, as are other infectious agents, cigarette smoke,[23] pollutants,[24] allergens, and respiratory irritants that have been implicated as disturbing lower airway physiology. Initiation of broad-spectrum antibiotic therapy and aggressive maneuvers to facilitate clearance of mucus are usually required to improve symptoms and restore lung function. Pulmonary exacerbations are now recognized as a major driver of overall disease progression, and aggressive attempts to recognize and treat these events before the advent of irreversible injury have become a priority.[25] As CF lung disease progresses, exacerbations characteristically become more frequent and severe, often requiring extended courses of intravenous antibiotics and hospitalization. End-stage lung damage associated with impairment of daily activities heralds a sequence of terminal events in the absence of lung transplantation, including hypoxemia, pulmonary hypertension, right ventricular dysfunction, hypercapnic respiratory failure, and death.

Table 68.2 Atypical Presentations of Cystic Fibrosis*

Respiratory	■ Bronchiolitis/asthma ■ ***Pseudomonas aeruginosa* or *Staphylococcus aureus* colonization of the respiratory tract** ■ Staphylococcal pneumonia ■ **Nasal polyposis** ■ **Nontuberculous mycobacterial infection**
Gastrointestinal	■ Meconium plug syndrome ■ Rectal prolapse ■ **Recurrent abdominal pain and/or right lower quadrant mass** ■ Hypoproteinemic edema ■ Prolonged neonatal jaundice ■ **Biliary cirrhosis with portal hypertension** ■ Vitamin deficiency states (A, D, E, K) ■ *Acrodermatitis enteropathica*–like eruption with fatty acid and zinc deficiency ■ **Recurrent pancreatitis**
Genitourinary	■ **Male infertility** ■ **Female infertility**
Other	■ Hypochloremic, hyponatremic alkalosis ■ **Mother of a child with cystic fibrosis**

*__Bold__ type signifies possible presentation in adolescents or adults with cystic fibrosis.

MICROBIOLOGY

Patients with CF demonstrate bacterial colonization of the airways early in life. Chronic infection of the lower airways, once established, is difficult to eradicate. *Staphylococcus aureus* and *Haemophilus influenzae* are usually the first organisms detected in CF lungs (Fig. 68.3) and often present

eTable 68.1 Summary of Inconclusive Cystic Fibrosis Diagnosis Scenarios

	NBS Status	Sweat Chloride Range (mmol/L)	Ancillary CFTR Testing	Genotype Results
CRMS/CFSPID Scenario 1	+	<30	Inconclusive/NA	<2 mutations with known clinical significance
CRMS/CFSPID Scenario 2	+	30–59	Inconclusive/NA	0-1 mutations of clinical significance
CFTR-related syndrome Scenario 1	No NBS	<30	Inconclusive/NA	<2 mutations with known clinical significance
CFTR-related syndrome Scenario 2	No NBS	30–59	Inconclusive/NA	0-1 mutations of clinical significance

CFSPID, cystic fibrosis screen positive, inconclusive diagnosis; CFTR, cystic fibrosis transmembrane conductance regulator; CRMS, CFTR-related metabolic syndrome (CFSPID and CRMS are equivalent terms); NA, not available; NBS, newborn screening.

Data from the CFTR 2 Database, https://cftr2.org; and Farrell PM, White TB, Ren CL, et al. Diagnosis of cystic fibrosis: consensus guidelines from the Cystic Fibrosis Foundation. *J Pediatr*. 2017;181S:S4-S15.e1. Erratum *J Pediatr*. 2017;184:243.

with a comparatively benign clinical picture.[26] Historically, acquisition of *Pseudomonas aeruginosa* or *Burkholderia cepacia* was regarded as a particularly ominous clinical finding because these infections are associated with accelerated decline in lung function and increased mortality.[27] With the increased prevalence of microbiologic screening and more aggressive antimicrobial treatment regimens, a more broad and diversified group of respiratory pathogens has emerged.[28] These pathogens include *methicillin-resistant S. aureus* (MRSA), multidrug-resistant gram-negative rod bacteria, nontuberculous mycobacteria, and fungal organisms.[29] When present, these new opportunistic infections may be associated[30] with declining lung function. Often the clinical significance and complex factors contributing to the presence of these organisms in sputum culture are multifactorial and thus require careful clinical consideration to determine the appropriate timing and intensity of treatment. This is particularly true because certain organisms, such as nontuberculous mycobacterial and fungal organisms, may represent benign colonizers of CF lower airways.

The prevalence of *P. aeruginosa* increases with age, infecting more than two-thirds of patients by the third decade of life. The frequency of detection earlier in life has increased in the era of newborn screening and may be as high as 20% in children younger than 2 years; detection in infants at the time of diagnosis is common. Acquisition of *P. aeruginosa* increases longitudinally (see Fig. 68.3) and may be associated with genotype severity—individuals homozygous for F508del demonstrate a higher prevalence of chronic infection.[31] The effect of CFTR modulators on the eradication of bacteria appears promising at the population level based on the effect of ivacaftor in patients with gating mutations but continues to emerge for more common CFTR mutations[32,33] and for microbiome analyses.[34,35]

Nosocomial acquisition of new infections and transmission of multidrug-resistant organisms is a substantial concern in CF care.[36] Because eradication of sentinel infection has become an increasing priority, identification and earlier treatment of initial infection (e.g., due to *P. aeruginosa*) based on frequent sputum monitoring is recommended for those not previously colonized.[37–39] Sputum bacteriology correlates reasonably well with specimens obtained directly from the lower respiratory tract, although microbial sequencing is lending new insights into the validity of this conclusion. Oropharyngeal swab cultures that yield *S. aureus* or *P. aeruginosa* are modestly predictive of results from bronchoscopic specimens, but negative pharyngeal cultures do not rule out growth of these organisms in lower airways.[40] Nevertheless, recent studies supporting sputum or oropharyngeal swab culture surveillance and subsequent treatment with intent to eradicate infection have demonstrated similar efficacy to more invasive detection regimens.[41] Other, more sensitive means to detect *P. aeruginosa,* such as polymerase chain reaction or circulating markers, may further improve sensitivity of noninvasive techniques. Quantitative bacteriology may be particularly useful for determining the relative contributions of isolated organisms in this setting.

As lung disease progresses, *P. aeruginosa* often becomes the predominant organism recovered from sputum and may be present in multiple strains with distinct antibiotic sensitivity patterns. The emergence of a mucoid phenotype due to elaboration of large amounts of *alginate*, an exopolysaccharide that protects the bacteria from adversity in its surroundings and also enhances adhesion to solid surfaces, is associated with worsened clinical outcome.[42] Mucoid organisms are found as microcolonies of pseudomonads embedded and growing in biofilms of alginate.[43] Biofilms inhibit phagocytosis and enhance bacterial adherence while limiting exposure to antibiotics and reactive intermediates produced by leukocytes.[44–47] Although the presence of a mucoid phenotype is clearly associated with colonization, new mucoid *Pseudomonas* infection or conversion to a mucoid phenotype may also be amenable to aggressive eradication strategies.[48,49] Isolation of *P. aeruginosa* from the lower respiratory tract of a child or young adult with chronic lung symptoms is highly suggestive of CF but has been reported in patients with primary ciliary dyskinesia, bronchiectasis, or other severe obstructive lung diseases.[50]

Although *P. aeruginosa* has remained the dominant pathogen in adult CF lung disease, MRSA has emerged as a significant contributor to disease progression and mortality.[51] In contrast, methicillin-susceptible strains are associated with improved outcomes.[52] Two studies using the U.S. CF registry have demonstrated an association between MRSA and worsened lung function, and another has shown MRSA infection to be an independent risk factor for mortality.[53,54] Considerable interest has emerged in the epidemiology and biologic significance of the staphylococcal chromosomal

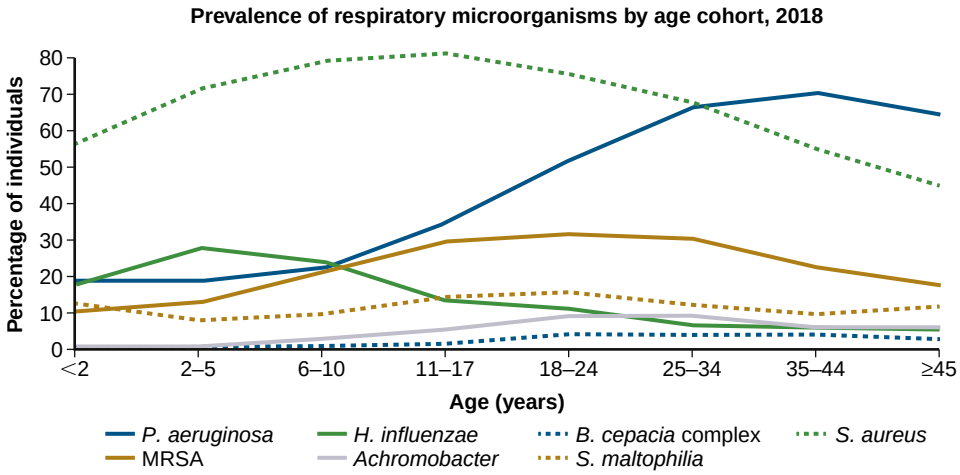


Figure 68.3 Alterations in sputum microbiology with age. Chronic infection with *Pseudomonas aeruginosa* and *methicillin-resistant Staphylococcus aureus* (MRSA) changes as a function of advancing age, based on data from cystic fibrosis care centers in the National CF Patient Registry. This is in contrast to a higher prevalence of *Haemophilus influenzae* and methicillin-sensitive *S. aureus* in childhood and adolescence among patients with cystic fibrosis. (Data from the Cystic Fibrosis Foundation, Patient Registry; Bethesda, MD; 2018.)

cassette containing the methicillin resistance gene and the Panton-Valentine leukocidin expressing strains, both of which have an effect on their virulence and impact disease severity.[29] Although the clinical significance of MRSA infection and colonization must be recognized, evidence is not sufficient to support aggressive eradication strategies in individuals with MRSA who are clinically stable.[55] Small-colony staphylococcus variants may also represent a distinct entity highly resistant to traditional therapy.[56] In addition, there is increasing recognition that MRSA exhibits biofilm-forming behavior in chronic infection.[57]

Numerous gram-negative pathogens in addition to *P. aeruginosa* have demonstrated a significant clinical impact on respiratory health, lending support to the notion that CF lung infection represents a significantly more complex microbiome than previously realized.[58] Of these, *B. cepacia* has remained the most ominous, due to its inherent multidrug antibiotic resistance and association with rapid decline in CF pulmonary reserve.[59] Infection from *B. cepacia* can spread from patient to patient, requiring stringent infection control measures within CF care settings.[60,61] Infection has been linked to the rapid clinical deterioration and death of a small percentage of patients with what has been referred to as *cepacia* syndrome.[62] Molecular analyses have shown that *B. cepacia* complex is composed of at least nine phenotypically indistinguishable but genetically distinct species (genomovars).[38,63,64] Genomovars II (*Burkholderia multivorans*) and III (*Burkholderia cenocepacia*) have been associated with *cepacia* syndrome, and genomovar III includes a highly transmissible strain that may be linked to expression of the cable pilus, which enhances infectivity and virulence.[64–66] Other gram-negative rods present in CF sputum include mucoid *Escherichia coli, Stenotrophomonas maltophilia, Achromobacter xylosoxidans, Klebsiella,* and *Proteus*. Of these, *S. maltophilia* and *A. xylosoxidans* appear to have the strongest association with poor respiratory outcomes, but their clinical significance warrants further evaluation. Additional gram-negative organisms such as *Pandoraea* and *Ralstonia* sp have been isolated from CF sputum samples, but further clinical investigation will be necessary to determine their pathogenic significance. Obligate anaerobes have also been identified from CF lung tissue. These are typically undetected by standard clinical laboratory microbiologic analyses and may be found in large abscess cavities on rare occasions.[67,68]

Infection with *nontuberculous mycobacteria* (NTM) is increasingly observed in the CF population, presumably due to concomitant antibacterial therapy resulting in a favorable ecologic niche, host susceptibility, improved detection, and environmental prevalence.[69–74] Up to 20% of adult patients in some clinics are colonized by NTM, and its incidence has been increasing in recent years. Although culture positivity is sometimes transient, the deleterious clinical impact of these organisms once established is increasingly appreciated.[75] *Mycobacterium avium* complex infection is of variable clinical significance, whereas rapidly growing organisms such as *Mycobacterium abscessus* can exhibit a virulent course, prompting aggressive and prolonged treatment regimens.[72] In contrast, *Mycobacterium tuberculosis* infection has only been seen in sporadic cases. Studies to standardize treatment for these emerging pathogens in CF are underway.[76] (See also Chapter 55 for a detailed discussion of NTM infections in CF patients.)

Nearly 40% of individuals with CF will grow *Aspergillus fumigatus* in the sputum during their lifetime; patients who have severe lung disease appear to have an even higher incidence of sputum positivity.[77] The pathogenic nature of *Aspergillus* in an otherwise immunocompetent CF host is not well established, although it may contribute to the burden of excess mucus production. However, *Aspergillus* is clearly associated with *allergic bronchopulmonary aspergillosis* (ABPA). ABPA is present in approximately 2% of CF patients and adds a considerable burden of care.[78,79] ABPA is described later and in Chapters 69 and 96.

IMAGING

The earliest radiographic finding in CF lung disease is typically hyperinflation of the lungs, reflecting obstruction of small airways. Central airway thickening and linear opacities produce a "tram track" appearance representing bronchiectasis (eFig. 68.1) and often progress with age (Fig. 68.4, eFig. 68.2). Frequently, these findings are most

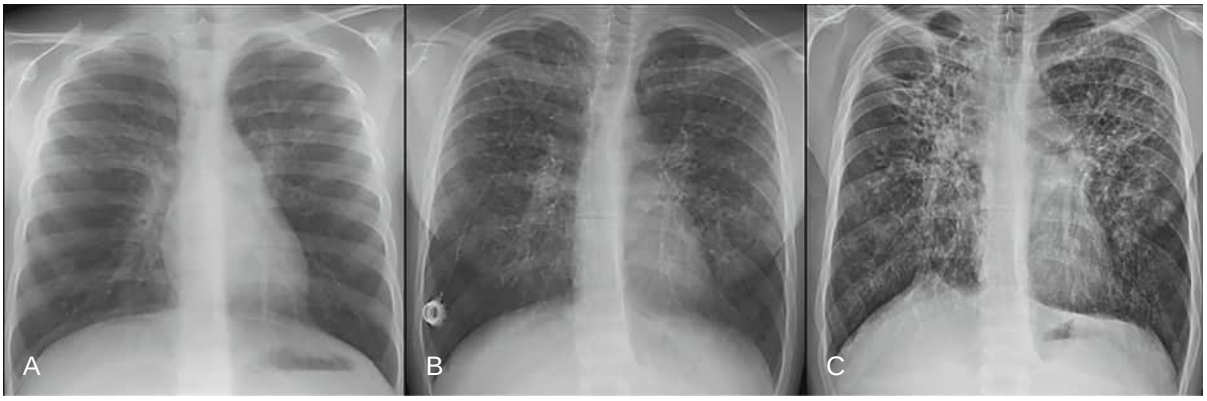

Figure 68.4 Cystic fibrosis: chest radiographic findings over 2 decades. (A) Frontal chest radiograph in a 9-year-old boy shows mid and upper lung predominant bronchovascular thickening, consistent with the bronchial wall thickening and bronchiectasis typical of cystic fibrosis. (B) Frontal chest radiograph performed in the same patient at age 19 years shows progression in the upper lobe predominant vascular thickening, now with a slightly more cystic appearance in the right upper lobe. (C) Frontal chest radiograph performed in the same patient at age 29 years, after the patient had become oxygen dependent, shows further worseninng of bronchial wall thickening and bronchiectasis, particularly in the right suprahilar region, now with hilar retraction suggesting upper lobe scarring. Bullae formation at the right apex is also now apparent. Note that the chest radiographic technique for this image used edge enhancement. (Courtesy Michael B. Gotway, MD.)

readily appreciated in the right upper lobe (eFig. 68.3) because this region is often involved before other areas. The appearance of bronchiectasis by *computed tomography* (CT) of the chest is highly characteristic of CF pulmonary involvement (see eFigs. 68.1B–E and 68.2B–E and Chapter 69). Although chest radiography is appealing due to accessibility and relatively low-dose radiation exposure, sensitivity for detecting acute or subtle chronic changes during a period of acute exacerbation remains limited.[80] Nonetheless, chest radiographs remain a standard first-line imaging test for surveillance and during acute exacerbations, for episodes of hemoptysis (eFig. 68.4), or to identify complications such as pneumothorax[81] (eFig. 68.5). Use of CF monitoring by chest CT is recommended biannually in stable CF patients.[82]

Chest CT, with its high-resolution cross-sectional imaging, is clearly superior for detecting mild disease and quantifying the extent and pattern of bronchiectasis (see eFigs. 68.1B–E and 68.2B–E).[83,84] Mosaic perfusion, manifesting as areas of inhomogeneous lung opacity resulting from air trapping and disordered parenchymal blood flow, is a common CT finding in patients with CF (eFig. 68.6). Small nodules due to bronchial and bronchiolar impaction are commonly observed (eFig. 68.7). CT studies have also demonstrated significant changes in young children, before obvious symptomatic disease, supporting the notion that CF lung disease begins early in life and disease detection is limited by the sensitivity of routine clinical procedures including spirometry.[83] Regardless of the imaging modality used, the degree of hyperinflation generally increases over time. As endobronchial infection and reactive inflammation emerge, peribronchial cuffing becomes increasingly apparent. Manifestations of bronchiectasis, including enlarged ring shadows or airway dilation and cysts, are common even early in life (see eFig. 68.1); upwards of 50% of CF patients demonstrate bronchiectasis by 3 to 5 years of age.[84]

During acute pulmonary exacerbation, a variety of radiographic findings may be noted. These include peripheral round densities and mucoid impaction seen radiographically as branching opacities. Such findings may be transient and resolve during therapy or be replaced by emergence of frank bronchiectatic or cystic changes. Additional findings, including subpleural blebs, often become evident during the second decade of life and are most prominent along the mediastinal border.[85]

The clinical justification for CT scanning in place of routine chest radiography is not well established. Clear indications may include management of a patient with focal disease being considered for lobectomy or of a patient experiencing acute deterioration—as a means to detect complications or evidence of new infection. Magnetic resonance imaging, which avoids radiation associated with CT, can define lung morphology, particularly as techniques have improved, although relative sensitivity and specificity of magnetic resonance techniques in CF have not yet been firmly established.[86] Recent imaging studies using hyperpolarized gas magnetic resonance imaging have begun to uncover early ventilation defects in young pediatric patients before obstruction is detected by spirometry. These findings correlate with the severity of obstruction; they mirror early defects of ventilation measured on more sensitive testing such as multiple breath washout and confirm that early imaging abnormalities are present in patients with preserved lung function.[87]

LUNG FUNCTION

Lung function in CF is believed to be normal at birth, although recent studies have demonstrated that, within weeks to months of delivery, the cycle of inflammation and infection has begun, and reduced cartilage size very early in life may predispose to airway obstruction.[88] Infants with CF can exhibit increased airway resistance, gas trapping, and diminished flow rates.[89–91] A few centers use infant pulmonary function testing to detect early evidence of airway obstruction and guide institution of therapeutic strategies before permanent lung injury has been established. *Lung clearance index*, a test performed by measuring the time for clearance of an inert gas through the multiple breath washout technique and a test not confounded by patient effort, has emerged as an important research tool used to detect early evidence of ventilation abnormality.[92–94] Reliable and consistent spirometry can be obtained routinely at 5 to 6 years of age, when children are able to cooperate.[95,96]

The earliest evidence of airway obstruction is typically limited to the small airways and thus is often first detectable by reduced forced mid-expiratory flow rates, reduced flows at low lung volumes, and gas trapping (i.e., elevated residual volume to total lung capacity ratio). Although infrequently applied during clinical management, abnormalities such as increased alveolar-arterial oxygen tension difference, frequency dependence of dynamic compliance, reduced response of flows to a helium-oxygen mixture, elevated slope of phase 3 of the single-breath nitrogen washout, and an elevated physiologic dead space are often present.[97] Spirometry is the most clinically useful test to follow the course of respiratory disease progression and is typically measured at each clinic visit. Equally important is assessment of the flow volume loop, which may demonstrate obstruction by concavity, with low flows especially in the terminal portion of the curve, earlier than either the *forced expiratory volume in 1 second* (FEV_1) or mean forced expiratory flow from 25–75% of the forced vital capacity. As discussed earlier, early ventilatory defects can be uncovered using imaging techniques in the research setting.

Over time, patients with active CF lung disease typically experience progressive deterioration of lung function. The annualized rate of decline in FEV_1 is approximately 2–3% of predicted FEV_1.[98] Despite recent advances, this progressive loss of pulmonary reserve often accelerates in young adulthood.[99] As respiratory disease progresses, peripheral airway obstruction yields to more generalized blockage and air trapping as increasingly damaged airways cease to contribute to gas exchange, mimicking a restrictive pattern by spirometry.[100]

The chronic cycle of inflammation and infection contributes to CF lung disease, and patients typically exhibit progressive decrements of arterial Po_2. Oxygenation declines slowly throughout life but may not become symptomatically limiting until late in the disease course. Patients who are able to sustain adequate oxygenation usually function well despite the presence of obstructive impairment.

When arterial P_{O_2} values are chronically below 55 mm Hg, patients are at high risk for development of pulmonary hypertension.[101,102] Clinically significant hypoxemia most commonly presents during sleep, particularly during rapid eye movement–associated hypoventilation, and it is a significant factor leading to pulmonary hypertension.[103] Desaturation at rest or with exertion as measured during a 6-minute walk test is a negative prognostic indicator and associated with increased risk of CF mortality.[104] Elevation of arterial P_{CO_2} and FEV_1 less than 30% define end-stage CF lung disease. Patients with FEV_1 less than 30% of predicted, arterial P_{CO_2} greater than 50 mm Hg, or arterial P_{O_2} less than 55 mm Hg have a predicted 2-year mortality of 50% and should be considered for lung transplantation.[105] Other prediction tools can facilitate appropriate patient selection for referral and outperform reliance on any single criterion.[106]

Bronchial hyperresponsiveness is a consistent finding in asthma, but its presence and clinical significance in CF remains controversial.[107,108] Bronchial hyperresponsiveness in CF has been demonstrated during exercise testing, during bronchoprovocation testing, or by the response to bronchodilators, with two-thirds of CF patients demonstrating decreased forced expiratory flows after a bronchoconstrictive challenge. In contrast to cross-sectional studies, repeated tests every 1 to 3 months for a year have demonstrated bronchodilator responsiveness at least once in 95% of subjects.[109] Despite its frequency, the pathogenesis of bronchial hyperresponsiveness in CF is unclear. The finding is unrelated to the severity of pulmonary disease or indices of atopy but appears to be more prevalent during winter months. Hyperresponsiveness diminishes during acute exacerbations of CF lung disease, but often returns as lung function improves following 2 weeks of intensive antibiotic therapy. Patients with CF may also have a lack of response to bronchodilators that may be related to diminished tone in bronchiectatic airways.

Exercise tolerance in CF is related to the severity of airway obstruction.[110] Nearly 50% of patients with moderate to severe airway obstruction may experience oxygen desaturation to below 90% during peak exercise.[111] Persons with CF have higher than expected ventilatory muscle endurance, and this endurance can be further improved with inspiratory muscle training. However, improved inspiratory muscle strength and endurance do not augment exercise performance, suggesting that this is not the limiting factor in exercise.

Exercise therapy in CF has many physiologic and biologic benefits although it does not improve standard spirometry. Nevertheless, standardized aerobic and resistive exercise does improve cardiorespiratory fitness and *quality of life* (QOL) and has been associated with a reduced risk of hospitalization.[112] Maximum oxygen consumption during exercise has been suggested as a better predictor of survival than routine pulmonary function testing, although the test is time-consuming and not available in all clinical settings.[113] Several more clinically efficient measures of physical fitness show strong correlation with maximum oxygen consumption and CF disease prognosis, further reinforcing the notion that improved physical health through exercise may benefit overall clinical status.[114]

UPPER RESPIRATORY TRACT DISEASE

Chronic rhinosinusitis is present in virtually all patients with CF. CF sinus disease manifests as chronic, relapsing symptoms of increased upper airway secretions, moderate airflow obstruction, and widening of the nasal bridge.[115] This can be noted during imaging (eFig. 68.8) as opacification of the paranasal sinuses and has been reported in more than 90% of patients during the first year of life. Nasal polyps are seen in an additional 15–20% of individuals with CF.[116] Nasal polyps usually present towards the end of the first or during the second decade of life and may be the clinical finding that triggers diagnostic evaluation.[117] The presence of acute and chronic nasal obstruction can diminish olfactory function and contribute to diminished dietary intake with subsequent nutritional decline.[118] Despite the presence of pronounced radiographic abnormalities, nasal symptoms can be surprisingly well tolerated. Complaints related to acute or chronic sinusitis manifest in less than 10% of children and approximately 24% of adults.[119,120] Nevertheless, colonization of the upper airway may contribute to lower airway disease (e.g., as a reservoir for CF pathogens), although more recent pediatric literature suggests that there may be discordance between upper and lower airway tract flora.[121] In symptomatic patients, sinus débridement remains a mainstay of therapy for those who have not responded to medical treatments, but there is inconclusive evidence for the role of endoscopic sinus surgical treatment in management of symptoms of lower respiratory tract disease.[122]

COMPLICATIONS OF RESPIRATORY TRACT DISEASE

Atelectasis is present in approximately 5% of CF patients during the first 5 years of life and diminishes in frequency with advanced age.[123] Atelectasis can be lobar or subsegmental, with the right lung most commonly affected, and may develop concurrently with pulmonary exacerbations or in the absence of clinical symptoms. Occasionally, atelectasis results from endobronchial aspergillosis presenting as mucoid impaction and volume loss.[124] In most instances, however, a discrete mucous plug is not evident on bronchoscopy.

Pneumothorax (see eFig. 68.5) is a well-recognized CF complication caused by air trapping and subsequent rupture of subpleural blebs. Although the finding is equal among sexes and fairly rare (about 1% per year), incidence increases sharply with age and disease severity. Up to 20% of adults with CF experience at least one pneumothorax during their lifetime,[125] and recurrence is common. Typical presentations include acute onset of chest pain, dyspnea, respiratory distress, or hemoptysis.[126] Simultaneous bilateral pneumothoraces have been described and may constitute a medical emergency. Tension pneumothorax, which is more common in CF than in other obstructive lung diseases, may be life-threatening. Small asymptomatic pneumothoraces may be discovered in patients on routine surveillance chest radiography.

Hemoptysis is a relatively common event in CF (see eFig. 68.4) and is believed to result from mucosal erosions and bronchial artery hypertrophy, which are a consequence of

chronic inflammation.[127] The presence of hemoptysis correlates with disease severity and is more common in the setting of chronic MRSA infection.[126] Blood streaking in the sputum is a frequent finding and may be intermittent and chronic. Massive hemoptysis (>240 mL blood in 24 hours) presents in approximately 5% of patients during their lifetime.[128] Due to the strong correlation between new-onset hemoptysis and exacerbation of lung infection, initial treatment should include antibiotic therapy, with omission of chest physiotherapy. Typically, aerosol treatments are temporarily held, and measures to promote clot stabilization are considered. There are anecdotal reports describing use of the antifibrinolytic agent tranexamic acid in this setting.[129] Beta-blockade has also been reported to provide benefit during acute and chronic hemoptysis, presumably by reducing blood pressure and blunting the sympathetic response to coughing.[130] Although bronchoscopy can help localize the site of bleeding, emergent bronchoscopy or radiographic imaging are of limited clinical utility and are not currently recommended in the emergent evaluation of hemoptysis. Instead, rapid assessment for emergent bronchial artery embolization (see eFig. 68.4F–G) is preferred. Advances in invasive vascular intervention and improved clinical management strategies have resulted in significantly reduced mortality, which was historically as high as 10% following massive hemoptysis.[131](See also Chapter 40.)

ABPA has a lifetime incidence of 2–8% among CF patients, although a few small cohort studies have reported incidence as high as 20%.[132,133] *Aspergillus* is a common environmental mold and is frequently recovered in sputum culture. Although up to 50% of patients with CF may demonstrate precipitating antibodies to *A. fumigatus* in their serum, an immunoglobulin E (IgE)-mediated allergic hypersensitization must develop to manifest symptoms of ABPA infection.[134] Clinical features include increased cough, dyspnea, wheezing, and expectoration of rusty-brown plugs with eosinophilic infiltrates by microscopy. Radiographic findings can be present, including a characteristic finger-in-glove pattern (see Fig. 96.7). Atelectasis and volume loss may also result from hyphae-laden mucoid impaction in segmental bronchi. A diagnosis of ABPA is made by fulfilling major and minor criteria that include characteristic clinical findings plus skin test hypersensitivity, elevated total IgE, and increased levels of IgG and IgE antibodies against *A. fumigatus* or other fungi.[78] (For full details on diagnosis, see Chapter 96.)

Staphylococcal and pseudomonal empyemas have been described in patients with CF, but respiratory tract infections typically spare the pleural space, making complications such as pleural effusion and empyema uncommon. Nonetheless, pulmonary exacerbations commonly present with pleuritic-type pain.[135]

Digital clubbing, which is caused by hyperplasia and hypertrophy of connective tissue and increased vascularity of the distal phalanges, appears in virtually all patients with advanced CF and is often present early in individuals with active lung disease (see Fig. 18.3). The cause of clubbing is unknown, and the finding may resolve following lung transplantation.[136] Severity generally correlates with extent of lung disease.[137] Hypertrophic pulmonary osteoarthropathy is a common clinical entity presenting with advanced CF lung disease in up to 15% of older adolescents and adults.[102] Radiographic evidence for periostitis may be present in up to 8% of subjects (see eFig. 18.1). Distal aspects of the tibia, fibula, radius, and ulna are most commonly affected. Symptoms can include pain, bone tenderness, swelling, and warmth over the involved areas. Pain with ambulation or following strenuous physical exercise is common.[138] Hypertrophic pulmonary osteoarthropathy is worsened during periods of poorer respiratory health and exacerbation and tends to subside with resolution of pulmonary exacerbation. During end-stage lung disease, persistent joint symptoms may require chronic analgesic therapy. Rare instances of cutaneous vasculitis causing self-limited, painless, palpable purpura, typically involving the lower extremities, have also been reported in CF.[139–141]

Respiratory failure is the greatest contributor to mortality and is the cause of death in more than 90% of CF patients. In early CF, hypoxemia is observed during exertion or sleep and progresses in concert with lung disease.[103,142] Hypercapnia is a late finding reflecting advanced pulmonary decline, which often worsens during clinical exacerbation. Pulmonary hypertension and right ventricular dysfunction may develop late in the disease process, resulting in hepatic congestion and peripheral edema.[143] The role of pulmonary hypertension in CF is an area of considerable interest, particularly with regard to determining optimal treatment regimens.[144] Hypoxemia, if not recognized or adequately treated, contributes to worsening pulmonary hypertension and cardiac failure. Pneumothorax, hemoptysis, and infections such as respiratory syncytial virus or influenza can cause acute respiratory failure that is reversible with aggressive treatment.[145,146]

GASTROINTESTINAL MANIFESTATIONS

Meconium ileus is observed in approximately 15% of newborns with CF and is highly specific for the diagnosis of CF in the neonatal period. Failure to pass thick inspissated meconium during the first 48 hours of life is associated with abdominal distention and rapidly advances to bilious emesis. Affected infants are at risk for intestinal perforation and peritonitis accompanied by shock. Radiographic features are typical of high-grade bowel obstruction and reveal multiple dilated loops of intestine and air-fluid levels (eFig. 68.9). A granular appearance of the lower abdomen may be noted due to accumulated meconium containing small air bubbles. The colon is characteristically small when visualized with contrast imaging (eFig. 68.10). Scrotal and peritoneal calcification may be observed if the ileum has perforated in utero. Meconium obstruction of the colon can also interfere with passage of stool, but it presents a distinct clinical scenario that has been termed the meconium plug syndrome and is much less specific for CF.[147]

Beyond the newborn period, approximately 20% of CF patients develop the distal intestinal obstruction syndrome annually. This relatively common sequela is characterized by obstruction in the cecum, proximal colon, or terminal ileum associated with voluminous, viscous, and incompletely digested intestinal contents and is otherwise similar to meconium ileus (eFig. 68.11). Partial obstruction may manifest as a chronic or recurrent condition with intermittent crampy abdominal pain as the only symptom. Fulminant, complete obstruction is associated

with failure to pass stool, resulting in abdominal distention and vomiting that may be bilious or fecal if allowed to progress. A mobile right lower quadrant mass may be palpable. Risk factors for distal intestinal obstruction syndrome include previous episodes, dehydration, change of diet, immobilization, bacterial overgrowth, hospitalization for pulmonary exacerbations, treatment with antibiotics, and constipating medications. Other causes of acute abdominal pain with obstruction should also be considered, including intussusception, intestinal adhesions from previous abdominal surgery, and appendicitis, which may be clinically less evident due to concurrent antibiotic therapy.[148] Appendicitis is thought to be uncommon in CF, with a 2% lifetime risk compared with 7–8% risk in the general population.[149] Nonfilling of the appendix with contrast enema has been observed in patients with CF. Radiographic and histologic findings of a dilated, mucus-filled appendix are typical features,[150,151] although the uninflamed appendix is also frequently enlarged on CT in the absence of appendicitis (eFig. 68.12). Inadequate pancreatic and bowel secretion of bicarbonate in CF may also contribute to duodenal irritation and recurrent epigastric pain by failing to buffer gastric acid.[152]

Gastroesophageal reflux is prevalent in CF, in part due to increased abdominal pressure associated with obstructive lung disease resulting in decreased lower esophageal sphincter tone. In addition, a direct effect of gastric acidification due to CFTR protein dysfunction resulting in decreased buffering capacity in the stomach may contribute.[153] Consideration of gastroesophageal reflux is important because the condition can impair nutritional status and may contribute to microaspiration, accelerating respiratory decline. The presence of gastroesophageal reflux has been associated with worsened outcome after lung transplantation, and patients with CF considered for transplant should be evaluated thoroughly in this regard. Certain transplant centers recommend surgical therapy for ongoing reflux during the peritransplant period.[154]

Rectal prolapse develops in nearly 20% of children with CF but is an infrequent event for adults.[155] Rectal prolapse in a child should raise suspicion for an underlying CF diagnosis, even if this is the only clinical finding. The clinical diagnosis of prolapse is often precipitated by the presence of bulky, sticky stools that adhere to rectal mucosa, associated poor nutritional status, and loss of perirectal fat that normally supports the rectum, as well as presence of high intra-abdominal pressure due to frequent paroxysmal coughing.

Colorectal carcinoma in adults with CF is up to10 times more frequent than in the general population, probably as a consequence of chronic inflammation. Colorectal carcinoma is up to 30 times more frequent in CF patients after organ transplantation, probably due to the additional risk associated with immunosuppression.[156] Current recommendations include colonoscopy screening at age 40 years with 5-year rescreening and 3-year surveillance intervals (unless a shorter interval is indicated by individual findings) and a CF-specific intensive bowel preparation.[156] Organ transplant recipients with CF should initiate colorectal screening at age 30 years within 2 years of the transplantation because of their additional risk.

PANCREATIC DISEASE

Exocrine pancreatic insufficiency, due to intraductal obstruction by thickened, dehydrated secretions, is present from birth in approximately 85% of patients with CF.[157,158] Adequate exocrine pancreatic secretion is present in up to 15% of patients and has been associated with certain (residual function) *CFTR* genotypes. Insufficient release of pancreatic enzymes into the gut impairs fat and protein digestion and reduces absorption by the small bowel. Pancreatic insufficiency results in frequent bulky, greasy, foul-smelling stools and protuberance of the abdomen due to increased intraluminal bacterial gas production. Assessment of pancreatic function by enzyme-linked immunosorbent assay measurement of stool fecal elastase-1 is diagnostic in the clinical assessment of pancreatic insufficiency.[159] Complete fatty replacement of the pancreas is common, as judged by CT (eFig. 68.13), and pancreatic lipomatosis and fibrosis are characteristic of pediatric CF. Pancreatic ductal dilation and calcifications are also observed in CF patients. Rarely, there may be cystic replacement of the pancreas, referred to as pancreatic cystosis.

Untreated malabsorption due to exocrine pancreatic insufficiency results in nutritional failure and impaired linear growth, which has been linked to worsened clinical outcomes.[160] Patients with CF often grow slowly because of factors other than poor nutritional intake and intestinal malabsorption. For example, increased expenditure of energy to accomplish the work of breathing may be an important contributor, and systemic inflammation may also play a role.[158] Fat-soluble vitamin deficiency due to nutritional failure was historically common in young children with CF but is much less common in the era of early diagnosis via newborn screening with early vitamin and pancreatic enzyme replacement.

Symptomatic pancreatitis with paroxysmal pain develops in less than 1% of adolescent or adult CF patients, usually in those who maintain at least some residual exocrine pancreatic function.[161] Recurrent painful pancreatitis can be the presenting feature of CTFR-related disorders.[162,163]

HEPATOBILIARY DISEASE

Diagnosis of cystic fibrosis liver disease[164] is formally made by the presence of two or more of the following: hepatomegaly and/or splenomegaly, confirmed by ultrasonography; abnormalities of alanine aminotransferase, aspartate aminotransferase, and γ-glutamyltransferase greater than 1.5 to 2 times the upper limits of normal for more than 6 months after excluding other causes of liver disease; ultrasonographic evidence of coarseness, nodularity, increased echogenicity, or portal hypertension; or, liver biopsy showing focal biliary cirrhosis or multilobular cirrhosis. Histologically, CF liver damage manifests as focal biliary cirrhosis and has produced clinically significant liver pathology in greater numbers of CF patients as they live longer. One description of clinically significant disease includes the constellation of an abnormal physical exam, characteristic liver function testing, and radiographic findings.[165] Liver disease may present as hepatosplenomegaly or most commonly as persistent elevation of hepatic enzymes (aspartate aminotransferase/alanine aminotransferase and/or bilirubin and γ-glutamyltransferase). Current guidelines

recommend a comprehensive evaluation for CF liver disease when enzymes are greater than 3 times the upper limit of normal or remain 1.5- to 2-fold increased for a period of 3 months. Patients with CF-associated liver disease rarely develop acute fulminant hepatic failure but may progress to advanced cirrhosis, portal hypertension, and clinically significant esophageal varices.[166] Steatosis is a common clinical finding and has been associated with malnutrition, essential fatty acid deficiency, and/or oxidative stress in the setting of CF hepatobiliary dysfunction.[165] Ultrasound is generally used to monitor severity of CF liver injury, including in longitudinal studies.

Biliary tract disease is common in CF. Cholelithiasis develops in approximately 10% of patients but causes significant clinical symptoms in less than 4% of cases.[167] The risk of stone formation is increased due to abnormal ion transport within the gallbladder, which may result in biliary colic or symptomatic cholelithiasis. A small or microgallbladder, seen in 20–30% of CF patients, is of unknown clinical significance.[168]

GENITOURINARY TRACT ABNORMALITIES

The vas deferens is absent in almost all adult men with CF.[169] Semen analysis can be used to identify the 1% of male CF patients who remain fertile. Volume of ejaculate in men with the disease is usually one-third to one-half of normal and exhibits complete absence of spermatozoa in addition to a number of chemical abnormalities that reflect aberrant secretions from the seminal vesicles.[170] Male infertility is increasingly overcome via sperm harvest paired with in vitro fertilization methods, which have become more widespread and effective. The patient and family may consider prenatal genetic testing of partners or spouses and early preimplantation genetic testing if in vitro fertilization methods are used. An increased incidence of inguinal hernia and hydrocele has also been reported.

Although significantly less common than vas deferens atresia, female infertility in CF may be as high as 20%.[171] Many women with CF and advanced lung disease and/or malnutrition are anovulatory. Another obstacle to conception is the presence of thick tenacious cervical mucus and increased endocervicitis. Dehydrated cervical mucus is characterized by abnormal electrolyte and other compositions, preventing the physiologic ferning of midcycle. As a result, CF abnormal mucus is thought to impede normal sperm migration.[171]

Pregnancy in women with CF appears to be increasing as clinical outcomes have improved. A longitudinal study of 325 pregnant women with CF demonstrated 258 live births (79%).[172] Pregnancy in women in a large observational study did not contribute to pulmonary decline or mortality over 2 years.[173] Successful pregnancy and delivery are possible and can be carried out safely, but it is essential that women with CF consider implications to their health as they embark on family planning.[174] CFTR modulators may increase fertility due to effects on cervical mucus; however, recommendations on their use during pregnancy are still emerging. Successful breastfeeding has also been reported among women with the disease.[175]

Urinary incontinence can be seen beginning in adolescence and does not clearly correlate with CF disease severity; rather, incontinence probably reflects chronic cough and increased abdominal pressure due to airflow obstruction.[176]

SWEAT GLAND DYSFUNCTION

Sweat sodium chloride is elevated in most CF patients due to abnormal reabsorption of chloride from the sweat duct lumen in the absence of CFTR (see also earlier). This may predispose individuals with CF to excessive salt loss in certain settings. Young children are especially susceptible to salt depletion, especially when exposed to warm, arid climates or when there is additional salt loss due to vomiting or diarrhea. Children in this circumstance typically present with lethargy, anorexia, and hypochloremic alkalosis and/or hyponatremia.[177]

TREATMENT

OVERVIEW

A concerted effort to address the pulmonary manifestations in a comprehensive fashion has led to improved CF outcomes.[178] Therapies including mucolytics,[179] hydrators of the airway surface,[180,181] inhaled antimicrobials,[182–184] systemic anti-inflammatory treatments,[185–187] and nutritional support are traditional mainstays of CF treatment (Table 68.3). These supportive therapies, in addition to comprehensive care undertaken at organized CF clinical centers, are partly responsible for a steadily improving life expectancy observed over the past 3 decades

Table 68.3 Supportive Cystic Fibrosis Therapeutics by Category

Agent	Predominant Mechanism of Action
RESTORATION OF AIRWAY SURFACE HYDRATION	
Hypertonic saline*	Osmotic increase of airway hydration; expectorant
Mannitol†	Osmotic increase of airway hydration; expectorant
MUCOLYTICS	
Dornase alfa	Cleavage of DNA polymers
ANTI-INFLAMMATORY	
Ibuprofen	Reduction of airway inflammation
ANTI-INFECTIVES	
Inhaled tobramycin	Chronic treatment of *Pseudomonas aeruginosa*
Inhaled aztreonam	Chronic treatment of *P. aeruginosa*
Dry powder tobramycin	Chronic treatment of *P. aeruginosa*
Azithromycin	Anti-inflammatory/anti-infective for chronic *P. aeruginosa* infection
NUTRITIONAL THERAPIES	
AquADEKs	Restoration of fat-soluble vitamin levels
Pancrelipase	Restoration of pancreatic enzyme levels

*Therapy commonly used but not approved by the U.S. Food and Drug Administration.
†Therapy approved in the United States, Europe, Australia, and New Zealand; other approvals under consideration.

in the United States (Fig. 68.5), resulting in a median life expectancy of 41 years in 2012 increasing to 47 years in 2018.[188] Similar improvements have been observed in other developed countries. More recently, treatments that address the basic defect by restoring CFTR function have emerged, resulting in marked clinical improvement for the majority of individuals with CF, promising to transform the disease.[189] Other therapies that address rare *CFTR* alleles not yet impacted by CFTR modulators, including genetic-based treatments, are in various stages of development (Fig. 68.6).

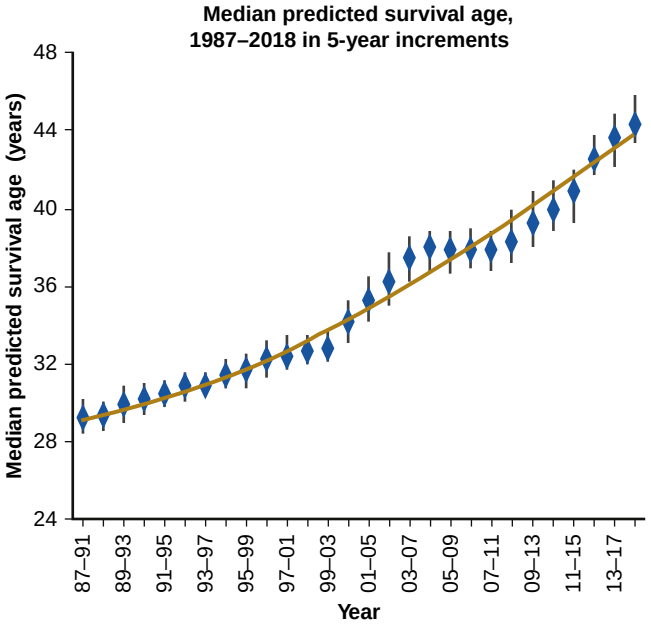

Figure 68.5 Median predicted survival in cystic fibrosis. Median predicted survival for *cystic fibrosis* (CF) patients in U.S. CF centers in the CF registry is depicted as the median for each 5-year time span from 1987 to 2018. Since the mid-1980s, predicted survival has increased from about 27 years of age to older than 40 years for the most recent 5-year time span. (Data from the Cystic Fibrosis Foundation Patient Registry, Bethesda, MD; 2018.)

MONITORING AND AGGRESSIVE APPROACH

Aggressive monitoring and treatment of pulmonary infections and other common CF complications have contributed significantly to improved clinical status in the disease.[99,190,191] Substantial attention has focused on efforts to delay or prevent chronic colonization with *P. aeruginosa,* with a number of studies evaluating various regimens to achieve sustained bacterial clearance. Coincident with this approach is increased attention to infection control as a means to forestall acquisition of virulent organisms, particularly in health care settings where risk from these pathogens is significant. Segregation of clinics by *Pseudomonas* status can reduce spread of highly prevalent organisms (i.e., standard infection control procedures alone may not be sufficient).[192,193] Observations of this type have led to rigorous guidelines for patient isolation and prevention against comingling and consequent infection.[194] Once established, *P. aeruginosa* is challenging to eradicate with antimicrobial therapy alone,[195–199] although this can be accomplished in certain patients,[49] including a subset of individuals initiating CFTR modulator therapy (see later). Chronic colonization with *Pseudomonas* is associated with a more rapid decline in respiratory status.[27,42,200] Virulent organisms such as *B. cepacia*[201,202] confer an even worse prognosis and have been associated with outbreaks due to nosocomial spread. Despite advances in lung function and inhibition of *Pseudomonas* growth, delaying progression of CF disease during adolescence remains a challenge. However, early aggressive care, particularly prior to substantial respiratory decline, is thought to forestall permanent loss of lung function.[203] As with chronic pulmonary infection, early and aggressive nutritional therapy, particularly among young children with CF, has been crucial to achieving improved outcomes.

CF centers have embarked on a rigorous quality improvement program to facilitate best practices in CF care. Outcomes are compared between centers and made publicly available to encourage continuous improvement.[204] A culture of cooperation among centers, patients, families, and the Cystic Fibrosis Foundation has led to evidence-based

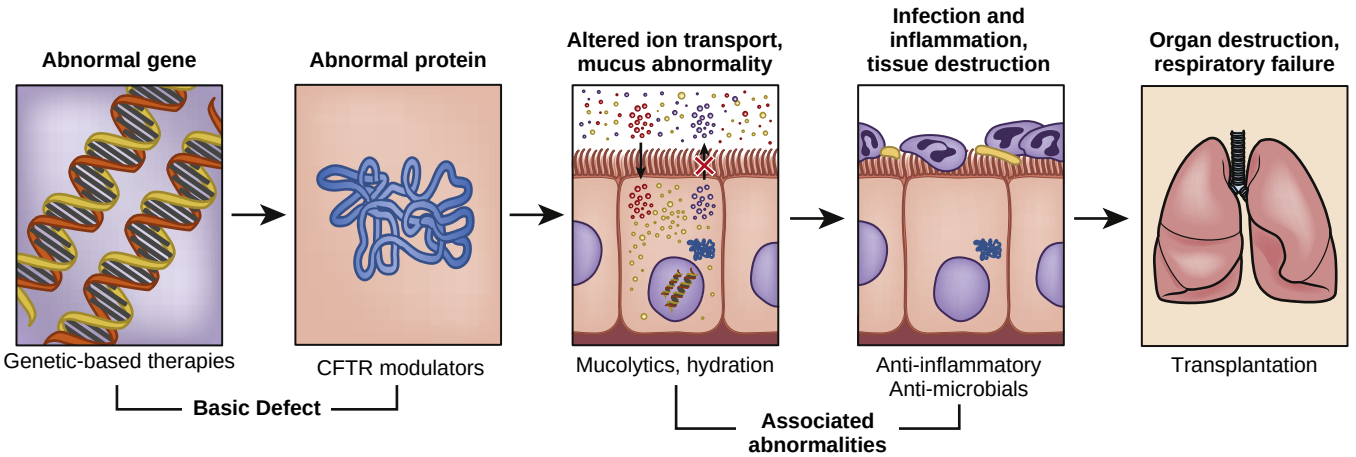

Figure 68.6 *Cystic fibrosis* (CF) therapeutics by category. This figure depicts the mechanisms and possible therapeutics for CF airway pathology. CF therapeutics attempt to address defective *cystic fibrosis transmembrane conductance regulator* (CFTR) function by genetic-based therapy or modulation of CFTR expression or function; to address the diminished airway surface liquid, abnormally viscous mucus, and disrupted mucociliary clearance; and, finally, to treat chronic airway infection and inflammation. When respiratory failure develops, lung transplantation is the remaining option.

guidelines, protocol-driven therapies, and rapid dissemination of results to facilitate advances in health care delivery.[205]

Cystic Fibrosis Transmembrane Conductance Regulator Potentiators, Correctors, and Other Treatments for the Basic Defect

On the basis of functional consequences of various *CFTR* mutations, specific therapeutic strategies to restore deficient or defective protein activity have been developed by altering CFTR expression or function (Fig. 68.7 and Table 68.4). Following ambitious high-throughput drug screening efforts to bolster their discovery,[206–210] benefits of these new CFTR modulators have rapidly come to fruition and expanded beyond initial indications. Rescue of CFTR protein function to sufficient levels, now termed "highly effective," as first established by the archetype CFTR modulator ivacaftor, is associated with marked improvement in the clinical outcome that is dramatically more efficacious than previous therapies.[189,211,212] *CFTR potentiators* activate CFTR channels located at the cell surface by potentiating cyclic adenosine monophosphate–mediated channel gating.[206,213–215] Ivacaftor, a potentiator-type modulator that improves CFTR gating, was the first to be approved and was initially demonstrated in CF patients with the G551D gating mutation, an allele represented in approximately 4% of those with the disease. Subsequently, ivacaftor was also shown to activate 23 additional CFTR alleles as a monotherapy, based on clinical and in vitro data that justified[216,217] expansion of its indications. The highly efficacious treatment benefit observed with ivacaftor therapy led to strong interest in recapitulating the effect among other, more common *CFTR* alleles.[218] This includes correctors of F508del CFTR misfolding, termed CFTR correctors. *CFTR correctors* restore normal CFTR processing of the most common *CFTR* mutation, F508del, and of other alleles with class II properties, and are used in one or two corrector combinations with CFTR potentiators to restore CFTR function. Agents that induce translational readthrough (or suppression) of premature termination codons (class I) to induce expression of full-length CFTR are also under development.[219–222] *CFTR amplifiers* augment translation efficiency and thus increase protein levels, which could augment function for various CFTR genotypes. Approaches beyond these small molecule

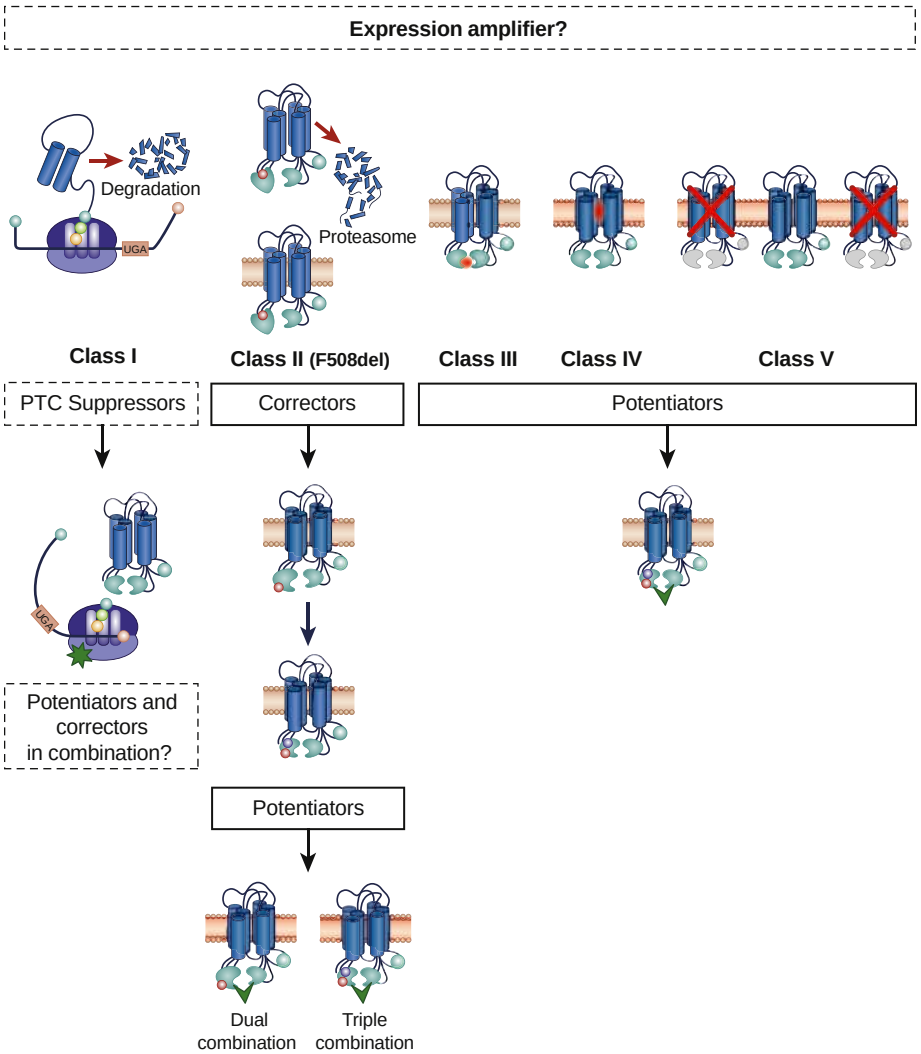

Figure 68.7 Schematic of approach to *cystic fibrosis transmembrane conductance regulator* (CFTR) restoration with small molecules, by mutation class. Therapeutic approaches with definitive studies are shown in solid boxes; those under investigation are noted by dashed boxes. CFTR mutations can be addressed pharmacologically based on their underlying molecular defect (see Chapter 67). CFTR expression amplifiers increase CFTR transcription and/or translation efficiency and would be expected to have broad-ranging effects across mutation classes. Nonsense mutations (a form of class I mutation) have the potential to be restored by *premature termination codon* (PTC)-suppressing drugs that induce full-length functional CFTR protein. Because some protein forms generated by translational readthrough are dysfunctional, the addition of correctors and potentiators may also be needed. Misfolded mutations (class II), including F508del, require multiagent therapy to restore processing and trafficking with a CFTR corrector and then to augment ion channel function with CFTR potentiators. CFTR proteins that are localized to the cell surface but are dysfunctional, or reduced in number, as in class III, IV, and/or V mutations (in addition to class VI, not shown), can be addressed by CFTR potentiators alone. *Green star,* PTC suppressor; *green circles*, correctors; *green chevrons,* potentiators. (Data from Mall MA, Mayer-Hamblett N, Rowe SM. Cystic fibrosis: Emergence of highly effective targeted therapeutics and potential clinical implications. *Am J Respir Crit Care Med*. 2019; and Bell SC, Mall MA, Gutierrez H, et al. The future of cystic fibrosis care: a global perspective. *Lancet Respir Med*. 2020;8[1]:65–124.)

Table 68.4 Approved Therapeutics Targeting Each CFTR Mutational Class

CFTR Modulator Class	Molecule	CFTR Mutations Affected	CFTR Mutation Class Affected
Potentiator	Ivacaftor	G551D/S Non-G551D gating mutations Surface localized CFTR Alleles F508del*	II III IV V
Correctors	Lumacaftor (VX-809) (in combination with ivacaftor)	F508del (homozygous)	II
	Tezacaftor (VX-659) (in combination with ivacaftor)	F508del (homozygous) F508del heterozygous (with residual function mutation)	II
	Elexacaftor (VX-445) (in combination with tezacaftor and ivacaftor)	F508del (homozygous or heterozygous)	II

*Investigational.
CFTR, cystic fibrosis transmembrane conductance regulator.

CFTR modulators are also being advanced. For example, gene replacement by viral and nonviral gene therapy remains an approach under active investigation,[223] as well as newer strategies that attempt to express CFTR through translation of delivered mRNA alone.[224,225] Because many CF patients (≈40%) are complex heterozygotes and encode more than one *CFTR* mutation,[226] combination therapeutics addressing more than one *CFTR* variant or use of multidrug therapy will likely dictate a need for individualized therapeutics optimized for particular patients in the future.[218]

Cystic Fibrosis Transmembrane Conductance Regulator Potentiators. *CFTR potentiators* activate mutant CFTR localized to the cell surface by potentiating channel gating stimulated by physiologic activation of cyclic adenosine monophosphate.[206,210,227–229] The impetus for development included the anticipated need to activate F508del CFTR once localized to the cell surface, in addition to the need to activate other mutant channels residing at the plasma membrane but dysfunctional due to aberrant gating, impaired conductance, or a reduced number of channels due to mild processing mutations or splice variants. Early attempts at potentiation included use of genistein, a natural flavonoid molecule that demonstrates strong activation of CFTR but is poorly absorbed and exhibits other undesirable physiologic properties.[228,230,231] Subsequently, ivacaftor and other investigational CFTR potentiators were discovered via high-throughput screening approaches that identified small-molecule potentiators optimized for druglike qualities through traditional medicinal chemistry approaches.[206,210,228–230] Ivacaftor induced about 50% CFTR activity in G551D/F508del CFTR-expressing primary epithelial cells, a benchmark for preclinical development of CFTR modulators.[206]

In a landmark trial conducted in older children and adults (age 12 years and older) with CF and with at least one copy of the G551D-*CFTR* gating mutation, ivacaftor caused a roughly 10% absolute improvement in FEV_1% predicted at 24 weeks, an effect durable through 48 weeks of testing, providing confirmation of positive prior phase II testing results.[189] In addition, multiple secondary clinical end points showed meaningful and statistically significant improvements, including a 55% reduction in the probability of experiencing a pulmonary exacerbation, improved weight gain, and an improvement in respiratory symptoms. Posttreatment sweat chloride testing also exhibited marked improvements (mean of sweat chloride was about 55 mEq/L, a value below the traditional diagnostic threshold). In a smaller study that enrolled pediatric G551D CF patients 6 to 12 years old,[212] benefit was also documented by lung clearance index measurements in CF patients with minimal detectable lung function abnormality by spirometry, likely reflecting improved function of the small airways.[232] The degree of improvement in spirometry among participants of the phase III trial of ivacaftor compares favorably with that of commonly used therapies for chronic CF care. In clinical studies to date, ivacaftor appeared safe and well tolerated, although monitoring of liver function tests is recommended.[233]

These findings formed the basis of clinical approval for ivacaftor in CF patients with the G551D mutations, and this treatment has rapidly been deployed to children and adults with closely related mutations. Registry-based comparisons demonstrated a reduced rate of decline in FEV_1 in individuals treated with ivacaftor,[234] and multiple studies have demonstrated reduced rates of exacerbation coupled with an approximately 30% reduction in *Pseudomonas* infection rates (depending on the population) that have been durable over time.[32,33,235] Mechanistic evaluations have shown improved airway pH,[236] mucus clearance,[235] mucus plugging,[237,238] and radiographic parameters of mucosal thickening by CT imaging,[239] attributable to the improved CFTR function. More detailed microbiome analyses have shown the potential for rebound of bacterial counts in those that do not eradicate *Pseudomonas*,[35] and measures of airway inflammation have been conflicting. Long-term use has reduced the risk of bacterial acquisition, but initial attempts to augment bacterial eradication with ivacaftor use have not demonstrated efficacy, although further research into this concept is warranted given continued improvements in CFTR modulator efficacy and antimicrobial strategies.[240] The relatively large magnitude of weight gain observed with ivacaftor in CF patients with G551D-*CFTR* has been attributed to its beneficial effect on intestinal pH via bicarbonate secretion that improves enzyme function

and raises the possibility that mucosal integrity might also be improved throughout the gut.[235,241] Other potential avenues for exploration include the effect of CFTR modulation on other manifestations of CF, such as glucose metabolism, innate immunity and leukocyte function, osteopenia, pancreatic insufficiency, and gastrointestinal absorption, many of which may be directly tied to CFTR activity.[242] As ivacaftor approval has extended to younger and younger children with CF, presently age 1 year and older, evidence has emerged that preservation of pancreatic function may be possible[243] and suggests the potential for the rescue of other organs if instituted early in life, as demonstrated in a G551D ferret model.[244]

Ivacaftor also increased CFTR activity in other class III mutations beyond G551D in vitro,[245] and the beneficial effects of ivacaftor were also observed in patients with other non-G551D gating mutations. Patients observed a large increase in FEV_1 and a similar decrease in sweat chloride compared with that seen in patients with G551D, indicating a class effect.[246] Ivacaftor also activates other groups of *CFTR* mutations that allow low levels of partially active CFTR channels to reach the cell surface; such mutations include conductance mutations, mild processing mutations, or noncanonical splice variants (meaning abnormal splicing does not take place with absolute fidelity, as with canonical splice mutations, leaving some channels with the wild-type sequence).[247] The beneficial effect of ivacaftor on partially active missense mutations from these CFTR classes is generally proportionate to basal CFTR function, reflecting the ability of increased gating to compensate in part for reduced surface expression or conductance.[217] In contrast, ivacaftor monotherapy had no meaningful effect in CF patients homozygous for F508del *CFTR*, establishing that CFTR potentiation alone is not effective without concomitant administration of a corrector molecule to bring F508del CFTR to the cell surface.[248] In sum, CFTR potentiator monotherapy can benefit approximately 10–15% of the CF population, noting this is often supplanted by dual corrector-potentiator therapy when a patient also expresses F508del.

Cystic Fibrosis Transmembrane Conductance Regulator Correctors. Significant efforts toward the goal of correcting the folding of F508del CFTR, thus restoring ion channel activity to the misfolded protein, have come to fruition, potentially transforming outcomes and rivaling the benchmark set by ivacaftor in G551D patients. With the use of multiagent corrector potentiator therapy, rescue of F508del CFTR function can be achieved efficiently, making highly effective CFTR corrector therapy applicable to nearly 90% of the population, as defined by genetics.[249] Early attempts included 4-phenyl butyrate to alter protein processing chaperones,[250,251] curcumin, and 8-cyclopentyl-1, 3-dipropylxanthine, which did not successfully translate from in vitro studies to clinical results.[252–254] More recent efforts have resulted from high-throughput library screens for chloride channel function following incubation of test compounds with F508del-expressing cells.[208,210,255] Pharmacologic activity of correctors includes improved processing and trafficking of CFTR and may also affect F508del CFTR half-life in the plasma membrane through altered surface recycling attributed to features of the cellular processing machinery or reduced endocytic trafficking, depending on their underlying mechanism.[256] The correctors now in clinical use, lumacaftor and tezacaftor, have been shown to interact with CFTR directly and may offer greater specificity than agents that alter general aspects of cell folding or cellular quality control.[257,258] Success toward correction of F508del CFTR in patients was first seen during initial phase II testing of lumacaftor (formerly VX-809).[259] Although results established that improved function of F508del CFTR in patients was achievable by a systemically delivered small molecule, the degree of CFTR rescue was insufficient to confer clinical improvement. Because F508del CFTR also exhibits abnormal channel gating, in addition to aberrant cellular processing, an approach to address insufficient activity is to coadminister a CFTR potentiator with a CFTR corrector.[257] Following successful phase II testing,[260] lumacaftor-ivacaftor therapy was shown to be efficacious in individuals homozygous for F508del in two large randomized controlled studies; however, the magnitude of benefit was modest (≈3% improvement in FEV_1 and ≈30% reduction in exacerbations) compared with prior experience with ivacaftor.[261] Long-term studies showed that the improved rates of exacerbation were sustained, and the reduced rate of lung function[262] decline and efficacy has been duplicated in younger patients.[263] Lumacaftor-ivacaftor was also associated with chest tightness upon initiation, a finding more common in individuals with severe pulmonary dysfunction, and lumacaftor induced drug-drug interactions involving CYP metabolism, including the induction of ivacaftor metabolism.[264] An alternative corrector, tezacaftor (formerly VX-661), which has a similar cellular mechanism as lumacaftor but more advantageous pharmacologic properties, resulted in similar efficacy as lumacaftor-ivacaftor (4% FEV_1 improvement), but did not induce chest tightness or induce the drug metabolism of ivacaftor.[265] Further, tezacaftor-ivacaftor was efficacious in people with CF who are complex heterozygotes for F508del CFTR and an array of CFTR mutations that are partially functional and responsive to ivacaftor in vitro; in these individuals, the magnitude of benefit was approximately 7% predicted FEV_1, reflective of both correction of the F508del mutation and potentiation of the residual functional allele.[217] Neither lumacaftor-ivacaftor nor tezacaftor-ivacaftor benefited CF patients heterozygous for F508del *CFTR* and a minimal function allele that does not respond to ivacaftor, providing evidence of a gene-dose effect but also illustrating the need to address this sizable population.[266]

Despite the success of corrector-potentiator therapy, the activity of correctors is inherently less efficient than potentiators for CFTR gating mutations, likely because F508del and trafficking is a multistep process, limiting the potential of any single pharmacologic intervention. Additive or synergistic rescue of F508del CFTR using more than one corrector with distinct mechanisms of action on the cellular level could potentially overcome this limitation, leading to efforts to advance multiagent corrector therapy, to be combined with CFTR potentiators.[267] The next-generation correctors, elexacaftor and other related agents, were discovered via high-throughput screening programs conducted in the presence of tezacaftor.[268,269] When used in combination, elexacaftor-tezacaftor-ivacaftor delivered pronounced efficacy in vitro, meeting or exceeding levels observed with

ivacaftor in gating mutations, including in cells derived from individuals with only a single responsive F508del allele. Initial clinical results matched this pronounced benefit in patients heterozygous for F508del and a minimal function allele in comparison to placebo and in patients homozygous for F508del in comparison to tezacaftor-ivacaftor.[268] In confirmatory testing, results were recapitulated, with patients heterozygous for F508del and a minimal function allele exhibiting an approximately 14% improvement in FEV_1, a 50% reduction in exacerbations, and sweat chloride changes that were greater than 50 mmol/L.[270] Patients homozygous for F508del experienced a 10% additional improvement in FEV_1 over tezacaftor-ivacaftor comparator therapy.[271] Overall, prior experience guided by ivacaftor use in patients with gating mutations suggests highly effective CFTR modulator therapy is likely to be transformative and could substantially alter the progression of disease if initiated prior to substantial lung dysfunction. Longer-term evaluation studies are in progress, as are efforts to examine efficacy in patients younger than 12 years.

Presently, multiple other corrector-potentiator regimens are also in development with potentially unique pharmacologic features that could be advantageous. Successful further development could set the stage for comparator studies in the future or attempts to optimize CFTR modulator therapy at the individual level using cell-based assays or other techniques. There are also pronounced efforts to understand how highly effective CFTR modulator therapy could be brought to bear on rare mutations that may be susceptible to improved activity with various correctors and potentiators. Given that exceedingly rare mutations make up a disproportionately large number of patients in whom CFTR modulator therapy is not yet proven, alternative approaches beyond routine clinical trials will be needed to foster availability of effective modulator therapy to this group of patients.[272]

Translational Readthrough. Readthrough of *premature termination codons* (PTCs) represents a potential approach to address CF caused by nonsense mutations, which could also be applicable to many other genetic diseases. The approach was identified when certain aminoglycoside antibiotics were found to interact with the eukaryotic rRNA within the ribosomal subunits.[273] Through this interaction, the fidelity of eukaryotic translation can be altered by interrupting the normal proofreading function of the ribosome.[274–280] Insertion of a near cognate amino acid at a PTC allows protein translation to continue normally.[275] Specificity is conferred by greater termination codon fidelity at the authentic (3′) end of mRNA and has been established in vitro by demonstrating that there is no detectable elongation beyond native termination codons.[281–284] This has subsequently been investigated as a potential approach to a number of relatively common genetic diseases aside from CF in which premature termination codons are relatively prevalent, including Duchenne muscular dystrophy,[285–287] Hurler syndrome,[1,288,289] ceroid lipofuscinosis,[290] nephropathic cystinosis,[291] and expression of mutated p53.[292]

Proof of concept experiments with aminoglycosides established that PTCs within *CFTR* in human subjects can be suppressed, resulting in the synthesis of full-length, functional CFTR protein.[281–284,293] The approach has also demonstrated success in mouse models of CF.[294,295] Following two small pilot trials indicating restoration of chloride secretion in CF subjects harboring PTCs,[284,284] a double-blind, placebo-controlled trial showed correction of nasal ion transport specifically in subjects with nonsense mutations following topical administration of gentamicin and, as expected, not in CF controls homozygous for F508del.[283] A trial examining systemic gentamicin in seven French subjects with Y122X *CFTR*, a mutation highly susceptible to readthrough therapy, also indicated rescue of CFTR activity in the airway and sweat duct.[181] Not all aminoglycoside trials in CF have demonstrated success, suggesting variable levels of protein correction.[296] Regardless, due to the known toxicity and poor bioavailability of aminoglycosides, more efficacious agents that avoid undesirable properties of aminoglycosides will be needed for the long-term genetic treatment of CF. One promising approach uses medicinal chemistry optimization to identify the antimicrobial, toxic, and readthrough effects of aminoglycoside scaffolds, a strategy demonstrating initial success using in vitro reporters of efficacy and toxicity,[297] and cell- and animal-based models of CFTR rescue.[298] Addition of CFTR correctors and potentiators have the potential to augment function further by activating the processing and function of CFTR readthrough products, which include missense mutations from near-cognate amino acid insertion.[299,300]

Other attempts to address nonsense mutations include novel compounds without the disadvantages of aminoglycosides, and efforts remain ongoing in this regard. One such molecule, ataluren (formerly PTC124), induced translational readthrough in experimental systems.[301,302] Although the agent is available for the treatment of Duchenne muscular dystrophy, clinical development ultimately failed for people with CF[303] after mixed results in preceding clinical trials[220,293,304,305] that raised questions about insufficient efficacy.[306,307] The effects of readthrough agents are likely substantially affected by low levels of steady-state *CFTR* mRNA due to nonsense-mediated decay. The level of nonsense-mediated decay has been associated with readthrough efficacy and may need to be addressed to achieve effective CFTR rescue.[220,308] Given new knowledge regarding the best models to identify and optimize CFTR drug candidates that has emerged since the identification of ataluren, it is possible that identification of new chemicals using alternate readthrough assays that incorporate the influence of nonsense-mediated decay might yield more efficacious compounds. Other strategies such as pseudouridinylation of the mRNA encoding nonsense mutations or gene editing the PTC sequence are in early development.[309]

Gene Therapy

Within years after discovery of the *CFTR* gene, initial enthusiasm for gene therapy was robust, but variable efficiency of vectors coupled with heterogeneous transgene expression and adverse effects from inflammation impeded progress in this area. Using NPD as an outcome, viral vectors demonstrated transgene delivery using adenovirus[310,311] and adeno-associated adenovirus,[312] but positive results have not been observed by all groups conducting studies of this type.[313] Improvements in Cl^- transport using lipid-based gene transfer vectors were initially limited to modest changes,[314–316] improvements in specific subgroups,[315–319]

or inconsistent CFTR expression[320–322] and therefore were not convincing. Depletion of immunogenic CpG motifs for plasmid delivery used during a large, long-term clinical trial by the UK Gene Therapy Consortium demonstrated safety and provided a roadmap for trials of this sort, but efficacy was again not convincing.[323] With the success of gene therapy in immune-privileged organs such as the eye, research into CF gene therapy has experienced renewed vigor, with the goal of a "one-time cure," especially for those not helped by CFTR modulator treatment. Use of the latest adeno-associated and hybrid lentiviral-based gene transfer is a major emphasis, but limitations including cargo size (noting *CFTR* is a large gene), durability of gene integration, and possible off-target effects remain challenging. Alternative approaches such as gene editing with CRISPR-Cas9 are also engendering considerable interest, although the efficiency of homology-directed repair of the target has been challenging thus far. All gene therapy approaches must navigate past the mucociliary barrier and must target specific cell types, such as basal progenitors, to induce sustained expression, unless repeat administration is envisioned.[324,325]

mRNA Replacement and Other Nucleotide Repair Strategies

Splicing mutation represents a relatively common minority of *CFTR* alleles seen in patients with CF. For example, one CF mutation is 3849+10kb C→T, which leads to inclusion of an 84-base pair cryptic exon in the mature mRNA.[326] This cryptic exon contains an in-frame nonsense codon, which leads to production of truncated nonfunctional proteins. Splicing machinery is heterogeneous both among patients and also among tissues within an individual, resulting in relatively heterogeneous expression of the disease. This forms the basis of examining usefulness of a CFTR potentiator in patients with relatively preserved CFTR expression due to alternatively spliced forms of CFTR and partially retained expression, and ivacaftor is now approved in the United States for the treatment of several noncanonical splice variants. The variation in splicing efficiency can also be exploited using antisense oligonucleotides to induce normal splicing by masking mutant splice sites.[309] Although this would require specific antisense oligonucleotides to be developed for each *CFTR* splice mutation, use of such technology has shown therapeutic efficacy in Duchenne muscular dystrophy.[327] Full-length RNA transduction is also being pursued for the treatment of genetic diseases and is being exploited in CF, with sequences optimized for translation efficiency. As with gene therapy, similar challenges with delivery of nucleotides and dependence on cell type will need to be addressed with these therapeutic strategies. To that end, editing the RNA sequence with nasal delivery showed promise using NPD as an outcome,[328] but it did not improve lung function following inhalation.[329]

RESPIRATORY THERAPIES

Physical Airway Clearance

The combination of cough augmented with chest vibration or percussion to loosen mucus represents a cornerstone of the daily care of CF to reduce airway obstruction and prevent CF exacerbations.[330] Daily clearance maneuvers, including chest physiotherapy by vibropercussion, hand-administered therapy, or the chest physiotherapy vest clearance systems, are considered standard of care.[331,332] Alternative airway clearance techniques include positive expiratory pressure, huff coughing, and the use of vibratory flutter valves.[332]

Exercise therapy can provide additional improvement in mucus clearance in concert with physical maneuvers.[333] Standardized, aerobic exercise programs targeting 70–85% of maximal heart rate have demonstrated benefits with regard to exercise tolerance but do not improve lung function. Similar results have been obtained in isometric exercise programs.[334] Supervised pulmonary rehabilitation in severe CF lung disease can be an important supportive modality (see also Chapter 139).

Airway Rehydration Therapy

Rehydration of the airway surface liquid to augment mucociliary clearance can be achieved with nebulized *hypertonic saline* (HTS), which causes a durable increase in mucociliary clearance in CF subjects.[181] A multicenter, randomized, placebo-controlled trial of HTS showed a modest improvement in pulmonary function and a 56% reduction in frequency of CF pulmonary exacerbation despite relatively poor compliance.[180] Evidence suggests that the effects of HTS are additive to rhDNase.[180,335,336] In infants too young for reliable spirometry, HTS improved infant pulmonary function tests ($FEV_{0.5}$) and lung clearance index, an effort-independent measure of pulmonary obstruction through inert gas washout, although it did not alter an already low rate of pulmonary exacerbations.[337] Confirmatory studies have established that lung clearance index improvements are reproducible and associated with other indicators of clinical benefit, such as weight gain.[82,338,339]

Because a minority of subjects develop bronchospasm following administration of HTS, inhaled β_2-agonist is generally recommended before HTS dosing; moreover, HTS should be used cautiously in those with severe pulmonary obstruction. Many patients exhibit excessive cough following HTS administration (a feature that limits use), although this will often decrease with repeated HTS use.[180] Lower concentrations (3%) can sometimes be used when excess cough or bronchospasm is a problem with the standard HTS (7%).

Airway treatments with the nonabsorbable sugar mannitol to hydrate the mucosal surface by generating an osmotic gradient represent an alternative to HTS. Following success in early-phase trials,[340] two large-scale clinical trials demonstrated reduced exacerbations and a small increase in lung function.[341,342] On the basis of this success, inhaled mannitol therapy is approved for use in some countries (including the United States in 2019), though intolerance of dry powder inhalation has been a barrier to substantial uptake. Other strategies to circumvent CFTR by inducing non–CFTR-dependent fluid secretion or inhibiting epithelial sodium channel–mediated fluid resorption remain an active area of research and clinical development.[343]

Dornase Alfa

Use of inhaled recombinant human dornase alfa, a pharmacologic treatment to improve the physical properties of mucus, has been shown beneficial in randomized, placebo-controlled trials among CF subjects and was among the first

CF-specific medicines to be approved for respiratory disease. Dornase alfa causes dissolution of excess DNA debris that accumulates due to bacterial infection, mucus stasis, and the large influx of neutrophils into the CF airway lumen. The drug augments pulmonary function, diminishes frequency of pulmonary exacerbation, and enhances QOL.[179] Trials examining dornase alfa therapy in individuals with severe CF pulmonary disease (forced vital capacity < 40% predicted) also show benefit.[344] With regard to milder lung disease, dornase alfa stabilized inflammatory markers in bronchoalveolar lavage fluid of young children[345] and improved radiographic measures of gas trapping,[346] suggesting the potential to benefit even when mucus production is not clearly evident. The treatment also improved ventilation inhomogeneity as determined by the lung clearance index in pediatric patients with minimal decrements in spirometry.[347] Thus, dornase alfa therapy is recommended for CF patients in all ranges of disease severity.[348]

Inhaled Antibiotics

Refractory infection is a sine qua non of bronchiectasis, and aggressive antimicrobial therapy is a mainstay of chronic CF care. The inhaled route provides higher doses of antibiotics directly to the mucopurulent airways, and several treatment strategies have been shown to improve CF lung function and reduce pulmonary exacerbations. Intermittent use of chronic inhalational antibiotics is intended to target the airways while avoiding systemic toxicity and to limit emergence of bacterial resistance through continuous selection pressure. The first drug to be approved for this purpose was inhaled tobramycin, which has been shown to improve pulmonary function, reduce exacerbation rate, and increase weight gain compared with placebo when administered twice daily during alternate 4-week periods.[82,349] Concerns about daily burden of therapy and patient nonadherence have led to the development of a dry powder formulation, which was shown to be noninferior to conventional nebulized tobramycin and improved patient satisfaction when tolerated.[182]

The inhaled monobactam aztreonam has also been developed for chronic use in CF. Initial studies demonstrated improved QOL and a prolonged gap between exacerbations.[350,351] In a large 6-month trial involving CF patients older than 6 years who previously used inhaled tobramycin, improved FEV_1 and reduced exacerbations were observed with inhaled aztreonam given every other month[352] compared with inhaled tobramycin every other month. A similar study in subjects with milder lung function abnormalities demonstrated more modest improvements in FEV_1 and QOL.[353] Inhaled colistin is often used as an alternative antipseudomonal agent in subjects with resistant strains, although it is not approved by the U.S. Food and Drug Administration for this purpose and is associated with side effects such as bronchospasm.[82,354,355]

It is not yet clear which antimicrobial agent is best for individual patients, and the choice of agent is generally driven by the dominant pathogen, antimicrobial resistance patterns, and patient preference. Nevertheless, antimicrobial resistance profiles do not predict clinical response effectively. The difficulty in predicting response is probably due to intrinsic resistance conferred by biofilms and intermicrobial interactions that alter susceptibility in the lung but are not modeled in routine clinical bacterial culture methods, a limitation that poses substantial clinical challenges in antibiotic selection.[356] Continuous alternating 28-day cycles of inhaled tobramycin and aztreonam for individuals who experience increased infection or symptoms during off-cycle are frequently used and may be beneficial.[357] A number of other inhaled therapies are in development, and treatments that target dissolution of biofilms are of particular interest.

Bacterial Eradication

The primary morbidity and mortality in CF are attributable to obstructive respiratory disease associated with chronic endobronchial infection by opportunistic bacteria. *P. aeruginosa* infection is clearly associated with decline in respiratory function, and early acquisition of *Pseudomonas* is associated with increased morbidity and mortality.[27,358–363] Consequently, infection and eradication via treatment with anti-pseudomonal antibiotics has been sought as a means to sustain lung function and delay mortality.[44,364] Early bacterial isolates from CF lungs are present at lower density, are generally nonmucoid, and display favorable microbial resistance profiles, reflecting a potential window of opportunity for treatment and eradication.[365,366] As noted earlier, *Pseudomonas* infection becomes more prevalent with increasing age; positive respiratory tract cultures are reported in up to 30% of infants, 30–40% of children aged 2 to 10 years, and 60–80% of adolescents and adults.[367] Newborn screening for CF allows earlier identification of *P. aeruginosa* infection in children prior to onset of significant lung disease that limits efficacy of treatment. Following detection of *P. aeruginosa* in asymptomatic children, standard of care includes clinical interventions to eradicate the organism. Antimicrobial regimens differ depending on the clinical setting but, for individuals detected by surveillance, 28-day treatment periods with inhaled antibiotics are sufficient to achieve reasonable eradication rates.[368] More aggressive strategies should be reserved for extenuating circumstances, such as with clinical deterioration or advanced disease. Although several studies have validated efficacy of various treatment regimens, no single approach has demonstrated clear superiority.[369] Suppression and eradication of *Staphylococcus* species, including MRSA, is possible and is possibly associated with clinical benefit.[370,371] Of note, prophylaxis for *S. aureus* has led to increased *Pseudomonas* infection, warranting caution.[372]

Macrolide Therapy. Although macrolide antibiotics do not exhibit significant antipseudomonal properties, the utility of these agents in diffuse panbronchiolitis, a rare disease that resembles CF (including chronic infection with *P. aeruginosa*), led to therapeutic trials in CF patients.[373–376] In a multicenter, randomized, placebo-controlled trial, alternating-day oral azithromycin demonstrated improved pulmonary function accompanied by a large reduction in pulmonary exacerbations.[377] Similar results were seen in a Canadian study using clarithromycin.[378] Beneficial effects of azithromycin have also been observed in CF patients not chronically infected with *Pseudomonas* (presumably due to less well-described anti-inflammatory effects), suggesting a contributory mechanism independent of antimicrobial properties. One large clinical trial demonstrated reduced rates of exacerbation,[379] although

an FEV_1 benefit was not observed. On the basis of current evidence, present guidelines assign a lower priority for chronic azithromycin in noninfected patients.[185] However, the use of azithromycin in young children has become more common because several trials have demonstrated safety and efficacy in decreasing pulmonary exacerbations and improving health metrics such as nutritional health. The rising incidence of NTM infections raises concern about long-term use of azithromycin due to the potential for inducible macrolide resistance. Some data suggested increased risk of promoting infection by NTM mycobacteria,[82] although this has been refuted by epidemiologic studies.[380] Nevertheless, annual screening for NTM is recommended and is particularly important among azithromycin-treated patients. Azithromycin use may inhibit the efficacy of inhaled tobramycin, a finding under evaluation in prospective clinical studies.[381]

Anti-inflammatory Therapy

Intense neutrophilic inflammation is characteristic of CF and remains a therapeutic target that has not been fully exploited.[69,382–384] Early trials utilizing chronic, alternate-day systemic corticosteroids showed a beneficial effect of prednisone (1 mg/kg) on CF lung function, but use remains limited by steroid toxicities, and chronic corticosteroid therapy is not generally recommended.[385–387] Inhaled steroids have frequently been studied in small trials. In some studies, reduced airway reactivity has been observed, but sustained effects on lung function have not been shown.[388,389] Use of oral steroids in CF is generally limited to individuals with an asthmatic phenotype. Concerns include the potential for bone demineralization, adrenal suppression, and growth retardation in pediatric patients.

A number of other anti-inflammatory molecules have been studied in CF, although identifying an appropriate therapeutic window that allows blockade of excessive inflammation without causing increased susceptibility to infection has been difficult. High-dose ibuprofen, a nonsteroidal anti-inflammatory drug, has been shown to diminish the rate of pulmonary function decline, but beneficial effects appear greatest in young children.[390] Other studies have confirmed these findings.[187,391] Despite this evidence, nonsteroidal anti-inflammatory drug therapy is not widely utilized in the United States due to concerns of chronic toxicities, particularly in older individuals, and the need for pharmacokinetic monitoring to achieve adequate serum levels.[392] For example, inadequate levels have been associated with paradoxical proinflammatory effects, leading to increased neutrophil migration.[187,393]

Attempts to extend the observed benefits of anti-inflammatory therapy to other eicosanoid-active agents (e.g., leukotriene inhibitors) have indicated variable results, including studies showing increased pulmonary complications with a nonselective leukotriene B4 antagonist.[394,395] Synthetic cannabinoids and more specific leukotriene modifiers are presently in development to improve efficacy. Along similar lines, initial attempts to block protease activity with inhaled antitrypsin were not effective,[396] although other inhaled neutrophil elastase inhibitors are under consideration. Other agents such as 3-hydroxy-3-methylglutaryl coenzyme reductase inhibitors, hydroxychloroquine, and methotrexate have not demonstrated convincing benefit, illustrating the challenge of successfully targeting this mechanism, which may be suited to young patients with less-established disease and fewer activated inflammatory pathways. Development remains challenging given limitations in anti-inflammatory biomarkers to guide early advancement, and given the large number of subjects needed to demonstrate reductions in exacerbations compared to improvements in lung function.[397]

OTHER SUPPORTIVE CARE

Pulmonary Exacerbations

Exacerbations of CF pulmonary disease are characterized by increased cough and sputum production, respiratory distress, diminished exercise tolerance, weight loss, decreased spirometry, worsened hypoxemia, or development of a major pulmonary complication such as hemoptysis.[398–401] Treatment includes intensified airway clearance measures and systemic antimicrobial therapy generally directed against the most recently acquired pathogens. Both inpatient and outpatient treatment are utilized; factors important to consider during management include severity of disease, baseline lung function, microbial organisms and resistance pattern, presence of additional complications, and the ability to adhere to an outpatient regimen. Acute pulmonary exacerbation is the most common indication for hospitalization in CF and is warranted when episodes are severe, refractory to outpatient care, or not suited to home therapy for psychosocial reasons. Hospitalization facilitates controlled administration of intravenous antibiotics to address exacerbating infections and provides a setting conducive to sustained intensification of chest physiotherapy. Although the historical standard for pulmonary exacerbations is hospital-based treatment, outpatient management that includes use of parenteral antimicrobials and mucus clearance procedures may achieve equivalent outcomes in appropriately selected patients.[402] In general, the primary goal in this setting is to improve clinical symptoms and to return pulmonary function to baseline. In some patients, however, lung function does not return to previous levels despite clinical improvement and can decline further in the days to weeks following intervention.[403–405] A severe decrement in spirometry from baseline at the onset of pulmonary exacerbation is a major risk factor for sustained loss of lung function, suggesting the need for early and aggressive treatment.[404–406]

Antibiotic therapy should be broad based due to the polymicrobial nature of CF lung disease and is typically selected on the basis of respiratory tract culture and susceptibility results. Notwithstanding this recommendation, in vitro sensitivity profiles are poor predictors of clinical response, indicating significant limitations to the general strategy.[406] Treatment of *Pseudomonas* is the first consideration, and two mechanistically distinct antibiotics should be administered to maximize efficacy. In some clinical scenarios where oral therapy is used, fluoroquinolones as single agents are a mainstay but can be associated with the risk of promoting bacterial resistance.[407] Aminoglycosides have optimal antimicrobial activity as intravenous

anti-*Pseudomonas* drugs but require careful monitoring to optimize therapy. Traditional dosing of aminoglycosides two to three times a day has shifted in favor of once-daily dosing.[408,409] Aminoglycoside schedules in the range of 8 to 12 mg/kg once daily achieve higher peak concentrations (20 to 30 μg/mL) that potentiate bactericidal effect and limit toxicity by extending the duration of low, near-trough drug concentrations, which approach undetectable levels in the setting of normal renal function.[100,410] Patients should be monitored during aminoglycoside therapy for emergence of nephrotoxicity and ototoxicity. Aminoglycosides are usually paired with a β-lactam to maximize efficacy. A third antibiotic may also be useful for controlling MRSA or other atypical organisms. Although there is no consensus regarding duration of therapy, a clinical response with respect to symptoms or pulmonary function is usually apparent 4 to 7 days after initiating treatment, depending on severity of the initial decrement and degree of underlying lung disease. Ten to 14 days appear adequate to achieve maximal improvement in lung function and sustained health in most cases.[411,412] With refractory infection, treatment for 3 weeks or more is sometimes warranted but may not be successful. Certain studies have demonstrated that the FEV_1 reaches a plateau following 10 days of inpatient treatment, raising a question concerning the benefit (and risk) of longer hospital and parenteral antibiotic courses.[413] Each treatment schedule therefore requires careful and somewhat individualized assessment by the clinician. Shorter treatments may improve QOL and compliance, limit drug-associated morbidities, and be less costly. However, prolonged regimens may be necessary to clear an infection, achieve sustained benefit, and preclude early recurrence of exacerbation. Prospective comparator studies evaluating treatment duration are currently underway.[414] Extended courses of antibiotic therapy should also include longitudinal respiratory tract cultures for bacterial and fungal organisms because antibiotic sensitivities can shift.[415] For patients requiring frequent or long-term home antibiotic therapy, subcutaneous central intravenous catheters can provide stable intravenous access to facilitate treatment. Chronic port access carries a risk of catheter-associated infections and thrombosis.[416] For this reason, exogenous estrogen should be avoided in female patients with central venous catheters if possible.

TREATMENT OF LUNG COMPLICATIONS

Treatments directed to control airway infection, limit inflammation, and optimize airway clearance represent the cornerstone of therapy in both early and advanced CF lung disease. Hypoxemic respiratory insufficiency should be recognized and treated with supplemental oxygen. Low-flow oxygen is effective at relieving nocturnal, exertional, and resting hypoxemia and does not usually cause significant hypercapnia.[417]

Pulmonary hypertension (PH) and increased mortality are strongly associated with the development of nocturnal or resting hypoxemia.[418] The development of PH is correlated with declining lung function and the development of respiratory failure; however, direct evidence that it increases the risk of mortality is lacking.[419] Treatment for PH, including diuretics, inotropic agents, and theophylline, provides little to no benefit in CF and is rarely used; however, sildenafil is associated with improved exercise capacity.[420,421] Right ventricular dysfunction is an end-stage finding in advanced disease with few viable treatment options beyond those that stabilize lung disease and symptomatically treat pulmonary hypertension.[422] Thus, advancing PH is largely an indication for referral for lung transplantation (see also Chapter 85).

Acute respiratory failure due to reversible insults can be managed by either noninvasive measures or invasive ventilatory support.[145,423,424] Although mortality associated with mechanical ventilation in CF is high, the intervention can be beneficial. It has been reported, for example, that one-third of CF patients with advanced lung disease survive events requiring intubation and ventilatory support.[146] Mechanical ventilation and extracorporeal membrane oxygenation can also be used as a bridge to lung transplant at appropriate centers[146,424–426] (see also Chapter 138).

Atelectasis in CF is managed by escalating the intensity and frequency of airway clearance, together with other therapies directed towards addressing pulmonary exacerbations. Systemic or inhaled corticosteroids may be helpful in the presence of asthma, ABPA, or significant airway inflammation refractory to antimicrobial therapy. There is little evidence that bronchoscopy and lavage are effective in treating atelectasis. However, bronchoscopic evaluation of atelectasis and treatment of mucoid impaction in association with endobronchial aspergillosis and ABPA have been described.[427,428]

ABPA is a common complication of CF, seen in about 10% of the CF population annually. ABPA typically responds to standard doses of systemic corticosteroids (1 mg/kg).[124] Inhaled corticosteroids,[429] paired with suppressive oral antifungal therapy,[430] and more recently, omalizumab[431] (an anti-IgE monoclonal therapy), has been shown to limit the systemic steroid burden in cases of steroid refractoriness or steroid intolerance.

Pneumothorax, when small and minimally symptomatic, may be managed by observation with the expectation of spontaneous resolution. Pneumothoraces of greater volume (e.g., >20%) or that compromise ventilation or physiologic stability require chest tube re-expansion immediately.[432] Recurrent pneumothoraces are common in advanced lung disease and are associated with higher mortality. Patients with nonexpandable lung after pneumothorax who experience significant morbidity may benefit from video-assisted thoracic surgery to take down adhesions followed by chemical and/or mechanical pleurodesis.[433] Prior pleurodesis is not considered a contraindication to lung transplantation, although it increases surgical complexity.[433]

Major hemoptysis is treated with antibiotics, limitation of aggressive physiotherapy, and inhaled respiratory health medications, although reinstitution of postural drainage therapy has become increasingly accepted in this setting. Supplemental vitamin K should be given if the prothrombin time is prolonged due to malabsorption. Clot stabilization with intravenous or inhaled tranexamic acid and systemic blood pressure reduction with beta-blockade may have some clinical utility but are not indicated as first-line therapies.[129,434] Massive hemoptysis may resolve with conservative therapy, but bronchial artery embolization provides

more definitive clinical control and should be considered in recurrent or refractory cases of submassive bleeding.[130] Recurrent submassive or massive hemoptysis episodes should prompt consideration for lung transplant referral.

Treatment of Gastrointestinal Complications

Meconium ileus often can be relieved with enemas refluxing water-soluble radiographic contrast into the terminal ileum under fluoroscopy.[131] If this is not successful, or there is concern for intestinal perforation due to severity of involvement, surgical consultation should be sought. The distal intestinal obstruction syndrome is typically treated with large volume-balanced electrolyte solutions containing osmotic laxatives (polyethylene glycol) and mucolytics (N-acetylcysteine).[435] Contrast enemas that reach the terminal ileum can complement this therapy. In the setting of significant abdominal distension or intractable emesis, bowel obstruction or bilious/fecal emesis may require surgical intervention.[436] Rectal prolapse can be voluntarily reduced in patients experienced with techniques involving the abdominal, perineal, and gluteal muscles. Young children often require manual reduction by gentle pressure in the knee-chest position.[436] Pancreatic enzyme replacement therapy, improved nutritional status, and control of lung disease usually prevent recurrence. Surgical stabilization of the rectum is required if prolapse is chronic and refractory to medical management.

Liver disease is thought to result from abnormal bile secretion due to CFTR dysfunction. Ursodeoxycholic acid (ursodiol) is used to treat primary biliary cirrhosis.[155] Although its impact on CF liver disease is unclear, several studies have demonstrated that ursodiol improves or stabilizes liver function tests. Long-term effect on CF hepatocellular injury, however, remains unknown.[437] Thresholds for initiating therapy and clinical outcomes are under investigation, although current guidelines recommend aggressive nutritional support and consideration of ursodiol treatment.[438] Bleeding esophageal varices that complicate cirrhosis can often be managed with banding or sclerotherapy. Portal hypertension and severe, refractory variceal bleeding have been treated successfully with portosystemic shunt procedures.[439] CF hepatic failure and ascites are treated in standard fashion. Liver transplantation is successful in CF, with survival rates at 1 and 5 years reported at greater than 80%.[440] CFTR modulator therapy may be associated with elevated hepatic enzymes, but this is also seen sporadically in CF, often in association with treatment for pulmonary exacerbations.[264]

Hyperglycemia can complicate CF at any age but is generally first encountered during the second and third decades of life.[441,442] Ketoacidosis is not typically a feature of CF-related diabetes mellitus. Treatment of elevated blood glucose in CF has become more aggressive as patient longevity has improved. This is in part due to appreciation of complications from diabetes among older adults with CF and increased recognition concerning the impact of CF-related diabetes mellitus on pulmonary disease progression and its association with declining lung function.[443] Vascular disease affecting the retina and kidneys has been documented in CF patients who have had prolonged hyperglycemia.[443,444] Intensive screening and management regimens have been recommended for control of blood sugar, including annual oral glucose tolerance testing for previously unaffected patients.[442,445–447] Insulin therapy is the mainstay of treatment, and the anabolic effects of insulin may be beneficial in this setting.[442,446–448] Increasing use of continuous glucose monitoring improves glucose control and clinical outcomes[449] (see also Chapter 128).

Surgical Therapy

Endoscopic sinus surgery and nasal polypectomy to relieve obstruction are the most common surgical procedures conducted in the CF patient population.[448,450,451] Although most individuals with CF experience improvement postoperatively, recurrence is common and often requires repetitive procedures.[452] The incidence of nasal polyposis tends to wane in adulthood.[450] More aggressive sinus surgery to marsupialize the sinus cavity may also be beneficial.[453] Other frequently encountered procedures include cholecystectomy to treat symptomatic gallstones.[452] Pulmonary resection has historically been considered when severe focal lung disease leads to clinical instability and accelerated decline in lung function. Although surgical therapy has been reported to stabilize the clinical course and reduce exacerbation frequency, such treatment has become rare due to improved therapeutic strategies and overall health of individuals with CF.[167,454–457] Patients under consideration for partial pneumonectomy must be carefully selected because short-term loss of lung function postoperatively is expected.[458] Massive hemoptysis refractory to standard interventional therapy may require lobectomy.

Lung Transplantation

Sequential double-lung transplantation is an accepted therapy for respiratory failure secondary to CF.[459] More than 3000 lung transplants have been performed for CF around the world, and the rate is increasing. The 5-year survival is just above 50% and improving, which compares favorably to survival following pulmonary transplantation performed in other lung diseases.[460] Given the limited survival and complexity of treatments required, consideration of lung transplantation requires careful psychological and social evaluation. Patients should be referred when death is expected over the ensuing 2 to 3 years.[106] Recent consensus guidelines emphasize early patient discussion and referral, especially with complicating factors that include patient size and gender, CF medical complications, and psychosocial barriers.[461] Following successful transplantation, CF patients may experience dramatically improved respiratory status and QOL, but significant medical treatment burden remains (see also Chapter 140).

Nutrition

Improved nutritional status in patients with CF is associated with better long-term clinical outcomes.[456] Individuals with the disease have increased caloric requirements attributable to intestinal malabsorption, increased work of breathing, and factors associated with infection and/or inflammation. Dietary recommendations include high caloric intake (20–50% greater than standard), high-protein diet with a moderate amount of dietary fat (35–45% of caloric intake), and limited processed carbohydrates.[462] Patients with a body mass index below the 25th percentile are typically considered to be in nutritional failure and warrant aggressive

dietary counseling and supplementation. If nutritional adjustments are unsuccessful, consideration of appetite stimulants, gastrostomy tube feedings, or other approaches may be warranted. This is in part because supplementation with elemental dietary preparations by mouth is unlikely to be sustained over an extended period of time.

Almost all patients with CF require pancreatic enzyme replacement therapy due to cystic destruction of the exocrine pancreas early in life. The enzymes are supplied as capsules containing acid-resistant enteric-coated granules, with doses of lipase from 3,000 to 40,000 units. The replacement therapy is typically administered based on patient weight and adjusted to ameliorate symptoms of malabsorption such as abdominal cramping, excessive flatulence, and fatty stools. Dose ranges should be limited to current guidelines (2500 lipase units/kg/meal; 10,000 lipase units/kg/day), because more intense drug schedules have been associated with fibrosing colonopathy.[463–466] Recombinant forms are in development, and enzyme replacement cartridges for nocturnal use can improve absorption of nocturnal feeding.[467] With earlier use of highly effective CFTR modulator therapy, pancreatic enzyme replacement may not be needed if pancreatic function can be preserved.[468]

A daily multivitamin is standard in CF care, and additional supplementation is dependent on clinical evaluation. Vitamins A and E are often adequately supplied by a standard (daily) multiple-vitamin preparation. Vitamin A deficiency is readily corrected by dietary supplementation. Symptomatic deficiency is rare and may result in increased intracranial pressure, xerophthalmia, and night blindness. Vitamin D deficiency presenting as rickets is rarely seen. That being said, patients with CF often have inadequate levels of vitamin D (<30 to 60 ng/mL) that can be refractory to high-dose supplementation. Bone demineralization is common, and association of inadequate vitamin D levels with poor health-related outcomes in other clinical scenarios has led to recommendations of aggressive supplementation. Vitamin E is deficient only in non-supplemented patients and rarely causes increased red blood cell destruction or neuroaxonal dystrophy.[469] Insufficient vitamin K may result in bleeding diathesis. Although clinically significant hemorrhagic problems manifest mostly in children, vitamin K deficiency in the setting of hemoptysis may present a significant challenge in older CF patients. Other vitamins and trace minerals, specifically zinc, may be deficient and require supplementation on an individualized patient basis.[470]

Psychosocial Factors

With the advent of newborn screening and with individuals with CF surviving into adulthood, psychosocial aspects of CF have broadened and continue to affect patients, families, and the community. Medical therapies offer significant benefit but can be limited by problems with psychosocial well-being, attitude, and ultimately adherence to treatment. Approaches to delivery of clinical care that promote a positive self-image and support the patient and/or family efforts to manage their own medical therapy while maximizing health-related QOL are likely to have substantial impact on outcomes. Partnering strategies between providers and patients to sustain daily care routines are recognized as a beneficial approach in CF.[471]

Providers with expertise in psychosocial support are invaluable to the CF care team.[463] Major depression and anxiety disorder is a common comorbidity as patients grow older and can interfere with good clinical outcomes. Aggressive monitoring and treatment of these aspects of CF are warranted and recommended annually for all patients with CF.[472] At present, no CF-specific medical treatments for major depression have been investigated.

Key Points

- Effective treatment and monitoring through a network of specialized *cystic fibrosis* (CF) care and research centers has led to improvement in morbidity and mortality among patients with CF.
- The diagnostic paradigms emphasize early detection by newborn screening and a high index of suspicion to recognize atypical cases later in life, which are generally caused by *cystic fibrosis transmembrane conductance regulator (CFTR)* alleles coding for partially active CFTR.
- Aggressive treatment of CF pulmonary exacerbations is required to delay progression and reduce complications of end-stage lung disease.
- Treatment strategies for chronic lung disease generally address downstream manifestations of CF pathophysiology. Such therapies include airway clearance techniques, hydration of airway surface liquid, mucolytics to enhance mucus clearance, antimicrobials, and chronic use of anti-inflammatory agents.
- The successful development and approval of ivacaftor for CF patients with the G551D *CFTR* mutation has provided a roadmap invigorating investigators working to develop novel modulators of CFTR function to correct the underlying defect caused by the most common *CFTR* alleles.
- Combination CFTR modulator therapy has been developed to treat lung disease in all patients with F508del CFTR (≈90% of the U.S. CF population as defined by genotypic prevalence). The most recent of these is a triple combination (elexacaftor/tezacaftor/ivacaftor).
- Ongoing efforts are aimed at various gene-based methods to cure all patients with CF.

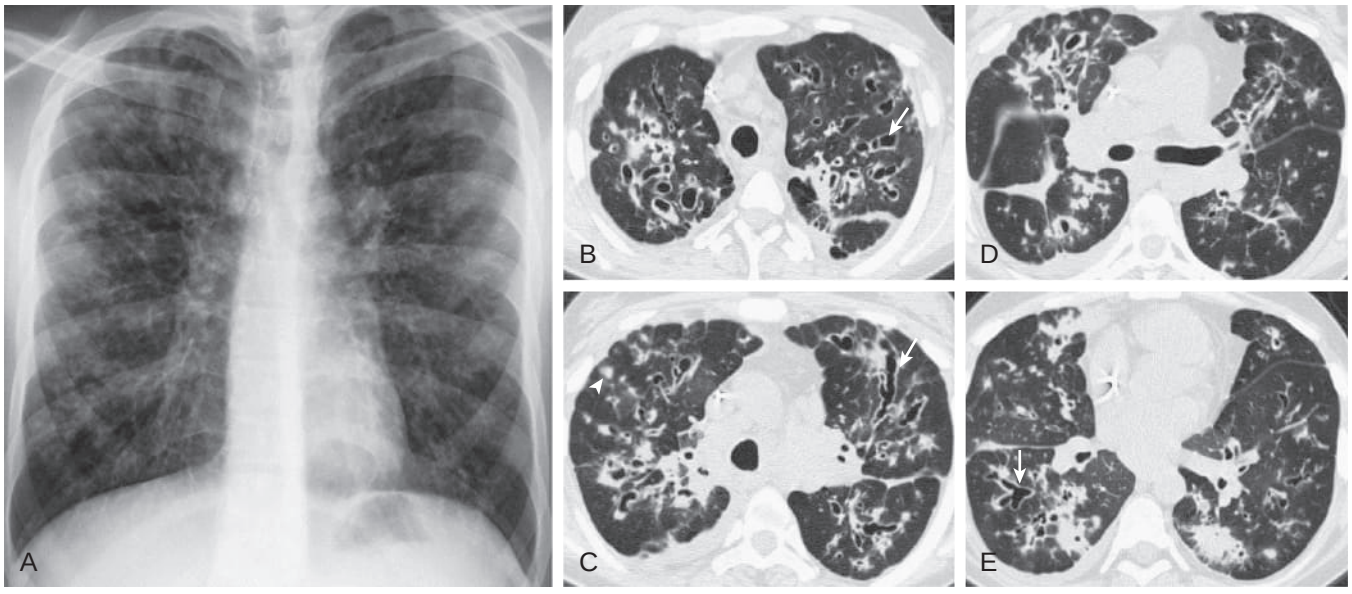
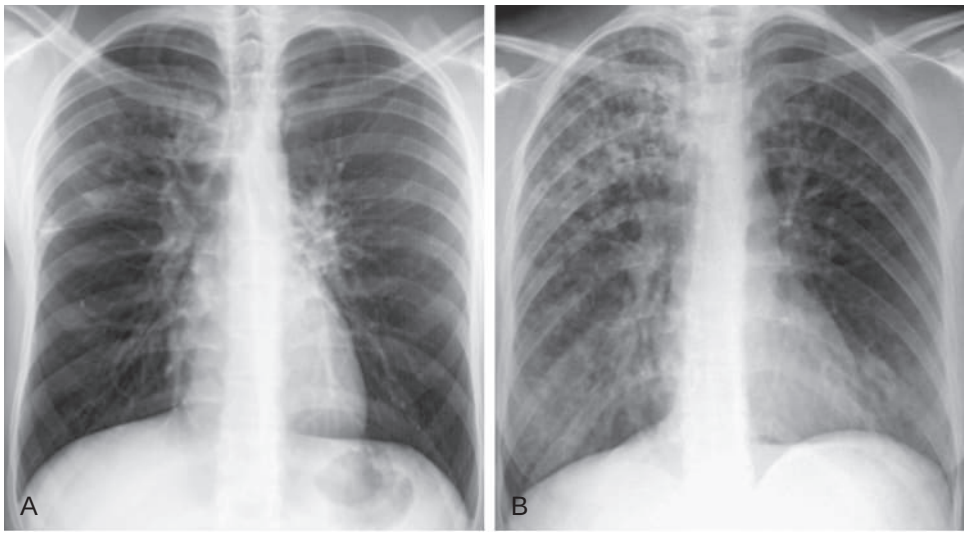
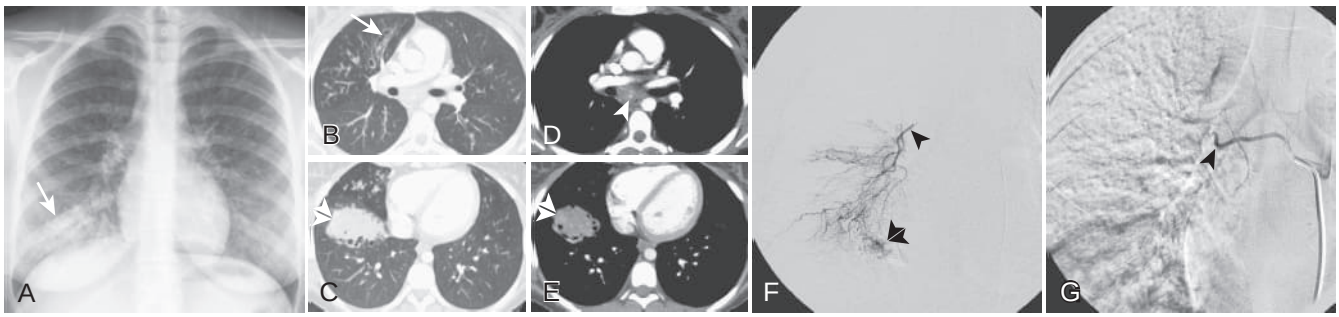
eFigure 68.1 Cystic fibrosis: chest radiographic and chest computed tomography findings. (A) Frontal chest radiograph in a 4-year-old patient with cystic fibrosis shows mildly increased lung volumes associated with central airway thickening and extensive linear opacity representing bronchiectasis and bronchial wall thickening. (B–E) Axial chest computed tomography displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*), as well as extensive bronchial wall thickening and small nodules (*arrowheads*), the latter reflecting distal bronchial and small airway impaction. (Courtesy Michael B. Gotway, MD.)



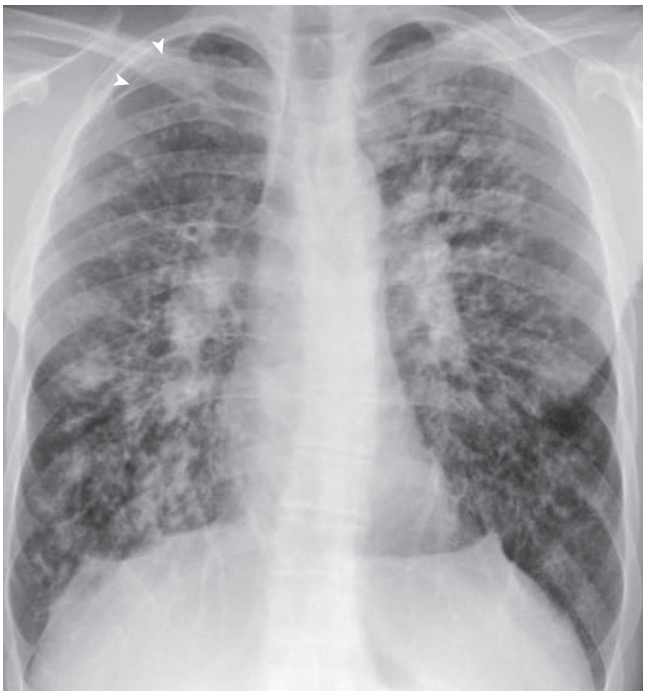
eFigure 68.2 *Cystic fibrosis* (CF): chest radiographic and chest computed tomography findings. (A) Frontal chest radiography in a young adult with CF shows large lung volumes associated with central airway thickening and extensive linear opacity representing bronchiectasis and bronchial wall thickening. (B–E) Axial chest computed tomography displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*), as well as extensive bronchial wall thickening and small nodules (*arrowhead*), the latter reflecting distal bronchial and small airway impaction. In comparison to eFig. 68.1 of a young child with CF, there is significantly worse disease in this older patient. (Courtesy Michael B. Gotway, MD.)



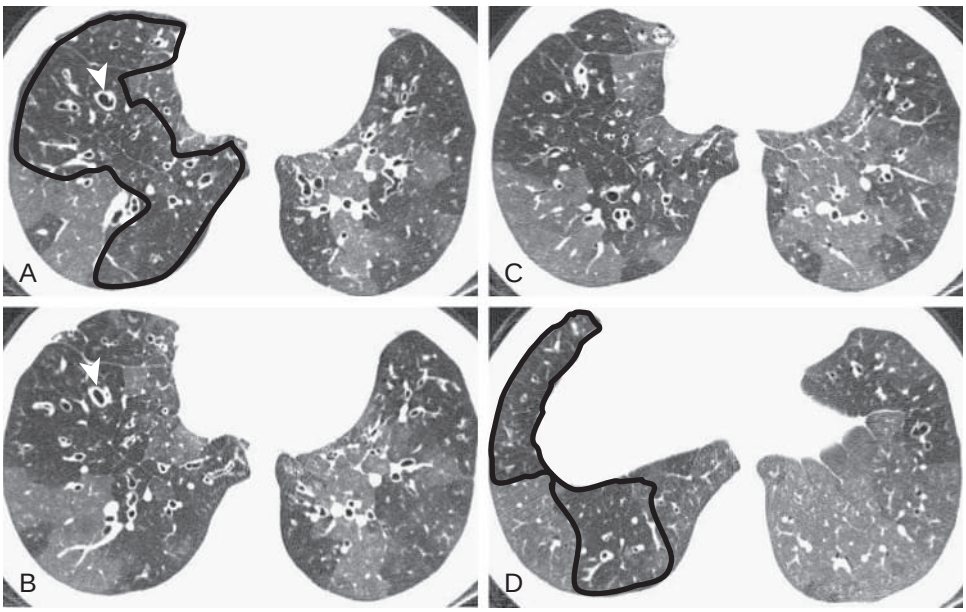
eFigure 68.3 Cystic fibrosis: predominant right upper lobe involvement. (A–B) Frontal chest radiograph in two separate patients with cystic fibrosis shows multifocal bronchial wall thickening and dilation, most pronounced in the right upper lobe. (Courtesy Michael B. Gotway, MD.)



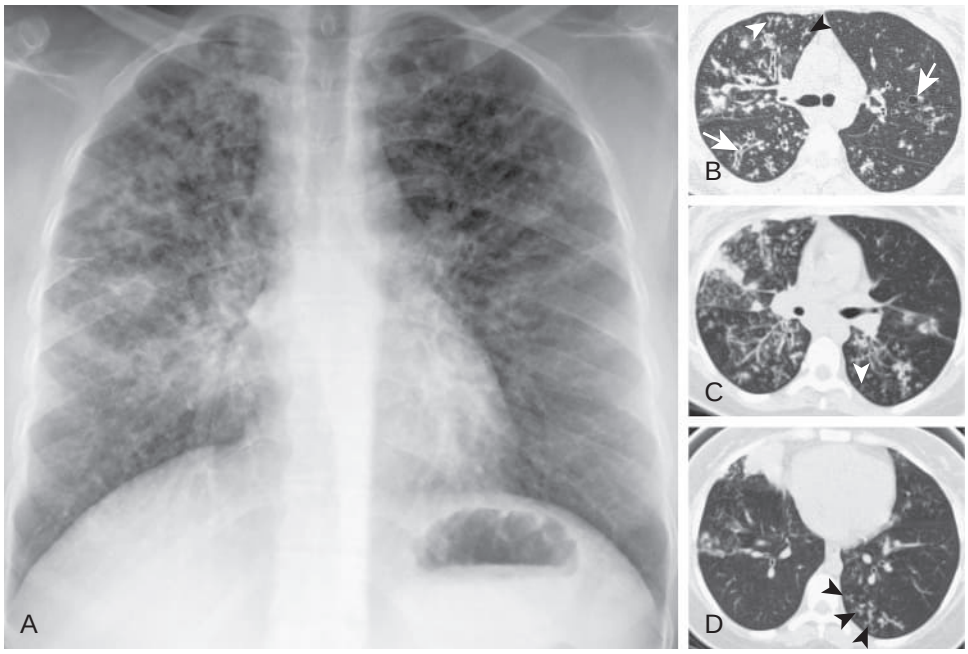
eFigure 68.4 *Cystic fibrosis* (CF) with hemoptysis treated with bronchial arterial embolization. (A) Frontal chest radiograph shows central perihilar predominant bronchial wall thickening and bronchiectasis. Focal consolidation (*arrow*) in the right lower lobe was new compared with prior studies. (B–E) Axial enhanced chest *computed tomography* (CT) displayed in lung (B–C) and soft tissue (D–E) windows shows multifocal bronchiectasis (*arrow*), typical of CF. Bronchial artery hypertrophy (*arrowhead,* D) is present, commonly observed in patients with chronic inflammatory airway diseases. (E) A mildly hyperattenuating mass (*double arrowheads*) is present in the anterior right lower lobe, correlating with the new finding at chest radiography and presumed to reflect hematoma in the setting of a patient with CF and new hemoptysis. (F–G) Precatheter (F) and postcathether (G) bronchial artery embolization images show an enlarged bronchial artery (*arrowhead*) associated with a prominent "vascular blush" (*double arrowhead*) in the region of the anterior right lower lobe mass at chest CT. The postembolization image (G) shows lack of opacification of the region of the vascular blush, and essentially no flow is now seen in the hypertrophied bronchial artery (*arrowhead*). (Courtesy Michael B. Gotway, MD.)



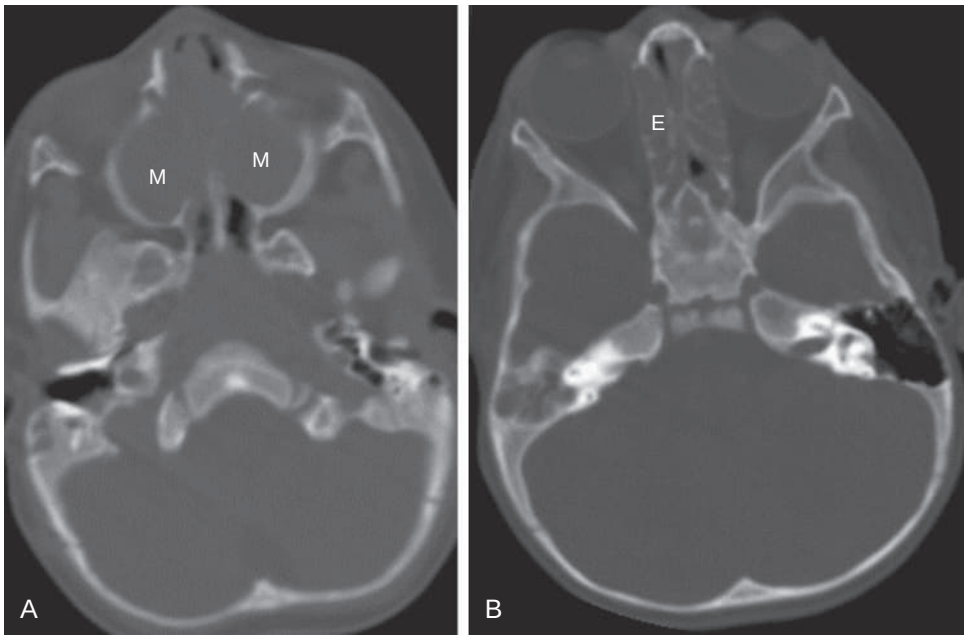
eFigure 68.5 Cystic fibrosis with spontaneous pneumothorax. Frontal chest radiography shows typical changes of cystic fibrosis, including extensive bronchiectasis and peribronchial consolidation with large lung volumes. A small, spontaneous right apical pneumothorax (*arrowheads*) is present. (Courtesy Michael B. Gotway, MD.)



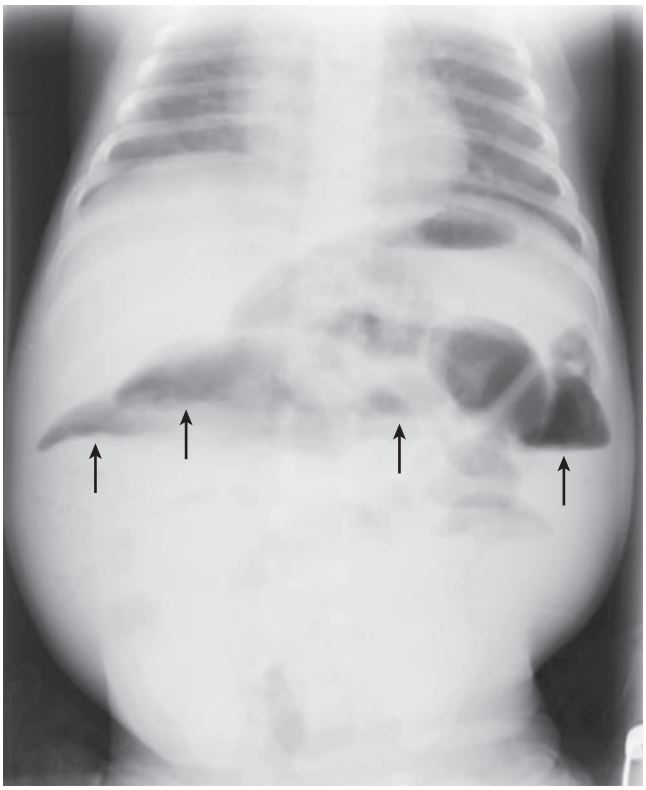
eFigure 68.6 Cystic fibrosis: mosaic perfusion. (A–D) Axial chest computed tomography through the lung bases displayed in lung windows shows cylindrical bronchiectasis (*arrowheads*) and extensive bronchial wall thickening, typical of cystic fibrosis. Extensive, bilateral inhomogeneous lung opacity is present, manifesting as geographic areas of increased and decreased pulmonary parenchymal attenuation. The areas of decreased attenuation (*black outlines* in A and D) show small pulmonary vessels, reflecting vasoconstriction and decreased pulmonary parenchymal perfusion due to air trapping, and are referred to as mosaic perfusion. Although the areas of increased attenuation resemble ground-glass opacity, they actually represent relatively normal but hyperperfused pulmonary parenchyma. Such findings may happen with large or small airway obstructive disorders. (Courtesy Michael B. Gotway, MD.)



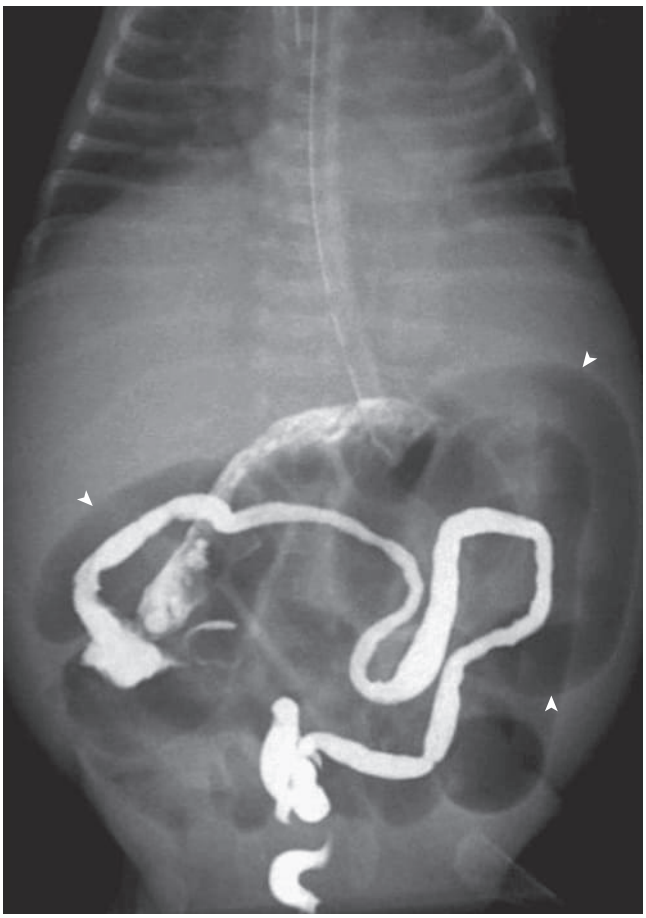
eFigure 68.7 Cystic fibrosis: chest radiographic and chest computed tomography findings of small airway impaction/obstruction. (A) Frontal chest radiography in a patient with cystic fibrosis shows large lung volumes associated with central airway thickening and extensive linear opacity, representing bronchiectasis and bronchial wall thickening. A number of small, poorly defined upper lobe opacities, particularly on the right, are evident. (B–D) Axial chest computed tomography displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*) and extensive bronchial wall thickening. Numerous small, solid, centrilobular nodules showing branching configurations, consistent with tree-in-bud opacity (*arrowheads*), are evident. (Courtesy Michael B. Gotway, MD.)



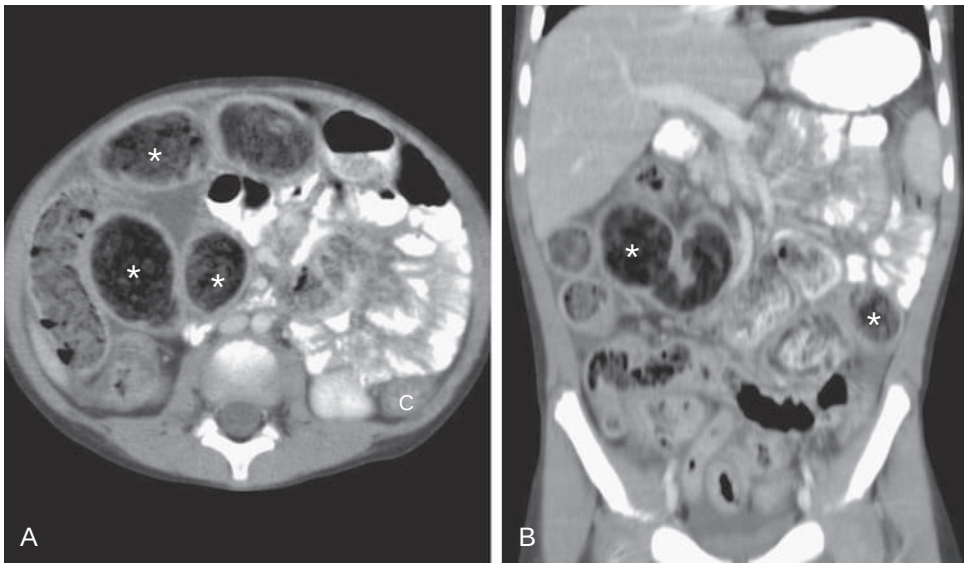
eFigure 68.8 Upper respiratory tract manifestations of cystic fibrosis: sinusitis. (A–B) Axial sinus computed tomography shows complete opacification of the maxillary sinuses *(M)* and ethmoid *(E)* air cells. (Courtesy Michael B. Gotway, MD.)



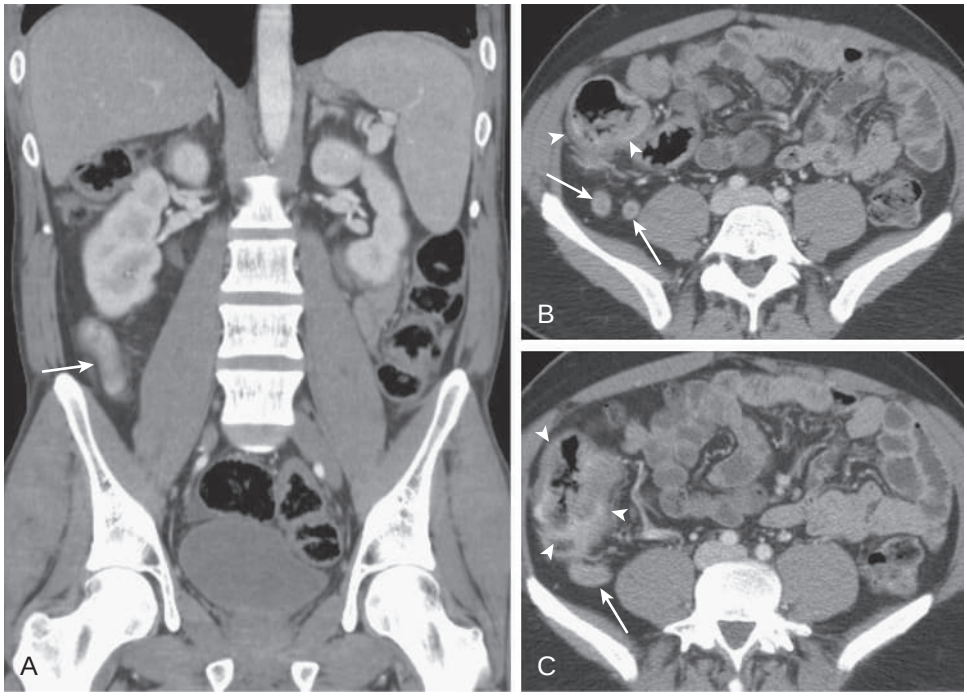
eFigure 68.9 Gastrointestinal complications of cystic fibrosis: meconium ileus with small bowel obstruction. Frontal view of the abdomen shows dilated small bowel with numerous gas-fluid levels (*arrows*) representing small bowel obstruction. The appearance is not specific for meconium ileus, but that diagnosis was proved subsequently. (Courtesy Michael B. Gotway, MD.)



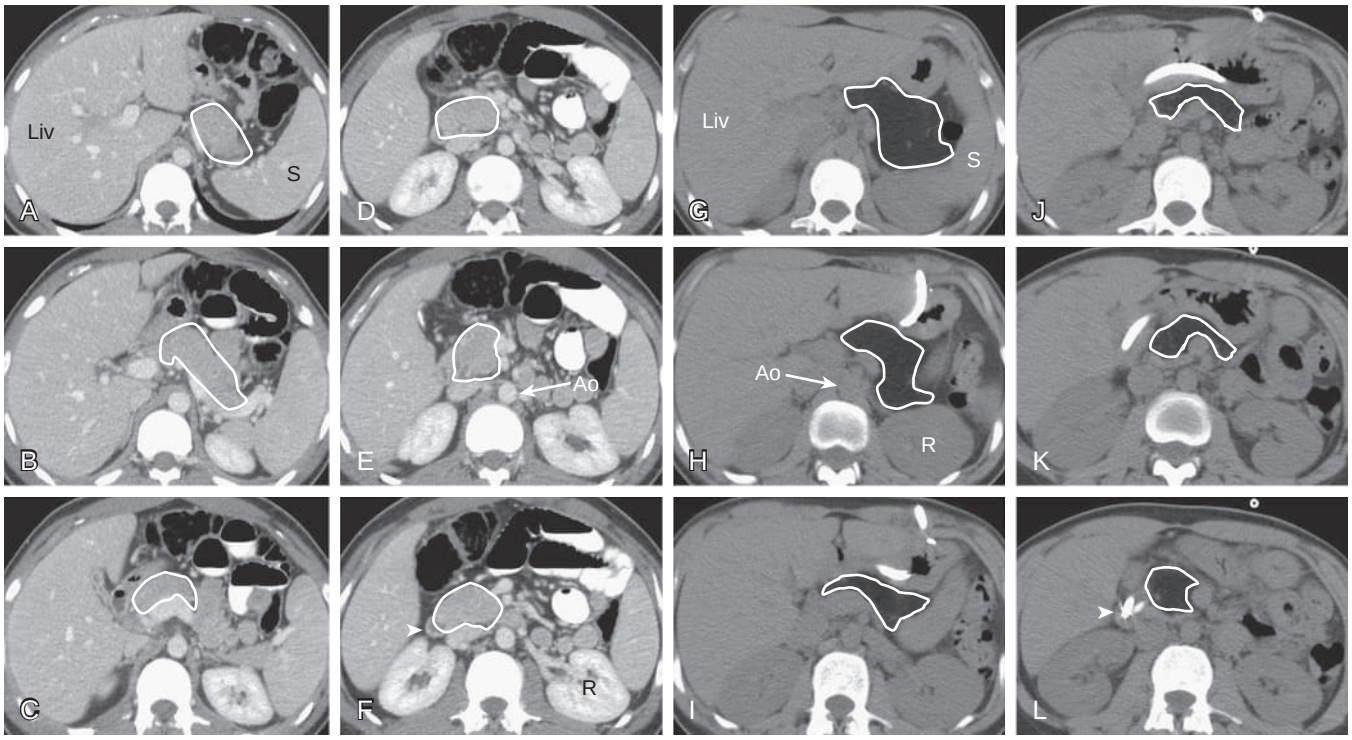
eFigure 68.10 Gastrointestinal complications of cystic fibrosis: meconium ileus. Postevacuation image following contrast enema shows a small, opacified colon, consistent with a microcolon. Distended small bowel (*arrowheads*) consistent with small bowel obstruction is present. (Courtesy Michael B. Gotway, MD.)



eFigure 68.11 Gastrointestinal complications of cystic fibrosis: distal intestinal obstruction syndrome. (A) Axial and (B) coronal contrast-enhanced abdominal-pelvic computed tomography in a child with cystic fibrosis shows opacified normal caliber proximal small bowel but dilated, debris-filled distal small bowel (*asterisks*) consistent with the distal intestinal obstruction syndrome. C, left colon. (Courtesy Michael B. Gotway, MD.)



eFigure 68.12 Gastrointestinal manifestations of cystic fibrosis: enlarged appendix. (A) Coronal and (B–C) axial enhanced abdominal computed tomography shows a dilated appendix (*arrows*); this finding was unchanged from a study several years earlier. The colon (*arrowheads*) is somewhat redundant and thick-walled, with mild infiltration of the pericolonic fat. (Courtesy Michael B. Gotway, MD.)



eFigure 68.13 Gastrointestinal manifestations of cystic fibrosis: fatty replacement of the pancreas. (A–F) Axial enhanced abdominal *computed tomography* (CT) in a patient without *cystic fibrosis* (CF) shows a normal pancreas (*white outline*); note close relationship of the tail of the pancreas to the spleen (*S*). The normal pancreas is obliquely oriented with the tail superiorly and left laterally positioned compared with the more medial and inferiorly located pancreas head (*white outline,* E–F); the head of the pancreas is closely related to the junction of the second and third portions of the duodenum (*arrowheads,* F and L). The enteric tube in L also marks the position of the duodenum). (G–L) Axial unenhanced abdominal CT in a patient with CF shows complete fatty replacement of the pancreas; note the homogeneous low attenuation, consistent with fat and equivalent in attenuation to subcutaneous fat, occupying the position of the pancreas (*white outline,* G–L). *Ao and arrow,* abdominal aorta; *Liv,* liver; *R,* renal/kidney. INTRODUCTION

Bronchiectasis is defined by dilation, or ectasia, of the large airways or bronchi. The primary clinical manifestations of bronchiectasis are recurrent, chronic, or refractory infections. Other significant sequelae include hemoptysis, chronic airflow obstruction, and progressive impairment of pulmonary function.

There are varied pathways that lead to the development of bronchiectasis (Table 69.1 and Fig. 69.1). Broadly, bronchiectasis may develop because of an incidental event or episode that does not necessarily reflect impairment of the patient's intrinsic host defenses. Such examples include a necrotizing pneumonia after aspiration or chronic infection distal to an obstructing bronchial mass or foreign body. Often, however, bronchiectasis evolves due to underlying genetic risk factors and/or recurrent exposures to environmental mycobacteria. Regardless of the underlying etiology of bronchiectasis, superimposed bacterial infection is common and frequently drives the progression and exacerbation of bronchiectasis.

A central issue in understanding the pathogenesis of bronchiectasis is whether infection is truly the proximate cause of bronchiectasis or whether infections develop because of an underlying predisposing condition. For example, a commonly held adage is that many cases of bronchiectasis in adults are associated with childhood bouts of pertussis, measles, or other infections, including adenovirus.[1,2]

It is important to emphasize that these findings provide, at most, only an associative link and not a causal link.[1] Although childhood infections can undoubtedly cause bronchiectasis, one might be skeptical of this simple construct, asking why formerly common childhood illnesses resulted in bronchiectasis in only a small proportion of patients. Recently emerging is the concept that neutrophils and other inflammatory cells release elastase and reactive oxygen intermediates in response to infection, and that this unresolved inflammatory response to infection may damage airways.[3,4]

CLASSIFICATION SCHEMA

Although there is considerable overlap and coexistence among the various forms of bronchiectasis, the radiographic patterns and distribution may provide clues to diagnosis, management, and prognosis.[5] Thus, characterizing the morphologic features and distribution of bronchiectasis is a useful exercise. Bronchiectasis is most accurately diagnosed by *high-resolution computed tomography* (HRCT). Radiographic correlates to HRCT findings are summarized in eFigs. 69.1 to 69.3.

Cylindrical bronchiectasis is described as failure of the involved airways to taper progressively in their distal course. Usually, in this condition, the bronchial walls are smooth or regular. *Varicoid* bronchiectasis is an allusion to varicose veins and is marked by irregular dilation, narrowing, and outpouching of the airways. *Saccular* bronchiectasis, also known as *cystic* bronchiectasis, includes focal or cystic distortion of the distal airways. These bronchiectatic forms are summarized in Figure 69.2. Cystic distortion may become confluent, producing the appearance of bronchiectatic consolidation and volume loss (eFig. 69.4).

A traditional "wet" versus "dry" bronchiectasis paradigm is now less commonly used because newer paradigms regarding phenotypes have emerged based on underlying diagnosis, type of infectious agent(s) causing or exacerbating the bronchiectasis,[6] and clinical phenotype.[7]

The most well-characterized, clinically relevant example is the *frequent exacerbator* phenotype.[8] Within this group, frequent exacerbations are the strongest predictor of future exacerbation frequency. Patients with frequent

exacerbations have a poorer *quality of life* (QOL), are more likely to be hospitalized and, at up to 5 years of follow-up, have a higher mortality, proportional to the number of exacerbations per year.[8]

EPIDEMIOLOGY

Incidence and prevalence of bronchiectasis is difficult to estimate but likely varies in different regions of the world.[9] The prevalence of *non-cystic fibrosis* (non-CF) bronchiectasis, based on narrow case-finding criteria, is estimated to be 139 cases per 100,000 persons, to be higher among women versus men (180 vs. 95 per 100,000), and to increase substantially with age (from 7 per 100,000 for ages 18–34 years to 812 per 100,000 for ages ≥75 years); annual incidence is estimated to be 29 cases per 100,000 persons. Disease prevalence based on broad case-finding criteria is estimated to be 213 cases per 100,000 persons.[9] This study suggested that, in the United States (in 2013), between 340,000 and 522,000 adults were receiving treatment for bronchiectasis and that 70,000 adults were newly diagnosed with bronchiectasis. More recent data indicate that bronchiectasis is much more common than previously reported, and the incidence has risen with an estimated annual growth rate of 8% since 2001.[10–12] Whether these rising rates reflect a true increase in incidence and/or enhanced detection due to more frequent use of *computed tomography* (CT) scans is not known. The observation that bronchiectasis was the *primary* diagnosis in only a minority (<20%) of all the bronchiectasis-associated hospitalizations supports the concept that greater incidental diagnosis is being made, at least in part, from more frequent use of CT scans.[13]

There are significant economic burdens of increased incidence and prevalence of bronchiectasis. The major drivers of annual health care costs appear related to hospitalizations, but total cost is currently unknown.[14]

In the United States and many parts of the world, there appear to be increasing numbers of bronchiectasis cases associated with *nontuberculous mycobacteria* (NTM) (see Chapter 55).[15–23] NTM appears capable of both initiating[24] and driving the evolution of bronchiectasis[25,26] through a chronic neutrophil-driven process in the airways, resulting in enhanced airway damage and initiation of the vicious cycle of inflammation.

PATHOPHYSIOLOGY

Various mechanisms operate to produce bronchiectasis. In the simplest terms, they may be thought of in terms of *traction, pulsion*, and *weakness* of the airways. In most cases, the pathogenesis becomes inextricably linked with and propelled by the destructive effects of chronic infection, as summarized in Figure 69.1.

Traction bronchiectasis implies that local retractile forces dilate the airways. As the lung undergoes fibrotic changes due to disorders such as sarcoidosis, interstitial lung disorders, or infections such as tuberculosis, those increased forces are transmitted to the airways. In contrast, in normal lungs, airways are held patent by a combination of negative intrapleural pressure, which maintains the lungs in an inflated state, and the cartilaginous rings of the trachea and the large and medium airways. The distending forces of the negative intrapleural pressure are transmitted to the airways by a diffuse system of interstitial tethering.

Pulsion bronchiectasis implies that intense inflammation originating in the lumen leads to permanent airway dilation. The prototype is *allergic bronchopulmonary aspergillosis* (ABPA). In ABPA, there are intense, immunologically mediated reactions to inhaled *Aspergillus* lodged in the airways. The proliferating fungi form large mucoid conglomerates that fill the central airways; a sequela of this airway inflammatory process and mucoid impaction is bronchiectasis (eFig. 69.5).

Weakness of the airways may take many forms. Classic postinfectious bronchiectasis presumably is mediated in part by damage to the walls of the airways, resulting in secondary loss of structural integrity.[27,28] This is

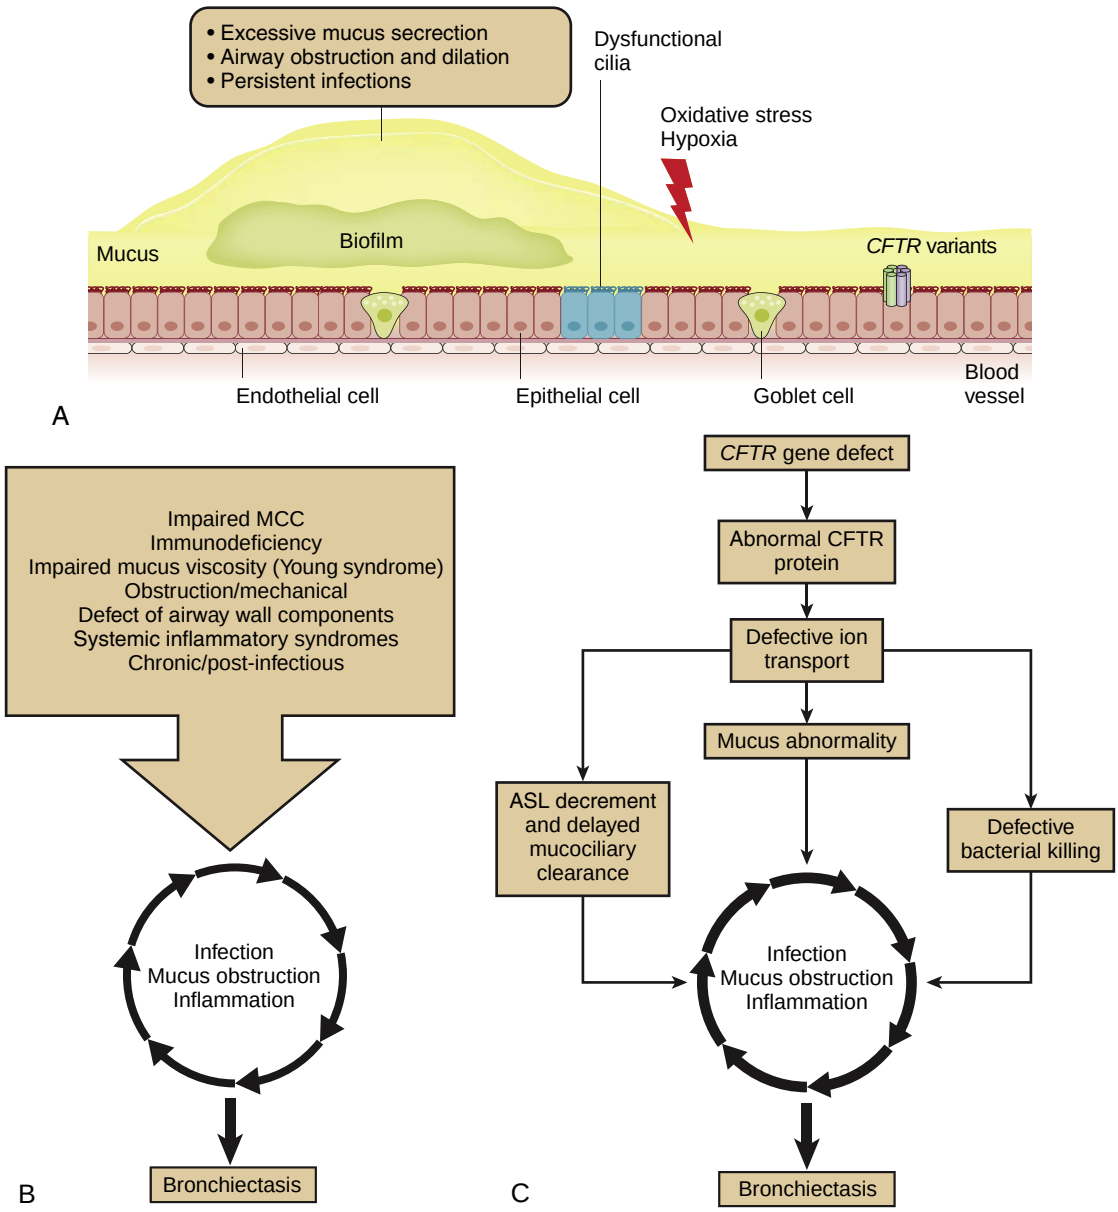

Figure 69.1 General pathophysiologic mechanisms for the development of bronchiectasis. (A) General pathophysiologic mechanisms in the airway epithelium leading to bronchiectasis. (B) Due to the underlying bronchiectatic defect (e.g., impaired *mucociliary clearance* [MCC]) and predisposition to infections (e.g., immunodeficiencies), there is biofilm formation and accumulation of mucus leading to chronic bacterial colonization. A vicious cycle ensues, wherein mucus accumulation predisposes to bacterial colonization and infection, which then incites more inflammation and bronchiectasis, leading back to greater impaired mucus clearance. (C) A prototypical example is cystic fibrosis, wherein a defect in the *cystic fibrosis transmembrane regulator* (*CFTR*) gene leads to a primary ion transport defect. These defects create abnormalities in *airway surface liquid* (ASL) and mucus clearance, inherent changes in airway mucus, and impaired bacterial killing resulting in the vicious cycle of bronchiectasis development in cystic fibrosis.

coupled with scarring and loss of volume of the local lung units, leading to regional increases in retractile forces. Examples of primary weakness of the airways contributing to bronchiectasis include Mounier-Kuhn syndrome (congenital tracheobronchomegaly due to atrophy of airway elastic fibers), Williams-Campbell syndrome (absence of cartilaginous rings in the segmental and subsegmental generations of bronchi), Marfan syndrome, and relapsing polychondritis.

Weakened airways and airway collapsibility impair the effectiveness of the cough mechanism. Coughing is an essential, primary element of lung defense. An effective cough sends columns of air rushing upward through the bronchial tree at peak speeds measured in the range of 600 mph.[29] To support these high flow rates, the cartilaginous rings must have the structural integrity to remain patent while the posterior membranous element invaginates into the lumen of the airway, thereby decreasing the cross-sectional diameter of the airway and accelerating airflow. Bronchoscopy of patients with bronchiectasis commonly reveals extraordinary collapsibility of the airways, virtually completely obstructing the bronchi with each cough. It seems likely that such amplified airway compressibility impedes the air-driven propulsion of secretions out of the

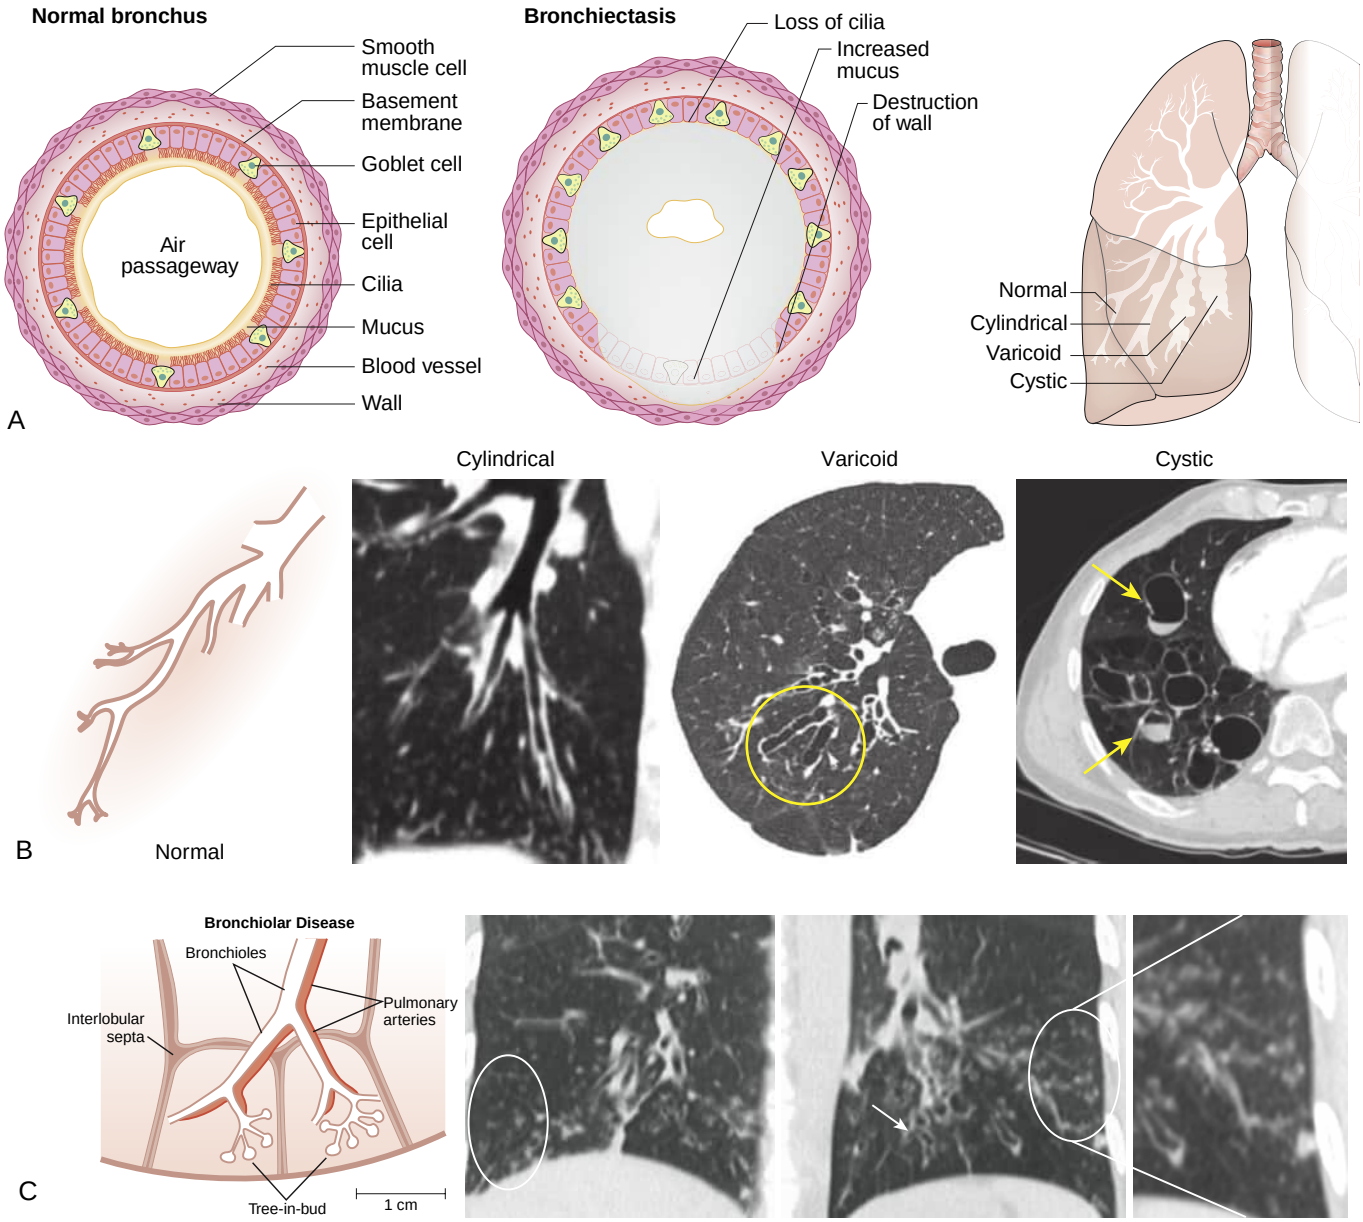

Figure 69.2 Radiographic examples of different forms of bronchiectasis. (A) The three top figures show a cross-section diagram of a normal airway, a bronchiectatic airway, and the three different forms of bronchiectasis on longitudinal view. (B) The middle panel shows a diagram of a normal bronchial tree demonstrating usual tapering as the airway branches distally (*far left*) and axial computed tomography images showing cylindrical bronchiectasis (*middle left*), varicoid bronchiectasis (*middle right, yellow circle*), and cystic bronchiectasis (*arrows, far right*). (C) The bottom panel shows a diagram of bronchiolitis (*left*) and a coronal computed tomography image (*right*) of inflammatory bronchiolitis manifested as tree-in-bud opacification *(white ovals)* (enlarged at *far right*) and bronchiectasis (*arrow*) in a patient with nontuberculous mycobacterial lung disease.

bronchial tree and helps perpetuate the chronic or recurring infections that mark most cases of bronchiectasis.

"VICIOUS CYCLE" AND MICROBIOLOGY

Because the lung is constantly exposed to the environment, resident or recruited lung phagocytes, such as macrophages, dendritic cells, and neutrophils, must play an important host defense role against inhaled or aspirated microbes. In addition, the host uses an array of other mechanisms to defend against microbial organisms that invade the respiratory tract, including the cough reflex, mucociliary escalator, antimicrobial peptides (lysozymes, secretory leukocyte protease inhibitor, defensins, and cathelicidin), secretory *immunoglobulin* (Ig) A, and, with more sustained infection, recruited T-effector lymphocytes. Airway epithelial cells are also able to contribute to the lines of defense by secreting antimicrobial peptides.[30,31] (See Chapter 15.) Thus, in addition to the three aforementioned mechanisms by which physical forces or primary weakness of the airway walls may result in bronchiectasis, the other major element in the pathogenesis of bronchiectasis is the vicious cycle of recurrent or sustained infection and inflammation, as described by Cole.[32,33]

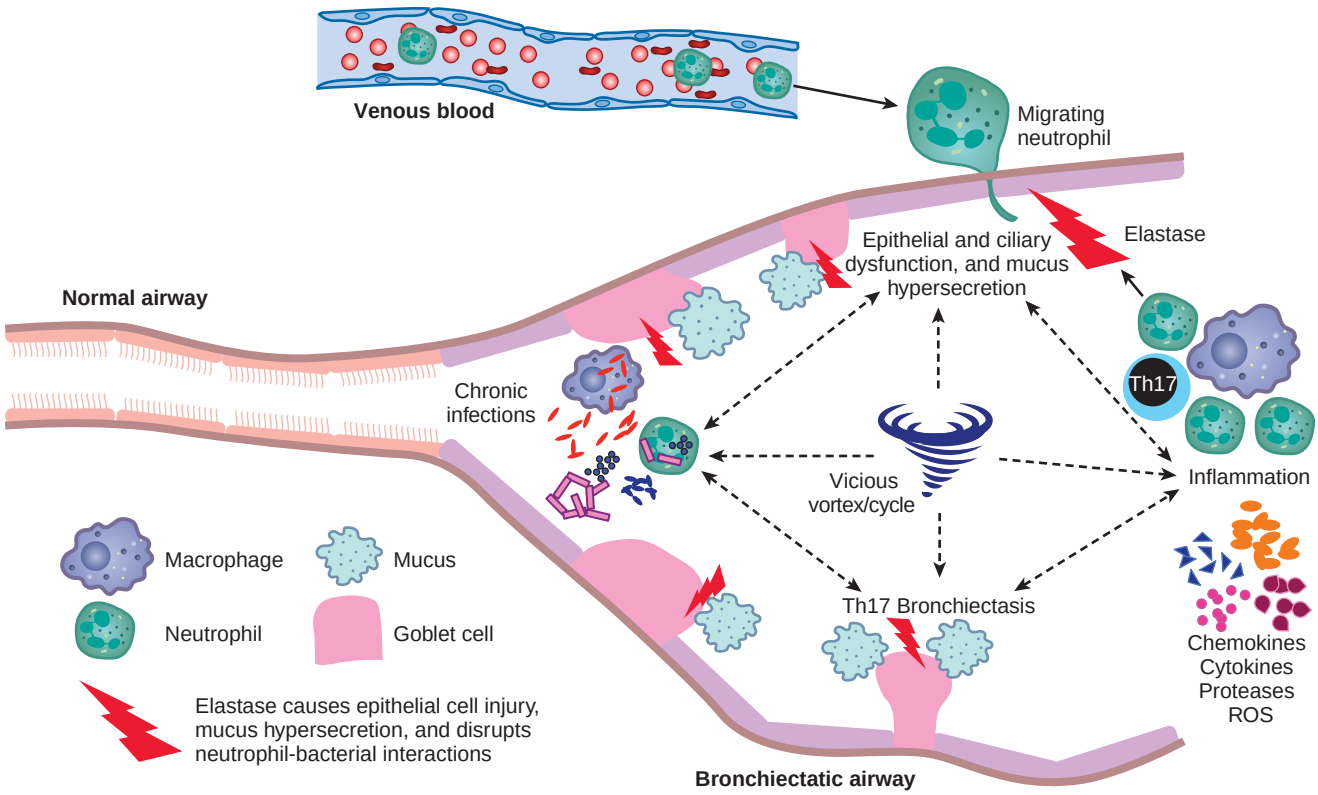

Figure 69.3 Cellular pathophysiologic mechanism of bronchiectasis. Cross-sectional view of the bronchiectatic airway demonstrating the components that play a role in the pathogenesis, including neutrophils, neutrophil elastase, goblet cells that produce mucus, and the chemokines and proinflammatory cytokines produced by macrophages and *T helper type 17 cells* (Th17). The epithelial and ciliary dysfunction, mucus hypersecretion, inflammation with unchecked protease (elastase) activity, chronic infection, and resultant bronchiectasis are intertwined and help perpetuate each other, creating the paradigm of the "vicious vortex/cycle" central to bronchiectasis pathogenesis. ROS, reactive oxygen species.

More recently, it has been proposed that a tetrad of events leads to bronchiectasis, the so-called "vicious vortex," a new term proposed because each of these factors may help perpetuate the other three (Fig. 69.3): (1) airway epithelial and ciliary dysfunction, and mucus hypersecretion; (2) chronic infections that induce further mucus hypersecretion; (3) inflammation, resulting in permanent airway injury and dilation; and (4) resultant bronchiectatic airways that are poor in mucociliary clearance, perpetuating the chronic infection, inflammation, and airway epithelial cell and ciliary dysfunction.[34] Transmural inflammation causes damage to the bronchi and bronchioles, which then become susceptible to chronic colonization by certain microorganisms, such as *Pseudomonas aeruginosa,* NTM, and *Aspergillus,* resulting in further injury and in less resistance to infection. Analysis of cellular and noncellular constituents in the bronchiectatic airways typically demonstrates intense infiltration by neutrophils, as well as by mononuclear cells and lymphocytes.[35] When the initial defenses are unable to contain the infection, an exuberant immune response ensues, orchestrated by airway epithelial cells and phagocytes through the release of inflammatory cytokines and chemokines that include macrophage inflammatory protein-2, *interleukin-8* (IL-8), and tumor necrosis factor-α. In consequence, airway infiltration by predominantly neutrophils, macrophages, and lymphocytes causes damage to the airway epithelium through the release of various proteolytic enzymes, such as neutrophil elastase and metalloproteinases, which results in erosion of mucosal barriers, creating microabscesses that can harbor bacteria. For instance, neutrophil elastase has also been shown to cause ciliary dysfunction, mucous gland hyperplasia, and increased mucus secretion, thus further impairing clearance, summarized in Figure 69.3.[36–38]

Moreover, elastase and other proteases released by neutrophils can cleave Fcγ receptors and complement receptor 1 from neutrophil surfaces, as well as digest Ig and complement components from bacterial surfaces. These activities impair opsonization of bacteria and reduce recognition of bacteria by neutrophils, leading to decreased phagocytosis and bacterial killing (see Fig. 69.3).[39,40] Neutrophils undergo both necrotic and apoptotic forms of cell death. Necrotic neutrophils can incite more inflammation and the release of highly viscous DNA, which contributes to the volume and inspissated quality of bronchiectatic mucus. Although phagocytosis of apoptotic neutrophils—a process known as efferocytosis, which requires engagement of phosphatidylserine on apoptotic cells and phosphatidylserine receptor on macrophages—can limit inflammation, elastase can inhibit efferocytosis by cleavage of phosphatidylserine.[41] In summary, damaged airways are vulnerable to infection, begetting more damage.

Simple colonization and infection of the airways is not sufficient to produce true bronchiectasis. Sputum from patients with smoking-related chronic bronchitis typically yields organisms such as *Haemophilus influenzae, H. parainfluenzae, Streptococcus pneumoniae,* and *Moraxella catarrhalis,* a microbial spectrum similar to that seen with bronchiectasis.[42–45]

In addition, in this setting, there is heavy cellular traffic and the presence of a variety of inflammatory mediators. However, significant bronchiectasis is uncommon among patients with typical chronic bronchitis. Hence it is probable that systemic conditions or additional focal disturbances as described earlier are required for the development of classic bronchiectasis. Of note, however, the appearance in respiratory secretions of *P. aeruginosa* on a chronic or recurring basis does pose the risk for deleterious effects on ciliary function and other host defenses.[46] Pseudomonal infections may be of particular importance due to their role in the formation of biofilms (see later). Indeed, chronic *P. aeruginosa* infection or colonization plays a major role in the pathogenesis of bronchiectasis and poorer health outcomes, including increased exacerbations and hospital admissions and an approximately threefold increased risk of death.[47] In a longitudinal study of the microbiologic characteristics of 89 patients with bronchiectasis over a 5-year period, 47% were colonized with *H. influenzae,* 12% with *P. aeruginosa,* and 21% had no identifiable pathogen. After 5 years, there was a slight increase in the number of those colonized with *P. aeruginosa.* As expected, those with the mildest disease had no identifiable pathogens, whereas those with the worst disease were colonized with *P. aeruginosa.*[48]

Genetic techniques have been used to identify the bacterial flora in patients with bronchiectasis. Using 16S ribosomal RNA gene pyrosequencing of paired induced sputum and bronchoalveolar lavage samples, the bacterial flora of lower airway samples was analyzed in 41 adult patients with non-CF bronchiectasis.[49] A group of core bacterial species, defined as those frequently detected, was found to consist of commonly recognized pathogens (e.g., *P. aeruginosa, H. influenzae,* and *S. pneumoniae*) but also organisms not typically detected by routine cultures (e.g., *Veillonella, Prevotella*).[49] Studies genetically categorizing the lung microbiome in patients with bronchiectasis and determining its significance relative to clinical end points, such as exacerbations, continue to be advanced. Although a study showed that there was no significant difference in the overall microbial community diversity between patients with stable bronchiectasis and those with exacerbations, it was clear that *Acinetobacter* and *Stenotrophomonas* were seen primarily during exacerbations.[50] In an editorial that accompanied this report, the authors raised the critical question of whether analyzing the mountain of 16S ribosomal RNA–derived microbiota data ("the forest") masks the importance of individual microbes detected ("the trees").[51]

BIOFILMS

In 1984, Costerton[52] hypothesized that *P. aeruginosa* in human infections "attaches to solid or tissue surfaces and grows predominantly in biofilms." These natural and pathogenic biofilms are covered by an exopolysaccharide matrix (glycocalyx) that serves as a barrier against hostile factors, such as host immune cells and antibiotics.[52] Since this discovery, there has been clear evidence for the importance of biofilms in promoting chronic bacterial infection in the airways of CF patients,[53] and in promoting infections with NTM and methicillin-resistant *Staphylococcus aureus*.[54] In addition, biofilms have been identified in bronchoalveolar lavage of patients without overt signs of infection.[55] *P. aeruginosa,* among its various attributes, uses cilia-driven motility, which appears critically important in the aggregation phase of early biofilm formation.[56] Once biofilm formation commences, features of growth and gene activation that release virulence factors are influenced by a type of cell-cell communication called *quorum sensing,* in which the individual bacteria share genetic information in a paracrine fashion. Owing to a combination of physicochemical factors that protect the microbes from host defense cells and/or antibiotics, infection may persist despite aggressive treatment. In vitro testing indicates that bacteria embedded in biofilms can survive despite exposure to concentrations of antimicrobials that exceed the minimal inhibitory concentration by 1000-fold.[57] We may anticipate that future understanding and optimal management of patients with bronchiectasis will entail interventions to modify or interfere with biofilms.[56] Among potential treatments, macrolides inhibit quorum sensing,[58] and *N*-acetylcysteine disrupts biofilm formation and enhances bacterial killing in in vitro studies.[59]

ASSOCIATED DISEASE STATES AND ETIOLOGIC CONSIDERATIONS FOR BRONCHIECTASIS

APPROACH TO DIAGNOSIS OF BRONCHIECTASIS ETIOLOGY

A diverse set of medical conditions is strongly associated with or complicated by bronchiectasis. Given the increasing attention to developing treatments for these unique and diverse etiologies, a systematic approach to diagnosis is recommended (Fig. 69.4).[60–62] Of special importance is the recognition of CF because of the highly efficacious and more specific therapies available to these patients (see also Chapter 68).

In addition to this schema, determining the etiologic cause of bronchiectasis may be enhanced by understanding distribution patterns on HRCT imaging. The anatomic distribution of bronchiectasis associated with various etiologies is outlined in Figure 69.5 (also see eFig. 20.52).

LUNG INJURY DUE TO ACUTE INFECTION

In the modern era in industrialized nations, most adequately treated episodes of lower respiratory tract infection resolve without residual damage. However, among the older generations who were not protected by readily available antibiotics and vaccines, some individuals offer a convincing history of recurring, localized infections after a discrete episode of "pneumonia" in their childhood or early adult years that presumably produced irreversible damage leading to bronchiectasis.[1]

Specific pathogens believed to cause bronchiectasis include *Bordetella pertussis,* mucoid strains of *S. pneumoniae, S. aureus, Klebsiella pneumoniae,* adenoviruses, rubeola (measles), and influenza. Chronic granulomatous pathogens commonly related to bronchiectasis include *Mycobacterium tuberculosis, Histoplasma capsulatum,* and NTM such as *Mycobacterium avium* complex (MAC). In

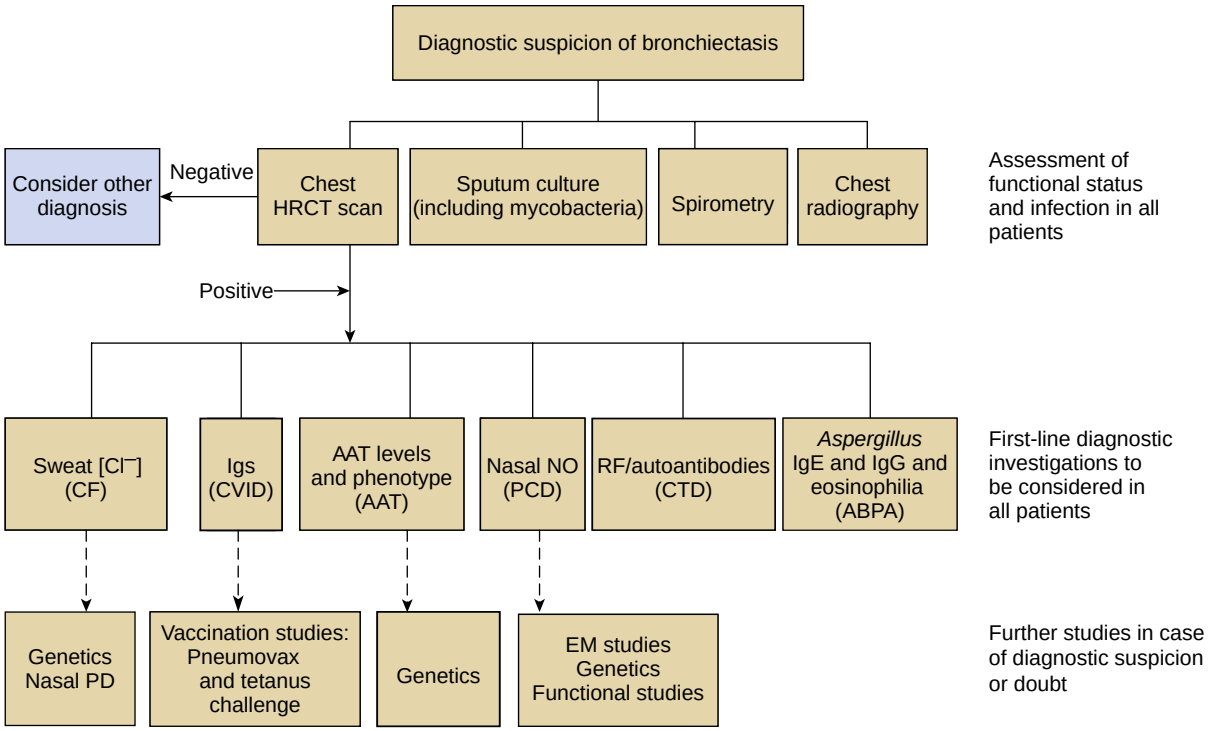

Figure 69.4 Diagnostic algorithm for the evaluation of suspected bronchiectasis. Although chest radiographs may suggest bronchiectasis, the diagnosis is confirmed by *high-resolution computed tomography* (HRCT). Sputum cultures and spirometry define the presence of infection and functional status. Subsequently, first-line laboratory and other ancillary tests are obtained to differentiate the more common causes of the bronchiectasis. Additional testing may be needed to diagnose less common causes if the initial evaluation is unrevealing. ABPA, allergic bronchopulmonary aspergillosis; AAT, alpha$_1$-antitrypsin; CF, cystic fibrosis; [Cl⁻], chloride concentration; CTD, connective tissue disease; CVID, common variable immunodeficiency; EM, electron microscopy; IgE, immunoglobulin E; IgG, immunoglobulin G; NO, nitric oxide; PCD, primary ciliary dyskinesia; PD, potential difference; RF, rheumatoid factor. (Modified from Drain M, Elborn S. Assessment and investigation of adults with bronchiectasis. *Eur Respir Monogr*. 2011;52:32–43.)

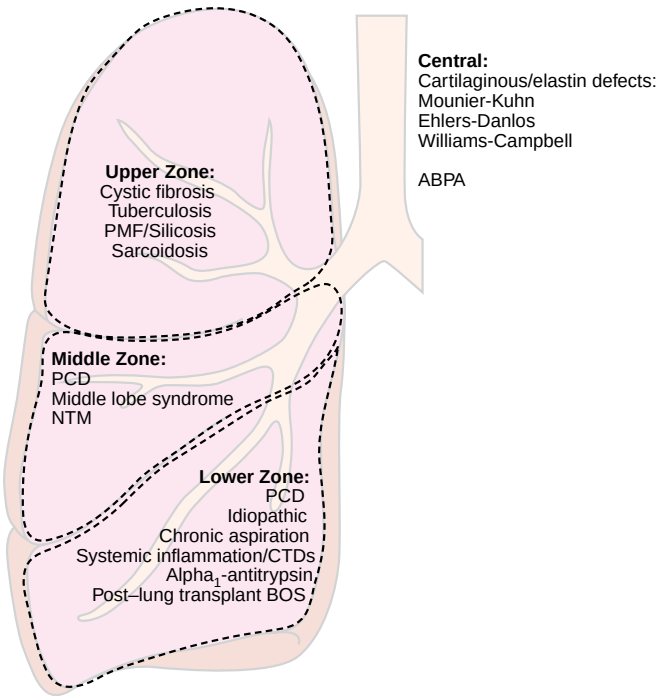

Figure 69.5 Anatomic clues to diagnosis of bronchiectasis. The causes of the bronchiectasis stratified by the predominant anatomic location of the lung abnormality; that is, upper, middle, or lower zone of the lungs and the central airway. ABPA, allergic bronchopulmonary aspergillosis; BOS, bronchiolitis obliterans syndrome; CTDs, connective tissue diseases; NTM, nontuberculous mycobacteria; PCD, primary ciliary dyskinesia; PMF, progressive massive fibrosis.

addition, mixed infection, including anaerobic mouth flora related to aspiration, may result in extensive damage to the parenchyma ("lung abscesses") with subsequent bronchiectasis.

BRONCHIECTASIS ASSOCIATED WITH NONTUBERCULOUS MYCOBACTERIA

NTM-associated bronchiectasis is discussed separately because the NTM may be a primary cause of bronchiectasis or a secondary infection complicating preexisting bronchiectasis. Chronic lung disease due to NTM is manifested by two main radiographic patterns, although both types may be found in a single patient: (1) an upper lobe fibrocavitary pattern seen mostly in persons with underlying lung disease, such as COPD, and (2) a nodular-bronchiectasis pattern with or without cavitary disease that often involves the right middle lobe, lingula, and/or right upper lobe seen in those with neither preexisting lung disease nor known genetic predisposition.[63,64] Although NTM can exacerbate preexisting bronchiectasis, such as that associated with CF,[65] *primary ciliary dyskinesia* (PCD),[66] prior tuberculosis,[67] and COPD,[68] it is also believed to cause bronchiectasis. Furthermore, there is increasing evidence that heterozygosity of the *cystic fibrosis transmembrane regulator* (CFTR) or *alpha$_1$-antitrypsin* (AAT) gene prediposes individuals to NTM infections resulting in secondary bronchiectasis.[69–71] Indeed, in the Bronchiectasis Research Registry for non-CF bronchiectasis, comparison of four different underlying

causes for bronchiectasis—idiopathic, AAT deficiency, *common variable immunodeficiency* (CVID), and PCD—revealed that those with AAT deficiency were significantly more likely to have NTM isolated from their respiratory samples than those with the other three underlying conditions.[72]

In patients with NTM lung disease, a careful family history should be obtained for bronchiectasis. We recommend that patients with NTM lung disease be screened for CFTR abnormalities, AAT anomalies, CVID, and swallowing dysfunction and, in certain groups such as those with sinusitis, infertility, and lower lung zone bronchiectasis, for PCD. Individuals with NTM-associated bronchiectasis who have no known predisposing factors have been observed by clinicians to possess marfanoid physical features, such as constitutively slender body habitus, scoliosis, and pectus excavatum, more commonly than anticipated by chance alone.[71,73–77] Of interest, this phenotype in those with NTM lung disease seems disproportionately to involve predominantly slender white or Asian women,[78,79] although it is also seen in men.[80] We and others have postulated that these skeletal abnormalities may be a marker for an underlying and yet-to-be identified genetic predisposition speculated to be related to a minor variant of Marfan syndrome or ciliary dysfunction.[71,74-76,81–83] In those with the marfanoid body habitus, do the airways dilate because of an intrinsic structural defect? This hypothesis is plausible because fibrillin-1 is a component of the extracellular matrix, and a fibrillin mutation is the cause of Marfan syndrome. Is there an immune defect that increases the risks for infections that set in motion the coughing and inflammation that lead to bronchiectasis? This supposition is supported by the fact that the morphologic anomalies seen with Marfan syndrome have been associated with increased localized production of transforming growth factor-β, a cytokine that increases susceptibility to mycobacteria.[84–87]

More recently, it has been hypothesized, based on gene sequencing, that a combination of variants of ciliary, immune-related, connective tissue, and *CFTR* genes, in addition to other factors such as body weight, age, and environmental exposure, cooperate to increase vulnerability to NTM lung disease.[88,89]

Regardless of the presence or absence of an underlying predisposing condition for NTM lung disease, there is also increasing evidence and experience that aspiration from swallowing dysfunction or *gastroesophageal reflux* (GER) may predispose to NTM infection.[90–92]

CYSTIC FIBROSIS

CF and CF variants are arguably the most common causes of bronchiectasis in the United States and other industrialized nations of the Western Hemisphere today. Being the most common autosomal recessive disorder among whites (1 in 2000–2500 live births),[93] CF is increasingly prevalent as improved therapies allow those who are afflicted to live longer (see Chapter 67 for full details on the incidence and prevalence of CF).

In addition to "typical" cases in which CF is recognized early in life, variants may be present in the population that predispose to bronchiectasis in adults. Among a large series of adult patients with bronchiectasis associated with NTM seen at National Jewish Health in Denver, 117 of 865 (13.5%) were found to have one or more abnormal alleles of the *CFTR* gene,[94] well in excess of the anticipated carrier rate of 6% in the general population. In 19 of these patients (2.2% overall), there were two abnormal alleles and, in the remaining 98 (11.3%), there was only one mutation. Of note, the mean age of these patients was 61 years. The clinical importance of these heterozygous mutations may be disputed; however, patients in this cohort had a high frequency of chronic airflow obstruction, sinusitis, difficulties with conception, and coinfection with pathogens typical of CF, including mucoid strains of *P. aeruginosa*, all features compatible with clinical CF.[94] Among another series of patients with bronchiectasis and/or NTM lung disease, 24 of 50 (48%) had one or more *CFTR* mutations.[95] Similarly, among a cohort of 63 patients with NTM lung disease studied at the National Institutes of Health, 36% had mutations in the *CFTR* gene.[96] Consistent with the assertion that these heterozygous mutations are clinically relevant is a series of 30 patients with clinical features of CF who were reported to have normal *CFTR* alleles on comprehensive gene sequencing.[97] The authors concluded that factors other than mutations in *CFTR* could result in a clinical condition consistent with CF. It is our contention that heterozygous anomalies in the CF gene act as a predisposing factor for NTM infections that lead to bronchiectasis.

Bronchiectasis has been described in a condition identified in the 1970s called Young syndrome. Although Young syndrome is not CF, it has a number of similar clinical features, such as bronchiectasis, sinusitis, and infertility.[98] However, unlike CF, the genetic basis for Young syndrome is not known and, because the definition includes azoospermia, it is seen only in men. Furthermore, whereas the azoospermia related to CF is due to congenital absence of the vas deferens, in Young syndrome it is due to obstruction in the distal epididymis (i.e., obstructive azoospermia).[99,100] In a comprehensive study of 15 patients with a clinical diagnosis of Young syndrome, the mean nasal mucociliary clearance was prolonged nearly threefold compared to nonsmoking control subjects, but the ciliary beat frequency and ultrastructural anatomy of the cilia were considered to be within normal limits.[100] Of interest, in one subject in whom a sample of epididymis was available, microtubular disarrangement, mostly missing or "displaced" microtubules, was seen in approximately 13% of the cilia examined.[100] Because the incidence of Young syndrome appears to be decreasing dramatically since it was originally reported in the 1970s, it has been hypothesized that Young syndrome may be due to poisoning from mercurous chloride (calomel), a compound contained in teething powder and antihelmintics, which has since been banned.[101,102] Furthermore, we posit that, with more comprehensive testing for the *CFTR* mutation, it is quite plausible that some cases diagnosed as Young syndrome were in fact CF.

DISORDERS OF IMMUNITY

The most common immunodeficiency associated with bronchiectasis is CVID. CVID is mostly sporadic but familial inheritance is seen in approximately 10% of cases.[103] CVID is best considered a syndrome comprised of a collection of

diseases with different genetic defects and characterized by reduced or absent serum IgG, IgA, and/or IgM, as well as reduced or absent antibody production to specific antigen challenge after exclusion of defined causes of hypogammaglobulinemia.[104] Specific molecular defects have been described in 2–10% of CVID patients.[105,106] Several cellular defects have been described, with the most prominent one being failure of immature B cells to differentiate into memory B cells and plasma cells. However, an array of defects in other immune cell types are commonly seen in CVID, including impaired dendritic cell function and reduced number and function of $CD4^+$ T-effector cells and T-regulatory cells.[103] Given the heterogenous clinical presentation, ranging from recurrent infections to autoimmune diseases, granulomatous inflammation, and lymphoid malignancies, CVID should not be viewed as a single disease entity.[103,107] It is believed that the recurrent infections with encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae,* and subsequent uncontrolled inflammation underlie the pathogenesis of bronchiectasis in CVID, which aligns with the generally accepted hypothesis set forth by Cole,[34] that a vicious cycle of chronic infection and inflammation is a key driver of bronchiectasis. Thus, recurrent infections and resultant bronchiectasis should raise the suspicion for CVID and should prompt further evaluation for an underlying immune defect.

Deficiency of *natural killer* (NK) cells has also been linked to the development of bronchiectasis and, of interest, a deficiency of circulating NK-cell subsets has been described with CVID.[108] Other less common to rare primary antibody deficiencies that can result in bronchiectasis include IgG subclass deficiency (total IgG is normal, but there is decreased level of one or more IgG subclasses: IgG1, IgG2, IgG3, IgG4), selective IgA deficiency (seen in up to 10% of the population studied), and a specific antibody defect (normal IgG, IgG subclass, IgA, and IgM but impaired antibody response to polysaccharide antigens).[109–111] Although agammaglobulinemia and CVID may be the most common primary immunodeficiencies associated with bronchiectasis, several other genetic primary immunodeficiencies can manifest with bronchiectasis, including those associated with *signal transducer and activator of transcription-3* (STAT-3) gain-of-function, *phosphoinositol-3-kinase* (PI3K) gain-of-function (*activated PI3K delta syndrome* or APDS), hyper-IgE syndrome (STAT-3 loss-of-function, DOCK8 and Tyk2 deficiency), cytotoxic T lymphocyte–associated protein 4 haploinsufficiency, and lipopolysaccharide-responsive beige-like anchor protein deficiency, among others.[112]

CVID in individuals older than 2 years is diagnosed by decreased serum levels of IgG and IgA of at least two standard deviations lower than normal for age and abnormal antibody responses to specific antigen challenge. For a specific diagnosis of CVID, the IgG level should be less than 4.5 g/L (normal: 7–18 g/L for adults), IgA should be absent or markedly reduced (normal: 0.7–3.5 g/L), and IgM should be normal or reduced (normal: 0.4–2.6 g/L). Rarely, IgM may be elevated due to a concomitant hyper-IgM syndrome or a class switch defect. An isolated reduction in IgG should prompt further analysis of IgG subclass deficiency (normal for adults in g/L: IgG1, 4.8–9.5; IgG2, 1.1–6.9; IgG3, 0.3–0.8; IgG4, 0.2–1.1).[103] In addition, it is important to exclude other causes of hypogammaglobulinemia, such as (1) nephrosis and other causes of Ig loss; (2) myriad drugs that can reduce Ig levels, including glucocorticoids, rituximab, alkylating agents, anticonvulsants (carbamazepine, valproic acid, phenytoin), and sulfasalazine; (3) underlying malignancy, such as chronic lymphocytic leukemia, lymphoma, and thymoma; and (4) various genetic abnormalities, such as X-linked agammaglobulinemia, Wiskott-Aldrich syndrome, ataxia telangiectasia, and severe combined immunodeficiency.[103,104,113] Of note, replacement with IgG does not always protect CVID patients from recurrent infections and bronchiectasis.[114] In patients with hypogammaglobulinemia on IgG replacement therapy, those able to secrete IgM (hyper-IgM syndrome) have a significantly lower risk of nontypeable *H. influenzae* carriage compared to those who lack IgM production (panhypogammaglobulinemia) despite equivalent trough levels of IgG.[115] Therefore, IgM probably plays a more prominent role in the protection against recurrent infection in CVID than previously thought, and patients should also be screened for low IgM because they might need prophylactic antibiotics in addition to IgG supplemention.[115]

Determining antibody responses to specific antigens (using commercially available vaccines) is most useful when there is a mild to moderate reduction in IgG.[103] Antibody responses to at least two protein-based vaccines (e.g., tetanus, diphtheria toxoid, or *H. influenzae* type b vaccine) should be assessed. A fourfold or greater increase in IgG level 4 weeks after immunization (or at least the presence of protective titers if less than a threefold increase from baseline) argues against CVID. The 23-valent pneumococcal vaccine (Pneumovax), which contains only polysaccharides, can be used to assess B cell responses independent of T cell help.[103] In contrast, the 13-valent pneumococcal vaccine (Prevnar) is used to assess B cell responses dependent on T cell help. In addition, in patients already receiving intravenous immunoglobulin, a *Salmonella typhi* polysaccharide vaccine may be used to assess the antigen response without discontinuing the therapy.[116] If testing for basal and stimulated immunoglobulins is suggestive of CVID, it is prudent to refer such patients to a clinical immunologist, because assessment of lymphocyte subset, B cell subsets, T cell function, and genetic testing for specific gene mutations are often warranted to prognosticate and formulate an optimal treatment regimen.

Among persons with acquired immunodeficiency syndrome, bronchiectasis has been identified in a significant proportion of those undergoing CT scans, including children.[117,118] Obviously this is skewed by the selection of those with respiratory problems for imaging. Presumably, the pathogenesis of the bronchiectasis involves severe, chronic, and recurrent infections with a variety of opportunistic pathogens.[119,120] An additional element that has not been fully addressed is the potential impact of oxidative damage associated with infection or other stressors on the AAT system.[121,122] Impairment of AAT function may contribute to the accelerated lung damage, including bronchiectasis, in persons with acquired immunodeficiency syndrome.[123,124]

Autosomal dominant hyper-IgE syndrome (AD-HIES) due to heterozygous STAT-3 mutation is a primary

immunodeficiency characterized by eczema, elevated serum IgE, and connective tissue and skeletal findings, and recurrent infections of the skin (abscesses), joints, gums, sinuses, middle ear, airways, and lung parenchyma.[125] These infections include severe recurrent bronchopneumonia, especially due to *S. aureus*, which leads to bronchiectasis and pneumatoceles. In addition, bronchiectasis in AD-HIES can also result from impaired remodeling of lung tissue due to a STAT-3 defect.[126] Bronchiectasis in AD-HIES predisposes to opportunistic NTM infection and invasive fungal infection, which contribute significantly to mortality in AD-HIES.

Chronic granulomatous disease (CGD) is caused by a mutation in one of the components of the *reduced nicotinamide adenine dinucleotide phosphate* (NADPH)-oxidase complex, subsequently resulting in deficient NADPH-dependent reactive oxygen species production. Individuals with CGD are vulnerable to severe recurrent bronchopneumonia, particularly with *S. aureus* and fungal infections, which can result in structural lung damage.[127] Although patients are often identified in early childhood due to the typical and severe infections, mild forms of CGD may present in adulthood, and thus CGD could be a cause of unexplained bronchiectasis.[128]

ALPHA$_1$-ANTITRYPSIN ANOMALIES

AAT deficiency may be associated with bronchiectasis.[129–132] Parr and colleagues[130] examined 74 patients with the protease inhibitor ZZ genotype, the most common genotype that results in AAT deficiency, and found that 70 (95%) had bronchiectatic changes on CT scan involving an average of 3.7 lobes and 20 (27%) had "clinically significant bronchiectasis," defined as bronchiectasis affecting four or more lobes *and* "regular sputum production." In contrast, a study of more than 200 bronchiectasis patients found that the frequency of abnormal AAT genotypes was not significantly different from those without bronchiectasis.[133] Thus, based on these studies, it seems that AAT anomalies are uncommon in unselected patients with bronchiectasis, whereas bronchiectasis is common in patients with known AAT deficiency.[134] Because the "Z" isoform of AAT may polymerize in the lungs and act as a chemoattractant for neutrophils, which can then release inflammatory mediators and elastase that incite airway damage, this is a plausible mechanism by which an abnormal AAT protein may predispose to bronchiectasis.[135] However, caution must be exercised in ascribing bronchiectasis to AAT deficiency because one potential confounder is that COPD itself may be associated with bronchiectasis as discussed later.

COPD

Over the past decade, likely due to increasing use of HRCT scans, a relatively high prevalence of bronchiectasis has been reported in patients with moderate to severe COPD and the presence of bronchiectasis has been associated with increased morbidity and mortality.[136–140] Given the 30–60% prevalence of bronchiectasis found in COPD patients in these studies, it would be important to evaluate AAT phenotypes to determine whether the bronchiectasis is associated more closely with severe COPD itself, with associated AAT anomalies, or with both. In one study, COPD patients with bronchiectasis had higher levels of the neutrophil chemoattractant IL-8 in their sputa, increased bacterial colonization of their lower airways, and more severe exacerbations than those without bronchiectasis.[139] Whether bronchiectasis is a sequela in COPD patients with frequent exacerbations, identifies a subgroup of COPD patients with a different pathogenic mechanism, or both, remains to be determined.[141]

PRIMARY CILIARY DYSKINESIA

PCD is an uncommon inherited condition, with an estimated prevalence of 1:10,000. PCD is caused by mutations of various genes that encode for dynein proteins that are components of cilia or for cytoplasmic proteins responsible for cilia assembly.[142,143] Respiratory manifestations result from defective ciliary structure and function in the middle ear, nose, sinuses, and tracheobronchial tree, and include chronic oto-sinopulmonary disease.[142,144–146] Because ciliary function is critically important for proper organogenesis and laterality of organs during embryonic development, there may also be complex congenital heart disease and inversion of the normal anatomic locations for the organs of the thorax and abdomen, whether *situs inversus universalis* (Kartagener syndrome) or *partialis*[147] (eFig. 69.6). Reduced fertility is another hallmark feature among men and women with PCD due to abnormal ciliary function that results in impaired sperm motility or fallopian tube dysfunction, respectively.

Because of impaired function of ciliated respiratory epithelium, PCD patients typically have a history of recurrent otitis media, sinusitis, chronic rhinitis, bronchitis, and bronchiectasis. Newborns with PCD often experience respiratory distress shortly after birth despite term gestation, which is believed to be a consequence of defective ciliary function causing inefficient clearance of lung fluid. In contrast to CF, the bronchiectasis associated with PCD tends to be lower lung zone predominant and milder in severity.[66,148] Compared to those with other causes of non-CF bronchiectasis, those with PCD are generally younger, have lower lung function, and perhaps have more exacerbations/hospitalizations.[72] Although PCD-associated bronchiectasis may not manifest until the late teens or early adulthood, asymptomatic or symptomatic bronchiectasis may be seen by imaging in PCD-affected children of all ages, including those younger than 5 years.[147] *H. influenzae*, *S. aureus*, and smooth strains of *P. aeruginosa* are commonly found in children with PCD, but infection or colonization with mucoid strains of *P. aeruginosa* typically does not happen until adulthood.[66,149] Other historical and clinical features associated with PCD include parental consanguinity, nasal polyps, pectus excavatum, and scoliosis.[149,150]

In contrast to CF, PCD is a genetically heterogeneous disease with numerous implicated genes leading to various abnormalities in ciliary structure and function. As a consequence, diagnosing PCD is not a trivial process.[62,66,152–154] A complement of functional and genetic tests is of value to diagnose PCD, and multiple tests may be required to confirm the diagnosis.[153]

Behan and coworkers[155] formulated and validated a clinical scoring tool, the *Primary Ciliary Dyskinesia Rule* (PICADAR), to help clinicians diagnose PCD in patients with chronic productive cough, using seven clinical parameters: situs inversus (4 points), full-term gestation (2 points), neonatal chest symptoms (2 points), neonatal intensive care admittance (2 points), congenital cardiac defect (2 points), chronic rhinitis (1 point), and ear symptoms (1 point). This PICADAR tool demonstrated a sensitivity and specificity of 90% and 75% for PCD diagnosis with scores of 5 or more out of a possible 14 points. A modified PICADAR score was subsequently developed for PCD screening in adult bronchiectasis because gestational age is often not known and thus omitted from the scoring criteria; in addition, "neonatal chest symptoms" and "neonatal intensive care admittance" were combined to "neonatal respiratory distress."[156] Using a cutoff score of 2 or more points with the modified PICADAR score, the sensitivity and specificity for PCD were 100% and 89%, respectively.[156]

Nasal nitric oxide (nNO) is a noninvasive test that has emerged as a screening test due to its high sensitivity for PCD.[153] Although nNO testing is still often limited to a few centers, the development of electrochemical portable analyzers that are relatively easy to operate will likely increase the availability of PCD screening.[157] Affected individuals have nNO that is significantly lower (<77 nL/min) than the range seen in unaffected individuals. Hypothesized mechanisms for the low nNO in PCD include reduced NO synthesis by the abnormal airway epithelium, increased NO breakdown by denitrifying bacteria, reduced storage capacity of NO in the paranasal sinuses, and NO trapped in obstructed paranasal sinuses.[158] It should be noted that approximately one-third of patients with CF have nNO below the diagnostic threshold for PCD, which underscores the importance of eliminating CF as a potential cause in anyone suspected of having PCD.[66,153,154] nNO is measured by aspirating nasal air while instituting measures to prevent sampling air from the lower respiratory tract (exhaled NO), which typically has much lower NO levels than nNO. A meta-analysis of 12 studies (514 PCD patients and 830 non-PCD subjects) comparing nNO with either ultrastructural analysis by *transmission electron microscopy* (TEM) alone or TEM plus genetic testing found nNO had a sensitivity of 98% and specificity of 96%.[159] But it is important to emphasize that patients with low nNO may also have negative genetic testing or normal/nondiagnostic TEM analysis for PCD.[160] The specificity of low nNO for PCD may be further compromised if CF and patients with acute viral infections, chronic sinusitis, nasal polyposis, human immunodeficiency infection, cigarette smoking, and diffuse panbronchiolitis are not excluded, because these conditions may be associated with low nNO.[152,153]

Genetic testing for PCD is becoming more available with development of commercial testing panels. Currently, mutations of more than 40 genes have been identified to cause PCD. Because it is likely that not all genes associated with PCD have been identified, the sensitivity of genetic testing for PCD is estimated to be about 50–80% with the 26-gene panel, increasing to 94% with the 32-gene panel.[62,153,154] Biallelic autosomal mutations or hemizygous X-linked mutations in one of the approximately 40 PCD genes are present in greater than 70% of patients with PCD.[161] The majority of these mutations are either deletion or nonsense mutations leading to a loss-of-function of ciliary proteins (e.g., DNAI1, DNAI2, or DNAH5) or cytoplasmic proteins involved in the preassembly of the cilia.[152] Mutation of any of the cytoplasmic proteins involved in cilia assembly results in loss of both outer and inner dynein arms, causing ciliary immotility or severe dysmotility, and mutation of genes that encode for dynein arm components results in partial or complete situs inversus. Complicating genetic diagnosis, several mutations implicated in PCD can be associated with normal ultrastructural findings (≈30% of cases) and may even demonstrate normal ciliary beat frequency and motility.[152,162]

The traditional gold standards for diagnosis of PCD are TEM of ciliated epithelium revealing ultrastructural defects of the cilia ultrastructure (e.g., absence of outer and/or inner dynein arms) and measurements of ciliary beat frequency or coordination via high-speed video microscopy. However, each has its own considerable limitations, as discussed later. Ultrastructural findings of abnormal cilia include complete or partial absence of outer or inner dynein arms, a lack of radial spokes, and transposition of one or more outer doublet microtubules into the central area of the cilia resulting in dyscoordinated and chaotic ciliary movement. These tests are limited by availability and expertise required, as well as the fact that, due to chronic sinopulmonary infection, the biopsied samples often contain inadequate or infection-induced damage to the ciliated epithelium, precluding accurate assessment.[152,163] Furthermore, based on clinical manifestations and genetic testing consistent with PCD, it is estimated that about 30% of PCD patients have normal or near-normal cilia ultrastructure, as exemplified by those with mutation of *DNAH11*.[152,154,164–166] Thus, absence of ultrastructural abnormalities does not rule out PCD.

Measurement of ciliary beat frequency and analysis of dysmotility, by high-speed video microscopy alone (120–500 frames/sec) or combined with ciliary wave form analysis (also known as ciliary beat pattern, which assesses ciliary coordination and the presence of a full sweep motion), require experienced investigators and specialized techniques. Despite optimal conditions, known limitations to assessing ciliary function include the presence of ciliary dysfunction due to infection, inflammation, and/or injury during sample collection, as well as the overlap of ciliary beat frequencies between PCD patients, disease controls, and even normal subjects.[152] Thus, an abnormal ciliary beat frequency or dysmotility does not definitively diagnose PCD and, conversely, a subset of genetically confirmed PCD patients have normal ciliary beat frequency. Hence, there was less enthusiasm for measurement of ciliary beat frequency in the 2018 guideline for diagnosing PCD.[153,154]

Among adult men, semen analysis may be useful to diagnose PCD. Dysmotile or immotile spermatozoa may be demonstrated using traditional light microscopy, using a slide prepared with a drop of nondiluted semen at 200× to 400× magnification. Abnormal motility is diagnosed if greater than 50% of sperm are immotile or nonprogressive, meaning that they move but do not make forward progression.[167] However, visualization of motile sperm does not rule out the possibility of PCD. Sperm tails may appear morphologically normal using light microscopy; therefore, ultrastructural analysis of the sperm flagella using TEM is needed to confirm the diagnosis. Sperm tails often, but not always,

demonstrate the same inner and/or outer dynein arm defects present in the respiratory cilia.[168] Although infertility due to impaired or absent sperm motility is supportive of a diagnosis of PCD, fatherhood (or motherhood) of PCD subjects has been reported, and thus male (or female) fertility does not rule out a diagnosis of PCD.[169]

Given the complexities and uncertainties of the various tests available to confirm the diagnosis of PCD and the order they should be performed, a recently published American Thoracic Society guideline on PCD diagnosis generated an algorithm that aids clinicians in PCD assessment (eFig. 69.7).[153,154]

BRONCHIAL CARTILAGE OR ELASTIC FIBER DEFECTS

Mounier-Kuhn syndrome, or congenital tracheobronchomegaly, is a rare disorder associated with gross enlargement or dilation of the trachea and segmental bronchi[170] (eFig. 69.8). The underlying defect is atrophy and even absence of elastic fibers and smooth muscle tissues of the large airways.[171] Atrophy of the connective tissue between the rings may result in outpouchings (diverticulae) that can serve as reservoirs for recurrent infections. Clinically, Mounier-Kuhn patients may present in early childhood or as late as the fourth decade with recurring lower respiratory infections. The diagnosis is readily made by finding extraordinary dilation of the trachea and central bronchi on CT scans, especially in the presence of tracheal and/or bronchial diverticula (see eFig. 69.8); for men, transverse and sagittal tracheal diameter greater than 25 mm and greater than 27 mm, respectively, is considered abnormally enlarged, whereas in women, the respective values are greater than 21 mm and greater than 23 mm.[172] Special considerations in management include positive end-expiratory pressure support and silicone or metallic stenting. Lung transplantation is an option, although unique issues associated with Mounier-Kuhn syndrome include recurrent infections when tracheal diverticula are present and difficulty with bronchial anastomosis due to discrepancy in the airway diameters between the donor and the recipient lungs.

Williams-Campbell syndrome arises due to absence of cartilaginous rings in the fourth- to sixth-generation subsegmental bronchi in a symmetrical distribution, although more proximal bronchi may also be involved.[173] In addition to the subsegmental and segmental bronchiectasis, bronchomalacia of the more proximal airways may be seen[174] (eFig. 69.9). Familial cases have been reported in this condition, although the precise genetic defect is not known. Patients with Williams-Campbell syndrome are particularly predisposed to proximal bronchomalacia after transplantation due to the combined effects of cartilage deficiency in their mainstem bronchi in addition to the usual decrement of blood supply to the proximal airways due to loss of collateral circulation of the transplanted lung.[175]

CONNECTIVE TISSUE DISORDERS

Among the various formally described heritable disorders of the connective tissues, Marfan syndrome, caused by mutations of the *fibrillin 1 (FBN1)* gene, with more than 600 different mutations of *FBN1* identified, has been reported to be associated with bronchiectasis.[176–178] Other lung disorders associated with Marfan syndrome include distal acinar emphysema, cystic degeneration, spontaneous pneumothorax, bullae, apical fibrosis, and a congenital pulmonary malformation known as middle lobe hypoplasia.[178]

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Conditions such as sequestration, agenesis, hypoplasia, and atresia may primarily cause bronchiectasis or may predispose to infections that secondarily cause bronchiectasis. Sequestrations presumably develop from accessory primordial lung buds, which may be invested within normal lung tissue (intralobar) or external to the normal lungs (extralobar). Sequestrations may or may not connect with the bronchial tree and often derive their blood supply directly from the aorta. Clinically, intralobar sequestration most commonly presents with recurrent and/or chronic lower respiratory tract infections beginning in the second or third decade of life, whereas extralobar sequestration is usually asymptomatic due to lack of communication with the airways. Radiographically, they usually appear as irregular, peculiar densities abutting the diaphragm in the posterior basal regions. Unilateral hyperlucent lung (Swyer-James-MacLeod syndrome) is characterized by unilateral bronchiolitis leading to hyperinflation. In some cases, bronchiectasis is present. The etiology and pathogenesis of this rare disorder are uncertain but may involve developmental or acquired disturbances of the bronchial tree.

IDIOPATHIC INFLAMMATORY DISORDERS

There is a wide array of idiopathic inflammatory conditions associated with bronchiectasis. They are all systemic illnesses that variably involve the lungs and may or may not result in bronchiectasis.

Sarcoidosis is by far the most common of these disorders (see Chapter 93). Broadly, sarcoidosis may involve the airways by several fundamental mechanisms: diffuse parenchymal scarring resulting in traction and airway distortion; endobronchial granulomatous inflammation, including stricture with poststenotic infection; or compression secondary to hypertrophic peribronchial lymphadenopathy.[179]

Rheumatoid arthritis (RA) may entail a variety of pulmonary manifestations. In two early series, bronchiectasis was seen in 3.2%[180] and 5.2%[181] of RA patients. More recently, bronchiectasis has been described in considerably higher percentages of RA patients undergoing HRCT scanning (20–35%)[182]; these studies were likely skewed by the selection of patients with respiratory problems. However, bronchiectasis was seen in 8% of RA patients without respiratory symptoms.[183] Of note, the majority of the patients in the previously discussed series did not have RA-associated interstitial lung disease as a presumed cause of the bronchiectasis. Potential causal mechanisms include increased propensity for infections, either intrinsic to RA or secondary to glucocorticoid or cytotoxic therapy. Clinically, the presence of bronchiectasis in RA patients was associated with an unfavorable prognosis in one series.[184]

Ankylosing spondylitis has been classically associated with upper lung zone fibrocystic degeneration and ankylotic fusion of the junctions of the ribs and vertebrae, resulting in restricted ventilation. However, in a large series from the Mayo Clinic, pulmonary involvement was described in only 1.2% of the patients.[185] Bronchiectasis independent of apical fibrocystic disease has been seen in a small series from the United Kingdom.[186]

Systemic lupus erythematosus may involve an assortment of pulmonary complications, including those intrinsic to the disorder itself, whereas others may be iatrogenic (see Chapter 92). Bronchiectasis was described in 21% of systemic lupus erythematosus patients studied with HRCT.[187] As with RA, the presence of Sjögren syndrome may be a comorbid element that predisposes to bronchiectasis.

Sjögren syndrome, keratoconjunctivitis sicca, and xerostomia (dry eyes and mouth) may exist in the primary form or in association with other collagen vascular diseases, such as RA or systemic lupus erythematosus. Pulmonary complications of Sjögren syndrome include lymphocytic interstitial pneumonia, lymphoma or pseudolymphoma, and/or pulmonary hypertension (see Chapter 92). Bronchiectasis has also been noted.[188–190] It is reasoned that lymphocytic inflammation results in impaired function of mucous glands, in turn resulting in decreased volumes and increased desiccation and viscosity of mucus. This leads to airway obstruction, poor clearance, and chronic infection. There have not been large CT scan surveys in patients with Sjögren syndrome to quantify the incidence of bronchiectasis.

Inflammatory bowel disease–associated bronchiectasis appears to be more common with ulcerative colitis than with Crohn disease.[191,192] In the majority of cases, the bowel disease antedates the lung manifestations, but the conditions may be temporally reversed. One unique observation of ulcerative colitis–associated bronchiectasis is that it may develop after therapeutic colectomy.[193] Proposed pathogenic relationships include a cryptogenic infection that incites both airway and intestinal inflammation, common epithelial targets of autoimmunity, or sensitizing agents that are inhaled and/or ingested, resulting in both lung and bowel disease.

Relapsing polychondritis is identified essentially as progressive inflammation, weakness, and deformity of cartilaginous structures, including the ears, nose, larynx, and tracheobronchial tree, typically associated with nonerosive polyarthritis. In addition, there may be inflammatory and/or functional disturbances of the eyes, auditory/vestibular components of the ears, and aorta (vasculitis with aneurysm). Respiratory involvement is characterized by tracheal and bronchial cartilage inflammation, resulting airway collapse, and airflow limitation (eFig. 69.10). Bronchiectasis in such patients may be due to primary bronchial damage and/or recurrent infection.[194]

ASPIRATION/INHALATION ACCIDENTS (See Also Chapter 43)

Spillage of foreign matter into the airways may result in bronchiectasis. There are two fairly distinct scenarios in which such matter might be aspirated into the lungs and cause sufficient damage to result in chronic deformity of the airways. One is the direct spillage of secretions from the oropharynx—infamous for containing a plethora of microorganisms, including microaerophilic and anaerobic bacteria—producing necrotizing pneumonia. The other is introduction of materials refluxed from the esophagus and/or stomach, which, in addition to the microorganisms noted earlier, contain food particles, hydrochloric acid, biliary or pancreatic secretions that contain various proteases, and microbes indigenous to the gut.[195]

Laryngeal protective functions are imperfect, and "microaspiration" is common. Thus, we might presume that aspiration leading to lower respiratory tract infections involves greater-than-usual volumes and/or more noxious contents. Also, it is reasonable to posit that once the airways have been damaged, a lesser inoculum may be adequate to incite the same damage, a variant of the "vicious cycle" theory.

Many factors influence the likelihood/frequency of aspiration. They include (1) depressed sensorium (trauma, alcohol or drug abuse, postictal confusion state, and general anesthesia), (2) altered brainstem function (cerebrovascular accident, polio, and primary neurologic diseases, such as multiple sclerosis, amyotrophic lateral sclerosis, or syringomyelia), (3) altered laryngeal structure/function (after surgery or irradiation), (4) esophageal disorders (dysmotility, obstruction by tumors or strictures, muscular dystrophy, achalasia, tracheoesophageal fistulas, or lower esophageal sphincter incompetence), and (5) gastric dysfunction (dysmotility or outlet obstruction).

Although all of these elements may contribute to the risk for infection (and bronchiectasis), it seems likely that GER is the most common factor. Among a cohort of bronchiectasis patients noted previously, approximately three-fourths of them had demonstrated abnormalities of esophageal morphologic features (dilation and thickening), function (dysmotility), anatomy (hiatal herniation), or competence (overt reflux).[196] Indeed, the frequency of esophageal disturbances was so high that one might question whether the esophageal findings were the cause of recurring infections/bronchiectasis or, in some cases, an effect. In the latter regard, among a series of patients with asthma and idiopathic pulmonary fibrosis, the incidence of esophageal dysfunction ranged from 80–95%.[197,198] It is plausible that labored breathing with wide disparities between intraabdominal and intrathoracic pressure and/or chronic coughing, which stresses and dilates the diaphragmatic ring, might disrupt the lower esophageal sphincter and subject the esophagus to distending forces.[199] An additional factor that could contribute to GER disease is the medical therapy used for these lung disorders; anticholinergics, β_2-agonists, theophylline, and corticosteroids can impair lower esophageal sphincter function,[200] and broad-spectrum antibiotics alter gastroesophageal flora.

For those suspected of disordered swallowing, tailored hypopharyngography using contrast materials of varying consistency may identify unsuspected aspiration, even in the absence of awareness or coughing. A speech therapist can also instruct patients on safer techniques for eating, drinking, and swallowing.

Impaired esophageal motility may be suggested on CT scans of the lungs, manifesting as grossly dilated esophagus, excessive luminal air in the esophagus, and/or thickened esophageal walls. Impaired motility may often be

demonstrated on a simple barium swallow. The extent of impaired contractility may be measured by esophageal manometry; this is essential if a reconstitution of the lower esophageal sphincter is contemplated. Demonstrating actual reflux may be challenging. If gross reflux is demonstrated on a routine study, it is sufficient for a presumptive diagnosis. However, if symptoms or other clinical features suggest GER disease, and the upper gastrointestinal series has negative results, an 18- to 24-hour pH probe with or without measurement of impedance may both identify and quantify reflux episodes.[197] Non-acid reflux may result in chronic cough and even lung injury.[201] Among the implications of these findings is that acid inhibition measures may not be sufficient to protect the airways. For individuals with evidence of recurrent aspiration, elevation of the head of the bed should be done routinely.

Toxic inhalation or thermal injury may also be associated with bronchiectasis. Acute and chronic inflammation of the tracheobronchial tree, bronchiolitis, bronchiolitis obliterans, and diffuse alveolar damage may be a consequence of exposure to toxic metal fumes (e.g., aluminum, cadmium, chromium, nickel) or toxic gases (e.g., ammonia, chlorine, phosgene, sulfur dioxide) (see Chapter 103). In severe cases, bronchiectasis may ensue because of infectious complications of the exposure, denuding of the ciliated epithelium, or progressive fibrosis. Similarly, chronic airway damage and bronchiectasis may evolve after thermal or smoke injury.

POSTOBSTRUCTIVE DISORDERS

Foreign bodies may be aspirated into the airways, especially in infants and children. Adults may aspirate with eating, trauma, or loss of consciousness. In some cases, the obstructing object may be radiopaque (teeth, bone, or metal objects) but, in most instances, the obstructing material (e.g., peanuts, vegetables) is not discernible by standard chest radiography. Tumors, benign or malignant, may also result in airway obstruction, poor drainage, recurrent/chronic infection, and bronchiectasis. The more common tumor types include bronchogenic carcinomas (particularly the squamous cell variety), carcinoid tumors, and papillomas. Extrinsic airway compression due most often to hypertrophic lymphadenitis from granulomatous diseases, such as sarcoidosis or infections and including tuberculosis or histoplasmosis, may severely narrow or even occlude large airways. In patients with "focal" bronchiectasis, particularly those with disease limited to only one region (eFig. 69.11), bronchoscopic examination to exclude an obstructing lesion should be performed early if other causes are not evident.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS (See also Chapter 96)

ABPA is a relatively uncommon condition, estimated in approximately 2.5% of patients with asthma.[202] ABPA is a hypersensitivity reaction, usually to *Aspergillus fumigatus,* but other fungi, including *Candida albicans,* may also be a source of the antigenic stimulus (allergic bronchopulmonary mycoses). The exaggerated type 2 T helper cell response seen in ABPA is likely due to *human leukocyte antigen* (HLA)-DR2/5 polymorphism resulting in greater efficiency in presenting *Aspergillus* allergens to T cells.[203] As a result of type 2 T helper cell expansion and release of IL-4, IL-5, IL-9, IL-10, and IL-13, there is increased expansion and influx of eosinophils and mast cells, as well as isotype switching to IgG and IgE.[203]

ABPA may manifest with fever, wheezing, eosinophilia, and fixed or fleeting pulmonary opacification (often upper lobes). The opacifications range from subsegmental to lobar and are due to eosinophilic infiltration and/or lymphocytic interstitial pneumonia. Other radiographic findings include atelectasis due to mucus plugging, manifesting clinically as expectoration of thick, brown mucous plugs. The inflammation and distention from the plugs typically result in thin-walled bronchiectasis that is often multilobar and central (Fig. 69.6). The mucoid impaction may show high attenuation, reflecting the organism's ability to fix calcium salts, iron, and manganese (see eFig. 69.5D and F).

The diagnosis of ABPA should be considered in patients with asthma or CF who have frequent exacerbations requiring anti-inflammatory drugs to affect symptomatic relief. The diagnostic criteria for ABPA have evolved but include a number of clinical, radiographic, and laboratory features.[203] A more current diagnostic criterion was proposed by the International Society for Human and Animal Mycology, which allows a diagnosis of ABPA to be made in the absence of radiographic changes[202,204,205] (Table 69.2). However, many patients with ABPA do not have all the criteria, especially with early disease or if taking glucocorticoids. If patients fulfill all the criteria for ABPA except for bronchiectasis, they are diagnosed with seropositive ABPA, likely an early stage of disease.

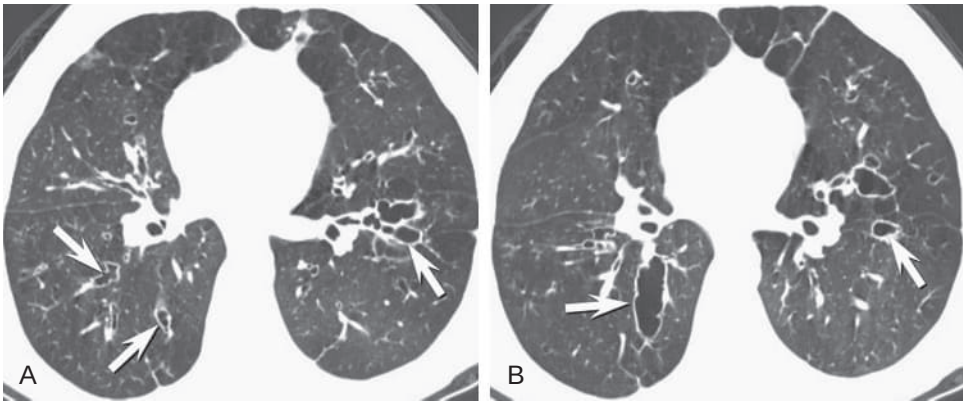

Figure 69.6 Bronchiectasis: allergic bronchopulmonary aspergillosis. (A–B) Axial chest computed tomography shows central bronchiectasis (*arrows*), typical of allergic bronchopulmonary aspergillosis. (Courtesy Michael B. Gotway, MD.)

Table 69.2 Diagnostic Criterial for Allergic Bronchopulmonary Aspergillosis

Predisposing condition: asthma or cystic fibrosis
ESSENTIAL CRITERIA
1. Type I immediate cutaneous hypersensitivity reaction (wheal and flare) to *Aspergillus fumigatus** or elevated serum IgE against *A. fumigatus* and
2. Elevated total IgE (>1000 IU/mL†)
OTHER CRITERIA (≥2 OF 3 NEEDED)
1. Presence of serum precipitating or IgG against *A. fumigatus*
2. Radiographic pulmonary opacities consistent with ABPA (e.g., pulmonary opacification and/or bronchiectasis)
3. Total eosinophil count >500 cells/μL in patients not on recent corticosteroids

*Although cutaneous skin testing is nearly 100% sensitive and is a useful screening test for ABPA, it is not specific for ABPA.
†Total of IgE <1000 IU/mL may be acceptable if patient meets all other criteria.
ABPA, allergic bronchopulmonary aspergillosis; IgE, immunoglobulin E; IgG, immunoglobulin G.
From Agarwal R, Chakrabarti A, Shah A, et al; ABPA Complicating Asthma ISHAM Working Group. Allergic bronchopulmonary aspergillosis: review of literature and proposal of new diagnostic and classification criteria. *Clin Exp Allergy*. 2013;43:850–873.

Distinguishing ABPA from CF can be difficult, given the similarities between the two disorders, including the presence of bronchiectasis and positive serologic tests for *Aspergillus*. The CF Foundation has established diagnostic criteria for ABPA in CF patients: (1) clinical deterioration not attributable to another cause, (2) IgE greater than 1000 IU/mL, (3) skin test positivity to *Aspergillus,* (4) precipitating antibody or specific IgG to *Aspergillus*, and (5) abnormalities on chest imaging unresponsive to antibiotics or standard chest physiotherapy.[203]

IDIOPATHIC BRONCHIECTASIS

Depending on the extent of evaluation and perhaps referral bias, "idiopathic" bronchiectasis, for which no known predisposition is identified, is estimated to account for 25–50% of cases of bronchiectasis.[1,206,207] Although the diagnosis of idiopathic bronchiectasis can only be made after known causes of bronchiectasis are effectively excluded, it often has a characteristic phenotype of bilateral lower lobe bronchiectasis and chronic rhinosinusitis.[1] Genotyping studies of class I and class II major histocompatibility complex molecules indicate that allelic polymorphism for certain HLA subtypes are statistically associated.[208–211] NK cell activation may play a role. NK cells use their killer cell Ig-like receptors to recognize abnormal HLA-C molecules on the surfaces of infected cells, and genotypic analysis of HLA-C–killer cell Ig-like receptor combinations have supported a role for increased NK cell activation in the pathogenesis of idiopathic bronchiectasis.[208] However, to the best of our knowledge, functional studies to confirm excessive NK cell activity in patients with idiopathic bronchiectasis have not been done. Nevertheless, this hypothesis is supported by the presence of bronchiectasis in patients with the transporter-for-antigen-presentation deficiency syndrome, a genetic disorder with impaired HLA class I expression and dysregulated NK, γδ cytotoxic T cell, and $CD8^+$ T cell function. In this disorder, the defective HLA class I expression results in increased NK and γδ T cell activities because HLA class I normally serves as an inhibitory ligand for these cell types.[212]

MISCELLANEOUS

There are numerous other causes of bronchiectasis, including such diverse entities as yellow nail syndrome and radiation therapy injury.

Yellow nail syndrome is an uncommon disorder marked by the triad of yellow, thick, dystrophic nails; chronic lymphedema of the face, hands, and lower extremities; and pleural effusions.[213] Women are more commonly affected than men; the median age of onset is 40 years, with cases ranging from infancy to the seventh decade. The most prominent pulmonary finding is bilateral exudative pleural effusions.[214] Recurrent sinusitis and lower respiratory tract infections are common, the latter resulting in bronchiectasis.[215] Contributing factors for bronchiectasis include abnormal lymphatic structure, increased vascular permeability, deficient immunoglobulin production, and/or ciliary dysfunction.

Radiation therapy, typically delivered for carcinoma of the breast or mediastinal tumors, including lymphomas, may result in profound damage to the central airways. This reaction is marked by focal damage to the cartilage and mucosa of the airways leading to distention and irregularities of the major bronchi in the field of irradiation. Bronchiectasis secondary to radiation therapy for neoplasms has become less common as radiation dosage and field used have become more refined. This condition may be recognized by lung parenchymal scarring in the field of irradiation (eFig. 69.12).

MANAGEMENT

The care of patients with bronchiectasis typically involves many layers, which may be partitioned into five broad components: airway hygiene, antimicrobial treatment, anti-inflammatory therapy, surgery, and miscellaneous. Although most patients with bronchiectasis require various elements of each of these components to enjoy optimal health, there is no standard formula for treating this disorder. The great majority of recurrently or chronically symptomatic patients benefit from a regular mucus-clearing regimen and periodic antibiotic therapy. For most patients, a pragmatic or trial-and-error approach is required to determine individual needs, preferences, and tolerances.

It is important to note that most elements described in this section have not been shown to be efficacious by randomized, controlled clinical trials. Thus, meta-analyses, such as those reported in the Cochrane Database of Systematic Reviews, generally cannot confirm the benefits or disutility of such approaches.[216–223] Perhaps because bronchiectasis is such a complex mix of varying conditions and has been an underappreciated "orphan" disease, a paucity of systematic research has been directed at this very troublesome

disorder, although this is changing. The available evidence and assessment of the value of integrated therapies have been summarized in two guidelines by the British Thoracic Society[60] and the European Respiratory Society.[61]

AIRWAY HYGIENE AND HYPEROSMOTIC AGENTS

Airway hygiene consists of nonantibiotic therapies directed toward mobilizing and eliminating inflammatory secretions from the tracheobronchial tree and from the paranasal sinuses. Modern devices to facilitate airway clearance of secretions include the Flutter valve, Acapella valve, Aerobika valve, and high-frequency chest wall oscillation devices. See eFig. 69.13 for a summary of potential airway clearance therapies. Also included under this rubric are steps to prevent/limit aspiration of oropharyngeal or gastroesophageal contents into the airways.

Hypertonic saline, 3% or 7% two to four times daily, has been shown to accelerate mucus clearance, decrease exacerbations, and improve lung function in CF patients.[224] However, its role in non-CF bronchiectasis remains to be seen because studies show conflicting results. When hypertonic saline was used for mucus clearance as part of an algorithm in combination with protocolized chest physiotherapy, exacerbations were reduced.[225] Inhaled dry-powder mannitol, recently approved for adult CF patients,[226] appears promising in airway clearance in bronchiectatic patients,[227,228] although it may be difficult to tolerate.

The mucolytic drug *N*-acetylcysteine (600 mg twice daily) was found to be effective at reducing exacerbations when taken orally,[229] although studies to confirm this small sample size trial are needed. Other mucoactive drugs, such as recombinant human deoxyribonuclease, failed to reduce exacerbations and had a trend toward more frequent and severe exacerbations in patients with idiopathic bronchiectasis.[230]

ANTIMICROBIAL THERAPY

Antimicrobial therapy historically has been the centerpiece of bronchiectasis care. However, there is no clear consensus on the major questions in this area, including whether treatment should be given on a routine, periodic schedule (rotating) or an as-needed basis for clinical exacerbations. In a meta-analysis of the use of prolonged oral antibiotics for purulent bronchiectasis, sputum volume/purulence was shown to decrease, but there were no significant beneficial effects in regard to rates of exacerbations, lung function, or death.[231] There are also limited data on the empirical selection of an antimicrobial agent or treatment guided by species identification and in vitro susceptibility testing. For patients unresponsive to empirical antibiotics or who experience frequent exacerbations, it appears prudent to obtain comprehensive microbiologic cultures, including for NTM and fungal organisms, and to tailor antibiotics based on the type of organism identified and drug susceptibility profile.

Aerosolized antibiotics also appear promising in treating or preventing exacerbations. Given the role of chronic *P. aeruginosa* in the pathogenesis and prognosis of bronchiectasis, there is ongoing research to develop strategies for acute and chronic treatment of this infection.

The success of inhalational antibiotics targeted toward *P. aeruginosa* in CF lung disease has prompted extensive evaluation of this strategy in non-CF bronchiectasis. In the earliest studies, addition of inhaled tobramycin to oral ciprofloxacin for *Pseudomonas*-associated exacerbation of non-CF bronchiectasis showed improved microbiologic outcome; however, there was no additional clinical benefit over ciprofloxacin alone, perhaps due to approximately threefold greater incidence of bronchospasm in the tobramycin arm.[232] In patients with CF, inhaled tobramycin twice daily given in alternating months decreased the frequency of exacerbations due to *P. aeruginosa.*[233] Even in patients without CF, inhaled tobramycin was found to be efficacious.[234] In a randomized study of nebulized gentamicin (twice daily for 12 months) versus saline for 65 patients with non-CF bronchiectasis, the gentamicin-treated subjects had reduced microbial burden, airway neutrophils, and sputum purulence.[235] Improved exercise capacity, decreased exacerbation frequency, and better health-related QOL measure were also seen in the gentamicin arm, with the caveat that patients were not blinded to the treatment.[236] Compared to nebulized saline, nebulized gentamicin given prophylactically for 12 months also showed significant reduction in markers of inflammation in both the airways and circulation.[237]

Inhaled ciprofloxacin has been studied for its efficacy in preventing exacerbations from *Pseudomonas* and several other chronic infections associated with frequent exacerbations. In companion Phase III studies (RESPIRE 1 and 2), the effect of ciprofloxacin in varied on-off cycles was examined in reducing time to next exacerbation.[238,239] Given the inconsistent results on the primary end point, inhaled ciprofloxacin was not approved. In a separate trial of aerosolized liposomal ciprofloxacin (150 mg liposome encapsulated plus 60 mg of free ciprofloxacin) in 582 subjects, there was no significant difference in the time to first exacerbation between the ciprofloxacin and placebo arms, although the ciprofloxacin arm had a significant reduction in the annualized exacerbation frequency.[240]

Inhaled aztreonam was studied in two companion trials (AIR-BX1 and 2) for effects of improved QOL by the *QOL-Bronchiectasis Questionnaire* (QOL-B) in patients with chronic *Pseudomonas* infection. A total of 540 patients were randomized to receive on-off periods of 38 days of inhalational aztreonam versus placebo. There was no significant difference in the primary end point of improved QOL. Subsets of patients experienced reduced exacerbations and improved QOL, but inhaled aztreonam was not approved for use in this subset of bronchiectasis patients.[241]

Finally, inhaled colistin, at a dose of 1 million international units (aerosolized), was studied in a randomized trial versus saline in 144 subjects with *P. aeruginosa* in their sputum and who were randomized after a course of intravenous antipseudomonal antibiotics for an exacerbation. The median time to first exacerbation was not significantly different in the colistin subjects compared with the placebo subjects. The patients receiving colistin had improved QOL and reduced bacterial sputum density of *Pseudomonas*.[242]

In summary, the role of inhalational antibiotics is not supported by large-scale pivotal studies. However, in many of the studies, subsets of patients had improvements in QOL or bacterial density. Therefore, expert opinion advocates the use of these therapies in individualized therapeutic regimens for patients with chronic *Pseudomonas* or other gram-negative infections.

Due to the role of *Pseudomonas* in propagating pathology and accelerating clinical decline, attention has been paid recently to eradication of initial infections.[61] Several groups have evaluated eradication protocols predicated on a period of systemic antipseudomonal antibiotics followed by suppression with inhalational antibiotic therapies, with varied success at achieving long-term eradication.[243,244] Approaches to *P. aeruginosa* eradication are summarized in eFig. 69.14.

ANTI-INFLAMMATORY THERAPY

The rationale for using the anti-inflammatory agents in bronchiectasis is to dampen the inflammatory cascade, with the goals of reducing symptoms and limiting the progression of disease and decline in lung function. Anti-inflammatory agents that have been examined in bronchiectasis include the *nonsteroidal anti-inflammatory drugs* (NSAIDs) and inhaled corticosteroids. Intermittent macrolides have been studied for their antimicrobial activities as well as their anti-inflammatory and other nonmicrobicidal activities (see next section).[245]

Nonsteroidal Anti-inflammatory Drugs

Because prostaglandins may play a role in augmenting airway secretions, NSAIDs, by blocking the cyclooxygenase pathway, have been studied in bronchiectasis. In a double-blind, placebo-controlled study in patients with bronchorrhea due to chronic bronchitis, diffuse panbronchiolitis, and bronchiectasis, inhaled indomethacin significantly decreased both the amount of sputum and the perceived dyspnea.[246] Another mechanism by which indomethacin may help in bronchiectasis is via inhibition of both neutrophil chemotaxis and neutrophil degradation of fibronectin, thereby decreasing airway inflammation and purulence.[247] In a comprehensive Cochrane Database review of randomized trials of NSAIDs in CF patients, high-dose ibuprofen was shown to slow the progression of lung disease, especially in children.[248] In contrast, there have been no randomized, controlled trials on the use of NSAIDs in non-CF bronchiectatic patients.[249]

The anti-inflammatory properties of statins were studied in a Phase II trial demonstrating reduction in cough and improved QOL.[250] Although larger trials failed to replicate these findings, treatment was associated with improved cough and QOL, indicating that further exploration of statins is warranted.[251]

Inhaled Corticosteroids

Although some studies show improved symptoms and lung function in CF patients treated with *inhaled corticosteroids* (ICS),[252,253] others, including a review of clinical trials, have not found ICS to be beneficial.[254,255] In non-CF bronchiectasis, relatively small studies indicate that ICS provides symptomatic relief (e.g., reduction in dyspnea, cough, and sputum production).[256–259] High doses of ICS are typically tried in bronchiectasis because of the notion that neutrophils, dominant in bronchiectatic airways, are relatively resistant to the (apoptotic) effects of corticosteroids.[260] Although bronchiectatic patients are often treated with β_2-agonists and ICS based on extrapolation by clinicians of treatment for COPD and asthma, there is limited evidence of their efficacy with bronchiectasis. Martinez-Garcia and associates[260] performed a pilot study comparing high-dose budesonide 800 μg every 12 hours to budesonide 640 μg plus formoterol once daily and found that the combined treatment with the lower dose of ICS resulted in a greater improvement of dyspnea score, health-related QOL assessment, and reduced ICS-associated side effects, such as pharyngeal irritation and dysphonia. Because of the potential risk for pneumonia with ICS use, as has been documented with COPD,[261] it seems prudent to limit the duration of ICS whenever possible, while monitoring closely for worsening respiratory symptoms and function. It is clear that larger studies are needed to determine the benefits and risks of ICS, long-acting β_2-agonists, or the combination as maintenance treatment or rescue therapy for exacerbations.[262]

THERAPIES FOR TREATMENT OF FREQUENT EXACERBATIONS

Intermittent Macrolide Therapy

Independent of their antimicrobial properties, macrolide antibiotics hold promise in inhibiting disease activity in bronchiectasis because of their immunomodulatory effects.[263] Intermittent macrolide therapy may help in bronchiectasis by decreasing the chloride diffusion potential gradient across the airway mucosa (resulting in decreased sputum volume), reducing airway levels of the neutrophil chemokine IL-8, inhibiting both neutrophil and *Pseudomonas* migration, suppressing *Pseudomonas* quorum sensing, disrupting the established biofilm layer, and enhancing alveolar macrophage phagocytic ability.[264,265] Thus macrolide therapy is posited to antagonize several of the mechanisms of pulmonary exacerbation and pathogenesis of bronchiectasis.

Clinical trials have explored the benefits of macrolides. In older studies, clarithromycin, but not amoxicillin or cefaclor, was shown to reduce sputum production in patients with chronic bronchitis or bronchiectasis.[266] Beneficial effects plus improvement in lung function have been shown in various trials using intermittent azithromycin therapy in CF patients chronically infected with *P. aeruginosa* and also in younger CF patients before they have been colonized with *P. aeruginosa.*[267] In a double-blind, placebo-controlled trial of approximately 120 patients with non-CF bronchiectasis and a history of frequent pulmonary exacerbations, low-dose erythromycin (400 mg twice daily) for 12 months significantly reduced (1) the number of pulmonary exacerbations overall by roughly one-third, as well as in those with baseline *P. aeruginosa* airway infection, (2) sputum production, and (3) lung function decline as measured by *forced expiratory volume in 1 second* (FEV_1).[268] However, erythromycin prophylaxis was associated with increased frequency of macrolide-resistant oropharyngeal streptococci.[268] Two double-blind, placebo-controlled trials of azithromycin (250 mg daily for 12 months or 500 mg thrice weekly for 6 months) resulted in significantly lower rates of exacerbations compared to placebo.[269,270] In an individual patient data meta-analysis that comprised three studies totaling 341 subjects with bronchiectasis, long-term macrolide antibiotics significantly reduced the frequency of exacerbations, improved the time to first exacerbation, and enhanced the QOL, especially in those with *P. aeruginosa* infection, although there was no significant improvement in FEV_1.[271] Finally, in a recently published randomized, controlled trial of 90 patients with PCD, thrice

weekly azithromycin therapy was found to reduce exacerbations compared to placebo patients.[272]

Azithromycin also carries risks. In one study there was a nearly threefold increase in macrolide resistance of bacteria in the azithromycin group and significantly higher incidence of abdominal pain and diarrhea, although these gastrointestinal symptoms did not prevent continuation of azithromycin.[273] In addition to the potential increase in antibiotic resistance in pyogenic bacteria, long-term azithromycin may predispose to drug-resistant NTM infections in patients with bronchiectasis.[273] Azithromycin was also shown to inhibit autophagy, a normal homeostatic cell recycling process increasingly recognized as important for the phagosomal killing of intracellular mycobacteria.[273] Other potential serious adverse effects of azithromycin include dysrhythmias and cardiac-related deaths, especially in those with underlying risk factors for cardiovascular disease.[274,275] In sum, at this time, because of their risk of harm, macrolides should probably be considered only in patients who would potentially benefit the most, for example, those with frequent exacerbations.

Inhibition of Neutrophil Elastase

Recurrent exacerbations in bronchiectasis are linked to neutrophilic influx into the airways. Subsequent elaboration of neutrophil serine proteases, including neutrophil elastase, may be at play in both chronic and acute inflammation. Thus, this pathway is postulated to drive recurrent cycles of inflammation and damage in the airways. Clinically, inhibition of these pathways is being explored to reduce the vicious cycle through inhibition of neutrophil elastase, which not only degrades elastin but also has other aforementioned deleterious effects. Recently, a large randomized control trial of a novel oral inhibitor of dipeptidyl peptidase I, a key enzyme in the activation of neutrophil elastase (INS1007, Insmed Corporation), has completed enrollment to demonstrate if this strategy reduces time to next exacerbation and frequency of exacerbation.[276] If successful, this strategy will add to the growing armamentarium for treatment of frequently exacerbating patients.

Recent expert guidelines suggest an integrated approach to treatment of frequent pulmonary exacerbations as outlined in eFig. 69.15.

SURGERY

The role of surgery in the management of bronchiectasis is uncertain. No formal systematic studies of the indications and efficacy of resectional surgery have been conducted among patients with bronchiectasis. Traditional indications for resectional surgery have included chronic disabling infection, recurrent infections of intolerable frequency, or irreversible lung damage distal to a foreign body or benign tumor. Hemoptysis that is life-threatening and/or recalcitrant to bronchial artery embolization may be an indication for surgery. A historical adage has been that surgery does not cure bronchiectasis. If true, it is likely due to our evolving understanding that most cases of bronchiectasis are due to innate risk factors that predispose to recurrence. However, surgery may be an appropriate palliative measure in selected cases, especially with severe localized disease, as not uncommonly seen in patients with NTM lung disease or in those with localized bronchiectasis and recalcitrant or recurrent superimposed infections.

Tracheal reconstruction surgeries, including tracheobronchoplasty or tracheal stenting, may confer symptomatic benefit for patients with Mournier-Kuhn.[277,278] Due to the rare nature of this disease, expert opinion from an experienced airway surgical team is vital for making this decision.

Bilateral lung transplantation has become increasingly recognized for patients who experience severe respiratory failure due to bronchiectasis. Due to the suppurative nature of bronchiectasis, single-lung transplantation is not recommended. Although limited evidence for long-term outcomes are available, single-center studies indicate that adults with bronchiectasis have similar long-term survival and recovery of lung function as other patient populations receiving bilateral lung transplant.[279] However, one study found that underlying immunodeficiency and pretransplantation diagnosis of chronic *Pseudomonas* infection may reduce posttransplantation outcomes.[280] The optimal timing is based on lung allocation scores. Although successful for some cases, there is limited evidence for optimal timing and tailoring of lung allocation scores for non-CF bronchiectasis, an area for future research.

MISCELLANEOUS

Additional measures, such as smoking cessation and vaccination against pneumococcal disease and influenza, are appropriate for all patients. Intuitively, these measures seem particularly important for those with bronchiectasis; however, no systematic information is available to confirm their usefulness in this setting. On the other hand, early recognition and remediation of exercise limitation and sleep-related hypoxia has demonstrated substantial benefits in regard to morbidity and mortality. As with all individuals, it seems sensible to ensure that patients with bronchiectasis have repleted vitamin D levels because this hormone has been shown to induce cathelicidin, an antimicrobial peptide.[281] Recently, it was reported that bronchiectasis patients with vitamin D deficiency have more frequent bacterial colonization (especially *P. aeruginosa*), worse airflow, more frequent exacerbations, higher levels of inflammatory markers in sputa, and more rapid decline in lung function over a 3-year follow-up than those with higher vitamin D levels.[282]

OVERALL APPROACH TO MANAGEMENT

Due to increasing complexity of bronchiectasis management, a thoughtful approach to management is necessary. Recent expert guidelines suggest several approaches. One strategy involves step-up therapy based on patient symptoms and severity of lung function and frequency of exacerbations.[283] In addition, a treatment strategy targeted toward aspects of pathophysiology with frequent reassessment of therapeutic response is a reasonable approach. Individualization of therapeutic approach is necessary and may vary by patient preference. We recommend the strategy outlined in Figure 69.7.

PROGNOSIS

All patients with bronchiectasis are affected by a poorer prognosis than age- and gender-matched healthy control subjects. Recent estimates demonstrate an approximately twofold increase in mortality in those with bronchiectasis

compared to healthy normal subjects.[284] Recently published analyses have identified a host of factors predictive of excessive mortality.[285] Prospective evaluation of these analyses has aided in the development of two propensity scoring systems that assess long-term prognosis in non-CF bronchiectasis: the *FEV_1, Age, Chronic Colonization, Extension, Dyspnea* (FACED) Score[286] and the *Bronchiectasis Severity Index* (BSI).[287] Both identified increased risk of mortality and hospitalization on the basis of worsening lung function, age, presence of *P. aeruginosa*, degree of dyspnea, and extent of radiographic bronchiectasis. Both systems result in similar prediction of outcomes when validated head to head.[288] In addition, the BSI scoring system emphasizes the role of prior hospitalization and frequency of exacerbation in the prediction of risk of subsequent hospitalizations.

In addition to excess mortality attributed to bronchiectasis, many patients experience increased morbidity due to pulmonary and sleep-related complications.[289] Patients also have increased risk of nonpulmonary medical issues, including cardiovascular disease, GER disease, malignancy, and cerebrovascular diseases than age-matched healthy control subjects.[290]

Recent developments of QOL instruments, including the QOL-B, focused on bronchiectasis and have aided the assessment of patients and have served as key clinical trial end points.[291]

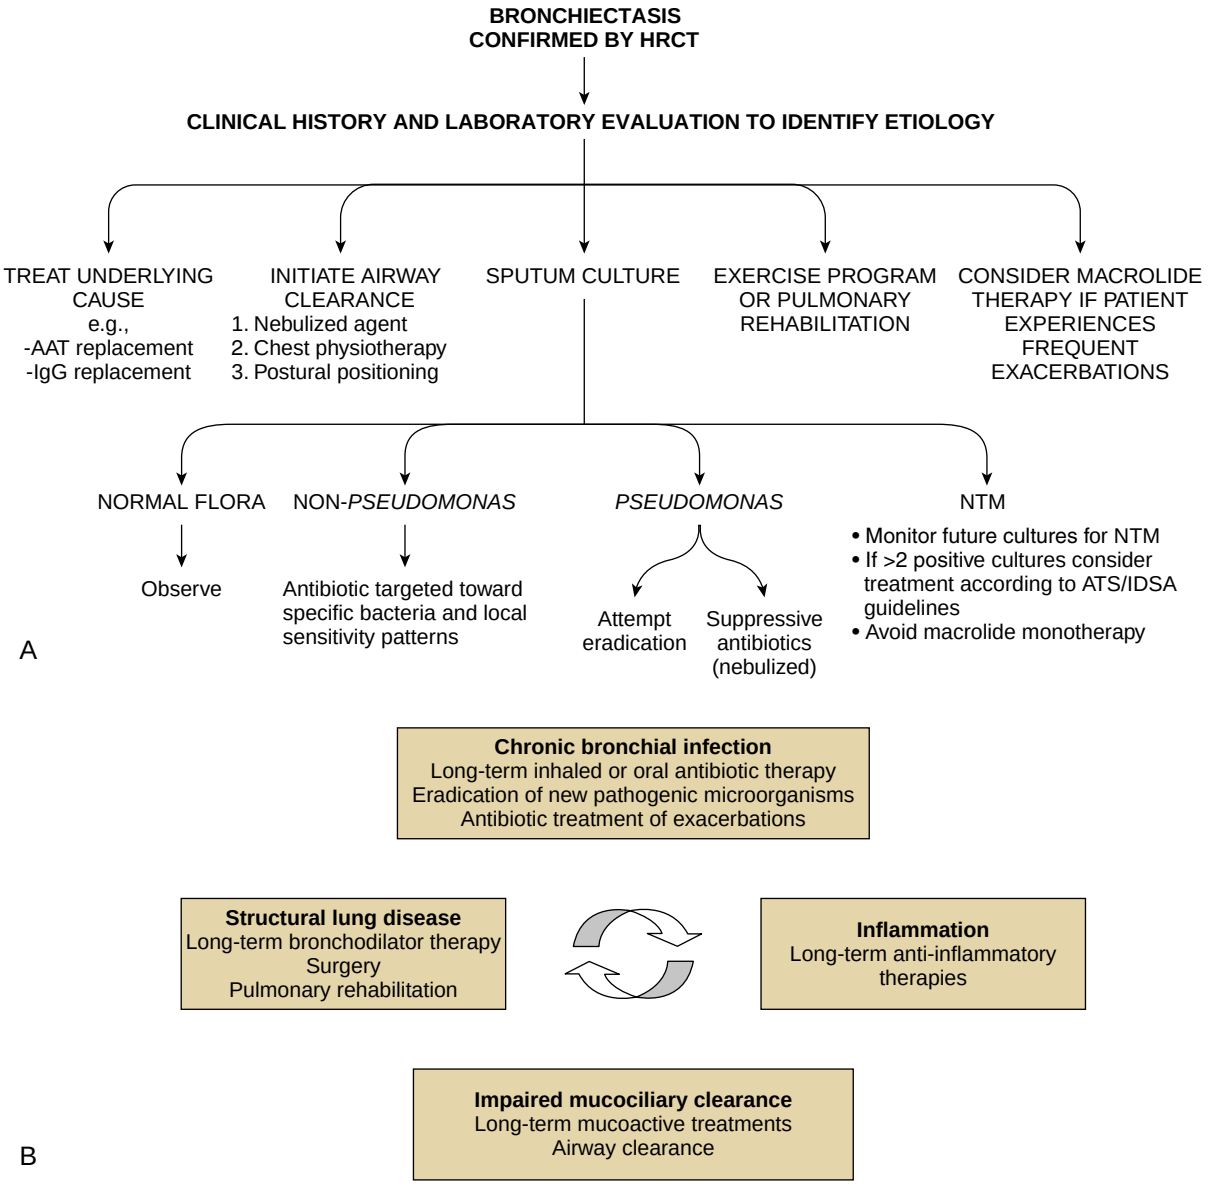

Figure 69.7 Comprehensive management of bronchiectasis. (A) Treatment includes measures that are common to all types and underlying causes of bronchiectasis, such as airway clearance, sputum microbial analysis, and pulmonary rehabilitation. More specific treatments are tailored to the underlying cause, such as *$alpha_1$-antitrypsin* (AAT) augmentation therapy for those with frank AAT deficiency or cystic fibrosis transmembrane regulator modifiers for those with cystic fibrosis. Antimicrobial therapy is based on whether it is for acute treatment or chronic suppressive therapy, and whether the goals are eradication or reducing the bacterial load to limit the symptoms. (B) Treatment strategies shown in the context of the vicious cycle hypothesis of bronchiectasis pathogenesis. ATS, American Thoracic Society; HRCT, high-resolution computed tomography; IDSA, Infectious Diseases Society of America; IgG, immunoglobulin G; NTM, nontuberulous mycobacteria. (A, Modified from McShane PJ, Naureckas ET, Tino G, Strek ME. Non-cystic fibrosis bronchiectasis. *Am J Respir Crit Care Med.* 2013;188(6):647–656; B, modified from Polverino E, Goeminne PC, McDonnell MJ, et al. European Respiratory Society guidelines for the management of adult bronchiectasis. *Eur Respir J.* 2017;50:1700629.)

Key Points

- Bronchiectasis is defined by the presence of permanent dilation of the medium to large bronchi. The main clinical significance of bronchiectasis is recurrent airway infections by bacterial and fungal organisms, resulting in chronic cough, sputum, weight loss, and respiratory compromise.
- Most bronchiectasis is due to a combination of host susceptibility factors, which may be overt or covert, recurrent infections, and the largely neutrophilic, inflammatory response. These factors lead to a vicious cycle of airway inflammation, infection, and mucus obstruction that may result in end-stage lung disease.
- Localized bronchiectasis is most often due to suboptimally treated bacterial infections, although bronchiectasis due to nontuberculous mycobacteria appears increasingly prevalent. Bronchiectasis due to nontuberculous mycobacteria is typically seen in postmenopausal women with lingular and right middle lobe involvement, although other lobes may be affected, and can also be seen in men, especially those with underlying COPD.
- Diffuse bronchiectasis is generally due to an underlying host disorder, such as cystic fibrosis, disorders of immunity, alpha$_1$-antitrypsin anomalies, COPD, primary ciliary dyskinesia, Mounier-Kuhn and Williams-Campbell syndromes, common variable immune deficiency, allergic bronchopulmonary aspergillosis, and chronic inflammatory states.
- Bronchiectasis has been associated with extrapulmonary disorders, such as ulcerative colitis and collagen vascular diseases. Severe fibrotic lung diseases from any cause may also result in a form of bronchiectasis known as traction bronchiectasis.
- The keys to management of bronchiectasis are the timely institution of empirical antimicrobials to treat the most likely pathogens and diligent airway clearance measures to improve symptoms. For patients unresponsive to empirical antibiotics or those with frequent exacerbations, sputum cultures should be obtained, drug susceptibility determined, and treatment tailored to more objective data. Surgical lung resection should also be considered for patients with severe localized disease recalcitrant to medical treatment; bilateral lung transplantation may be necessary for diffuse disease in appropriate patients.
- New approaches to the treatment of initial and chronic *Pseudomonas aeruginosa* infection are important in the consideration of infectious management.
- Prognostic guidelines and understandings of disease severity, including the frequent exacerbator phenotype, have helped to guide new research endeavors targeting appropriate populations.
- Strategies aimed at the vicious cycle of inflammation and infection show promise for improving quality of life and reduction of exacerbations. Anti-inflammatory agents, such as nonsteroidal anti-inflammatory drugs, inhaled corticosteroids, and low-dose intermittent macrolides, show promise in alleviating symptoms and reducing the rate of disease progression, but definitive recommendations for their use remain to be defined. Recent guidelines integrate these therapies for the treatment of patients with frequent exacerbations.

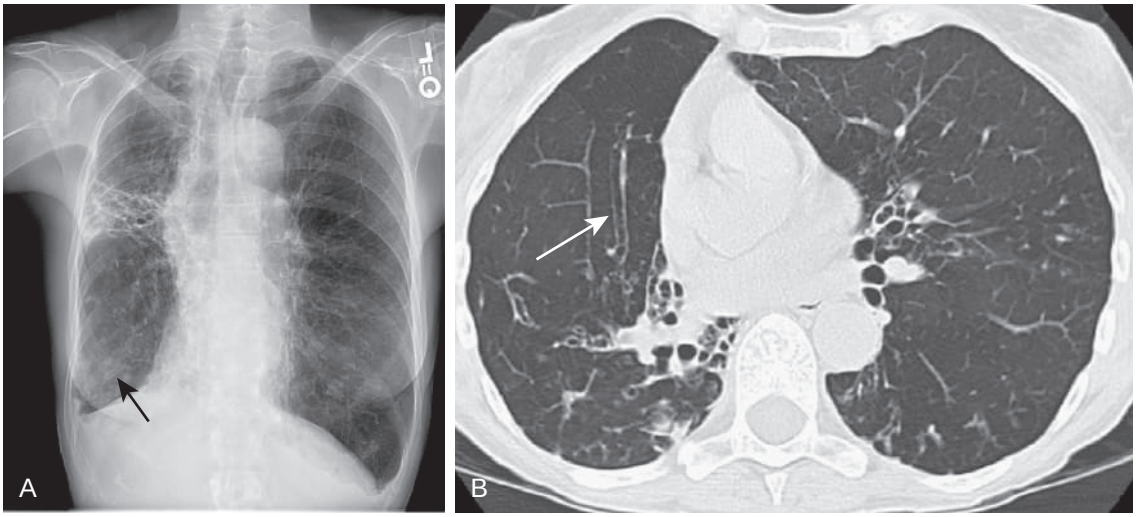
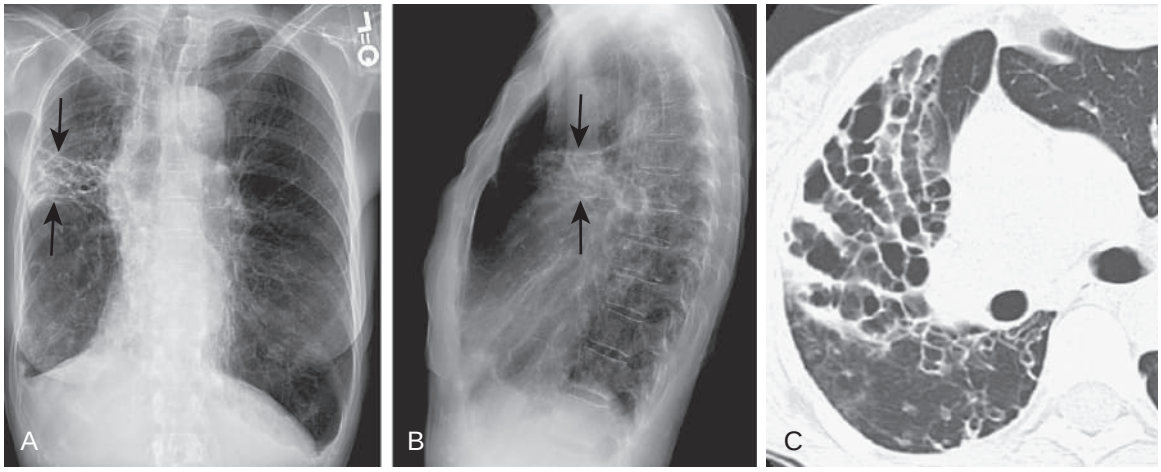
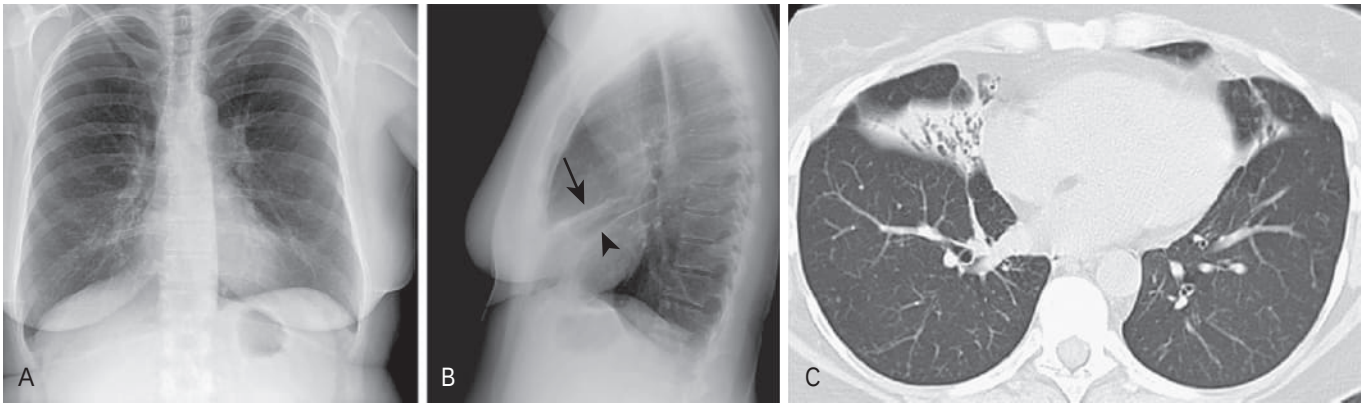
eFIGURE IMAGE GALLERY



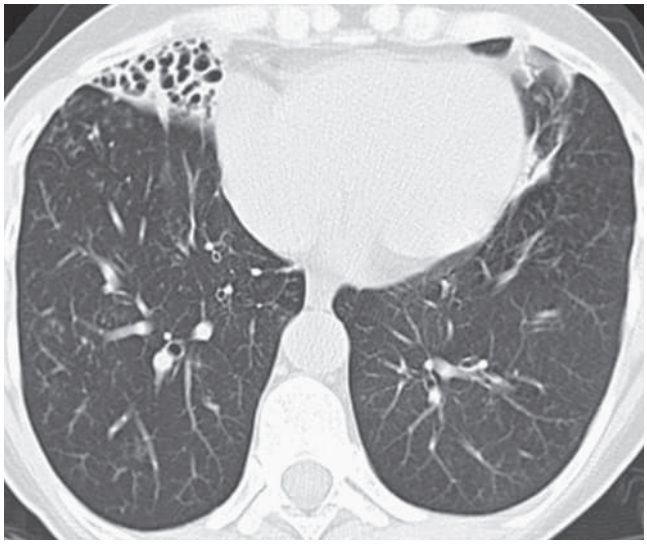
eFigure 69.1 "Tram tracks" on the routine chest radiograph in bronchiectasis, in the same patient as in eFig. 69.2. (A) In the right lower lobe are parallel, nontapering shadows, or "tram tracks" (*arrow*), representing bronchiectasis. (B) The airway is seen as cylindrical bronchiectasis (*arrow*).



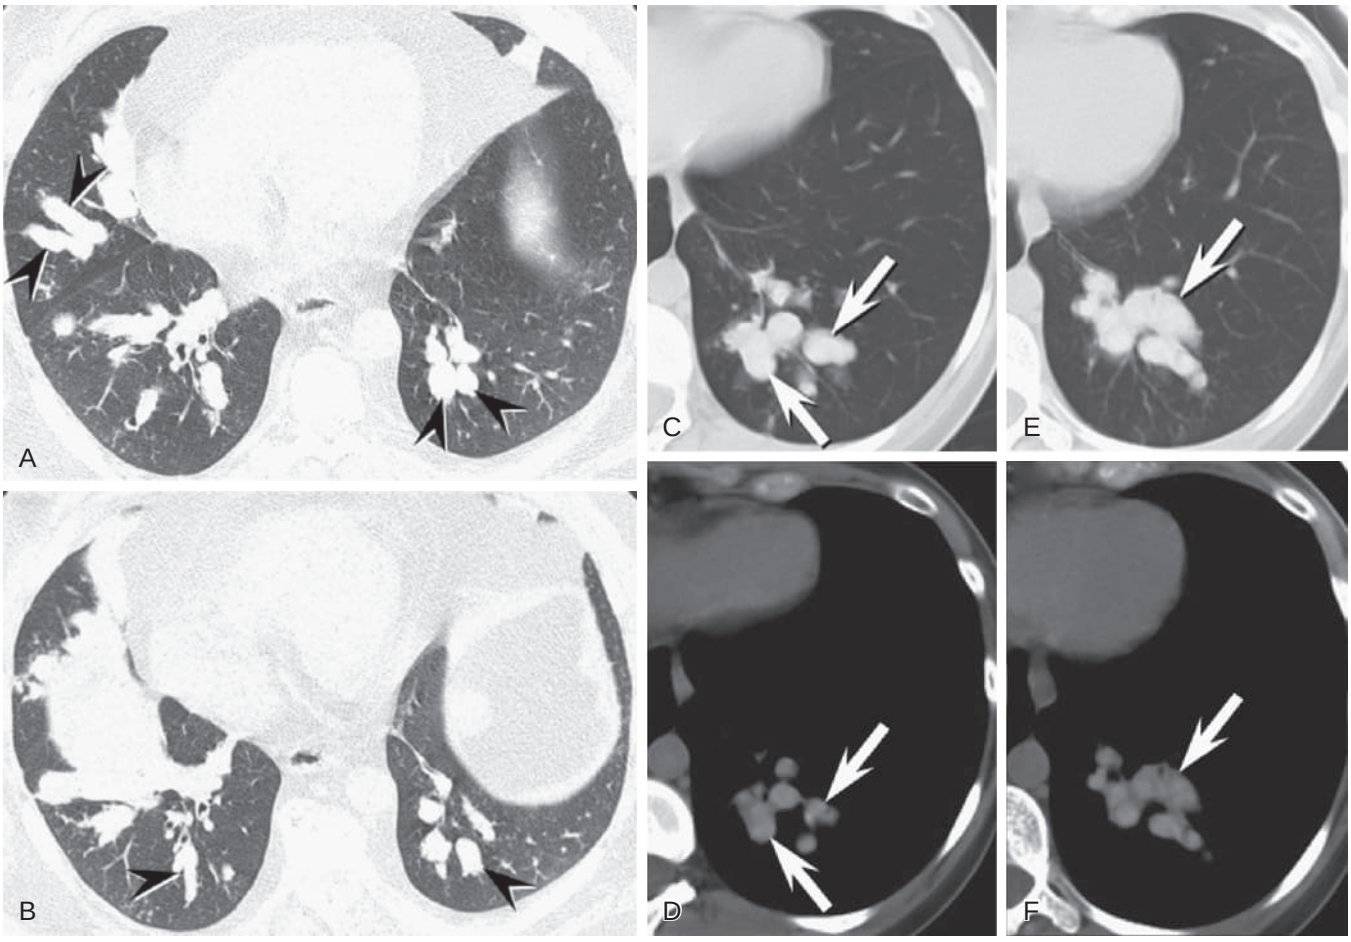
eFigure 69.2 Multiple ring shadows on chest radiography in bronchiectasis in the same patient as in eFig. 69.1. (A) On the posteroanterior view, thin-walled cystic shadowing is seen in the right mid-lung field (*between arrows*). The trachea and mediastinum are shifted to the right, indicating extensive volume loss. (B) The lateral view confirms the presence of multiple ring shadows in the mid-zone (*between arrows*). (C) Computed tomography scan indicates severe varicose bronchiectasis involving the entire right middle lobe and the anterior segment of the right upper lobe.



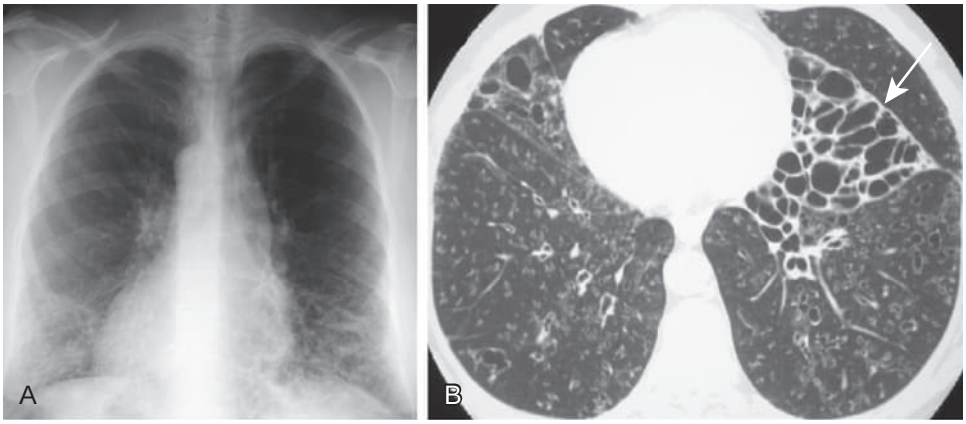
eFigure 69.3 Atelectasis and bronchiectasis involving the right middle lobe and lingula on chest radiographs and a computed tomography scan. This 60-year-old woman has had recurring "pneumonia" throughout life. (A) Posteroanterior view shows subtle effacement of the right heart border and cardiophrenic sulcus as well as a hazy opacity at the left heart border. (B) On the lateral view, there are two oblique densities representing the atelectatic right middle lobe (*arrow*) and lingula (*arrowhead*). (C) Computed tomography scan demonstrates bronchiectasis and atelectasis of the right middle lobe and inferior segment of the lingula.



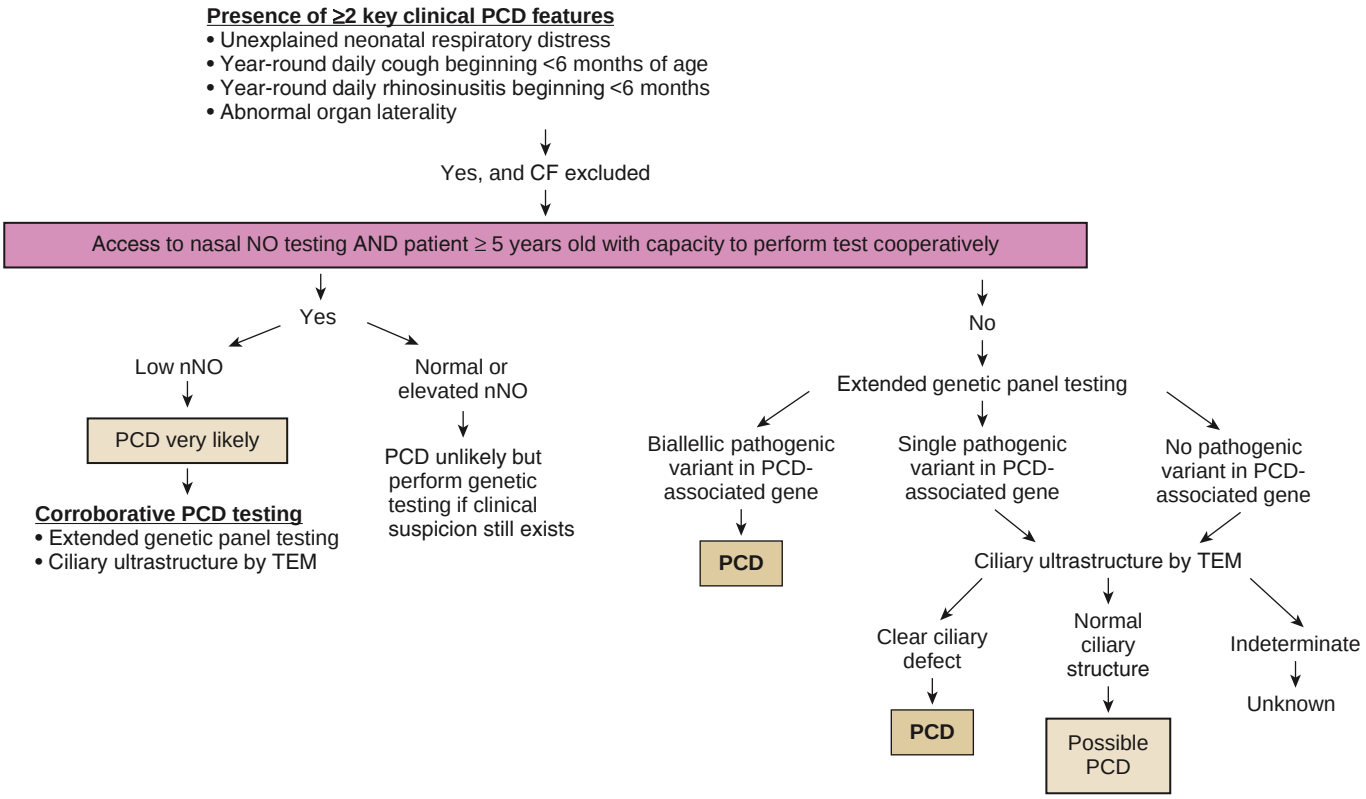
eFigure 69.4 Bronchiectatic consolidation. The inferomedial aspect of the right middle lobe is involved with a coarse cystic process, with essentially no normal remaining lung. Similar changes are often seen in the inferior segment of the lingula. In many cases such findings are associated with nontuberculous mycobacterial infection; however, in this case, the patient was infected only with gram-negative bacilli, including *Pseudomonas aeruginosa* and *Alcaligenes xylosoxidans*.



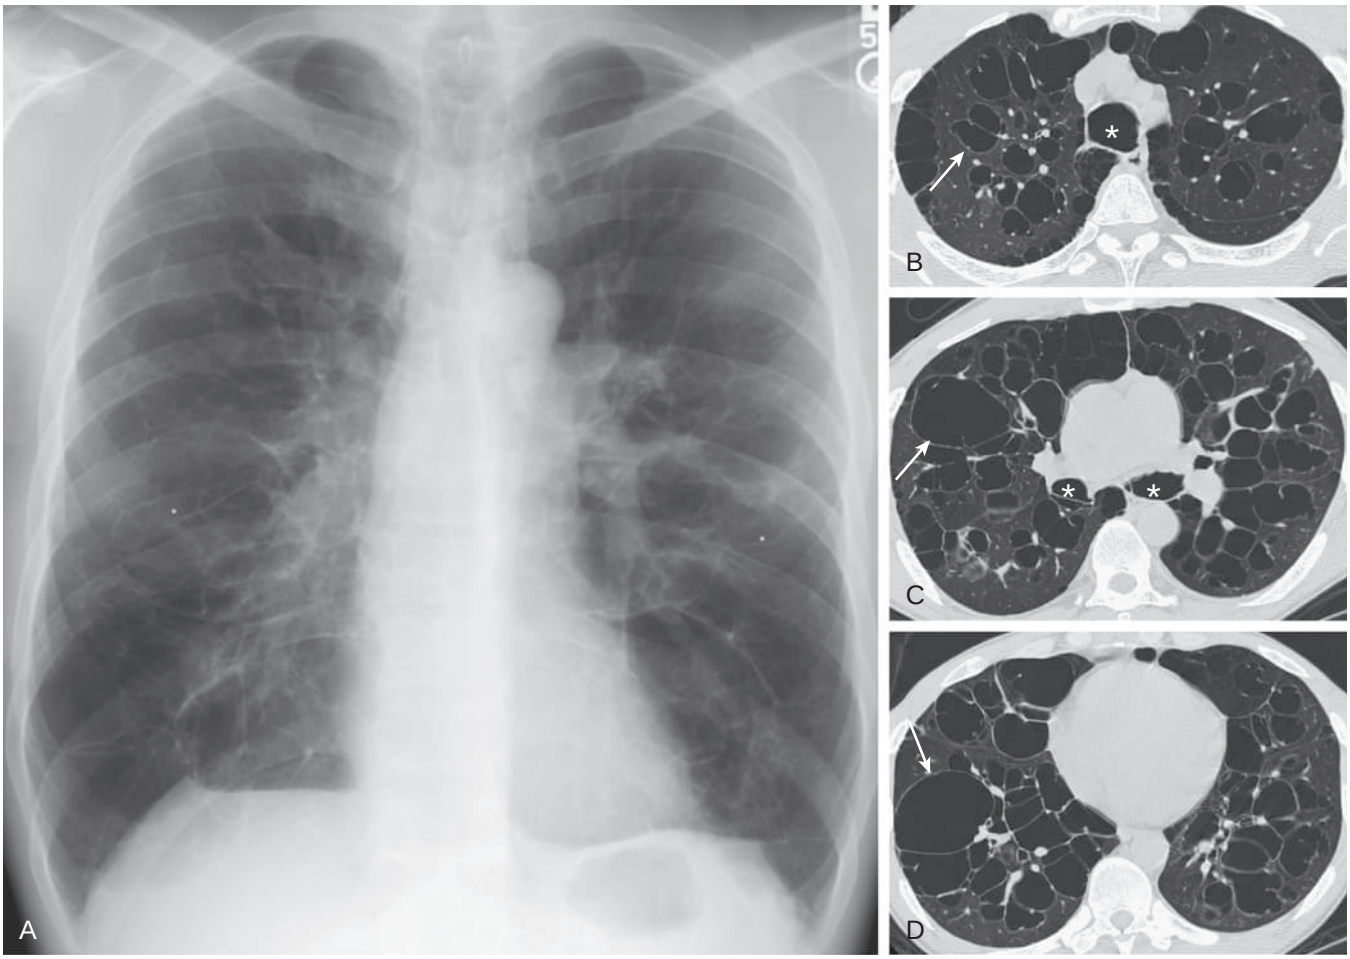
eFigure 69.5 Allergic bronchopulmonary aspergillosis with bronchiectasis and bronchial mucus impaction. (A–B) Axial chest computed tomography displayed in lung windows shows multifocal, bilateral tubular opacities (*arrowheads*) consistent with mucus impaction. (C–F) Axial chest computed tomography from another patient displayed in lung (C and E) and soft-tissue (D and F) windows shows tubular branching opacities (*arrows*) in the left lower lobe consistent with mucus impaction. Note that the opacities show faintly increased attenuation on the soft tissue windows (*arrows* in D and F), representing mucus impaction containing calcium salts and/or metallic ions. (Courtesy Michael B. Gotway, MD.)



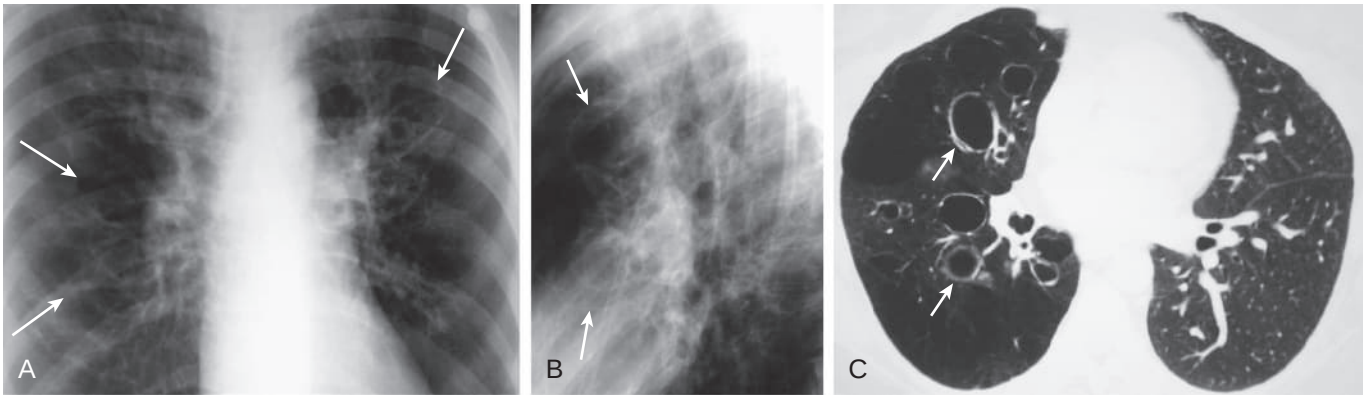
eFigure 69.6 Bronchiectasis: Kartagener syndrome. (A) Frontal chest radiograph shows dextrocardia with basal predominant linear opacities, the latter consistent with bronchial wall thickening and bronchiectasis. (B) Axial chest computed tomography shows dextrocardia and severe cystic bronchiectasis, particularly on the left (*arrow*). Note the left lung shows a morphologic configuration resembling a right middle lobe (same *arrow*). Numerous small nodules are consistent with small airway impaction. (Courtesy Michael B. Gotway, MD.)



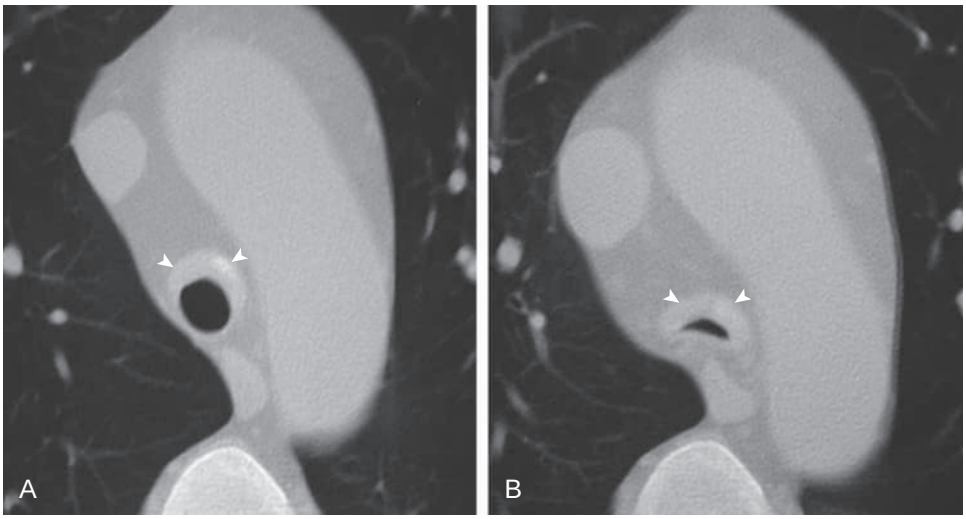
eFigure 69.7 Diagnostic algorithm for primary ciliary dyskinesia. Initial evaluation consists of determining the absence or presence of four predictive clinical parameters. If clinical suspicion is raised, then *nasal nitric oxide* (nNO) is the next screening test; an abnormally low nNO warrants excluding *cystic fibrosis* (CF) first, because a significant minority of CF individuals have low nNO. If testing for nNO measurement is not available, then genetic testing would be required. The traditional gold standards of ultrastructural analysis (by *transmission electron microscopy* [TEM]) and assessment of ciliary beat frequency/coordination require experienced investigators and/or specialized techniques. Ultrastructural analysis suffers from poor sensitivity (i.e., ≈30% of *primary ciliary dyskinesia* (PCD) patients have normal or near-normal TEM features), and video microscopy to assess ciliary movement suffers from low specificity (i.e., ciliary dysfunction may be a feature of chronic infection/inflammation even in the absence of a primary ciliary defect). (Modified from Shapiro AJ, Davis SD, Polineni D, et al. Diagnosis of primary ciliary dyskinesia. An official American Thoracic Society clinical practice guideline. *Am J Respir Crit Care Med*. 2018;197:e24–e39.)



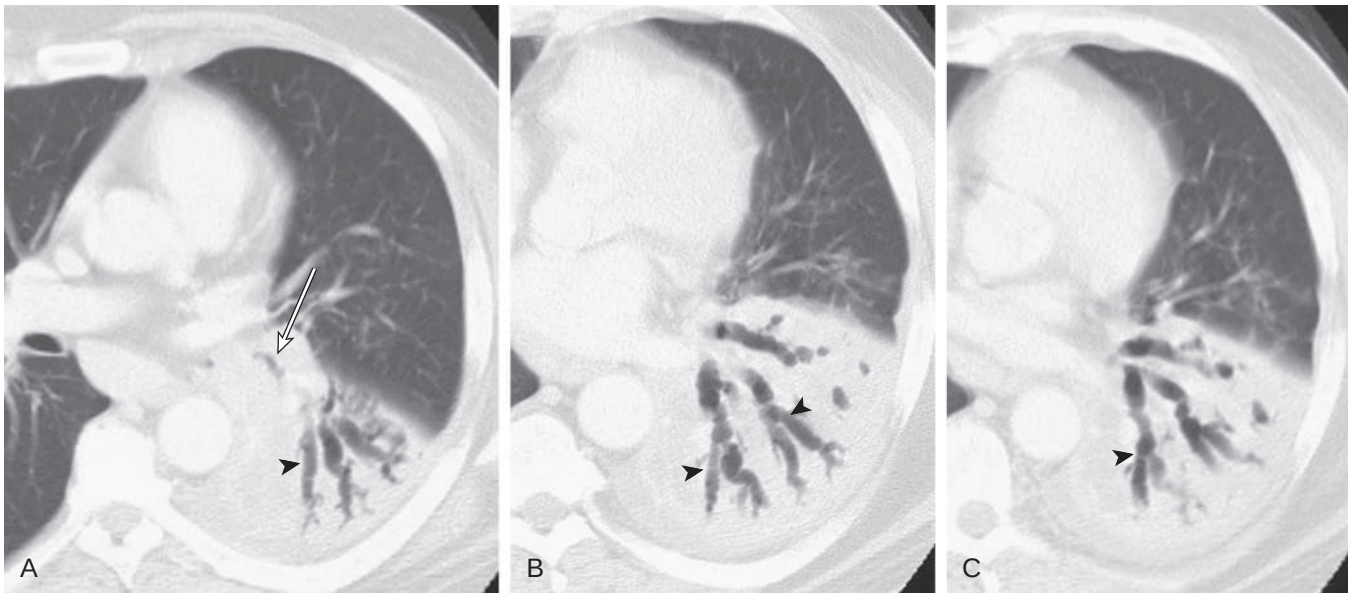
eFigure 69.8 Bronchiectasis: Mounier-Kuhn syndrome. (A) Frontal chest radiograph shows large lung volumes consistent with obstructive pulmonary disease. Bilateral linear and reticular opacities represent the walls of severely dilated bronchi. (B–D) Axial chest computed tomography images show multifocal, thin-walled cystic bronchiectasis (*arrows*) associated with dilated trachea and central bronchi (*asterisks*). The tubular nature of the cystic bronchiectasis can be appreciated best in the right upper lobe (*arrow*, B). In the left upper lobe, note that the cysts are closely associated with pulmonary arteries, which allows the cysts to be identified as bronchial in origin. (Courtesy Michael B. Gotway, MD.)



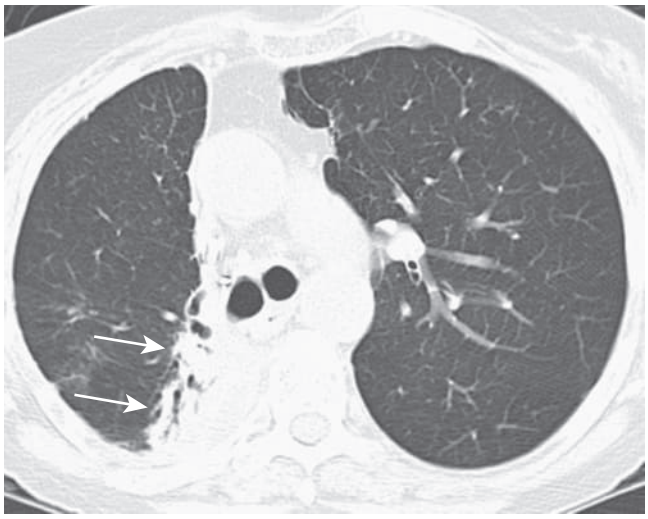
eFigure 69.9 Bronchiectasis: Williams-Campbell syndrome. Frontal (A) and lateral (B) chest radiographs show bilateral linear and reticular opacities (*arrows*) representing the walls of severely dilated bronchi. (C) Axial chest computed tomography after left lung transplantation shows severe cystic bronchiectasis (*arrows*) in the native right lung. (Courtesy Michael B. Gotway, MD.)



eFigure 69.10 Relapsing polychondritis. (A) Axial inspiratory chest computed tomography shows thickening of the anterior two-thirds of the trachea (*arrowheads*). A tiny focus of calcification is present within the thickened trachea at the 1 o'clock position. (B) Axial chest computed tomography performed after a forced vital capacity maneuver shows excessive trachea collapse (*arrowheads*) consistent with airway malacia. The constellation of findings is typical of relapsing polychondritis. (Courtesy Michael B. Gotway, MD.)



eFigure 69.11 Postobstructive bronchiectasis. (A–C) Axial chest computed tomography shows severe narrowing of the left lower lobe bronchus (*arrow*) due to carcinoid tumor. Multifocal bronchiectatic consolidation (*arrowheads*) is present throughout the left lower lobe. (Courtesy Michael B. Gotway, MD.)



eFigure 69.12 Bronchiectasis in a field of therapeutic x-irradiation. This 68-year-old woman had been diagnosed with a non–small cell carcinoma of the lung. She received radiation therapy to the right hilar region approximately 18 months previously. Her computed tomography scan shows dense fibrosis and bronchiectasis in the radiation field (*arrows*). Inferior to this abnormality, she had a necrotic cavitary process associated with *Mycobacterium avium* complex infection.

KEY POINTS

INTRODUCTION

The upper airways extend from the nares to the subglottis and include diverse anatomic structures with a wide variety of functions. Along with assisting in breathing, the structures of the upper airway contain the nerves for the sensory functions of taste and smell, create a functionally safe swallow by separating the process of swallowing from that of breathing, and allow communication through the generation of voice and speech. The nasal cavity has a defined role in filtering and humidifying air for presentation to the lower airway.[1–3] The larynx protects the airway to prevent aspiration and regulates airflow and vocalization. The pharynx and oral cavity assist in these functions by controlling and shaping substances to be swallowed and modulating voiced sounds from the larynx into words and speech. The upper airway is controlled by both voluntary and involuntary mechanisms. Therefore, respiratory function can be affected through uncoordinated or inefficient muscular activity, centrally mediated neurologic reflex activity, and/or humoral or immunologic responses. The exact function of some areas within the upper airway, such as the paranasal sinuses, is unclear.

Pathologic changes in the upper airways are often associated with lower airway disease. Swallowing disorders may result in aspiration, leading to inflammatory and infectious complications in the lungs. Chronic inflammation of the paranasal sinuses is frequently associated with asthma and appears to be driven by similar inflammatory pathways, which has been called the *unified airway theory*.[4–7] This theory posits that the upper and lower airways can be considered one organ, sharing both the mechanisms of injury and the benefits from treatment. Long-standing infection in the sinuses has been implicated as a possible reservoir for recurrent pulmonary infection.[8–10] Laryngeal dysfunction may create symptoms similar to, and mistaken for, asthma. Finally, stenosis of the subglottis or cervical trachea is often misdiagnosed as asthma. This chapter discusses the anatomy and clinical conditions of the upper airway and their influence on lower airway function.

THE NOSE

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

The nose is the initial site of air entry for the majority of breaths. The external nose has important structural components that, when compromised, may inhibit nasal airflow. The nasal dorsum is made up of three structurally distinct subunits (Fig. 70.1). The upper third of the nasal dorsum is supported by the nasal bones. At their distal end, the nasal bones articulate with the upper lateral cartilages in a region known as the keystone area. The upper lateral cartilages define the middle third of the nose. The structure of the lower third, or nasal tip, is defined primarily by the lower lateral cartilages. The nasal septum divides the right and left sides of the nose and provides additional structural support to the lower two-thirds of the nose. The quadrangular cartilage forms the anterior septum. The bone of the vomer, the perpendicular plate of the ethmoid, and the maxillary crest form the posterior and inferior aspects of the septum.

Airflow through the nose may be limited by the cross-sectional area of the external and internal nasal valves (Fig. 70.2). The external nasal valve area is determined by the relationship between the lower lateral cartilage, the septum, and the inferior turbinate. The internal nasal valve is determined by the angle between the upper lateral cartilage and septum. Facial musculature attaching to the upper and lower cartilages of the nose can widen these principal areas of resistance and enhance nasal breathing.[11,12] Patients with narrowing or structural weakness in these regions may suffer from nasal obstruction. The external and internal nasal valves are frequently the target of nasoseptal reconstructive surgery.

Another common area implicated in narrowing of the nasal cavity and subsequent nasal obstruction is the nasal

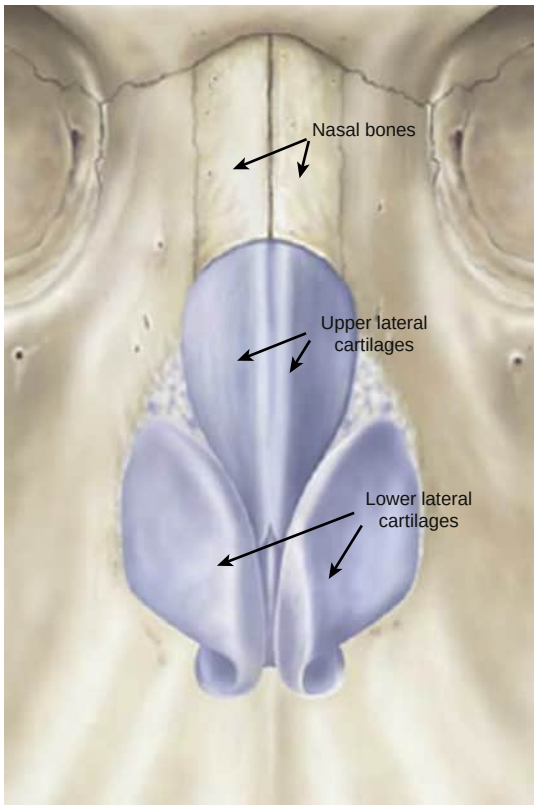

Figure 70.1 Vertical thirds of the nose. The upper, middle, and lower third of the nose are structurally supported by the nasal bones, the upper lateral cartilages, and the lower lateral cartilages, respectively. (From Hafezi F, Naghibzadeh B, Nouhi AH. Applied anatomy of the nasal lower lateral cartilage: a new finding. *Aesthetic Plast Surg.* 2010;342:244–248.)

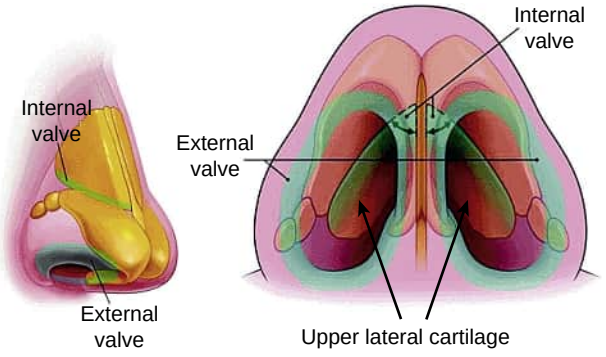

Figure 70.2 The internal and external nasal valves. The external nasal valve exists at the level of the inner nostril and is formed by the caudal edge of the lateral crus of the lower lateral cartilage, the soft tissue alae, the membranous septum, and the sill (the anterior nares) of the nostril. The internal nasal valve accounts for approximately half of the total airway resistance and is bordered medially by the septum, inferiorly by the nasal floor, laterally by the inferior turbinate, and superiorly by the caudal border of the upper lateral cartilage. (From Howard BK, Rohrich RJ. Understanding the nasal airway: principles and practice. *Plast Reconstr Surg.* 2002;109:1128–1146.)

septum. Deviation of the septum diminishes the cross-sectional area of the affected nasal passage and can significantly impact nasal airflow. Most patients have some degree of septal deviation, so anatomic changes in this area must be correlated with clinical findings when determining if a patient would benefit from treatment of a septal deviation. Nasal trauma may lead to septal deviations and spurs; many patients will relate a history of trauma to the nose. Developmental variations are perhaps a more common cause of deviation and of spurs of the nasal septum than is trauma. Overgrowth of the quadrangular cartilage may result in bowing of the cartilage or in forming spurs at the junction of the cartilage and bones that make up the nasal septum. Nasal obstruction related to septal deviation may respond either to surgical or to medical treatment. In patients with concomitant turbinate hypertrophy or chronic rhinitis, treatment with intranasal corticosteroids may diminish mucosal swelling and provide an adequate airway despite the septal deviation. Surgery to straighten the septum has few risks and complications and is an effective method for improving the nasal airway in patients with narrowing secondary to septal deviation. Although implicated as a cause for acute or chronic rhinosinusitis, septal deviation is a very rare cause for inflammatory sinus disease. While a septoplasty may be indicated to improve nasal breathing or enhance surgical access for endoscopic sinus surgery, in the majority of cases, surgical correction of the septal deviation is unlikely to influence the disease course of acute or chronic rhinosinusitis.

Air that enters the nasal sill (or anterior nares) and passes through the internal nasal valve accelerates as it passes through this area of narrowing. There is also a change in direction of airflow because inspired air shifts from a vertical to a horizontal trajectory at this site. This combination of acceleration and change in flow vector causes the majority of airborne particles to be deposited in the anterior nasal cavity.[13,14] Airflow through the nose slows as the nasal passages widen beyond the internal nasal valve.

Upon entry into the nasal cavity the stratified squamous epithelium of the nasal sill quickly transitions to a respiratory epithelium. Located along the lateral nasal wall, the turbinates (or conchae) serve to warm and humidify air passing through the nasal cavity. Rich vasculature, including venous sinusoids, allows the turbinates to enlarge and shrink in response to various stimuli.[15–17] Fenestrated subepithelial capillaries facilitate heat and gas exchange, enhancing humidification during nasal inhalation.[17] Engorgement of the turbinates increases the surface area and mucosal contact with inspired air. The slowing of airflow beyond the internal nasal valve provides prolonged mucosal contact during nasal inspiration and allows efficient humidification and filtration of inspired air so that, even at extremes of ambient temperature and humidity, air that reaches the trachea is very close to body temperature and is at 98% humidity.

The respiratory mucosa of the turbinates contains both goblet cells and seromucous glands. These structures combine to produce a mucus blanket mobilized by coordinated beating of this ciliated epithelium. Nasal irritants, microbes, and other particles are swept through the nasal cavity by this mucociliary clearance mechanism to be swallowed, preventing exposure of the lower airways. The lower airways are further protected by immune function within the nasal mucosa. Both the innate and humoral immune arms of the immune system function within the nasal mucosa, resulting in the secretion of immunoglobulins (primarily immunoglobulin A)[18,19] and microbial toxins, such as lysozyme and lactoferrin.[20,21] Emerging evidence suggests that commensal microbes inhabiting

the mucosal surface or mucus layer of the nasal cavity contribute to the host defense mechanisms within the nasal cavity through competitive colonization and immune regulation.[22,23]

The turbinates are dynamic structures that swell and shrink in response to multiple stimuli. Gravity, nasal irritants, allergic response, and autonomic neural input all regulate the blood supply and venous drainage of the submucosal tissue of the inferior turbinate, resulting in marked fluctuations in turbinate size.[17,24] The size of the inferior turbinate fluctuates throughout the day, with the left and right sides alternately swelling and shrinking in a phenomenon known as the nasal cycle.[24] Pathologic enlargement of the inferior turbinate is one of the most common causes of nasal congestion and nasal obstruction.[25,26]

The tubular structure of the turbinates contributes to a laminar airflow pattern through the nasal cavity.[27,28] Aggressive resection of the turbinates enlarges the cross-sectional area of the nasal cavity but risks paradoxical worsening of nasal obstruction by altering the flow pattern from laminar to turbulent. The humidification function of the turbinates can also be lost with resection, resulting in possible dryness and crusting. This constellation of symptoms after turbinate resection has been referred to as *empty nose syndrome*.[29] A conservative surgical approach to nasal obstruction with turbinate hypertrophy is therefore recommended in patients who do not receive adequate relief from medical therapy.

The superior aspects of the nasal septum, middle turbinate, and superior turbinate are lined with olfactory epithelium. Successful olfaction requires that airborne or mucus-soluble particles reach this epithelium. Odorant-specific receptors of the olfactory epithelium send projections intracranially through the bone of the cribriform plate. Axons from the olfactory epithelium synapse within the olfactory bulb, and these signals are then routed for central processing. Smell disorders may arise from mucosal inflammation and edema that prevent odorant exposure to the olfactory epithelium. This is frequently a reversible condition. Direct viral injury of the olfactory epithelium has also been postulated as a cause for smell loss, which may result in long-term dysfunction.[30,31] Acute smell loss has been identified as a key screening symptom for COVID-19 disease.[32–34] In a prospective tracking study of more than 2.5 million individuals in the United Kingdom and United States, including more than 18,000 who underwent polymerase chain reaction testing for severe acute respiratory syndrome coronavirus-2 infection, loss of smell was the symptom most strongly associated with a positive COVID-19 test, with an odds ratio of 6.4 in the UK cohort and 10.0 in the U.S. cohort. The odds ratio for skipped meals, fatigue, and fever were all less than 3 in both cohorts.[32]

Sneezing is a nonspecific, involuntary response to nasal irritation. Allergens, microbes, and other nasal irritants may precipitate this reaction when they contact the nasal mucosa and trigger histamine release. The trigeminal nucleus coordinates the sneeze reflex, which involves muscles of the pharynx, larynx, oral cavity, and chest wall. The pressure generated from a sneeze may expel irritants and can contribute to spread of infections. In susceptible individuals, sudden exposure to bright light may trigger the sneeze reflex. This photic sneeze reflex is an autosomal dominant trait impacting approximately one-fourth of the human population.[35]

PATHOLOGIC CONDITIONS OF THE NASAL CAVITY

Rhinitis

Rhinitis, or inflammation of the nasal cavity, may result from multiple causes. Rhinitis may be classified by duration (acute vs. chronic) and by cause (allergic vs. nonallergic). Acute rhinitis is a self-limited inflammation, most commonly secondary to viral infection. Many of the clinical features of acute rhinitis may result from the immune response to viral pathogens. Release of inflammatory cytokines and chemokines, including *interleukin* (IL)-6, tumor necrosis factor-α, and interferon-γ, results in tissue edema, increased mucus production, and vascular dilation.[36] The clinical manifestations of these changes are well known as symptoms of the common cold: nasal congestion and obstruction, increased nasal drainage, and diminished sense of smell. Nasal irritants, including perfumes, smoke, and cleaning products, can cause a similar constellation of symptoms, although typically of shorter duration.

Allergic Rhinitis

Epidemiology. *Allergic rhinitis* (AR) is a common disorder estimated to be the sixth most common chronic illness in the United States.[37] The prevalence of AR is 10–20% in the United States and Europe.[38] An estimated 18 million adults in the United States suffer from AR, resulting in significant health care expenditures.[39] A diagnosis of allergic rhinitis adds approximately $1500 per patient per year in direct health care costs.[39] A similar prevalence of AR is evident in children, and AR in this population is associated with a significant decrease in both physical and emotional health, as well as sleep disturbance.[40] Thirteen million Americans in the workforce suffer from AR, and it is estimated that 3.5 million workdays and 2 million school days are lost each year due to this condition.[41,42] Overall, annual direct and indirect costs of AR in the United States have been estimated at $5 to $8 billion and $11 billion, respectively.[43]

The incidence of allergic rhinitis has been rising over the past 3 decades. One explanation for this is the *hygiene hypothesis*, which proposes that early exposure to antigens allows for proper immune system development and a reduced risk for AR and other atopic disease.[44] With improved hygiene and a reduction in exposure to antigens, children may develop an exaggerated immune response, as demonstrated by AR. Early microbial exposure may be particularly important in the prevention not only of atopic but also of autoimmune disease.[45–48]

Diagnosis. AR symptoms may be seasonal or perennial, depending upon the specific allergen. Pollens from trees and grasses are the most common triggers for seasonal symptoms, whereas dust mites and pet dander represent common triggers for perennial disease. Offending allergens may be identified through a variety of approaches. Skin reaction to allergens may be measured through either prick testing or intradermal injection using serial end point dilution techniques. Both approaches carry a rare but important risk for anaphylaxis.[49] Testing centers must have

personnel and equipment to deal with such emergencies. Immunoassays for allergen-specific *immunoglobulin* (Ig) E, such as ImmunoCAP (Phadia AB/ThermoFisher), have largely replaced radioallergosorbent tests as an alternative to intradermal skin testing. Immunoassays demonstrate a similar sensitivity as skin testing. The efficacy of both dermal testing and immunoassays depends on proper antigen selection. Knowledge of local flora is particularly important in patients with seasonal AR. This knowledge is also essential in identifying clinically significant allergens. Identification of offending allergens allows counseling of allergen avoidance and may be used to initiate immunomodulatory therapy.

Pathophysiology. After an initial allergen exposure, inhaled antigens provoke both early and late-phase reactions in the nasal cavity. The early phase is initiated by the recognition of a specific allergen by IgE subunits on the surface of mast cells and basophils. IgE activation results in antibody cross-linking, which, through a series of downstream mediators, causes degranulation of mast cells and basophils with release of preformed mediators, primarily histamine. Tryptase release and de novo formation of leukotrienes may also contribute to nasal inflammation and symptoms. Exposure to inflammatory mediators results in marked tissue edema and mucus secretion, which manifest clinically as rhinorrhea, nasal congestion, and obstruction, frequently in association with sneezing. These symptoms develop within minutes of allergen exposure.

The late phase of AR typically arises 4 to 8 hours after allergen exposure. Nasal congestion is typically the dominant symptom. Chemoattractants and adhesion molecules released in response to the initial inflammatory mediators promote infiltration of leukocytes, eosinophils, basophils, $CD4^+$ lymphocytes, and monocytes. Activation of these cells results in the release of a second wave of inflammatory mediators.[50] The early and late-phase reactions in AR mimic those of allergic asthma.

Priming of the immune response may be important in the pathophysiology of AR. Repeated allergen exposure results in amplification of mucosal hyperresponsiveness. In patients with seasonal AR, the severity of allergic response depends not only on the current pollen count and allergen exposure but also upon the cumulative exposure for a given allergy season. Because of this phenomenon, severe symptoms of AR may persist late in the allergy season despite a waning pollen count. This increased allergen sensitivity may be secondary to both a neural hyperresponsiveness and amplification of the immune response through recruitment of mast cells and basophils. Immune system priming is not an allergen-specific phenomenon; patients also report increased sensitivity to nonspecific nasal irritants, including smoke and perfume.[51,52]

Association With Asthma. AR and asthma are linked through both pathophysiology and epidemiology.[50,52,53] Eighty percent of patients with allergic asthma also suffer from AR. The presence of AR is a risk factor for the future development of asthma. Guidelines suggest screening patients with persistent AR for asthma and evaluating asthmatic patients for rhinitis.[52,53]

The *unified airway theory* suggests that inflammatory cells from an inflamed area within the airway may impact distant airway locations. In patients with AR and asthma, segmental bronchial allergen challenge results in an inflammatory response not only in bronchi, but also in the nasal cavity.[54] When treated with intranasal corticosteroids, these same patients demonstrate a decrease in both nasal and bronchial hyperreactivity.[55,56]

Treatment. There are three primary modalities of treatment for AR: allergen avoidance, pharmacotherapy, and immunomodulatory treatments. Consensus panels suggest evaluating the severity and frequency of AR symptoms to guide treatment. Severity of symptoms is categorized as mild or moderate to severe as determined by the level of impact on daily activities and sleep disturbance. Symptoms are classified as *intermittent* if the duration is less than 4 days per week or for fewer than 4 weeks or as *persistent* if the duration satisfies both of these criteria.[53] Fig. 70.3 depicts a consensus management strategy for AR.[57] The vast majority of patients are effectively treated with pharmacotherapy and allergen avoidance. Saline irrigation results in modest symptomatic improvement and may reduce the need for medications with more significant side-effect profiles. Evidence-based AR treatment recommendations for allergen avoidance, individual medications, and immunotherapy were revised in 2010[58] and again in 2017[59] to incorporate considerations for combination pharmacotherapy options. Recommendations for allergen avoidance strategies for patients with AR are similar to those for patients with allergic asthma and require identification of offending allergens. After identification of clinically significant allergens, environmental precautions may be instituted.

Immunotherapy

Although pharmacologic treatment of AR may be quite effective in managing symptoms, immunotherapy offers the only approach known to impact the natural history of the disease. *Subcutaneous immunotherapy* (SCIT) regimens involve once- or twice-weekly subcutaneous antigen injections with gradual escalation of the antigen dose. This is the most well-studied and commonly used approach in the United States. More recently, *sublingual immunotherapy* (SLIT) has emerged as an option that avoids injection and may be administered at home. The *U.S. Food and Drug Administration* (FDA) has approved four SLIT treatments in the United States: Grastek (ALK-Abelló) for treatment of timothy grass or cross-reactive grass pollens, Oralair (Stallergenes SA) for treatment of five different grass pollens, Odactra (ALK-Abelló) for dust mites, and Ragwitek (ALK-Abelló) for short ragweed pollen.[60] Additional SLIT allergen extracts are approved in Europe and have been used off-label in the United States. The overall treatment course for SCIT or SLIT is 2 to 3 years.

With repeated allergen exposure, a shift in allergen-specific T cells to a regulatory phenotype results in suppression of type 2 T-helper inflammatory cytokines and enhanced production of IL-10 and antigen-specific IgG4. This results in suppression of allergen-specific IgE and mast cells and appears to inhibit antigen capture and presentation to T cells.[61] This immune modulation may also

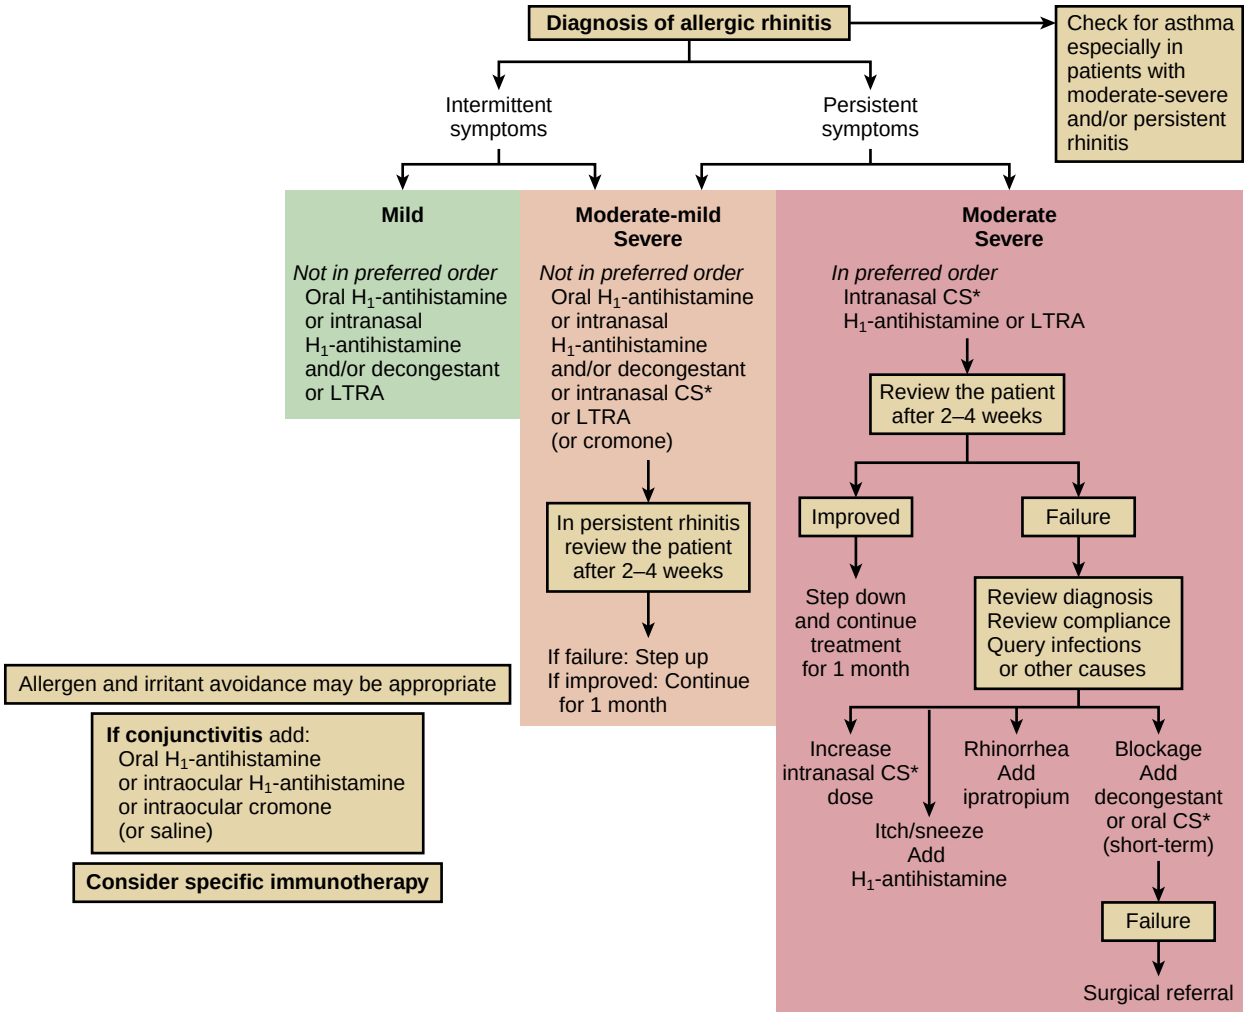

Figure 70.3 Algorithm for the management of allergic rhinitis. CS, corticosteroid; LTRA, leukotriene-receptor antagonist. *Total dose of topical CS should be considered if inhaled steroids are used for concomitant asthma. (From Bousquet J, Schünemann HJ, Samolinski B, et al. Allergic rhinitis and its impact on asthma (ARIA): achievements in 10 years and future needs. *J Allergy Clin Immunol.* 2012;130:1049–1062.)

diminish the onset of additional atopic disorders, such as asthma in patients with AR.

Systemic responses to immunotherapy are rare and typically mild. Nevertheless, deaths have been reported from anaphylactic response during immunotherapy, and vigilance is required. SCIT has a higher, although still very low, incidence of systemic response than SLIT; SLIT has a high rate of mild local (mucosal) side effects that rarely impact the treatment regimen.[62] Practitioners who administer allergy shots require appropriate training and access to emergency equipment to address the rare systemic response. With sublingual administration, patients often self-administer the allergen, and proper patient selection and education are critically important. Multiple trials demonstrate efficacy of both SCIT and SLIT; they appear to have similar efficacy, but head-to-head trials are lacking.[63–65] The determinants of SCIT versus SLIT use are evolving as additional sublingual options receive FDA approval and clinical experience in the United States increases.[66]

Nonallergic Chronic Rhinitis

Overall, nonallergic rhinitis is poorly characterized. *Vasomotor rhinitis* may happen in a subgroup of nonallergic patients thought to have aberrant parasympathetic innervation in the nose. Patients frequently note rhinorrhea in association with eating or a change in the weather. This disorder is more common in elderly patients and may respond well to ipratropium nasal spray. Additional noninflammatory disorders of the nasal cavity, including nonallergic rhinitis with eosinophilia, may improve with nasal steroid treatment. Symptomatic treatment with saline irrigation is another popular treatment for nonallergic rhinitis.

THE PARANASAL SINUSES

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

The paranasal sinuses are aerated cavities within the skull that connect to the nasal cavity. There are four sets of paired sinuses: the maxillary, ethmoid, frontal, and sphenoid. The sinuses are lined with a pseudostratified, ciliated epithelium. Goblet cells within the epithelium produce mucus, and the coordinated action of the cilia moves this mucus through the sinus cavities and into the nose. Once thought to be sterile, it is now known that bacterial communities inhabit the

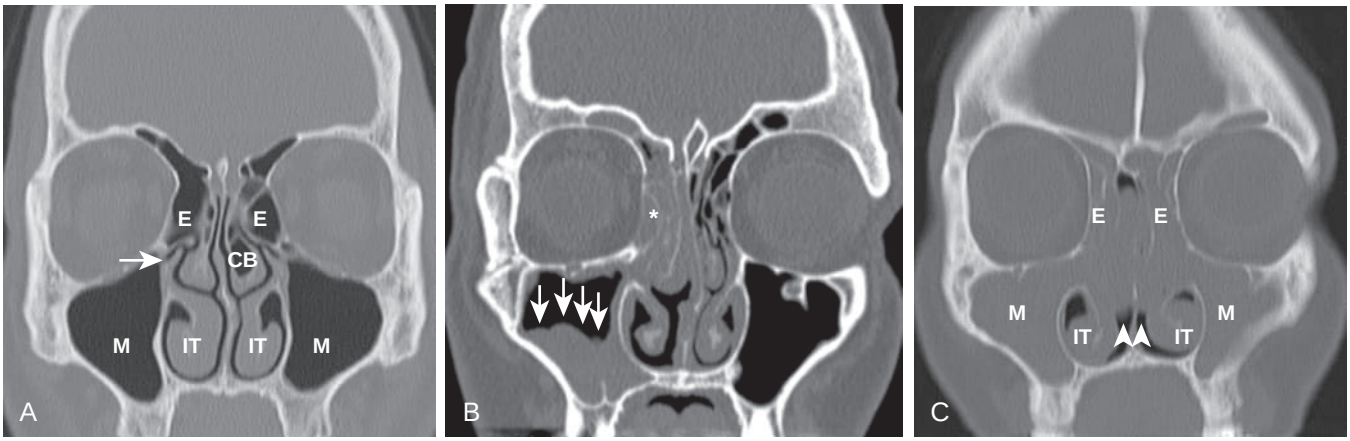

Figure 70.4 Coronal *computed tomography* (CT) imaging of the paranasal sinuses. (A) Normal anatomy, including well-aerated maxillary (M) and ethmoid (E) sinuses bilaterally, patency of the osteomeatal complex (*arrow*), and normal appearance of the inferior turbinates (IT). Incidentally noted is a left concha bullosa (CB), a normal variant involving aeration of the middle turbinate, which arises in approximately 30% of patients. (B) CT findings consistent with acute sinusitis. There is unilateral opacification of the ethmoid sinuses (*asterisk*) and a fluid level within the right maxillary sinus (*arrows*). Acute sinusitis may present with unilateral or bilateral disease, and routine CT imaging is not recommended. (C) Bilateral chronic sinusitis with nasal polyposis. There is complete opacification of the maxillary (M) and ethmoid (E) sinuses bilaterally. *Arrowheads* demonstrate bilateral nasal polyps, a soft tissue density within the nasal cavity and adjacent to the inferior turbinates (IT).

mucosal surfaces of the paranasal sinuses in both health and disease.[22,67,68]

The function of the sinuses has not been clearly established. They may serve a protective role in force dissipation with blunt trauma to the head or face. The paranasal sinuses can impact vocal resonance, which may have aided their evolution. The sinuses may allow for enhanced facial aesthetics. They may play a role in mucus production and immune surveillance in the nasal cavity.

The four paired sinuses are named after the bones they aerate. The maxillary and ethmoid sinuses are the first to develop and are present at birth. The frontal and sphenoid sinuses develop later. A visible frontal sinus is often not present until age 4 or 5 years, and continued aeration and development persist throughout the teenage years.[69] Asymmetric aeration of the sinuses is common, particularly in the later-developing frontal and sphenoid sinuses. The frontal sinus may be absent in up to 10% of normal patients.[70,71] An increased incidence of frontal sinus aplasia and diminished overall paranasal sinus aeration is seen in patients with congenital disorders that impact the sinuses, such as cystic fibrosis.[72]

Mucus produced in the sinuses is propelled into the nasal cavity by coordinated ciliary motion. The maxillary (Fig. 70.4) and sphenoid sinuses are connected to the nasal cavity by discrete ostia, which often have a diameter of no more than 4 mm. The ethmoid sinuses are made up of a labyrinth of small air cells located between the orbit and the nasal septum. The ethmoid sinus typically drains through clefts between air cells rather than through discrete ostia. Collectively, the anterior ethmoid air cells drain through the middle *meatus* located between the middle turbinate and the lateral nasal wall. Whereas the posterior ethmoid air cells drain through the superior meatus, which is located between the superior turbinate and lateral nasal wall, the frontal sinus drainage tract is determined by the variable anatomy of the underlying anterior ethmoid air cells and eventually leads to the middle meatus.

Blood supply to the paranasal sinuses is provided through both the internal and external carotid systems. The *sphenopalatine artery* (SPA) is the terminal branch of the internal maxillary artery, which originates from the external carotid artery. The SPA enters the nasal cavity through the sphenopalatine foramen just behind the posterior wall of the maxillary sinus. The majority of the blood supply to the nasal cavity is provided by the SPA. The blood supply to the superior nasal cavity and to much of the ethmoid system arises from the anterior and posterior ethmoid arteries. These vessels are branches from the ophthalmic artery of the internal carotid system and typically run within the skull base along the roof of the ethmoid sinuses. All of these vessels may contribute to refractory or "posterior" nosebleeds. Epistaxis originating from the SPA is amenable to embolization or surgical ligation of the SPA. The anterior and posterior ethmoid arteries are not amenable to embolization due to their origin from the ophthalmic artery and the associated risk for blindness. In cases of refractory epistaxis, these vessels are amenable to surgical ligation.[73]

PARANASAL SINUS DISEASE

Overall, inflammatory disease of the paranasal sinuses is poorly understood. Sinusitis represents a wide variety of pathologic conditions that may cause either acute or chronic inflammation. Paranasal sinus inflammation is almost inevitably accompanied by inflammation of the nasal cavity, or rhinitis. Thus, the term *rhinosinusitis* is commonly used to describe this condition.

Although the diagnosis of acute rhinosinusitis may be made with clinical symptoms and time course alone, objective evidence of sinus inflammation is required for a diagnosis of chronic rhinosinusitis.[74–76] Table 70.1 demonstrates the diagnostic criteria for acute, chronic, and recurrent acute rhinosinusitis. The duration of symptoms is the primary factor used to differentiate between acute and chronic rhinosinusitis. Acute sinusitis lasts up to 4 weeks. Patients

Table 70.1 Diagnostic Criteria for Rhinosinusitis

Term	Definition
ACUTE	
Acute rhinosinusitis	Up to 4 weeks of purulent nasal drainage (anterior, posterior, or both) accompanied by nasal obstruction, facial pain-pressure-fullness, or both: ■ *Purulent nasal discharge* is cloudy or colored, in contrast to the clear secretions that typically accompany viral upper respiratory infection and may be reported by the patient or observed on physical examination. ■ *Nasal obstruction* may be reported by the patient as nasal obstruction, congestion, blockage, or stuffiness, or may be diagnosed by physical examination. ■ *Facial pain-pressure-fullness* may involve the anterior face, periorbital region, or manifest with headache that is localized or diffuse.
Viral rhinosinusitis (VRS)	Acute rhinosinusitis caused by, or presumed to be caused by, viral infection. A clinician should diagnose VRS when symptoms or signs of acute rhinosinusitis are present for fewer than 10 days and the symptoms are not worsening.
Acute bacterial rhinosinusitis (ABRS)	Acute rhinosinusitis caused by, or presumed to be caused by, bacterial infection. A clinician should diagnose ABRS when: ■ Symptoms or signs of acute rhinosinusitis are present 10 days or more beyond the onset of upper respiratory symptoms, *or* ■ Symptoms or signs of acute rhinosinusitis worsen within 10 days after an initial improvement (double worsening).
CHRONIC AND RECURRENT	

Chronic rhinosinusitis	Twelve weeks or longer of two or more of the following signs and symptoms:
	■ Mucopurulent drainage (anterior, posterior, or both)
	■ Nasal obstruction (congestion)
	■ Facial pain-pressure-fullness *or*
	■ Decreased sense of smell *and*
	■ Inflammation is documented by one or more of the following findings:
	  ■ Purulent (not clear) mucus or edema in the middle meatus or ethmoid region
	  ■ Polyps in nasal cavity or the middle meatus, *and/or*
	  ■ Radiographic imaging showing inflammation of the paranasal sinuses.

Recurrent acute rhinosinusitis	Four or more episodes per year of ABRS without signs or symptoms of rhinosinusitis between episodes. Each episode of ABRS should meet diagnostic criteria.

From Rosenfeld RM, Piccirillo JF, Chandrasekhar SS, et al. Clinical practice guideline (update): adult sinusitis. *Otolaryngol Head Neck Surg*. 2015;152(suppl 2):S1–S39; and Rosenfeld RM. Clinical practice guideline on adult sinusitis. *Otolaryngol Head Neck Surg*. 2007;137(3):365–377.

with signs and symptoms for 12 weeks or longer are diagnosed with chronic sinusitis. Patients with symptoms lasting from 4 to 12 weeks are deemed to have subacute sinusitis, and clinical judgment is recommended in determining whether to manage based on acute or chronic rhinosinusitis guidelines. Whereas the duration of symptoms is used to distinguish between acute and chronic disease, the pathophysiologic features, symptoms, and treatment of these entities are different. *Acute bacterial rhinosinusitis* is an acute infectious disorder, and patients present with fever and facial pain as characteristic symptoms. *Chronic rhinosinusitis* (CRS) is primarily an inflammatory disorder in which the role of microbes is not well established. Patients with CRS typically note nasal congestion, thick nasal drainage, and facial pressure, but fever[77] and pain are uncommon in the absence of acute exacerbations.

Objective findings of rhinosinusitis may be present on routine physical examination during evaluation of the anterior nasal cavity or anterior rhinoscopy. Acute rhinosinusitis may be diagnosed by history and anterior rhinoscopy alone; imaging studies are not recommended for uncomplicated acute sinusitis.[74–76,78] Objective evidence of inflammation in patients with chronic sinusitis is often difficult to establish on anterior rhinoscopy, so nasal endoscopy or imaging of the sinuses is often required to establish the diagnosis. With a nasal endoscope, the middle and superior meatus can be closely examined. Polyps or significant edema in these regions satisfies the objective criteria for inflammation required for a CRS diagnosis. Thick mucus can be sampled under endoscopic guidance to guide antimicrobial therapy. *Computed tomography* (CT) (see Fig. 70.4) is the preferred method of imaging for the paranasal sinuses; radiographs of the paranasal sinuses lack sufficient specificity and sensitivity and have little clinical utility.[78] *Magnetic resonance imaging* (MRI) is not indicated for routine inflammatory sinus disease. MRI, however, is quite useful in the assessment of sinonasal tumors, intracranial complications of sinusitis, and encephaloceles, and in the diagnosis and treatment planning for invasive fungal sinusitis.

ACUTE RHINOSINUSITIS

Epidemiology

Acute rhinosinusitis is extremely common and typically of viral etiology. It is estimated that adults suffer two to five episodes of viral rhinosinusitis (i.e., the common cold) annually. School-age children may suffer 7 to 10 colds per year.[74] In the United States, upper respiratory tract infection is the third most common reason for a primary care provider consultation, with approximately one-third of these attributed to acute rhinosinusitis.[79] Gwaltney and colleagues[80] demonstrated that 60% of viral upper respiratory infections demonstrate radiologic evidence of inflammation within the ethmoid and maxillary sinuses on CT imaging. This study also highlights the futility of CT

imaging for distinguishing between acute viral and acute bacterial rhinosinusitis.

From 0.5–2% of viral rhinosinusitis episodes will progress to *acute bacterial rhinosinusitis* (ABRS).[74] The proposed pathophysiology is that virally mediated mucosal inflammation and edema result in ciliary dysfunction and obstruction of the sinus ostia. This disruption of mucociliary clearance results in mucus stasis and a vulnerability to bacterial superinfection. The most common organisms seen in ABRS are noted in Table 70.2.

Treatment

Distinguishing the self-limited, viral-induced inflammation of the common cold from ABRS is a challenge often faced by primary care physicians. Clinical guidelines suggest that a detailed history is somewhat effective in making this distinction. Patients who do not demonstrate significant clinical improvement after 10 days or experience a worsening of symptoms after 5 days of the onset of symptoms, also referred to as double sickening, are more likely to have ABRS.[75,76,78] In addition, facial pain beyond what is expected from a viral upper respiratory infection or evidence of extrasinus extension of infection, such as periorbital edema, may be used to diagnose ABRS. Although patients who meet these clinical criteria demonstrate decreased duration and severity of symptoms when treated with antibiotics, the magnitude of improvement is relatively small.[75] Watchful waiting and antibiotic therapy are both reasonable options for patients with ABRS. A shared decision-making approach with patients is recommended, and updated guidelines provide patient education materials to help with this decision.[76] Patients who opt for watchful waiting should have access to medical professionals so that they may be treated with antibiotics if their symptoms worsen or fail to improve after 1 week. Patients with suspected complications of ABRS should be treated with antibiotics and referred to an otolaryngologist for urgent evaluation. Amoxicillin with or without clavulanate is recommended as a first-line treatment for uncomplicated ABRS, with trimethoprim-sulfamethoxazole encouraged for penicillin-allergic patients.[76,78] Alternatives for penicillin-allergic patients include doxycycline or a respiratory fluoroquinolone.[76,78,81] Diagnostic imaging, including both radiographs and CT images of the sinuses, do not adequately distinguish between ABRS and acute viral rhinosinusitis and are not recommended unless extrasinus spread of infection is suspected.[76,78]

Table 70.2 Microbiology of Acute Bacterial Rhinosinusitis in Adults

Organism	Range of Prevalence (%)
Streptococcus pneumoniae	20–43
Haemophilus influenzae	22–35
Streptococcus spp	3–9
Anaerobes	0–9
Moraxella catarrhalis	2–10
Staphylococcus aureus	0–8
Other	4

Recurrent acute rhinosinusitis, defined as four or more episodes of ABRS per year, may arise in the context of predisposing anatomic variations, exacerbations of CRS, immune compromise, or without identifiable predisposing factors.[75] Surgical intervention with widening of sinus ostia and removal of ethmoid septations may decrease the frequency and severity of symptoms.[82,83] Balloon sinus dilation, either in the clinic or in the operating room, may also be considered for treatment of recurrent acute rhinosinusitis. Whereas ABRS may be diagnosed without objective (endoscopic or CT) findings of inflammation, CT imaging demonstrating inflammation and elucidating patient anatomy is required before traditional endoscopic surgery or balloon sinus dilation for recurrent acute rhinosinusitis.[84] Although uncommon, complications arising from rhinosinusitis are seen more frequently in acute than in chronic rhinosinusitis. Infection may spread to the orbit or intracranial cavity, a complication more common in children.[85,86] Suppurative complications of acute rhinosinusitis frequently arise from infections of odontogenic origin, particularly from the *Streptococcus milleri* group. Urgent evaluation and treatment, often including surgical drainage of affected sinuses and associated abscesses, is required to minimize the risk for visual loss, seizures, meningitis, and even death.

Invasive fungal sinusitis is a life-threatening condition developing in patients with significant immune compromise. Diabetics with poorly controlled blood glucose levels and patients undergoing bone marrow transplantation are at highest risk. The diagnosis is suspected in this patient population with the development of facial pain, swelling, cranial neuropathies, or unexplained fevers. Imaging studies (CT and MRI) (Fig. 70.5) are helpful in raising suspicion for the diagnosis, particularly if there is loss of contrast enhancement on MRI.[87,88] The diagnosis is established by biopsy demonstrating fungal invasion into the sinus tissues. Frozen section of diseased tissue demonstrates good sensitivity and expedites this analysis.[89,90] Cultures may be helpful to guide antifungal treatment; the morphologic features of fungal elements seen on pathologic evaluation may also assist in identifying the offending fungi. Extrasinus invasion is most common with mucormycosis. Treatment involves surgical débridement, systemic antifungal medications and, when possible, reversal of the underlying immune dysfunction. Even with appropriate medical care, mortality for this condition approaches 50%.[91] Aggressive surgical débridement must therefore be considered in the context of the patient's goals of care.

A slowly progressive, indolent form of invasive fungal sinusitis is seen in patients with less severe immune compromise. Solid-organ transplant recipients and patients with chronic corticosteroid use are at risk for this disorder. *Aspergillus* is the most common pathogen. The treatment principles are the same as for patients with acute invasive fungal sinusitis.

CHRONIC RHINOSINUSITIS

Epidemiology

CRS has an uncertain incidence because the diagnosis often requires both subjective symptoms and nasal endoscopy or CT evaluation. Surveys, which rely only on patient symptom reports, suggest that more than 15% of

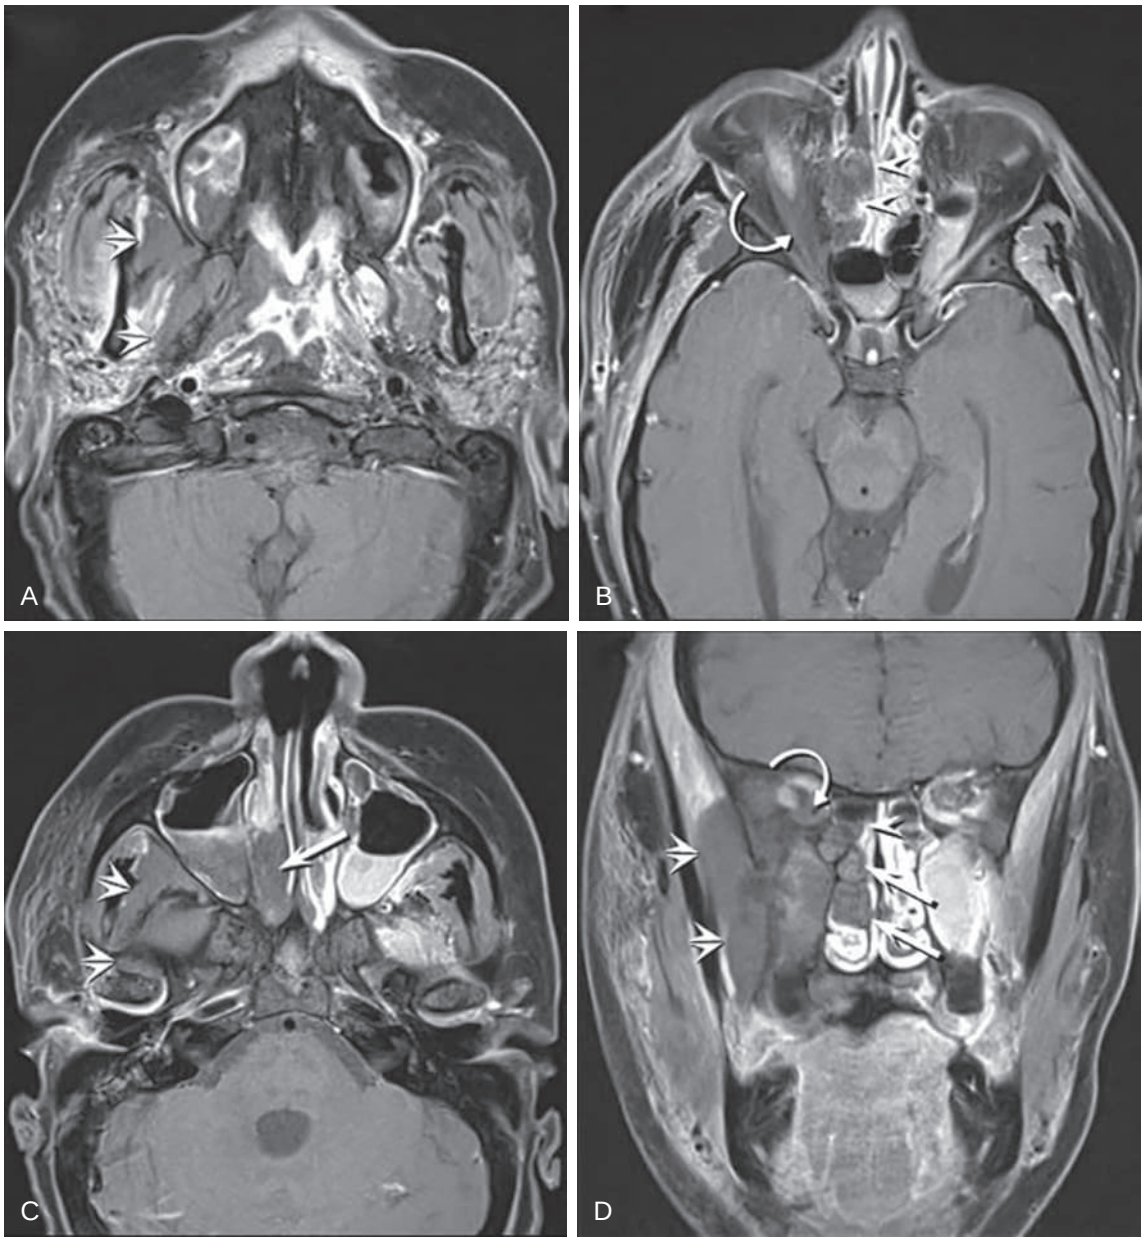

Figure 70.5 Angioinvasive fungal sinusitis. (A–C) Axial and (D) coronal contrast-enhanced fat saturation T1-weighted magnetic resonance images show necrotic tissue with loss of contrast enhancement. The abnormality extends from the right middle/superior turbinates (*arrows*) and posterior right ethmoid region (*arrowheads*) laterally as far as the right infratemporal fossa (*double arrowheads*). Note involvement of the posteroinferior right orbit, particularly the right inferior rectus muscle (*curved arrows*). (Courtesy Joseph M. Hoxworth, MD, Consultant and Associate Professor of Radiology, Department of Radiology, Mayo Clinic College of Medicine.)

the U.S. population suffers from CRS,[92,93] likely a significant overestimation of the true incidence.[74] The prevalence of physician-diagnosed CRS using diagnostic coding reporting in a limited geographic area was closer to 2%.[94] Nonetheless, the impact of CRS on overall quality of life is estimated to be similar to that of COPD and congestive heart failure.[95] In the United States, the overall cost burden for chronic sinusitis is estimated at $8.6 billion per year.[96]

Pathophysiology

CRS is characterized by persistent mucosal inflammation of the paranasal sinuses. The cause of this inflammation is variable and often poorly understood. Numerous theories have been proposed for mechanisms that drive the inflammation in CRS, including systemic immune dysfunction,[97–99] staphylococcal superantigens,[100] pathologic bacterial biofilms,[101–103] aberrant immune response to fungus,[104] and microbial dysbiosis (e.g., imbalance of the resident microbial population).[22,105–108] Several subtypes of CRS have been well established.

The bacteriology of CRS differs from that of acute sinusitis. *Staphylococcus aureus, Pseudomonas aeruginosa,* and anaerobic bacteria are more commonly cultured from patients with chronic disease than with acute disease. Recent studies using culture-independent bacterial identification demonstrate that healthy sinuses contain diverse bacterial communities, which may serve a protective role in the sinuses. Chronically inflamed sinuses are characterized

by a loss of bacterial diversity with overgrowth of a pathologic species[22,105–108] (see also Chapter 17).

Association With Allergy and Asthma

The role of allergy and atopy in CRS is unclear. Studies suggest a higher rate of positive skin tests in patients with CRS[109] but may be confounded by selection bias. Although a causal role for allergy in patients with CRS has not been demonstrated, in atopic patients with CRS, treatment of allergy improves patient outcomes.[110]

CRS with nasal polyps (CRSwNP) demonstrates a more clear association with asthma. Nearly 30–40% of patients with polyps describe wheezing and respiratory discomfort. In addition, 26% of patients with polyps report a diagnosis of asthma compared to 6% of control patients.[111] Patients with asthma also demonstrate a high incidence of sinus mucosal thickening on CT imaging.[112,113] Asthmatic patients also demonstrate a high incidence of nasal polyps; of note, nonatopic asthma is more strongly associated (13%) with nasal polyps than is atopic asthma (5%).[114] As additional evidence of the association of asthma and CRSwNP, asthmatic patients who undergo endoscopic sinus surgery for CRSwNP demonstrate clinical improvement in both upper and lower airway disease.[115–117]

CHRONIC RHINOSINUSITIS WITH NASAL POLYPOSIS

CRS patients are frequently categorized based upon the presence or absence of nasal polyps. A more detailed analysis of the pathophysiology of these patient populations demonstrates that both CRS with and without nasal polyps represents a heterogeneous group of disorders with distinct pathogenic mechanisms. Furthermore, the endotype (i.e., the CRS subtype associated with a pathobiologic mechanism) appears to predict the efficacy of various treatment approaches.[118] Many CRSwNP patients are characterized by type 2 inflammation: inflammatory pathways involving IL-4, IL-5, IL-13, and IgE, which strongly associate with tissue eosinophilia, asthma comorbidity, and severity of sinus disease (see Fig. 70.4C).[119] These patients typically respond well to systemic steroid treatment, which blunts type 2 inflammation, and they are good candidates for biologic therapy targeting IL-4, IL-13, IgE, and IL-5 (see "Treatment" section later).

Conversely, patients with a predominately IL-17–mediated response and neutrophilic inflammation may develop polyps but are generally refractory to corticosteroid treatment.[120] Long-term macrolide therapy has been proposed as an important treatment adjunct for CRSwNP patients with predominately neutrophilic inflammation.[118,121,122]

Although nasal polyps may be visible on anterior rhinoscopy and may even extend to or beyond the nasal vestibule, more frequently nasal endoscopy is required to visualize nasal polyps. Patients typically present with nasal congestion, obstruction, thick nasal drainage, and anosmia. Facial pressure is common. Severe pain, headache, and fever are unusual in the absence of acute exacerbations of chronic disease. Fatigue and difficulty sleeping are also common symptoms.

Patients with asthma and nasal polyps should be queried regarding sensitivity to aspirin and *nonsteroidal anti-inflammatory drugs* (NSAIDs). *Aspirin-exacerbated respiratory disease* (AERD) is found in a subset of CRSwNP patients and is characterized by nasal polyps, asthma, and NSAID sensitivity. Patients with AERD demonstrate abnormalities in arachidonic acid metabolism, characterized by increased production of proinflammatory products of the 5-lipoxygenase pathway after exposure to cyclooxygenase-1 inhibitors, such as aspirin and NSAIDs, which results in shunting through the lipoxygenase pathway and in upper and lower airway inflammation. Patients often develop persistent rhinitis in their late teenage years, with asthma and sinusitis developing over the next several years. Aspirin and NSAID sensitivity may develop at any point along the course of the disease.[123] AERD represents a significant proportion of patients with asthma (9%)[124] and CRSwNP (13%).[114] These patients demonstrate a more refractory clinical course in the treatment of their sinus disease. Aspirin desensitization improves both asthma and sinus disease in this patient population.[125–128]

Patients with unilateral nasal polyps should be evaluated for sinonasal neoplasms with imaging and consideration of biopsy. Before performing a biopsy of a sinonasal mass, the clinician should evaluate the relationship of the mass to the skull base to rule out an encephalocele. Assessment of surrounding vasculature is also critically important because both aneurysms of the carotid artery and juvenile nasal angiofibromas may present as a nasal mass. Biopsy of these entities may lead to severe hemorrhagic complications.

Allergic fungal rhinosinusitis (AFRS) is a distinct category of chronic sinusitis. Unlike the majority of chronic inflammatory sinus disease, AFRS is often unilateral. This diagnosis is established by the presence of nasal polyps, eosinophilic mucus with Charcot-Leyden crystals, and skin or blood testing demonstrating allergy to fungus.[129] The incidence of AFRS is higher in African American patients, and the disorder is more common in humid regions, including the southern United States.[130,131] Bone expansion and erosion may result in initial difficulty distinguishing AFRS from sinonasal neoplasms. In such cases MRI findings are also helpful in the diagnosis of AFRS (Fig. 70.6).

Congenital disorders resulting in impairment of mucociliary clearance have a high incidence of CRS. Because nasal polyps are unusual in pediatric patients, their presence should trigger evaluation for cystic fibrosis and ciliary dyskinesia. Pathologic evaluation of polyps in these patients is likely to demonstrate a neutrophilic infiltrate and a predominately type 1 T–helper cell–mediated inflammatory process.[132,133]

Treatment

Treatment of CRSwNP is challenging. Most patients receive only temporary, if any, benefit from antibiotic therapy.[76,78,134,135] Topical steroid sprays and saline irrigations often provide improvement[135,136] but rarely provide adequate symptomatic relief for patients with a significant polyp burden. Systemic steroid therapy frequently provides significant symptomatic improvement.[76,78,137] Unfortunately, systemic side effects limit long-term use of this medication, and symptoms often recur quickly after

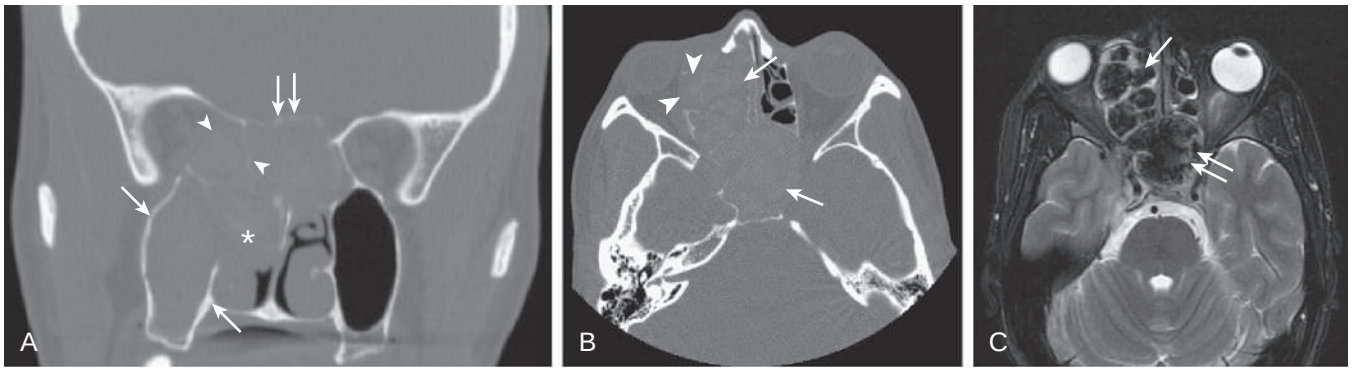

Figure 70.6 Allergic fungal rhinosinusitis. Coronal (A) and axial (B) computed tomography images demonstrate allergic fungal rhinosinusitis. The sinus contents are increased in density and expansile in nature with associated bone remodeling and erosion involving the medial right maxillary sinus (*single arrows*, A), sphenoid sinus walls and ethmoid partitions (*arrows*, B), and anterior skull base (*double arrows,* A). The right lamina papyracea (the medial wall of the orbit) has also been eroded (*arrowheads*, A–B), with the ethmoid contents bowing laterally into the medial right orbit. Lobulated opacity in the right nasal cavity (*asterisk*, A) is consistent with sinonasal polyposis, one of the diagnostic criteria for allergic fungal rhinosinusitis. Axial T2-weighted magnetic resonance imaging (C) demonstrates a loss of signal within the affected sinuses (*arrow*, right ethmoid sinuses; *double arrows*, sphenoid sinuses), which is characteristic of allergic fungal rhinosinusitis. (Courtesy Michael B. Gotway, MD.)

cessation of exogenous glucocorticoids. Initial enthusiasm for antifungal irrigations has waned with the publication of trials that demonstrate not only a lack of efficacy, but worsened symptoms when compared to placebo saline irrigation.[134,138] Current guidelines recommend against use of antifungal irrigations for patients with CRS.[78,139] Endoscopic sinus surgery with removal of polyps and cleaning of mucus and debris from within the sinuses results in significant symptomatic improvement.[140] Systemic corticosteroids are frequently initiated before surgery for CRSwNP to decrease mucosal inflammation, which improves hemostasis and endoscopic visualization during surgery. Corticosteroids also enhance control of asthma during endotracheal anesthesia and the postoperative period. Even in the setting of appropriately performed endoscopic sinus surgery, recurrence of polyps is common. Combining medical and surgical interventions is essential in this patient population. Surgery enhances postoperative access to the sinuses, allowing enhanced penetration of topical steroid irrigations. Steroid-impregnated implantable materials have also been used to extend the duration of symptomatic improvement after surgery.[141–143]

New biologic treatments hold promise for the treatment of CRS. Dupilumab (anti–IL-4 with anti–IL-13 activity) has been approved by the FDA for treatment of CRS with nasal polyps.[144,145] Studies evaluating this treatment focused on patients with severe disease burden and often with concomitant asthma, likely selecting for patients with type 2 inflammation. Concerns related to cost and requirement for continued therapy may limit the clinical utility of this medication. Omalizumab, an anti-IgE monoclonal antibody, has been used to treat refractory asthma and appears also to benefit patients with CRSwNP. Data on the efficacy of omalizumab as a treatment for CRSwNP have been submitted to the FDA with the goal of approval as a treatment for this disorder.[135,146] IL-5 is an important driver of eosinophil differentiation and survival, and anti–IL-5 antibodies (mepolizumab, benralizumab, reslizumab) have been FDA approved for treatment of eosinophilic asthma. Studies targeting patients with asthma have demonstrated some efficacy for CRS.[147,148]

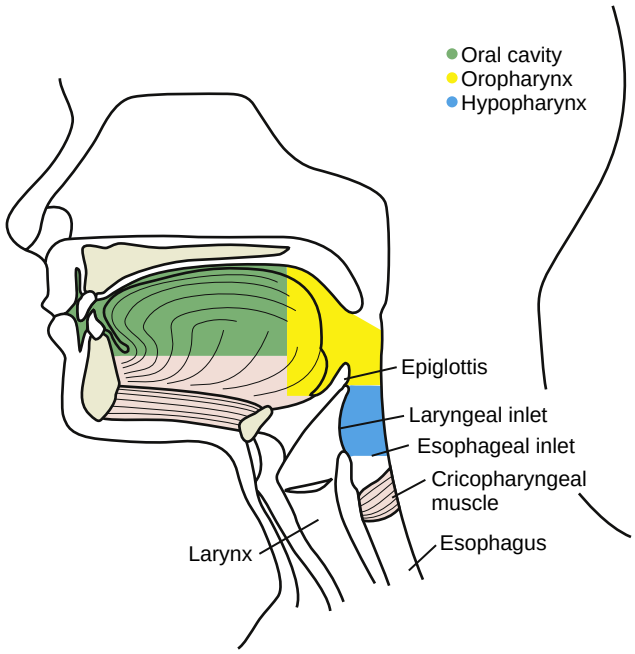

Figure 70.7 Schematic of the oral cavity (*green*), oropharynx (*yellow*), and hypopharynx (*blue*) along with the esophageal inlet and cricopharyngeal muscle.

THE ORAL CAVITY, OROPHARYNX, HYPOPHARYNX, AND LARYNX

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

Oral Cavity

The *oral cavity* is defined as the space from the lips to the end of the hard palate. It contains the teeth, the buccal and gingival mucosa, the mandible and hard palate, the floor of the mouth, and the tongue anterior to the circumvallate papilla (Fig. 70.7). The oral cavity structures are mostly under voluntary control. The oral cavity functions to control the ingestion of food substances. The structures

control the food during mastication and preparation of a bolus suitable for presentation to the oropharynx for reflexive swallowing. Mastication and preparation involve the muscles of mastication for opening and closing of the jaws and the muscles in the lips and cheeks to control the size of the cavity and the muscles of the tongue to move the food particles around the mouth and shape them into the required bolus. In addition to controlling the intake of substances, the structures in the oral cavity are responsible for voluntary modulation of air exhaled from the lungs. This voluntary control is used to control the rate of the air exhaled and to shape the noises created by airflow into speech and song.

Oropharynx

The *oropharynx* is defined as the space from the end of the hard palate to a plane parallel to the top of the epiglottis (see Fig. 70.7). This space includes the structures of the lateral pharyngeal walls, made up by the middle constrictors, the palatoglossus and the palatopharyngeus, the palatine tonsils, the soft palate and uvula, the vallecula, and the base of the tongue. Although these muscles and structures are under voluntary control for assistance in the rate of exhaled air from the lungs and shaping sounds released from the vocal tract, they are under reflexive control for swallowing. Once the sensory nerves are triggered by the exposure to a bolus of solids or liquids, the central nervous system sends a reflexive response to swallow. This reflex leads to an orderly contraction of the tongue base, soft palate, and lateral pharyngeal walls to propel the bolus posteriorly, seal off the nasopharynx, and propel the bolus to the hypopharynx, respectively.

Hypopharynx

The *hypopharynx* is defined as the space from a plane perpendicular to the tip of the epiglottis beyond the superior and lateral aspect of the larynx down to the esophageal inlet (see Fig. 70.7). This includes the structure of the lateral pharyngeal walls, including the inferior constrictors and mucosal membranes, as well as the bilateral pyriform sinuses. As for the oropharynx, the skeletal muscles that make up these structures are under voluntary control for assisting in regulation of airflow out of the lungs and shaping the airflow into speech and as reflexive central nervous system control for swallowing. The distal end of the hypopharynx culminates in the upper esophageal sphincter. This is a region of the pharynx that controls opening of the proximal esophagus to allow passage of food into the alimentary tract and to prevent the inadvertent regurgitation of food or secretions back into the pharynx and upper airway. Although the upper esophageal sphincter is several centimeters in length, the primary portion is made up of the cricopharyngeal muscle (see Fig. 70.7). This circumferential, sling-like skeletal muscle is maintained in a tonic contracted and closed state. The act of swallowing initiates reflexive inhibition of the neural input, resulting in muscular relaxation. As the larynx and pharynx are pulled upward and forward by the actions of other muscles, the relaxed upper esophageal sphincter is stretched open. This allows the passage of the food bolus. The bolus can fail to pass either because of failure of relaxation of the cricopharyngeal muscle segment or failure to stretch the area open through pull of coordinated muscles on the relaxed upper esophageal sphincter segment. Either will result in the retention of foods and secretions, which can then spill into the upper airway.

Larynx

The *larynx* is made of the bone, cartilage, and muscular and mucosal structures from the epiglottis to the bottom of the cricoid ring. It is divided into three regions based on the lymphatic drainage patterns. These regions include (1) the supraglottis from the tip of the epiglottis to the top of the vocal folds (also known as the vocal cords), including the upper part of the arytenoid; (2) the glottis, which includes the tissue from the top of the vocal folds to 1 cm below the top of the vocal folds; and (3) the subglottis, which is below the vocal folds to the first ring of trachea (Fig. 70.8).

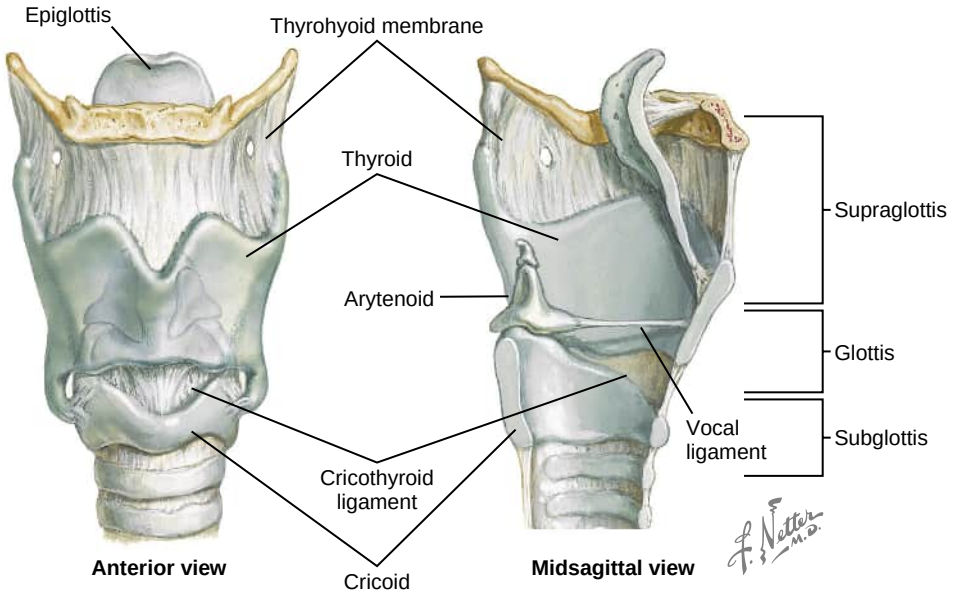

Figure 70.8 Schematic view of the larynx with the cartilage and ligamentous structures. The supraglottis, glottis, and subglottic subdivisions are marked. (Modified from Netter FH. *Atlas of Human Anatomy*. ed 5. Philadelphia: Elsevier; 2010. Netter illustration from www.netterimages.com, ID: 1495. Copyright Elsevier Inc. All rights reserved.)

Bone and Cartilage. The structural bone and cartilages of the larynx include the hyoid bone, paired thyroid lamina, and cricoid ring. These structures have ligamentous and cartilaginous attachments to each other to allow them to function as one organ. Specifically, the hyoid is attached to the thyroid cartilage by the thyrohyoid ligament. The thyroid laminae are attached to the cricoid laterally by the fibrous cricothyroid joint and anteriorly by the cricothyroid ligament and membrane. The hyoid bone is attached to the skull base by the styloglossus muscle, to the mandible by the geniohyoid muscle, and to the tongue base by the hyoglossus muscle. The laryngeal cartilage is attached to the pharyngeal wall through the inferior pharyngeal constrictor muscle and to the cricoid ring by the cricothyroid joint, membrane, ligament, and muscle. The cricoid is attached to the trachea through fibrous attachments. These connections support the airway. Other cartilaginous structures within the larynx include the arytenoid complex cartilages known as cuneiform, corniculate, and arytenoid cartilages and the epiglottic cartilage. The mucosal and muscular structures of the larynx include the aryepiglottic folds connecting the arytenoid complex to the epiglottis; the false vocal folds, running from the body of the arytenoid to the base of the epiglottis; and the true vocal folds, running from the arytenoid to the thyroid cartilage (Fig. 70.9). The laryngeal ventricle is a cleft between the true and false vocal folds. It contains mucus-producing cells and minor salivary glands that lubricate the tissue of the larynx during breathing and speaking. In addition, the shape of the ventricle probably creates turbulence in airflow that is significant for vocal fold vibration during speaking[149] but of relatively little significance for airflow during breathing.

Arytenoid Complex. The arytenoid cartilage is attached to the cricoid ring through a series of anterior and posterior ligaments that form the capsule of the synovial cricoarytenoid joint. The corniculate and cuneiform cartilages have fibrous attachments to the arytenoids and are located on top of and anterior to the arytenoid cartilage, respectively.

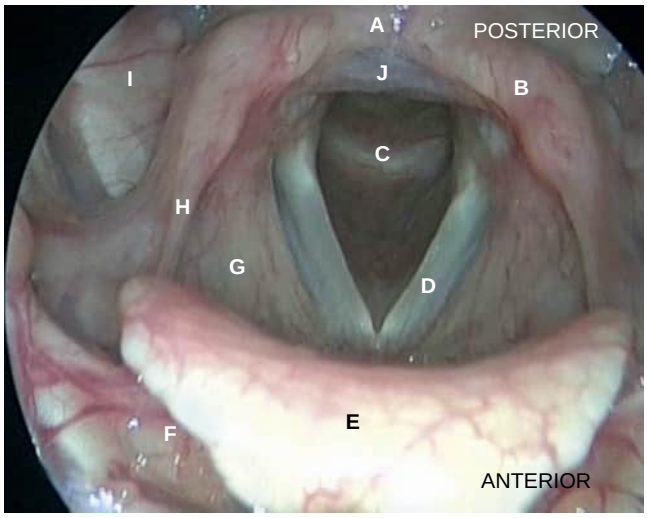

Figure 70.9 Upper airway anatomy: endoscopic view. *A,* Esophageal inlet; *B,* arytenoid; *C,* trachea; *D,* true vocal folds; *E,* epiglottis; *F,* vallecula; *G,* false vocal folds; *H,* aryepiglottic folds; *I,* pyriform sinus; *J,* interarytenoid region.

The true function of these structures is unknown, but they are thought to increase and stiffen the aryepiglottic fold and may therefore aid in prevention of aspiration during swallowing and prevent supraglottic collapse of the airway during breathing. The cricoarytenoid joint allows movement of the arytenoid on the cricoid ring for vocal fold abduction and adduction, which is controlled by the action of the intrinsic laryngeal musculature on the arytenoid. Specifically, the lateral cricoarytenoid muscle attaches from the lateral aspect of the cricoid to the muscular process on the posterolateral aspect of the arytenoid. Contraction of the lateral cricoarytenoid muscle creates inward rotation of the arytenoid on the cricoid and closes the laryngeal airway during swallowing, speaking, and exhalation. This activity is supplemented by the action of the interarytenoid muscle, which runs between the upper bodies of the arytenoids and pulls the arytenoids together. The interarytenoid muscle is probably more important during voice production than during breathing. The posterior cricoarytenoid muscle attaches from the posterior aspect of the cricoid ring also to the muscular process on the posterolateral aspect of the arytenoid. Contraction of the posterior cricoarytenoid muscle creates outward rotation of the arytenoid on the cricoid and opens the airway during inspiration.

Epiglottis. The epiglottis has ligamentous attachments to the hyoid bone (hyoepiglottic ligament) and thyroid cartilage (thyroepiglottic ligament) and fibromuscular attachments to the arytenoid complex (aryepiglottic fold). As the names of these attachments imply (origin to insertion), the epiglottis moves in relation to these supportive structures during breathing and swallowing. This movement is passive. As the tongue base and pharyngeal walls contract and the hyoid and attaching laryngeal supporting framework are pulled upward, the epiglottis tilts posteriorly (passive inversion) to cover the top of the airway and divert the bolus to be swallowed to the outside of the larynx (pyriform sinuses). The epiglottis does not completely cover the airway, but rather steers the bolus through the pyriform sinus and outside of the laryngeal airway. Patients who lose the epiglottis secondary to cancer treatment can be taught to swallow again by strongly contracting the tongue base to pull the larynx forward, thereby partially covering the laryngeal airway. Usually this results in a small amount of residue deposited on the top portion of the larynx and/or vocal folds that then must be cleared out of the larynx into the hypopharynx with a throat clear or cough and swallowed a second time. This is known as a "supraglottic swallowing technique" and is useful in preventing aspiration in cases of epiglottic loss or malfunction.

Mucosal and Fibromuscular Structures. The mucosal and fibromuscular structures include the aryepiglottic folds, false vocal folds, and true folds. As stated previously, the aryepiglottic folds run from the arytenoid complex to the epiglottis. They separate the pyriform sinus of the hypopharynx from the supraglottic larynx and form a sling of tissue around the vocal folds to prevent aspiration during swallowing. They consist of fibrofatty tissue and contain minor salivary glands and mucus-producing cells. If a significant portion of the aryepiglottic fold is removed during surgery, the liquid or food bolus can fall into the larynx and increase the risk for aspiration. At the inferior portion of the

aryepiglottic fold is the false vocal fold. This is a fibrofatty collection of tissue also covered with epithelium containing minor salivary glands and mucus-producing cells. The true function of the false vocal folds is unknown, but they most likely affect the resonance characteristics of the voice rather than the process of breathing or swallowing. The aryepiglottic folds and false vocal folds are part of the supraglottis and can be covered with either respiratory epithelium or squamous epithelium.[150]

The true vocal folds are composed of the *thyroarytenoid* (TA) and *lateral cricoarytenoid* (LCA) muscle covered with mucosa. The mucosa is a stratified squamous epithelium supported by a specialized submucosa or lamina propria differentiated into three layers. This differentiation is likely secondary to use of the vocal folds for phonation, which causes the supporting fibroblasts to produce and secrete proteins and carbohydrates.[151] These extracellular particles are then layered in a particular order, with dense collagen as the deepest layer, an elastin-rich middle layer, and glycosaminoglycans and glycoproteins forming a spongy superficial layer. The middle and deep layer form a transition zone known as the vocal ligament, which runs from the anterior aspect of the thyroid cartilage to the vocal process of the arytenoid. This ligament allows the superficial layers to separate from the deeper layers as the vocal folds vibrate to produce voice and is probably responsible for the relatively wide vocal pitch range that humans are able to produce. The TA-LCA muscle runs from the anterior aspect of the thyroid cartilage and attaches along the body of the arytenoid cartilage. As the TA contracts, it adducts, tenses, shortens, and thickens the vocal fold. This is important because, as the TA-LCA muscle changes tension and shape, it has an indirect effect on the vocal fold mucosa, which is involved in vocal fold vibration. The vibration frequency of an object is related to the driving force for vibration and the tension and mass of the object. Therefore, as we adjust the tension in the vocal fold, through voluntary contraction of the intrinsic skeletal muscle of the larynx, we affect the frequency of vocal fold vibration, which is perceived as the pitch of the voice. In the case of vocal fold tension and mass, the most important muscles are the TA-LCA along with the cricothyroid muscle. As the cricothyroid muscle, which originates on the cricoid ring anteriorly and inserts on the thyroid cartilage, contracts, the thyroid cartilage is subluxed on the cricoid ring. This results in stretching the vocal fold and increasing the tension, which drives up the frequency of vibration and the pitch of the voice.

Pathophysiology. The pharynx and larynx have prominent and complex functions in the upper airway to separate the alimentary tract from the respiratory tract for human survival. For swallowing and breathing, the pharynx and larynx must work in a coordinated manner. If these systems fail to function properly, the airway can be obstructed or pharyngeal contents can be aspirated, leading to lung disease.

DISORDERS OF SWALLOWING

Epidemiology

Disorders of swallowing caused by either neurologic or muscular diseases interrupting the normal sequences of upper airway and pharyngeal activity can lead to the aspiration of pharyngeal contents either directly, during the swallowing act, or indirectly, from refluxed gastric contents. Aspiration of large quantities of liquid material or of large solid substances can lead to airway obstruction with asphyxiation and death. Acute aspiration of small amounts of substances has been shown to produce acute pulmonary inflammation.[152] Aspiration of acidic materials appears to be more inflammatory than aspiration of less acidic materials.[153] If the aspiration is an isolated single event, the inflammation resolves with little consequence.[152] However, repeated aspiration can damage the alveolar lining of cells and capillaries and lead to bacterial invasion, mucosal desquamation, and mononuclear cell inflammation.[153] In lung transplant patients, chronic aspiration of refluxed gastric contents has been associated with increased failure rates of grafts through the development of bronchiolitis obliterans syndrome.[154] Although the exact mechanism is unknown, it appears to be related to fibrosis developing as a response to chronic repeated inflammation. This response may be reduced through the use of agents that reduce inflammation[155] (see also Chapters 43 and 72).

Disorders of swallowing, commonly called dysphagia, affect 2–11% of the general population.[156] The etiology is varied. Dysphagia may arise in response to normal aging due to weakening of the pharyngeal musculature. Dysphagia may also arise from neurologic disease (e.g., stroke), motor neuron disease, or Parkinson disease, due to mistiming of the swallow with poor coordination or to weakness or spasticity of the pharyngeal musculature. Finally, dysphagia often results from medical intervention for the treatment of head and neck disease or after intubation for respiratory failure.

Dysphagia is reported to develop in 40–50% of patients intubated for more than 48 hours.[157–159] Furthermore, the incidence of postextubation dysphagia rises by 14% for each additional day of intubation and is significantly more common in older patients.[158,160] The cause of dysphagia due to prolonged intubation is not completely understood. However, because the incidence is remarkably high, all patients intubated for prolonged periods should be evaluated with at least a bedside swallow examination before the initiation of oral feeding after extubation.[157] Clinical studies have also revealed that aspiration after extubation from prolonged intubation may be silent due to changes in laryngeal and pharyngeal sensation; therefore, some authors recommend more aggressive intervention with *flexible endoscopic examination of swallowing* (FEES) to document aspiration.[160] Silent aspiration can be identified by FEES, but the procedure has no impact on outcomes. Although dysphagia with aspiration does not always lead to pneumonia,[160] dysphagia alone is correlated with prolonged hospital stays.[159] The incidence of postintubation dysphagia can be reduced by using smaller endotracheal tubes and by careful monitoring to prevent excessive endotracheal tube cuff pressure.[161,162]

Symptoms of Disorders of Swallowing

The most common symptoms in patients with disordered swallowing are chronic coughing, weight loss, and repeated episodes of pneumonia. On questioning, patients report that they cough during meals. In general, a greater

difficulty with swallowing liquids is indicative of neurologic dysfunction or muscular weakness, and a greater difficulty with solids is more indicative of obstruction. The examiner should inquire about what substances cause the most difficulty, the timing of the cough in relation to eating, the length of time required to finish a moderate-sized meal, and where food appears to create the greatest difficulty during the swallow.

Coughing early during the act of swallowing indicates poor oral motor control of the bolus. Patients with neurologic disorders may notice that they cannot control the food within the oral cavity so that the food prematurely spills into the oropharynx or hypopharynx before the patient is ready to swallow. Patients find that substances that break apart easily or consist of both liquids and solids are most difficult because portions of the bolus can escape. Coughing during or after the swallow is most indicative of pharyngeal dysfunction due to either disordered reflex timing of the pharyngeal contraction or muscular weakness that prevents the bolus from moving through the pharynx as required.

Prolongation of mealtimes often leads to malnutrition and weight loss. Patients with an intact swallow mechanism can usually finish a complete meal in 15 minutes. Longer mealtimes are suggestive of dysphagia. When patients go beyond 30 minutes for a meal, they typically begin to lose interest in eating. In most cases, this prolongation is socially unacceptable, and dining companions begin to leave the table, forcing the patient to stop eating.

Dysphagia can be roughly divided into pharyngeal phase dysphagia and esophageal phase dysphagia. Patients with pharyngeal phase problems will complain of substances sticking in the back of their "throat" and coughing because of aspiration of retained substances, whereas patients with esophageal phase disorders will complain of food lodging in the chest that needs to be regurgitated or "washed down" with liquids. Cough may also be stimulated at the distal esophagus, but this is after the swallow and is generally nonproductive and not associated with the development of pneumonia.

Evaluation of Dysphagia

Evaluation is best done by a team of physicians and speech-language pathologists interested in disorders of swallowing. After a careful history, the patient can be given a sip of water during palpation of the laryngeal complex. As the patient swallows, the larynx should elevate briskly about 2 cm. In addition, the patient should not cough and should then be able to speak without a wet-sounding voice. If the patient passes this initial screening, then he or she should be asked to take multiple sips to see if the swallowing reflex breaks down. Next, complete head and neck evaluation and indirect endoscopy of the hypopharynx and larynx is undertaken to assess lip and tongue mobility and strength and for patterns of retained secretions or food particles. Patients with normal tongue function should be able to protrude the tongue and move it side to side without associated movement of the mandible. Retention of food particles within the oral cavity or inability to move the tongue freely is indicative of weakness or restricted motion. Indirect endoscopy identifying pooling at the base of the tongue within the vallecula is suggestive of weakness of the tongue base, pooling of secretions within the pyriform sinuses is indicative of pharyngeal weakness, and pooling of secretions in the esophageal inlet is indicative of failure of cricopharyngeal opening or obstruction of the esophagus.

To confirm these patterns of weakness, FEES[163] or modified barium swallowing examination can be performed. These tests are usually performed by a qualified speech-language pathologist. Rather than just being a screening test for aspiration, these examinations should be used to identify which deficits within the swallowing act are responsible for the dysphagia. In addition, during FEES or a modified barium swallow, various adaptive/compensatory swallowing adjustments can be tried. These diagnostic evaluations result in essential treatment approaches and can direct treatment strategies.

Treatment

Treatment for disorders of swallowing involves precise identification of the region and type of the swallowing deficits. If muscular weakness is identified, patients can be given a series of exercises targeting specific areas either of the tongue base[164,165] or of the lateral pharyngeal walls.[166] If neurologic deficits are identified, resulting in reflex timing issues or if the muscular deficits are insurmountable, patients can be taught compensatory strategies to improve the safety of the swallow. These strategies include repositioning of the patient during the swallow so that the bolus is less likely to fall into the airway, chin tuck to keep the bolus in the mouth during mastication, or head turning to close off the weakened side of the pharynx during the swallow act. Finally, if none of these techniques is beneficial and the patient and the family are interested, a feeding tube can be inserted to prevent weight loss and lessen the burden of needing to ingest a sufficient amount of calories orally to maintain weight. If repeated aspiration persists, laryngotracheal separation or narrow field laryngectomy, a less invasive procedure for laryngeal diversion, should be considered.

GASTROESOPHAGEAL AND LARYNGOPHARYNGEAL REFLUX DISEASE

Association with Asthma and COPD

The relationship between reflux disease, asthma, and COPD is complex. Although the association between reflux and severe asthma is well accepted, the empirical evidence for causation of one by the other is lacking. Lung disease may be related to reflux disease by different mechanisms. First, direct microaspiration of contents refluxed into the lungs on a chronic basis may lead to pulmonary remodeling. The extent of injury is related to the amount and characteristics of the aspirate, the frequency of aspiration, and the effectiveness of protective lung-clearance mechanisms. This is one proposed mechanism for the development of bronchiolitis obliterans syndrome in transplant patients. Second, reflux or reduced clearance of food from esophageal dysmotility may cause vagally induced bronchospasm. Vagally induced bronchospasm is associated with increased acidification of the lower esophagus and may be ameliorated by deacidification of the gastric contents in patients with difficult-to-control asthma.[167] Treatment with a *proton pump inhibitor* (PPI) improves asthma control in individuals with symptomatic *gastroesophageal reflux disease* (GERD) but not in those without symptoms.[168,169]

However, as previously stated, the association between reflux disease and lung disease does not prove causation. Medications for the treatment of asthma may increase reflux, as may changes from chronic lung disease. Albuterol is known to lower the resting pressure of the lower esophageal sphincter and decrease esophageal contraction amplitude. These changes may increase the incidence of reflux.[170] Prednisone, which is often prescribed in patients with difficult to control asthma, has been shown to increase esophageal acid exposure times.[171] COPD can lead to hyperinflation with flattening of the diaphragm. The diaphragm, specifically the crura around the esophageal hiatus, forms a critical part of the lower esophageal sphincter, and flattening of the diaphragm decreases the protective reflux barrier of the diaphragm. An increased transdiaphragmatic pressure gradient, as seen in patients with COPD, predisposes to the movement of gastric contents into the esophagus.

Evaluation of Gastroesophageal Reflux Disease and Laryngopharyngeal Reflux Disease

There are no universally accepted physical findings in the upper aerodigestive tract pathognomonic for extraesophageal reflux disease.[172] *Extraesophageal reflux disease* refers to the manifestations of reflux such as laryngitis, dysphonia, cough, and bronchospasm, which are separate from the classic esophageal reflux symptoms such as heartburn. Although attempts have been undertaken to develop a reflux finding score for physical changes in the larynx in patients with presumed extraesophageal reflux,[173] attempts at validation of these findings through correlation with pH studies have been unsuccessful. Therefore, the various laryngeal examination findings previously ascribed to *laryngopharyngeal reflux disease* (LPRD) are nonspecific and must be taken into context of a larger evaluation process.

After a careful history for symptoms of both classic GERD and extraesophageal reflux disease has been completed, most patients will be placed on an empirical trial of antireflux medications in combination with behavioral modification instructions. If the trial results in amelioration of the symptoms, the symptoms are commonly believed to be secondary to reflux disease. This method of evaluation for reflux with an empirical trial of medications is problematic because there may be a considerable placebo effect. Meta-analysis of randomized controlled clinical trials has shown that the effect of medications in alleviating symptoms is not significantly different from the effect of placebo.[174] However, most of these trials did not rely on objective testing for LPRD as entrance criteria. Some clinicians proceed to 24-hour pH monitoring and/or impedance testing. The latter, when combined with pH testing, allows detection of both acid and nonacid reflux. Although 24-hour pH analysis is considered the gold standard for esophageal reflux, pH testing over shorter time periods is often very helpful. Testing of pH within the hypopharynx to assess extraesophageal spillage of gastric contents is an area in its infancy, and there is significant debate as to what constitutes an abnormal finding.[175]

Treatment of Gastroesophageal Reflux Disease

Treatment of GERD or extraesophageal reflux disease causing pulmonary problems is best started with dietary modifications and twice-daily PPI medications. The rationale for these aggressive management strategies is that the pharynx, larynx, and trachea have few, if any, natural protective mechanisms for the neutralization of aspirated gastric contents.[176,177]

If there is strong suspicion of GERD or extraesophageal reflux causing pulmonary disease, consideration can be given to surgical therapies, such as Nissen fundoplication. Studies evaluating the true response of symptoms from extraesophageal reflux disease to surgical intervention show conflicting results. This is due in part to the significant difficulty in diagnosing extraesophageal reflux accurately and in understanding the role extraesophageal reflux may play in the pulmonary disease process.[178] The best results are obtained when classic GERD is identified and surgery, such as Nissen fundoplication, is performed for significant reflux within the lower esophagus.[179–181]

PARADOXICAL VOCAL FOLD MOTION DISORDER AND LARYNGOSPASM

Definition and Diagnosis

Also known as vocal cord dysfunction or inducible laryngeal obstruction, *paradoxical vocal fold motion disorder* (PVFMD) is a descriptive term for inappropriate adduction of the vocal folds during breathing. The mistimed vocal fold closure creates difficulty breathing and is often misdiagnosed as asthma. The diagnosis of PVFMD is made on the basis of history, followed by spirometry and laryngeal examination. Patients present with a constellation of symptoms, including difficulty breathing; a sensation of a foreign body or lump in their throat; a dry, nonproductive cough; and possibly chest tightness. These symptoms can manifest at rest, after talking, or after physical exertion. A distinct subset of this condition is associated with physical exertion and exercise. This has been called exercise-related PVMD or, more recently, exercise-induced laryngeal obstruction. Often the symptoms are exacerbated as the patient increases the intensity of the precipitating behavior. The disease is commonly misdiagnosed as asthma; however, the symptoms are refractory to standard asthma management protocols. In patients with PVFMD, spirometry performed during an episode may reveal flattening of the inspiratory limb of the flow-volume curve, indicative of a variable extrathoracic obstruction[182–184] (see Fig. 32.2, right panel). Flexible laryngoscopy, considered by some to be the gold standard for diagnosis,[182,185,186] may reveal paradoxical closure of the vocal folds during breathing. Typically, paradoxical closure is observed during active inhalation through either the mouth or the nose but is considered pathognomonic by some when seen at the end of a speech utterance.[183] Provocation testing through increased exercise challenge, odor exposure, or even methacholine challenge may increase the sensitivity of laryngoscopy in the identification of paradoxical closure. However, even with these challenges, the sensitivity of endoscopy is still only 60% in patients with symptoms.[187] Therefore, a presumptive diagnosis and empirical treatment may be warranted in all patients with symptoms who do not respond well to medical management for asthma.

Laryngospasm, closing of the vocal folds preventing inhalation, is a physiologic protective reflex to prevent aspiration when foreign particles or liquid (e.g., drowning) stimulate the vocal folds or supraglottic structures. Laryngospasm is most commonly encountered during extubation from general anesthesia. It is managed with positive-pressure

ventilation and small doses of paralytic agents to weaken vocal fold closure. Severe episodes are complicated by postobstructive pulmonary edema, which can require management in the intensive care unit. In the absence of a known stimulus, recurrent episodes of laryngospasm can develop in patients with progressive neurologic disease[188,189] or can be associated with severe forms of PVFMD. These often lead to recurrent trips to the emergency department and can be misdiagnosed as bilateral vocal fold paralysis. Patients with recurrent episodic laryngospasm should undergo a complete neurologic examination to rule out a neurologic disorder. In the absence of neurologic disease, laryngospasm will often respond to the same management strategies used for patients with PVFMD.

Etiology

The etiology of PVFMD is unclear. PVFMD is associated with asthma and GERD.[190] High levels of stress, chronic postnasal drip, and environmental exposure to inhaled or aspirated irritants, allergies, or GERD may lead to laryngeal hyperresponsiveness, which in turn triggers paradoxical laryngeal closure. In one study,[190] when patients with PVFMD were compared with normative data on the Minnesota Multiphasic Personality Inventory, 40% of the patients with PVFMD demonstrated elevation on the hypochondriasis and hysteria scales and minor elevation on the depression scale, in a pattern consistent with conversion disorder. An additional 29% of these patients had significant differences in these scales but did not fit the classic conversion disorder pattern, whereas only 24% of patients had scores suggestive of no psychopathologic conditions.

The association of PVFMD with asthma, GERD, and environmental exposure to irritants raises the possibility of an organic cause in some patients with the disease. Some authors have suggested that, when an organic cause is suspected, the term *irritable larynx* should be used to describe the disorder.[184] In one study of patients with asthma, 19% had coexistent PVFMD, whereas only 5% of asymptomatic control subjects had any evidence of paradoxical vocal fold closure.[191] It is best to consider inappropriate adduction of the vocal fold during breathing as an abnormal physical examination finding with a wide range of etiologies: stress reactivity, GERD/LPRD, environmental exposure, peripheral neuropathy (sensory), or unable to be determined.

Treatment

The first step in the treatment of PVFMD is recognition of the disease. The clinical presentation is often confusing because patients may have coexistent asthma or GERD and may be resistant to the idea that behavioral change could result in any significant reduction in their symptom severity. One study estimated that the association with asthma and GERD is as high as 65% and 51%, respectively.[185] This association, along with a desire to use medication to treat the problems, usually leads to attempted medical trials for asthma management and therapy for GERD. With these strategies, the symptoms may be reduced modestly, but the acute attacks of intermittent dyspnea, cough, and chest tightness can still be difficult to control. Therefore, referral to an otolaryngologist to perform laryngeal endoscopy may be required. If the true coexistence of asthma is questionable because there is little, if any, response to bronchodilator therapy, repeat pulmonary function testing before and after bronchodilator therapy, and possibly with methacholine challenge, is indicated. If test results are positive, management of the reactive airway disease should be maximized. If test results are negative, all medical therapy should be stopped because the asthma medications may be exacerbating the disease by irritating the laryngeal mucosa, increasing patient anxiety, or increasing the risk for gastroesophageal reflux. If symptoms lead to a suspicion that GERD or LPRD is a contributing factor, it is reasonable to treat the patient with dietary modifications and PPI therapy. Dietary modifications include eating small meals, avoiding foods known to cause reflux, and avoiding reclining after eating. Therapy with PPIs should be initiated on a twice-daily basis 30 to 60 minutes before the first and last meal of the day. Reflux that reaches the hypopharynx most frequently happens after meals. Therefore, PPIs should be given before the meal so that a therapeutic serum level can be achieved before the stimulation of acid production by the ingested food. If symptoms have not improved by 2 to 3 months after the initiation of therapy, formal pH impedance testing should be considered. It is also reasonable to consider that acid reflux may not be playing a significant role in the pathogenesis of the patient's disease.

After careful history and endoscopy to rule out other causes of airway obstruction, the treatment of acute episodes of PVFMD includes reassurance, breathing instruction, and possibly the use of a helium and oxygen mixture (heliox) to reduce the turbulence of airflow past an obstruction and thus reduce the pressure needed to generate airflow[192,193] (see also Chapter 39). Often, acute exacerbations will precipitate visits to an emergency department. The patient presents with dyspnea, a rapid respiratory rate, and stridor. Rather than immobile vocal folds or an obstructing mass lesion, endoscopy usually reveals that the vocal folds are held in a paramedian position through inspiration and expiration. If patients are asked to cough or clear their throat, the vocal folds will usually abduct. Vocal fold abduction can be further stimulated by reassuring the patient and attempting to provide a calm, relaxed environment. Inhaling through the nose and exhaling through the nose or pursed lips (metered breathing) may also be beneficial. Alternatively, the patient can be asked to breathe through a straw. Introducing a restriction in the airway with the nose and lips or with a straw facilitates the patient's ability to control his or her breath and promotes laryngeal relaxation with appropriate laryngeal activity. Respiratory control or metered breathing reduces the laryngeal hypersensitivity by reducing either the respiratory rate or breath volume or both. This type of respiratory retraining is the key to management of patients with PVFMD.[194,195]

Difficulties in establishing diagnostic criteria for PVFMD are even greater than for asthma. With asthma, objective pulmonary function measures can document reversible airflow obstruction, or methacholine bronchoprovocation can demonstrate bronchial hyperreactivity. Patients with PVFMD may show flattening of the inspiratory limb of the flow-volume curve, as is seen in patients with variable extrathoracic airway obstruction, but these changes can be transient or mimicked by submaximal inspiratory effort. Therefore, there are no objective measures of the disease, and establishing objective diagnostic criteria is not possible. Treatment may involve placebo effects from medications for other disorders, such as GERD or asthma, or active

respiratory retraining to engage the patient in regaining control of his or her breathing, as described earlier. Due to the difficulty in establishing diagnostic criteria, there have been few randomized controlled trials of respiratory retraining in patients with PVFMD. Limited evidence from case series has shown a reduction in the severity of patient symptoms and improvements in quality of life, which can be maintained through periodic long-term follow-up.[196]

VOCAL FOLD PARALYSIS

Unilateral

Unilateral vocal fold paralysis rarely produces symptoms of airway obstruction other than dyspnea with phonation. Although changes in pulmonary function can be measured during both quiet and active breathing, these are rarely clinically significant.[197] When obstruction is present, the proposed mechanism is either (1) the action of inspiratory airflow producing a Bernoulli effect on the flaccid vocal fold (e.g., pulling the cord inward due to low pressure and thereby increasing obstruction) or (2) inappropriate reinnervation of the paralyzed vocal fold with active signals for adduction during inspiration (e.g., synkinesis).[198] The findings can be corrected through surgery to stabilize the flaccid vocal fold complex, botulinum toxin injections to reduce the effects of the inappropriate reinnervation, or surgery to reduce the nerve supply to the synkinetic vocal fold.[199] It is rare that any of the treatments are required for unilateral vocal fold paralysis.

Bilateral

Bilateral vocal fold paralysis most commonly develops secondary to surgery in the anterior compartment of the neck for thyroid disease.[200] The recurrent laryngeal nerves are either crushed or cut during the intervention, and vocal fold abduction for inspiration and adduction for phonation are lost. Immediately after the onset of the injury, some patients are able to tolerate the loss of vocal fold abduction because the vocal folds are flaccid and immobile in a lateral position. The voice is weak and breathy. However, the recurrent laryngeal nerve contains all axons for abduction and adduction in a single fascicle. As axons regrow, the vocal fold muscles may regain tone without active adduction or abduction. Because of the increased mass of the adductor muscles compared to the abductor muscle, the vocal folds adopt a more medial position. Vocal fold tone recovers in the majority of patients who sustain an injury to the recurrent laryngeal nerve.[201] This process of neural regeneration takes 3 to 9 months and leads to slowly progressive improvement in voice but progressive airway compromise. Patients often adapt to this progressive airway compromise by decreasing their level of activity.

A small percentage of patients develop bilateral vocal fold paralysis secondary to a Chiari malformation with increased intracranial pressure and compression of cranial nerve X in the foramen magnum by the base of the brain as it herniates through the foramen. This condition can be extremely difficult to diagnose. Finally, a small percentage of patients will have an idiopathic etiology. In these instances, the paralysis can develop bilaterally simultaneously or unilaterally, separated by years.[202]

Patients with bilateral vocal fold paralysis typically report minimal voice changes and note marked dyspnea on exertion. Careful history usually reveals the cause as prior surgical intervention,[200] and general examination reveals prolongation of inspiration with mild to moderate inspiratory stridor. Endoscopic examination reveals bilateral vocal fold immobility with possible elongation of the vocal folds on inhalation.[200] Pulmonary function testing demonstrates a classic pattern of variable extrathoracic obstruction with flattening of the inspiratory limb of the flow-volume curve and little change in the expiratory limb (see Fig. 32.2, right panel). When maximal inspiratory flow falls below 1.5 L/sec, most patients are markedly symptomatic, and intervention is warranted. If inspiratory flow is maintained around 2 L/sec, most patients can perform modest activity, such as climbing one flight of stairs or walking on level surfaces.

The treatment of bilateral vocal fold paralysis is aimed at enlarging the airway or bypassing the glottis with a tracheotomy. If patients choose the latter, consideration should be given to the creation of a skin-lined tracheostomy tract. This will reduce the risk for granulation tissue growth at the stoma, provide a safe stable stoma for patients to manage by themselves on a long-term basis, and allow patients to use an appliance that will hold a one-way valve so that digital occlusion is not required for phonation.[203] Bilateral vocal fold paralysis can also be treated by injecting botulinum toxin into the muscles of adduction. This reduces the adductor force and allows improved function of the abductor muscles. The voice is fairly well preserved because the patient can usually override some of the effects of the botulinum toxin. The disadvantage of this treatment option is that it requires repeat injections.[204] Transverse cordotomy or partial arytenoidectomy are also surgical options for treatment designed to remove the posterior portion of the vocal fold or a portion of the arytenoid cartilage, respectively. This enlarges the cartilaginous portion of the laryngeal airway by 1 to 2 mm without interfering too greatly with the anterior vibratory function of the vocal folds. However, because the posterior portion of the airway is enlarged on a static basis, air will leak out during phonation, and the voice will be reduced in volume and be breathy in quality. This is referred to as "the great compromise" because the larger the airway for breathing and activity tolerance, the worse the voice. The patient and surgeon must decide on a balance.[205] In addition, one or both of the vocal folds can be sutured in a lateral position through myriad different techniques referred to as suture lateralization. Some of these techniques are potentially reversible and can be used in patients in whom recovery of function is possible to improve their airway during this period.[206] Finally, experimental surgical strategies for management with electrical stimulation of the abductor muscles (laryngeal pacemaker) to open the glottis are being conducted.[207] Initial results indicate that abduction for breathing can be achieved without compromise of vocal fold closure for voice production. An alternative experimental approach involves surgical reinnervation of the posterior cricoarytenoid muscle to achieve vocal fold abduction. This approach sounds attractive but to date has not achieved consistent results.

LARYNGEAL STENOSIS

Scarring of the larynx, usually in the posterior portion, referred to as *posterior glottis stenosis* (PGS), most commonly

develops secondary to endotracheal tube–related injury. In fact, when patients present with bilateral vocal fold immobility after prolonged intubation, 95% of the time the immobility is secondary to scar formation in and around the cricoarytenoid joints.[200] This is a decidedly different process from bilateral vocal fold paralysis, but clinically and endoscopically it can be difficult to distinguish the two because visual inspection reveals the vocal folds to be immobile in both situations. Helpful clinical clues to diagnosis are the events and timing around the onset of symptoms. The most common events associated with onset are prolonged intubation, multiple intubations, and/or intubation with an excessively large endotracheal tube. As the endotracheal tube rubs against the mucosa of the posterior larynx, the mucosa is eroded and inflammation develops. Reflux may play a role in adding to inflammation or mucosal erosion.[208] Secondary infection of the mucosal ulceration may also play a role in adding to inflammation. After the endotracheal tube is removed, the mucosa heals by secondary intention over a 6-week period. Thus, the patient notices deterioration of breathing more rapidly after a mucosal injury than after a neurologic injury; after a neurologic injury, as described earlier, the difficulty with breathing develops over a 3- to 6-month period as the nerve recovers partial tone.

Examination also reveals subtle differences in patients with PGS from those with bilateral vocal fold paralysis. Careful endoscopic evaluation usually reveals scar tissue over and around the cricoarytenoid joint. This can be subtle, with a relatively normal appearance and only slight reduction in the normal size and shape of the posterior portion of the larynx, or obvious, with overt scar tissue built up in the posterior portion of the glottis.[209] Finally, pulmonary function testing usually reveals a fixed extrathoracic pattern with flattening of both the inspiratory and expiratory limbs of the flow-volume loop.

Distinguishing between PGS and bilateral vocal fold paralysis is clinically significant because treatment options and outcomes are different. Both PGS and bilateral vocal fold paralysis can be treated with tracheotomy. In PGS, the initial surgical treatment should be aimed at release of the scar tissue holding the joint in the fixed position. If this is not possible due to loss or remodeling of the cartilaginous joint structure, portions of the cartilage or vocal fold can be removed. If possible, mucosal advancement flaps should be designed to cover the site of surgical excision. Because the tissue of the posterior glottis is scarred, a simple incision through prior scar tissue is less likely to provide sustained significant release and more likely to heal with recurrent scar. Injudicious surgery can make the problem worse. The majority of patients with either PGS or bilateral vocal fold paralysis can have successful endolaryngeal surgery that will enlarge the airway to prevent a lifetime of tracheotomy dependence.

UPPER AERODIGESTIVE TRACT MALIGNANCIES

Malignancies of the upper aerodigestive tract are a significant cause of morbidity and mortality. Cancers of the upper aerodigestive tract constitute approximately 4% of all malignancies.[210] *Squamous cell carcinoma* (SCC) is the predominant cancer in this location, and smoking and alcohol use are the traditional risk factors. Surgery, radiation, and chemotherapy all play an important role in the treatment of this disease; a thorough discussion of this topic is beyond the scope of this chapter.

In the oropharynx, recent evidence has identified *human papillomavirus* (HPV) as an emerging, and now dominant, cause of malignancies. In all, 80–90% of newly diagnosed SCC of the tonsils or base of the tongue are HPV induced. HPV-associated oropharyngeal SCC represents a distinct clinical entity with a significantly better prognosis than non–HPV-associated oropharyngeal SCC. National Cancer Center Network guidelines now recommend HPV testing for all oropharyngeal malignancies. HPV-16 is identified as the most common HPV subtype associated with oropharyngeal malignancy.[211] In SCC of the oral cavity, oral tongue, and larynx, HPV is less commonly found; in this region, tobacco and alcohol use remain the primary risk factors. Whereas the incidence of these non–oropharyngeal SCCs is declining likely secondary to a decrease in tobacco use, the incidence of oropharyngeal carcinoma is rising, likely due to HPV.

Laryngeal cancers usually present early with voice changes. However, if the cancer arises in the supraglottic area, the subglottis, or pyriform sinus, or if the patient ignores the changes in voice and the diagnosis is otherwise delayed, airway obstruction can be one of the presenting symptoms. In these instances, the diagnosis is made through endoscopic evaluation, and the airway should be managed with endoscopic debulking of the tumor before definitive therapy is undertaken.[212]

SUBGLOTTIS AND CERVICAL TRACHEA

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

The subglottis is the area within the cricoid ring from the bottom of the vocal folds to the top of the first tracheal ring. The latter is the only complete ring in the airway and structurally functions to support the larynx and suspend the trachea. The subglottis is lined with a respiratory mucosa with goblet cells for mucus production and minor salivary glands as well. Mucus and saliva travel upward because of the actions of the ciliated epithelium and airflow and help humidify the airway and lubricate the vocal fold mucosa. In the adult human, the subglottis is the narrowest portion of the airway and ranges from 15 to 18 mm in diameter. It is roughly a round or slightly oval tubular space that is narrowest just below the vocal folds and widens out at the bottom at the transition into the cervical trachea. The space extends for 1 to 2 cm in vertical dimension from the bottom of the vocal folds to the first tracheal ring. The shape of the subglottis is probably important for establishing laminar flow through the glottis. This is important for both the clearance of secretions and generating flow that will efficiently drive vocal fold vibration. Irregularities in the subglottic mucosa often lead to turbulent airflow with crust formation, which can further compromise the airway. Below the subglottis lies the cervical trachea, consisting of the first four or five tracheal rings.

SUBGLOTTIC AND CERVICAL TRACHEAL STENOSIS

Pathophysiology

Because the subglottis is surrounded by a firm cartilaginous structure, and the mucosa lies over the surface with only a normal submucosa for support of the epithelium, the area is particularly prone to injury from surgical manipulation or intubation, reflux disease, and autoimmune disease. Injury to the mucosa by any one of the prior processes can lead to exposure of the perichondrium, which then responds with inflammation and scar tissue formation. The scar tissue impedes airflow and mucus clearance, which can create a fixed extrathoracic airway obstruction.

The cervical trachea is most commonly injured through intervention from prolonged intubation (eFig. 70.1) or tracheotomy. Again, sloughing of mucosa from traumatic manipulation due to a movement of an endotracheal tube or repetitive deep suctioning can lead to exposure of the cartilage with inflammation and secondary collapse. Neoplasia of the minor salivary glands or squamous mucosa can also lead to obstruction.

Diagnosis

The diagnosis of subglottic or cervical tracheal stenosis is made on the basis of the patient's medical history, surgical history, and symptoms. The symptoms are primarily dyspnea on exertion and stridor heard on inspiration and on expiration. If the patient has had a prior intubation or tracheotomy, the possibility of physical obstruction due to scarring should be considered. If a patient has known granulomatosis with polyangiitis, consideration should be given to involvement of the subglottic mucosa with inflammation, vasculitis, and granuloma formation (eFig. 70.2). In the case of idiopathic subglottic stenosis, patients are often treated for reactive airways disease without success.[213] These patients will benefit from early endoscopy/visualization of the subglottic region rather than weeks to months of ineffective treatment. As the name implies, there is no known cause for idiopathic subglottic stenosis. It has been presumed to be autoimmune, and the relationship with extraesophageal reflux disease is established, but the causal nature is unknown.[208,214] Because idiopathic subglottic stenosis is found almost exclusively in women, some authors have proposed a hormonal cause.

High-resolution CT imaging (see eFigs. 70.1 and 70.2) and/or three-dimensional reconstruction of the CT images may help in diagnosis and characterization of the stenotic airway segment. But these imaging modalities are not always available and, even if available, they may miss a short area of obstruction. Pulmonary function tests will demonstrate a characteristic plateau on the flow-volume curve (see Fig. 32.2, right panel), and the measured maximal flow can provide an estimate of the functional diameter of the flow-limiting segment (see eFig 32.3).

The diagnosis of stenosis is confirmed with endoscopic visualization of the area. Endoscopy of the subglottis and cervical trachea for confirmation of stenosis is easily accomplished with a transnasal scope in the office setting using local anesthesia. Lidocaine (4%) can be applied topically to the nose and can also be sprayed onto the vocal fold from above with a curved cannula or from below by injecting it percutaneously into the subglottis and asking the patient to cough. Then the flexible scope can be passed through the vocal folds and the area evaluated.

Treatment

Surgery is the primary mode of treatment of subglottic and cervical tracheal stenosis. The type of surgery, either endoscopic or open, and the use of adjuvant agents, such as steroid injections, or fibroblast activity inhibitors, such as mitomycin C, depend in part on the cause and characteristics of the stenosis. Usually treatment begins with an endoscopic approach. Rigid endoscopy allows palpation of the area to determine the nature of the scar tissue and the length of the segment of the airway that is involved. If the segment is relatively short (<1.5 cm in length), occludes less than 50% of the airway diameter, and is primarily soft tissue in nature, it will likely respond to endoscopic incision and dilation and/or balloon dilation performed in a nontraumatic manner.[215] The incisions, which can be made with either cold steel or a laser, control the area of injury and allow the surgeon to identify the nature of the stenosis without further injury of the cartilaginous airway support. If the laser is used injudiciously, however, the surgeon can create more injury and damage to the cartilage. New-generation lasers have a very short pulse structure, resulting in minimal heat dissipation into the tissue beyond what is seen. Once the extent of the stenosis is identified, the surgeon can use that information to decide on the amount of dilation that the area will accept. The area is then dilated with a balloon to the appropriate size.

For very short stenotic segments or webs, any technique, such as dilation alone, to break up the web usually works after one or two procedures. When performed with the appropriate technique, the area of stenosis should remain dilated after the procedure during visual inspection. If the area collapses immediately after the dilation, it is unlikely that the procedure will have lasting benefits. In addition to endoscopic incision and dilation, short and relatively discrete segments of cartilage collapse, such as may be seen at a tracheotomy site, can be resected endoscopically. Care should be exercised so that no more than 90 to 120 degrees of trachea are treated at one time. This may necessitate staging of the procedures with two or three attempts to resect the area.[216] The primary goal of endoscopy is to characterize the stenotic segment. If the segment is too long, involves too much cartilage, or collapses immediately after completion of the procedure, it is probably wise to proceed to open resection of the segment.

Acknowledgment

We thank Dr. Mark Courey for his contributions to this chapter in a previous edition of this textbook.

Key Points

- The upper airway contains diverse anatomic structures with a variety of functions that contribute to breathing, vocalization, smell, and taste.
- New-onset anosmia is the most specific early symptom of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2; COVID-19) infection.
- Asthma and chronic rhinosinusitis with nasal polyps are heterogeneous disorders. Subgroups of each disorder are driven by type 2 inflammation and respond to new biologic therapies.
- Allergic rhinitis and asthma are linked in both pathophysiologic and epidemiologic characteristics. Patients with persistent allergic rhinitis should be screened for asthma, and patients with asthma should be evaluated for allergic rhinitis.
- Although multiple medical therapies demonstrate efficacy in the treatment of allergic rhinitis, immunotherapy is the only approach known to alter the natural history of the disease.
- Asthmatic patients with comorbid chronic sinusitis often experience improvement in both upper and lower airway disease after both medical and surgical treatment of chronic rhinosinusitis.
- In swallowing, the oral cavity creates a bolus of the ingested substance and presents this, in an orderly fashion, to the oropharynx and hypopharynx, where the reflexive portion of swallowing takes place. This requires structural and functional integrity and is under control of the central nervous system.
- The larynx is divided into the supraglottis, glottis, and subglottis and functions to regulate inspiratory and expiratory airflow. During swallowing, the larynx is pulled up and forward, to allow the upper esophageal sphincter to open. The bolus passes through the pyriform sinus and into the esophagus.
- During breathing, the vocal folds normally open for inspiration and then close slightly during exhalation to control the rate of air egress. In paradoxical vocal fold motion disease, it is believed that these actions are reversed. The mechanism for this reversal is unknown. However, behavioral interventions designed to retrain breathing are often beneficial in patients demonstrating this finding.
- Paradoxical vocal fold motion disease can often be confused with asthma, but it is typically unresponsive to medical management.
- The contribution of gastroesophageal reflux disease and extraesophageal reflux disease to respiratory disorders is incompletely understood. Most of the evidence supporting an association is derived from studies that measure patient response to empirical therapy.
- Bilateral vocal fold paralysis, posterior glottic stenosis, and subglottic stenosis can often cause airway obstruction that may be misdiagnosed as asthma. Diagnosis requires suspicion based on events in the patient history and endoscopic evaluation. Treatment is usually surgical and is designed to enlarge the airway.

INTRODUCTION

The large intrapulmonary airways are the trachea, mainstem bronchi, and right bronchus intermedius. The trachea is a semirigid tube serving as a conduit for the entire tidal volume with each breath. It begins just below the larynx and extends approximately 10 to 16 cm to the main carina. The trachea is closely associated with the esophagus, which travels toward the gastroesophageal junction along the left posterior tracheal border; the thyroid gland, which sits anterolateral to the proximal cervical trachea; major blood vessels (e.g., aortic arch, innominate artery, superior vena cava, azygos vein); and mediastinal lymph nodes.

Like the trachea, the large bronchi are surrounded by smooth muscle, contain cartilage, and do not participate in gas exchange. The tracheobronchial mucosa consists of a ciliated pseudostratified columnar epithelium containing mucus-producing goblet cells, submucosal gland duct openings, and cough receptors and is one of the initial sites of innate defensive responses against inhaled invaders.

The subglottic, proximal one-third of the trachea is extrathoracic, whereas the distal two-thirds of the trachea is intrathoracic. The trachea contains 16 to 22 C-shaped cartilage rings anteriorly and laterally, which stiffen the trachea and are connected posteriorly by a membranous wall. The trachealis muscle runs longitudinally along the posterior membrane and is innervated by muscarinic output via the vagus nerve. The posterior membrane is somewhat flexible and moves inward during exhalation.

During cough, the flexible tracheal posterior membrane facilitates dynamic compression of the intrathoracic trachea, reducing tracheal cross-sectional area and increasing cough velocity (see Chapter 37). For example, a 50% decrease in tracheal diameter increases mean linear cough velocity fourfold,[1] improving mucus clearance.

Because the large airways contribute to innate airway host defense via cough and mucociliary clearance, are the site of most of the airflow resistance in airways, and are surrounded by critical mediastinal organs, it is no surprise that the manifestations of large airway disorders are protean and can be serious. Unlike the small airways, which are a "silent zone," the large airways are a common source of symptoms and can be evaluated via pulmonary function testing, imaging, and direct visualization (i.e., flexible bronchoscopy).

Large airway disorders can be classified into two general categories: those that are intrinsic, or within the airway or airway wall, and those that are extrinsic, or outside the airway. In intrinsic disorders, the large airways can become narrowed, fibrotic, thickened, or malacic; in extrinsic disorders, they can be compressed or invaded by benign or malignant lesions of surrounding organs, lymph nodes, or vasculature. The roles of the tracheobronchial airways in innate immune host defense are described in Chapter 15. This chapter focuses on the diagnosis and management of intrinsic and extrinsic large airway disorders.

CLINICAL FEATURES

For tracheal disorders, the most serious signs and symptoms are the acute onset of stridor or wheeze (see Videos 18.12 and 18.6) and respiratory distress suggesting possible life-threatening tracheal obstruction. Although the tracheal lumen diameter is often decreased by greater than 75% (to <5 mm) in patients with stridor or dyspnea at rest, these symptoms also depend on patient-specific factors, such as comorbid cardiac and pulmonary disease, functional status, and activity levels.[2] In a patient at risk of tracheal obstruction (e.g., lung cancer, prolonged intubation), these symptoms should prompt immediate evaluation and treatment, with the primary goal of maintaining a patent airway.

For the large airways, the most common symptoms are cough, sputum production, dyspnea, hemoptysis, and wheeze. Because these symptoms are nonspecific and are also found in patients with inflammatory and infectious

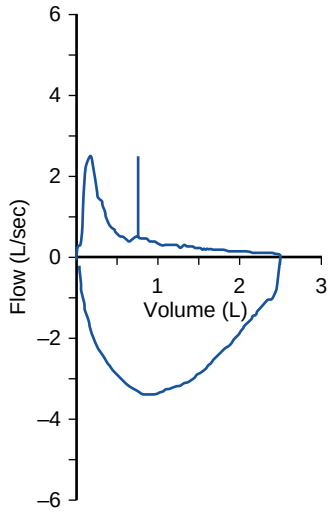

Figure 71.1 Flow-volume loop showing a characteristic rapid decrease in peak expiratory flow due to excessive tracheal collapse. Note that maximal expiratory flow (peak flow) is also reduced. (Courtesy Suil Kim, MD, PhD.)

lower airway diseases (e.g., asthma, COPD, bronchiectasis, pneumonia), large airway disease is often overlooked or misdiagnosed. The key to diagnosing a large airway disorder is having a high index of suspicion. For example, recurrent aspiration, recurrent pneumonia, or cough triggered by eating or drinking should suggest tracheoesophageal fistula in patients with risk factors such as esophageal cancer, tracheal cancer, prolonged intubation, or tracheostomy. In patients with respiratory symptoms suggestive of an obstructive airway disease or infection, the absence of a clinical response to bronchodilators or antibiotics should raise suspicion of a large airway disorder and trigger diagnostic testing rather than additional ineffective treatment.

DIAGNOSTIC APPROACH

The diagnostic approach to a suspected large airway disorder includes spirometry with flow-volume loops, chest imaging, and flexible bronchoscopy.

SPIROMETRY AND FLOW-VOLUME LOOPS

In stable patients, the first step in evaluating a suspected large airway disorder is to obtain spirometry with flow-volume loops, which may reveal plateaus of maximal inspiratory or expiratory airflow that help to localize obstruction (see Chapters 31, 32, and 39). For example, an inspiratory plateau suggests variable extrathoracic obstruction involving the proximal extrathoracic trachea (see Fig. 39.4). An expiratory plateau suggests variable intrathoracic obstruction involving the intrathoracic large airways, as can be seen in tracheobronchomalacia. Plateaus of both inspiratory and expiratory flows suggest fixed tracheal obstruction, as can be seen in tracheal stenosis. Certain features of the flow-volume loop, such as a sudden drop in expiratory flow (Fig. 71.1), plateauing of both inspiratory and expiratory flows, notching of expiratory flow, and oscillations of expiratory flow (see Fig. 39.3), are highly suggestive of large airway disorders.

The classic curves showing the relationship between driving pressure and airflow through a series of critical orifices (see eFig. 32.3) indicate that the diameter of the tracheal lumen must be reduced to less than 8 mm to produce an abnormal flow-volume loop.[2] The FEV_1 is less sensitive than the flow-volume loop in detecting tracheal obstruction, remaining greater than 90% predicted until the orifice diameter is reduced to 6 mm.[3] Of note, in tracheobronchomalacia, airflow limitation on flow-volume loops does not correlate well with *computed tomography* (CT) evidence of tracheal collapse.[4] In clinical practice, the corollary also applies: CT and airway inspection can suggest near total collapse, while the airflow on flow-volume loops is essentially normal. Spirometry and flow-volume loops should be relied upon to determine if tracheal narrowing is physiologically significant.

CHEST IMAGING

After spirometry and flow-volume loops, chest imaging is the next step in evaluating suspected large airway disorders. Chest radiographs can reveal tracheal dilation (i.e., tracheomegaly or Mounier-Kuhn syndrome) or tracheal narrowing (i.e., saber-sheath trachea) but are rarely diagnostic. CT is the imaging test of choice to evaluate the trachea and large bronchi. An axial CT chest scan without contrast is often adequate to localize tracheobronchial pathology and determine if it is focal or diffuse and intrinsic or extrinsic. Contrast is recommended if there is suspicion for mediastinal tissue impinging on the trachea or bronchi, as in fibrosing mediastinitis, or if there is concern for abnormal venous collateral vessels, as in tracheal varices. Multiplanar or three-dimensional reconstructions can create a more complete visualization of tracheal lesions. Magnetic resonance imaging may provide added benefit in characterizing lesions compressing or invading the trachea, such as mediastinal masses or vascular anomalies.[5] If the history, examination, or flow-volume loops suggest tracheobronchial obstruction or collapse, inspiratory, end-expiratory, and/or dynamic CT images should be obtained to evaluate the tracheal lumen at different parts of the respiratory cycle, which is important in diagnosing *tracheobronchomalacia* (TBM) and *excessive dynamic airway collapse* (EDAC).

BRONCHOSCOPY

The definitive procedure for the diagnosis of large airway disorders is visualization of the airways using a flexible bronchoscope. Many large airways disorders cause characteristic mucosal and structural abnormalities that can be identified on white light (standard) bronchoscopy and diagnosed with endobronchial biopsies. Narrow band imaging, which makes blood vessels appear very dark, may be slightly more sensitive than white light bronchoscopy in detecting dysplasia but has not been routinely incorporated into airway inspections.[6]

Radial probe endobronchial ultrasound can be used to evaluate cartilage integrity and wall thickness in tracheobronchomalacia and to determine if malignancies of adjacent structures, such as the esophagus, are invading the

trachea or left mainstem bronchus[7–9] (see Chapter 27). Flexible bronchoscopy can also be used to evaluate the shape and cross-sectional area of the lumen during quiet tidal breathing, forced breathing maneuvers, and cough (a technique termed dynamic bronchoscopy) in patients suspected of having TBM and/or EDAC.[10] For severely obstructed airways, thin and ultrathin bronchoscopes may be able to pass the obstruction safely and allow visualization of the airways distal to the lesion, providing valuable information for planning endobronchial therapy (see Chapter 27). In clinical practice, visual inspection remains the most common method of estimating luminal area and degree of obstruction.[11] Specialized airway sizing tools can be used to measure airway diameter before stent placement.

MANAGEMENT

The decision to treat large airway disease is based on the cause, symptoms, degree of obstruction, and the severity of potential complications. Infections and inflammatory diseases are managed medically unless there is compromise of the airway resulting in respiratory insufficiency. In asymptomatic patients with large airway disorders, regular surveillance is usually indicated. However, significant obstruction, disease progression, and concern for serious complications, such as hemoptysis, should prompt intervention even in patients without symptoms.

Management should be coordinated with a careful strategy to maintain airway patency. Flexible bronchoscopy through a benign or malignant tracheal stenosis can result in complete obstruction and respiratory failure due to edema or bleeding caused by scope trauma or biopsies. Rigid bronchoscopy can minimize these risks by allowing rapid dilation of benign stenosis and coring of malignant obstruction without interruption to ventilation. Endobronchial therapies include laser, microdébrider, electrocautery, airway stents, cryotherapy, and balloon dilation (see Chapter 28). There is growing evidence that endobronchial interventions for simple, benign strictures can produce long-lasting results.[12–15] In patients with life-threatening symptoms, such as massive hemoptysis and respiratory failure due to malignant large airway obstruction, endobronchial therapies can be used to palliate symptoms before definitive surgical resection for early-stage lung cancer or radiation therapy for unresectable disease.

Surgical resection is the definitive treatment for many tracheal diseases such as benign stenosis and localized tracheal tumors. The likelihood of a good surgical outcome depends on the cause of the large airway lesion, the natural history of the disease, whether the surgery is a reoperation, whether there was a previous tracheal appliance, and the location and length of resection (tracheal resections exceeding 4 cm in length are associated with increased anastomotic complications).[16,17]

STENOSIS AND MALACIA

Many large airway disorders decrease the cross-sectional area of the airway lumen, increasing resistance and reducing airflow if driving pressure remains constant.

The term *central airway obstruction* refers to airflow obstruction in the large airways, whereas the terms *tracheobronchial stenosis* and *tracheobronchial malacia* refer to relatively fixed narrowing of the large airways and weakness of the cartilaginous large airway walls, respectively.

STENOSIS

Large airway stenoses can be benign or malignant. They can be intrinsic and caused by exophytic growth into the airways, focal strictures (usually benign), granulation tissue, and airway wall thickening. They can also be extrinsic and caused by compression from structures outside the airways, or they can be both intrinsic and extrinsic (e.g., a combination of exophytic growth and compression). Multiple classification systems for tracheal stenosis based on the degree of obstruction,[18] the location of stenosis,[19] and symptoms, such as dyspnea, change in voice, and dysphagia,[20] or a combination of these features,[21–23] have been developed to facilitate evaluation and treatment of stenosis.

In stenosis, quantifying luminal obstruction is essential for planning interventions, making comparisons over time, and communicating among managing specialists. Numeric visual estimation by bronchoscopy is the most common method for measuring luminal obstruction. CT-based measurements of luminal cross-sectional area reduce interobserver variability and are more reproducible than visual estimates. New machine learning software also improves precision and accuracy of the measurements, but these technologies are not widely available.[11] Because luminal area can vary with the phases of respiration and along the length of the stenosis, it is difficult to measure stenoses reproducibly.

MALACIA

Malacia of the large airways leads to excessive airway collapse, narrowing the airway lumen and reducing airflow. Cartilage weakness causes malacia of the anterolateral cartilaginous walls, whereas laxity of the muscular posterior membrane results in excessive collapse of the posterior wall. Unlike stenosis, malacia of the intrathoracic large airways limits airflow only during expiration. Because standard CT scans are obtained at end-inspiration, and because symptoms of large airway obstruction are nonspecific and can be mistaken for more common obstructive airway diseases such as asthma and COPD, malacia tends to be missed. Suspicion for malacia is often raised by a narrowed tracheal lumen on expiratory CT or by abnormalities in the expiratory flow-volume loop mentioned above (see Figs. 71.1 and 39.3).

Similar to stenosis, the amount of airway collapse due to malacia is measured by CT and visual inspection. Several classification systems have been devised to assist clinicians in diagnosing malacia.[10] However, there may be poor concordance between the degree of collapse, airflow, and symptoms.[24] Thus, malacia can be overlooked in symptomatic patients with airflow limitation and overdiagnosed in patients without these features.

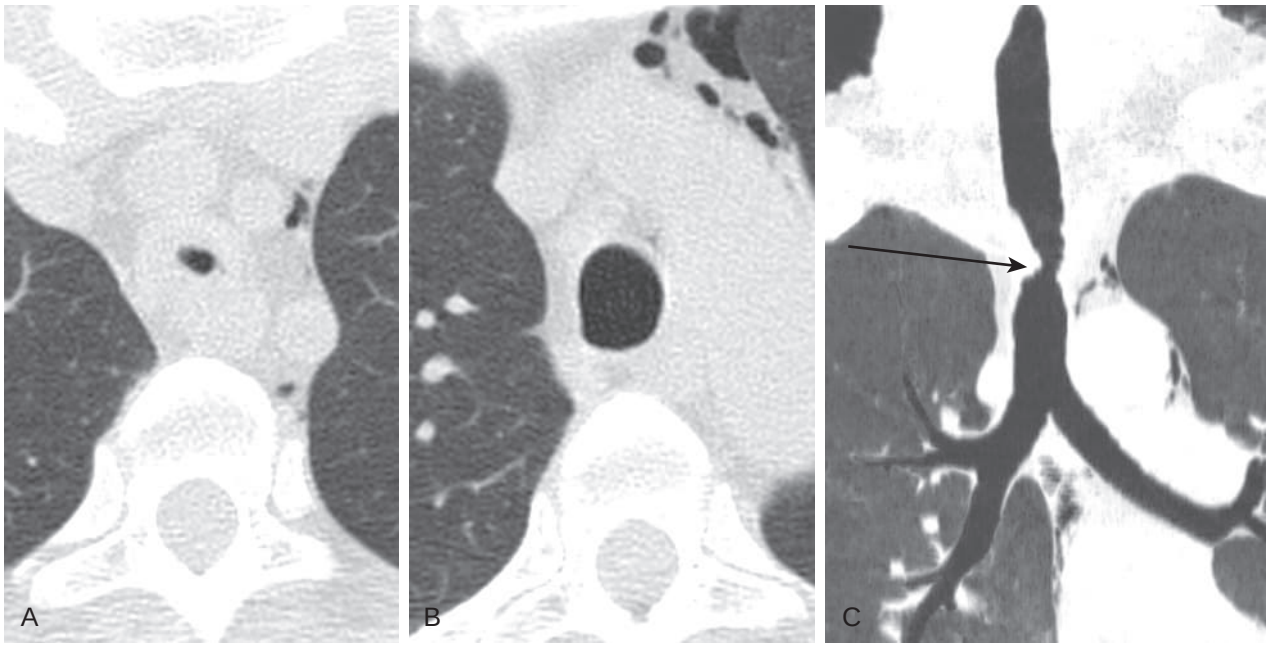

Figure 71.2 Tracheal stenosis. (A) Severe focal narrowing is present in the upper trachea in a patient with postintubation stricture. (B) The tracheal diameter is normal distal to the stricture. (C) Coronal reformatted minimum intensity projection image demonstrates the focal region of narrowing (*arrow*) in the upper trachea. (Courtesy Brett Elicker, MD, Department of Radiology, University of California San Francisco.)

INTRINSIC DISORDERS

For the intrinsic disorders, those primarily causing stenosis or obstruction are discussed before those primarily causing malacia.

BENIGN TRACHEAL STENOSIS

Benign tracheal stenosis is caused by a variety of disorders. Idiopathic laryngotracheal stenosis is characterized by mucosal and submucosal hypertrophy, sparing the cartilage. It is almost exclusively seen in women.[25] Causes of acquired tracheal stenosis include prolonged intubation, tracheostomy, infection, sarcoidosis, and autoimmune disease (e.g., *granulomatosis with polyangiitis* [GPA], ulcerative colitis).

Postintubation tracheal stenosis can result when endotracheal tube cuff pressure exceeds mucosal capillary pressure (≈30 cm H_2O), resulting in mucosal ischemia. If ischemia is prolonged, the mucosa dies via necrosis and becomes fibrotic, causing tracheal stenosis (Fig. 71.2). Risk factors include female sex, obesity, diabetes mellitus, hypertension, and cardiovascular disease.[15]

Posttracheostomy tracheal stenosis results from damage to the tracheal cartilage during tracheostomy placement or from subsequent mucosal injury caused by the tracheostomy tube or cuff. Although the incidence of postintubation tracheal stenosis has decreased with the introduction of low-pressure endotracheal tube cuffs, the incidence of proximal tracheal stenosis has increased as greater numbers of percutaneous tracheostomies are performed.[26] Risk factors include the use of a percutaneous technique, the insertion of a tracheostomy tube size greater than 6, and obesity.[27]

Postinfectious tracheal stenosis is most commonly caused worldwide by tuberculosis. It is estimated that 10–37% of patients with pulmonary tuberculosis develop endobronchial disease at risk of progressing to airway stenosis.[28] Similarly, granulomatous infections with fungus and bacteria such as *Klebsiella rhinoscleromatis*[29] can lead to tracheal stenosis. Infections with human papillomavirus can cause tracheobronchial stenosis as a complication of recurrent respiratory papillomatosis (see later).

Large airway stenosis can be caused by GPA, sarcoidosis, amyloidosis, and inflammatory bowel diseases. The airways are involved in approximately 10–33% of patients with GPA.[30–32] Treatment of stenosis caused by immune or inflammatory disease consists of immune suppression and endobronchial interventions. Surgery can be considered in refractory cases.

When tracheal stenosis is caused by diseases not easily treated medically, the approach depends on several features. First, symptoms such as dyspnea, dysphagia, and dysphonia should be considered as indications for treatment, while asymptomatic patients can often be serially monitored with CT and airway inspection.[19–21] Second, spirometry and flow-volume loops may suggest critical stenosis requiring intervention. Third, CT can define the location and severity of stenosis, which is essential for procedural planning. Finally, flexible bronchoscopy remains the gold standard for characterizing the stenosis and directing therapy.[23]

A decision tool to treat benign tracheal stenosis is shown in Figure 71.3. Simple stenotic lesions (i.e., short-segment concentric stenosis, <1 cm in length, without malacia) can be treated with endobronchial interventions without surgery.[9–12] The optimal treatment for complex stenotic lesions (i.e., many shapes, long segments, >1 cm, with associated malacia) is surgical resection with reconstruction unless the stenosis is located high in the subglottis or is greater than 4 to 6 cm in length.[22] Dilation with or without

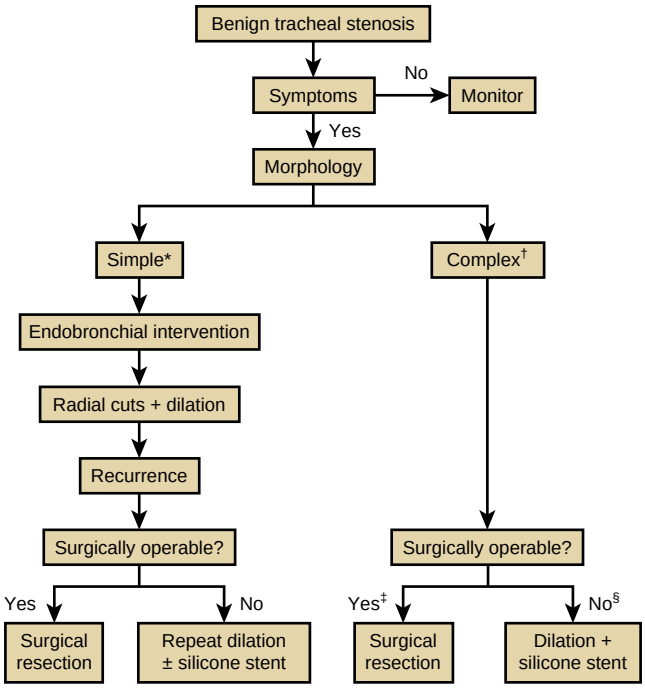

Figure 71.3 Decision tool for benign tracheal stenosis. Management is based on the presence of symptoms, the morphology of the stenosis, and the surgical operability of both the stenotic lesion and the patient. *Simple stenosis: concentric, <1 cm in length, without malacia. †Complex stenosis: many shapes, >1 cm in length, with malacia. ‡1–4 cm in length, not high subglottic, and operable candidate. §>4–6 cm in length, high subglottic, or inoperable candidate.

silicone stent placement may be the only option for patients who are ineligible for or awaiting surgery.

MALIGNANT LARGE AIRWAY DISEASE

Primary tracheal tumors (see Fig. 20.29) are rare, responsible for less than 0.2% of airway neoplasms,[33] and are usually malignant. Squamous cell carcinoma and adenoid cystic carcinoma account for approximately two-thirds of tracheal tumors.[34] Less common primary tracheal tumors include mucoepidermoid carcinoma and pleomorphic adenoma, indolent tumors that can invade locally and metastasize. Pulmonary carcinoid tumors most often arise in major bronchi but can rarely be found in the trachea.[35]

Squamous cell carcinomas generally affect men in their 60s. Adenoid cystic carcinomas show no gender predilection and present in a younger population (≈40s). Of interest, although smoking is associated with the development of squamous cell carcinoma of the trachea, it is not a risk factor for adenoid cystic carcinoma. Patients may be asymptomatic, with the lesion detected incidentally, or have symptoms such as chronic cough unresponsive to standard therapy, sputum production, wheezing, dyspnea, hemoptysis, and obstructive pneumonia. Squamous cell carcinoma of the large airways can invade surrounding structures and cause fistulas.

The approach to large airway tumors has two parts. First, complications such as massive hemoptysis or critical tracheobronchial obstruction should be urgently addressed to stabilize the patient.[36] Second, once the patient is stable, staging with *positron emission tomography* (PET)-CT and invasive lymph node sampling should be expedited to determine optimal treatment. Surgical resection for localized malignant tracheal tumors yields 5- and 10-year survival rates of 39–79% and 18–51%, respectively.[37] For squamous cell carcinoma with nodal involvement, definitive chemotherapy plus radiation is an option. Palliative radiation alone can sometimes relieve symptoms of malignant central airway obstruction. For adenoid cystic carcinoma, the optimal management strategy is not clear, although the cancer is radiosensitive and radiation therapy is used to treat unresectable disease and residual disease after resection. For adenoid cystic carcinoma, complete surgical resection is a more important prognostic factor than nodal staging.[38]

TRACHEOBRONCHOPATHIA OSTEOCHONDROPLASTICA

Tracheobronchopathia osteochondroplastica (TPO) is a benign disorder of the trachea and mainstem bronchi. It is characterized by submucosal cartilaginous or bony nodules that connect to airway cartilage and protrude into the lumen of the large airways, sparing the posterior wall. The exact prevalence is unknown because it rarely causes symptoms and is often detected incidentally on imaging or bronchoscopy performed for other reasons. The etiology remains unknown, although associations with chronic inflammation, atrophic rhinitis, mycobacterial disease, and immunoglobulin A deficiency have been reported.[39–42] When present, symptoms include cough, dyspnea, wheeze, and recurrent airway infections, which may be mistaken for asthma or chronic bronchitis.[43] Large nodules can cause hemoptysis, lobar obstruction, and postobstructive pneumonia.[44] If located in the subglottis, nodules can lead to hoarseness and sore throat.

CT images show calcified nodules arising from cartilage rings in the anterolateral walls of the large airways (Fig. 71.4A). The posterior tracheal wall is spared, a key feature that distinguishes TPO from other causes of tracheal nodules, such as amyloidosis, sarcoidosis, fibromas, and carcinomas. TPO is diagnosed by recognizing submucosal nodules along the cartilaginous tracheal wall during airway inspection (see Fig. 71.4B). Biopsy is not required for diagnosis and is often unsuccessful because the nodules are heavily calcified. If biopsied, nodules reveal cartilaginous and osseous metaplasia.

The goal of treatment is to ameliorate symptoms. In rare cases of severe tracheobronchial obstruction (see Fig. 71.4C), therapeutic options include forceps removal, laser extraction, cryotherapy, external beam radiation, stent placement and, if endobronchial therapies are unsuccessful, surgical resection.[45,46] Tracheostomy has also been performed as a last resort when endobronchial interventions have failed.

TRACHEOBRONCHIAL AMYLOIDOSIS

Amyloidosis is characterized by the extracellular deposition of fibrillar protein in insoluble β-pleated sheets. Causes include chronic inflammation, plasma cell dyscrasias, heritable mutations that promote fibrillogenesis, and senescence

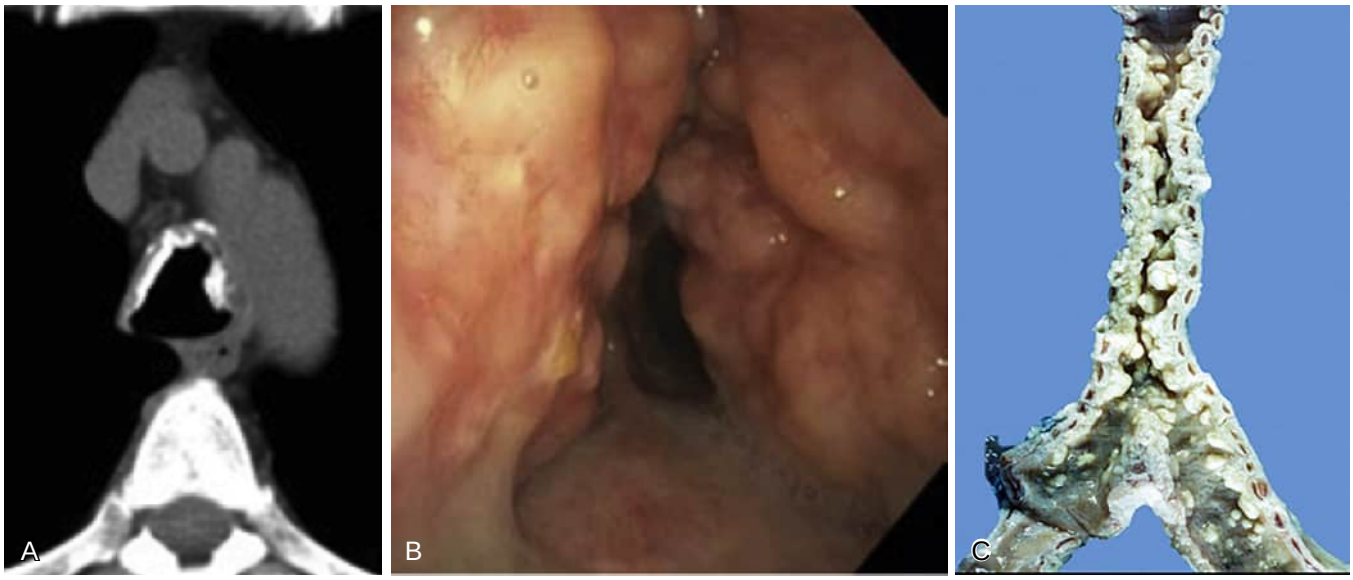

Figure 71.4 Tracheobronchopathia osteochondroplastica. (A) Axial computed tomography displayed in soft tissue windows shows partially calcified nodules involving only the anterior two-thirds of the trachea. (B) Airway inspection in the same patient shows submucosal nodules arising from the anterior tracheal wall and sparing the posterior wall. (C) Gross tracheal specimen from autopsy performed on a different patient shows extensive calcified and ossified nodules throughout the tracheal wall. (in senile systemic amyloidosis). Amyloidosis can be systemic or localized to a particular organ.[47] There are few data in the literature to determine the incidence or prevalence of systemic amyloidosis. A small Mayo Clinic study from Olmsted County, Minnesota, cited a yearly incidence of 5.1 to 12.8 per million person-years,[48,49] whereas a study from the United Kingdom estimated the incidence there at just more than 8.0 per million inhabitants per year.[50] Numbers for localized disease are more difficult to acquire.

Amyloid involvement of the respiratory tract is uncommon. Pulmonary amyloidosis can present as one of five subtypes: tracheobronchial, nodular (solitary or multiple), senile pulmonary, mediastinal-hilar, or diffuse interstitial.[51] *Tracheobronchial amyloidosis* (TBA) is a rare idiopathic disorder not typically associated with systemic or lung parenchymal amyloidosis.[52] As such, there is typically no association with other disease entities, such as plasma cell dyscrasias for primary or immunoglobulin light-chain amyloidosis, or inflammatory conditions, such as rheumatoid arthritis for secondary or serum amyloid protein A amyloidosis. Similarly, it is not known if there are any precipitants of this form of amyloid. TBA is estimated to account for only 1.1% of all amyloidoses.[53] The peak age of onset is 50 to 60 years of age, and it is equally prevalent in men and women.[51,54] Symptoms of TBA often go unnoticed because they are nonspecific and can include cough, dyspnea, hoarseness, or hemoptysis, leading to delays in diagnosis. Patients are often treated for recurrent pneumonia, asthma, or tracheobronchitis before the correct diagnosis is made.[47]

Amyloid is deposited in the submucosal tissue plane of the large airway circumferentially and can be associated with calcifications. CT images show diffuse circumferential wall thickening and nodularity of the trachea and mainstem bronchi (Fig. 71.5A).[55] The differential diagnosis includes infectious laryngotracheitis, radiation injury, submucosal tumor spread, and TPO. Flexible bronchoscopy reveals diffuse mucosal edema and hyperemia, friable mucosa, or small nodules or masses occluding the trachea and mainstem bronchi (see Fig. 71.5B).[54] TBA lesions can be sessile, nodular, or polypoid. Sessile lesions are hard, yellow plaques that can cause airway stenosis if distributed diffusely. Nodular or polypoid lesions are firm and nonmobile with overlying hypervascular mucosa, which is friable and is often mistaken for malignancy. Endobronchial biopsy of amyloid lesions reveals amorphous hyaline material, positive Congo red staining, and yellow-green birefringence under polarized light.[52,56]

The goal of TBA treatment is maintaining a patent airway. Endobronchial interventions, such as *neodymium-doped yttrium aluminum garnet* (Nd:YAG) laser, argon plasma coagulation, stent placement, freezing, and resection, can be used singly or in combination to keep the large airways patent (see Chapter 28). Radiation therapy has been shown to slow the progression of TBA and is now considered a first-line therapy in patients with bulky or distal disease not amenable to endobronchial intervention.[56,57] The efficacy of various systemic therapies (e.g., corticosteroids, colchicine, autologous hematopoietic stem cell transplantation) is unclear.[53] Surgical resection should be considered for localized TBA if endobronchial or radiation therapy interventions have failed.

INFECTIONS

Infections can cause large airway obstruction and stenosis as a sequela of acute inflammation and scarring.[58] During the acute phase of infection, edema and necrosis can lead to airway obstruction with thickening of the airway walls and irregular luminal narrowing. Subsequent healing of these infections can result in fibrosis and stenosis. Although numerous agents cause infections in the respiratory tract, few have been linked to the development of tracheal stenosis.

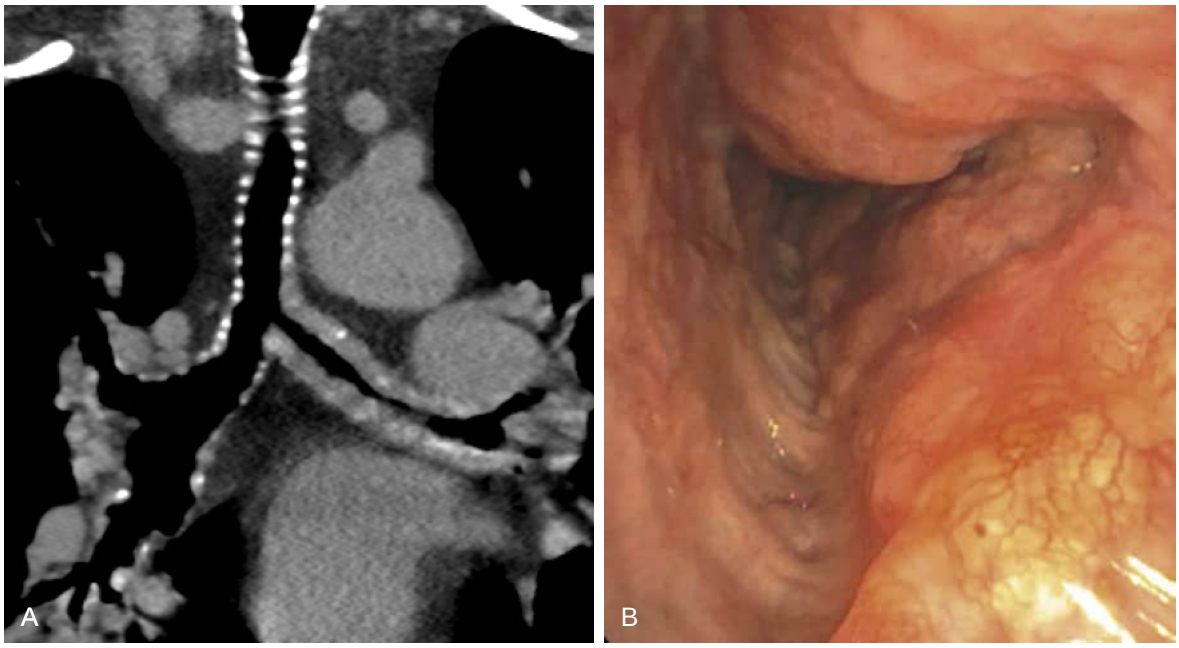

Figure 71.5 Tracheobronchial amyloidosis. (A) Coronal computed tomography displayed in soft-tissue windows shows diffuse circumferential thickening and irregularity of the left mainstem bronchus. (B) Airway inspection in the same patient shows hyperemic and thickened mucosa circumferentially with small nodules and sessile, yellow plaques narrowing the bronchial lumen. (Courtesy Lakshmi Mudambi, MD.)

Tuberculosis

Endobronchial tuberculosis is common,[59] and tracheobronchial stenosis has been reported in up to 90% of patients with endobronchial tuberculosis despite adequate treatment. In rare cases, airway stenosis can be the sole manifestation of infection. The most common symptom of tracheal tuberculosis is intractable cough.[59] CT images show circumferential tracheal thickening, deformation of the tracheal rings, and tracheal stenosis.[60] The presence of mediastinitis suggests active tuberculosis. Airway inspection reveals mucosal ulcers, surrounding erythema and edema, and hyperplastic inflammatory polyps.[61]

Fungal Infections

Fungal infections in immunosuppressed patients also cause large airway stenosis but are difficult to diagnose. *Aspergillus fumigatus* and, to a lesser extent, mucormycosis have been found to cause tracheobronchial infection[58,62] in patients at high risk for fungal infections, such as solid-organ transplant recipients or those with hematologic malignancies or neutropenia, or on immunosuppressive medication.[63] CT images may show parenchymal involvement in addition to irregular tracheal thickening. Flexible bronchoscopy can reveal white plaques, hyperemic mucosa, "sticky" secretions suggestive of fungal disease, and evidence of airway necrosis given the angioinvasive nature of these organisms.[64] White material may represent calcium deposited by the *Aspergillus* (see Fig. 26.3B). Biopsy of the plaques can be diagnostic[65] in the correct clinical setting of a severely immunocompromised patient with respiratory complaints in the absence of other pathogens. If the lesion fails to respond to appropriate antifungals, the resulting stenosis can be treated endobronchially using tracheal balloon dilation,[66] laser therapy, cryotherapy, stent placement, and surgical resection (see Chapter 28).

Bacterial Infections

Bacterial infections localized to the large airways are often overlooked because most instances of tracheitis or tracheobronchitis also involve concomitant infection of the lower respiratory tract. One organism associated with tracheal infections leading to obstruction and stenosis is *Klebsiella rhinoscleromatis*. *K. rhinoscleromatis* primarily infects the nares and paranasal sinuses but can also cause infection in the upper airway and trachea. The diagnosis is made by identifying the pathognomonic Mikulicz cells in the nodules of rhinoscleroma; these cells are round or oval macrophages with small nuclei that contain the causative bacterium, *K. rhinoscleromatis*.[67] This indolent infection is endemic in Africa, South America, and other developing countries and is quite rare in the developed world. Tracheal infection with *K. rhinoscleromatis* can ultimately lead to a chronic granulomatous infection resulting in diffuse tracheal stenosis.[29,68] Treatment may require surgical intervention for obstructing lesions and long-term antimicrobial therapy.

Respiratory Papillomatosis

Recurrent respiratory papillomatosis presents in a juvenile or an adult form (see Chapter 78). The juvenile form is caused by perinatal infection with *human papillomavirus* (HPV) and presents in childhood.[69] It is characterized by multiple benign airway papillomas and recurs frequently. HPV subtypes 6 and 11 cause greater than 90% of cases, whereas infection with subtypes 16 and 18 increases risk of malignant transformation to squamous cell carcinoma (see eFig. 78.25).[70] The adult form is more common in men and in smokers and is caused by HPV transmitted via oral sex.[71] In the adult-onset form, papillomas tend to be solitary or multilobulated and rarely recur after resection (see Fig. 26.3C).

Symptoms are nonspecific and include cough, dyspnea, wheeze and, if the larynx is involved, hoarseness. Rarely,

respiratory papillomatosis can lead to critical tracheal obstruction. Endobronchial resection (see Chapter 28) and adjuvant medical therapy are the mainstays of treatment. Intralesional cidofovir, an antiviral nucleotide analogue, and bevacizumab, a vascular endothelial growth factor inhibitor, have shown promise in the treatment of recurrent, severe, or obstructive tracheobronchial papillomas.[72–74]

INFLAMMATORY

Granulomatous inflammatory diseases, such as sarcoidosis, inflammatory bowel disease, and GPA, and autoimmune conditions, such as relapsing polychondritis, can target the tracheobronchial tree. Scarring often results from the edema and necrosis seen with inflammation, causing stenosis. Chronic airway inflammation can also weaken cartilage, leading to tracheobronchial malacia.

Relapsing Polychondritis

Relapsing polychondritis is a rare autoimmune disorder characterized by inflammation of cartilage in the ears, nose, joints, and large airways. The airways are involved in about 50% of cases and account for about 10% of deaths.[55] The larynx and trachea are the most common sites of airway involvement. Repeated episodes of tracheal chondritis can lead to tracheal obstruction due to tracheomalacia and/or tracheal stenosis. When smaller bronchi are involved, the respiratory phenotype is less severe than with tracheal disease.[75]

Spirometry and flow-volume loops may reveal plateaus of maximal airflow suggestive of tracheal obstruction (see "Diagnostic Approach" earlier), especially when cartilage fibrosis leads to tracheal stenosis. Of note, relapsing polychondritis does not cause a diffusion defect. CT images (see Fig. 20.30) reveal thickened cartilage in the cartilaginous tracheal wall with sparing of the posterior membrane (see Fig. 92.6). The parenchyma is also spared. PET scans may reveal high activity in tracheal cartilage, helping to distinguish between active and fibrotic lesions. Flexible bronchoscopy can delineate the degree of stenosis or malacia.

The mainstay of treatment is immunosuppression with systemic corticosteroids. Biologics have been studied, but the numbers of treated patients are small and the results inconsistent[76] (see Chapter 92). Stepwise treatment with positive pressure ventilation, tracheal stenting, and tracheostomy should be considered if tracheal obstruction due to relapsing polychondritis worsens despite maximal medical treatment.

Sarcoidosis

Sarcoidosis is characterized by the formation of noncaseating granulomas in one or more organs. The lung is involved in greater than 90% of sarcoidosis patients, with endobronchial involvement approaching 70%. In contrast, tracheal involvement is uncommon, seen in only 1–3% of all pulmonary cases.[28,77] In the trachea, sarcoidosis can present as intrinsic granulomatous infiltration or extrinsic compression from enlarged mediastinal lymph nodes. The proximal one-third of the trachea is more commonly affected than the distal trachea or lower airways.[28] Symptoms are nonspecific and include cough, dyspnea, and wheeze. Bronchoscopic findings include cobblestone mucosa and whitish granulomatous material in areas of stenosis (see Fig. 26.2C). Like other forms of sarcoid, tracheal sarcoid is treated with systemic steroids. If there is evidence of reversible airway obstruction on spirometry, inhaled corticosteroids or bronchodilators may be considered[78] (see Chapter 93).

Granulomatosis with Polyangiitis

GPA is a necrotizing granulomatous vasculitis affecting small blood vessels in the upper and lower airways and kidneys (see Chapter 87). GPA has been reported to involve the tracheobronchial tree in 12–23% of patients.[30,31] Of interest, although GPA affects women and men equally, greater than 90% of patients with GPA-related tracheal stenosis are women.[79] The reason for this female predominance is unknown. GPA should also be considered in patients with unexplained hemoptysis (see Chapter 40).

CT images in patients with tracheal GPA show circumferential, smooth, or nodular mucosal thickening (see eFig. 70.2), irregular borders, and ulceration.[80] Although not commonly involved, the cartilage rings can be narrowed and deformed. Flexible bronchoscopy may reveal subglottic stenosis, tracheal stenosis, tracheal ulcers, and inflammatory pseudopolyps. Transbronchial biopsy is insensitive, revealing histopathologic features diagnostic of GPA in less than 20% of specimens.[30,81] In some patients, a presumptive diagnosis of an *antineutrophil cytoplasmic autoantibody*–associated vasculitis, such as GPA, can be made if the clinical picture and positive antineutrophil cytoplasmic antibody argue against an alternative etiology. Treatment depends on the seriousness of the disease. Severe tracheobronchial disease often responds to systemic treatment with the combination of corticosteroids together with either cyclophosphamide or rituximab. If tracheobronchial stenosis persists or recurs despite prolonged immunosuppressive therapy, endobronchial therapies, including tracheal dilation, conservative laser surgery, and stenting, should be considered.[82]

Inflammatory Bowel Disease

Pulmonary manifestations of inflammatory bowel disease are uncommon, and tracheal involvement is even rarer, reportedly as low as 0.2% for ulcerative colitis and 0.4% for Crohn disease.[83] Ulcerative colitis can manifest as a tracheobronchitis, producing dyspnea and hoarseness. CT scanning shows tracheobronchial wall thickening, and flexible bronchoscopy reveals tracheobronchial ulcers in the mucosa, severe luminal narrowing, and cobblestoning. If biopsied, the ulcers show necrosis with submucosal inflammation characterized by lymphoplasmacytic infiltration within the epithelium and lamina propria without granuloma formation.[84] Infection must be excluded. Exacerbations of the gastrointestinal and pulmonary systems often happen simultaneously, quite possibly due to their common embryologic tissue origin.[84] Crohn disease results in extraintestinal manifestations more often than ulcerative colitis but, similarly, pulmonary involvement is rare and can present as tracheitis, tracheobronchitis, or tracheal stenosis.[85] Treatment with high-dose corticosteroids is often successful.

BRONCHOLITHIASIS

Broncholithiasis is characterized by calcified material eroding into the tracheobronchial lumen, leading to inflammation and obstruction of the airway.[86] Most often, the calcified material is a calcified lymph node, often the result of earlier granulomatous infection, endemic fungal diseases such as *Histoplasma capsulatum*, or the result of silicosis.[87,88] Alternatively, broncholiths can originate from aspirated foreign material that has calcified within the tracheobronchial lumen, calcified endobronchial hamartomas, carcinoid tumors, or calcified tracheal cartilage rings that protrude into the lumen.[89] Clinically, broncholithiasis can range from being asymptomatic to causing cough, lithoptysis (expectoration of calcified material), postobstructive pneumonia, and hemoptysis. In severe cases, erosion of the broncholith into the tracheobronchial lumen can lead to a bronchoesophageal fistula.[90] Although chest radiographs may show calcifications within clusters of lymph nodes, diagnosis is most often made by CT scan (see eFig. 56.4). Bronchoscopy can sometimes miss the lesion if the broncholith only partially erodes into the airway.

Treatment is conservative if the patient is asymptomatic or has minimal symptoms, such as an infrequent cough. This involves cough suppression and treatment of any pneumonias. If the symptoms escalate, more definitive therapy is warranted, which can include bronchoscopy to evaluate the broncholith and facilitate its removal. If removal by forceps is not possible, bronchoscopy with Nd:YAG lasers (bronchoscopic lithotripsy) may be effective. If these methods are unsuccessful, surgery can be considered but should be reserved for those who are symptomatic and have not responded to endobronchial therapy.[87,91]

VASCULAR MALFORMATIONS

Tracheal varices are rare but are important to recognize because they are potential sources of massive hemoptysis if biopsied. They can be caused by obstruction of the pulmonary veins or of the superior vena cava due to pulmonary venous hypertension, portal hypertension, congenital cardiac diseases, or mediastinal masses.[92,93] In addition to hemoptysis, patients may present with symptoms of the underlying cause of the varices (e.g., superior vena cava syndrome). Diagnosis is made by bronchoscopy in the setting of hemoptysis or incidentally during bronchoscopy performed for another reason. Airway inspection reveals tracheal varices that appear as polypoid tracheal nodules along with dilated mucosal vessels. Tracheal varices should be suspected in patients with hemoptysis, tracheal nodules, and mediastinal collateral vessels on CT, a feature that distinguishes tracheal varices from other causes of tracheal nodules, such as amyloidosis and sarcoidosis. As mentioned, magnetic resonance imaging may be useful for identifying and mapping vascular abnormalities.

TRACHEOBRONCHOMALACIA AND EXCESSIVE DYNAMIC AIRWAY COLLAPSE

Tracheobronchomalacia (TBM) refers to weakness of the cartilaginous anterolateral walls of the trachea and mainstem bronchi. It is caused by cartilage breakdown that results in loss of structural rigidity and excessive collapse of the trachea and large bronchi during exhalation. In contrast, *excessive dynamic airway collapse* (EDAC) refers to exaggerated bulging of the posterior tracheal membrane into the airway lumen during exhalation. Both TBM and EDAC can cause severe, symptomatic upper airway obstruction and may present individually or together in the same patient.

In adults, TBM is most often acquired. Causes include chronic airway inflammation due to chronic bronchitis,[94] cystic fibrosis,[95] and gastroesophageal reflux[96]; cartilage inflammation due to relapsing polychondritis[97]; chronic extrinsic compression by adjacent structures, such as thyroid goiters[98] or tumors; cartilage necrosis induced by endotracheal and tracheostomy tubes[99]; and radiation. Tracheobronchomegaly (Mounier-Kuhn syndrome) can also cause TBM. In contrast, EDAC, which is mainly found in patients with chronic obstructive airway diseases, is thought to be caused by an increased transmural pressure gradient during exhalation[10] and by weakening of the muscular posterior membrane.[100]

Because symptoms due to TBM and EDAC are nonspecific (e.g., cough, dyspnea, recurrent airway infections), diagnosis requires a high index of suspicion and focused testing. As mentioned, flow-volume loops may show a rapid decline of expiratory flow after a sharp peak suggestive of large airway collapse (see Fig. 71.1) or signs of notching or oscillations of the expiratory flow (Fig. 39.3) to suggest the diagnosis; however, they are not by themselves diagnostic.[101,102] Traditionally, TBM and EDAC have been diagnosed when the cross-sectional tracheal area measured by bronchoscopy or dynamic CT (Figs. 71.6A–B) decreases by greater than 50% during forced exhalation as a result of exaggerated cartilaginous collapse (TBM; see Fig. 71.6C), posterior bulging into the lumen (EDAC; see Fig. 71.6D), or an overlap of both TBM and EDAC.[103–105] However, in many healthy control subjects without these conditions, their trachea collapses posteriorly by 50% or more on forced exhalation,[24] indicating that this threshold is inadequate to define abnormal collapse. Instead, tracheal collapse requiring treatment usually approaches 95–100% during forced exhalation[10,106,107] (see Fig. 39.3). Thus, reduced maximal expiratory flow rates and the appearance of the flow-volume curve, although not diagnostic, may be better indicators of clinically significant collapse than visual assessment.

The decision to treat TBM or EDAC should be based on the presence of symptoms due to excessive tracheal collapse. In an asymptomatic patient, treatment is generally not indicated. In a symptomatic patient, treatment of the underlying cause (e.g., bronchodilators and airway hygiene for COPD, steroids for relapsing polychondritis) may ameliorate symptoms. If medical management is ineffective, continuous positive airway pressure can pneumatically stent the airway open, reducing dynamic airway collapse and facilitating mucus clearance.[108,109] Airway stents[110,111] and surgery,[107] including tracheobronchoplasty (splinting of the posterior membrane with a polypropylene mesh or acellular dermis[113]) or tracheobronchial resection and reconstruction, can be considered in very symptomatic patients who do not respond to noninvasive treatment and have focal tracheobronchial disease. A successful stent trial helps identify patients who will benefit from surgical airway stabilization via tracheoplasty.[107] Successful endoscopic therapy

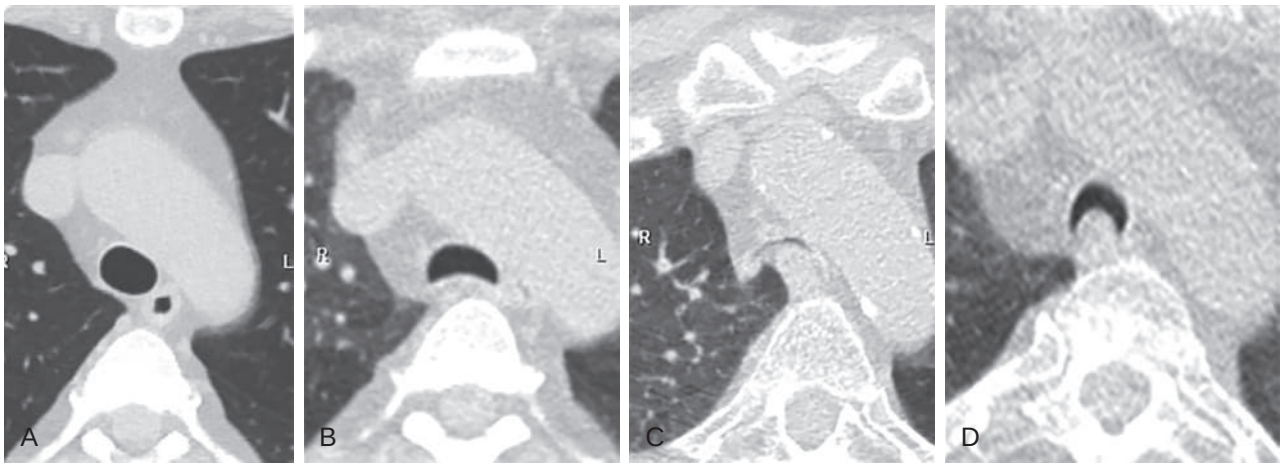

Figure 71.6 Tracheomalacia and *excessive dynamic airway collapse* (EDAC). (A–B) Normal, paired *computed tomography* (CT) images through the midtrachea at the level of the aortic arch show a normal trachea at full inspiration (A) and end-exhalation (B). The posterior tracheal membrane normally bows inward slightly at end-exhalation. (C) Tracheomalacia. The CT image shows excessive flattening of the anterolateral cartilaginous walls at end-exhalation. (D) EDAC. The CT image shows excessive bulging of the posterior membrane into the lumen at end-exhalation. (Courtesy Michael B. Gotway, MD.)

to tighten the posterior membrane with laser has also been reported but requires further study.[114]

EXTRINSIC DISORDERS

FIBROSING MEDIASTINITIS

Fibrosing mediastinitis, also termed sclerosing mediastinitis or mediastinal fibrosis, is a rare disease causing external tracheal compression. It is the result of an exaggerated granulomatous response in mediastinal lymph nodes to a variety of pathogens leading to fibrosis, compression, and invasion of adjacent structures, including the trachea, esophagus, and blood vessels (see Chapter 116). Common triggers include *Histoplasma capsulatum* and, to a lesser extent, *Mycobacterium tuberculosis*.[115] *Aspergillus flavus*, sarcoidosis, and immunoglobulin G4-related disease have also been reported to cause fibrosing mediastinitis.[116,117]

In addition to tracheal compression, the most serious complication of fibrosing mediastinitis is pulmonary arterial and venous obstruction (see Fig. 116.5). Most patients with fibrosing mediastinitis have unilateral disease and can remain undiagnosed for years because symptoms are nonspecific. Chest radiographs can reveal a widened mediastinum due to mediastinal adenopathy and fibrosis, but CT with contrast is indicated to assess the degree of mediastinal involvement along with the extent of airway narrowing and vascular compromise. Bronchoscopy can reveal narrowing of the tracheal lumen and massive tracheal variceal formation along the posterior tracheal wall if superior vena cava syndrome is present. There are no standard treatment options, but therapy focuses predominantly on symptomatic management, including stenting of arteries and veins.

FISTULAS

Tracheoesophageal fistulas (TEFs) are abnormal congenital or acquired connections between the trachea and esophagus. This section focuses on the acquired form, which is most often caused by esophageal or lung cancer. From 5–15% of patients with esophageal cancer and 1% of patients with lung cancer develop TEFs.[118–120] Less common, TEFs are caused by benign conditions, such as prolonged intubation, tracheostomy, surgery, and radiation. Symptoms include cough with eating or drinking, recurrent pneumonia, recurrent aspiration, dysphagia, and malnutrition. In TEF due to cancer, survival has been reported to be a few weeks to months.[121–123]

Airway inspection is indicated in patients when symptoms, barium esophagram, or CT imaging suggest TEF. The fistula may be visible with heaped, irregular margins and secretions from the esophagus escaping into the trachea (Fig. 71.7A) and can be associated with significant tracheal stenosis. Small fistulas may be difficult to identify due to local erythema and edema. In such cases, orally administered methylene blue before bronchoscopy can help identify them.[124]

The goal of treatment is blocking the seepage of esophageal and stomach contents into the airways to prevent aspiration-related airway injury and pneumonia and to improve nutrition. This can be attempted by stenting or surgery. In benign TEF, surgical repair with curative intent is the preferred approach because it can produce good long-term results and because stents, while occasionally placed as a bridge to surgery, cannot be placed indefinitely.[125–127] In malignant TEF or in inoperable benign TEF, stenting of the trachea and/or esophagus can ameliorate symptoms and prolong survival.[7,118,121,122] Surgical repair is normally not attempted in malignant TEF because the underlying condition is incurable and because resection does not yield satisfactory results.[120]

To treat TEF, stents can be placed in the trachea, esophagus, or both. An esophageal stent is indicated in patients with esophageal stenosis and no tracheal obstruction. Side effects of esophageal stent placement include gastroesophageal reflux disease and dietary changes needed to maintain stent patency. On occasion, airway obstruction develops after placement of an esophageal stent, requiring removal or revision with or without placement of a tracheal stent.

Tracheal stenting is performed first if the patient has tracheal obstruction, if there is clinical concern for the development of tracheal obstruction after placement of an esophageal stent, or if the esophageal tumor is not causing stenosis (see Fig. 71.7B–E). Tracheal stents are usually well tolerated but may

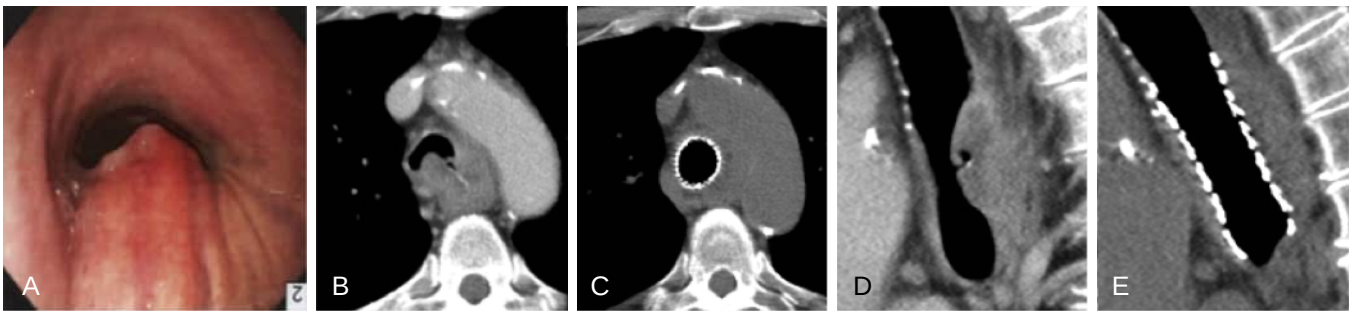

Figure 71.7 Tracheoesophageal fistula. (A) Airway inspection shows a mixed obstruction of the mid-trachea with necrosis and secretions, suggesting a fistula. (B–C) Paired axial computed tomography images show an esophageal mass invading the posterior trachea before (B) and after (C) placement of a covered self-expanding metal stent. (D–E) Paired sagittal computed tomography images clearly show a fistula (D) before stent placement (E). (Courtesy Lakshmi Mudambi, MD.)

produce an intractable cough. Patency is maintained with daily nebulization of bronchodilators and saline solutions.

Double stenting (i.e., placement of a tracheal and esophageal stent) can be considered if the patient has tracheal obstruction and a stenotic esophageal tumor causing dysphagia, a very large fistula not completely occluded by either a tracheal or esophageal stent, or tracheal obstruction that develops after placement of an esophageal stent.[7,128,129] Double stenting can increase the size of the fistula and prevent healing. It should be avoided in patients with potential for cure, surgical correction, or long-term survival.

EMERGING THERAPIES

THREE-DIMENSIONAL PRINTED AIRWAY STENTS

Airway stents are used to maintain tracheal patency and to block fistulous tracts in the trachea (see Chapter 28). In some patients, a deformed trachea can result in poor fit of commercially available stents, leading to complications such as migration, impaired mucus clearance, granulation tissue, and perforation. Three-dimensional printed airway stents address this issue by precisely fitting the patient's trachea. They have recently been approved by the U.S. Food and Drug Administration. The stents are made by injecting medical-grade silicone into a three-dimensional printed mold engineered from three-dimensional CT reconstructions of the patient's trachea.[130] The literature on three-dimensional printed stents is currently limited to case reports, but early results are promising.[131,132]

TRACHEAL REPLACEMENT

Primary tracheal resection with direct end-to-end anastomosis is the definitive treatment for various focal tracheal disorders. The principal limitation is involvement of more than 4 cm of trachea, which significantly increases the risk of anastomotic failure likely due to increased tension on the anastomosis.[16] In patients requiring long tracheal resections, several methods of tracheal replacement (e.g., synthetic prosthetics, allografts, autologous tissue, and tracheal transplantation) have been used to restore function. Currently, none of these methods meets the criteria of an ideal tracheal replacement. Such criteria would include lateral rigidity and stiffness, longitudinal flexibility, air-tightness, support of a functional ciliated respiratory epithelium, biocompatibility, and absence of need for immunosuppression.

Tracheal replacement with synthetic stents,[133,134] aortic allografts reinforced with tracheal stents,[135,136] and cadaveric tracheal allografts[137] has been associated with significant morbidity and mortality. Tracheal allotransplants have been used to reconstruct tracheas in benign tracheal disease.[138,139] This approach is limited by the need for immunosuppression (making it unsuitable for malignant disease), a compromised blood supply (risking necrosis of the transplanted trachea), and the lack of published data on long-term outcomes.[140] In malignant tracheal disease, autologous transplants constructed from fasciocutaneous, omental, or muscle flaps reinforced with strips of cartilage or mesh to simulate cartilage rings have been used in tracheal reconstruction.[141] Artificial tracheas made from biocompatible three-dimensional printed tubular scaffolds and the subject's own pluripotent stem cells have shown promise as tracheal substitutes and are an area of active research.[142]

Key Points

- Because symptoms due to large airway disorders are nonspecific and often mimic those of more common conditions, such as asthma or COPD, the diagnosis of large airway disorders requires a high index of suspicion.
- Spirometry with flow-volume loops, computed tomographic imaging, and flexible bronchoscopy provide complementary information required to evaluate large airway disorders.
- Of the diagnostic tests, flexible bronchoscopy is the gold standard test for the assessment of large airway disorders.
- Surgical resection is the definitive treatment of focal tracheal disease and should be considered in symptomatic patients.
- Endobronchial interventions are first-line therapies for several large airway disorders and can palliate symptoms in nonsurgical disease.
- Intervention for symptomatic tracheal collapse is usually not indicated until collapse approaches 95–100% of cross-sectional area of the trachea during forced exhalation and is supported by finding abnormal expiratory flows on spirometry or flow-volume loop.
- Novel therapeutic approaches, such as three-dimensional printing of tracheal stents and tissue-engineered tracheal replacements, show promise.

INTRODUCTION

Although other chapters focus on the major diseases primarily affecting the large intrathoracic airways, including asthma, bronchitis, cystic fibrosis, and bronchiectasis, a constellation of entities primarily affect *peripheral* airways. Early diagnosis of these small airway diseases remains difficult, however. Early in the disease course, the large cross-sectional area and reduced airflow of peripheral airways protect patients from symptoms of dyspnea and limit detection of flow abnormalities on functional testing. Diseases affecting the peripheral airways may nonetheless have profound effects on lung function. Because pathologic narrowing of peripheral airways is difficult to detect, these airways may be considered a silent zone of the lung. Although tests to identify peripheral airway obstruction have suffered from a lack of sensitivity, heightened recognition of the entities affecting peripheral airways and diagnostic advances have increased the frequency of diagnosis. Nevertheless, the epidemiology of disorders of the peripheral airways remains largely unknown.[1] This chapter takes into account the heightened clinical recognition and evolving efforts at classification as our understanding of these entities advances. The chapter first reviews the anatomy of the peripheral airways. The predominantly inflammatory and fibrotic bronchiolitis entities are then addressed, with the recognition that there may be substantial overlap in clinical and histologic features.

ANATOMIC AND PHYSIOLOGIC FEATURES

Among other roles, the intrathoracic airways serve as a conduit between the outside environment and alveolar units. Moving distally from the trachea, the bronchi transition to bronchioles and ultimately to the terminal respiratory units. These transitions are defined by changes in the constellation of cell types and by architectural features. Bronchi range in size from 10 down to 1 mm in diameter and are characterized by incomplete cartilaginous rings, ciliated epithelium, goblet cells, submucosal glands, and smooth muscle innervated by muscarinic output via the vagus nerve. Bronchioles are defined by their lack of cartilage; their sparse population of ciliated, simple, columnar epithelium and secretory club cells; and their lack of goblet cells and glands. Bronchiolar smooth muscle is not innervated by the vagus nerve, and the diameter of bronchioles typically ranges from 2 down to 0.5 mm. As bronchioles branch, they go from lobular to terminal and then respiratory segments. Terminal bronchioles are the last divisions of conducting airways, whereas alveoli bud from respiratory bronchioles (Table 1.2; see also Chapter 1).

Because of their relatively small total cross-sectional area, bronchi are responsible for most airflow resistance in the lung. In contrast, bronchioles contribute little to total airflow resistance at high and normal lung volumes. This limited contribution is attributable to dichotomous branching that arranges vast numbers of bronchioles in parallel. Within the conducting region of the lung, bronchioles branch into terminal bronchioles, whereas in the respiratory zone, where gas exchange takes place, respiratory bronchioles branch into alveoli. This branching translates into a much larger total cross-sectional area for bronchioles relative to bronchi. At low lung volumes, the relative contribution of bronchioles to total airflow resistance increases because, as residual volume is approached, the flexible, thin-walled bronchioles, supported only by connective tissue, may collapse. Despite significant disease of the bronchioles, however, *pulmonary function test* (PFT) results may be normal. In advanced disease, PFTs may demonstrate upward concavity (curvilinearity) of the flow-volume curve, especially at low lung volumes, an increased slope of phase III (the alveolar plateau) of the single-breath nitrogen washout test, and air trapping. Although mid–*forced expiratory lung flow* ($FEF_{25\%–75\%}$) had been proposed as an early criterion for post–lung transplantation bronchiolitis, subsequent studies have challenged its predictive utility.[2]

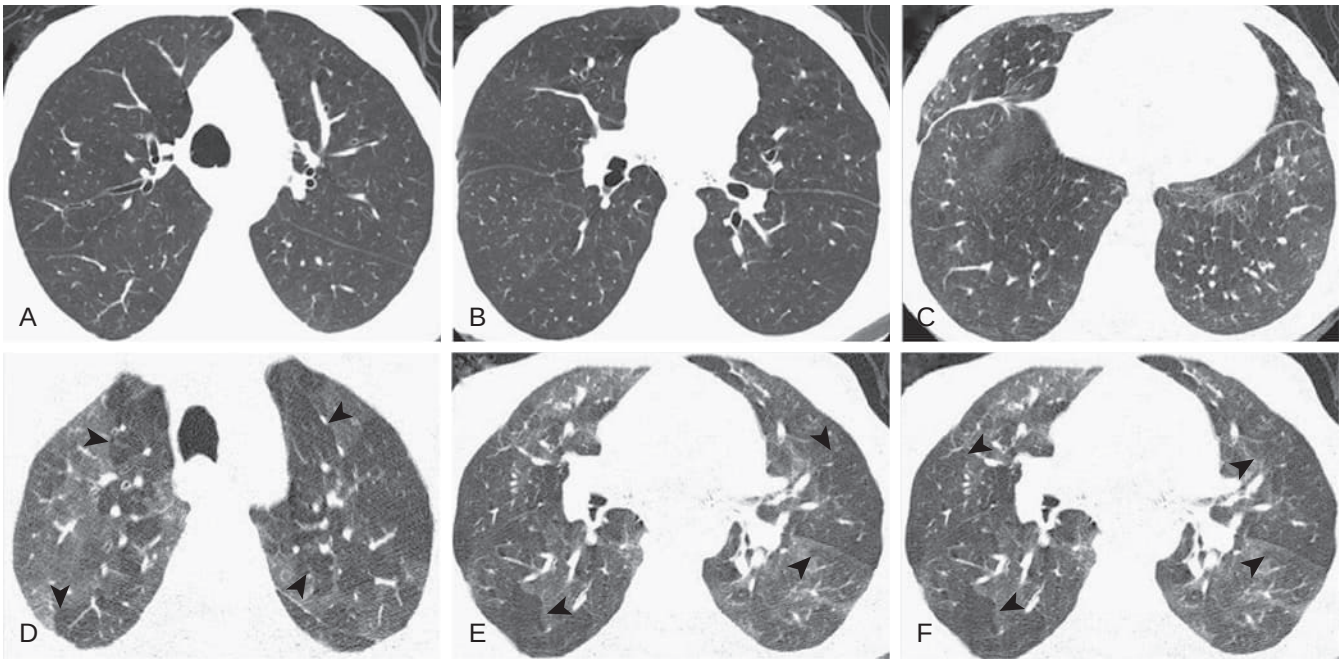

Figure 72.1 High-resolution *computed tomography* (CT) scan demonstrating air trapping during expiration. (A–C) Axial chest CT images performed through the upper (A), mid (B), and lower (C) lungs obtained during inspiration (see Video 140.2) in a bilateral lung transplant recipient show only minimal inhomogeneous lung opacity. Expiratory chest CT images performed through the upper (D), middle (E), and lower (F) lungs show extensive accentuation of the bilateral inhomogeneous opacity (see Video 140.3). The areas of increased attenuation represent normal collapsing lung during exhalation. The areas of relatively decreased attenuation (*arrowheads*) represent air trapping due to constrictive bronchiolitis as a result of chronic rejection.

Computed tomography (CT) scans or magnetic resonance imaging with hyperpolarized gases, similarly, may demonstrate inhomogeneity of ventilation and air trapping (Fig. 72.1, see Video 140.3); see also Chapter 10).

DEFINING BRONCHIOLITIS

Bronchiolitis refers to a nonspecific cellular and mesenchymal reaction of the bronchioles. Developing a straightforward classification, however, is difficult. Perhaps most important, bronchiolitis is a catchall term subsuming several unique clinical syndromes and a histopathologically diverse set of lesions identifiable in many diseases. Next, there are many diseases that, in addition to causing bronchiolitis, also cause disease proximal (e.g., bronchiectasis) or distal (e.g., organizing pneumonia) to the bronchioles. As a result, some avoid defining the precise site of involvement, instead referring to peripheral airways (<2 mm diameter) as small airways. Lastly, clinical bronchiolitis syndromes may demonstrate more than one histologic pattern temporally and spatially. These factors complicate defining a mutually exclusive classification system. Therefore, definitive diagnosis of a specific bronchiolitis entity requires clinical, diagnostic (imaging, PFTs), and frequently histopathologic evaluation. Definitive diagnosis depends on excluding bronchial and alveolar involvement seen in alternative diagnoses. A hybrid classification schema based on both histopathologic findings and clinical syndromes is presented in Fig. 72.2. The early branch points in this schema are driven by histopathologic findings, whereas later branch points are driven by clinical syndromes and exposures.

INFLAMMATORY AND INFECTIOUS BRONCHIOLITIS

This group of bronchiolitis syndromes involve inflammation or infection and are characterized by a predominantly cellular infiltration of the bronchioles. Cellular infiltration can be localized to the wall (mural) or lie within or around the bronchiole (Fig. 72.2).

INFLAMMATORY BRONCHIOLITIS

Infectious Bronchiolitis

Although relatively rare in adults, acute *infectious bronchiolitis* is common in infants and young children. Indeed, within the pediatric population, this entity is referred to simply as bronchiolitis. *Respiratory syncytial virus* infection is the cause of 70% of infectious bronchiolitis, although rhinovirus, metapneumovirus, influenza virus, and other viral and bacterial infections can also cause this syndrome.[3] Infection damages bronchiolar epithelial cells. Edema, epithelial sloughing, ciliary dysfunction, and mucus secretion result in small airway obstruction and atelectasis. In severe cases, there may be peribronchiolar lymphocytic infiltration and even mural necrosis (Fig. 72.3A, see Fig. 72.2 [classified under the category inflammatory bronchiolitis]). Bronchiolitis within the first few years of life can result in protracted wheezing and asthma development, particularly through the first decade and possibly into adulthood. Long-term sequelae appear to be modified by genetic and environmental factors, including environmental tobacco smoke exposure.[4]

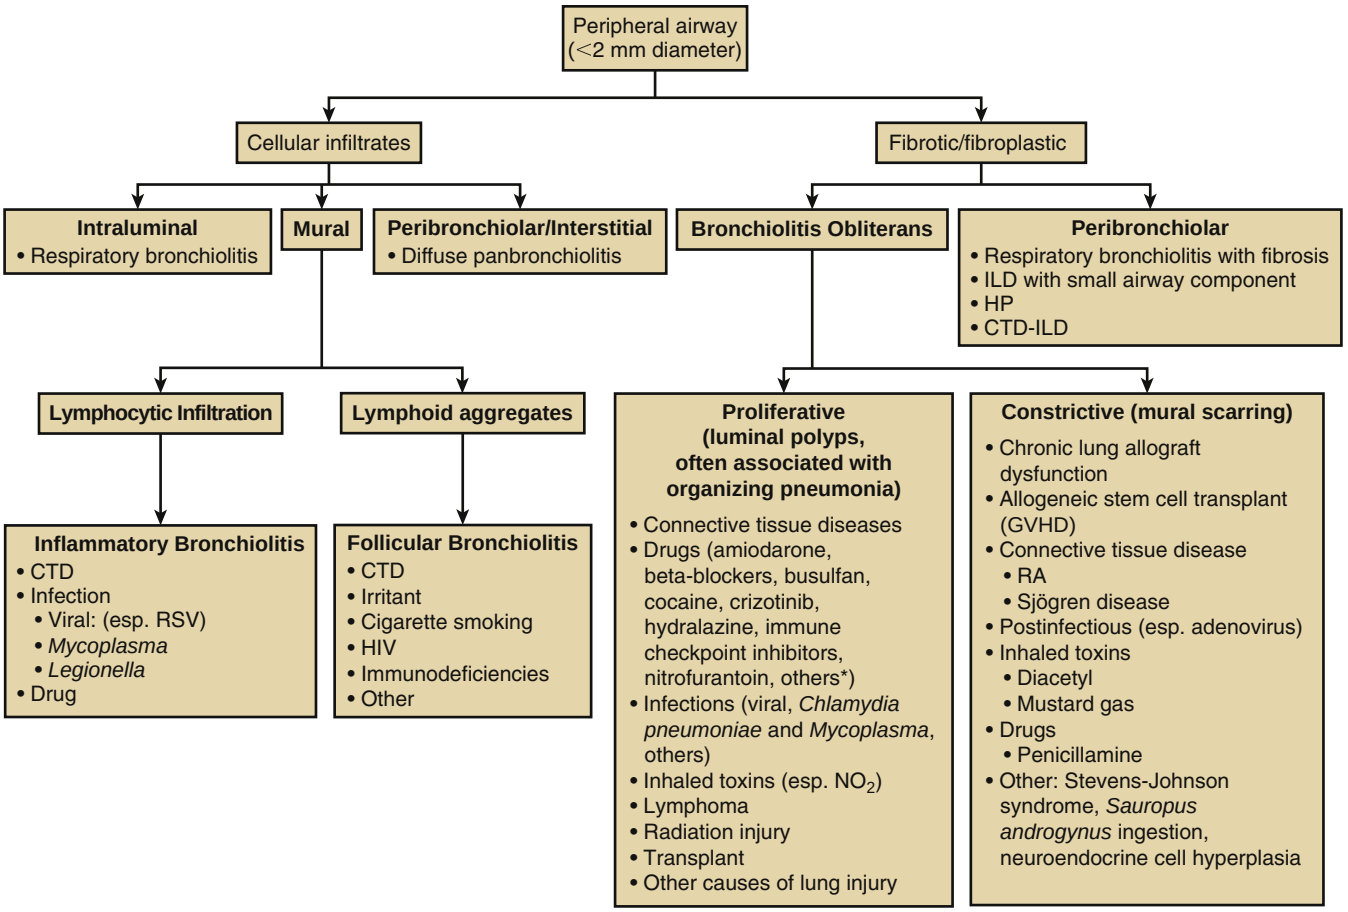

Figure 72.2 Classification schema for bronchiolitis. Traditionally, bronchiolitis has been defined by clinical syndromes and histopathologic lesions, making classification difficult. In this schema, early classification branch points are defined by histopathologic findings (e.g., cellular infiltrates in the small airways vs. fibrosis). Later branch points are defined by specific clinical entities. *See http://pneumotox.com/ for a complete list. CTD, connective tissue disease; esp., especially; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HP, hypersensitivity pneumonitis; ILD, interstitial lung disease; NO_2, nitrogen dioxide; RA, rheumatoid arthritis; RSV, respiratory syncytial virus.

Typically affecting children younger than 2 years, bronchiolitis begins as an acute upper respiratory tract infection with rhinorrhea, nasal congestion, and/or cough. Within days the cough worsens, and dyspnea and fever develop. Although wheezing, chest wall retractions, and cyanosis may be seen, respiratory failure is uncommon. Examination typically demonstrates mildly depressed oxygen saturation, tachypnea, mild chest wall retractions, expiratory wheezing, and crackles. In more severe cases, nasal flaring, grunting, pronounced chest wall retractions, prolonged expiratory phase, and cyanosis may be seen. Epithelial sloughing with bronchiolar obstruction may cause hyperinflation and gas exchange abnormalities.[5] In general, infectious bronchiolitis is diagnosed based on clinical signs and symptoms. When obtained, radiographs may be normal or have evidence of pneumonia or bronchitis, whereas focal consolidation may be indicative of bacterial coinfection.[6,7] Outpatient supportive therapy with nasal bulb suctioning and hydration is usually sufficient, but some patients require hospitalization for fluid administration and/or respiratory support. This self-limiting infection typically resolves within weeks. A number of studies have investigated additional therapies and shown no clear evidence of benefit for bronchodilators, corticosteroids, antibiotics, chest physiotherapy, or leukotriene inhibitors.[8,9] Of note, respiratory syncytial virus–specific monoclonal antibody therapies have not proven efficacious for acute management but are recommended as prophylaxis for selected high-risk infants.[8,10]

RESPIRATORY BRONCHIOLITIS

Respiratory bronchiolitis (RB) is a pathologic entity characterized by pigmented alveolar macrophage accumulation in respiratory bronchioles and adjacent alveoli. Peribronchiolar inflammation or fibrosis and epithelial metaplasia extending into adjacent alveoli (i.e., lambertosis) may be present (see Fig. 72.3B). Although nearly universally seen in cigarette smokers, it may also be seen after particulate exposures.[11–13] RB rarely causes symptoms or physiologic abnormalities per se. It is most commonly diagnosed incidentally by imaging (see Fig. 72.2 [classified under the intraluminal category]). In some cases, more extensive fibrosis extends into the alveolar septa and is associated with clinical and radiographic evidence of interstitial pneumonia. In these cases, the term *RB-associated interstitial lung disease* (RB-ILD) is applied (see Chapter 90).[11,12] In

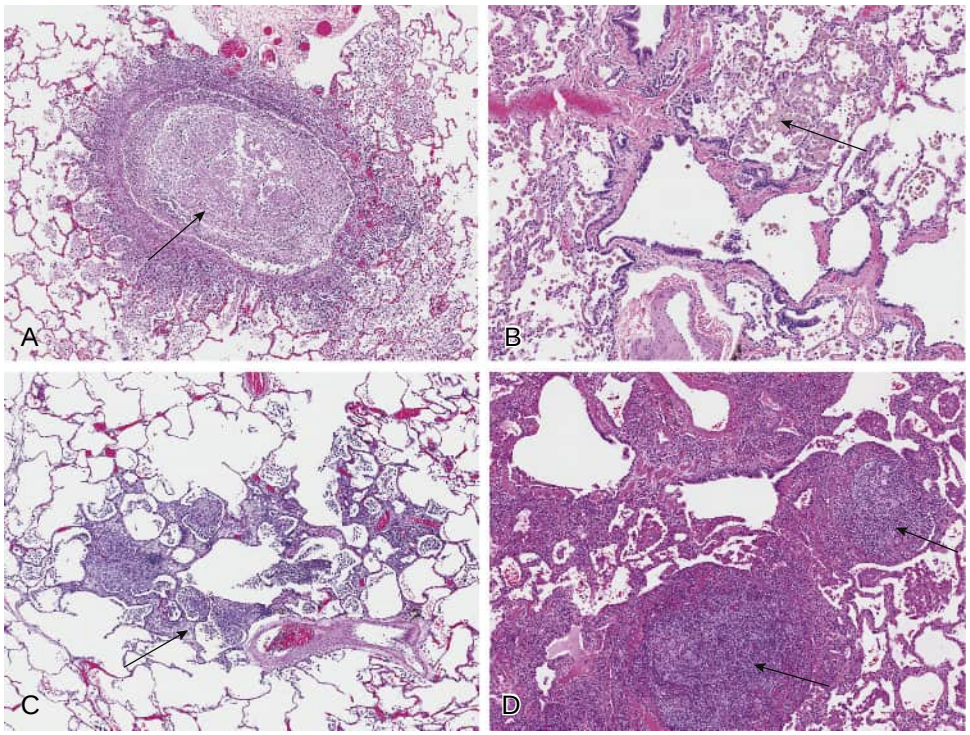

Figure 72.3 Pathologic patterns of bronchiolitis. (A) Infectious bronchiolitis. The bronchiolar wall shows marked acute inflammation with neutrophils and apoptotic debris (*arrow*) extending from the sloughed epithelial surface transmurally to the adjacent alveolar spaces. (B) Respiratory bronchiolitis. The terminal bronchiole and peribronchiolar alveolar spaces show consolidation by lightly pigmented "smoker's" alveolar macrophages (*arrow*). Mild peribronchiolar fibrosis is present. (C) Diffuse panbronchiolitis. The terminal bronchiole shows mural lymphoid inflammation, luminal inflammation and organization, and peribronchiolar interstitial expansion by foamy macrophages (*arrow*). (D) Follicular bronchiolitis. Prominent lymphoid aggregates with well-formed germinal centers (*arrow*) are noted adjacent to bronchioles.

RB-ILD, patients present with subacute cough, dyspnea, and crackles, as well as restriction and reduced diffusing capacity on PFTs.[14] *High-resolution computed tomography* (HRCT) imaging shows a distinctive pattern of bronchial wall thickening, centrilobular nodules, reticulation, and diffuse or patchy ground-glass opacities.[15,16] Smoking cessation leads to resolution or stabilization of disease in most patients, and the risk of progression to respiratory failure and death appears less than is observed with the related smoking-associated ILD—desquamative interstitial pneumonia.[17] Subjective and objective improvements after corticosteroid treatment have been described but not studied prospectively.[17]

DIFFUSE PANBRONCHIOLITIS

Diffuse panbronchiolitis (DPB) is an unusual inflammatory disease of the respiratory bronchioles. Formally described in 1969, a 1982 survey in Japan estimated a prevalence of 11 cases per 100,000 people.[18,19] Although reported outside of East Asia, this entity is predominantly observed among those with Japanese ancestry, which may reflect an increased prevalence of genetic risk factors.[20,21] On histologic examination, DPB is characterized by the triad of bronchiolocentric inflammation, lymphoid hyperplasia, and accumulation of interstitial foam cells (see Fig. 72.2 [classified under the category peribronchiolar/interstitial] and Fig. 72.3C).[22–24] Of note, similar findings are also seen in bronchiectasis, underscoring the importance of developing a diagnostic approach to bronchiolitis that considers clinical, functional, radiographic, and histopathologic findings.

Given the rarity of DPB, epidemiologic data are limited. Clinically, DPB has a slight male predilection, and symptoms manifest in early to mid-adulthood.[19,20,24] Chronic sinusitis is exceedingly common and frequently precedes pulmonary symptoms. Before diagnosis, patients report years of nasal discharge or congestion, cough, dyspnea, and sputum production that exceeds 50 mL/day.[25] Radiographs demonstrate hyperinflation, diffuse small nodular opacities and, in advanced disease, ring shadows and "tram track" opacities consistent with bronchiectasis. In early disease, HRCT findings may include centrilobular nodules, sometimes termed a tree-in-bud pattern, and air trapping on expiratory images. Mosaic perfusion is atypical. In advanced disease, bronchiolar wall thickening, dilation, and cysts are seen.[26,27] PFTs demonstrate a progressive airflow obstruction with reduced diffusing capacity. Less commonly, a mixed obstructive-restrictive pattern may be observed.[21] Although clinical diagnostic criteria have been proposed for Japan, surgical lung biopsy is required in countries and populations in which the disease is rare.[20] If untreated, DPB leads to bronchiectasis, pulmonary hypertension, respiratory failure, and ultimately death. Although the etiology of DPB remains obscure, both genetic and environmental factors are believed to be important.[28–31] *Human leukocyte antigen* (HLA)-Bw54 is associated with a 13-fold increase in risk for diffuse panbronchiolitis.[29] Polymorphisms of the genes

for *interleukin* (IL)-8[30] and mucins[31,32] have been associated with diffuse panbronchiolitis.

Macrolides are the cornerstone of treatment.[33] As with macrolide therapy for other forms of bronchiolitis, their salutary effects likely involve a variety of immunomodulatory mechanisms rather than antimicrobial properties.[34,35] More than 40 studies have described these immunomodulatory effects across a variety of disease states. Within diffuse panbronchiolitis, the most consistently reported effect of macrolides is suppression of neutrophilic airway inflammation, with associated decreases in neutrophil chemoattractants and other proinflammatory cytokines.[36] Of note, 14- and 15-membered lactone ring macrolides (e.g., erythromycin, clarithromycin, azithromycin) are effective in treating DPB, whereas 16-membered lactone ring macrolides (e.g., tylosin, spiramycin) are not. Macrolide therapy is generally continued for at least 6 months.[33] For severe cases, lung transplantation has been performed, although the disease may recur in the allograft.[37]

Originally DPB was a highly fatal disease. In the 1980s, 5- and 10-year survivals were approximately 62% and 33%, respectively. With macrolide therapy, increased disease diagnosis, and early, aggressive treatment of bacterial infections, 10-year survival now exceeds 90%.[34] Recurrent respiratory infections are common, and *Pseudomonas* infection, often arising late in the disease, is associated with markedly increased mortality.[20]

FOLLICULAR BRONCHIOLITIS

Follicular bronchiolitis (lymphoid hyperplasia) is characterized by peribronchiolar hyperplastic lymphoid follicles with germinal centers (see Fig. 72.3D).[38,39] These follicles, which have high endothelial venules, lymphatics, and defined zones with T cells and B cells with follicular dendritic cells, resemble Peyer patches in the gut and are termed *bronchus-associated lymphoid tissue* (BALT).[39] BALT is commonly observed in transbronchial biopsies from lung transplant recipients and is not generally thought to be pathologic in this context. Indeed, in mouse lung transplant models, BALT regulatory T cells were necessary for protection against antibody-mediated rejection.[40]

BALT hyperplasia is pathognomonic for follicular bronchiolitis. Although idiopathic primary pulmonary lymphoid hyperplasia has been described, follicular bronchiolitis commonly indicates pulmonary involvement of a systemic immunologic condition, such as rheumatoid arthritis, Sjögren syndrome, lupus, *coatomer-associated protein subunit alpha syndrome* (COPA), human immunodeficiency virus, Evans syndrome, bronchiectasis, and other infections or immunodeficiencies. It can also be seen in association with smoking or other irritants and other airway or interstitial lung disease states[39,41] (see Fig. 72.2 [classified under the lymphoid aggregates category]).

Clinical symptoms of follicular bronchiolitis are often mild, with cough and dyspnea being most consistently reported.[42,43] PFT findings may show restrictive, obstructive, or mixed patterns. HRCT findings include small (<3 mm) centrilobular or peribronchial nodules and ground-glass opacities.[44] Treatment is directed at the underlying disease.

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans can be stratified into constrictive and proliferative bronchiolitis. Although there is some overlap between these entities, this stratification is largely supported by histopathologic and clinical evidence. Unique entities featuring bronchiolitis obliterans are listed in Fig. 72.2; more common entities are discussed in greater detail later.

Histologically, constrictive bronchiolitis defines a submucosal and peribronchiolar fibrotic process that circumferentially and externally compresses the bronchiolar lumen (Fig. 72.4A). Patchy and focal in distribution, progressive fibrosis observed in constrictive bronchiolitis ultimately results in slit-like or completely obliterated bronchiolar lumens. Clinically, patients describe progressive dyspnea and nonproductive cough. Auscultation demonstrates early inspiratory crackles and occasional squeaks. PFTs performed late in the course of disease demonstrate obstruction and air trapping. Radiographs may have normal findings or show hyperinflation. HRCT can demonstrate ground-glass nodules, air trapping and, in advanced disease, bronchiectasis. Currently, the most common presentation of constrictive bronchiolitis is in the context of *chronic lung allograft dysfunction* (CLAD) after lung transplantation.[45]

Histologically, proliferative bronchiolitis is defined by the proliferation of transluminal polypoid organizing fibroblastic tissue, also known as a Masson body (see Fig. 72.4B).[46] Isolated proliferative bronchiolitis is rare, observed only in specific inhalational (e.g., nitrogen gas) exposures or localized injuries. Much more commonly, fibroblastic tissue extends from the bronchioles into adjacent alveoli. The term organizing pneumonia defines this organizing fibroblastic tissue in alveoli. Given the relatively common coexistence of proliferative bronchiolitis and organizing pneumonia, the term *bronchiolitis obliterans with organizing pneumonia* (BOOP) had been used. There is little overlap, however, between the clinical entities featuring constrictive bronchiolitis and those featuring BOOP. Furthermore, BOOP presents as a restrictive pattern on PFTs compared with the obstructive pattern seen in constrictive bronchiolitis. For these reasons, this nomenclature caused confusion and, in response to this confusion, in 2002 the American Thoracic Society and European Respiratory Society jointly recommended abandoning the term BOOP in favor of organizing pneumonia with appropriate qualifiers. When idiopathic, the term cryptogenic organizing pneumonia is used[47] (see Chapter 90). In rare situations, acute injury causing proliferative bronchiolitis may progress into constrictive bronchiolitis.

Despite this evolution in nomenclature, "bronchiolitis obliterans" continues to be used imprecisely in clinical practice and in the biomedical literature. The terms BOOP, bronchiolitis obliterans with intraluminal polyps, and bronchiolitis obliterans applied to both bronchiolitis obliterans and organizing pneumonia persist. Of importance, organizing pneumonia tends to be responsive to corticosteroid treatment, whereas constrictive bronchiolitis is typically resistant. This absence of a precise nomenclature makes studies of the epidemiology, clinical features, and treatment responsiveness of "bronchiolitis obliterans" difficult to interpret. Given the substantial differences in both etiology

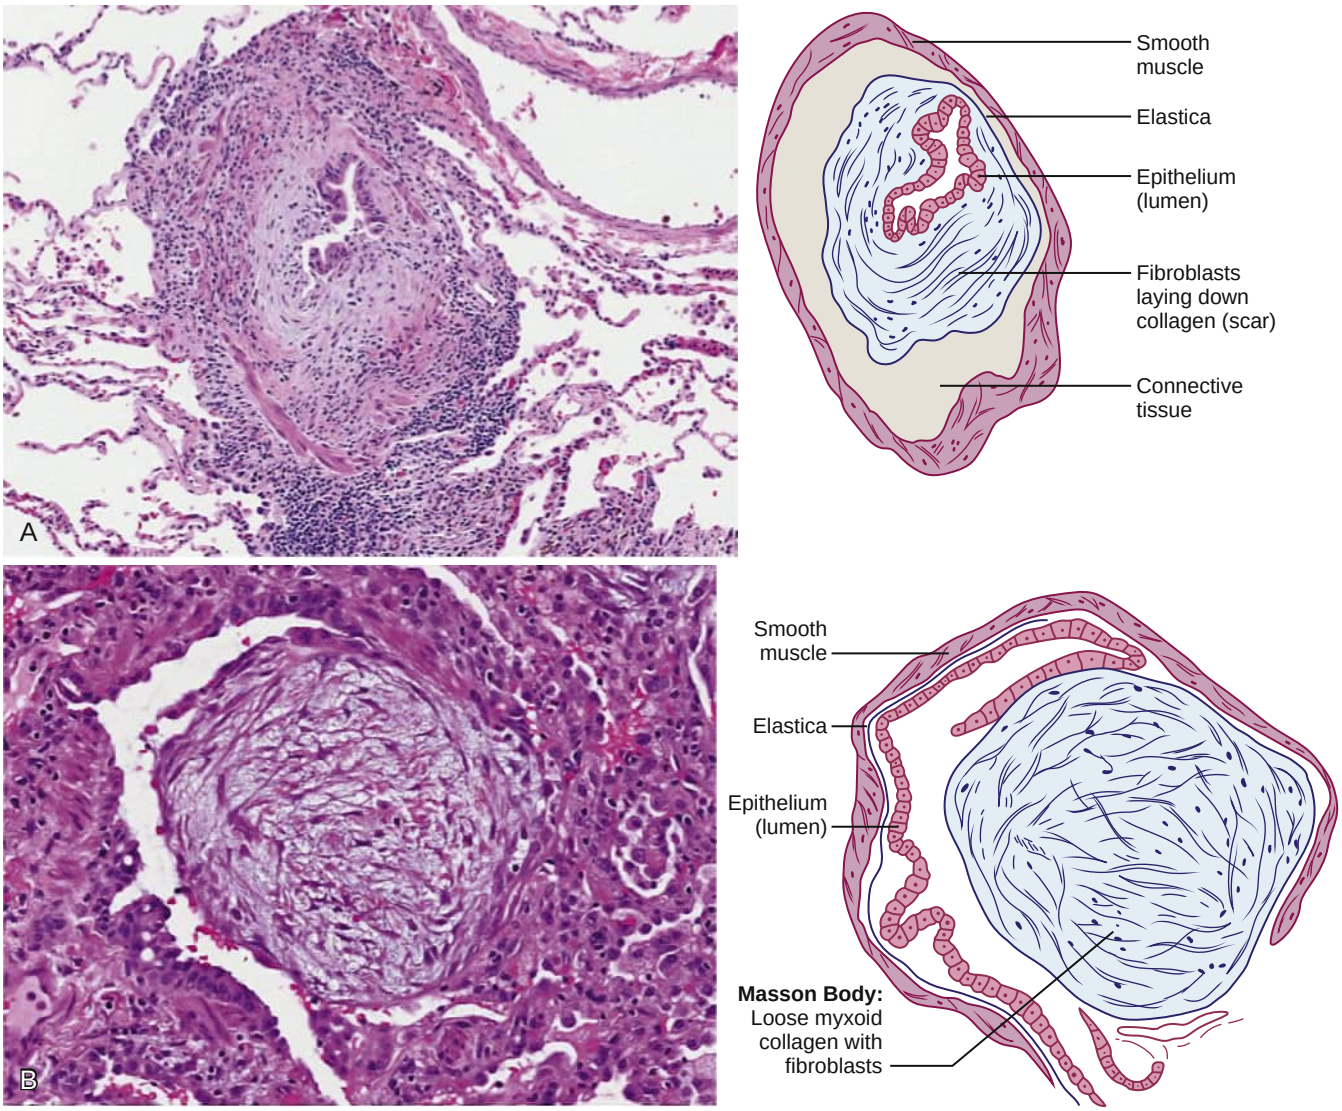

Figure 72.4 Pathologic patterns of bronchiolitis obliterans. (A) Constrictive bronchiolitis. Circumferential subepithelial intramural fibrosis is present. This fibrosis separates the normally approximated epithelium and elastica (the elastin-rich layer of the lamina propria). This scarring results in luminal constriction and narrowing, often with irreversible complete obstruction. (B) Proliferative bronchiolitis. Although the diameter of the airway remains unchanged, the functional area of the lumen is reduced by a rounded intraluminal polypoid plug of granulation tissue, extending from the subepithelium and filling the airway lumen (also known as a Masson body).

and prognosis, we favor using the terms *constrictive* and *proliferative* to define these bronchiolitis subtypes more clearly.

Although these categories are defined histopathologically, in practice, there is a lot of overlap. We will discuss the following entities, which are mostly constrictive but may exhibit proliferative features as well.

CONSTRICTIVE BRONCHIOLITIS AFTER LUNG TRANSPLANTATION (See Chapter 140)

Chronic Lung Allograft Dysfunction

Since the late 1980s, there have been steady increases in the rates of lung transplantation performed, with more than 4500 procedures worldwide in 2016. Although survival rates are improved compared with the pre-2008 era, the median posttransplantation survival is only 6.5 years.[48] The most common cause of death after the first year posttransplantation is *chronic lung allograft dysfunction* (CLAD).[49] CLAD is a clinical syndrome of obstructive or restrictive defects defined by a persistent, greater than 20% decline in *forced expiratory volume in 1 second* (FEV_1) from posttransplantation baseline, with baseline defined as the average of the two best posttransplantation FEV_1 measurements taken more than 3 weeks apart (see Table 72.1). Constrictive bronchiolitis is the most common pathologic feature in CLAD and is thought to be the main cause of decline in FEV_1, particularly for the predominantly obstructive form of CLAD, known as *bronchiolitis obliterans syndrome* (BOS). Registry data show the majority of lung transplant recipients die or develop CLAD within 4 years.[45] The presence of a total lung capacity decline of 10% or more and persistent chest CT opacifications define the restrictive allograft syndrome subtype of CLAD, for which pleural and/or parenchymal fibrotic pathology are also associated.[50]

Adding to the confusion, this terminology has changed over time. Until 2014, BOS was defined as any decline in FEV_1, without regard to *forced vital capacity* (FVC), similar to what is currently called CLAD.[51,52] From 2014 to 2019, CLAD was defined by a decline in FEV_1 *or* FVC.[53] Since 2019, BOS has been considered only the obstructive subtype of CLAD, and CLAD is diagnosed only based on FEV_1.[49] Nonetheless, even in patients meeting criteria for restrictive allograft syndrome, explant tissue typically demonstrates concomitant constrictive bronchiolitis.

Various factors can cause persistent FEV_1 loss in lung transplant recipients, thought to be unrelated to CLAD or constrictive bronchiolitis, including chest wall disease, pleural effusions, pulmonary edema, airway stenosis, obesity, aging, diaphragmatic dysfunction, native lung hyperinflation, or scarring from focal infections. For these, the consensus definition recommends a resetting of the FEV_1 baseline once such factors have been stable for 6 months.[49] Whether or not this FEV_1 baseline is reset in practice, patients with incipient CLAD should undergo an evaluation for these potential confounders, including CT scans and bronchoscopy. Chest CT can also be useful in evaluating for restrictive versus obstructive CLAD, which would be associated with fibrotic changes or air trapping, respectively[54,55] (see Fig. 72.1 and Video 140.3). Transbronchial biopsy can be used to evaluate for acute rejection pathology but only rarely demonstrates histopathologic evidence of constrictive bronchiolitis.

The onset of CLAD is variable based on donor, recipient, and environmental factors (discussed later). Patients report progressive dyspnea and, occasionally, dry cough. In advanced disease with bronchiectasis, the cough is productive. Pulmonary function tests demonstrate irreversible airflow obstruction with reduced diffusing capacity. As CLAD progresses, findings consistent with bronchiectasis may be seen.

Table 72.1 Chronic Lung Allograft Dysfunction Classification System

CLAD 0	FEV_1 > 80% of baseline*
CLAD 1	FEV_1 > 65–80% of baseline
CLAD 2	FEV_1 > 50–65% of baseline
CLAD 3	FEV_1 > 35–50% of baseline
CLAD 4	FEV_1 ≤ 35% of baseline

*Baseline is the average of the two best *forced expiratory volume in 1 second* (FEV_1) measurements that are more than 3 weeks apart but can be adjusted in the case of 6 months of stability for certain non–*chronic lung allograft dysfunction* (CLAD) causes.

Modified from Verleden GM, Glanville AR, Lease ED, et al. Chronic lung allograft dysfunction: definition, diagnostic criteria, and approaches to treatment—a consensus report from the Pulmonary Council of the ISHLT. *J Heart Lung Transplant*. 2019;38:493–503.

Chronic Lung Allograft Dysfunction Pathogenesis. Constrictive bronchiolitis is likely a final histologic lesion resulting from a failure in epithelial cell regeneration in the context of chronic, predominantly alloimmune injury (Fig. 72.5). Emerging evidence suggests that epithelial integrity requires active signaling to prevent proliferation of the adjacent mesenchyme so that when damage to the epithelium

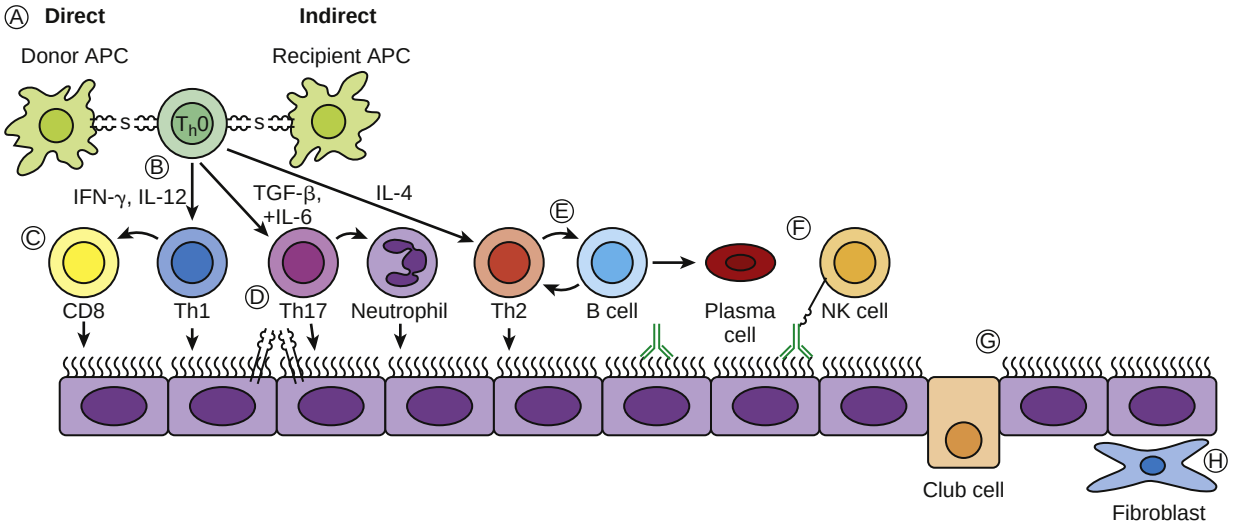

Figure 72.5 Overview of chronic lung allograft dysfunction pathogenesis. (A) Donor antigens are presented on donor *major histocompatibility complex* (MHC) (directly) or on recipient MHC (indirectly) to T cells. (B) T cells differentiate based on the local cytokine milieu into *T helper* (Th)1, Th2, or Th17 subtypes of CD4 cells and activated CD8 cells. (C) These cell types cause direct cytotoxicity in areas of vascular endothelium, manifest as A-grade rejection, and airway epithelium, termed B-grade rejection. (D) Airway injury drives epithelial cell damage responses, such as up-regulation of MHC leading to further amplification of alloimmune responses. (E) B cells interact with T cells and *antigen-presenting cells* (APCs), generating antibodies and differentiating into long-lived antibody-secreting plasma cells. (F) Antibodies also contribute to epithelial cell damage through complement fixation, direct cytotoxicity, or in concert with natural killer (NK) cells via antibody-dependent cell-mediated cytotoxicity. (G) Club cells and other cells responsible for protecting and regenerating the epithelium may initially compensate for the increased epithelial cell turnover but are eventually exhausted, particularly in the setting of compromised vasculature associated with transplantation. (H) Fibroproliferative cells may then replace denuded airway and commit the epithelium to fibrotic replacement via autocrine signaling. Of note, these steps (A–F) of chronic lung allograft dysfunction pathogenesis may not happen in this order or at all in cases. IFN-γ, interferon-γ; IL, interleukin; TGF-β, transforming growth factor-β.

exceeds its capacity for repair, profibrotic cells are activated to patch the denuded airway.[56] This biology may explain why a deficiency of club cells, cells that both protect and repopulate bronchiolar epithelium, is associated with constrictive bronchiolitis.[57,58] Other factors limiting epithelial cell regeneration, such as microvascular injury or telomere dysfunction, are also linked to CLAD risk.[59,60] Similarly, processes that result in airway injury have been linked to CLAD, including primary graft dysfunction[61]; infection with *Pseudomonas,*[62] *Aspergillus,*[63] cytomegalovirus,[64] and other viruses[65,66]; air pollution[67]; and gastroesophageal reflux.[68] Bronchioles might be particularly susceptible to potentiating effects of air pollution because the increase in cross-sectional area related to branching in the bronchiolar region results in a slowing of airflow and a preferential accumulation of airborne particles in this region.[69] Once shunted toward a fibrotic pathway, mesenchymal cells can then become self-perpetuating, further hampering restoration of normal physiology.[70]

Cellular Immune Responses. Among injury responses, alloimmune injury appears most important to CLAD pathogenesis. CLAD risk is linked to acute cellular rejection episodes.[71] Acute cellular rejection of the lung allograft is diagnosed on transbronchial biopsy specimens as perivascular lymphocytosis or lymphocytic bronchiolitis, classified as A-grade and B-grade rejection, respectively, based on *International Society of Heart and Lung Transplantation* (ISHLT) nomenclature (see Chapter 140).[72] Lymphocytic bronchitis (in the large airways) has also been associated with CLAD risk.[73,74] Severity of acute rejection appears important because untreated "minimal" or A1-grade acute cellular rejection does not appear to increase CLAD risk.[74–76]

Enhanced expression of donor *major histocompatibility complex* (MHC) antigens has also been found in bronchiolar and alveolar epithelium of lung transplant recipients with acute rejection and CLAD, likely secondary to type 1 lymphocytic inflammation.[77,78] Donor MHC antigens presenting donor self-antigen are then recognized by the recipient immune system, further propagating alloimmune responses.[79] An increasing burden of donor-recipient HLA mismatches has also been shown to be a CLAD risk factor.[80] In addition to this direct pathway of allorejection, there is also indirect antigen presentation, where recipient antigen-presenting cells present phagocytosed donor antigens.[81] Calcineurin inhibitor–based immunosuppression targets this type 1 immune response. Indeed, the clinical success of lung transplantation is coincident with the advent of calcineurin inhibitors. Of interest, although variability in tacrolimus-based immunosuppression levels has been associated with CLAD, suggesting a detrimental effect of transient lack of immunosuppression,[82] supratherapeutic immunosuppression levels are associated with increased infection risk but no change in rates of acute rejection.[83] Thus, although type 1 immune responses are potentially a potent driver of CLAD, this pathway is effectively inhibited by current immunosuppression strategies, suggesting that other pathways could be responsible for CLAD in practice.

Type 17 and, to a lesser extent, type 2 alloreactive T cell responses are also associated with CLAD and appear to be relatively resistant to calcineurin inhibitors.[84] In particular, type 17 inflammation can recruit neutrophils, and neutrophilic inflammation has been linked to early development of CLAD. A syndrome of greater than 15% neutrophils in bronchoalveolar lavage, combined with a 10% or greater decline in FEV_1, is often reversible with azithromycin treatment, at which point it is termed *neutrophilic reversible allograft dysfunction* (NRAD).[85] Clinical features of NRAD overlap with lymphocytic airway inflammation, which is associated with IL-17 and can reverse after azithromycin treatment.[86] Mechanistically, tacrolimus paradoxically increases the IL-17–dependent production of the neutrophil chemoattractant chemokine IL-8 by airway smooth muscle cells, and this effect can be reversed by azithromycin.[87]

Humoral Immune Responses. Lung transplant recipients may develop antibodies to donor HLA antigens. The de novo development of *donor-specific antibodies* (DSAs), in particular to HLA-DQ, has been linked to more rapid onset of CLAD.[88] A syndrome of *antibody-mediated rejection* (AMR) can manifest as obstructive or restrictive pulmonary function defects; histopathologic features of neutrophil margination, capillaritis, and/or arteritis; complement component 4d deposition on alveolar capillaries; and serologic evidence of DSA. Although some patients present with indisputable AMR, diagnostic uncertainty is common. Thus the ISHLT definition of AMR groups patients into "definite," "probable," and "possible" categories based on the presence of allograft dysfunction and four, three, or two of the following features, respectively: DSA, complement component 4d staining on lung biopsy, compatible lung histology, and exclusion of other causes.[89] Even within this definition, there is disagreement on the criteria for the component features.

Lung transplant recipients with severe AMR have substantial morbidity. Thus, some lung transplantation centers have treated de novo DSA and AMR with combination therapy that includes some or all of the following: corticosteroids, intravenous immunoglobulin, plasmapheresis, monoclonal antibodies to the B cell antigen CD20, proteasome inhibitors, and complement inhibitors.[90] However, there are no randomized controlled trial data to guide therapy. Although clearance of DSA with therapy is associated with freedom from BOS,[91] it is not clear that interventions that result in DSA clearance improve outcomes.[92,93] Crosstalk between alloreactive type 2 and follicular helper T cells and B cells via cytokines and costimulatory molecules results in B cell activation and differentiation into plasma cells. Thus, persistence of DSA may also be a biomarker for alloimmune responses more broadly.

Other Immune Responses. Autoimmune responses may also contribute to the development of CLAD. Lung injury may expose self-antigens that would otherwise be masked from the immune system. Type V collagen and K-α1 tubulin, in particular, are expressed in small airway epithelial cells and exposed during rejection and lung remodeling. Autoantibodies to these proteins are risk factors for CLAD in humans.[94] In rodent models, these autoantibodies can be induced by anti-MHC antibodies, and induction of tolerance to type V collagen can protect from allograft rejection in rodent models.[95]

Finally, innate immune responses play key roles in potentiating adaptive immune responses in the context of lung transplantation. Single nucleotide polymorphisms in innate immune genes, such as *toll-like receptor 4* (TLR4), have been linked to CLAD.[96] Natural killer cells are postulated to play important roles in both amplifying and dampening alloimmune responses, in primary graft dysfunction, in AMR, and in responses to infections.[97]

BRONCHIOLITIS OBLITERANS SYNDROME AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

Although a mismatch between lung and immune system MHC antigens is present in both lung transplantation and allogeneic stem cell transplantation, constrictive bronchiolitis appears less frequent after the latter. In the context of allogeneic stem cell transplantation, the clinical syndrome of constrictive bronchiolitis is termed BOS, and the distinction between restrictive and obstructive forms of chronic lung dysfunction is not generally addressed. The comparison between these two contexts of BOS is complicated by differences in definitions, however. Pulmonary *graft-versus-host disease* (GVHD) resembles constrictive bronchiolitis histologically after lung transplantation. However, surgical lung biopsies are rarely performed to confirm the diagnosis, given the potential surgical risk. Thus, pulmonary GVHD is generally diagnosed as the clinical syndrome termed BOS.

BOS was defined in a 2014 consensus statement by the presence of all four of the following criteria: (1) an obstructive FEV_1/slow vital capacity ratio, (2) FEV_1 less than 75% of predicted with a 10% or greater decline over 2 years, (3) absence of infection, and (4) either evidence of extrapulmonary GVHD or evidence of air trapping by CT or spirometry.[98] With this definition, one study estimated the prevalence of GVHD at about 10% at 36 months after transplantation.[99] Other studies suggest a prevalence of as low as 2–3% at a similar time point after transplantation.[100] More liberal pulmonary GVHD diagnostic criteria have been proposed. For example, post–stem cell transplantation airflow obstruction, defined as greater than 5% per year decline in FEV_1 and minimum FEV_1/FVC of less than 0.8, has a reported prevalence of 26%.[101]

BOS is usually preceded or accompanied by typical findings of GVHD: mucositis, esophagitis, and/or skin rash.[102] Four to 6 months after the onset of GVHD, patients may develop dyspnea and a nonproductive cough that may be severe and rapidly progressive. Physical examination may reveal scattered wheezing and frequently bibasilar crackles. Hypoxemia is common.[100] Spirometry and radiographic findings are similar to those observed in BOS in lung transplantation.

Extrapulmonary GVHD, including skin, gastrointestinal, or hepatic inflammation, is the most significant risk factor for BOS. Other risk factors include a busulfan-containing preparative regimen, stem cells from the peripheral blood, viral infections, lung disease pre–stem cell or post–stem cell transplantation, and ABO blood type incompatibility.[103] Its rarity after autologous stem cell transplantation implies an association with alloimmune responses, but the pathogenesis remains incompletely understood. Quarterly spirometry for at least 1 to 2 years after allogenic stem cell transplantation and with new manifestations of GVHD can aid in early identification of BOS.[103] Mild declines in FEV_1 can be treated with inhaled corticosteroids with or without an inhaled β_2-agonist. With the diagnosis of BOS, treatment with a tapered steroid burst and initiation of fluticasone, azithromycin, and montelukast ("FAM") treatment are recommended.[104] Calcineurin inhibitors, lymphocyte proliferation inhibitors (e.g., mycophenolic acid), or sirolimus for systemic GVHD are generally continued. Additional therapies, including extracorporeal photopheresis and etanercept, have been added in cases of continued progression, without clear evidence of efficacy.[103] A trial of azithromycin for the prevention of post–stem cell transplantation GVHD was stopped early because of increased mortality attributed to the risk of hematologic relapse, so prophylactic azithromycin is generally not recommended.[105]

BRONCHIOLITIS OBLITERANS AND CONNECTIVE TISSUE DISEASES

Constrictive bronchiolitis may present uncommonly with connective tissue or collagen vascular diseases, in particular, rheumatoid arthritis.[106] It predominantly affects women who are at least 10 years out from a rheumatoid arthritis diagnosis. Patients present with rapid onset of progressive dyspnea, nonproductive cough, and spirometric evidence of airflow obstruction. In a case series, all-cause mortality was 27% over a median follow-up of 5 years, with FEV_1 stabilization achieved in the context of (although not necessarily because of) steroids, macrolide antibiotics, and other immunosuppression therapies.[107] Cases of constrictive bronchiolitis have also been reported with Sjögren syndrome.[108] Older literature linking bronchiolitis obliterans and other connective tissue diseases frequently refers to BOOP which, as discussed earlier, is a distinct pathobiology.

BRONCHIOLITIS OBLITERANS AFTER INFECTION

Although acute infectious bronchiolitis is common in children, postinfectious bronchiolitis obliterans is quite rare. The syndrome is defined by persistent airway obstruction, as assessed by symptoms, imaging, and spirometry, subsequent to a lower respiratory tract infection and unresponsive to at least 2 weeks of steroids and bronchodilators.[109] Despite similarity in the names, this disease entity appears distinct from acute bronchiolitis. Postinfectious bronchiolitis obliterans is most common in South America and linked to adenovirus infection, rather than respiratory syncytial virus infection. This epidemiologic difference has been linked to more potent T helper type 1 immune responses associated with adenoviral infection.[110] There are no well-controlled studies to guide management of these patients. Although lung function generally improves in pediatric patients, defects may persist.[111]

BRONCHIOLITIS FROM INHALED OR INGESTED TOXINS

A generalized inflammatory response of the peripheral airways may follow inhalation of toxicants in gases, vapors, fumes, or aerosols (see Chapter 103). The location of damage is determined in part by the toxicant solubility. Highly soluble irritants, such as sulfur dioxide and ammonia,

dissolve in the lining fluid of the upper airway, causing damage primarily there. Less soluble gases, such as oxides of nitrogen, are able to pass into and therefore damage the peripheral airways.[112] Such exposures continue to represent significant industrial and environmental hazards.[113] Nitrogen dioxide for example, may be found in silo gas (silo filler's disease), jet and missile fuel, metal pickling fumes, and certain fires. Exposure results in an acute respiratory distress syndrome that evolves to proliferative bronchiolitis.[114] Acutely, patients may develop cough, dyspnea, cyanosis, hemoptysis, hypoxemia, and loss of consciousness. These symptoms and signs may last hours to weeks before resolving. Corticosteroid therapy is frequently used in the initial management, based on limited evidence.[113] Although most patients recover, some may die from respiratory failure. Finally, some patients develop irreversible obstructive abnormalities 2 to 8 weeks after exposure. Persistent obstruction may even be seen in patients who had no initial illness. Rather, these patients typically have a gradual onset of dyspnea and nonproductive cough that may progress to respiratory failure and death.[115]

Diacetyl and other alpha-diketones used in flavoring food have been linked to proliferative and constrictive bronchiolitis (see Fig. 72.2). These fumes are a particular risk in occupational settings where these chemicals are heated or powdered. In popcorn manufacturing, diacetyl-related constrictive bronchiolitis is termed popcorn lung.[116] Exposed workers are at increased risk for obstructive lung disease that may present with cough, wheeze, or dyspnea.[117] Diacetyl may directly activate fibroproliferative pathways in airway epithelial cells[118] or initiate autoimmune responses through hapten formation.[119] Diacetyl is found in many consumer products, including electronic cigarettes, although constrictive bronchiolitis from exposures outside of industrial settings appears extremely unusual.[116] Minimizing exposure and spirometric screening are reasonable prevention strategies.

Constrictive bronchiolitis has been reported through military exposures. A cohort of Iranian soldiers exposed to mustard gas during the Iran-Iraq war were found to have an increased frequency of chronic respiratory symptoms; a subset of these were diagnosed with constrictive bronchiolitis based on HRCT and, in some cases, lung biopsy. Minimal progression of obstruction was observed on spirometry, with a regimen including inhaled corticosteroid and long-acting β-agonist, azithromycin, and *N*-acetylcysteine.[120] A cohort of soldiers from the United States with otherwise unexplained dyspnea had a high prevalence of constrictive bronchiolitis based on surgical lung biopsy,[121] but subsequent studies have not confirmed this association.[122]

A number of other inhaled and ingested toxins have been linked to constrictive bronchiolitis. Treatment with penicillamine and gold have been linked to constrictive bronchiolitis, although in some cases it may be difficult to distinguish between medication effect and underlying disease.[123] *Sauropus androgynus*, a leafy vegetable popular in Asia and ingested for its slimming properties, has been linked to hundreds of cases of constrictive bronchiolitis.[124] Inhalational exposure during preparation of fiberglass with polymer resin and methylethyl ketone peroxide catalyst has been attributed as the cause of constrictive bronchiolitis among boat workers.[125]

TREATMENT OF CONSTRICTIVE AND PROLIFERATIVE BRONCHIOLITIS

Therapies to reverse the small airway remodeling observed in constrictive bronchiolitis have been largely ineffective. However, therapies to prevent progression of injuries preceding constrictive bronchiolitis have met with some success. In the case of exposure to toxic fumes, for example, corticosteroid therapy for organizing pneumonia or fibroproliferative bronchiolitis appears helpful.[126] In other contexts outside of lung transplantation, a trial of corticosteroids should be considered when there is evidence of these inflammatory bronchiolitis pathologies. If a response is identified, the corticosteroid should be continued for at least 2 to 3 months, then reduced slowly, to minimize the likelihood of relapse. In some cases it may be necessary to continue low-dose or alternate-day therapy for months or years.[127]

In the case of CLAD, azithromycin therapy has demonstrated efficacy in preventing progression and reversing acute airflow obstruction in a randomized trial.[128] This is thought to be particularly true for the subset of patients with NRAD; however, reversal of airway neutrophilia is not consistently linked to efficacy. Separately, prophylactic treatment with azithromycin started at the time of discharge from the initial transplantation was shown to be protective against CLAD development.[129] However, another trial of prophylactic azithromycin did not find evidence of protection from CLAD.[130] Together, these data suggest that macrolide therapy can be important for a subset of lung transplant recipients, but its efficacy for CLAD is modest when compared with its efficacy for diffuse panbronchiolitis.

Substantial attention is paid to identifying and treating other patient-specific risk factors for CLAD. Examples include surveillance bronchoscopy for acute rejection,[131] cytomegalovirus-specific antiviral prophylaxis,[132] reducing aspiration through lifestyle modifications and gastric fundoplication,[133] and treatment of certain community-acquired respiratory viral infections.[134–136]

Intensified corticosteroids do not improve outcomes for lung transplant recipients with CLAD. Of 30 lung transplant recipients randomized to the leukotriene inhibitor monteleukast for CLAD, there was no overall benefit. Additional studies will be needed to determine whether certain subsets, such as those with milder airway dysfunction, might be more likely to benefit.[137] Extracorporeal photopheresis has been used to treat patients with CLAD but without high-quality evidence, and this therapy is the subject of an ongoing clinical trial.[138] Hydroxymethylglutaryl coenzyme A reductase inhibitors have been investigated for CLAD with mixed results.[139] Although there is little evidence that smooth muscle contraction plays a significant role, β-adrenergic agonists are frequently attempted to provide symptomatic relief. Lung transplantation is an option for some patients with CLAD and other forms of constrictive bronchiolitis.[140] After retransplantation, median CLAD-free survival is about 1 year less than after primary transplantation, based on registry data.[141]

Bronchopulmonary dysplasia, which has some features of bronchiolitis, is discussed at ExpertConsult.com.

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is a respiratory complication of premature birth. Since the first description of BPD in 1967,[142] the management of prematurity has evolved, including the use of antenatal glucocorticoids, perinatal surfactant, and modified mechanical ventilation. This evolution has resulted in different clinical and histopathologic entities termed "old" and "new" BPD.

Old BPD was identified in newborn babies with infant respiratory distress syndrome after prolonged treatment with high concentrations of inspired oxygen and positive-pressure ventilation.[143] Characteristic histologic features include unusual abnormalities of the bronchioles, including marked metaplasia, obliteration, and cystic changes.[144] The entity also has been described in adults after acute respiratory distress syndrome[145] and may be more frequent than is currently recognized. The pathologic process includes significant fibrosis of alveolar septa and resembles the honeycombing seen in other fibrotic interstitial lung diseases.[144,146]

New BPD is clinically milder and probably reflects developmental arrest in an immature lung rather than barotrauma and oxygen toxicity.[147] It may be the result of the contemporary management of premature infancy, which has improved survival of increasingly immature infants.[148,149] Histopathologic examination reveals enlarged air spaces with simplified alveolar and alveolar-capillary development. Unlike in the original disease, airway abnormalities are uncommon.[149]

Key Points

- Because of the large cross-sectional area of the peripheral airways, symptoms and physiologic changes of diseases involving the peripheral airways develop late in disease and can be silent.
- Bronchiolitis can be broadly categorized into inflammatory, proliferative, or constrictive subtypes.
- Inflammatory and proliferative bronchiolitis are more likely than constrictive bronchiolitis to be reversible or respond to immunosuppression. Certain bronchiolitis subtypes respond to macrolide antibiotics, especially diffuse panbronchiolitis and neutrophilic reversible allograft dysfunction.
- Constrictive bronchiolitis is the dominant pathology in chronic lung allograft dysfunction. Chronic lung allograft dysfunction is the major long-term limitation to survival after lung transplantation and appears to reflect multiple immune and nonimmune pathobiologies.
- Bronchiolitis obliterans after allogeneic stem cell transplantation results from chronic graft-versus-host disease.

KEY POINTS

INTRODUCTION

Our understanding of lung cancer development has dramatically expanded in the past 20 years. We now understand how *stochastic* (random) events affect the airway epithelium and how they set the stage for a series of processes leading the cells to transformation and invasion of the microenvironment. The hallmarks of cancer have been described[1–4] (Table 73.1) to help understand how cancers evolve to survive and circumvent a series of key regulatory processes. This chapter considers key processes relevant to lung cancer progression. Some of these processes remain largely unknown, such as the mechanisms underlying and linking metabolic reprogramming of the airway epithelium, promotion of genomic instability, and suppression of T cell antitumor function via immune evasion. This discussion includes how point mutations can activate oncogenes or inactivate tumor suppressor genes leading to *driver* mutations that give selective advantage to tumor cells or become *passenger* mutations irrelevant to the progression of the tumor. A series of new concepts (Table 73.2) is examined, including how clonality of the tumorigenic process and tumor evolution over time (including subclonal populations) are being studied to understand the natural history and heterogeneity of tumors. At the same time, the complexity, redundancy, and heterogeneity of these pathways make mutational targeting in *non–small cell lung cancer* (NSCLC) a moving target. Precision medicine-based treatment is successful only in a subset of lung tumors. This indicates the need to characterize clinically related molecular tumor phenotypes, especially those related to driver mutations in tumor suppressor genes and oncogenes.

MOLECULAR BIOLOGY

CARCINOGENS

Both environment carcinogen exposure and natural toxic by-products of cell metabolism cause mutations that lead to cancer. As discussed in Chapter 74, many carcinogens have been studied for their effects on cellular fate. The best understood are tobacco carcinogens and their effect on DNA. Among the many components in tobacco smoke, and in outdoor and indoor air pollution, are *polycyclic aromatic hydrocarbons* (PAHs). Long-term exposure to PAHs may cause lung cancer. PAHs induce phase I metabolic enzymes (e.g., CYP1A1) and phase II enzymes (e.g., glutathione S transferases) that lead to the formation of active carcinogens, such as

Table 73.1 Hallmarks of Cancer

Established 2000[1]	Added in 2011[2]
Sustained proliferation	Metabolic reprogramming
Evasion of tumor suppressors	Genomic instability
Invasion and metastasis	Tumor-promoting inflammation
Replicative immortality	Immune evasion
Angiogenesis	
Resisting apoptosis	

Table 73.2 Key Concepts in Cancer Biology

Clonal and subclonal evolution

Neoantigens
Spatial and temporal tumor heterogeneity
Immune evasion

diol-epoxides and radical cations. These reactive metabolites produce *DNA adducts*, which are portions of DNA bound to a carcinogenic chemical. Such adducts cause DNA mutations, alterations in gene expression, and eventually tumorigenesis.[5] DNA adducts can alter chromatin structure. They alter the transcription of genes that modify epithelial biology and microenvironment. Key mutations in xenobiotic metabolic enzymes (involved in metabolism and elimination of potentially toxic compounds) as well as the tumor suppressor gene *TP53* and DNA repair machinery are clearly associated with susceptibility to lung cancer. The exact mechanism of action for tumor induction remains unclear. We know that PAHs are metabolized by multiple enzymes into metabolites such as BP-7,8-dihydrodiol-9,10-epoxide that will react with DNA to produce adducts. Specific adducts can cause mismatches in DNA replication and alter promoter methylation and/or binding.[6] These PAHs can also induce formation of protein adducts that trigger elevation of reactive oxidant species that affect DNA, lipids, and proteins as well as their oxidative states to cause altered gene regulation and protein function, leading to carcinogenesis. Much work is being done in an attempt to understand how mixtures of PAHs contribute to tumorigenesis. For example, one potential mechanism involves aryl hydrocarbon receptor–dependent versus –independent pathways because they induce epigenetic alterations that may ultimately regulate the immune response during lung cancer development.[7]

METABOLIC REPROGRAMMING

Tumorigenesis is dependent, at least in part, on the reprogramming of cellular metabolism, which itself is a consequence of oncogenic driver mutations. Metabolic reprogramming constitutes one of the 10 hallmarks of cancer development.[2] We propose that these metabolic derangements predispose cells to develop genomic instability, as discussed below. It is well known that oncogenic drivers regulate metabolic programs and that these oncogenic events need to be supported via increased access to energy facilitated by a bioenergetic upgrade. Deregulated uptake of glucose and amino acids such as glutamine plays a central role in cancer cell reprogramming.[8,9] The tumorigenic process requires enablers such as glutamine and metabolic support to meet increased biosynthetic demand. Glutamine addiction has been recently recognized as a new therapeutic target in cancer.[10] Preliminary studies suggest that metabolic reprogramming happens early in tumorigenesis, while the epithelium still appears normal but demonstrates a number of epigenetic (DNA methylation) and genetic alterations.[11] These alterations may be the consequence of metabolic reprogramming that favors glutamine uptake and that promotes chromosomal instability. Chromatin-modifying enzymes mediate DNA methylation and histone modifications upon recruitment to specific target gene loci in response to various stimuli.[12] In sum, metabolic pathways are reprogrammed early on in the airway epithelium, which may lead to epigenetic alterations and ultimately contribute to genomic instability.

GENOMIC INSTABILITY

Genomic instability refers to the increased propensity to acquire alterations in the genome. It is another hallmark of cancer development[13] and is characteristic of most solid tumors. In hereditary cancers, however, genomic instability results from mutations in DNA repair genes; in sporadic cancer, the mechanism is not well understood.[14] Genomic sequencing data suggest that sporadic carcinogenesis is not due to mutations in either DNA repair genes or mitotic checkpoint genes. Thus, genomic instability in human cancers may be linked to some other mutagenic factor, such as carcinogens or oncogene-induced DNA damage. Genomic instability happens early in tumor development. Multiple specific alterations have been recognized in the at-risk airway epithelium (Figure 73.1), including DNA adducts, DNA methylation,[15] chromatin structure alterations, chromosomal alterations, copy number gains and losses,[16,17] point mutations, expansion of microsatellite regions (a marker of faulty mismatch repair), gene expression alterations,[18] proteomic changes,[19–22] and metabolic changes.[11,23] DNA can be damaged by intrinsic (e.g., germline defect) and extrinsic (e.g., tobacco) mechanisms. Failure of repair, replication, chromosomal segregation mechanisms, and cell cycle checkpoint control may lead to chromosomal, microsatellite, and nucleotide instability.[24]

Cancer starts with mutations in somatic cells, leading to genomic instability and cell transformation. Transformation is followed by dysregulated growth, morphologic remodeling, and changes in metabolism. Genomic instability can also be tracked following spatial and temporal evolution of the genomic changes during tumor progression.[25] Sequencing multiple regions of NSCLCs, researchers have found evidence of branched evolution (subclonal), suggesting truncal mutations are common in the creation of the original malignant clone.

Driver mutations arise before and after progression of the tumor in the form of branches on a tree corresponding to subclones, with unique *driver* (oncogenic) and *passenger* (not functionally relevant) mutations. Environmental carcinogens induce lung cancer by increasing the rate of mutations in airway epithelial cells. The chemical properties of carcinogens

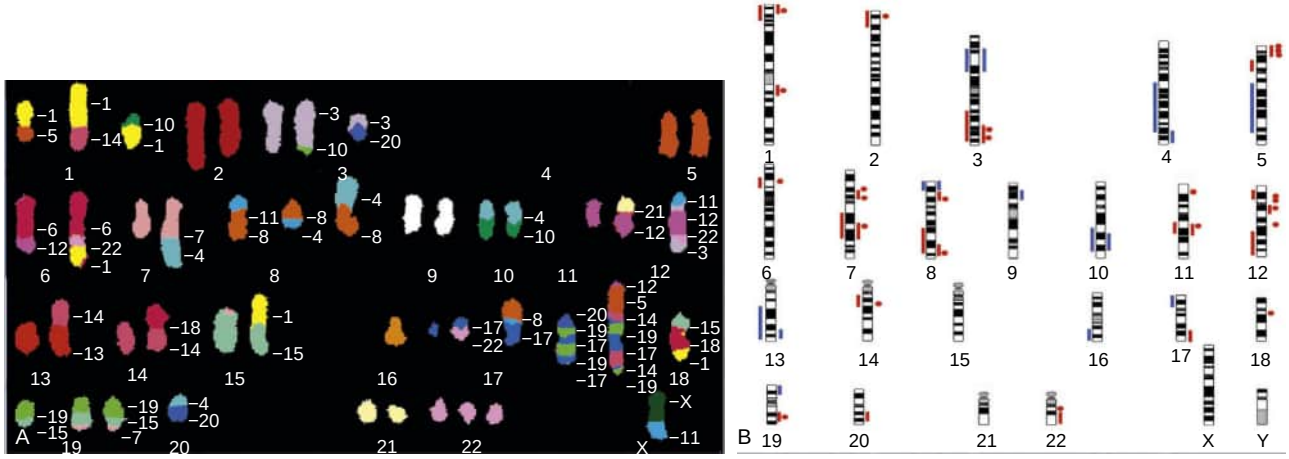

Figure 73.1 Chromosome and genomic changes in lung cancer. (A) Spectral karyotyping of a lung adenocarcinoma showing numerous numerical and structural chromosome changes. In this image, each color is specific to a certain chromosome; therefore, the chromosomes with two or more colors demonstrate rearrangements. In translocations, the origin of the genetic material is listed on the right of the chromosomes. (B) Summary of genomic imbalances reported in lung cancer. Small cell lung cancer is represented on the left of the chromosome idiograms; non–small cell lung cancer is represented on the right. Copy number gain is represented by *red bars*, focal amplification by *red dots*, and copy number loss by *blue bars*. (From Varella-Garcia M. Chromosomal and genomic changes in lung cancer. *Cell Adh Migr*. 2010;4[1]:100-106.)

direct their interaction with DNA, leading to recurrent and recognizable patterns of mutations in the genome called *mutation signatures*.[26] These have been reconstructed from statistical analyses of cancer genomes in smokers[27] and in *small cell lung cancer* (SCLC) in smokers.[28] The contribution of each signature to the mutational profile of individual cancer reveals associations with tobacco exposure and defective DNA maintenance processes such as mismatch repair mechanisms.

Identification of mechanisms underlying oncogenic transformation in epithelial cells remains a major challenge in cancer biology. Gaining insights into early tumor formation is also key to the development of chemopreventive strategies. The influence of smoking status in the clonal history of the tumors is important. The smoking mutation signature (signature 4) is characterized by a high proportion of C→A transversions.[26] Yet, over time, tumors from former and current smokers have shown a decrease in the proportion of C→A transversions in subclonal mutations compared to early clonal mutations, which suggests a relative decrease in the mutational burden attributed to smoking during tumor development.[25,29] The decrease in C→A transversions was followed by an increase in C→T and C→G mutations, which indicates *apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like* (APOBEC) activity.[26] APOBEC proteins are a group of cytidine deaminase enzymes associated with tumor heterogeneity and genome doubling.[30] Doubling of the genome leads to aneuploidy and subsequent chromosomal aberrations and genomic instability. This chromosomal instability mediates tumor heterogeneity and is associated with an increased risk of recurrence or death, as shown in the Tracking Non–Small-Cell Lung Cancer Evolution Through Therapy Consortium.[29] This also suggests that APOBEC mutagenesis may be playing a role in subclonal expansion in these tumors.

The effect of smoking on tumor development can be quite delayed and manifest only after late mutations allow them to emerge. Prolonged tumor latency after smoking has been identified in several studies. In a study conducted by De Bruin and colleagues, a tumor from a patient who stopped smoking 20 years before surgery bore the smoking signature in more than 30% of truncal mutations, which suggests that these events took place within a smoking tumorigenic setting more than 20 years ago.[25] Likewise, Jamal-Hanjani and colleagues reported seven patients who, although they had stopped smoking for several years before surgery, presented with a smoking mutational signature suggesting tumor latency for several years before the cancer manifested.[29] There was an association between the proportion of subclonal genomic alterations and recurrence.[29,31] Finally, many late driver mutations, which correspond to alterations reported in other tumor types, are involved in genome maintenance processes such as DNA damage response, chromatin remodeling, and histone methylation. These late mutations may remove constraints on the neoplastic genome, providing advantages to the emerging subclones, and enabling progression to later stages of the disease.[29]

DNA DAMAGE RESPONSE

The *DNA damage response* refers to the process by which the cell maintains the integrity of the genome after insult. This response engages critical enzymatic activity to recognize DNA damage and correct it. A robust DNA damage response suppresses cancer, whereas a failure in the response has been associated with cancer development. The largest *attributable risk* (i.e., risk explaining the outcome) to lung cancer development at the molecular level is the acquisition of mutations in oncogenic pathways. Mutations happen stochastically over time in the airway epithelium and may eventually modify critical signaling pathways.[32]

The most common DNA lesions from tobacco smoke exposure are DNA adducts (as discussed above) and secondary mutations, *reactive oxygen species* (ROS)-dependent formation of 8-oxo-deoxyguanosine, formation of DNA single and double-strand breaks and phosphorylated histone 2AX foci. Phosphorylated histone 2AX foci can be used as a simple assay indicative of DNA double-strand breaks. These alterations are repaired specifically by 8-oxoguanine glycosylase and base excision repair. A slight infidelity in the DNA replication and repair machinery can lead to a GC to TA *transversion*, a very common somatic mutation in cancer.

(A mutational *transition* is the substitution of similarly shaped bases [e.g., a purine for a purine] whereas a *transversion* is the substitution of differently shaped bases [e.g., a purine for a pyrimidine]). DNA damage may trigger apoptosis or lead to erroneous replication of the damaged DNA, causing mutations. Targeted or whole-exome sequencing can quantify genomic alterations.[33] Deregulated expression of DNA repair proteins, such as *poly (ADP-ribose) polymerase* (PARP), involved in single-stranded DNA break repair, has been studied in lung cancer as a possible biomarker and clinically useful target. Extensive DNA damage can lead to the depletion of intracellular NAD^+ and energy depletion–induced necrosis. PARP is specifically cleaved by caspases, preventing DNA repair and promoting apoptosis. PARP-1 is involved in base excision repair and has targeted therapies available[34] to destroy cancer cells by a *synthetic lethal approach* (i.e., when a combination of deficiencies in the expression of two or more genes leads to cell death; a deficiency in only one of these genes does not).

HOST TUMOR INTERACTION AND INFLAMMATION

Lung cancer can arise from a background of chronic inflammation. Chronic inflammatory mediators favor carcinogenesis, tumor growth, invasion, and metastasis. They can also deplete immune mechanisms that might limit tumor growth. The link between cancer and inflammation depends on pathways controlled by transcription factors such as nuclear factor-κB, STAT-3, and HIF-1 and on accumulation of tumorigenic factors in tumor cells and their microenvironment. STAT-3 and nuclear factor-κB boost tumor-associated inflammation, which can suppress antitumor immune responses. *Interleukin* (IL)-1, IL-6, tumor necrosis factor, and prostaglandin synthases enhance the inflammatory milieu by modulating the expression of tumor-promoting factors. Cancer may be an inflammatory disease after all.

The well-established link between inflammation and lung cancer risk is based on strong epidemiologic evidence that COPD confers a risk for lung cancer independent of smoking history.[35–37] Inflammation gene expression signatures are clearly associated with risk for lung cancer.[18,38,39] The reason some smokers develop COPD, some develop lung cancer, and some develop both diseases remains unclear.[40] Cigarette smoke contains high concentrations of oxidants and ROS together with thousands of different types of particles. Nuclear factor-κB activation and subsequent transactivation of inflammation-related genes appear to play a central role in both COPD and cancer.[41] How some smokers remain free of disease while others develop COPD or cancer may be determined by the activation of specific genes in response to cigarette smoke.[39]

Toll-like receptors (TLRs), which recognize a variety of pathogen-associated molecular patterns, are key to the initiation of the innate and adaptive immune responses. Recent evidence shows that functional TLRs are also expressed on a wide variety of tumors, suggesting that TLRs may play important roles in tumor biology, and are being evaluated as therapeutic targets.[42,43] Activation of tumor cell TLRs not only promotes tumor cell proliferation and resistance to apoptosis but also enhances tumor cell invasion and metastasis by regulating metalloproteinases and integrins. Moreover, the activation of TLR signaling in tumor cells induces the synthesis of proinflammatory factors and immunosuppressive molecules, which enhances the resistance of tumor cells to cytotoxic lymphocyte attack and leads to immune evasion. Thus, the neoplastic process may usurp TLR signaling pathways to advance cancer progression, which suggests that targeting tumor TLR signaling pathways may open novel therapeutic avenues.

Inflammation and tumor-infiltrating inflammatory cells have been shown to induce and help sustain tumor angiogenesis and sustain cellular proliferation.[44] In lung cancer, the chronic airway inflammation of COPD provides support for tumor growth.[45] Chemokines, or inflammatory cytokines, predispose to cancer by activating multiple pathways of tumor progression, including leukocyte recruitment and function, cellular senescence, tumor cell proliferation and survival, invasion, and metastasis.[46] *KRAS*-mutated models have also contributed to a better understanding of this process, because the inflammatory process accounts for immune evasion and aggressiveness of *KRAS*-mutated carcinoma.

Finally, early in tumorigenesis, major histocompatibility complex-1 antigen presentation is down-regulated at the tumor cell surface and becomes functionally impaired, which significantly weakens the ability of $CD8^+$ cytotoxic T lymphocytes to recognize the tumor cells.[47] In addition, *human leukocyte antigen* (HLA) *loss of heterozygosity* (LOH; loss of one functional allele) increases in the progression from adenocarcinoma in situ/minimally invasive adenocarcinoma to lung adenocarcinoma and correlates with loss of chromosome 6p.[48] HLA LOH is found in 40% of NSCLCs and is associated with high subclonal burden of *neoantigens* (i.e., novel antigens specific to the tumor), APOBEC-mediated mutagenesis, upregulation of cytolytic activity, and PD-L1 positivity.[49] The ability of a cancer cell to present neoantigens on its cell surface is required for a tumor-specific T cell–mediated antitumor immune response and successful cancer immunotherapies.[50] Tumor neoantigens are recognized by specific T cell receptors in the context of major histocompatibility complex molecules. They can arise from altered proteins as a result of mutations or from viral proteins. The impairment of tumor neoantigen presentation as a consequence of LOH in HLA class I has been suggested as a mechanism of immune evasion in NSCLC.[49] In that study, both lung adenocarcinomas and squamous cell carcinomas with HLA LOH acquired a higher mutational burden compared to tumors without HLA LOH, with a significant increase in subclonal mutations. Furthermore, tumors harboring HLA LOH were enriched in neoantigens predicted to bind the missing HLA alleles and expressed high PD-L1 staining on immune cells. Thus, HLA LOH may facilitate the subclonal expansion of cells harboring previously antigenic mutations that have become undetectable to the immune system. Taken together, these results suggest that a malignancy derived from epithelial cells needs to be considered as a process taking place within the tissue microenvironment, not within individual cancer cells, and that characterizing HLA LOH may have implications in immunotherapeutic approaches targeting neoantigens.

CELL OF ORIGIN

The study of the cell of origin aims to determine how cancer-initiating stem cells continuously renew and seed distant

sites and to understand the role of these cells in resistance to chemotherapies. Searching for the lung cancer cell of origin is highly controversial because true lung stem cells are still undefined in vivo, although basal cells,[51] club cells, and alveolar type II cells[52] are presumably responsible for the maintenance of the lung epithelium. Putative stem cell populations are identified with pluripotency markers like OCT4, NANAOG, SOX2, and KLF4.[53] Depending on the location in the airways, stem cells may vary. Proximally, the pseudostratified airway epithelium provides most of the cells explaining the development of squamous cell carcinoma. The exact phenotype and precursor have not yet been established, although basal cells are the presumed culprit. Cells expressing cytokeratin 5, cytokeratin 14, nerve growth factor receptor, and TP63 appear to maintain a risk of tumor development after smoking cessation, and we suspect some subpopulations of these cells are the precursors of tumors in the large airways.

Lung cancer primary stem cells are characterized by the expression of markers such as CD133, ALDH1A1, of higher levels of ABC transporters,[54] or of lung developmental pathways such as NOTCH and SHH. These cells have been shown to be tumorigenic and to possess clonogenic activity.[55] Identifying such progenitor cancer cells may uncover therapies to target these populations specifically.

SCLC is thought to develop from pulmonary neuroendocrine cells in the lung. The best evidence for this is from mouse studies in which Rb and p53 are deleted in specific cell types.[56,57] Mouse SCLCs often arise in the lung epithelium, where neuroendocrine cells are located, and the majority of early lesions are composed of proliferating neuroendocrine cells. Mice in which Rb and p53 are deleted in a variety of non-neuroendocrine lung epithelial cells do not develop SCLC.[58] Song et al. developed a genetic tool whereby a fusion protein was expressed specifically in the pulmonary neuroendocrine cells in mice, enabling manipulation of gene activity and lineage tracing of these cells. These cells were shown to form focal tumors with loss of *p53* and *Rb*.[59] This model allowed the careful study of SCLC biology and confirmation of the importance of pulmonary neuroendocrine cells.

Additional publications offer a new and critical molecular characterization of SCLC.[60] Rudin et al. reported a comprehensive genomic analysis of SCLC[61] with high-throughput sequencing techniques; they demonstrated that SCLCs are composed of multiple known and new molecular abnormalities. Exome capture sequencing analysis of 42 SCLC samples paired with normal samples identified 26,406 somatic mutations, 7977 of which would result in altered protein production. They confirmed known SCLC molecular alterations to genes such as *TP53*, *RB1*, *PIK3CA*, *CDKN2A*, and *PTEN*. In addition, they identified other genes coding for proteins with a wide array of cellular functions such as the Ras family regulator, chromatin-modifying enzymes, transcription regulators, kinases, and protein phosphatases of G-protein–coupled receptors. Further genetic mutational clustering identified specific pathways at the epicenter of SCLC pathogenesis, which included *phosphatidylinositol-3′-kinase* (PI3K), Hedgehog, NOTCH, mediator complex, glutamate receptor, DNA repair, and the SRY-related HMG-box genes (SOX) family. This study showed a high mutational frequency of several SOX genes and amplification and overexpression of SOX2 in close to 25% of the SCLCs analyzed. Lastly, they identified new mutations to genes coding for tyrosine kinases such as FLT1, FLT4, KDR, and KIT as well as several fusion proteins such as RLF-MYCL1 that could be potential therapeutic targets.

FIELD OF CANCERIZATION

Whereas lung cancer may originate from only one or a few airway epithelial cells, it is clear that exposure to tobacco smoke increases the risk of the entire bronchial tree to lung cancer, leading to the concept of field cancerization. Field cancerization was first proposed in the 1950s,[62] and its molecular correlates were later confirmed in the airways of human smokers.[63] Exposure to carcinogens, genetic predisposition, and the altered microenvironment contribute to the acquisition of multiple molecular aberrations simultaneously. Because the airway epithelium is the transformative organ in the field of cancerization, there have been multiple efforts to characterize the epigenetic,[64,65] genomic,[39] transcriptomic,[38,66] and proteomic[67] changes contributing to the tumorigenic process in the bronchial epithelium of individuals at risk for lung cancer.

Previously, early proteomic changes acquired in preinvasive lesions were found to be predictive of the presence of a lung cancer in the field of cancerization.[20,21] Yet, very limited information exists about the proteomic determinants of transformation of the bronchial epithelium. Bronchial airway epithelial cells transition from a quiescent state to a proliferative one after prolonged exposure to tobacco smoke. To investigate the mechanisms leading to the transformative events in the normal airway epithelium, changes at the protein level were identified by multidimensional liquid chromatography-tandem mass spectrometry.[11] The investigations demonstrated that the *Warburg effect*, described in the tumor cells more than half a century ago[68,69] as an altered metabolism in which the cells exhibit increased glucose uptake and lactate production even in the presence of oxygen and recognized as a hallmark of cancer,[2] can be identified in the cytologically normal bronchial epithelial cells of at-risk individuals, thereby implicating metabolic reprogramming early on in the pathogenesis of lung cancer. The results demonstrated profound proteomic alterations in the field of cancerization in individuals at high risk for lung cancer and dramatic metabolic reprogramming very early in the process. Dysregulated protein expression provided new insights into the pathogenesis of lung cancer and the hope to stratify at-risk individuals. These findings also may refine the risk assessment and provide new targets to be considered for prevention strategies.

Developing and implementing precision prevention approaches has been constrained by our limited understanding of precancer biology, in contrast to the extensive study of advanced disease. Understanding how precancer leads to cancer is the subject of active investigation and has been accelerated by the PreCancer Atlas initiative.[70,71] The progression of squamous dysplasia (also found in the oropharynx, larynx, esophagus, and cervix) is better understood[72] than that of the preinvasive lesions of the small airways. This is mainly due to the difficulty in accessing the lesions in the distal airways. More recently, the behavior of precursor lesions and early cancers is being

actively investigated,[48,73–76] which may help understand how progression can be stopped at the preinvasive stage. In one such study, it was shown that adenocarcinoma in situ, although preinvasive, has the full genomic alteration profile displayed in invasive lung adenocarcinoma.[76] Some molecular prognostic signatures that will require independent validation were also identified and offer a novel opportunity to study these tumors in detail.

The interplay between the transforming airway epithelium and development of preinvasive lesions happens in a complex immune microenvironment. The interactions between the host and the environment, including airway microbes, are dynamic, and all contribute in shaping an immune response. Recent investigations from Krysan et al. revealed the clonal development of neoantigens among precursor lesions likely to progress into cancer.[75] They used whole-exome sequencing to evaluate potential immunogenic epitopes associated with somatic mutations and demonstrated the presence of significant numbers of premalignancy-associated neoantigens and an altered adaptive immune surveillance in response to them. These observations suggest that the immune system is able not only to recognize early cellular transformation, but also to mount an antitumor immune response. The determinants of this antitumor evasion to progression-associated neoantigens and the relevance of immune surveillance in lung cancer are topics of intense research.

TUMOR HETEROGENEITY

Intratumor heterogeneity represents a major challenge because it can result in inaccurate diagnosis, prognosis, and prediction of response to treatment. Lung cancer is a very heterogeneous disease both spatially and temporally, with one of the highest mutational burdens across different cancer types.[26,77] Tumor heterogeneity can be studied using an evolutionary approach. In 1976, Peter Nowell applied evolutionary models to study tumor progression and treatment failure and proposed a clonal evolution model in which a tumor arises from a single mutated cell ("clone") and progresses as a result of subsequent alterations, in which more aggressive clones replace the original clones.[78] Advances in new sequencing technologies allowing genome-wide sequencing have elucidated a more complex clonal structure than previously thought.[26]

Several models of evolution of mutations have been proposed to understand and attack this constantly shifting heterogeneous process. In *neutral* evolution, all driver alterations are thought to be present in the original neoplastic cell and subsequent alterations are neutral, meaning that there is an absence of selection, and heterogeneity arises from stochastic processes as a by-product of tumor progression.[79] In *punctuated* evolution, it is postulated that tumor heterogeneity is generated in the early development of the neoplasia, followed by neutral evolution.[80,81] *Branching* evolution, also known as the trunk-branch model, is currently the preferred model and is defined by the gradual accumulation of driver mutations in subclonal populations.[82] In this model, the "trunk" of the tumor consists of progenitor clones bearing early somatic alterations driving tumorigenesis. Those early alterations are potentially ubiquitous events. In contrast, later somatic events are heterogeneous events present in the subclones that make up the "branches" of the tumor and that drive tumor progression. Sequencing multiple regions of the same tumor has been the most successful strategy to investigate intratumor heterogeneity and clonal evolution in lung adenocarcinoma to date.[25,29,31] The studies suggest that intratumor heterogeneity and branched evolution might be a universal phenomenon across lung adenocarcinomas.

Molecular analysis of lung tumors also supports the existence of temporal tumor heterogeneity. Most known driver alterations have been mapped to the trunks of the tumors, which suggests that canonical alterations (i.e., changes in well-established pathways) arise early in tumor evolution. Truncal known driver mutations almost always appear before genome duplications, suggesting a particular role in tumorigenesis. On the other hand, truncal genome doubling events take place before subclonal diversification but after the acquisition of driver mutations, which suggests that chromosomal instability may be a crucial step that induces copy number alterations followed by a burst of mutational heterogeneity. Furthermore, the association of drug resistance and relapse with chromosomal instability[83] supports the hypothesis that the ability of chromosomal instability to generate extensive subclonal divergence could be compromising the effectiveness of therapeutic strategies targeting truncal driver mutations.[25] Besides, data from these studies suggest that certain alterations in non-canonical cancer genes (i.e., genes in alternate pathogenic pathways) may also drive tumor development and subclonal diversification.

The study of intratumor and intertumor heterogeneity has also been dramatically enhanced by single cell analysis. This may happen at the transcriptomic (single cell RNA sequence), genomic (single nucleotide variant, copy number variant), or proteomic (mass cytometry) level (Fig. 73.2). These approaches allow the more comprehensive understanding of key changes "cell by cell" rather than at a population level. Subpopulations of cancer cells and immune cells can be identified,[84,85] especially with rare antigen-specific T or B cells, and their unique properties untangled. This field is only beginning and is expected to advance our understanding of tumor biology.

TUMOR INVASION

Invasiveness has been considered a hallmark of cancer because it represents the aggressive nature of tumors. The invasive and metastatic stage of cancer progression correlates with poor clinical prognosis and represents a major barrier to treatment. Metastatic tumor cells go through stages of detachment from the primary tumor sites, invasion into circulation, extravasation into the appropriate secondary site, and establishment of a microenvironment supporting their energetic requirements. The ability of a preinvasive lesion to progress into an invasive disease is determined by a variety of tumor and host factors. *Next-generation sequencing* (NGS) studies have deduced the sequence of events in which cancer cells acquire genomic alterations.[29,86] Key evolutionary alterations in the trajectory of tumors have been identified[87] and include mutations in *TP53, KRAS, EGFR, BRAF*, histone methylation enzymes, APOBEC enzymes, and DNA damage response genes, as discussed earlier. Cell motility and invasion enable tumor cells to penetrate

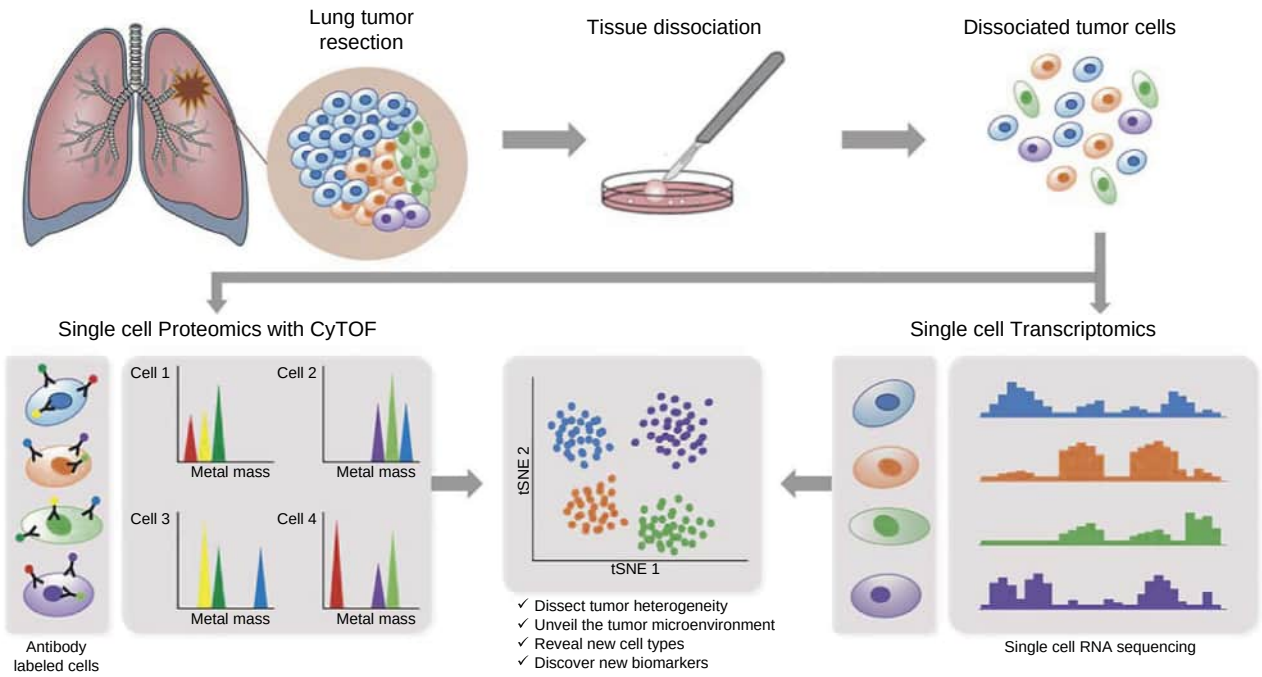

Figure 73.2 Investigating intratumor heterogeneity and the tumor microenvironment with single cell approaches. A lung tumor resection is dissociated into single cell suspension that can be used in different applications. Mass cytometry (CyTOF) uses metal-labeled antibodies to detect a limited number of proteins in cells. Single cell RNA sequencing reveals the transcriptome of each individual cell. Both can be analyzed through computational strategies to dissect intratumor heterogeneity.

basement membranes and extracellular matrices and to migrate into adjacent tissues. Invasive tumor cells have dysregulated adhesion and motility in response to extracellular signals from growth factors and cytokines.

The primary process by which cancer cells are able to migrate and establish a niche is known as *epithelial to mesenchymal transition* (EMT).[88] The reverse process, *mesenchymal-epithelial transition* (MET), allows the cancer to establish in a different microenvironment.[89] Cancer cells activate EMT to enable metastasis and niche formation, events that remain relatively rare in primary tumors.[90] Invasion also involves other cell types, such as macrophages, that contribute to immune suppression and tumor progression. For example, tumor-associated macrophages supply growth factors to cancer cells. Finally, metastasis does not necessarily happen only in the final stages of cancer progression and can also be found before the primary site is discovered. Tumor cells may undergo EMT in the early phases of tumor initiation because tobacco smoke is known to induce EMT.[91] Thus, invasion is a process that may involve EMT at multiple steps in tumor progression.

CLINICALLY RELEVANT MOLECULAR TARGETS IN LUNG CARCINOMA

Tumor heterogeneity is also reflected at the epidemiologic level in the diversity of different targetable driver mutations in lung carcinoma that co-opt signaling mechanisms to drive uncontrolled growth and metastasis. This topic is discussed later in this chapter, as well as how therapeutic targeting of these pathways can lead to improved outcomes in these mutated and targetable areas. Of note, PD-L1 expression is occasionally considered a "targetable" finding, but the theory and practice of immunotherapy are very different from the targetable pathways discussed here. That said, the immune environment in oncogene-driven carcinomas, particularly in never smokers, may be distinct, and immunomodulatory therapy may be less effective in the setting of most mutation-driven lung carcinomas than in the more heterogenous lung tumors without single driver mutations.[92]

Driver mutations are mutations in pathways that confer evolutionary growth and survival advantages to tumors and, once present, are highly clonally preserved. The pathways described below all contain driver mutations or fusions exploiting these pathways for tumor growth and survival. An important point regarding targetable and driver mutations in NSCLC is that they are relatively rare but have a great deal of clinical importance for individual patients with metastatic disease. These mutations also convey dramatically different prognoses and overall survival with treatment than lung carcinomas without these defined drivers. Thus, NGS of every highly locally advanced or metastatic adenocarcinoma has become the standard of care on which to base appropriate treatment decisions.[93] NGS testing is affordable and cost-effective in the upfront setting for metastatic lung adenocarcinoma.[94]

NGS refers to a variety of massively parallel techniques of genetic sequencing that have dramatically reduced cost and increased sequencing speed. In genetic testing of tumor

samples, NGS can sequence up to hundreds of genes of interest and may include RNA sequencing to identify gene fusions or rearrangements, mutations, and copy number alterations. Panel-based NGS is superior to and more cost-effective than single gene testing because it allows for testing of many genes at once in a single test, including rare mutations for which single gene testing may not be available or cost-effective. NGS testing also facilitates clinical trial enrollment for novel targeted therapies by allowing for detection and enrollment or rare mutations. NGS is vital because rare but targetable mutations may make a dramatic difference in treatment options and outcomes.

Tumoral sampling, or alternatively, liquid biopsy (e.g., a blood sample analyzed for circulating tumor DNA by sequencing), for *epidermal growth factor receptor* (EGFR) or other mutation testing needs to be performed both at initial diagnosis and with disease progression. Another important issue with targetable mutations is *central nervous system* (CNS) involvement. Some mutations or fusions such as ALK+ disease have a predilection for metastasizing to the CNS. Also, CNS penetration of targeted therapies may be suboptimal, making the CNS a common "sanctuary" site for recurrence or progression. Figure 73.3 and Table 73.3 summarize the relative contributions of multiple currently targetable and common mutations in NSCLC and note currently available targeted agents.[3] The frequency of specific NSCLC mutations varies significantly by patient population; depending on the population, approximately 50% of non-squamous NSCLC patients have some form of driver mutation present.[13]

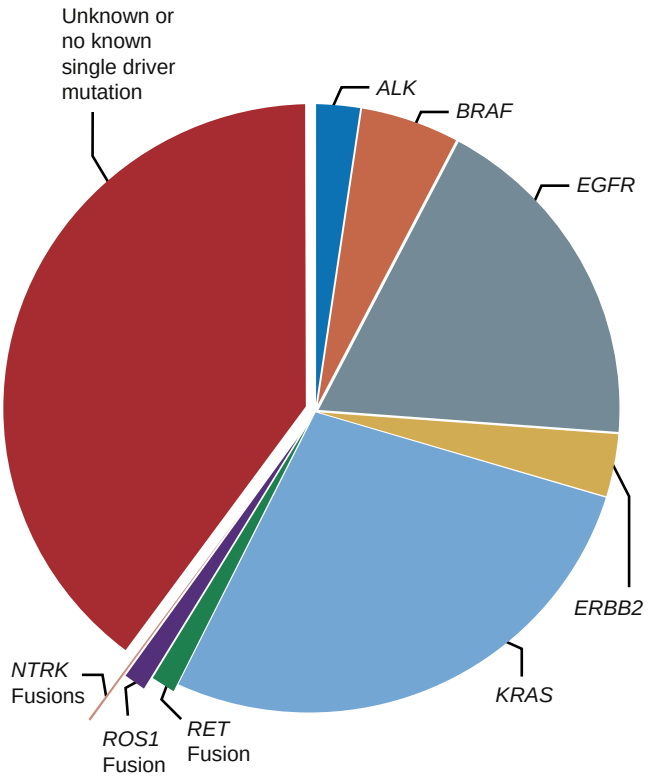

Figure 73.3 Common and targetable mutations/fusions in *non–small cell lung cancer* (NSCLC). Relative percentage of the most common targetable mutations/fusions in NSCLC.[130] This is based on data available from the American Association for Cancer Research Genomics Evidence Neoplasia Information Exchanger (GENIE) consortium. It is important to note that mutational frequency for different targets varies a great deal based on population characteristics including geographic origin, environmental exposures, and tobacco exposure. Approximately 50% of nonsquamous NSCLC have a known driver mutation, but this varies based on sample population.[13]

EGFR/HER2 PATHWAY

The EGFR pathway is the best characterized of the major targetable pathways stimulating lung carcinoma and serves as an excellent example of a targetable mutation with highly effective and specific therapies. As noted in Figure 73.4, EGFR is a receptor-activated tyrosine kinase, which activates a signaling cascade including ERK, Akt, and c-SRC. Constitutive/continuous activation leads to inappropriate production of cyclin D1 and ongoing inappropriate activation of proliferation and survival signals. EGFR (ERBB1) and the related *human epidermal growth factor receptor-2* (HER2; ERBB2), are members of the ERBB family of receptor tyrosine kinases. As with most of the described drivers, EGFR and HER2 serve as predominant drivers of proliferation and are rarely found with other driver mutations in new lung cancer diagnoses. *EGFR (ERBB1)* mutationally driven NSCLC is also the most common targeted mutation in lung cancer, arising in 9–46% of cases depending upon geographic origin and patient characteristics.[95,96] There are multiple primary mutations or genetic alterations that lead to aberrant pathway activation. The most common mutations are *EGFR* L858R (on exon 20) and exon 19 deletions. Mutations in the related gene *HER2 (ERBB2)* also lead to abnormal activation of the pathway via PIK3CA and Akt activation and act as oncogenic drivers. *HER2 (ERBB2)* is mutated in approximately 3% of NSCLC patients.[3] Most common in breast carcinoma, *HER2 (ERBB2)* amplifications are also seen in a rare subset of lung adenocarcinomas and influence initial care options.

Table 73.3 NCCN Recommended Selected Targeted Therapies for Driver Mutation–Driven NSCLC

Driver Genotype	Selected Targeted Therapies
ALK fusions	Alectinib Brigatinib Ceritinib Crizotinib Lorlatinib (second-line therapy)
BRAF	BRAF inhibitor + MEK inhibitor Dabrafenib Trametinib Vemurafenib Cobimetinib
EGFR	Osimertinib Erlotinib Afatinib Dacomitinib Gefitinib
ERBB2	Ado-trastuzumab emtansine
KRAS	AMG 510 (under investigation)
NTRK fusions	Larotrectinib Entrectinib
RET	Selpercatinib Pralsetinib
ROS1 fusions	Crizotinib Entrectinib Ceritinib Lorlatinib (second-line therapy)

NCCN, National Comprehensive Cancer Network; NSCLC, non–small cell lung cancer.

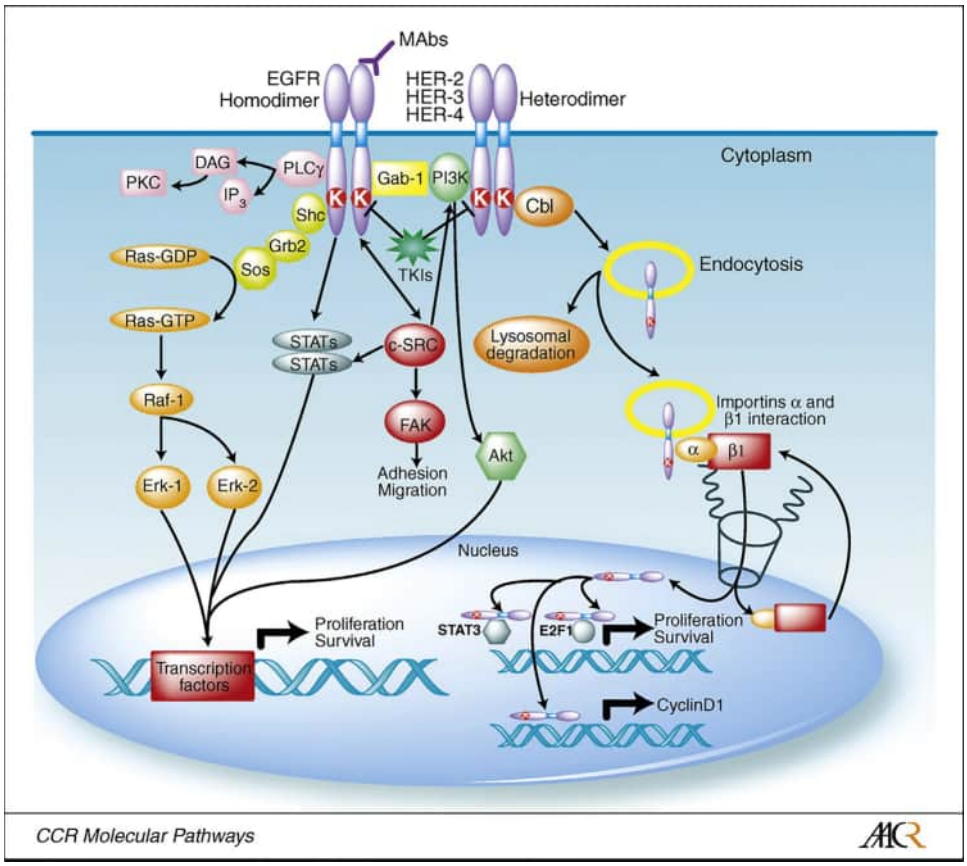

Figure 73.4 Summary of Ras, EGFR, and HER2 signaling. Note the convergent signaling between Ras/KRAS, EGFR, and HER2 signaling pathways as well as downstream ERK and AKT conserved pathways. (From Scaltriti M, Baselga J. Epidermal growth factor receptor pathway: a model for targeted therapy. *Clin Cancer Res*. 2006;12[18]:5268–5272.)

Targeted Agents and Clinical Concerns

EGFR alterations are one of the best-established targets of therapy in mutationally driven lung carcinoma. There are multiple generations of *tyrosine kinase inhibitors* (TKIs) focused on targeting the L858R mutation and exon 19 deletions, which are the primary EGFR-TKI sensitizing mutations. Responses with other less common mutation sites may vary based on the specific mutation site and the specific TKI. First-generation TKIs targeted at EGFR include erlotinib and gefitinib. These reversibly bind the adenosine triphosphate binding site of the receptor and prevent activation. Toxicities include those related to inhibition of wild-type EGFR, such as hand-foot syndrome (i.e., redness, swelling, pain and tingling in the palms and soles), rash, diarrhea, and gastrointestinal upset. Second-generation inhibitors such as afatinib irreversibly bind the adenosine triphosphate binding site; however, their clinical use is limited by their significant and more frequent toxicity. Multiple mechanisms of resistance exist for these first-generation and second-generation medications including most commonly the T790M mutation (responsible for approximately 60% of resistance in this setting).[97] This resistance is thought to be secondary to steric hindrance inhibiting binding of first- and second-generation agents in the EGFR binding pocket. Third-generation TKIs aimed at EGFR have preferential binding characteristics for the mutated receptor. This results in a significantly improved side effect and toxicity profile with improved clinical efficacy and tolerability. Third-generation TKIs, such as osimertinib, are targeted at mutated receptors including that caused by T790M and are highly effective after resistance has developed to first- or second-line TKIs. Recent data have also demonstrated superior performance in the first-line setting as well. Optimal sequencing of therapy still remains somewhat unclear, although the improved tolerability and efficacy favor third-generation TKIs as first-line therapy.[98]

Major mechanisms of resistance include focal mutations in *EGFR* (e.g., T790M, C797S), or amplifications or alterations in the genes coding for other crosstalk pathways (*PIK3CA, KRAS, MET* amplification), or conversion into SCLC. Serial biopsy and NGS are vital to discover the specific mechanism of resistance responsible for growth in an individual patient and to guide further therapy. Strategies to compensate for resistance are being tested in clinical trials, including combination therapy with inhibitors of other pathways, such as MET, alongside EGFR inhibitors. Conversion into SCLC is a mechanism of resistance with a dismal prognosis.

Targeted agents for the related HER2/ERBB2 pathway include trastuzumab, which is primarily used alongside first-line combination chemotherapy. Other agents such as ado-trastuzumab emtansine, a targeted antibody-drug conjugate, are options, though responses are lower in lung cancer compared to breast carcinomas.

Prognosis and Outcomes

Compared to NSCLC with nontargetable mutations, metastatic EGFR-mutated NSCLC has a significantly better prognosis, with most patients with metastatic disease living

longer than 18 months (though still with limited 5-year survival).[99] The frontline use of third-generation inhibitors, with an approximately 19-month median progression-free survival and response rates of approximately 80%, will likely continue to improve outcomes.

KRAS PATHWAY

KRAS and its associated genes are some of the most commonly mutated genes in multiple human carcinomas, including lung, gastrointestinal, and pancreatic carcinomas. *KRAS* is a member of the RAS superfamily (see Figure 73.4). *KRAS* acts as a molecular switch with a guanosine triphosphate (active) and guanosine diphosphate (inactive) state; normally, *KRAS* remains predominately in the inactive state. *KRAS* mutations, seen in approximately 11–30% of lung cancers, lead to increased time in the activated state and the propagation of growth and survival signaling via multiple synergistic mechanisms. *KRAS* signaling also enhances the tumor microenvironment; it can remodel the surrounding stroma and lead to cytokine production impairing immune responses.[100]

Most mutations in *KRAS* are in codons 12, 13, or 61. In lung adenocarcinoma, the most common *KRAS* mutation is the G12C mutation. These mutations are thought to block guanosine triphosphate hydrolysis or to slow or decrease the conversion to the inactive state, and thereby shift the KRAS molecule to an active configuration leading to abnormal proliferation, survival, and stroma modulation favoring tumor growth and comparative immune privilege.

Targeted Agents and Clinical Considerations

KRAS is a challenging and evolving target compared to the other mutations on this list. Unfortunately, there are no *U.S. Food and Drug Administration* (FDA)-approved *KRAS*-targeting drugs, although a novel inhibitor, AMG 510, is undergoing "fast track" evaluation and multiple new medications are in clinical trials.[101,102] AMG 510 is a novel steric inhibitor that binds in a selective and irreversible manner to the *KRAS* G12C[103] protein, maintaining *KRAS* in the inactive state. Data are still preliminary and, as of this writing, in abstract form, but a disease control rate of 100% (stable or partial response to therapy) was observed in the first 23 patients with initial evaluation. CNS progression is a concern, and additional clinical trials are ongoing.

Prognosis and Outcomes

KRAS may be a poor prognostic indicator for chemotherapy response, though the data from retrospective clinical trials are mixed. Recent data seem to indicate that *KRAS* status is less informative than PD-L1 marker status for predicting response to immunotherapy.[104]

ALK/ROS1/NTRK GENE FUSIONS

The *anaplastic lymphoma kinase (ALK)* gene codes for a receptor tyrosine kinase. It is highly expressed in nervous system development, with limited expression in most normal adult tissue.[105] In carcinoma, the *ALK* gene is coupled with a gene rearrangement partner such as *EML4* (most common in NSCLC), and these partner fusions lead to increased expression (via the fusion partner promoter) and increased or constitutive activation (via partner protein domains). These *ALK* fusions are the driver mutations in approximately 3–7% of NSCLC.[106] Of note, the downstream activation pattern may be dependent upon the fusion partner. In lung cancer, with the classic *ALK-EML4* fusion, there is increased downstream proliferation and survival signaling via multiple pathways including ERK, PI3K, AKT, JAK-STAT, RAS, and MEK pathways.

Targeted Agents and Clinical Considerations

Crizotinib, a TKI originally designed to target MET, was the first approved *ALK*-directed therapy, showing excellent initial response rates up to 74% and a *progression-free survival* (i.e., the time after a given treatment that cancer growth remains at least a stable size) of up to 11 months. More potent second- and third-generation *ALK* inhibitors are now available and are preferred in the first-line setting for *ALK* fusions. Outcomes with second-generation *ALK* inhibitor alectinib are excellent, with median progression-free survival of 34 months when given as first-line therapy.[107] Unfortunately, despite excellent initial response rates, the tumor still recurs, though the median survival with appropriate choice and timing of therapy, so-called *treatment sequencing,* after diagnosis of metastatic disease may exceed 7 years. Mechanisms of resistance in *ALK*-mutated tumors most commonly arise from secondary resistance mutations in the *ALK TKI* portion of the fusion. Resistance patterns and susceptibility to second- and third-generation agents vary depending upon the mutation sites. As with *EGFR* mutations, once a tumor progresses, repeat tumor biopsy and NGS are vital to guiding therapy. With NGS, the right therapy can be given at the right time to treat a patient despite mutations leading to resistance to prior drugs. Targeted medications have different resistance mutations, and giving these drugs in the appropriate order (i.e., treatment sequencing) allows for longer-term responses before a tumor is resistant to all available therapies. Given the excellent response rates with treatment, identifying and starting therapy even when patients have poor functional status is vital in these uncommon populations. Even bedbound patients with poor functional status may have dramatic improvement with therapy if their poor functional status is due to their carcinoma.

The *c-ros oncogene (ROS1)* codes for the protein ROS1, a tyrosine kinase receptor with significant homology/similarity to ALK. ROS1 fusions account for 1–2% of NSCLC driver mutations.[3] As an oncogenic driver similar to ALK, it is found as a fusion protein fused to multiple potential gene variant partners, with a greater diversity of fusion variants than is found with ALK.[108,109] Similar to ALK, there are multiple generations of TKIs available in the ROS1+ setting, and crizotinib is a viable first-line option. Initial therapy is usually crizotinib with an initial *overall response rate* (i.e., the percentage of patients whose tumor shrinks in response to treatment) of greater than 70% and a median overall survival of 51 months for metastatic disease, based on the PROFILE trial.[108] This is in stark contrast to the poor prognosis of traditional NSCLC. CNS metastases are a common theme in ALK and ROS1+ disease and remain an issue of concern for long-term prognosis.

Gene fusions leading to aberrant gene activation are a conserved theme in NSCLC and other carcinomas. They are

rare but have a very large impact on treatment options. The most recent example of this is the discovery of *NTRK* fusions in NSCLC. These mutations are very rare and account for only 0.1–1% of NSCLC, but these patients have excellent responses to targeted therapy with two targeted agents recently approved, entrectinib and larotrectinib. These FDA approvals follow a trend in which approvals for targeted therapies are increasingly *disease agnostic*, meaning that they address a specific mutation regardless of the tumor type. This demonstrates a common theme for some oncogenic drivers where mutational signaling, not the cancer histology, drives the disease and patient outcomes.

BRAF

BRAF mutations (most commonly V600E) are present in approximately 1–3.5% of NSCLC.[110] BRAF is an intracellular (not a receptor) protein kinase in the Raf family whose activation leads to downstream *mitogen-activated protein kinase* (MAPK) and MEK activation with Akt and ERK family involvement. The most common currently targetable mutation is the V600E mutation found in some NSLC as well as in many melanomas (≈50%). This mutation allows signal transduction of BRAF as a monomer and dramatically increases its kinase activity by several hundred-fold. These changes lead to constitutive activation and downstream proliferation and survival signaling driving tumor progression.[110] This V600E mutation is a sensitizing mutation for therapy with combined BRAF and MEK inhibition or inhibition of BRAF alone. The strong clinical preference is combined therapy with a MEK inhibitor such as trametinib and a BRAF inhibitor such as dabrafenib. This combination prevents early resistance via changes in MAPK signaling. This MEK blockade also reduces the risks of inadvertent epidermal skin squamous cell carcinoma formation from synergistic skin baseline RAS mutations and paradoxical BRAF inhibitor-induced MAPK signaling in the skin.[111] Clinical outcomes with targeted therapy given as first-line treatment were excellent with a greater than 70% clinical control rate (stable disease + overall response) and median duration of response of approximately 10 months.[112]

MET/PIK3CA

Resistance may be mediated by multiple vital signal transduction pathways that are either independently present or interact with the above targetable mutations. Signaling via MET, a tyrosine kinase receptor, is one such resistance pathway. When phosphorylated, MET activates multiple pathways including PI3K, AKT, and RAS. Of note, the ligand for MET is often expressed by stromal cells and may stimulate activation of wild-type MET. In lung carcinoma, overexpression of wild-type MET has been described as a resistance mechanism for EGFR-mutated lung carcinoma.[113] MET overexpression may be seen in 24–40% of NSCLC.[114,115] Clinical trials are in progress to evaluate MET inhibition alongside EGFR TKIs for management of resistance. The MET inhibitor capmatinib received accelerated FDA approval for the treatment of MET exon 14 skipping mutation-positive lung carcinoma based on the GEOMETRY trial, with an overall response rate of 68% in the first-line setting and a tumor response duration of greater than 12 months.[116] Clinical trials continue with other MET inhibitors for this indication.[117]

The PIK3CA pathway is another highly conserved signaling pathway often with mutations coexisting alongside other patterns of mutation in NSCLC. PIK3CA mutations are highly represented among squamous cell carcinomas, but the full prognostic import is still unclear.[118] PIK3CA and AKT targeting is being explored in clinical trials in NSCLC but there remains a good deal of work to be done.

SCLC has unfortunately lagged behind in the discovery of targetable mutations. SCLC remains best defined by nearly universal alterations in Rb and p53 activity or expression. However, there is ongoing work related to subtyping SCLC cellular subpopulations,[119] including multiple neuroendocrine or mesenchymal-like cells. These cells have differentiation markers such as NEUROD1, YAP, and ASCL1 and may have differential responses to different signaling targets. Expanding our understanding of how these cellular subpopulations survive and interact to contribute to tumor heterogeneity may lead to new targeted therapies for SCLC.

Overall, mutationally targeted therapy, when appropriately selected, has profound advantages in tolerability and efficacy over traditional chemotherapy for appropriate NSCLC patients and serves as a bright star in the NSCLC landscape with improving outcomes and a growing understanding of the complex signaling underpinnings of targeted therapy resistance.

IMMUNOTHERAPY AS TARGETED MOLECULAR THERAPY?

The use of immuno-oncology has been revolutionary in the treatment of lung cancer. In particular, the use of immunomodulatory agents targeting PD-1 and PD-L1 are standard of care therapies in most locally advanced or metastatic lung carcinomas. However, they are not traditionally referenced as targeted therapies because, unlike the targeted therapies noted above, they do not interfere with intrinsic tumoral signaling pathways and disrupt tumor growth or survival signals. Instead, they modulate the patient's overall immune function and disrupt the host-tumoral environment to improve the antitumor immune response. This topic is covered more extensively in Chapter 77, which focuses on lung cancer treatments.

FUTURE CHALLENGES IN TARGETED THERAPY IN LUNG CARCINOMA

Despite dramatic improvements in care, there remain significant challenges in improving targeted therapy for lung carcinoma. The main challenges for this therapy include determining optimal implementation, recognizing tumoral evolution and resistance, early detection of lung cancer, monitoring the patient with lung cancer, and applying targeted therapy to SCLC. These challenges directly link to the molecular biology of lung cancer reviewed above and offer opportunities for the lung cancer researchers of the future.

Implementation remains a challenge in targeted therapy for lung carcinoma. Because of the genomic

instability associated with lung cancer, many different signaling pathways may drive tumor progression. These include rare but targetable mutations such as NTRK or ROS1. Full NGS tumor panel testing is needed to find rare mutations or fusions. Despite National Comprehensive Cancer Network recommendations, these tests are not always performed in community-based oncology practices due to cost considerations.[93] However, NGS panel testing should be offered to all metastatic NSCLC patients.[120] Cost-effectiveness analysis suggests that broad next-generation testing may be more cost-effective than more limited testing, and community-based use of NGS is growing. Outreach for rare but very treatable mutations remains vital.[121] An example would be *NTRK* fusions. These are rare (≈1/1000 patients), and testing can require both DNA and RNA sequencing by NGS panels. Thus, this testing will not benefit 999 out of 1000 lung cancer patients, but it can profoundly improve quality and quantity of life for the one positive lung cancer patient, due to excellent targeted therapies. The challenges of biopsy and re-biopsy can complicate the testing process because many patients may not be good candidates for re-biopsy needed to guide further treatment.[122] This means that patients may receive suboptimal therapy after development of resistance. The lack of biopsies can also limit enrollment for clinical trials to expand treatment options for lung carcinoma. Liquid or plasma-based biopsy with sequencing offers potential to improve options, though it has important limitations of sensitivity depending upon disease burden. This technology is rapidly improving to meet this challenge.

Resistance to therapy is the existential issue in treating lung cancer. The same intra-tumoral heterogeneity that allows for tumor evolution also drives resistance and recurrent disease. Better understanding of how tumor subpopulations shift and communicate at the single cell level may be vital to design better clinical trials using drug combinations for treatment. Without this understanding, structuring appropriate combination therapies in these highly diverse tumors will continue to be challenging. A useful if simplistic analogy may be found in the use of combination therapy in treating tuberculosis and HIV to minimize multidrug-resistant clones and to force the pathogens into genetic changes that are suboptimal for growth.

Early detection of lung cancer is another challenge in this mutationally driven tumor patient population. Although early detection led by low-dose chest computed tomographic screening is a dramatic success story in lung cancer, it has not been able to address the significant populations of light or never smokers who are often affected by lung cancer driven by known oncogenic targets. Implementing lung cancer screening also carries risks of false-positives and increased population morbidity. Liquid biopsy is far less sensitive in the early detection setting.[123] Thus, many patients with targetable mutations are found with metastatic disease. This remains a clinical and scientific challenge.

Monitoring patients for early recurrence is a related problem given the low level of disease. The use of liquid biopsy, however, has become an attractive modality for monitoring disease progression and response to therapy.[124,125] As technology and sensitivity improves, liquid biopsy may contribute to risk stratification for computed tomographic screening,[126] thereby personalizing the management of nodules and reducing the risks of false-positive testing.

SCLC is the most aggressive and rapidly lethal lung carcinoma. Taken by itself, it is the sixth leading cause of cancer death, on par with all of leukemia. Unlike NSCLC, it has initial excellent responses to therapy but almost inevitably recurs with metastatic disease resistant to therapy. Advances have been made with immunotherapy, but mutationally targeted therapy for SCLC lags far behind NSCLC. SCLC is notorious for its cellular plasticity and heterogeneity with multiple coordinating cellular subpopulations supporting metastasis and later chemotherapy resistance.[127–129] Single cell analytic tools are needed to understand how molecular subtypes function and communicate in SCLC in order to disrupt this communication and lead to targeted killing of vital tumor subpopulations.[60]

Acknowledgments

We thank Maria Fernanda Senosain, graduate student in Dr. Massion's laboratory, for providing Figure 73.2.

Key Points

- Lung cancer arises from epithelial cells after a long series of metabolic, epigenetic, and genetic alterations. Mutation signatures, such as those caused by smoking, are associated with the disease process. The cell of origin of lung cancer is still under investigation.
- Most carcinogens damage DNA in a specific manner to induce aberration in the replication machinery and the repair process, causing genomic instability.
- Next-generation sequencing of targetable driver genes is the standard of care in the management and treatment of metastatic *non–small cell lung carcinoma* (NSCLC). Implementation and use of broad panel–based next-generation sequencing of NSCLC is cost-effective and leads to life-changing treatment options for many lung carcinoma patients.
- Targetable mutations in NSCLC can vary in frequency based on population but can have a dramatic impact on optimal treatment options and prognosis.
- Driver mutations direct the malignant process by giving selective advantage to clones of cells; driver mutations are now identified in many receptors and intracellular signaling molecules, including *EGFR/HER2*, *KRAS*, *ALK/ROS1/NTRK* gene fusions, and *BRAF*.
- Repeat liquid or solid biopsy and sequencing of tumors after recurrence are vital in NSCLC with targetable mutations to adjust therapy for specific resistance patterns.
- Prognosis for many targetable mutations in NSCLC is excellent; however, resistance is inevitable and combination or sequential therapy is important to address resistance.
- Small cell lung cancer has no known targetable mutations to date, though it is nearly universally associated with p53 and Rb mutations.

INTRODUCTION

Lung cancer is the leading cause of worldwide cancer death, and its mortality is projected to increase sharply from about 1.7 million new deaths per year in 2018 to nearly 3 million deaths per year by 2035,[1] with increases expected in all World Health Organization regions. Lung cancer mortality is anticipated to increase the most in the Western Pacific Region, where deaths are expected to more than double from 750,000 to 1.5 million deaths. The increasing death rates in most of the world, with some notable exceptions in North America[2] and Northern Europe,[3] reflect the ongoing tobacco use epidemic along with aging of the world's populations. Lung cancer remains the most common cause of cancer death in the United States, with an estimated 142,670 deaths expected in 2019. The overall death rate in the United States has decreased by nearly 50% since the peak in 1990, reflecting reductions in harmful exposures from smoking, environmental and occupational exposures, and improvements in earlier detection, management, and treatment of lung cancers.

Despite the reduction in incidence in the United States, lung cancer remains a major public health concern both in the United States and worldwide. Survival following a lung cancer diagnosis remains poor, with a 5-year survival rate of about 20%. The 5-year survival rate has changed little until recently because lung cancers are most often diagnosed at advanced stages when treatment is less effective.[4,5] Only recently has there been evidence that screening for lung cancer using low-dose computed tomography is an effective means of reducing mortality.[6] In 2013 the U.S. Preventive Services Task Force issued a recommendation for lung cancer screening for high-risk individuals.[7] Advances in the treatment of lung cancer have also been slow to improve survival for most patients. Since the early 2000s, treatment targeted to molecular signatures in lung tumors, such as *epidermal growth factor receptor* (EGFR) inhibitors and immune checkpoint inhibitors, has resulted in improved survival in particular subgroups of patients.[8–11] Unfortunately, the development of drug-resistant mutations is a problem that affects overall survival for patients with lung cancer, and continued drug development is crucial. More recently, immunotherapeutic regimens have been developed that greatly improve survival for a selected subset of patients with late-stage lung cancers. To understand the profile of a high-risk individual and aid in the development of chemopreventive agents and targeted treatments, it is essential to understand smoking patterns and the genetics underlying lung cancer development.

GEOGRAPHIC, GENDER, AND ETHNIC VARIABILITY

As shown in Figure 74.1, there is extreme geographic and gender-specific variability in the rates of lung cancer among countries. Shown are the mortality rates in the highest 20 and lowest three countries along with rates in selected other countries. The ratio in rates between genders varies from 11.6 in Belarus to 1.0 in Brazil, with a world average that is three times higher in men than in women.[12] Rates are lowest in sub-Saharan Africa, except South Africa, with rates in most countries less than 10/100,000. Rates are highest in Europe, North America, and Eastern Asia. These highly variable rates among countries and between genders reflect variable exposure patterns and likely relate primarily to variations in smoking patterns across world populations. Studies in the United States, however, show pronounced variation in lung cancer risks among ethnic groups living in the same regions of California and Hawaii, with African Americans and Hawaiians having 20–90% higher risks for lung cancers depending on histology.[13] Historically, African American men have had a higher incidence of non–small cell lung cancer than other groups, despite their lower smoking exposures. *Small cell lung cancer* (SCLC) incidence is particularly elevated in Hawaiians.

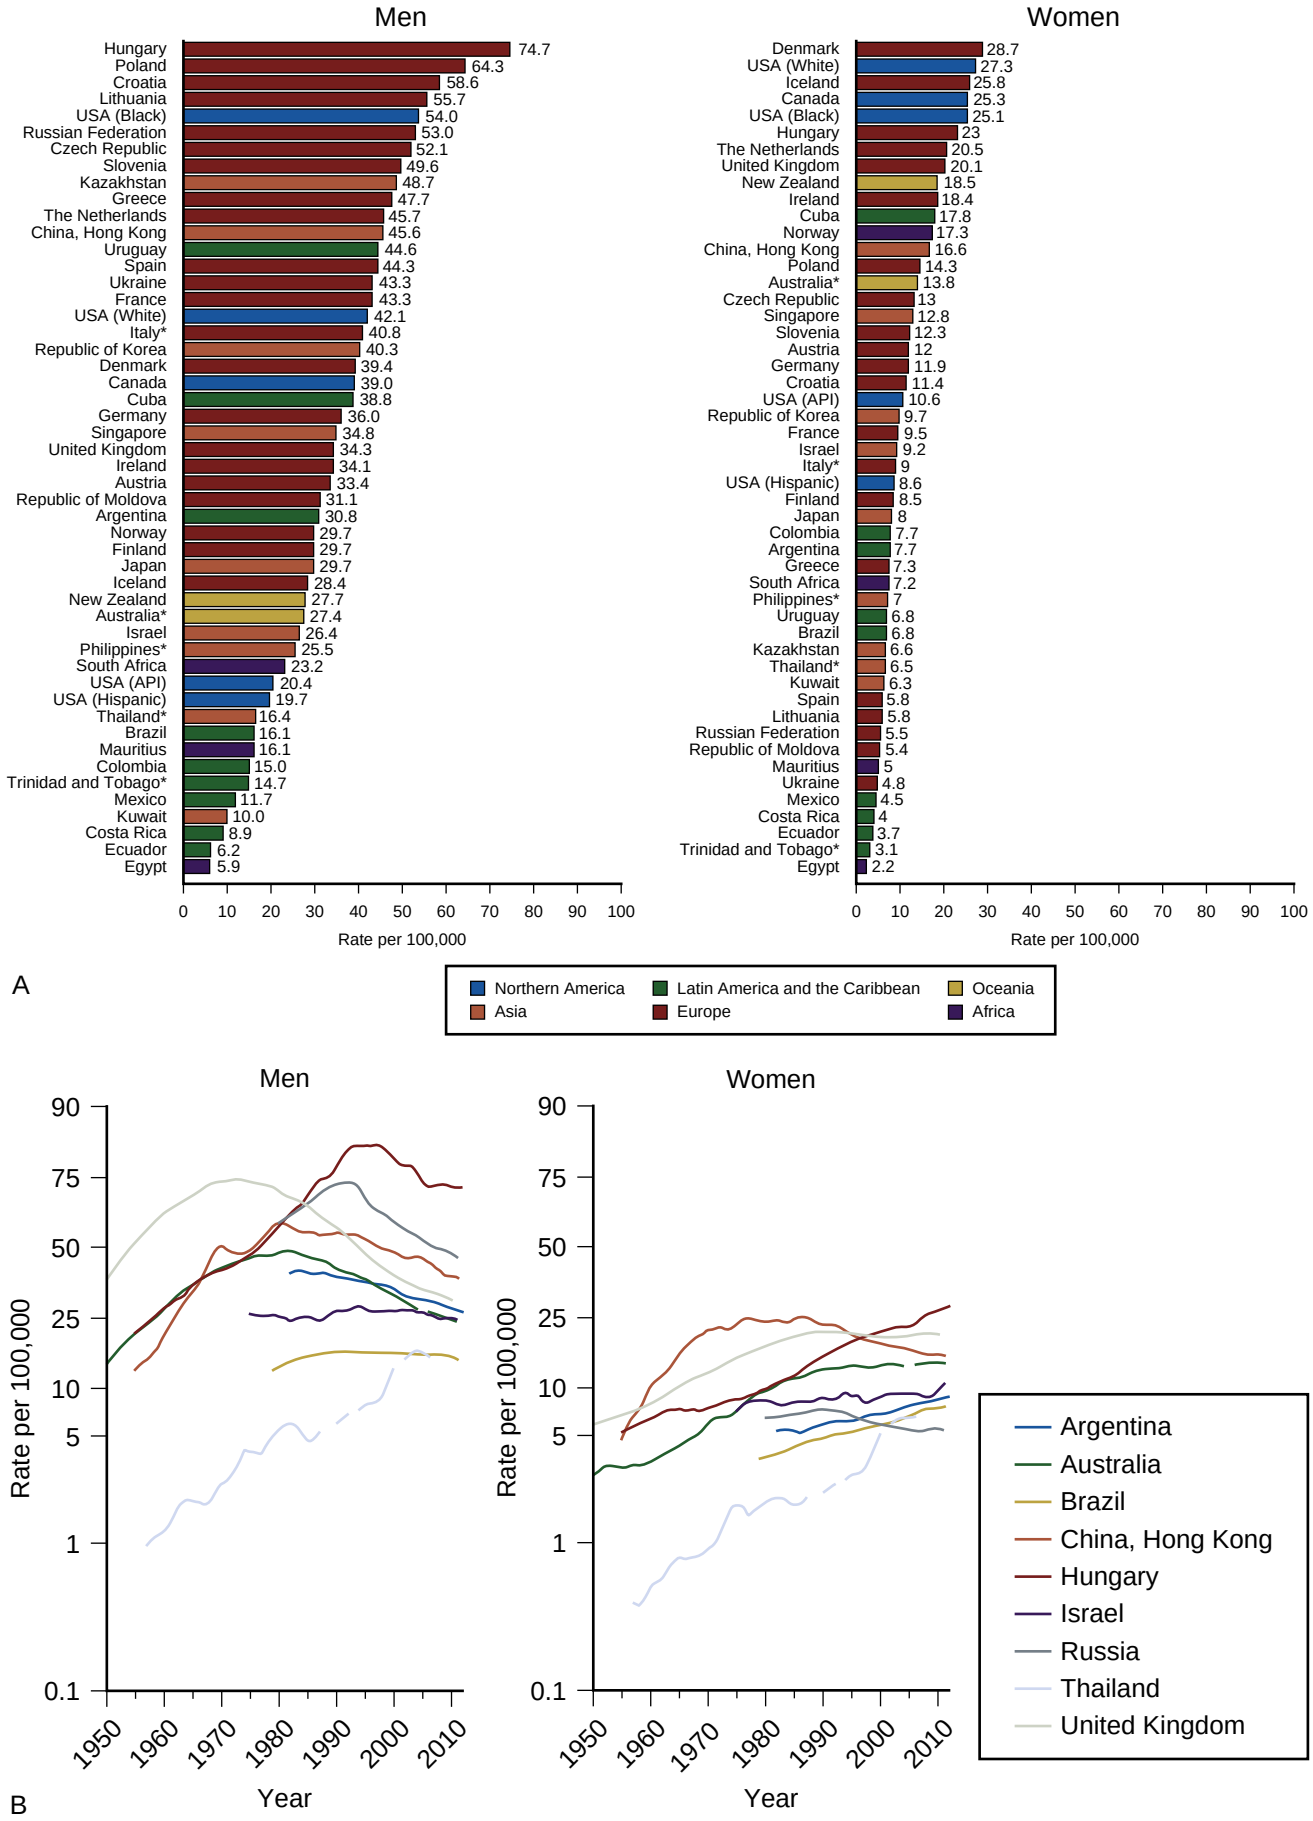

Figure 74.1 Lung cancer mortality rates and trends, by sex. (A) Ranking of age-standardized lung cancer mortality rates for selected countries for all ages, by sex, for the period 2003 to 2007, color-coded by region. Note that the U.S. data vary by gender and major ethnic groups. (B) Lung cancer mortality trends by sex, selected countries, 1950 to 2012. Observed age-standardized lung cancer mortality rates with a 5-year moving average. Global rates can be seen to vary widely among countries and over time. (Data from Forman D, Bray F, Brewster DH, et al., editors. Cancer incidence in five continents, vol. X. IARC Scientific Publication No. 164. Lyon: International Agency for Research on Cancer, World Health Organization, 2014.)

Recent national trends show that populations of African American and European descent in the United States have similar incidence rates due to further decreases in smoking patterns in African Americans.[14]

SMOKING

Lung cancer is a well-established example of a malignancy largely determined by environmental exposure, with risks associated with cigarette smoking,[15–18] with certain occupations such as mining, shipbuilding, petroleum refining, and with asbestos exposure.[4] In Western countries, about 85–90% of the lung cancer risk is attributable to cigarette smoking. However, lung cancer develops in only about 15% of current smokers, suggesting a differential susceptibility to the effects of tobacco carcinogens. In addition, 10–15% of lung cancers arise in never-smokers. Little is understood about risk in never-smokers, although exposure to secondhand cigarette smoke and air pollution certainly contribute to the risk of lung cancer. Secondhand tobacco smoke exposure has been associated with an approximately 30% increased risk for lung cancer in never-smokers, with the increased risk ranging from 20–50%[19,20] depending on the number of years of exposure.[21] In a meta-analysis of 22 studies, the authors reported that exposure to tobacco smoke in the workplace increased the risk of lung cancer by 24%, a risk that was highly correlated with duration of exposure[22] (see also Chapter 65).

There is overwhelming evidence for the carcinogenic effects of cigarette smoking and other environmental exposures and for the association of these exposures with multiple somatic mutations in lung tumors. Known mutations and loss of heterozygosity in oncogenes and tumor suppressor genes involved in lung carcinogenesis accumulate in individual somatic cells during lung tumor initiation and progression.[23–25] In 2016, a comprehensive analysis of mutation profiles in 660 adenocarcinomas and 484 squamous lung cancers was presented as a part of the Cancer Genome Atlas, which found 8.7 and 9.7 mutations per megabase in these cancers.[26] Six mutational signatures were observed, with the most common signature being C to T transversions reflecting smoking exposure.[26] A subset of tumors showed profiles reflecting mismatch repair defects or APOBEC signatures, which can reflect DNA repair after viral exposures. Susceptibility to selected mutations also varies according to host-specific factors. For example, mutations in *EGFR* are much more common in women, Asians, never-smokers, and those with adenocarcinomas,[27] whereas mutations affecting *KRAS* are more common in men, individuals of European descent, smokers, and those with squamous histology.[26] Susceptibility to somatic mutations may be due to individual differences in risk associated with the inhalation of known carcinogens (i.e., individuals differ in their susceptibility to these environmental insults).[28,29] Evidence indicates that allelic variation at genetic loci affects inherited susceptibility to lung cancer. Studies of inherited susceptibility to lung cancer, including major susceptibility loci and loci with less pronounced effects, are described later in this chapter.

SMOKING BEHAVIOR AND RISK FOR LUNG CANCER

In the early 1900s, lung cancer was infrequent. In North America and Europe, the dramatic increase in lung cancer risks beginning after World War I resulted from the confluence of several factors. First, modern automated cigarette production allowed broader distribution of cigarettes, which resulted in a substantial increase in the availability and use of tobacco products. During World War I, tobacco companies targeted the military for distribution of cigarettes, which were viewed as improving the troops' mood and alertness. During World War II, standard rations contained cigarettes. At that time, the causal link between smoking and lung cancer risk was unknown. Establishing the causal relationship between cigarette smoking and lung cancer risk required the development of many of our modern epidemiologic and statistical approaches. Although a correlation between cigarette use and lung cancer was established in the mid-1950s,[15,30] many concerns were raised that this correlation might reflect various biases and poor statistical measures. Berkson argued that the specific association between lung cancer and smoking might reflect bias in studying individuals with prevalent lung cancers, who might survive longer if they smoked.[31] Avoiding Berkson's bias has led to the emphasis on studying incident rather than prevalent cases of a disease when practicable. Fisher argued that some genetic factor might contribute to both smoking and lung cancer risk so that no causal inference could be made.[32] This hypothesis was largely disproved in a study of monozygous twins discordant for smoking behavior,[33] although this study showed lower relative risks than are typically observed in case-control studies, suggesting some evidence for joint effects of genetic factors on both smoking and lung cancer risk.[34] Finally, modern logistic regression techniques were developed for modeling binary factors with covariates to deal with potential confounders that might have influenced the causal inference of smoking on lung cancer risk.[35] Despite the advances in understanding their harm, cigarettes are still made available at low cost to military personnel and were promoted and made readily available to the military during the Gulf War.[36] Causal modeling shows that a large fraction, 35–79%, of the excess veteran deaths due to heart disease and lung cancer are attributable to military-induced smoking.[37]

Notwithstanding the growing evidence in the 1950s and early 1960s that tobacco smoking increases lung cancer risk, progress was slow in the acknowledgement of the association. From 1953 to 1954, smoking rates declined as public awareness of the link between smoking and lung cancer risk emerged, but "filtered" cigarettes were introduced to allay public concerns about smoking and health effects.[38] The 1964 Surgeon General's report used a consensus approach very effectively to consolidate evidence that cigarette smoking increases lung cancer risk. Since 1964, annual reports from the Surgeon General have continued to document the impact of smoking on health in the United States, which has led to a continual decrease in smoking.[38] Although the recognition that smoking is the major determinant in lung cancer risk was a key observation in public health, developing strategies to change behavior and reduce risk has been an ongoing challenge.

The Surgeon General's report in 1964 that linked lung cancer risk to tobacco smoke had an immediate effect in reducing smoking behavior. Given the approximately 20-year lag between exposure to smoking and lung cancer development, the impact of these reductions on lung cancer risk was slow to be realized; however, lung cancer rates have dropped by nearly 50% in U.S. men since their high in 1992.[39] Lung cancer rates in women have shown only a mild decrease, largely because female tobacco smoking trends have been flat. Based on 2018 data, about 34 million adults in the United States smoke cigarettes (16% of men and 12% of women), and every day about 1600 children under the age of 18 smoke their first cigarette.[40]

According to the World Health Organization,[41] the tobacco use epidemic killed 100 million people in the 20th century and could kill 1 billion people in the 21st century without the introduction of population-level approaches to stem its use. A comprehensive review of tobacco control policies is beyond the scope of this chapter and has been comprehensively reviewed elsewhere,[42] but selected policies that are highly effective are briefly described (see also Chapter 66). First, restricting access by adolescents to nicotine-containing products reduces adoption of tobacco smoking and decreases nicotine dependence.[43] Second, nicotine product consumption is sensitive to cost, with higher *elasticity*, meaning a greater sensitivity to cost increases, in younger consumers.[44] Taxation is an acceptable approach to tobacco control for many governments but can increase illicit behavior and smuggling. Research has documented a causal role for marketing of tobacco-containing products in increasing adoption in adolescents and their subsequent use.[45] Finally, clean air laws for public spaces and tobacco smoking bans reduce harm from smoking and also reduce overall smoking behavior.[46] Tobacco control policies in North America, Western Europe, and other higher-income countries have greatly reduced tobacco use by applying a multiple-component approach. In contrast, e-cigarette and noncombustible tobacco use has risen dramatically,[47] particularly in adolescents and young adults. In most regions, e-cigarette use has not been taxed, access for adolescents has not been limited, and marketing has been unregulated. This lack of control has allowed a new epidemic of nicotine dependence to appear. Although the risk for lung cancer among e-cigarette users is likely to be lower than risks from use of combustible tobacco products, harm reduction through the use of these new products remains poorly characterized. A recent meta-analysis showed that e-cigarette users are less likely to have quit smoking successfully than cigarette users who attempted smoking cessation without using e-cigarettes.[48] Also, modeling the potential of decreased harm among smokers and increased adoption of smoking due to dual e-cigarette and combustible smoking shows an increased population-level harm related to adoption of e-cigarettes.[49] Additionally, e-cigarette use has recently led to an outbreak of severe acute lung diseases, including pneumonitis and acute respiratory distress syndrome.[50]

There are 3500 chemical particulate constituents of tobacco smoke, of which more than 70 are known carcinogens.[51,52] These carcinogens include a wide array of compounds, but most undergo activation to more reactive species during the process of conjugation and removal. The activation of *polycyclic aromatic hydrocarbons* (PAHs) and arylamines by cytochrome P-450s (e.g., CYP1A1, CYP1A2, and CYP3A4) leads to the formation of reactive chemical species that can bind covalently to DNA to form carcinogen-DNA adducts.[53] PAHs such as benzo(a)pyrene are first oxidized by aryl hydrocarbon hydroxylase or CYP1A1 (the structural gene for P-450 1A1), resulting in the formation of an arene oxide. This metabolite can be further activated to form a dihydrodiol.[54] Dihydrodiol can then be further metabolized across the olefinic double bond by both cytochrome P-450 (CYP3A4) and other oxidation systems,[55] thus forming a diol epoxide. Diol epoxides are unstable and rearrange to form highly reactive carbocations (carbon atoms bearing three bonds and positively charged). For example, benzo(a)pyrene-7,8-diol 9,10-epoxide forms covalent bonds primarily with the exocyclic amino group of guanosine. This reaction has been shown to be responsible for activating mutations in the *HRAS-1* proto-oncogene in several experimental systems.[56] Alternative and competing routes of metabolism can lead to inactivation of carcinogens (e.g., PAHs) through the formation of conjugates (glutathiones, glucuronides, and sulfate esters) or phenols and tetrahydrotetrols, which facilitate excretion. The balance between metabolic activation and metabolic detoxification, as well as the efficiency of DNA repair mechanisms, has been proposed to affect cancer risk in an individual exposed to PAHs.

Two nicotine-specific nitrosamines that are relatively abundant constituents of all tobacco smoke products are *4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone* (NNK) and *N′-nitrosonornicotine* (NNN). NNK is rapidly converted in biologic systems to the reactive species *4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol* (NNAL)[57] (Fig. 74.2). These compounds can be removed via glucuronidation or can be activated further by cytochrome P-450 metabolism. Genetic analysis has shown that *single nucleotide polymorphisms* (SNPs) in *HSD11B1* and *AKR1C4* associate with NNAL. Variation in CYP2A6, which is the primary cytochrome P-450 involved in metabolizing nicotine and NNAL, is strongly associated with lung cancer risk; it may have roles in both controlling smoking behavior and in modulating risk through NNAL adduct formation.[58] Nicotine-associated nitrosamines have been increasingly associated with lung cancer risk and are not found in cannabis smoke, which to date has not shown a convincing relationship with elevated lung cancer risk.[59] This provides additional indirect evidence that nicotine-specific nitrosamines contribute to the elevated lung cancer risk specifically associated with tobacco smoke.

OCCUPATIONAL AND ENVIRONMENTAL FACTORS

Although the vast majority of lung cancer is the result of environmental exposures, there is a complex interplay between exposure and individual susceptibility. Genetic susceptibility is discussed later. In addition to tobacco smoking, the major environmental causes of lung cancer include occupational exposures and environmental air pollution.

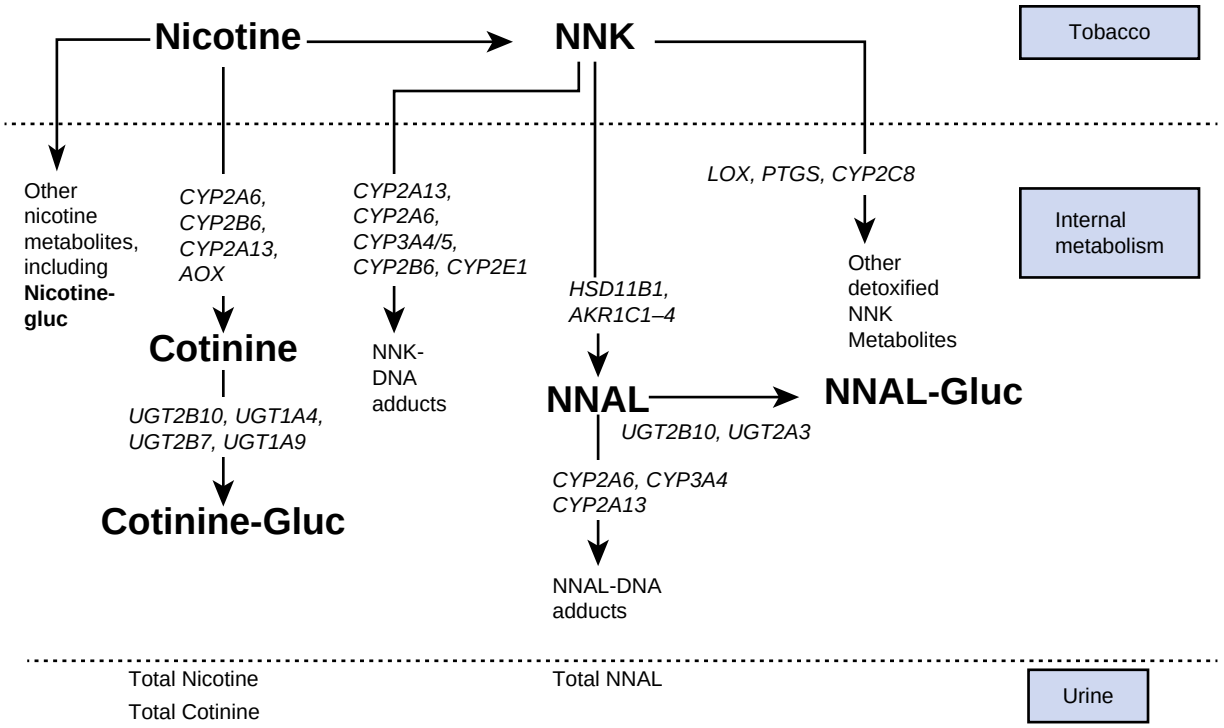

Figure 74.2 Selected genes of NNK to NNAL and of nicotine to cotinine metabolism. Total NNAL, nicotine or cotinine includes their glucuronides. (From Ter-Minassian M, et al. Genetic variability in the metabolism of the tobacco-specific 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL). *Int J Cancer.* 2012;130:1338-1346.)

OCCUPATIONAL EXPOSURES

Lung cancer has been found to be associated causally with many workplace exposures, including to asbestos, arsenic, beryllium, cadmium, chromium, diesel exhaust, nickel, radiation, silica, and vinyl chloride, in addition to others. Occupational exposure to lung carcinogens has been estimated by case-control studies to account for 9–15% of lung cancer cases.[60] As lung carcinogens have been identified in the workplace and as regulations have been established to prevent workers from being exposed, this proportion has been decreasing over time in the high-income countries, whereas industrial exposures have increased in many low- to moderate-income countries. Cigarette smoking also potentiates the effect of some of the known occupational lung carcinogens, such as asbestos. Some of the most common occupational lung carcinogen exposures are discussed in the following sections.

Asbestos

Asbestos, a well-established occupational carcinogen,[61,62] refers to several forms of fibrous, natural silicate minerals.[63] The epidemiologic evidence that asbestos causes lung cancer dates to the 1950s. In a retrospective cohort study published in 1955, Doll observed that asbestos textile workers at a factory in the United Kingdom had a tenfold elevation in lung cancer risk and that the risk was most heavily concentrated during the timeframe before regulations were implemented to limit asbestos dust in factories.[64] A sevenfold excess of lung cancer was subsequently observed among insulation workers in the United States,[65,66] with peak incidence at 30 to 35 years after the initial exposure to asbestos.[67] The risk of lung cancer has been noted to increase with increased exposure to asbestos[68] and to be associated with each of the principal commercial forms of asbestos.[69] Whether asbestos acts directly as a carcinogen or indirectly, for example, by causing chronic inflammation that eventually leads to cancer, remains controversial.[70–72] For the mechanism of asbestos-induced lung cancer, two competing hypotheses have been proposed: (1) lung cancer arises as a consequence of the asbestos-induced inflammatory lung disease, asbestosis, and (2) lung cancer arises directly from asbestos exposure, while the asbestosis reflects cumulative asbestos dose. Regardless of the mechanism, asbestos is a known lung carcinogen, and the number of exposed workers is increasing in South America, Asia, and the former Soviet Union.[62]

Asbestos and cigarette smoking are independent causes of lung cancer and, in combination, they act synergistically to increase risk. A recent follow-up study of the original Selikoff cohort used to estimate risk has allowed precise quantitative characterization of this synergy (Fig. 74.3).[73] The risk of the combined exposure is much higher than would be expected if one merely added the risks together, showing a strong interaction between the two. In fact, the risks are approximately multiplicative in persons with asbestosis and at least additive in exposed workers without asbestosis who also smoke. Lung cancer mortality was increased by asbestos exposure alone among nonsmokers (rate ratio, 3.6; 95% *confidence interval* [CI], 1.7 to 7.6), by asbestosis among nonsmokers (rate ratio, 7.4; 95% CI, 4.0 to 13.7), and by smoking without asbestos exposure (rate ratio, 10.3; 95% CI, 8.8 to 12.2). The joint effect of smoking and asbestos alone was additive (rate ratio, 14.4 [95% CI, 10.7 to 19.4]) and with asbestosis, supra-additive (rate ratio, 36.8 [95% CI, 30.1 to 45.0]). Insulator lung cancer

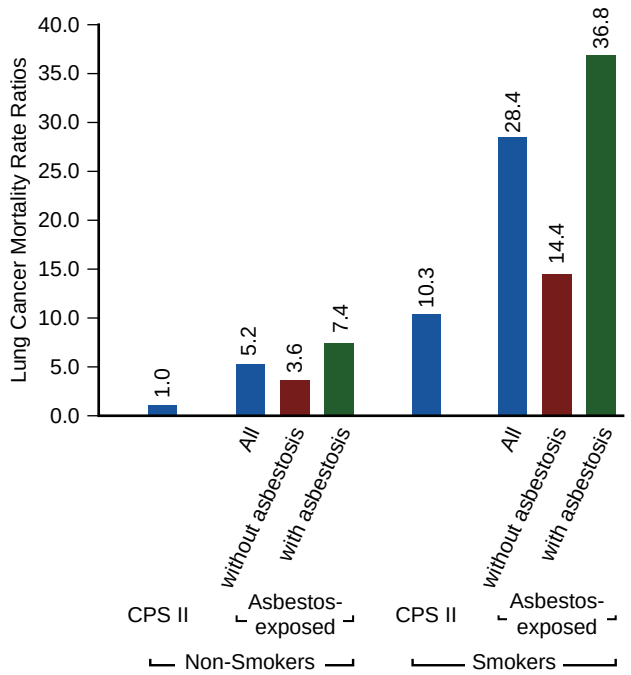

Figure 74.3 Lung cancer mortality rate ratios by asbestos exposure, asbestosis, and smoking status. The risks of smoking and asbestos are approximately multiplicative in persons with asbestosis and at least additive in exposed workers (insulators) without asbestosis who also smoke. CPS II, a control group not exposed to asbestos, from the Cancer Prevention Study II of the American Cancer Society. (From Markowitz SB, Levin SM, Miller A, Morabia A. Asbestos, asbestosis, smoking, and lung cancer. New findings from the North American insulator cohort. *Am J Respir Crit Care Med*. 2013;188[1]:90–96.)

mortality halved within 10 years of smoking cessation and converged with that of never-smokers 30 years after smoking cessation.[73]

Diesel Exhaust

The most definitive study to date evaluating the relationship between quantitative estimates of exposure to diesel exhaust and lung cancer mortality after adjustment for smoking and other potential confounders was the Diesel Exhaust in Miners Study conducted by the National Cancer Institute.[74] The investigators performed a nested case-control study in a cohort of 12,315 workers in eight non-metal mining facilities, which included 198 lung cancer deaths and 562 incidence density-sampled control subjects individually matched on mining facility, sex, race/ethnicity, and birth year (within 5 years), from all workers who were alive before the day the case subject died. They estimated diesel exhaust exposure, represented by *respirable elemental carbon* (REC), by job and year for each subject, based on an extensive retrospective exposure assessment at each mining facility. They observed statistically significant increasing trends in lung cancer risk with increasing cumulative REC and average REC intensity. Cumulative REC, which lagged 15 years, yielded a statistically significant positive gradient in lung cancer risk overall (P [trend] = 0.001); among heavily exposed workers (i.e., above the median of the top quartile [REC ≥ 1005 μg/m^3 per year]), risk was approximately three times greater (*odds ratio* [OR], 3.2; 95% CI, 1.3 to 7.7) than that among workers in the lowest quartile of exposure. Among never-smokers, ORs were 1.0, 1.5 (95% CI, 0.3 to 7.5), and 7.3 (95% CI, 1.5 to 36.6) for workers with 15-year lagged cumulative REC tertiles of less than 8, 8 to less than 304, and 304 μg/m^3 per year or more, respectively. They also observed an interaction between smoking and 15-year lagged cumulative REC (P [interaction] = 0.086) so that the effect of each of these exposures was attenuated in the presence of high levels of the other, all providing further evidence of diesel carcinogenicity in humans.[74,75] The International Agency for Research on Cancer subsequently classified diesel exhaust as a class I known human carcinogen.[76]

Other Occupational Exposures

Population-based studies have reported additional lung cancer associations with the following compounds and/or processes: ionizing radiation (uranium mining), vinyl chloride (pulp and paper workers), arsenic (smelting of ores containing arsenic, pesticide application, wood preservation), beryllium (ceramic workers, missile technicians, nuclear reactor workers, jewelers), chromium (stainless steel production, welding, tanning industries), and nickel (battery makers, ceramic makers, electroplaters, glass workers, jewelers, metal workers, welders).[77] A discussion of occupational exposures to ionizing radiation is included later.

RADIATION

Epidemiologic studies of populations exposed to high doses of radiation show that lung cancer is causally associated with exposure to ionizing radiation. Two types of radiation, classified by the rate of energy transfer to the tissue, are relevant to lung cancer: high-*linear energy transfer* (LET) radiation (e.g., neutrons and radon) and low-LET radiation (e.g., x-rays and γ-rays). High-LET radiation produces ionization of relatively higher density in tissues than low-LET radiation; therefore, in equivalent doses, more biologic damage is produced by high-LET than low-LET radiation.

HIGH-LET RADIATION: RADON

Radon is an inert gas produced naturally from radium in the decay series of uranium. Two of the radon decay products emit alpha particles that can damage the DNA of cells of the respiratory epithelium. Epidemiologic studies of underground miners of uranium and other ores have established exposure to radon daughters as a cause of lung cancer.[78,79] In the underground miners exposed to radon in the past century, very high lung cancer risks were observed; in the miners in more contemporary workplaces, the observed risks have been much less because exposure concentrations have been better controlled, but still show clear evidence of existing cancer risk.[78] Cigarette smoking and radon decay products synergistically influence lung cancer risk, that is, to greater degree than simply adding the risks of each together.[80,81] For this reason, the bulk of the lung cancer burden caused by radon exposure in the general population is concentrated within cigarette smokers.[79]

Radon is of broader societal interest because it is a ubiquitous air pollutant that enters buildings from the underlying

soil and sometimes through the water. On average, indoor exposures to radon for the general population are much less than for occupational groups such as uranium miners; but the results of case-control studies of indoor radon exposure have documented that residential exposure to radon in indoor air is significantly associated with increased lung cancer risk.[82,83]

The assumptions made by the Environmental Protection Agency and the Biological Effects of Ionizing Radiation VI Committee of the National Research Council have led to estimates that approximately 15,000 to 21,000 lung cancer deaths per year in the United States are caused by radon.[84] About 2900 of these cases are estimated in nonsmokers. In the United States, the Environmental Protection Agency has called for testing of all residences and mitigating the exposure when guideline values are exceeded.

LOW-LET RADIATION: X-RAYS AND γ-RAYS

Earlier epidemiologic data relating low-LET radiation to lung cancer stem from three principal populations[85]: (1) the atomic bomb survivors in Japan, (2) patients with diseases such as ankylosing spondylitis or tuberculosis who received multiple radiation treatments, and (3) occupational groups in professions exposed to radiation. The single high-dose exposure of the atomic bomb survivors was associated with significant lung cancer risk.[86] Regardless of age at the time of the blast, the excess of lung cancer appeared when the survivors reached older ages at which cancer usually develops.[87] Quantitative risk models are available that describe how risk increases with radiation dose.[85] Over the past several decades, medical radiation has replaced radon as the leading contributor to the radiation exposure in the population. In general, a substantial proportion of the U.S. population is now exposed to ionizing radiation from medical diagnostics, particularly from computed tomography scans. The exposure is of sufficient magnitude to be of concern as a cause of increased population risk for cancer.[88–90]

The findings from the *National Lung Screening Trial* (NLST) showed that *low-dose spiral computed tomography* (LDCT) screening significantly reduced lung cancer mortality among those at high risk for lung cancer defined by age (55 to 74 years) and smoking history (≥30 pack-year smoking history).[6] Based on the findings of the NLST, the U.S. Preventive Services Task Force recommends annual screening in the high-risk group as defined in the NLST.[91] However, LDCT screening will result in increased exposure of smokers to ionizing radiation. In making their recommendation in support of LDCT screening, the U.S. Preventive Services Task Force acknowledged that there is uncertainty about the magnitude of the radiation-associated risks. Characterizing the magnitude of risks associated with LDCT screening is an important future priority because risk models that have attempted to quantify these risks indicate they are not trivial[92] (see also Chapter 20).

AIR POLLUTION

During a typical day, the average adult inhales about 10,000 L of air. Consequently, even the carcinogens present in the air at low concentrations are of concern as a risk factor for lung cancer (see also Chapter 102).

ATMOSPHERIC AIR POLLUTION

Outdoor (ambient) air can contain a number of hazardous agents. Many of these are generated by the combustion of fossil fuels, including carcinogens such as PAHs and metals such as arsenic, nickel, and chromium.[62] Depending on the pollution sources, the constituents of air pollution vary by locale and over time. Particulate matter, which has multiple sources in urban air, has been studied as a potential lung cancer risk factor. In a study in six U.S. cities, a 40% increase in lung cancer risk was found in residents in the city with the highest concentration of fine particles in the atmosphere compared to the city with the lowest concentration.[93] The data from the American Cancer Society's Cancer Prevention Study II showed that each 10 g/m^3 increase in concentration of fine particles carried an increased lung cancer risk of 14%.[94] A European study of more than 300,000 individuals from nine countries observed that the risk of lung cancer increased significantly as the concentration of particulate matter increased.[95] Further evidence indicating an association between constituents of ambient air pollution and increased lung cancer mortality continues to accrue, with reports from Japan,[96] China,[97] and New Zealand.[98]

INDOOR AIR POLLUTION

Indoor air pollution arises from pollutants that enter from the outside as well as those that originate indoors from tobacco smoking, building materials, soil gases, household products, and combustion from heating and cooking.[99] In the more developed countries, two of the most important indoor pollutants that influence lung cancer risk in never-smokers are passive smoking[91] and radon.[100] In the developing world, the major source of indoor air contamination results from the use of unprocessed solid fuels, notably coal (a fossil fuel) but also biomass fuels, for cooking and space heating.[101] Mumford and coworkers[102] inferred that smoky coal was a major determinant of the geographic distribution of lung cancer in Xuan Wei, China, a finding corroborated by an animal model.[103] Evidence supporting a causal association was subsequently strengthened by studies documenting that switching from use of unvented fire pits to stoves with chimneys[104] or to portable stoves[105] cut the lung cancer risk by half.

Indoor burning of biomass, such as wood, is associated with lung cancer risk, but the association is weaker than for fossil fuel burning. This was illustrated in a pooled analysis of seven case-control studies, in which the risk of lung cancer was strongest for indoor burning of coal in Asia (OR, 4.9; 95% CI, 3.7 to 6.5) and much weaker—but still statistically significant—for indoor burning of wood in Europe and North America (OR, 1.2; 95% CI, 1.1 to 1.4).[106] These findings were corroborated in a meta-analysis of published studies.[107] Indoor burning of solid fuel is a major cause of lung cancer in China and one that is preventable. Based on statistical models, projections indicate that reductions in the indoor burning of solid fuel would substantially reduce lung cancer deaths.[108]

DIET AND OBESITY

The possible role of diet in modifying the risk for lung cancer has been the focus of intensive investigation, driven initially by the rationale that specific micronutrients might have anticarcinogenic activity. The most thoroughly investigated dietary factors are also those that appear to have the greatest implications for prevention: fruits, vegetables, and specific antioxidant micronutrients commonly found in fruits and vegetables.

The results of case-control and prospective cohort studies have tended to show that individuals with high dietary intake of fruits or vegetables have a lower risk for lung cancer than those with a low intake.[110] To understand the basis of this protective association, researchers have grouped fruits and vegetables into classes and examined them individually in relation to lung cancer risk. For example, tomatoes and cruciferous vegetables[110,111] have been associated with a reduced risk for lung cancer in a number of studies. These food-based analyses can help clarify whether protection arises from the complex mixture that composes fruits and vegetables or from specific biochemical constituents present in particular fruits and vegetables.

Fruits and vegetables are the major dietary source of antioxidant micronutrients. Much of the research on diet and lung cancer has been motivated by the hypothesis that diets high in antioxidant micronutrients may protect against oxidative DNA damage and thereby protect against cancer. For example, this was one of the hypothesized roles for β-carotene,[112,113] the focus of now-controversial clinical trials. Two strategies are used to evaluate the relationship of micronutrients to lung cancer risk in observational epidemiologic studies: (1) estimating micronutrient intake from food frequency questionnaires and (2) measuring serum concentrations of micronutrients. Prospective studies of both dietary intake[114] and prediagnostic blood concentrations suggest that carotenoids are inversely associated with lung cancer risk.

However, the protective association predicted between β-carotene and lung cancer on the basis of these observational epidemiologic studies was not confirmed in three randomized, double-blind, placebo-controlled chemoprevention trials.[115–117] In fact, two of these studies with participants at high risk for lung cancer (heavy smokers and asbestos-exposed workers) were stopped early because significantly *increased* risk for lung cancer was observed in the β-carotene group compared with the placebo group.[116] The precise mechanism underlying this clinical trial observation is not known but is postulated to be a disturbance in the balance between cellular oxidants and antioxidants. Specifically, carotene acts as an antioxidant. Tobacco smoking is highly oxidative and decreases plasma carotenoids. The protective effects of β-carotene at dietary intake amounts may be lost or reversed with high-dose supplements because some cellular oxidants are needed for normal homeostasis (such as apoptosis and detoxification reactions by cytochrome P-450 complexes). Hence, high doses of antioxidants such as β-carotene can inactivate more cellular oxidants than necessary and interfere with their protective function.[118,119]

With regard to obesity, disentangling the effects of smoking and lung cancer itself (which can cause cachexia) is difficult when studying incident lung cancer cases and matched controls. Therefore, a causal inference procedure called Mendelian randomization[120] using genetic instruments defined by SNPs that can predict *body mass index* (BMI) has been adopted as an alternative procedure. A Mendelian randomization analysis[121] of multiple cancers showed a positive association between adult BMI, genetic score, and lung cancer (OR, 1.3; 95% CI, 1.1 to 1.5). Additionally, in the consortium, an analysis of 29,266 lung cancer cases and 56,450 controls identified a causative role of higher fasting insulin in the etiology of squamous cell and SCLC but not of adenocarcinoma.[122,123] However, the association of obesity and lung cancer risk remains controversial. A large 12-year pooled analysis of 1.6 million Americans, Europeans, and Asians showed that, whereas increased BMI was generally associated with decreased risk for incident lung cancer, greater waist circumference and waist-hip ratio were shown to increase risk after adjusting for BMI. Central obesity concurrent with overall low BMI may identify a high-risk lung cancer population.[123a]

OTHER CAUSATIVE ASSOCIATIONS

As noted earlier, the results of recent analysis of large-scale consortia studies have allowed assessment of many potential risk factors of relative low risk, but which are significant when considering the numbers of at-risk persons. The consortia have been vital for discovering common genetic traits as well as important complex phenotypic characteristics such as obesity, metabolic disturbances, hormone use, height, and alcohol use.

In an analysis of 22 case-control and cohort studies from the International Lung Cancer Consortium, moderate alcohol consumption was inversely associated with lung cancer risk after adjusting for smoking.[124] Aspirin and nonsteroidal anti-inflammatory drug use conferred modest protection for lung cancer, especially in ever-smokers after appropriate adjustments, but assessment of optimal dosing was not possible.[125] Oral contraceptive use was associated with a reduced lung cancer risk (OR, 0.8; [CI, 0.7 to 1.0]), as was hormone replacement therapy (OR, 0.8 [CI, 0.7 to 0.9]).[126] Both estrogen and combination estrogen-progesterone therapies were associated with decreased risk, with no clear dose-response with years of use. The incidence of lung cancers of all cell types was reduced, with the largest effect in squamous cell (OR, 0.5; [CI, 0.4 to 0.8]), with no interaction with BMI or smoking status.

Lung, bladder, and kidney cancer mortality rates due to arsenic exposure have very long latencies, with increased risks manifesting 40 years after exposure reduction. In fact, arsenic in drinking water may have one of the longest cancer latencies for a human carcinogen.[127]

GENETIC SUSCEPTIBILITY TO LUNG CANCER

In 1963, Tokuhata and Lilienfeld showed familial aggregation of lung cancer.[128,129] After they accounted for personal smoking, the results suggested the possible interaction of

genes, shared environment, and common lifestyle factors in the etiology of lung cancer. In their study of 270 people with lung cancer and 270 age-, sex-, race-, and location-matched controls and their relatives, the authors found a 2.0- to 2.5-fold increased lung cancer mortality among smoking relatives of people with lung cancer compared with smoking relatives of control subjects. Nonsmoking relatives of people with lung cancer were also at higher risk than nonsmoking relatives of control subjects.

Since this study, authors of several other studies have reported familial aggregation of lung cancer.[130,131] In southern Louisiana, authors of case-controlled studies reported an increased familial risk of lung cancer[131] and other smoking-related cancers[132] among relatives of lung cancer cases after accounting for the effects of age, sex, occupation, and smoking history. The risk of lung cancer for parents of cases was fourfold compared with parents of controls. After controlling for the confounding effects of the measured environmental risk factors (occupation and smoking), being a first-degree relative of a lung cancer case conferred a 2.4-fold higher lung cancer risk. The largest single study of familial aggregation involved the evaluation of people with lung cancer and control subjects in Iceland.[133] In this population-based approach, the risk of lung cancer was 2.7-fold higher in parents of lung cancer cases compared to parents of controls and the risk increased to 3.5 for parents of early-stage lung cancer cases (age of onset ≤60 years). The risk to siblings was increased 2.0-fold in general but increased to 3.3-fold for siblings of people with early-onset lung cancer. Studies of risk for lung cancer among relatives of never-smokers are limited[19,134,135] but also show some increased risk, although usually with a weaker association than among lung cancer cases overall, which are predominantly in smokers. Mayne et al. studied never-smokers and former smokers (i.e., those who stopped smoking at least 10 years before they were interviewed) and reported that a positive family history of lung cancer was associated with increased lung cancer risk after adjustment for age and smoking status.[135] Finally, a meta-analysis of 28 case-control and 17 cohort studies found an approximately twofold increased risk of lung cancer associated with family history.[136] Risk was generally higher for relatives of people in whom lung cancer was diagnosed at a young age and when multiple family members were affected.

Overall, these results indicate a similar effect of about twofold higher risk for lung cancer among first-degree relatives of lung cancer cases, similar to what is observed for other common cancers, although this risk is modulated by the smoking patterns of the relatives.

HIGH-RISK SYNDROMES CONFERRING AN INCREASED RISK OF LUNG CANCER

Lung cancer risk is greatly elevated in selected rare syndromes. Leonard et al. reported that survivors of familial retinoblastoma are at increased risk for SCLC.[137] Kleinerman et al.[138,139] reported lung cancer developing among individuals with germline retinoblastoma mutations and a history of heavy smoking.[140] The standardized mortality ratio for lung cancer in those who survived hereditary retinoblastoma was 15-fold.[140] Overall, retinoblastoma survivors tend to smoke less than the general population, suggesting that targeting counseling to avoid this risky behavior in this high-risk population may be effective.[141] The retinoblastoma gene (*RB1*) is inactivated in 90% of SCLCs, indicating the biologic relevance of this gene in SCLC etiology.[142]

Germline mutations in the *TP53* gene cause the inherited Li-Fraumeni syndrome. Individuals with this syndrome are at greater increased risk for many cancers, including breast and lung cancers, sarcomas, leukemias and lymphomas, and adrenocortical tumors. The standardized incidence ratio for lung cancer was estimated at 38 in a prospectively collected cohort of *TP53* mutation carriers.[143] Cigarette smoking was associated with a threefold increase in risk for Li-Fraumeni carriers.

Mutations in the *EGFR* gene are often found in adenocarcinomas of the lung arising in never-smoking women and in Asian populations.[144] One family with multiple lung adenocarcinomas was found to have segregation of an *EGFR* mutation, indicating that rarely inherited mutations of this locus can increase the risk of lung cancer.[145] Gazdar collected data from nine families carrying the very rare inherited T790M mutation of *EGFR* and found that carrying the T790M mutation conveys a very high 31% lifetime risk to never-smokers.[146] This mutation is very rare and, as of September 2019, the GNOMad browser reported the allele frequency of this missense mutation to be 2.8×10^{-5}.[147,148] One Japanese family with an inherited mutation of *MET* associated with lung cancer was found by exome sequencing.[149] In these rare conditions, increased screening is warranted for early lung cancer detection. Both inherited *RB1* and *TP53* mutations make individuals highly susceptible to ionizing radiation, and a targeted prevention strategy using magnetic resonance imaging is encouraged.[150]

Studies of families with multiple relatives affected by lung cancer identified a region on chromosome 6q23-25 harboring a susceptibility region.[151] An updated analysis[152] found strong evidence for this factor only in families with four or more affected relatives in two or more generations. Studying a string of markers called a haplotype, the investigators found that light or heavy smoking conferred high risk, indicating the individuals in these families are particularly sensitive to tobacco exposure. In this chromosomal region, a germline mutation in *PARK2* was linked to lung cancer risk in one family with eight affected family members.[153] The authors found additional evidence suggestive of linkage for regions on chromosomes 1q, 4q, 6p, 6q, 8q, 9p, and 20q.[154,155]

COMMON LOW-PENETRANCE GENES: GENOME-WIDE ASSOCIATION STUDIES

In three articles published at the same time in *Nature* and *Nature Genetics*, researchers using *genome-wide association studies* (GWASs) identified the same region of chromosome 15q as being significantly associated with lung cancer risk.[156–158] The region that the authors identified included a neuronal nicotinic acetylcholine receptor gene cluster comprising *cholinergic receptor nicotine alpha 5* (*CHRNA5*), *CHRNA3*, and *CHRNA4* subunits. Nicotinic receptors are composed of pentamers that include alpha and beta units and are expressed in all tissues, but at higher levels in the brain. In all three studies, the authors identified the 15q region as being associated with an approximately 1.3-fold increased

risk of lung cancer among individuals heterozygous for the mutation and about a 1.8-fold increase for individuals homozygous for the mutation. Since these initial studies, multiple investigations of the 15q region have been conducted.[155] These studies identified novel variants in acetylcholine receptors with a substantial influence on both smoking behavior and lung cancer risk.

Findings from other GWASs led to multiple reports of regions on chromosomes 6p21 and 5p15 being associated with lung cancer risk.[159–161] These regions show considerable variability in the association according to histologic subtype. The *human leukocyte antigen* (HLA) region on chromosome 6p21 is largely associated with squamous cancer,[162,163] although other SNPs show associations only with adenocarcinomas. In the chromosome 5p15 region, variation affecting *cleft lip and palate transmembrane 1-like* (CLPTM1L) influence squamous lung cancer,[161,164–166] whereas variations that influence *human telomerase reverse transcriptase* (hTERT) are more associated with adenocarcinoma risk.[163] Additional regions are associated with squamous cell carcinomas: 12p13 *(RAD52),* 9p21 *(CDKN1B/ANRIL),* and 2q32. Imputation analysis yielded several new loci influencing primarily squamous lung cancer risk in European-descent populations.[167] Notably, an uncommon stop mutation, K3326X, in *BRCA2* found in less than 1% of Europeans was associated with a twofold overall increased risk for lung cancer, a 2.5-fold increased risk for squamous carcinomas, and a twofold increased risk for small cell lung cancer.[168] This increased risk of cancer development has also been noted in other smoking-related cancers, including head and neck[169] and esophageal cancers, along with squamous skin cancer, which is also a highly environmentally influenced cancer. The variant was associated with decreased risk of ovarian cancer among *BRCA1* or *BRCA2* carriers[170] and only confers at 1.3-fold increased risk for breast cancer.[170] Imputation analysis also identified variants of *TP63* influencing lung cancer risk in individuals of European descent and a previously identified[171] rare *CHEK2* variant protective for lung cancer risk.

Additional associations have been noted for adenocarcinomas. Authors of a GWAS conducted in the Han Chinese population found evidence for lung cancer risk associations in the 5p15 region, along with regions not identified in individuals of European ancestry: the 3q28 (*TP63*), 13q12 (*MIPEP-TNFRSF19*), and 22q12 (*MTMR3-HORMAD2-LIF*) regions.[172] With additional samples, Dong et al. identified more regions of risk in the 10p14, 5q32, and 20q13 regions.[173,174] In the Japanese population, Shiraishi et al. replicated the 5p15 and 3q28 findings reported in the Chinese population and the 6p21 findings in individuals with European ancestry and identified a novel region on 17q24.3 at rs7216064 near the *BPTF* gene.[174a]

Insufficient work has been completed to identify susceptibility genes in never-smokers of European descent for lung cancer using a GWAS approach, in part because these individuals are not as common in the population, making it more difficult to identify the numbers of subjects needed for a GWAS. However, this was possible in Asia; in never-smoking women in Asia, Lan et al.[175] replicated the 6p21, 5p15, and 3q28 findings discussed previously and reported new regions of interest in 10q25 and 6q22.77. A large study of individuals with European ancestry further clarified associations of lung cancer in never-smokers with the *hTERT* region.[176] Even fewer studies have been completed in the Black population. Associations between lung cancer risk and SNPs in the 15q25, 5p15, and 6p21 regions identified in individuals of European ancestry were replicated in Black individuals.[177–179] A recent GWAS study of African Americans from multiple U.S. sites did not identify new loci specific to this population but did identify novel African American–specific variants in the CHRNA5 region.[179]

In a review by Bosse and Amos,[180] all the known loci identified through 2018, when the OncoArray project[181] had been completed, were described. This project genotyped about 500,000 individuals for several cancers, including lung. GWAS studies from the OncoArray project identified several novel loci, many of which act as *expression quantitative trait loci*, and genomic loci that influence the expression level of messenger RNA, implicating genetic regulation as drivers of lung cancer risk.[182] Additional studies since 2018 have identified the *LCORL* gene as affecting risk for strongly familial lung cancer,[183] along with a new variant on chromosome 9p, several variants identified by gene-environment interaction analysis,[184] and three regions identified by analysis of gene-gene interactions,[185] including an interaction between *SYNE1* in the chromosome 6 region implicated in familial lung cancer risk with *RNF43.* Additionally, several variants were identified through an integrative study of Chinese- and European-descent populations[186] (eFig. 74.1).

The heritable genetic evidence to date clearly supports the hypothesis of a genetic component to the risk of lung cancer, with multiple genetic loci influencing risk. The aggregation of lung cancer in families remaining after adjustment for smoking history of each relative suggests that a segment of the population is at risk due to inherited mutations. Rarely, high-risk mutations cause greatly increased risk for lung cancer development and individuals with these mutations require careful management to avoid increasing risk from ionizing radiation. The findings from GWASs of more common and lower-penetrance SNPs associated with lung cancer risk contribute information about the biology of lung cancer development. Selected high-risk variants such as the K3326X variant of *BRCA2* convey sufficient risk to suggest implementing screening, in a similar way as would a positive family history of lung cancer. As more genome-wide studies are conducted, we may anticipate that genetic information will become useful for selecting individuals who will benefit from lung cancer screening and precision prevention.

Acknowledgments

This work was supported in part by National Institutes of Health grants U01CA209414 and U19CA203654 and the Cancer Prevention Research Institute of Texas grant RR170048. Dr. Amos is a Research Scholar of the Cancer Prevention Research Institute of Texas. We acknowledge Drs. Jonathan Samet, Anthony Aberg, and Malcolm Brock for earlier chapter contributions, and we thank Rowland Petite for assisting in updating eFig. 74.1.

Key Points

- In the United States, lung cancer remains the leading cause of cancer death for both men and women.
- The predominant cause of lung cancer is exposure to tobacco smoke, with active smoking causing most cases, but passive smoking also contributing.
- The reductions in smoking prevalence in men in the late 1960s through the 1980s will continue to drive lung cancer mortality rates down during the first portion of the 21st century.
- Fortunately, exposures to major occupational respiratory carcinogens have largely been controlled in the United States (though not globally), but the population is still exposed to environmental causes of lung cancer, including asbestos and radon, the second leading cause of lung cancer death.
- Gender similarities and differences exist in lung cancer. The most important fact is that, among smokers, a similar smoking history results in similar lung cancer risk for women and men. Among never-smokers, compared to men, women have a higher overall incidence of lung cancer, particularly of adenocarcinoma with epidermal growth factor receptor mutations.
- Certain heritable genetic risk factors render some individuals more susceptible to environmental carcinogens, especially tobacco. As more genome-wide studies are conducted, genetic information will likely become more useful for selecting individuals who will benefit from lung cancer screening and precision prevention.

eFigure 74.1 Magnitude of genetic associations for 58 reported lung cancer susceptibility loci. The *left* and *right* panels show *odds ratio* (OR) and –log10 (*P* values), respectively. The top set of results were previously described by Bosse and Amos,[180] whereas results below the line are newly reported loci. Bars illustrate the smallest *P* values or the maximum OR reported per locus. Tick symbols inside bars are results of the individual studies. *Top,* note that ORs lower than 1 were converted into their reciprocal (1/OR) for illustration purposes. The first three loci below the line are results from gene-gene interaction analyses reported by Li et al.[185]

INTRODUCTION

Screening for lung cancer using low-dose computed tomography has now been shown to reduce mortality from lung cancer among high-risk individuals. However, in any screening program, attention must be given to the balance of benefit and potential harms from downstream management of screening-detected findings. This chapter discusses the evidence and support for screening and the components of high-quality screening.

EVIDENCE FOR LUNG CANCER SCREENING

The mortality from lung cancer is greater than for prostate, breast, and colon cancer combined. Most individuals are diagnosed when symptomatic at advanced stages of disease when survivorship is worse, making early detection appealing. Screening is the systematic examination of asymptomatic people to detect and treat disease. For screening to be beneficial, the disease must be relatively common, have high mortality, and must be more treatable when detected early, before symptoms develop. In addition, the screening process must benefit those diagnosed with lung cancer without harming the large number of people without the disease. The goal of screening for lung cancer is to detect disease at an earlier stage when it is more treatable (e.g., with surgery); this would indicate that the screening had achieved a favorable stage shift. In the absence of lung cancer screening, 75% of those diagnosed with lung cancer present with advanced disease for which the 5-year survival rate is 6–30%. This is compared to those found with localized disease for which the survival rate is 60%. To prove the benefit from screening, trials must not only be powered to demonstrate improved mortality and stage shift but also must be designed to detect a difference compared to usual care or another screening modality.

Although early cohort studies utilizing regular screening chest radiographs demonstrated an increased prevalence of lung cancers compared to control groups, there was no mortality benefit seen. Sputum cytology alone and in conjunction with chest radiography screening did not affect outcomes. The *Prostate, Lung, Colorectal and Ovarian* (PLCO) trial randomized 154,901 participants ages 55 to 74 to annual chest radiography screening versus usual care at 10 different sites and definitively showed no lung cancer mortality benefit.[1] Screening with *computed tomography* (CT) scan in several single-arm studies found a higher incidence of lung cancer detection at an early stage of disease but could not demonstrate a mortality benefit because of lack of a comparison group. These studies provided the impetus for randomized, controlled trials to assess outcomes from screening with *low-dose computed tomography* (LDCT). LDCT is performed using less ionizing radiation than standard CT scan (8 vs. 32 mSv). (See Chapter 20.)

Several European trials were conducted at single or small numbers of centers. These trials varied in age criteria, smoking history and, in one study, screening interval (annual vs. biennial LDCT), all with a comparison to usual care.[2–5] They were all similar in that they were not powered or designed to detect a difference in lung cancer mortality and therefore could not provide strong enough evidence to support large-scale implementation of lung cancer screening.

The *National Lung Screening Trial* (NLST) addressed these issues. The NLST has been the largest randomized trial of LDCT to date, conducted at 33 centers in the United States.[6] It enrolled 53,454 participants aged 55 to 74 years with at least a 30 pack-year smoking history, with former smokers having quit within the past 15 years.[6] Participants were randomized to annual LDCT for 3 years or annual chest radiograph. The study achieved its primary end point with a 20% lung cancer mortality reduction in the LDCT arm. The all-cause mortality rate was also 6.7% lower in those screened with LDCT. The overall number needed to screen to prevent one lung cancer death was 320.

The *Dutch-Belgian Randomized Lung Cancer Screening* (with the Dutch acronym NELSON) trial was the next largest trial of LDCT powered to detect a mortality difference compared to usual care.[7] Men and women aged 50 to 75 years who were current or former smokers who had quit within 10 years of enrollment with a minimum of 15 pack-years were recruited to participate at four centers. Following a baseline LDCT, participants underwent subsequent screening at 1, 3, and 5.5 years. At 10 years of follow-up, the cumulative rate ratio for death from lung cancer was 0.76 (confidence interval, 0.61–0.94) in the screened group compared to the control group. The decrease in mortality of 24% was similar to that of the NLST. More benefit was seen in women, although this group was relatively small.[7] The trial used computer software to evaluate noncalcified screening-detected nodules according to volume and volume doubling time. Growth between two scans was defined as a volume increase of at least 25%. A nodule identified on a baseline scan was also considered to be negative if the volume was less than 50 mm^3, if there was no growth at 3-month follow-up in nodules 50 to 500 mm^3 in size, or if volume-doubling time was 400 days or more.[8] Using these definitions, the sensitivity of screening following one round was 94.6% with a negative predictive value of 99.9%.[9]

The findings of these two seminal studies have provided definitive evidence in support of screening for early detection and mortality reduction in lung cancer. It is important to recognize, however, that lesions most often detected are benign. Therefore, management of screening-detected nodules is an important consideration because inappropriate management has the potential to lead to downstream harms from invasive diagnostic procedures. This is one of a number of factors that could potentially impact the generalizability of the finding of these large randomized trials.

GENERALIZABILITY

Although the NLST demonstrated a mortality reduction, questions have been raised about generalizability of the results to the eligible U.S. population. There are three main areas that may limit the ability to generalize the NLST results. The *demographics* of the estimated 8 million Americans meeting criteria for screening are considerably different from the NLST participants.[10] In comparison, the NLST participants were younger, healthier, better educated, and less likely to be current smokers. These findings are in line with the "healthy volunteer effect" seen in screening trials in which there is a self-selection of more educated, health-conscious participants with better access to health care.[11] The *expertise* available in the communities where individuals will be screened raises some concern that the results of screening may not be realized. In the NLST, screening was conducted at largely urban, tertiary care hospitals with expertise in all aspects of lung cancer care, including multidisciplinary clinics and dedicated thoracic radiologists. Even though the nodule detection rate was high, the number of participants requiring invasive interventions was quite low. Whether this conservative use of invasive testing will continue at the community level is uncertain. This is of concern because variation in the utilization of CT-guided lung biopsy for diagnosis in incidental nodule management has been demonstrated.[12] Finally, the *surgical outcomes* achieved in the NLST may not be the same for the general U.S. population. The surgical mortality in the NLST was less than 1%. This is less than U.S. national averages, which range from 3–5%, and is likely due in part to the settings where surgery was conducted. The NLST enrollment sites were large centers with dedicated thoracic surgeons performing high volumes of procedures, features associated with better outcomes when compared to centers with a lower volume of procedures.[13,14] Surgical mortality that exceeds that of the NLST could diminish the mortality benefit from screening. As lung cancer screening is more broadly implemented, procedure utilization and outcomes should be collected to address questions of generalizability.

COMPONENTS FOR EFFECTIVE LUNG CANCER SCREENING

Given the evidence to support reduced mortality with lung cancer screening, the *U.S. Preventive Services Task Force* (USPSTF) gave a grade B recommendation in favor of screening.[15] Several professional societies endorse lung cancer screening and have identified essential components that should be part of all programs to ensure high-quality lung cancer screening (Table 75.1). A subset of these topics is covered later in this chapter; radiology aspects are covered in Chapter 20.

PATIENT ELIGIBILITY

Persons deemed eligible for lung cancer screening should be at high enough risk of developing lung cancer that the mortality benefit related to screening outweighs any harms associated with the screening process. As previously discussed, the NLST and the NELSON trials are the only clinical trials to date powered sufficiently to demonstrate a mortality benefit from screening.[6,7] Eligibility for screening in the United States has largely been defined by the entry criteria for subjects participating in NLST, specifically persons aged 55 to 74 years with a smoking history of at least 30 pack-years, currently smoking, or having quit within the past 15 years.[6] Eligibility for screening has also been informed by the *Cancer Intervention and Surveillance Modeling Network* (CISNET) models developed using individual-level data from the NLST and the PLCO trial. CISNET considered 576 different scenarios, with different combinations of ages at which to start and stop screening, intensities of smoking including a range of minimum smoking history and duration of time since quitting, and intervals between screening studies.[16] As would be anticipated, models broadening the criteria to include a larger screening-eligible population averted more lung cancer deaths but required far more screening studies, with an associated increase in the harms associated with screening. Conversely, models that narrowed the criteria required fewer studies to achieve benefit but with benefit limited to a smaller eligible population.

Based on NLST and the CISNET analysis, the USPSTF recommends "annual screening for lung cancer with low-dose computed tomography in adults aged 55 to 80 years who

Table 75.1 Components Necessary for a High-Quality Lung Cancer Screening Program[57]

WHO IS OFFERED LUNG CANCER SCREENING
Programs must confirm that a policy is in place about who will be offered screening that is in line with evidence-based guidelines.
HOW OFTEN, AND FOR HOW LONG, TO SCREEN
Programs must confirm that there is a policy about the frequency and duration of screening that is in keeping with USPSTF recommendations.
HOW THE CT SCAN IS PERFORMED
An LDCT scan should be performed based on the American College of Radiology and Society of Thoracic Radiology technical specifications.
LUNG NODULE IDENTIFICATION
Programs should have a policy about the size and characteristics of a lung nodule to be used to label the test as positive.
STRUCTURED REPORTING
A lung cancer screening program should use a structured reporting system, such as LungRADS, and collect data about compliance with the system.
LUNG NODULE MANAGEMENT ALGORITHMS
Programs must have clinicians with expertise in the management of lung nodules and treatment of lung cancer. The program should have developed lung nodule care pathways with the ability to order additional testing and communicate results to the patient and/or provider. There should be a mechanism to track nodules and collect outcomes.
SMOKING CESSATION
Programs must integrate smoking cessation services for active smokers.
PATIENT AND PROVIDER EDUCATION
Programs are responsible for the oversight and supplementation of provider-based patient education.
DATA COLLECTION
Programs must collect data related to each component of a lung cancer screening program, the outcomes of testing, as well as the cancers diagnosed, and report this data annually to an oversight body.

CT, computed tomography; LDCT, low-dose computed tomography; USPSTF, U.S. Preventive Services Task Force.

have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years."[15] This recommendation was modified by the *Centers for Medicare and Medicaid Services* (CMS), which ultimately endorsed lung cancer screening for the population matching NLST entry criteria (ages 55–74 years), with the exception of increasing the age range to 77 years, acknowledging the upper boundary for age at NLST entry of 74 years and the 3-year duration of LDCT imaging.[17]

The USPSTF and CMS recommendations for screening eligibility should not be interpreted as identifying all individuals at high risk for lung cancer because they are based solely on the stringent NLST entry criteria and the CISNET models. There is concern that individuals at high risk for lung cancer, but who do not meet established eligibility criteria, will not be considered for screening or may have screening declined by insurance providers. The appropriateness of this concern is supported by lung cancer risk prediction calculators such as those used by Tammemagi and colleagues (PLCOm2012) and Katki and colleagues, which include multiple variables beyond age, smoking intensity, and smoking duration in the assessment of clinical risk.[18–20] The PLCOm2012 model includes age, race/ethnicity, education, body mass index, COPD, personal cancer history, family history of lung cancer, and smoking status/intensity/duration/quit time.[21] The use of this PLCOm2012 model in the PLCO dataset resulted in improved sensitivity and positive predictive value for finding lung cancer when compared with application of NLST and USPSTF criteria.[21,22] Arguments supporting targeting of screening to higher-risk individuals identified by using validated risk prediction calculators include a lower rate of false-positive findings, a lower number needed to screen to avert a lung cancer death, and avoidance of screening a lower-risk population less likely to realize benefit.

It is important to recognize that even among persons identified as being at high risk for lung cancer, there are individuals for whom screening should not be recommended. First, screening should be performed in asymptomatic persons. Individuals with symptoms suggestive of lung cancer should undergo usual diagnostic evaluation, as opposed to screening. Second, screening should be performed only in persons whose competing health issues, if present, are not anticipated to limit the benefit gained from early cancer diagnosis.[23] Third, persons undergoing screening should be both able and willing to undergo treatment if a cancer is identified. The USPSTF criteria state that "Screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery."[15] Figure 75.1 provides a suggested algorithm for considering patient eligibility for lung cancer screening.

Rigor should be exercised in decisions about screening individuals who do not meet either USPSTF or CMS criteria. In such cases, screening is not recommended. The recommendation against screening is based on the imbalance of benefit, which is unproven in groups other than those meeting the eligibility criteria, and of harm, including the likelihood of false-positive results found more frequently in individuals at low risk, the consequences of evaluation for false-positive results including unnecessary biopsies and surgeries, unnecessary cost, and exposure to radiation. If clinicians continue to have substantial concern about whether to screen because of perceived lung cancer risk, employment of an objective measurement of risk may be useful. For example, the National Comprehensive Cancer Network consensus guidelines recommend lung cancer screening for patients who meet USPSTF guidelines, as well as for another group of younger individuals (age ≥50 years) with less smoking history (≥20 pack-years), and an additional risk factor other than secondhand smoke that increases the risk of lung cancer to 1.3% or more over 6 years.[24] The 2018 CHEST Guideline and Expert Panel Report suggests that a lung cancer risk of 1.51% or more over 6 years, as determined by the PLCOm2012 calculator, could be used as an example of defining "high risk," which could be factored into a decision regarding whether or not to recommend screening for an individual who does not meet USPSTF or CMS criteria.[25]

PATIENT EDUCATION AND SHARED DECISION-MAKING

Shared decision-making (SDM) requires that health care providers collaborate with their patients to make decisions together based on the best available evidence and

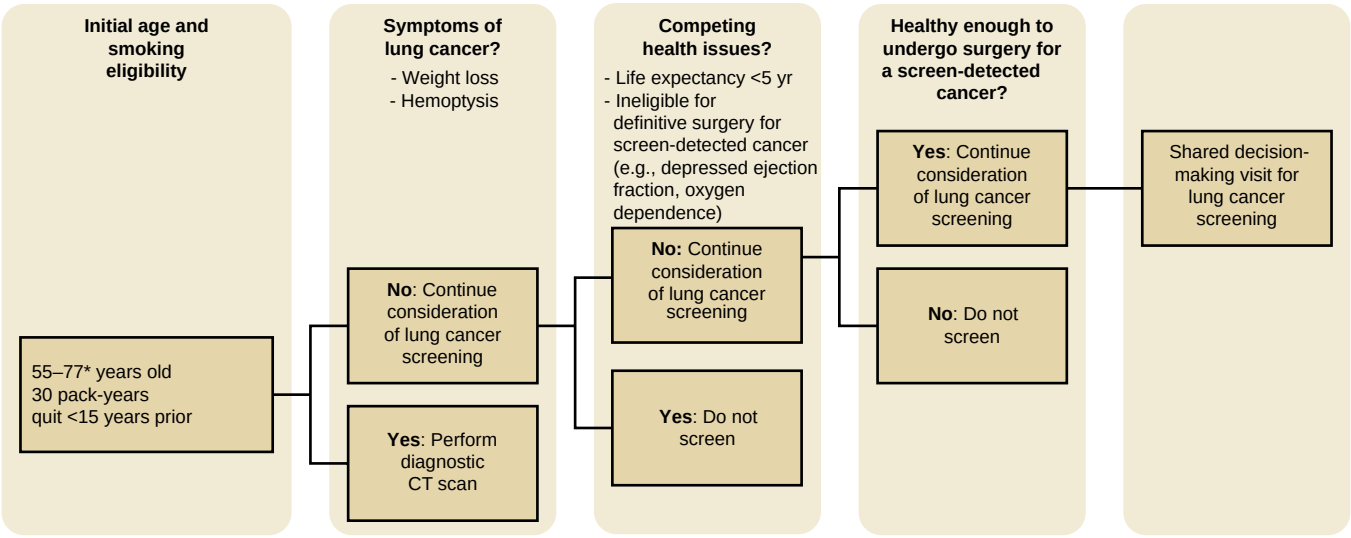

Figure 75.1 Algorithm for considering patient eligibility for lung cancer. *Centers for Medicare and Medicaid Services eligibility criteria. CT, computed tomography.

pertinent patient values and preferences. The goal of SDM for lung cancer screening is to increase the likelihood that patients understand the screening options, benefits, and harms, and are comfortable making decisions aligned with their preferences and values. The lung cancer screening evidence base has informed us about the potential benefit and harms of screening. The balance of benefit and harm varies based on individual characteristics related to the risk of developing lung cancer, the risk of evaluating findings detected by screening, the benefit of finding and treating early-stage lung cancer, and the risk of competing mortality. For a substantial portion of those eligible for lung cancer screening, decisions about whether to proceed with screening are *preference sensitive*, meaning that the risk/benefit ratio is balanced so that there is no right or wrong choice and the decision should be based on patient preference.

For this reason, and with the previously stated goal in mind, CMS coverage of lung cancer screening requires that individuals have a "lung cancer screening counseling and shared decision-making visit" prior to receiving LDCT.[17] The CMS coverage determination lists the components of this visit, which include SDM that incorporates decision aids. Decision aids can be designed as printed handouts or as web/video-based tools. They present information in easy-to-digest graphic or numeric formats to help foster an understanding of the evidence base that empowers those making the decision. Other aspects of the required SDM visit include an assessment of lung cancer screening eligibility, a description of elements of the screening process (e.g., adherence to annual screening, potential need for additional diagnostic evaluation), and counseling about smoking cessation.

Though most concede that the principle of SDM is the ideal result of all clinician-patient interactions, some are concerned that the burden of conducting an SDM visit may reduce the uptake of lung cancer screening without strong evidence that an SDM visit improves traditional lung cancer screening outcomes. Nonetheless, there is accumulating evidence about the benefit of a lung cancer screening SDM visit on knowledge and satisfaction with screening decisions and about the most effective SDM strategies. The use of lung cancer screening decision aids has been shown to increase patient knowledge about LDCT screening and its tradeoffs.[26–29] An SDM visit within a centralized screening program demonstrated that 95% of those who came to the visit went on to complete screening. Knowledge about eligibility criteria, as well as the benefits and harms of screening, was poor prior to the visit, improved immediately after the visit (at the time of the decision), and waned 1 month later. The visit made the patients more comfortable with their screening decision.[30] Others have explored the ideal means of conducting an SDM visit. In one setting, the addition of an informational film to a booklet led to improved knowledge and reduced decisional conflict when compared to the use of the booklet alone, without affecting decisions to undergo lung cancer screening.[31] In another study, an in-person SDM visit was compared to an SDM visit by telephone. Satisfaction with decisions was high, decisional conflict low, and 88% completed the screening exam. These metrics did not differ between the SDM delivery methods.[32]

Despite the growing evidence of benefit, there remain concerns about the uptake and quality of SDM visits. One study of patient-reported physician-patient discussions about lung cancer screening suggested that only 18% of active smokers aged 55 to 74 years discussed lung cancer screening with their provider in 2017.[33] Another study performed a qualitative content analysis of 14 clinician-patient conversations about screening. Using a validated measure of SDM, the Observing Patient Involvement in Decision Making scale, the authors found a low overall quality of the discussions (mean score of 6 on a scale of 0 to 100), and that physicians universally recommended screening and did not discuss the potential harms. Decision aids were not used, and the conversations lasted a mean of 59 seconds.[34] Further efforts will help define the ideal means of conducting and implementing high-quality SDM for lung cancer screening in a variety of settings.

NODULE MANAGEMENT

Lung nodules are commonly identified on LDCT screening exams. The prevalence and incidence of lung nodules vary depending on the definition of what constitutes a positive result. The higher the nodule size threshold for a positive result or the stricter the criteria (e.g., inclusion of growth rate from volumetric imaging), the lower the prevalence and incidence. For reported randomized, controlled trials, the prevalence of a lung nodule has ranged from 1.6% (positive result required growth on 3-month surveillance CT for nodules 50–100 mm^3) to 30.3%, and the cumulative incidence ranged from 6.0–46.1%.[35] Fifty-nine percent of those screened in the Veterans Affairs lung cancer screening demonstration project had a nodule of any size, while 12.7% had a nodule more than 8 mm in diameter.[36] *Subsolid* nodules, which include ground-glass nodules and those that are partly solid, have been reported in up to 16.9% of those screened.[37] Despite these differences, all studies have found that the majority of nodules identified during screening are benign.

Appropriate management of nodules detected by screening is essential to maximizing the benefit and minimizing the harms of lung cancer screening. The goal of nodule management is to minimize testing in those with benign nodules while rapidly identifying and treating those with malignant nodules. To this end, a widely used grading system based on the risk of malignancy has been developed by the *American College of Radiology* (ACR) and is being used to assist with uniform reporting and management of smaller lung nodules. Use of this structured reporting system (Lung-RADS; https://www.acr.org/-/media/ACR/Files/RADS/Lung-RADS/LungRADSAssessmentCategoriesv1-1.pdf?la=en) can help minimize the frequency of surveillance for small benign nodules but may sacrifice a bit of sensitivity for small malignant nodules (see Chapter 41).

Clearly benign nodules (e.g., calcified nodules or subpleural lymph nodes) do not require additional surveillance. (See Fig. 41.1 for examples of benign nodules on CT.) Solid nodules 8 mm or less in diameter are followed with CT imaging (intervals based on the size). Pure ground-glass nodules are monitored until they become more solid, and partly solid nodules are managed based on the size of the solid component of the nodule. Subsolid nodules (i.e., pure ground-glass and partly solid) make up the majority of overdiagnosed cancers. Overdiagnosis, which is an inherent drawback to screening, is the detection of a cancer that would not have otherwise become clinically significant (e.g., life-limiting). Individuals may undergo unnecessary diagnostic procedures and treatments with the potential morbidity and personal distress for a finding that would not have otherwise limited their life expectancy.

Solid nodules more than 8 mm in diameter are managed based on their estimated probability of malignancy (quantitative or qualitative prediction) and features impacting the yield of adjunctive testing (positron emission tomography scanning, transthoracic needle biopsy, bronchoscopic biopsy, or surgical resection). Nodules of this size with a very low probability of malignancy are monitored with serial CT imaging. Those with a low to moderate probability of malignancy, and a low yield from adjunctive testing, are also monitored for growth with serial CT imaging. Those with a low to moderate probability of malignancy and a moderate to high yield from adjunctive testing are further evaluated with positron emission tomography scans or a nonsurgical biopsy (transthoracic needle biopsy or bronchoscopic biopsy). Nodules with a high probability of malignancy may proceed directly to resection or be further evaluated with a nonsurgical biopsy if the results would lead to a change in the need for resection.

Several malignancy risk prediction models have been developed to assist with the estimation of malignancy probability in lung nodules, whether detected by screening or incidentally.[38–43] A model developed in the screening setting and validated in the NLST cohort yielded sensitivity, specificity, positive predictive value, and negative predictive value of 85.3%, 93.9%, 27.4%, and 99.6%, respectively.[43] This model has been shown to have a higher accuracy than the Lung-RADS system and has been incorporated into screening-detected nodule management algorithms.[41] Another model developed in the screening setting increased accuracy over traditional models by including additional nodule measurements.[39]

Low rates of procedures (1.2–6.9% of those screened), major complications (7.8% of procedures), and death potentially related to procedures (0.8% of procedures) have been reported in many trials of lung cancer screening.[35] These rates reflect the quality of nodule management in the sites that participated in clinical trials. It is unclear if systems and processes of care outside of clinical trial settings would produce similar results. Even higher rates of procedures and complications may be seen in other settings.[12] Complication rates (22.2–23.8%) in a population-based community setting were reported to be more than twice as high as those reported by the NLST, with incremental costs of more than $50,000 per major complication.[44]

MANAGEMENT OF OTHER SCREENING-DETECTED FINDINGS

The LDCT screening scan acquires images from the lower neck to the upper abdomen. The current screen-eligible cohort has risk factors (age, smoking history) for other cancers and chronic diseases as well as comorbidities that impact their risk and well-being (hypertension 60%, hyperlipidemia 50%, COPD 30%, coronary artery disease 15%, diabetes mellitus 15%).[45] For these reasons, abnormal findings in organs other than the lungs can be found at the time of screening (Fig. 75.2). Whether these additional findings add value to lung cancer screening or add to the potential for harm is currently unclear. Screening programs must be aware of these potential findings, inform those being screened of this possibility, and have a plan in place to manage them.

The most common abnormal findings include chronic airway disease (36%), emphysema (47%), and coronary artery calcification (51%).[45] The prevalence of interstitial lung abnormalities was 9.7% in one study. At 2-year follow-up, findings of nonfibrotic interstitial lung abnormalities improved in 49% of cases and progressed in 11%. Fibrotic interstitial lung abnormalities improved in 0% and progressed in 37% of cases.[46] Other potentially actionable findings include mediastinal adenopathy, pleural disease including effusions, thyroid and adrenal nodules, and aortic aneurysms (see Fig. 75.2). It is valuable for a screening program to be aware of current guidelines for

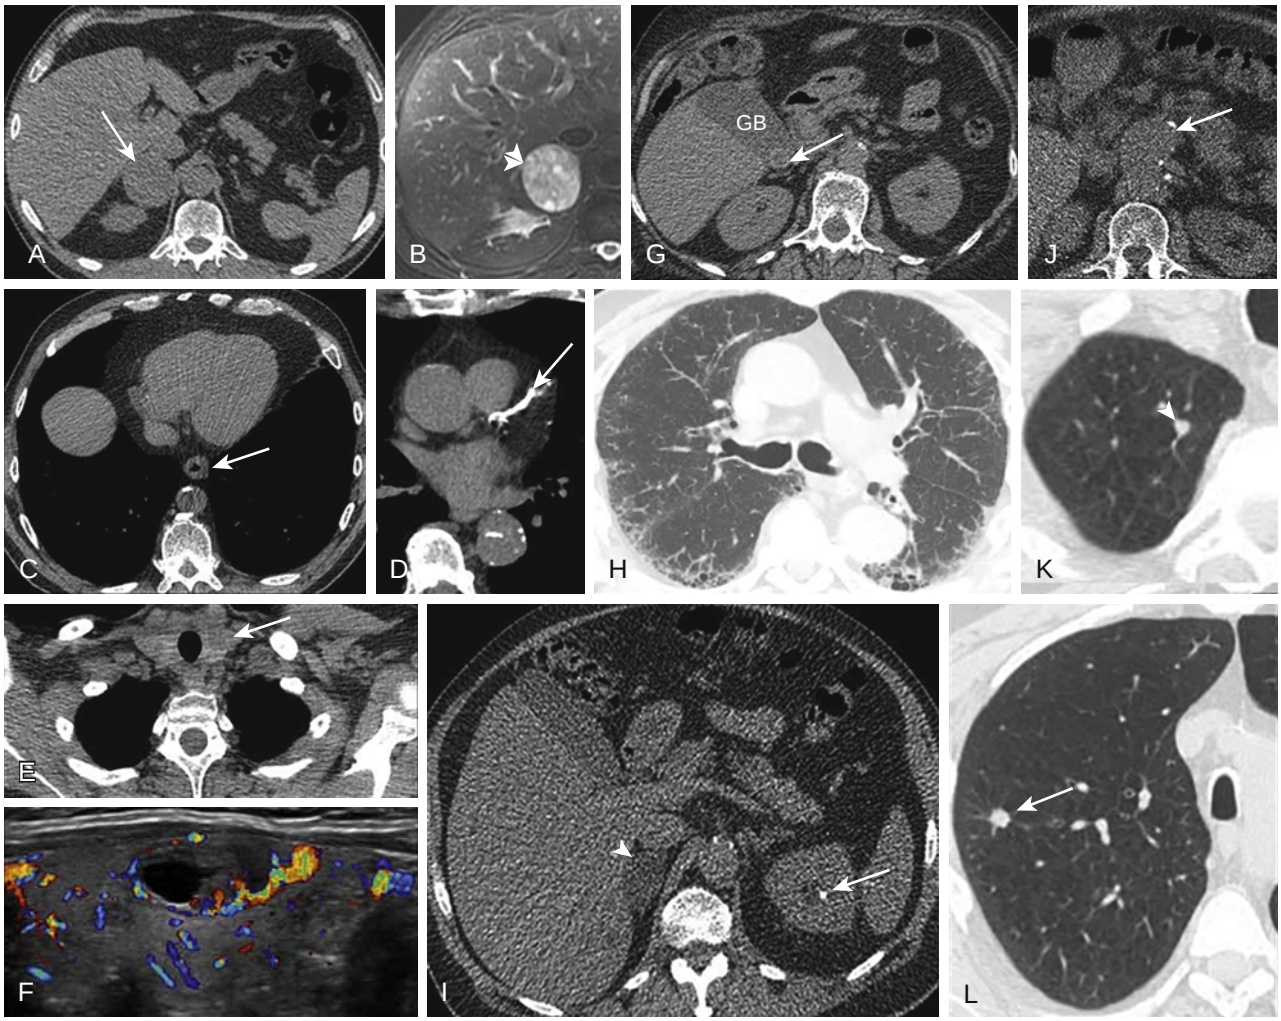

Figure 75.2 Findings, many incidental, on low-dose lung cancer screening computed tomography. (A) Nonspecific right adrenal mass (*arrow*) found on *low-dose lung cancer screening computed tomography* (LDCT). (B) The right adrenal mass shows T2 hyperintensity on dedicated MRI (*double arrowheads*). Resection proved pheochromocytoma. (C) Axial LDCT shows nonspecific thickening of the distal esophagus (*arrow*). Upper endoscopy revealed reflux esophagitis. (D) Axial LDCT (focused on the heart) shows heavy calcification of the left anterior descending artery (*arrow*). (E) Axial LDCT shows incidental left thyroid nodule (*arrow*) measuring 1.6 cm. (F) Thyroid ultrasound shows peripheral vascularity but no features to suggest malignancy; the lesion was considered low-risk and followed for stability. (G) Axial LDCT shows cholelithiasis (*arrow*). (H) Axial LDCT (lung windows) shows bibasilar reticulation and subpleural cystic change, suggesting fibrotic lung disease. (I) Axial LDCT shows a small left-sided nonobstructive renal calculus (*arrow*) and right adrenal adenoma (*arrowhead*), which was lipid-rich and presumed benign. (J) Axial LDCT shows a partially visualized peripherally calcified upper abdominal aortic aneurysm (*arrow*). (K–L) Axial LDCT shows a circumscribed 4.5 mm right upper lobe nodule (*arrowhead*) and mildly irregular more inferiorly located right upper lobe nodule measuring 10 mm (*arrow*) with a background of severe centrilobular emphysema. the management of these findings and to engage with specialists in these areas who can guide the development of management algorithms for the program. Despite the high rate of identifying these abnormalities, less than 5% lead to an invasive diagnostic or therapeutic procedure.[45,47–50] The evaluation of these findings adds to the cost of screening and can account for up to 50% of a screening program's reimbursement, funding that can help support the program.[45,47–49]

SMOKING CESSATION (see Chapter 66)

Smoking cessation reduces lung cancer mortality more effectively than screening. An analysis of the NLST participants randomized to the control arm found that 7 years of abstinence achieved the same 20% mortality reduction seen with LDCT. Furthermore, the combination of smoking abstinence and LDCT screening was additive; those who had quit smoking and undergone screening achieved a lung cancer mortality reduction of 38%.[51] It is currently unclear whether involvement in a lung cancer screening program influences the rate of smoking cessation. Higher rates of smoking cessation at 2 years were found in the screening arm of the UK Lung Screening trial (15% vs. 10%) but not in either the Danish Randomized Lung Cancer Screening Trial (11.9% vs. 11.8%) or the NELSON trials (13.7% vs. 15.5%). There is evidence that smoking cessation rates are higher in those with screening-detected nodules.[52] While there is controversy as to whether smoking cessation counseling is more effective in the context of screening as a "teachable moment," there is no argument that counseling is appropriate and that there are benefits associated with quitting. Smoking cessation improves the impact and cost-effectiveness of lung cancer screening.

CMS requires that smoking cessation counseling be incorporated into the screening process for Medicare-insured patients.[17] Examination of the screening framework readily identifies steps where counseling can be introduced or referrals made to smoking cessation services: by providers at the time of eligibility determination or during SDM visits, in conjunction with the ordering or performance of the screening LDCT, and at the time of delivery of test results.

Currently, smoking cessation interventions applied in the screening setting should follow standard protocols developed in general smoking populations (see Chapter 66). Research is being conducted to determine if alternative or additional measures are more effective in the screening setting.

IMPLEMENTATION

It is widely recognized that achieving reliable cancer screening at a population level is enormously challenging. Even when screening is broadly accepted, known to save lives, and embedded in routine health care, such as is currently the case for breast, colorectal, and cervical cancers, screening processes are often disorganized and inefficient.[53] Guiding principles, such as those outlined above, are fundamental to establishing best practices; successful implementation and maintenance of screening adherent to those principles present practical challenges in real-life settings. It is important that we learn from the long experience of breast, colorectal, and cervical cancer screening about the many barriers that can prevent individuals and populations from being screened, and draw on that knowledge to anticipate predictable pitfalls and to develop processes more likely to be inclusive and sustainable.[54] An online resource sponsored by the *American Thoracic Society* (ATS) and American Lung Association for planning and implementing lung cancer screening programs is available at https://www.lungcancerscreeningguide.org/.

TYPES OF SCREENING PROGRAMS

Designing and implementing a lung cancer screening program demands a keen understanding of local factors, including the type of system in which the program is embedded; the technical capabilities of communication and data systems, including the *electronic health record* (EHR); distribution of resources available to the program; the culture of other institutional screening practices; and the availability as well as willingness of the multiple disciplines involved in lung cancer care to participate.

Screening program structures fall into three general categories: *centralized*, *decentralized*, and *hybrid*. A brief description of centralized and decentralized programs is outlined in Table 75.2; hybrid programs combine aspects of both centralization and decentralization. The structure and extent of a screening program implemented at a given site will be heavily influenced by local resources, which will define the type and scope of program that can be feasibly achieved.

A FRAMEWORK FOR IMPLEMENTATION OF LUNG CANCER SCREENING

Beaber and colleagues proposed a general conceptual screening model for a consortium entitled *Population-based Research Optimizing Screening through Personalized Regimens* (PROSPR), which is intended to unify the screening process across breast, cervical, and colorectal cancer screening.[53] This framework should be generalizable to screening for any cancer, including lung cancer, and can be used as a roadmap to identify where challenges in delivery of screening may be encountered as well as where meaningful

Table 75.2 Types of Screening Programs

Type	Description	Advantages/Disadvantages
Centralized	Screening program assumes responsibility for the entire spectrum of care, from eligibility determination through diagnosis and treatment Feasible for large, comprehensive health care systems capable of providing primary through specialty care internally	**Advantages:** Ability to automate identification and recruit eligible patients Single internal EHR for streamlining communication Standardization of radiographic processes for LDCT performance and result reporting Capability to facilitate and provide comprehensive care for abnormal findings Quality metrics internally measurable **Disadvantages:** Administrative burden Manpower needs for comprehensive care spanning all aspects of screening, evaluation and management
Decentralized	Default process in absence of coordinated comprehensive health care system Screening process steps located in separate systems Reliance on primary care provider to steward screening Most breast and colorectal cancer screening takes place in decentralized settings	**Advantages:** Screening can be performed with existing processes and manpower No requirement for overarching process development or management **Disadvantages:** Fragmented care Communication challenges between sites of care Assessment of quality likely more difficult
Hybrid	Includes components of both centralized and decentralized programs	As outlined above

EHR, electronic health record; LDCT, low-dose computed tomography.

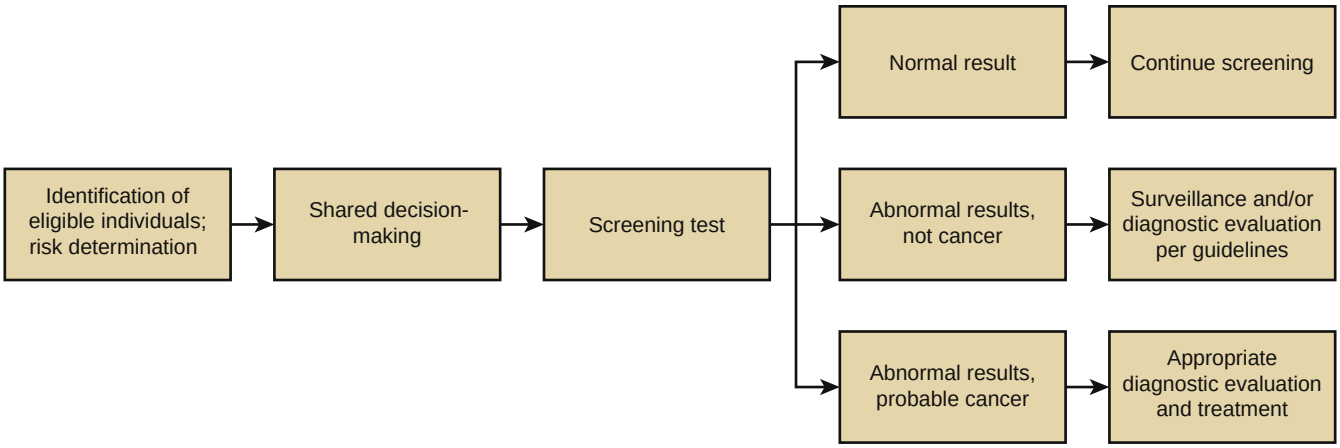

Figure 75.3 Provider-level lung cancer screening process. This model outlines a framework for screening of lung cancer, based on frameworks proposed for breast, cervical, and colorectal cancer screening. The nine elements (boxes) can be addressed individually to target challenges to screening and opportunities for improvement. (Modified from Beaber EF, Kim JJ, Schapira MM, et al. Unifying screening processes within the PROSPR consortium: a conceptual model for breast, cervical, and colorectal cancer screening. *J Natl Cancer Inst.* 2015;107[6]:djv120; and Armstrong K, Kim JJ, Halm EA, Ballard RM, Schnall MD. Using lessons from breast, cervical, and colorectal cancer screening to inform the development of lung cancer screening programs. *Cancer.* 2016;122[9]:1338–1342.)

measures of quality might be targeted. A simplified version of this model is outlined in Figure 75.3, with the notable addition unique to lung cancer screening of the required SDM visit between a practitioner and an individual prior to performance of a screening LDCT.

The framework proposed by the PROSPR consortium helps us understand that lung cancer screening is inherently multidisciplinary. Primary care providers, nurse navigators, radiologists, and thoracic oncology specialists (pulmonary medicine, thoracic surgery, medical oncology, radiation oncology, etc.) all participate in aspects of the flow of patients through screening. Moreover, there must be institutional oversight of the test performance of the actual screening LDCT as well as reporting to a centralized registry. The framework also helps recognize and address important potential pitfalls to successful screening as they arise. In addition, the ATS and *American College of Chest Physicians* (ACCP) have published a policy statement on lung cancer screening program development outlining three main stages to be considered: planning, implementation, and maintenance.[55] This addresses a variety of site-specific strategies to incorporate the nine elements of comprehensive lung cancer screening to fit in with local workflow. The components of screening and potential quality metrics have been discussed previously in detail; the remainder of this section will address a few of the specific areas of the framework that may be useful in the development of sustainable, successful screening programs.

Identification and Engagement of Individuals Eligible for Screening

Although this first step in screening may seem straightforward, differences between existing recommendations may cause confusion about which individuals should be screened and highlight the importance of a program clearly defining the eligibility criteria that will be used. As already noted, the USPSTF criteria for screening are fairly simple: persons aged 55 to 80 years with a 30 pack-year history of smoking, currently smoking or having quit within the past 15 years, and medically fit for treatment with a life expectancy sufficient to reap benefit from treatment.[56] CMS criteria for screening differ slightly in limiting the age range to 55 to 77 years.[17] National Comprehensive Cancer Network and ACCP guidelines suggest that risk assessment using a validated model should be considered for individuals who do not meet USPSTF criteria, with high risk for lung cancer defined as at or more than 1.3%[24] or 1.51%[25] or more over 6 years. A centralized screening program should define a standardized approach to determining eligibility; a decentralized program will have a more difficult task to maintain standardization unless there is gatekeeping at the level of ordering the screening LDCT. In the ACCP and ATS policy statement on components necessary for high-quality lung cancer screening, Mazzone and colleagues recommended that at least 90% of all screened subjects should match a program's stated approach to eligibility.[57]

This first step of identifying and recruiting individuals eligible for screening is critically important. High-risk individuals will benefit from screening only if they can be engaged. Programs may be able to harness the EHR to automate identification of potentially eligible individuals; the decision about the appropriateness of screening based on other medical factors will need to be made by an individual's primary provider. Multiple barriers to engaging eligible individuals include lack of access to primary care, low socioeconomic and/or educational status, poor or absent health insurance, inability to find substitutes for childcare or work, fear of pain or bad news, and cultural or language differences, among others. These are reflected in the imperfect screening rates observed even for screening processes that are embedded in medical practice and widely recognized by the public. In 2015, 71.6% of women aged 50 to 74 years had screening mammography, while 62.9% of adults age 50 to 75 years received colorectal cancer screening.[58,59] In 2015, the first year that lung cancer screening was covered as a Medicare benefit, only 5.8% of eligible adults underwent screening LDCT.[60] Successful implementation will require intentional planning for this first pipeline step in lung cancer screening and should include broad interventions to

increase public awareness of the importance of screening, intensive education of primary care and other front-line providers on the benefit and potential harms of screening and in lung cancer risk assessment, and concerted efforts to address identifiable barriers to care. Special consideration for educating minority populations is advisable because data from the NLST demonstrates that Blacks had a greater mortality benefit from screening than did their white counterparts.[61]

Resources for Ensuring Consistency of the Screening Test

Once an individual is recruited into screening, the next steps of the framework involve the screening test, which can be broken into several components: the SDM visit, the performance of the screening LDCT, and the radiologist's reading of the LDCT, including reporting of results to a central registry. As previously discussed, standardization of all components is important to provide consistent, high-quality screening. Resources for clinical decision support are numerous. Two representative tools include an interactive website supported by the University of Michigan, http://www.shouldiscreen.com/, and a patient-focused print resource from the ATS, https://www.thoracic.org/patients/patient-resources/resources/decision-aid-lcs.pdf. Structured, standardized reading and reporting of LDCT results are crucial to efficient screening, particularly given the high rate of false-positive findings. Lung-RADS, a tool for standardizing reports and management recommendations, is broadly available and was updated in 2019.[62] All screening programs should use Lung-RADS or a similar uniform approach; standardizing reporting and management recommendations should minimize confusion about interpretation and evaluation of true as well as false-positive findings. ACR has published technical specifications for LDCT performed for lung cancer screening, to which diagnostic imaging centers performing screening LDCT should adhere.[63] ACR also maintains the central registry for screening programs or imaging centers to submit data and screening results as required by CMS for Medicare-insured patients.

Communication Across the Screening Process

As with all patient care, communication between points of care essential to achieving best outcomes may present the greatest challenge to a lung screening program. In the PROSPR framework outlined in Figure 75.3, each arrow represents a point of communication. Each point has an inherent risk of misinformation or loss of information between providers or between providers and patients and potential delays in care. During implementation planning, or in reviews of existing screening programs, these should be carefully examined because they represent sites where potential for error or suboptimal care exists and where process improvement may be beneficial.

- In centralized screening programs, where all points of care exist within a single system, uniform access to a single EHR should streamline communication, prevent "leakage" of clinically important information, and facilitate clinical evaluation of results. This does not obviate the burden of navigation and follow-up, but the administrative resources available to manage flow through the screening process should be harnessed to ensure oversight of a patient's journey through screening.
  - Documentation of process steps, including the SDM discussion, the performance, results, and central reporting of the LDCT, and clinical actions based on LDCT results, should be available to any provider or navigator involved in the care of the individual. This should minimize the possibility of information falling through the cracks. It does not, however, ensure that quality care is rendered, which will still require tracking of patient outcomes as well as examination of each step in the screening process by measurements defined by internal program standards or by nationally recommended metrics.
  - Communication of results to patients should be timely and sensitive to patient needs. Large systems may be capable of automated delivery of results directly to patients. If information is sent by letter or via electronic portal in the absence of direct discussion with a provider, care should be taken to state results clearly and provide recommendations to the patient, in order to avoid unintended patient distress.
- In decentralized or hybrid screening programs, points of care may be fragmented and located in separate systems using separate EHRs. Communication of information will depend on the diligence of the sending and receiving parties. Consider the situation of a primary care provider who identifies an eligible patient, engages in a shared decision discussion, and orders a screening LDCT at a freestanding radiology practice. The radiologist should follow ACR technical specifications for performance of the LDCT and use Lung-RADS to report results. The task of reporting to a central registry, which requires specific clinical information as well as the LDCT results, should be assigned to someone. A report is sent to the ordering provider, who is responsible for communicating results to the patient and for follow-up of abnormal pulmonary or extrapulmonary findings, which may require referral of the patient to one or more specialists.
  - Communicating results to patients should follow the same principles as outlined above for a centralized system.
  - Accurate, efficient communication between separate providers who do not share an EHR requires reliable mechanisms to track a patient's progress from evaluation to closure of a specific issue. Accountability is no different than for usual care, with the burden of responsibility for all necessary evaluations assumed by both primary providers and specialists. Achieving efficient, accurate communication in a decentralized or hybrid screening process is as essential but will likely be more challenging than in a centralized program.

For a discussion about the future directions for lung cancer screening, concerning implementation, screening eligibility, and molecular and imaging biomarkers, see ExpertConsult.com.

FUTURE ADVANCES

IMPLEMENTATION

High-quality lung cancer screening programs are being implemented across the country. In the first few years after CMS approval of payment for lung cancer screening in the United States, the uptake of screening was slow. The slow uptake likely reflected the time it takes for knowledge to disseminate and programs to be built. More recent evaluations have suggested that there has been steady growth in access to screening programs. Much work still needs to be done in order to provide broad access to screening, particularly in disadvantaged communities.[64] Efforts to make high-quality screening accessible and equitable for all may be aided by changes in eligibility criteria, technologic advances leading to novel ways to access care, quality metric development and tracking, ongoing education, and the efforts of community outreach programs.

Technology advances may help to accelerate broad implementation of screening. The identification of eligible individuals through electronic health record searches, the ability to connect with eligible individuals through telehealth portals, the initial interpretation of CTs by artificial intelligence platforms,[65] and the prediction of lung nodule risk with deep learning models are all likely to be available over the next decade. Patient management software systems, whose guidance and reminders can optimize compliance with guideline-based care, will be routinely used.

SCREENING ELIGIBILITY

If everyone currently eligible for lung cancer screening were screened, approximately 30–40% of all current lung cancers in the population would be detected.[66] Decades of efforts to minimize cigarette smoking in the population have led to progressively lower smoking rates. The decline in smoking rates will lead to fewer lung cancers overall, and a smaller percentage of all lung cancers will be related to cigarette smoking.[66] If screening eligibility criteria remain the same, a smaller portion of all lung cancers will be detected by screening.

The decline of cigarette smoking will make it more difficult to identify individuals at risk of developing lung cancer. Other tools will be necessary to assist with the selection of screening candidates. Lung cancer risk calculators that include known risk factors, in addition to age and smoking history, have been able to improve accuracy somewhat over current eligibility criteria. The cohort identified may also be at increased risk of complications from the management of screening-detected findings and have higher competing mortality. Additional data from recently completed screening trials and clinical screening registries will help to refine risk models and enhance their clinical utility. Improvement in the management of findings detected by screening and reductions in imaging radiation doses will further minimize screening harms. By improving the balance of benefit and harm, the pool of individuals eligible for screening will be expanded.

MOLECULAR AND IMAGING BIOMARKERS

The development of molecular and imaging biomarkers is likely to influence the future of lung cancer screening. Molecular biomarkers are being developed in hopes of identifying individuals who are most likely to benefit from imaging-based screening. These include genomic, proteomic, and metabolomic markers in the blood, breath, urine, and airway mucosa. Highly specific biomarkers will allow lower-risk individuals with lung cancer to be screened safely, while highly sensitive biomarkers will minimize the risk of testing in the currently screening-eligible (high-risk) cohort.

Molecular biomarkers are also being developed to help guide the management of lung nodules. Biomarkers with high specificity will help to accelerate lung cancer treatment, and markers with high sensitivity will help to minimize procedures for those with benign nodules. Lung nodule risk prediction will also incorporate radiomic models, in which clinical imaging data are mined by computer analysis. The accuracy of these tools may augment or replace traditional risk models and support clinician judgment. Because there is a tradeoff of benefit and harm with the implementation of any test, the clinical utility of both molecular and imaging biomarkers will need to be defined.[67]

Advances in systems, knowledge, and technology will improve the balance of benefit to harm for lung cancer screening, leading to fewer lung cancer deaths.

Key Points

- Lung cancer screening with low-dose computed tomography in individuals at risk based on age and smoking history has been shown to reduce mortality from lung cancer.
- There is variation in eligibility for lung cancer screening among professional society guidelines, the United States Preventive Services Task Force, and the Centers for Medicaid and Medicare Services but, in general, asymptomatic individuals with a 30 pack-year history currently smoking or having quit within the past 15 years, aged 55 to 77 or 80 years, and well enough for curative surgical treatment are eligible.
- Guidelines are in place outlining components needed for high-quality lung cancer screening. These include nodule identification and management, patient and provider education, and smoking cessation.
- Shared decision-making for lung cancer screening aims to increase the likelihood that patients understand the screening options, benefits, and harms, and are comfortable making decisions that are aligned with their preferences and values. A shared decision-making visit should be conducted prior to lung cancer screening.
- The majority of nodules identified by screening are benign. Appropriate management of nodules is essential to maximize benefit and minimize harm.
- Lung cancer screening is multidisciplinary; primary care providers, nurse navigators, radiologists, and thoracic oncology specialists (pulmonary medicine, thoracic surgery, medical oncology, radiation oncology, etc.) will all participate in aspects of the flow of patients through screening. Implementation and type of program depends on resources available.
- Smoking cessation reduces lung cancer mortality more effectively than screening. Smoking cessation programs should be an integral part of every screening program.
- The future of lung cancer screening will include refinement in eligibility criteria, expanded implementation, and the incorporation of molecular and imaging biomarkers.

Key Readings

Minimally Invasive Staging: Endobronchial Ultrasound, Endoscopic Ultrasound, and Combined Endobronchial Ultrasound–Endoscopic Ultrasound
Invasive Staging: Mediastinoscopy
KEY POINTS

INTRODUCTION

With an estimated 2.09 million new cases globally in 2018, lung cancer remains the most common cause of cancer deaths worldwide.[1] In the United States, lung cancer accounts for an estimated 230,000 cases and more than 140,000 cancer deaths annually.[2] Added together, the number of cancer deaths from breast, colon, and prostate cancer each year would not equal the number of cancer deaths due to lung cancer alone. A common misconception among the general public is that breast cancer accounts for more cancer deaths in women. However, lung cancer is the primary cancer cause of death in women, accounting for 25% of cancer-related deaths among women and, since 1987 in the United States, killing more women than breast cancer. Particularly alarming is the fact that young women are the fastest rising demographic of new cigarette smokers in the United States, with many having made the association between weight control and cigarette smoking. The risk of lung cancer is also 2.5 times more common in female lifetime nonsmokers compared with male nonsmokers. Although more U.S. men died of lung cancer than did women in 2015 (74,000 vs. 61,000), simulation modeling predicts that this gender gap will likely close by 2045. And by 2065, more women will die of lung cancer than will men (26,900 vs. 23,400).[3]

One of the more disturbing trends in lung cancer is the explosion in rates of lung cancer in countries of the developing world. These rates may actually be underestimates of the true rates of lung cancer because many cases may go undiagnosed or unreported in areas where health care is not readily available.[4] An example of how serious this problem has become is found in China, where there were 787,000 new cases and 631,000 deaths in 2015. The age-specific incidence rate in 2014 was 37 per 100,000; there were 457,000 new cases in urban areas, which is 1.4 times higher than in rural areas.[5] Chinese men smoke an average of 11 cigarettes per day, which is equivalent to the highest average rates of smoking ever seen among males in the United States. In fact, the consumption of cigarettes in China alone may surpass that of all developed countries combined.[4,6] Overall, 67% of Chinese men smoke. In view of such statistics, it is imperative that the medical community devotes much of its educational efforts and resources toward the elimination of cigarette smoking worldwide, which would nearly eliminate the development of lung cancer.

This chapter reviews how patients present with lung cancer, the current strategies for diagnosis, the new staging system published in 2017, special cases and concerns, and the importance of palliative care. As much as possible, evidence-based review of the best currently available literature has been included. The role of the pulmonologist is described for every aspect of lung cancer care, from diagnosis to staging to caring for the complications of the disease itself.

PRESENTATION/INITIAL EVALUATION

The symptoms of lung cancer are often nonspecific, thereby delaying recognition and leading to an advanced disease stage at the time of diagnosis. In fact, the major goal of lung cancer screening is to find lung cancer at

an early stage before symptoms develop, when it is more likely to be curable (see Chapter 75). Only a minority of patients in a screened population, but up to 98% of patients in a hospitalized population, will present with symptoms.[7–9] Tables 76.1 and 76.2 list some of the common symptoms and signs associated with the presentation of lung cancer. Most are nonspecific; however, some clues can be gleaned from the history, thus raising the clinician's suspicion that lung cancer is present. Although many smokers cough, lung cancer patients usually admit to a change in the character of their cough. The cough can increase in frequency or strength or may not be relieved with the usual remedies. Chest pain can be present in 25–50% of patients at the time of presentation for evaluation for lung cancer.[8,10] The pain is generally dull in nature, tends to be persistent, remains in the same location, and is not relieved with local measures. Chest pain is usually related to involvement of the pleura but can be related to extension into the mediastinum or chest wall. It is important to note that chest pain in and of itself does not preclude the patient from consideration for surgery with curative intent. Dyspnea is frequently a complaint of patients with bronchogenic carcinoma, described by half of all new patients at presentation.[8] There is a litany of reasons for dyspnea related to lung cancer, including some that may be immediately life threatening, such as pulmonary embolism, hemorrhage, pericardial tamponade, endobronchial obstruction with tumor, postobstructive pneumonia, and stenosis of the central airways due to tumor.

Hemoptysis in a smoker should always raise the suspicion of lung cancer. Hemoptysis can present as blood streaking of the sputum and can be noted over a lengthy period of time before presentation to the physician's office because it is often attributed to smoking-related bronchitis. The clinician should not be led astray, even if the chest radiograph is normal, because up to 5% of those patients with a smoking history and a normal radiograph can harbor lung cancer.[11] Because of the vascular nature of lung cancer, patients can also present with massive hemoptysis. Weight loss, a nonspecific symptom, in the right clinical setting should raise the suspicion of both lung cancer and metastatic disease. Weight loss alone has been correlated with an advanced presentation and poor outcome from lung cancer.[12]

Some presenting signs have particular significance and can direct a workup. Hoarseness can point to involvement of the recurrent laryngeal nerve and should focus attention to that location on *computed tomography* (CT) scanning. An enlarged supraclavicular lymph node can indicate spread of intrathoracic tumor and can lead to a safe and expeditious needle biopsy with concomitant diagnosis and staging at the bedside. Particular attention should also be paid to symptoms and signs suggestive of potential paraneoplastic syndromes. Finally, patients may present with symptoms that warrant immediate referral to palliative care (see also Chapter 141).

Chest imaging may be performed as part of the initial evaluation of nonspecific respiratory symptoms or may incidentally discover lung cancer. Lung cancer may increasingly be detected in the context of lung cancer screening. Chest radiography is the most common imaging modality in the primary care setting to prompt referral to a pulmonologist, but it lacks sufficient resolution to differentiate benign from malignant disease, and a negative result does not exclude lung cancer.

CT is the standard and most common imaging modality for a patient with suspected lung cancer. CT may also be the first test performed, whether the suspicious findings were detected incidentally or in the context of screening, and CT is required at initial evaluation if the lung nodule or mass was initially detected on chest radiography (see comments later). After an abnormality consistent with a lung cancer is detected, attention must turn immediately to the suspected disease stage, and further imaging and invasive testing to confirm the diagnosis should proceed accordingly. In other words, the next steps to diagnosis are guided by determining the most expeditious, safe, and cost-effective way to (1) establish the diagnosis of cancer and (2) simultaneously determine the stage by sampling the suspected site of disease representing the highest stage, when feasible. In addition, ensuring that there is adequate tissue for molecular testing has become

Table 76.1 Presenting Symptoms With Bronchogenic Carcinoma

Symptoms	Patients (%)
Cough	45–75
Weight loss	8–68
Dyspnea	37–58
Hemoptysis	27–57
Chest pain	27–49
Hoarseness	2–18

From Midthun DE, Jett JR. Clinical presentation of lung cancer. In: Pass HI, Mitchell JB, Johnson DH, et al, eds. *Lung Cancer: Principles and Practice.* Philadelphia: Lippincott-Raven; 1996:422.

Table 76.2 Expanded Clinical Evaluation

SYMPTOMS ELICITED IN HISTORY
Constitutional—weight loss > 10 lb
Musculoskeletal—focal skeletal pain
Neurologic—headaches, syncope, seizures, extremity weakness, recent change in mental status
SIGNS FOUND ON PHYSICAL EXAMINATION
Lymphadenopathy (>1 cm)
Hoarseness
Superior vena cava syndrome
Bone tenderness
Hepatomegaly (>13 cm span)
Focal neurologic signs, papilledema
Soft tissue mass
ROUTINE LABORATORY TESTS
Hematocrit < 40% in males
Hematocrit < 35% in females
Elevated alkaline phosphatase, γ-glutamyl transferase, aspartate aminotransferase, calcium

critically important in the era of targeted therapy and immunotherapy.

In summary, patients with lung cancer can present asymptomatically, with relatively nonspecific symptoms or with constitutional symptoms suggestive of metastatic disease. There are often clues in the history that should alert the clinician that lung cancer is a possibility and that further investigation is warranted.

TUMOR-NODE-METASTASIS STAGING OF LUNG CANCER

Pulmonologists play a key role in the diagnostic and staging evaluation of patients with lung cancer.[13] Disease stage portends prognosis and dictates treatment options.

The staging of *non–small cell lung cancer* (NSCLC) has evolved since its inception in 1974.[14] The 1997 classification, proposed by Mountain,[15] was based on a single-institution database of 5319 patients. In contrast, the seventh revision of the staging system, led by the *International Association for the Study of Lung Cancer* (IASLC), was based on an international database of more than 100,000 patients with lung cancer.[16,17] Similarly, the eighth edition is informed by a global database of approximately 95,000 patients treated between 1999 and 2010.[18,19]

The process of developing a staging system is complex and comprehensive. The IASLC is the largest multidisciplinary global organization to study lung cancer, and it appointed a Staging and Prognostic Factors Committee to develop staging guidelines. The eighth edition was based on a very broad collection of data from all modalities of care, 35 institutions, and 16 countries, with the intention to use the database to improve care provided to lung cancer patients. An extensive statistical analysis of the database was performed by the Cancer Research and Biostatistics Group. Outcomes within the database varied by region and type of source data, so stage classifications were made on the basis of the presence (or absence) of differences in prognosis between and within categories and stage groupings that were consistent across multiple comparisons (clinical, pathologic, N0, any N, within a geographic region, histologic type, etc.). Final classifications were made with an understanding of the nature and limitations of the available data, along with clinical and historical considerations to influence how heavily particular analyses were weighed.[19,20] This large database of patient outcomes led to descriptors of more specific tumor characteristics than previously determined. Such characteristics were shown to affect treatment outcomes in subgroups of patients. For example, the more detailed size classifications of patients without nodal and metastatic disease can alter whether adjuvant chemotherapy can be given (based on being stage II rather than stage I) in different subsets of patients with N0M0 disease who receive surgical resection.[21] In the previous seventh edition of lung cancer staging, T2 tumors that were greater than 4 to 5 cm in size and N0M0 were classified as stage IB, whereas in the eighth edition, based on more extensive data, they are classified as stage IIA. Refinements and updates of the staging system will be needed periodically as additional data, new therapies, and scientific discoveries in lung cancer emerge.

Stage classification allows standardized descriptions of the anatomic extent of a cancer and consists of three components: extent of the primary *tumor* (T), involvement of lymph *nodes* (N), and presence or absence of distance *metastasis* (M). This standardized nomenclature facilitates communication about a particular patient, provides an understanding of the extent of disease among patients enrolled in clinical trials, and allows clinicians to make informed treatment decisions.[19]

The following section reviews the eighth edition of the lung cancer staging system, with a focus on changes compared to prior editions. In addition, studies highlighting significant quality gaps in lung cancer staging are reviewed.

EIGHTH EDITION LUNG CANCER STAGE CLASSIFICATION

The eighth edition of the TNM classification of lung cancer became the worldwide standard as of January 1, 2017; it was implemented in the United States and Canada as of January 1, 2018. The TNM system principally guides the staging of NSCLC. In contrast, *small cell lung cancer* (SCLC) is generally classified and managed according to a more simplified system of limited versus extensive disease.

The T, N, and M components of the staging system are divided into several categories. Various characteristics or "descriptors" define what comprises a given T, N, or M category. Specific combinations of T, N, and M categories constitute stage groupings. Tables 76.3 and 76.4 display the eighth edition T, N, and M descriptors and stage groupings. A prefix specifies the type of staging assessment. *Clinical* (c) stage is based on all information available before surgical resection, including symptoms and physical signs, imaging studies, and the results of diagnostic procedures. *Pathologic* (p) stage is defined by the results of surgical resection (including an aborted one) in addition to all clinical information. Of note, most (85%) of the patients included in the global database used to develop the eighth edition of the staging system underwent surgery (± other therapies) and thus added pathologic staging information to the system. Based on survival data of different groupings of patients, several important changes were adopted in the eighth edition of the staging system.

Tumor size remains an important prognostic factor, with T1 and T2 further divided into 1-cm increments. These cutoffs were determined through extensive analysis of survival data, with log-rank tests confirming prior TNM size cutoffs and providing evidence to support further subdivisions into 1-cm increments. T descriptors underwent Cox regression analysis adjusted for age, sex, histologic type, and geography, with results showing a clear difference in 5-year survival and prognosis for each centimeter increase in tumor size between 1 and 5 cm and in larger tumors with worse prognosis (T3: >5 and ≤7 cm, T4: >7 cm).[22] The eighth edition also addresses how size should be measured. The maximal dimension of the solid component (on imaging,

Table 76.3

Definitions for T, N, and M Descriptors in Eighth Staging Classification		Label
T (PRIMARY TUMOR)		
T0	No primary tumor	
Tis	Carcinoma in situ (squamous or adenocarcinoma)	Tis
T1	Tumor ≤3 cm	
T1(mi)	Minimally invasive adenocarcinoma	T1a *(mi)*
T1a	Superficial spreading tumor in central airways*	T1a *ss*
T1a	Tumor ≤1 cm	T1a *≤1*
T1b	Tumor >1 but ≤2 cm	T1b *>1–2*
T1c	Tumor >2 but ≤3 cm	T1c *>2–5*
T2	Tumor >3 but ≤5 cm or tumor involving:	
	visceral pleura†	T2 *Visc Pl*
	main bronchus (not carina), atelectasis to hilum†	T2 *Centr*
T2a	Tumor >3 but ≤4 cm	T2a *>3–4*
T2b	Tumor >4 but ≤5 cm	T2b *>4–5*
T3	Tumor >5 but ≤7 cm	T3 *>5–7*
	or invading chest wall, pericardium, phrenic nerve	T3 *Inv*
	or separate tumor nodule(s) in the same lobe	T3 *Satell*
T4	Tumor >7 cm	T4 *>7*
	or tumor invading: mediastinum, diaphragm, heart, great vessels, recurrent laryngeal nerve, carina, trachea, esophagus, spine	T4 *Inv*
	or tumor nodule(s) in a different ipsilateral lobe	T4 *Ipsi Nod*
N (REGIONAL LYMPH NODES)		
N0	No regional node metastasis	
N1	Metastasis in ipsilateral pulmonary or hilar nodes	
N2	Metastasis in ipsilateral mediastinal/ subcarinal nodes	
N3	Metastasis in contralateral mediastinal hilar or supraclavicular nodes	
M (DISTANT METASTASIS)		
M0	No distant metastasis	
M1a	Malignant pleural/pericardial effusion‡ or pleural/pericardial nodules	M1a *Pl Dissem*
	or separate tumor nodule(s) in a contralateral lobe	M1a *Contr Nod*
M1b	Single extrathoracic metastasis	M1b *Single*
M1c	Multiple extrathoracic metastases (1 or >1 organ)	M1c *Multi*

*Superficial spreading tumor of any size but confined to the tracheal or bronchial wall.
†Such tumors are classified as T2a if >3 cm and ≤4 cm, T2b if >4 cm and ≤5 cm.
‡Pleural effusions are excluded that are cytologically negative, nonbloody, transudative, and clinically judged not to be due to cancer.
M, metastisis; N, node; T, tumor; TX, NX: T or N status not able to be assessed.

clinical stage) or the invasive component (on microscopy, pathologic stage) should be used to assign a T category. Of note, the maximal dimension of the ground-glass or lepidic component should also be recorded[23] (see also Chapter 41).

The T category also depends on invasion of adjacent structures. Central tumors involving a main bronchus are considered T2, regardless of distance from, but without involvement of, the main carina. Tumors associated with atelectasis extending to the hilum, whether involving a lobe or the entire lung, are also T2. Involvement of the diaphragm has been reclassified as T4. The classification of additional tumor nodules was maintained from the previous classification. The presence of a satellite nodule in the tumor-bearing lobe defines T3, whereas an additional nodule in a different lobe of the ipsilateral lung defines T4.

The N category has remained unchanged in the last two iterations of the staging system and is determined by the location of the involved nodes (relative to the primary tumor). The IASLC lymph node map is presented in Fig. 76.1, and the associated nodal definitions with key anatomic borders are detailed in eTable 76.1.

The M category has been further divided into M1a, b, and c, as prognosis was found to worsen increasingly from a to c. Malignant pleural effusions were reclassified as M1a disease in the seventh edition of the staging system, and this has been maintained; the classification of contralateral tumor nodules as M1a disease is also maintained. Single (M1b) versus multiple (M1c) extrathoracic metastases are now distinguished.

The stage groupings in the eighth edition are provided in Table 76.4. Stage IA tumors are subdivided into IA1, IA2, and IA3 according to tumor size. Stage III has been divided into three subgroups, with T3/T4 and N3 tumors now constituting stage IIIC disease. Stage IV has also been divided into stages IVA (M1a or b) and IVB (M1c).

The evaluation of lung cancer patients with multiple pulmonary sites of disease is challenging. In the context of the eighth edition of the TNM staging system, revisions to the classification of lung cancer with multiple pulmonary sites of involvement were proposed. Four

eTable 76.1 IASLC Nodal Anatomic Borders

Nodal Station	Description	Definition
#1 (left/right)	Low cervical, supraclavicular and sternal notch nodes	■ *Upper border:* lower margin of cricoid cartilage ■ *Lower border:* clavicles bilaterally and, in the midline, the upper border of the manubrium 1L and 1R are limited by the midline of the trachea
#2 (left/right)	Upper paratracheal nodes	2R: ■ *Upper border:* apex of lung and pleural space and, in the midline, the upper border of the manubrium ■ *Lower border:* intersection of equal margin of innominate vein with the trachea 2L: ■ *Upper border:* apex of the lung and pleural space and, in the midline, the upper border of the manubrium ■ *Lower border:* superior border of the aortic arch As for #4; in #2 the oncologic midline is along the left lateral border of the trachea
#3	Prevascular and retrotracheal nodes	3a: Prevascular On the right: ■ *Upper border:* apex of chest ■ *Lower border:* level of carina ■ *Anterior border:* posterior aspect of sternum ■ *Posterior border:* anterior border of superior vena cava On the left: ■ *Upper border.* apex of chest ■ *Lower border:* level of carina ■ *Anterior border:* posterior aspect of sternum ■ *Posterior border:* left carotid artery 3p: Retrotracheal ■ *Upper border:* apex of chest ■ *Lower border:* carina
#4 (left/right)	Lower paratracheal nodes	4R: Includes right paratracheal nodes, and pretracheal nodes extending to the left lateral border of trachea ■ *Upper border:* intersection of caudal margin of innominate vein with the trachea ■ *Lower border:* lower border of azygos vein 4L: Includes nodes to the left of the left lateral border of the trachea, medial to the ligamentum arteriosum ■ *Upper border:* upper margin of the aortic arch ■ *Lower border:* upper rim of the left main pulmonary artery
#5	Subaortic (aortopulmonary window)	Subaortic lymph nodes lateral to the ligamentum arteriosum ■ *Upper border:* the lower border of the aortic arch ■ *Lower border:* upper rim of the left main pulmonary artery
#6	Para-aortic nodes (ascending aorta or phrenic)	Lymph nodes anterior and lateral to the ascending aorta and aortic arch ■ *Upper border:* a line tangential to the upper border of the aortic arch ■ *Lower border:* the lower border of the aortic arch
#7	Subcarinal nodes	■ *Upper border:* the carina of the trachea ■ *Lower border:* the upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right
#8 (left/right)*	Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes ■ *Upper border:* the upper border of the lower lobe bronchus on the left; the lower border of the bronchus intermedius on the right ■ *Lower border:* the diaphragm
#9 (left/right)	Pulmonary ligament nodes	Nodes lying within the pulmonary ligament ■ *Upper border:* the inferior pulmonary vein ■ *Lower border:* the diaphragm
#10 (left/right)	Hilar nodes	Includes nodes immediately adjacent to the mainstem bronchus and hilar vessels, including the proximal portions of the pulmonary veins and main pulmonary artery ■ *Upper border:* the lower rim of the azygos vein on the right; upper rim of the pulmonary artery on the left ■ *Lower border:* interlobar region bilaterally
#11	Interlobar Nodes	Between the origin of the lobar bronchi #IIs*: between the upper lobe bronchus and bronchus intermedius on the right #IIi*: between the middle and lower lobe bronchi on the right
#12	Lobar nodes	Adjacent to the lobar bronchi
#13	Segmental nodes	Adjacent to the segmental bronchi
#14	Sub segmental	Adjacent to the subsegmental bronchi

The boundaries delineated in this table are useful when interpreting computed tomography scans and performing bronchoscopy for staging of patients.

Average overall survival in the IASLC global database of patients receiving a diagnosis between 1999 and 2010.
IASLC, International Association for the Study of Lung Cancer; NSCLC, non–small cell lung cancer.
From Detterbeck FC, Boffa DJ, Kim AW, Tanoue LT: The eighth edition lung cancer stage classification. *Chest.* 2017;151(1):193–203; with data from Goldstraw P, Chansky K, Crowley J, et al. The IASLC Lung Cancer Staging Project: proposals for revision of the TNM stage groupings in the forthcoming (eighth) edition of the TNM classification for lung cancer. *J Thorac Oncol.* 2016;11(1):39–51.

patterns of disease are distinguished: second primary lung cancers, tumors with a separate solid tumor nodule, multiple tumors with prominent ground-glass (as assessed by imaging) or lepidic (as assessed by pathology, with an appearance of tumor cells spreading along the alveolar surface without distortion) features, and diffuse "pneumonic-type" lung cancers. Fig. 76.2 includes representative examples of these four patterns of disease and the associated application of the TNM classification.

Revisions to the stage classification are based on differences in prognosis. Average 5-year overall survival in the IASLC global database is shown according to the eighth edition TNM staging system in Table 76.5. Although stage has a significant impact on prognosis, it is essential to remember that prognosis is also affected by patient factors, such as age, performance status and comorbidities, and factors related to care (access, quality) and treatment (choice of treatment and response).

STAGING OF SMALL CELL LUNG CANCER

A simpler stage classification exists in SCLC based on a two-stage system of limited and extensive stage disease.[24] However, the TNM staging system is applicable in SCLC and has been shown to have prognostic value in these patients as well.[25,26] Limited stage denotes disease confined to the ipsilateral hemithorax and regional lymph nodes, which can be included in a single tolerable radiation port (broadly corresponding to TNM stages I–III). Extensive stage denotes tumor beyond the boundaries of a radiation port and includes contralateral supraclavicular or hilar involvement, malignant pericardial or pleural effusions, and distant metastasis.

The vast majority of patients with SCLC will not be candidates for surgical resection (35–40% locally advanced and 60–65% metastatic), but stage distinction is important because patients with limited-stage disease are still candidates for chemoradiation with curative intent. Patients with extensive-stage disease are treated with chemotherapy alone and consolidative or palliative radiation if clinically indicated.

QUALITY GAPS IN LUNG CANCER DIAGNOSIS AND STAGING

The importance of diagnosis and accurate staging seems obvious, yet evidence suggests it is often poorly done.[27,28] Studies based on clinical and administrative databases have highlighted significant quality gaps in the diagnosis and staging of lung cancer patients.[29–34]

Suboptimal staging has been associated with worse patient outcomes.[32,33] Farjah and colleagues[33] examined the impact of multimodality mediastinal staging on health outcomes using the Surveillance, Epidemiology, and End Results data. Although a minority of patients underwent multimodality staging (CT ± *positron emission tomography* [PET] ± invasive staging), this was associated with a significantly lower risk of death.[33] Similarly, Ost and colleagues[32] demonstrated that care was consistent with guidelines in only a minority of patients evaluated for lung cancer; yet, when care was consistent, this was associated with significantly fewer complications.[29,32] Navani and colleagues[34] assessed agreement between clinical and pathologic TNM stages among clinical trial (control group) participants with stage I to IIIA NSCLC. The authors found that clinical TNM staging disagreed with pathologic TNM staging in 48% of cases, with the majority of patients being clinically understaged; these discrepancies could have lead to different treatment decisions.[34]

The need for multiple tests and the variable availability of certain tests (PET scan, *endobronchial ultrasound* [EBUS]) may also significantly impact timeliness of care in lung cancer patients. Time to diagnosis and treatment of lung cancer frequently exceeds recommended delays.[35,36] The association between timeliness of lung cancer care and patient outcomes, however, has been variable and at times paradoxical, with a few studies even showing that less timely care was associated with a better survival.[35] Nonetheless, the most recent American College of Chest Physicians guidelines recommend timely investigation of lung cancer patients.[37] In addition, the British National Institute for Health and Care Excellence guidelines recommend rapid access clinics for the investigation of patients with suspected lung cancer.[38] Suggested targets for timeliness may vary among countries; the British guidelines suggest an acceptable delay is 2 months from referral to the beginning of treatment. Quality indicators for the evaluation of patients with lung cancer have also been proposed based on guidelines and links to patient-centered outcomes.[39,40] Mazzone and colleagues[40] have proposed seven quality indicators for the evaluation of patients with lung cancer (eTable 76.2).

HISTOLOGY AND PROGNOSIS

In considering the prognosis for NSCLC, personalized treatment should take into account histologic features and tumor growth patterns in addition to tumor characteristics gleaned from molecular analysis. For example, within the two most common histologic types of NSCLC (adenocarcinoma and squamous cell carcinoma), different growth patterns affect prognosis.[41] The various invasive patterns of adenocarcinomas belong to three prognostic groups with increasing risk metastasis and poorer prognosis: lepidic pattern (grade 1), acinar and papillary pattern (grade 2), and micropapillary and solid pattern (grade 3). In squamous cell carcinoma, which can have keratinizing, nonkeratinizing, or basaloid elements of differentiation, keratinization is associated with a better prognosis.[42] In other instances, mixed histologies, such as adenosquamous, may have similar probabilities of having targetable mutations as a pure adenocarcinoma.[43] In the case of large cell neuroendocrine histology of NSCLC, the survival curve overlaps with that of SCLC, so prognosis is worse than in other NSCLC histologies.[44]

Over the past decade, significant advances have been made in the oncology, molecular biology, pathology, radiology, and surgery for lung adenocarcinomas, which remain the most common type of lung cancer. To address the spectrum of adenocarcinomas, an international multidisciplinary classification of adenocarcinomas was developed to provide uniform terminology and diagnostic criteria, especially for what was formerly called bronchioloalveolar carcinoma. This initiative was meant to improve the overall approach to small nonresection cancer specimens (i.e., needle aspirations, core needle specimens, cytology from body fluids), surgical specimens, and the multidisciplinary strategic management of tissue for molecular and immunohistochemical studies[45] (Table 76.6).

APPROACH TO STAGING

Certain tenets of lung cancer staging must be emphasized. Before classifying a patient within a certain stage, the clinician should make every effort to verify the stage by investigating radiologic abnormalities with tissue sampling if necessary. This is particularly important when surgical resection would be precluded based on abnormal noninvasive radiologic tests. Thus a patient who would otherwise be resectable, except for a single abnormality suspicious for metastasis, should have tissue confirmation of that abnormality before being deemed unresectable. Whenever possible, diagnosis and staging should be achieved in a single procedure (i.e., mediastinal lymph node or other metastatic site sampled) rather than by sampling the primary tumor and then separately biopsying a metastatic site. When obtaining tissue from patients with advanced-stage NSCLC, sufficient tissue should be obtained for molecular testing. Important nuances of noninvasive and invasive staging are described in the next sections of this chapter. As is pointed

eTable 76.2 Assessment of Feasibility and Relevance of Quality Indicators at Three Different Clinical Sites

	SITE 1			SITE 2			SITE 3		
Quality Indicator	**NR (%)**	**Yes (%)**	**Time***	**NR (%)**	**Yes (%)**	**Time***	**NR (%)**	**Yes (%)**	**Time***

Table 76.6 Categories of New Adenocarcinoma Classification Where Former Bronchioloalveolar Carcinoma Concept Was Used

1. Adenocarcinoma in situ, which can be nonmucinous and rarely mucinous
2. Minimally invasive adenocarcinoma, which can be nonmucinous and rarely mucinous
3. Lepidic predominant adenocarcinoma (nonmucinous)
4. Adenocarcinoma, predominantly invasive with some nonmucinous lepidic component (includes some resected tumors, formerly classified as mixed subtype, and some clinically advanced adenocarcinomas formerly classified as nonmucinous bronchioloalveolar carcinoma)
5. Invasive mucinous adenocarcinoma (formerly mucinous bronchioloalveolar carcinoma)

This new classification of adenocarcinomas was developed to provide uniform terminology and diagnostic criteria, especially for what was formerly called bronchioloalveolar carcinoma.

From Travis WD, Brambilla E, Noguchi M, et al. International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society International Multidisciplinary Classification of Lung Adenocarcinoma. *J Thorac Oncol*. 2011;6:244–285.

out, no single imaging study is infallible, so reliance on scans alone to predict malignancy is simply not appropriate.

Patients with stage I and II NSCLC without medical contraindication should be referred for surgical resection, which is considered the gold standard of treatment for lung cancer. Although there are no large randomized controlled trials comparing surgical resection to other modalities, available data show a mortality benefit for surgical resection over radiotherapy alone, chemotherapy alone, or ablative therapies in medically operable patients.

In cases of a solid pulmonary nodule greater than 8 mm in diameter, a surgical diagnosis should be considered when the clinical probability of malignancy is high (>65%), when the nodule is hypermetabolic by PET, when nonsurgical biopsy is suspicious for malignancy, or when a fully informed patient prefers a definitive diagnostic procedure. For surgical diagnosis, video-assisted thoracoscopy is recommended to obtain a diagnostic wedge resection. If malignancy is present on frozen section intraoperatively, then further resection (lobectomy or segmentectomy in selected cases) and lymph node dissection will be pursued as dictated by patient comorbidities and fitness for more extensive surgery. CT-guided transthoracic needle aspiration has a sensitivity of 90% in a high-prevalence population, but there is a risk of nondiagnostic results in about 20% of individuals with malignant nodules,[46] so it lacks adequate negative predictive value to exclude cancer in cases with high probability of malignancy (see Chapter 41). When the risk of malignancy is high, anything other than a definitive benign diagnosis (i.e., inflammation is not definitive) should not prevent further invasive approaches at biopsy. When the clinical probability of malignancy is low or intermediate, nodules can be followed with serial CT scanning over time versus minimally invasive biopsy (CT-guided transthoracic needle or bronchoscopy) depending on clinical setting, growth pattern of the nodule on imaging, and patient preferences.

The question will arise as to which patients with stage I should undergo mediastinal staging before surgery or biopsy of the primary site. In patients with peripheral (outer third of the lung) clinical stage IA tumors (negative nodal involvement by CT and PET), preoperative evaluation of mediastinal nodes is not required. However, even if there is no mediastinal nodal involvement by CT and PET, a central tumor (inner two-thirds of lung), a tumor greater than 3 cm, or a tumor with N1 involvement, the patient should undergo a needle biopsy technique (EBUS, *endoscopic ultrasound* [EUS], or combined EBUS-EUS) instead of surgical staging as the first staging modality because the prevalence of occult mediastinal involvement of tumor is significant (10–30%)[47–50] (Figs. 76.3 to 76.5).

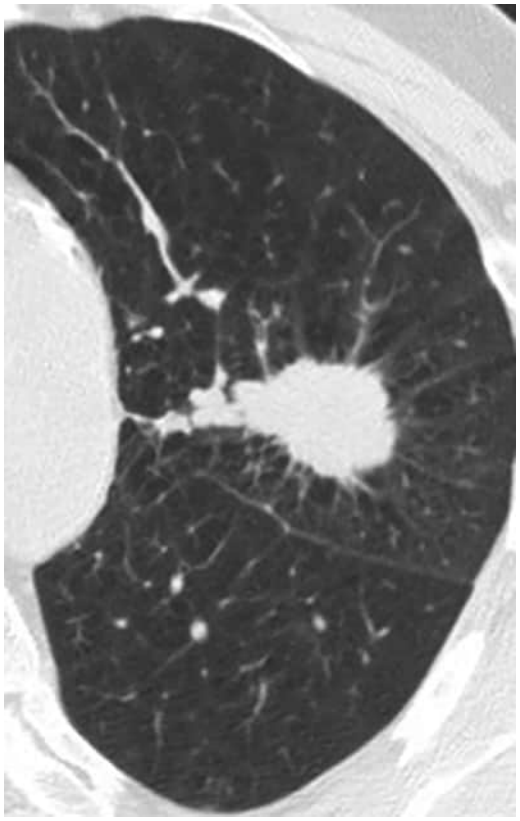

Figure 76.3 Stage I non–small cell lung cancer (3.2-cm mass). If the mediastinum is negative on positron emission tomography–computed tomography, invasive staging of the mediastinum is still recommended due to size of the primary lesion. (Courtesy Dr. Michael B. Gotway.)

Stage III and IV patients may have multiple targets to sample, so the site that would establish the highest stage while maintaining safety and sample quality should be targeted (Figs. 76.6 to 76.8).

SUSPECTED METASTATIC DISEASE

Imaging with ^{18}*F-fluoro-2-deoxy-*D*-glucose* (FDG)-PET scan has greater accuracy than CT for the evaluation of mediastinal lymph node involvement in lung cancer, so it is a widely used adjunct to CT imaging (now commonly a fused CT-PET scan) for the diagnosis and staging of lung cancer. In the appropriate clinical setting, it can be an accurate means of differentiating benign from malignant lesions and identifying unexpected distant metastasis. PET scanning is based on the biologic activity of neoplastic cells, which demonstrate increased cellular uptake of glucose and a higher rate of glycolysis compared with normal cells,[51] resulting in an accumulation of FDG-6-phosphate.[52] The accumulated

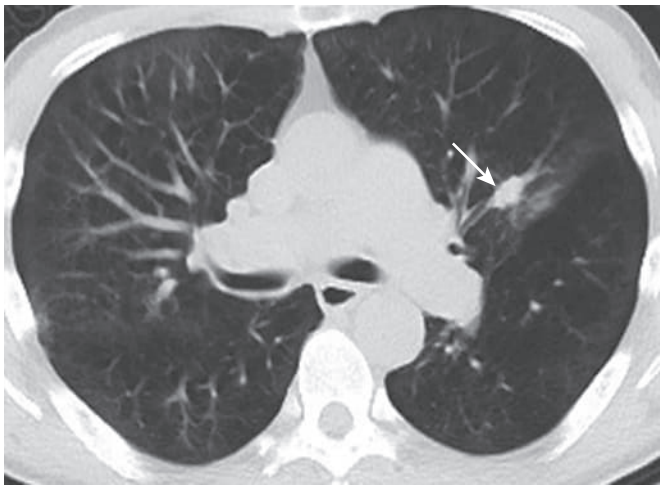

Figure 76.4 Stage I non–small cell lung cancer (central 1-cm nodule). If mediastinum is negative on positron emission tomography–computed tomography, staging is still recommended due to central location of the primary lesion *(arrow)*.

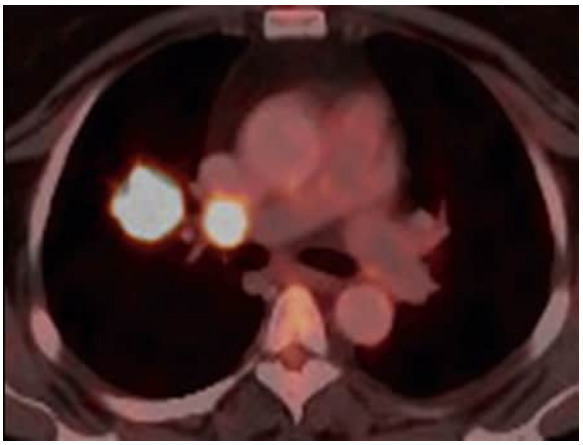

Figure 76.5 Stage IIB non–small cell lung cancer with a 2.9-cm right upper lobe nodule and a positron emission tomography (+) 10R lymph node. This patient needs mediastinal staging for two reasons: because the nodule is centrally located and because there is N1 activity on positron emission tomography–computed tomography.

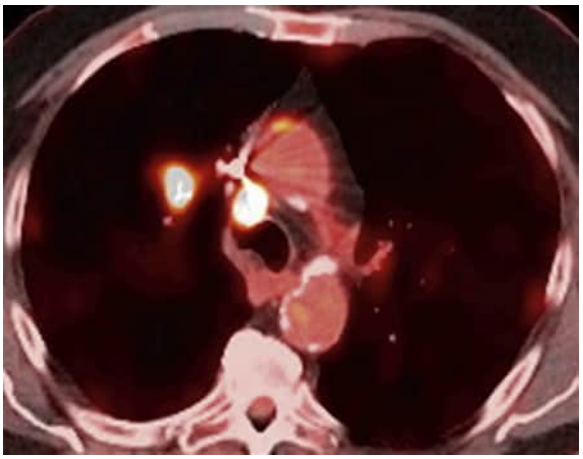

Figure 76.6 Stage IIIA: right upper lobe tumor and a N2 lymph node (station 4R). Mediastinal staging is needed in stage IIIA and should begin on the left with contralateral (N3) lymph nodes sampled in sequence until a positive sample is achieved; in this case 4R was positive.

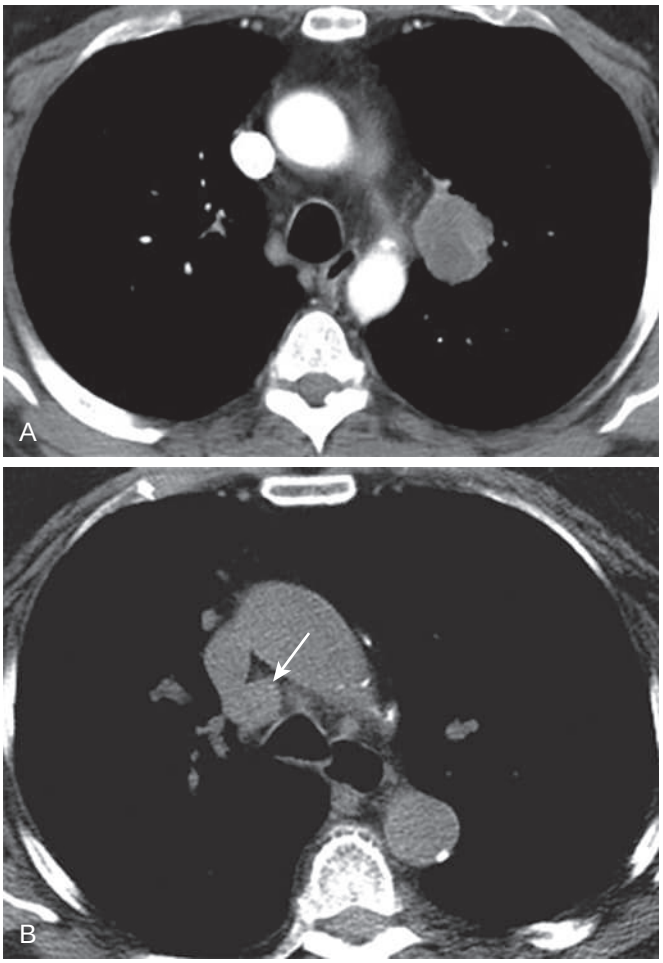

Figure 76.7 Stage IIIB: non–small cell lung cancer. (A) Left upper lobe mass. (B) An N3 lymph node (station 4R). Mediastinal staging is required and should start on the right at 4R *(arrow)* because a positive result there will establish both the diagnosis and the highest tumor stage to define treatment.

isotope is seen using a PET scan camera. A meta-analysis demonstrated a pooled sensitivity of 74% (95% confidence interval, 69–79%) and specificity of 85% (95% confidence interval, 82–88%).[53] There is a low sensitivity of PET for lesions of 1 cm or less, which is likely related to lower metabolic activity in small-nodule lower-grade malignancies.[54] In patients with lung cancer confined to the chest and potentially curable, it is found that the rate of false positives in PET scans is too high to obviate the need for invasive mediastinal staging (transbronchial, transthoracic, or transesophageal needle aspiration; mediastinoscopy; or more extensive surgery).[47]

Brain metastases have long been associated with patients with stage IIIA or higher NSCLC who have neurologic clinical findings and with all patients with SCLC. More recently, data have accumulated showing an association of brain metatasis in patients with asymptomatic stage II to III NSCLC.[55–61] Pooled sensitivity and specificity of nine studies on patients with NSCLC and no neurologic findings on clinical evaluation found a median prevalence of brain metastases of 3% (range, 0–21%).[47] At present, the National Comprehensive Cancer Network guidelines recommend a brain *magnetic resonance imaging* (MRI) with contrast (or contrast CT if MRI is not possible) for stage

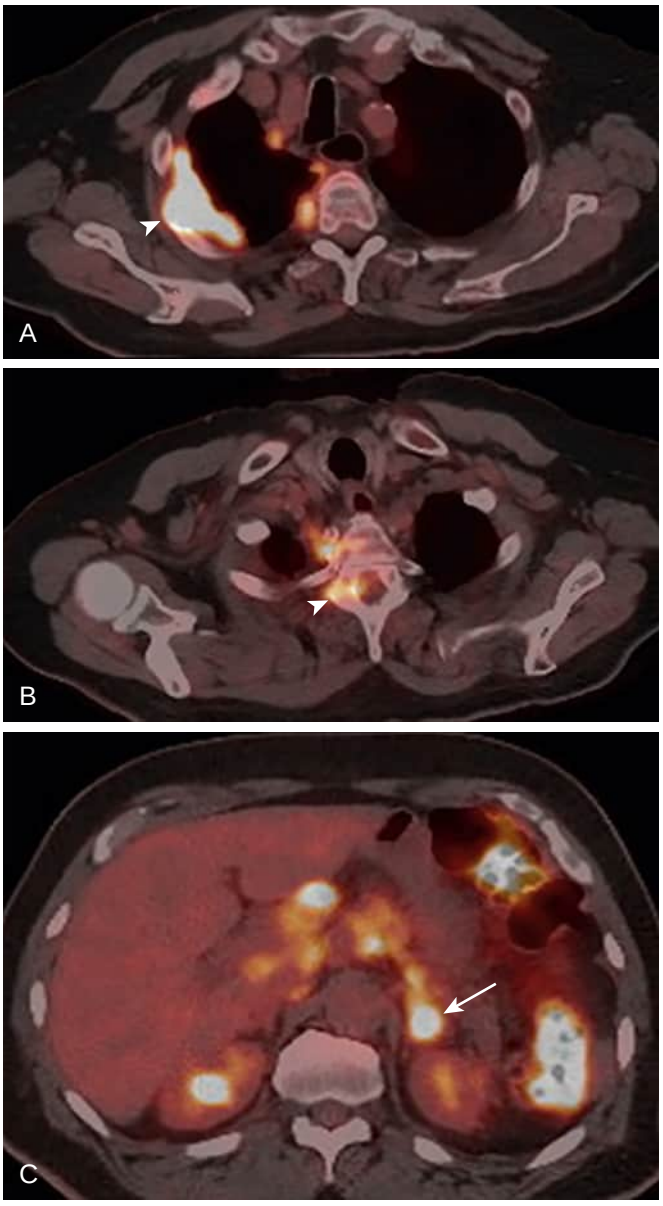

Figure 76.8 Optimized lung carcinoma staging. Endoscopic ultrasound–guided biopsy of the left adrenal gland *(arrow)* (C) was chosen as the safest and highest yield location for diagnosis because, although osseous metastatic disease was present *(arrowheads;* A–B), bone biopsies yield little material for molecular analysis. The diagnosis of adenocarcinoma of the lung was established and confirmed as stage IV. The patient was positive for an anaplastic lymphoma kinase fusion on molecular analysis and was a candidate for an oral tyrosine kinase inhibitor.

II or higher NSCLC,[62] although other guidelines have suggested starting brain imaging with stage III or higher NSCLC. Brain MRI is considered more sensitive than CT scanning of the brain, thus identifying more and smaller lesions; however, some studies have not shown that this difference in sensitivity has led to clinically meaningful survival differences. Therefore, CT scan with contrast is an acceptable alternative in patients who cannot obtain an MRI.[63]

When confronted with a patient suspected of having lung cancer with metastatic disease, tissue confirmation for diagnosis with patient safety in mind is the first step. However, to be accurate, efficient, and minimally invasive, the goal should be to obtain a biopsy from a metastatic site so that both diagnosis and staging may be confirmed in a single procedure. If there is a solitary extrathoracic site that is suspicious for a metastasis, tissue confirmation of that site with a fine-needle aspiration or biopsy should be attempted if feasible. Modalities used for such biopsies may include CT-guided approaches (e.g., commonly for liver, bone, or contralateral lung metastasis), thoracentesis for the diagnosis of a malignant pleural effusion, thoracoscopic biopsy, or EUS fine-needle aspiration of left adrenal metastases. Patient-centered care and risk/benefit ratios factor in to decisions on invasive staging procedures. The pneumothorax risk of CT-guided transthoracic needle lung biopsy was up to 15% in a large population-based study, although less than half required chest tubes (see Chapter 21).[64] Although image-guided liver biopsy carries less risk than lung biopsy, there is a complication rate of 0.5–1% for hemorrhage requiring transfusion, pneumothorax, malignant tract seeding, infection, perforation of viscera, or death.[65] Although a bone biopsy under CT guidance is an even safer procedure, the cellularity may be less than lung or liver biopsies,[66] and the decalcification process required to prepare the specimen may leave insufficient material for molecular analysis. Based on the safety of the proposed procedure to document metastatic disease, there are also situations in which patients have lesions in multiple distant sites suspected of metastases but in whom biopsy of a metastatic site would be technically too difficult or risky, so the diagnosis of the primary lesion should be obtained by the least invasive method.[67]

In addition to choosing a diagnostic procedure that allows concurrent diagnosis and staging of NSCLC, it is now necessary to obtain a sufficient amount of tissue for genetic testing and programmed death-ligand 1 assessment, both of which have potential treatment implications.[68] It is relevant that the majority of patients presenting with lung cancer are diagnosed at an advanced stage when molecular profiling is needed to determine candidacy for targeted therapy and immunotherapy and, in such patients, minimally invasive procedures are recommended for diagnosis and staging. As nonsurgical techniques, such as EBUS–*transbronchial needle aspiration* (TBNA), have emerged as first-line tests; cytology specimens (including pleural fluid)[69] or small-volume biopsies are increasingly being used for molecular testing.[47,70]

LOCALLY ADVANCED DISEASE/ SUSPECTED MEDIASTINAL INVOLVEMENT

In patients with known or suspected NSCLC and no evidence of systemic metastases, attention must immediately turn to mediastinal staging. Accurate staging of the mediastinum is critically important in guiding optimal management. The following section reviews noninvasive staging and invasive staging of the mediastinum.

NONINVASIVE STAGING

CT scanning of the chest is the most widely available noninvasive modality for evaluation of the mediastinum in patients with lung cancer and is recommended as the first test for all patients with suspected or confirmed lung cancer.[71–73] CT scan can define the location, size, and

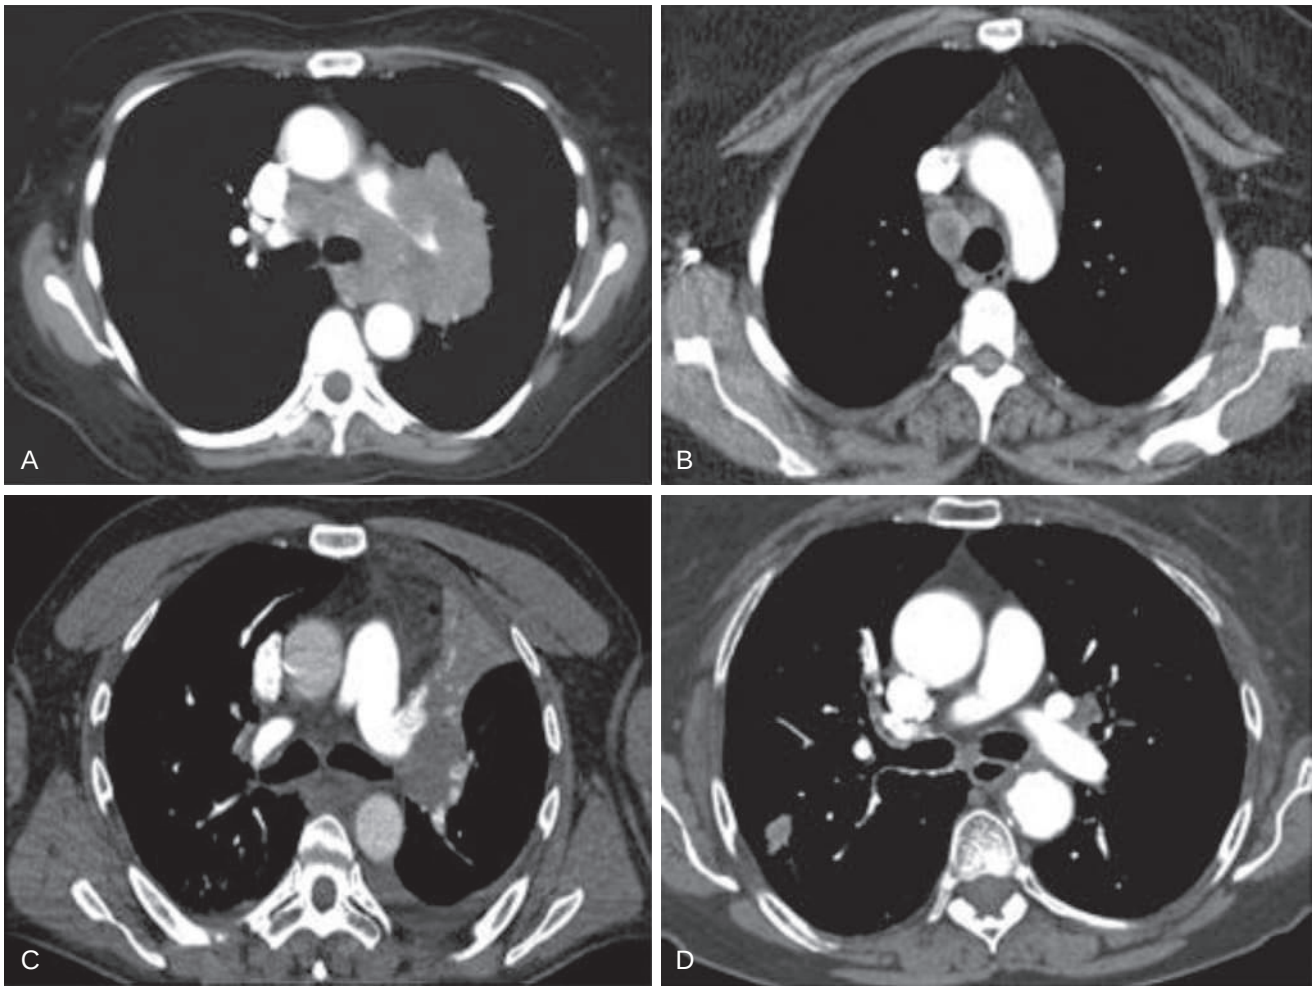

Figure 76.9 American College of Chest Physicians intrathoracic radiographic (computed tomography scan) categories of lung cancer. (A) Mediastinal infiltration by tumor. (B) Enlarged discrete N2 and N3 nodes. (C) A central tumor or a tumor with enlarged N1 nodes but a normal mediastinum. (D) A peripheral small tumor (seen in lower left corner of image) with normal-sized lymph nodes. (From Silvestri GA, Gonzales AV, Jantz, MA, et al. Methods for staging non–small cell lung cancer: diagnosis and management of lung cancer, 3rd ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest.* 2013;143:e211S–e250S.)

characteristics of the primary lesion and the anatomic location and size of lymphadenopathy. CT thus provides the necessary information to structure the subsequent diagnostic and staging evaluation, frequently allowing physicians to establish diagnosis and stage with a single invasive procedure. This approach is strongly favored because it streamlines the investigation process and reduces complications.

In the majority of studies evaluating the accuracy of CT for mediastinal staging, CT scans are performed with administration of *intravenous* (IV) contrast material. Although IV contrast is not absolutely necessary when performing CT scans for this indication, it helps to distinguish vascular structures from lymph nodes and to delineate mediastinal invasion by centrally located tumors. The most widely accepted criterion for suspected malignant involvement of mediastinal nodes is a short-axis lymph node diameter greater than or equal to 1 cm on a transverse CT scan.

To help with decisions about mediastinal staging, the American College of Chest Physicians defines four intrathoracic CT radiographic categories of lung cancer, based on the primary tumor and the mediastinum (Fig. 76.9). Group A represents mediastinal infiltration by tumor, in which discrete nodes can no longer be discerned or measured. Group B includes patients with discrete mediastinal node enlargement. Groups C and D comprise patients with normal mediastinal nodes and a central tumor (C) or a peripheral tumor (D). The presence of a centrally located tumor or suspected ipsilateral hilar (N1) disease translates into a 20–25% chance of pathologic node involvement (group C), whereas mediastinal involvement is much less likely in patients with peripheral clinical stage I tumors (group D).[47] This categorization describes patterns of either mediastinal involvement, or lack thereof, that can guide next steps in invasive staging. For example, group A may not need systematic nodal staging by EBUS-TBNA or mediastinoscopy because nodal anatomy is not clearly delineated. Rather, an ultrasound-guided transthoracic needle sample can be obtained from the most easily accessible site in the mediastinum to document disease and potentially obtain material for molecular analysis. Group B is an ideal scenario for systematic EBUS-TBNA evaluation of the mediastinum, starting from the highest station, N3 nodes, and progressing to N2 and potentially N1 nodes. The need for systematic mediastinal staging in groups C and D depends on features mentioned earlier regarding primary tumor size, location, and presence of radiographic N1 disease.

The accuracy of CT scanning for noninvasive staging of the mediastinum in patients with lung cancer was systematically reviewed as part of the third edition of the *American College of Chest Physicians Clinical Practice Guidelines* (Methods for Staging NSCLC).[47] The combined studies yielded 7368 evaluable patients (30% median prevalence of mediastinal metastases). The median sensitivity and specificity of CT scanning for identifying mediastinal nodal metastases were 55% and 81%, respectively. The median positive predictive value was 58% (i.e., >40% of nodes deemed suspicious on CT are actually benign), whereas the median negative predictive value was 83% (i.e., almost 20% of nodes deemed benign by CT criteria are actually malignant). An important message thus emerges: CT scanning can neither reliably rule in nor exclude mediastinal metastases. Despite these important limitations, CT provides important anatomic guidance for selection of biopsy targets, and the most appropriate invasive diagnostic procedures.

PET scanning plays a prominent role in the evaluation of patients with suspected lung cancer. This is also true with regard to mediastinal evaluation, with some important caveats. Standardized quantitative criteria for an abnormal PET scan in the mediastinum are unfortunately lacking. The assessment of nodal uptake is a qualitative one and is based on a comparison of uptake in the node of interest with the background mediastinal activity. Alternatively, a standard uptake value of 2.5 or greater has been used as a threshold level for malignancy. PET is primarily a metabolic examination and has limited anatomic resolution. Integrated PET-CT scanners, however, now provide both anatomic (CT) and functional (PET) images simultaneously. As stated earlier, the sensitivities and specificities are not sufficiently accurate to warrant reliance on PET-CT scanning alone, and tissue confirmation of PET findings is imperative (Fig. 76.10).

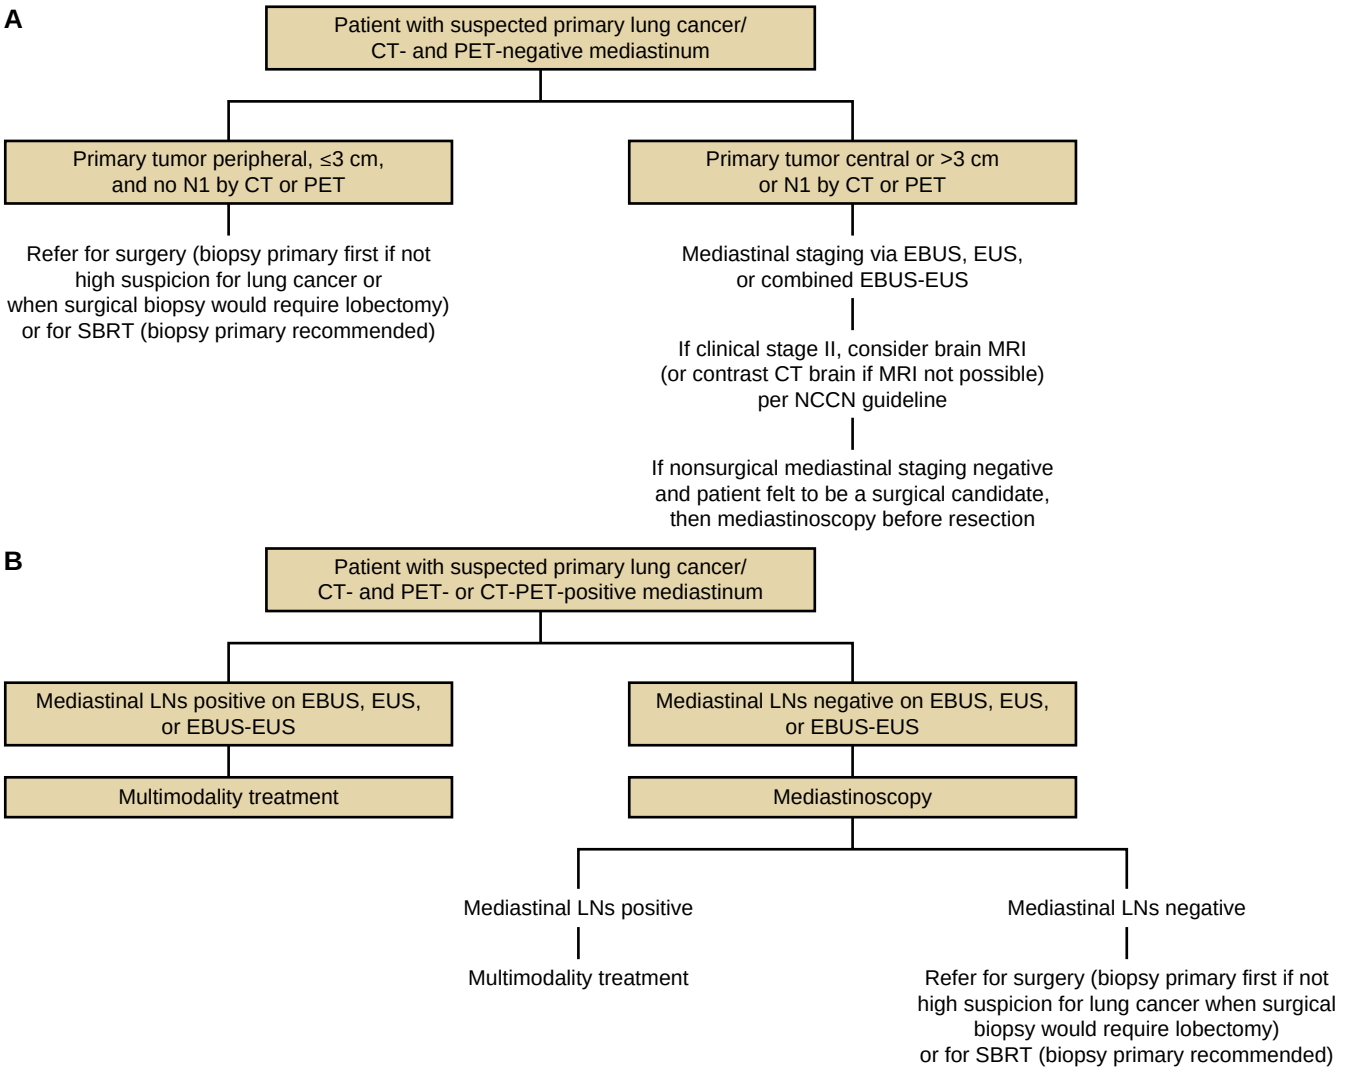

Figure 76.10 Algorithms for preoperative mediastinal node staging in non–small cell lung cancer. Staging algorithm for patients with suspected primary lung cancer (A) with CT- and PET-negative mediastinum and for those (B) with a CT- or PET-positive mediastinum. CT, computed tomography; EBUS, endobronchial ultrasound; EUS, endoscopic ultrasound; LNs, lymph nodes; MRI, magnetic resonance imaging; NCCN, *National Comprehensive Cancer Network*; PET, positron emission tomography; SBRT, stereotactic body radiation therapy. (Modified from De Leyn P, Dooms C, Kuzdzal J, et al. Revised ESTS guidelines for preoperative mediastinal lymph node staging for non–small-cell lung cancer. *Eur J Cardiothorac Surg.* 2014;45[5]:787–798.)

MINIMALLY INVASIVE STAGING: ENDOBRONCHIAL ULTRASOUND, ENDOSCOPIC ULTRASOUND, AND COMBINED ENDOBRONCHIAL ULTRASOUND–ENDOSCOPIC ULTRASOUND

Bronchoscopy with EBUS-guided TBNA has largely surpassed conventional TBNA and mediastinoscopy for the diagnosis and staging of lung cancer. Ultrasound-guided needle techniques, including EBUS, EUS, or combined EBUS-EUS are now recommended as tests of first choice for confirmation of mediastinal involvement in accessible lymph node stations. The sensitivities of these techniques are approximately 89%, 89%, and 91%, respectively[47] (see Chapter 27).

EBUS and EUS may have complementary roles with regard to the lymph node stations that are accessible to each technique. Studies suggest that the combination of the two provides near-complete access to all mediastinal lymph node stations, thus improving the sensitivity for detecting mediastinal nodal metastases and reducing the need for surgical procedures.[74–76] The minor added benefit may not justify adding EUS to EBUS because EBUS can reach and sample all lymph node stations accessible by EUS except stations 8 and 9. It is extremely rare that these two stations are involved in lung cancer without concomitant involvement of stations 2, 4, or 7.[77]

In studies comparing EBUS-TBNA to mediastinoscopy in patients with potentially resectable NSCLC, there were no differences in the diagnostic yield between the two modalities.[78] In addition to superior safety, one of the advantages of EBUS-TBNA compared to mediastinoscopy includes the ability to access N1 lymph nodes, including hilar and interlobar lymph nodes.[79] This is particularly advantageous in staging of clinical stages I and II NSCLC because patients with N1 disease are an intermediate group of patients who have a variable prognosis.[80] If N1 disease is present, such patients can be appropriately excluded from stereotactic body radiation therapy.[81] Alternatively, if N1 nodes that are PET avid are found on biopsy to be benign, the patient can be downstaged and have an opportunity for a more curative treatment paradigm. Using noninvasive staging alone may lead both to inappropriate upstaging and downstaging.[47] The advantages of biopsy in stage III and IV NSCLC are also clear because the sensitivity and specificity of noninvasive radiologic staging are not adequate to exclude or confirm occult mediastinal involvement.

INVASIVE STAGING: MEDIASTINOSCOPY

Mediastinoscopy is the historic gold standard for invasively staging the mediastinum in patients with known or suspected lung cancer, but ultrasound-guided needle techniques (EBUS-TBNA, EUS–fine-needle aspiration, or their combination) are now recommended as the best first invasive diagnostic procedures due to their safety and accuracy. If negative for malignancy in a patient with lung cancer, EBUS or EUS should be followed by another biopsy technique (e.g., CT-guided biopsy) or surgical biopsy (i.e., mediastinoscopy or video-assisted thoracoscopy), particularly in patients with enlarged mediastinal lymph nodes on CT or increased FDG uptake on PET scan.[47,74,82,83]

A section on special considerations in lung cancer is available at ExpertConsult.com, including discussions of superior sulcus tumors and Pancoast syndrome, superior vena cava syndrome, oligometastatic NSCLC, and paraneoplastic syndromes.

Key Points

- When obtaining a careful history and physical examination, physicians should explore symptoms or signs caused by the direct invasion, obstruction, or metastatic effects of tumor and potential paraneoplastic effects.
- A new staging system, the eighth edition of the *tumor-node-metastasis* (TNM) classification for lung cancer of the International Association for the Study of Lung Cancer, based on survival data from a large international population with lung cancer, has changed the T and M but not the N classifications. The revised classifications and stages should predict survival and guide therapy more accurately than the former TNM system.
- Noninvasive staging has limitations. Computed tomography and positron emission tomography can neither reliably rule in nor exclude mediastinal metastases. Despite these important limitations, positron emission tomography–computed tomography provides important anatomic guidance for selection of biopsy targets and the most appropriate invasive diagnostic procedures.
- Ultrasound-guided needle techniques, including endobronchial ultrasound, endoscopic ultrasound, or both, are now the first-line tests for confirmation of mediastinal involvement in accessible lymph node stations in patients with lung cancer.
- In considering where to direct a biopsy, the goal is to maximize the ability to diagnose and stage with the fewest number of biopsies. For example, a biopsy of an involved supraclavicular node can determine a diagnosis of non–small cell lung cancer and its stage with one extremely safe biopsy.
- When obtaining tissue from patients with advanced-stage non–small cell lung cancer, sufficient tissue should be obtained for molecular testing.

SPECIAL CONSIDERATIONS IN LUNG CANCER

SUPERIOR SULCUS TUMORS AND PANCOAST SYNDROME

Pancoast syndrome is a constellation of symptoms and signs that includes shoulder and arm pain along the distribution of the eighth cranial nerve trunk and first and second thoracic nerve trunks, Horner syndrome, and weakness and atrophy of the hand.[84–86] The underlying cause is usually local extension of an apical lung tumor located in the superior pulmonary sulcus (Pancoast tumor, eFig. 76.1). The most common cause of this symptom complex is NSCLC, typically squamous cell; however, SCLC and a number of other types of tumors and infections may rarely present in this manner.[84] The most common initial symptom is shoulder pain, which is produced by tumor involvement of the parietal pleura; brachial plexus; vertebral bodies; and first, second, and third ribs. The pain may radiate along the upper back or shoulder into the axilla and along the distribution of the ulnar nerve. Patients are commonly treated for arthritis or bursitis of the shoulder for months before the correct diagnosis is determined. Horner syndrome consists of ptosis, miosis, and anhidrosis and is caused by the invasion of the paravertebral sympathetic chain and the inferior cervical (stellate) ganglion.[84] Pancoast syndrome is present in approximately one-third of patients with superior sulcus tumors reported in the literature. The intrinsic muscles of the hands may become weak and atrophied as the tumor progresses. With further extension through the intervertebral foramina, spinal compression and paraplegia may develop.

The chest radiograph may show an apical tumor, although in some cases a tumor can be identified only on a CT scan of the chest. If the diagnosis is suspected but the chest radiograph is negative, then a CT chest scan should be obtained. CT also provides additional information about the extent of the tumor and is especially helpful in identifying other pulmonary nodules and mediastinal adenopathy. MRI of the chest is considered to be superior for evaluating patients with superior sulcus tumors because of better assessment of invasion through the pleura and subpleural fat, better evaluation of plexus involvement, and better definition of subclavian vessel involvement.[87] Magnetic resonance angiography may give the best assessment of vascular invasion of the subclavian vessels. Bronchoscopy is frequently the first diagnostic test for apical tumors, although it has a diagnostic yield of only approximately 50% for these very peripheral lesions.[88,89] CT-guided transthoracic needle aspiration has a very high diagnostic yield (>90%) even if the bronchoscopy is nondiagnostic.[90] Superior sulcus tumors are usually staged as T3N0M0 (stage IIB) or higher depending on size of the tumor (T3 or T4) and extent of lymph node involvement. In a large series, 25% of patients were stage IIB, 22% were IIIA, and 53% were stage IIIB (T4 or N3).[91] Obviously, some patients are stage IV at diagnosis, but they were excluded from that report. It is estimated that one-third to one-half of all superior sulcus tumors have identifiable distant metastasis at diagnosis. In addition to the stage of disease and performance status, other important poor prognostic factors include weight loss and vertebral body or supraclavicular involvement. The presence of N1 or N2 nodal involvement and incomplete resections have a worse prognosis.[91,92] In patients treated for localized disease (stage IIB or IIIA), the brain is the most common site of relapse.[93] In the past, the most common treatment for localized superior sulcus tumors due to NSCLC was preoperative radiotherapy of 30 to 50 Gy followed by resection. This resulted in a 5-year survival of 25–35%.

More recently, the practice has been to perform neoadjuvant chemoradiotherapy followed by resection. This is based on results of the North America Intergroup Trial in which patients with a negative mediastinoscopy were treated with two cycles of etoposide and cisplatin chemotherapy and concurrent thoracic radiotherapy (45 Gy in 5 weeks). In the resected specimen, a pathologic complete response or minimal microscopic disease was identified in 66% of patients. The overall survival at 5 years was 44% and for those with a complete resection was 54%.[94] In a phase II trial in Japan, chemotherapy with mitomycin, vindesine, and cisplatin with concurrent thoracic radiotherapy led to a 5-year survival of 56%.[95] Data from phase III trials supporting surgery after induction chemoradiotherapy for Pancoast tumors enrolled patients with N0-1 disease, so this same paradigm in patients with N2 disease is controversial.[96] Although the optimal regimen of treatment has not been proved, a reasonable choice is that used in the U.S. Intergroup Trial study described earlier.

SUPERIOR VENA CAVA SYNDROME

The blockage of blood flow in the *superior vena cava* (SVC) results in SVC syndrome.[97] Bronchogenic carcinoma accounts for the vast majority of these cases in older adults.[98,99] In teenagers and young adults, SVC syndrome is usually due to non-Hodgkin lymphoma. Patients report dyspnea and a sensation of fullness in the head and/or light-headedness when bending over. They may also note facial swelling. Cough, pain, and dysphagia are less frequent symptoms. Physical examination findings included dilated neck veins, a prominent venous pattern on the chest, facial edema, and a plethoric appearance. The chest radiograph typically shows widening of the mediastinum or a right hilar mass. On occasion, it may be normal. Dilated veins on the anterior chest wall and compression of the SVC may be demonstrated with a contrast-enhanced CT scan. SVC syndrome is not generally a medical emergency, and patients should not be treated without a tissue diagnosis. Bronchoscopy or mediastinoscopy can be safely performed in the setting of SVC syndrome.[100] SVC syndrome due to SCLC is best treated with chemotherapy. In general, after treatment, symptoms will start to resolve in 5 to 7 days because SCLC is chemosensitive.[101] NSCLC is best treated with concurrent chemoradiotherapy (see earlier discussion of treatment of stage IIIA/IIIB NSCLC). For immediate relief of SVC obstruction, vascular stenting should be strongly considered. A Cochrane meta-analysis reported that SVC stents relieved obstruction in 95% of cases.[101] Stenting has been associated with a complication rate of 3–7%.

OLIGOMETASTATIC NON–SMALL CELL LUNG CANCER

The theory behind oligometastatic disease proposes that cancer metastasis appears along a continuum, from only

local disease to widely metastatic disease. Some patients have a limited number of metastatic tumors in transition between localized and widespread metastatic disease; these tumors are believed to have a more indolent biology, and affected patients have been shown to have longer survival.[102–104] Prospective randomized controlled trials show improved outcomes in other cancers, such as of the colon, when metastasis-directed therapy is added, but data are still emerging in lung cancer.[105,106] For patients with a synchronous resectable N0 primary NSCLC, grade 1C evidence favors resection or radiosurgical ablation of an isolated brain metastasis or resection of an isolated adrenal metastasis[107] (eFig. 76.2).

PARANEOPLASTIC SYNDROMES

Hormonal, neurologic, hematologic, or other remote effects of cancer not related to the direct invasion, obstruction, or metastatic effects of tumor are generally termed paraneoplastic syndromes. Paraneoplastic syndromes related to bronchogenic carcinoma are reported in 10–20% of patients (eTable 76.3).

eTable 76.3 Paraneoplastic Syndromes Associated With Bronchogenic Carcinoma

System	Paraneoplastic Syndrome
Musculoskeletal	Clubbing Hypertrophic osteoarthropathy Polymyositis Osteomalacia Myopathy
Cutaneous	Dermatomyositis Acanthosis nigricans Pruritus Erythema multiforme Hyperpigmentation Urticaria Scleroderma
Endocrinologic	Cushing syndrome Syndrome of inappropriate secretion of antidiuretic hormone Hypercalcemia Carcinoid syndrome Hyperglycemia/hypoglycemia Gynecomastia Galactorrhea Growth hormone excess Calcitonin secretion Thyroid-stimulating hormone
Neurologic	Lambert-Eaton myasthenic syndrome Peripheral neuropathy Encephalopathy Myelopathy Cerebellar degeneration Psychosis Dementia
Vascular/hematologic	Thrombophlebitis Arterial thrombosis Nonbacterial thrombotic endocarditis Thrombocytosis Polycythemia Hemolytic anemia Red cell aplasia Dysproteinemia Leukemoid reaction Eosinophilia Thrombocytopenic purpura
Miscellaneous	Cachexia Hyperuricemia Nephrotic syndrome

MUSCULOSKELETAL EFFECTS

Clubbing of the digits may be a manifestation of lung cancer or other diseases. Clubbing may involve the fingers and toes and consists of selective enlargement of the connective tissue in the terminal phalanges. Physical findings include loss of the angle between the base of the nail bed and the cuticle, rounded nails, and enlarged fingertips. Clubbing is an isolated finding and is usually asymptomatic. Nonmalignant causes of clubbing include pulmonary fibrosis, congenital heart disease, and bronchiectasis. *Hypertrophic pulmonary osteoarthropathy* (HPO) is an uncommon process associated with lung cancer. HPO is characterized by painful arthropathy that usually involves the ankles, knees, wrists, and elbows and is most often symmetrical. The pain and arthropathy are caused by proliferative periostitis that involves the long bones but may also affect metacarpal, metatarsal, and phalangeal bones. Patients may have clubbing of fingers and toes in addition to the painful arthralgias. The pathogenesis of HPO is uncertain, but it may arise from a humoral agent. For patients who smoke and have a new onset of arthralgias, HPO must be considered. A radiograph of the long bones (i.e., tibia and fibula) usually shows characteristic periosteal new bone formation. An isotope bone scan typically demonstrates diffuse uptake by the long bones. Large cell and adenocarcinoma are the most common histologic types associated with HPO. The symptoms of HPO may resolve after resection. For inoperable patients, treatment is with nonsteroidal anti-inflammatory agents. Case reports have observed resolution or marked improvement of symptoms with bisphosphonate treatment.[108]

Although still a topic of debate, population-based studies from Scandinavia suggest a frequency of malignancy of 15–25% in patients with dermatomyositis-polymyositis.[109] The highest risk of malignancy is in the first 2 years after the diagnosis of dermatomyositis-polymyositis. A reasonable approach to cancer surveillance in these patients is a careful history and physical examination, chest radiograph, basic laboratory tests, and age-appropriate cancer screening examinations. Other tests should be based on abnormalities detected during the basic evaluation.

HEMATOLOGIC EFFECTS

Anemia frequently develops in patients who have lung cancer and may be caused by iron deficiency, chronic disease, or bone marrow infiltration. Eosinophilia is more

commonly associated with Hodgkin disease, but it may also be seen in patients who have lung cancer. Production of various cytokines by neoplastic cells may result in eosinophilia, leukocytosis, or thrombocytosis, of which thrombocytosis is by far the most common. The association of deep venous thrombosis and malignancy was described by Trousseau more than a century ago, and lung cancer is the most common malignancy associated with Trousseau syndrome. The causes of the hypercoagulable state remain poorly understood. One large study documented clinically significant association of idiopathic thrombosis and the subsequent development of overt cancer; however, other investigators concluded that the literature does not enable firm recommendations about whether to screen for a malignant neoplasm in patients who have unexplained venous thromboembolism.[109a] Thromboembolism in the patient who has malignancy is often refractory to warfarin treatment. Treatment with *low-molecular-weight heparin* (LMWH) on a chronic basis may be effective. In a randomized trial, patients with cancer and deep vein thrombosis, pulmonary embolism, or both were randomized to receive LMWH (dalteparin) subcutaneously once daily or oral warfarin daily for 6 months.[110] At 6 months, the probability of recurrent thromboembolism was 9% with dalteparin treatment and 17% with warfarin, a difference that was highly significant. The risks of major bleeding or any bleeding were not different in the two groups. The other advantage of LMWH is that it is unnecessary to monitor the anticoagulant effect, except in some patients with renal insufficiency. A 2008 Cochrane analysis concluded that, for long-term treatment in patients with cancer, LMWH reduced venous thromboembolism events, but not death, compared with vitamin K antagonists. There was no significant difference in the risk of bleeding.[111] More recently, direct oral anticoagulants have also shown encouraging results in the treatment of venous thromboembolism in cancer patients and can be considered in this patient population as well.[112–115]

HYPERCALCEMIA

Hypercalcemia in association with malignancy may arise from a bony metastasis or, less commonly, from secretion by the tumor of a *parathyroid hormone–related protein* (PTHrP) or other bone-resorbing cytokine. The most common cancers to cause hypercalcemia are those of the kidney, lung, breast, head and neck, and myeloma and lymphoma. In one study of 690 consecutive lung cancers, 2.5% of cases had tumor-induced hypercalcemia.[116] Squamous cell histology is the most common cell type associated with hypercalcemia, and generally patients have advanced disease (stage III or IV) and are unresectable. Symptoms of hypercalcemia include anorexia, nausea, vomiting, constipation, lethargy, polyuria, polydipsia, and dehydration. Confusion and coma are late manifestations, as are renal failure and nephrocalcinosis. Cardiovascular effects include shortened QT interval, broad T wave, heart block, ventricular arrhythmia, and asystole. Individual patients may manifest any combination of these signs and symptoms in various degrees.

Hypercalcemia of malignancy that is not caused by bony metastases results from accelerated bone resorption, decreased bone deposition, or increased renal tubular reabsorption of calcium. Accelerated bone resorption is caused by activation of osteoclasts by cytokines or PTHrP in most cases. Serum parathyroid hormone levels are usually normal or low, but an elevated level of PTHrP can be detected in the serum in approximately one-half of these patients.[116] Cytokines or PTHrP are secreted autonomously by the tumor. Not only does PTHrP cause renal calcium reabsorption, but also it interferes with renal mechanisms for reabsorption of sodium and water, with resultant polyuria. Polyuria and vomiting result in dehydration; decreases in glomerular filtration further aggravate the hypercalcemia.

Mild elevation of serum calcium may not require treatment, so the decision is based on the patient's symptoms. For patients who have widely metastatic and incurable malignancy, it may be most appropriate to give supportive care only and not treat mild hypercalcemia. The average life expectancy in this situation is 30 to 45 days, even with aggressive treatment.[117] However, most patients who have a serum calcium of 12 to 13 mg/dL or higher are treated.

The four basic goals of treatment are to (1) correct dehydration, (2) increase renal excretion of calcium, (3) inhibit bone resorption, and (4) treat the underlying malignancy. Because of the polyuria, patients with hypercalcemia are volume contracted. Initial treatment is with IV normal saline, using 3 to 6 L per 24 hours as tolerated, with careful attention to volume status. Previously, a loop diuretic such as furosemide or ethacrynic acid was added to maximize calcium excretion, but this has become less common due to the efficacy of the bisphosphonates in inhibiting bone resorption. Thiazide diuretics are not used because they increase calcium reabsorption in the distal tubule. Fluids and diuretics generally result in only a mild decrease of the calcium; additional treatment is needed to inhibit the accelerated bone resorption. The bisphosphonates have a high affinity for bone and inhibit osteoclast activity. Zoledronate, a newer bisphosphonate, is the most effective; the usual dose is 4 mg given IV over 15 minutes.[118] Normal calcium levels are achieved within 4 to 10 days in 85% of patients and last a median of 30 to 40 days. Adverse effects are generally mild and transient and include fever, hypophosphatemia, asymptomatic hypocalcemia, and occasionally renal failure. Calcitonin inhibits bone resorption, increases renal calcium excretion, and has a rapid onset of action, but the duration of action is short lived. Calcitonin is a relatively weak agent and when used alone does not usually normalize the serum calcium of patients who have marked hypercalcemia. Use of calcitonin is appropriate when the calcium is greater than 14 mg/dL or needs to be lowered urgently (onset of action is 4–6 hours) while waiting for the more effective but slower-acting agents to take effect or when relief of bony pain is desired. The effects of calcitonin and bisphosphonates are additive. Tachyphylaxis to calcitonin may be seen after 48 hours. Other agents, such as gallium nitrate or plicamycin, have been used to treat hypercalcemia but have not generally been adopted as first-line therapies because of inconvenience of administration schedules or associated toxicities.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Causes of hyponatremia include tumors, pulmonary infections, central nervous system disorders, and drugs. Although only 10% of patients with SCLC exhibit the *syndrome of inappropriate antidiuretic hormone* (SIADH) secretion, SCLC accounts for approximately 75% of cases of SIADH. Antidiuretic hormone (vasopressin) is secreted in the anterior hypothalamus and exerts its action on the renal collecting ducts by enhancing the flow of water from the lumen into the medullary interstitium, thereby concentrating the urine. The criteria for the diagnosis of SIADH include (1) hyponatremia associated with serum hypoosmolality (<275 mOsm/kg); (2) inappropriately elevated urine osmolality (>200 mOsm/kg) relative to serum osmolality; (3) elevated urine sodium (>20 mEq/L); (4) clinical euvolemia without edema; and (5) normal renal, adrenal, and thyroid function. The serum uric acid is usually low, and the urine osmolality/serum osmolality ratio is frequently greater than 2. The severity of symptoms is related to the degree of hyponatremia and the rapidity of the fall in serum sodium. In one large series of SIADH patients, only 27% had signs or symptoms of hyponatremia despite median sodium of 117 mEq/L (range, 101–129 mEq/L). Symptoms of hyponatremia include anorexia, nausea, and vomiting. With a rapid onset of hyponatremia, symptoms caused by cerebral edema may include irritability, restlessness, personality changes, confusion, coma, seizures, and respiratory arrest. In minimally symptomatic or asymptomatic patients, fluid restriction of 500 to 1000 mL per 24 hours is the initial treatment of choice. Conivaptan is an IV vasopressin receptor antagonist that has been shown to be useful in correcting hyponatremia, but its use is limited to the hospital. Oral vasopressin receptor antagonists[119,120] have also been approved for use in this setting.

If further treatment is needed, oral demeclocycline (900–1200 mg/day) can be considered. Demeclocycline induces a nephrogenic diabetes insipidus and blocks the action of antidiuretic hormone on the renal tubule, thereby increasing water excretion. The onset of action varies from a few hours to a few weeks, so this drug is not recommended for acute emergency treatment. Demeclocycline has potential kidney toxicity. In patients who have more severe or life-threatening symptoms (serum sodium < 115 mEq/L), treatment consists of IV saline, supplemental potassium, and diuresis with loop diuretics, such as furosemide or ethacrynic acid. With severe confusion, convulsions, or coma, it may be appropriate to treat with 300 mL of 3% saline given over 3 to 4 hours in combination with a loop diuretic (saline without a diuretic will not increase the sodium concentration). Rapid correction of the sodium may have life-threatening consequences, and caution is advised.[121] The rate of correction of the sodium is best limited to a maximum of 20 mEq/L/day until a level of 120 to 130 mEq/L is reached. Faster correction has been associated with the development of central pontine myelinolysis, which may result in quadriplegia, cranial nerve abnormalities that manifest as pseudobulbar palsy, alteration in mental status, and subsequent death. In accordance, in the course of treating hyponatremia, the serum sodium must be monitored frequently to ensure that correction is not too rapid. For patients with SIADH due to SCLC, treatment with chemotherapy should be initiated as soon as possible and is likely to result in improvement in the hyponatremia within a few weeks. After an initial response to chemotherapy, SIADH may recur when the tumor relapses.

ECTOPIC CORTICOTROPIN SYNDROME

Ectopic production of corticotropin or corticotropin-releasing hormone with associated Cushing syndrome has been identified in patients who have SCLC, carcinoid tumor (lung, thymus, or pancreas), and neurocrest tumors, such as pheochromocytoma, neuroblastoma, and medullary carcinoma of the thyroid.[122] Of those with ectopic corticotropin secretion, SCLC accounts for 75% of cases, although only 1–2% of patients with SCLC develop Cushing syndrome. Cushing syndrome is seldom caused by NSCLC.

Classic features of Cushing syndrome include truncal obesity, striae, rounded (moon) facies, dorsocervical fat pad (buffalo hump), myopathy and weakness, osteoporosis, diabetes mellitus, hypertension, and personality changes. However, the rapid growth of SCLC means that patients are more likely to present with edema, hypertension, and muscular weakness than with the classic features of Cushing syndrome. Hypokalemic alkalosis and hyperglycemia are usually present. Patients with SCLC and Cushing syndrome appear to have shortened survival compared to those without the syndrome, perhaps because of more frequent opportunistic infections. The best screen for Cushing syndrome is the 24-hour urinary free cortisol measurement. Elevation of cortisol production, lack of suppression with high-dose dexamethasone, and plasma corticotropin levels greater than 200 pg/mL (40 pmol/L) are highly suggestive of ectopic corticotropin as the cause of Cushing syndrome in the absence of a pituitary adenoma. The plasma level of corticotropin is elevated in many, but not all, patients. Treatment of Cushing syndrome due to ectopic corticotropin has included adrenal enzyme inhibitors, such as metyrapone, aminoglutethimide, and ketoconazole, given alone or in combination. Ketoconazole given orally at a dosage of 400 to 1200 mg/day or metyrapone 250 to 750 mg 3 times per day may control hypercortisolism within a few days to weeks, but the response is variable.[123] Dose adjustments are based on achieving normal urinary free cortisol levels or morning plasma cortisols of 7 to 11 μg/mL. Symptomatic hypoadrenalism may result from treatment, and some authorities recommend a replacement dose of glucocorticoid when an enzyme inhibitor is started. When Cushing syndrome arises from SCLC, it is advisable to proceed with appropriate chemotherapy and carefully watch for superimposed infections, as is necessary for any patient receiving high-dose corticosteroids. Cushing syndrome related to a bronchial carcinoid or thymic carcinoid is best treated by surgical resection of the tumor.

NEUROLOGIC EFFECTS

The paraneoplastic neurologic syndromes associated with lung cancer, mostly small cell type, are quite variable and can affect any level of the central or peripheral nervous system. They include *Lambert-Eaton myasthenic syndrome* (LEMS), subacute sensory neuropathy, encephalomyelopathy, cerebellar degeneration, autonomic neuropathy, retinal degeneration, and opsoclonus.[124] The frequency of any of these neurologic syndromes in SCLC is approximately 5%, and neurologic symptoms may precede the diagnosis by months to years.[125,126] Most patients who have SCLC and an associated paraneoplastic syndrome have limited disease–SCLC that may or may not be obvious on initial evaluation. Careful radiographic evaluation of the lungs and mediastinum is indicated in a smoker who has a suspected paraneoplastic neurologic syndrome. In this setting even subtle abnormalities of the mediastinum require a biopsy. A PET scan may help identify an occult lesion and facilitate biopsy confirmation of the diagnosis.[127,128] Many reports have suggested that patients with paraneoplastic neurologic syndromes have a better prognosis than those without the paraneoplastic syndromes with similar stage and histology.

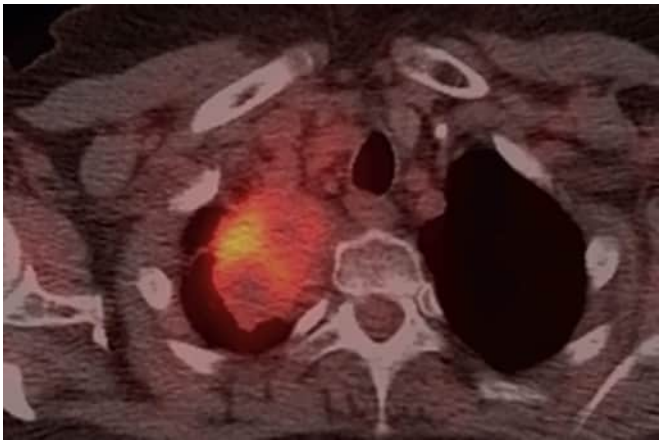
These paraneoplastic neurologic syndromes are thought to be immune-mediated responses against neural antigen abnormally expressed by the tumors. This is based on the identification of antibody and T cell responses against nervous system antigens. A number of onconeural antibodies have been found in the serum that react with both the nervous system and the underlying cancer.[124] However, not all patients with paraneoplastic syndromes have identifiable antibodies in their serum. The literature is confusing because of different names used by various investigators. The anti-Hu antibody is the same as *antineuronal nuclear antibody type 1* (ANNA-1), and the *antiribosomal* (anti-Ri) antibody is identical to ANNA-2. Both of these antibodies, but predominantly ANNA-1, have been associated with SCLC. ANNA-1 binds to the nuclei of all neurons in the central and peripheral nervous system, including the sensory and autonomic ganglia, the myenteric plexus, and cells of the adrenal medulla. Such antibodies should not be confused with the *anti–Purkinje cell antibody* (anti-Yo), which is characteristically found in patients who have subacute cerebellar degeneration as a manifestation of gynecologic malignancy or breast cancer. The *collapsin response-mediator protein-5* (CRMP-5) antibody, also known as anti–CV-2, has been associated with SCLC and thymomas.[124]

In a review of 162 sequential patients who had elevated ANNA-1 (anti-Hu), 142 (88%) were proved to have cancer, 132 of whom had SCLC.[126] In 97% of these cases, the diagnosis of SCLC followed the onset of the associated neurologic syndrome, usually by less than 6 months but, in 20%, by greater than 6 months. Of special note is that 90% of cases had disease limited to the lung or to the lung and mediastinum (limited disease–SCLC). In a report from Europe, 144 patients out of 200 with anti-Hu antibodies had a tumor in the chest.[125] Of these, 111 were proved to be SCLC. In one large series ANNA-1 antibodies were identified in 16% of all patients with SCLC. These antibodies were associated with limited-stage disease, complete response to therapy, and longer survival compared with patients who had SCLC and no ANNA-1 antibody. These neurologic syndromes seldom improve with treatment, so the goal is to prevent progression by starting treatment of the underlying tumor as soon as possible.

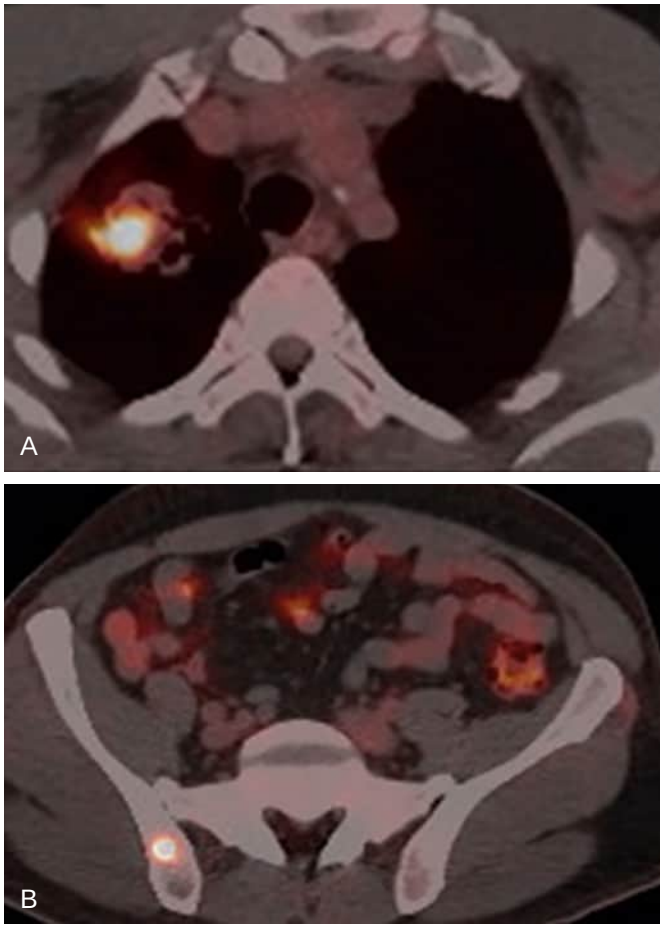
Less common manifestations of neurologic paraneoplastic syndromes are orthostatic hypotension and intestinal dysmotility. The gastrointestinal symptoms may present as nausea, vomiting, abdominal discomfort, or altered bowel habits suggestive of intestinal pseudo-obstruction. Many of these patients present with gastrointestinal symptoms and significant weight loss before the diagnosis of SCLC.

LEMS is characterized by muscle weakness, hyporeflexia, and autonomic dysfunction.[129,130] Cranial nerve involvement may be present and does not differentiate LEMS from myasthenia gravis. LEMS has been strongly associated with antibodies directed against presynaptic anti–voltage-gated calcium channels of peripheral cholinergic nerve terminals. These anti–voltage-gated calcium channel antibodies, identified in greater than 90% of patients with LEMS, block the normal release of acetylcholine at the neuromuscular junction. In contrast, myasthenia gravis is associated with anti–acetylcholine receptor antibodies, which are present in approximately 90% of myasthenic patients. Malignancy is present in approximately one-half of patients who have LEMS, and SCLC is by far the most common malignancy. In a study of 63 patients with SCLC examined prospectively, only 3% had clinical and electrophysiologic signs of LEMS, 8% had elevated anti–voltage-gated calcium channel antibodies, and 26% had other neurologic symptoms unrelated to LEMS.[131] The diagnosis of LEMS is based on characteristic electromyographic findings that show a small amplitude of the resting compound muscle action potential and facilitation with rapid, repetitive, supramaximal nerve stimulation or after brief exercise of the muscle. A single-fiber electromyogram is optimal for making the diagnosis. LEMS is the predominant paraneoplastic neurologic syndrome that may improve with successful treatment of the associated lung cancer. The use of acetylcholinesterase inhibitors is of limited benefit in LEMS.[132] Diaminopyridine enhances the release of acetylcholine and has been used with sustained improvement over months in the majority of patients with LEMS either with or without cancer.[133]

eFIGURE IMAGE GALLERY



eFigure 76.1 A positron emission tomography–computed tomography scan demonstrating a right upper lobe Pancoast tumor.



eFigure 76.2 Oligometastatic disease. This patient was offered surgical resection of the right upper lobe adenocarcinoma (A), followed by stereotactic body radiotherapy to the iliac bone metastasis (B, only site of metastatic disease) and then chemotherapy. Surgical paradigms in oligometastatic lung cancers may be considered in highly selected cases.

KEY POINTS

INTRODUCTION

Worldwide, lung cancer is the leading cause of cancer death and is projected to be a major health problem well through the first half of the twenty-first century, particularly in women and in developing countries, which continue to observe rising incidence rates.[1–3] The main histologic subtype of lung cancer is *non–small cell lung cancer* (NSCLC), which accounts for 85% of cases and includes adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. The other lung cancer cell type is *small cell lung cancer* (SCLC). Survival rates are grouped based on the stage, but additional factors, including cell type (NSCLC vs. SCLC), the presence of actionable mutations, age, and comorbidities can also affect treatment outlook. The 5-year relative survival rate for lung cancer is 19.4% (16% for men and 22% for women) and is higher for NSCLC (23%) than for SCLC (6%).[4] The low survival rate reflects the fact that the majority of patients with lung cancer are diagnosed with advanced stages of disease.

Treatment is primarily based on disease stage and the patient's *performance status* (PS) at the time therapy is initiated. Advances in understanding the molecular pathogenesis of lung cancer underscore the heterogeneity of the disease. Molecular characterization of NSCLC currently serves as a critical guide to treatment in patients diagnosed with metastatic disease and in those who relapse after primary therapy. In general, stage I NSCLC (early stage) is treated with surgery alone. Stage II NSCLC (intermediate between early and locally advanced) is treated with surgery followed by chemotherapy. Stage III disease (locally advanced) treatment is beset with controversy but, in general, includes multimodality therapy with chemotherapy and surgery for resectable stage IIIA or a combination of chemotherapy and radiotherapy followed by immunotherapy. Stage IV NSCLC (metastatic disease) is treated with systemic therapy. However, there are important exceptions to these general rules, which are discussed later in this chapter.

SCLC usually presents with disseminated disease, and treatment strategies have focused on systemic therapy. Although SCLC is highly responsive to both chemotherapy and radiotherapy, it commonly relapses within months despite treatment.

Most patients will require multidisciplinary input over the course of their diagnosis and treatment. Development of multidisciplinary programs supported by members of the major disciplines involved in lung cancer care, namely the pulmonologist, thoracic surgeon, and the medical and radiation oncologists, and a "tumor board," with the addition of chest radiology, pathology, and nursing, is pivotal to ensure patients receive expeditious coordination of care, receive optimal treatment, and are considered for enrollment in clinical trials.

Major advances in lung cancer therapeutics include minimally invasive surgical techniques, refinements in radiotherapy, and a burgeoning of new systemic therapies targeting molecular pathways and the immune system. Systemic therapies and/or radiotherapy can be applied in a neoadjuvant or adjuvant fashion. A few terms used in this chapter are as follows:

- *Neoadjuvant* therapy indicates therapy given before surgery; it has the potential to reduce tumor volume, treat micrometastases, and improve outcomes.
- *Adjuvant* therapy is therapy given after surgery; it is aimed at treating any residual tumor or micrometastases with the aim of preventing tumor recurrence.
- *Concurrent* therapy is therapy given at the same time; for example, when chemotherapy and radiation therapy are given at the same time.
- *Sequential* therapy is therapy given sequentially; for example, when the radiotherapy follows chemotherapy.
- *Definitive* therapy is therapy intended to be curative, not palliative.
- *Consolidation* therapy is given after remission is achieved with the goal to sustain a remission.
- *Maintenance* therapy is given to patients in remission in an attempt to prevent relapse.

Radiotherapy advances include progressing from two-dimensional techniques (where bony landmarks on a patient or radiograph are used to shape a treatment field), to more *conformal* techniques (where *computed tomography* [CT] images are used to design radiation fields to treat a tumor target optimally while sparing other organs).

Treatment conformality and accuracy are also improved with modern techniques that use motion management (to see how a tumor moves with breathing) and customized shaping of radiation beams around a target.

The efficacy of treatments can be assessed by different metrics:

- *Median survival time* (MST) refers to the length of time 50% of the patients survive with a disease after a certain treatment.
- *Progression-free survival* (PFS) is the length of time a patient with lung cancer lives before the tumor progresses.
- *Overall survival* (OS) is the time from diagnosis or treatment until a patient's death.

Outcomes for diseases with excellent prognoses (such as early-stage breast cancer or low-risk prostate cancer) are often reported as percent OS at 5, 10, or 20 years after diagnosis or therapy (5-, 10- or 20-year OS). In contrast, outcomes for lung cancer are often reported as MST, 2-year OS, or PFS, reflecting the higher likelihood of disease recurrence or death.

- *Hazard ratios* (HRs) are used to describe differences in survival between two different treatments and to express survival benefit as a reduction in the risk of death. An HR of 1 for OS means the death rates are the same in both treatment groups while an HR of less than 1 means survival was better in one of the treatment groups. For example, if a study drug compared to placebo resulted in an HR of 0.60, the study drug reduced the risk of dying by 40%.

This chapter describes the current treatment of NSCLC and SCLC. As much as possible, evidence-based review of the best currently available literature has been included.

PROGNOSTIC AND PREDICTIVE FACTORS IN LUNG CANCER

A *prognostic* factor provides information about patient outcomes. Prognostic factors associated with improved survival include good PS (measured on the Karnofsky scale or the *Eastern Cooperative Oncology Group* [ECOG] scale), lesser extent of disease (stage), younger age, absence of weight loss, and female sex.[5–10] Women are diagnosed with less-advanced disease than men and, when adjusted for age, stage, and selected histologic subgroups, have improved outcomes after treatment for lung cancer.[9] Additional factors include the presence or absence of symptoms related to a specific site of metastasis, absence of smoking or smoking cessation, and NSCLC subtype (squamous histology slightly better than nonsquamous histology).[11–15] The maximal standard uptake value of the primary tumor on positron emission tomography has been inversely correlated with survival.[16] In patients with advanced NSCLC treated with platinum-based chemotherapy, absence of Kirsten rat sarcoma *(KRAS)* gene mutation and low or no expression of the DNA excision repair protein ERCC1 is associated with improved prognosis.[17,18] In a meta-analysis, *KRAS* mutations were associated with poorer survival, especially in adenocarcinoma.[17]

A *predictive* factor helps identify patients who will benefit from a specific treatment.[19] Predictive factors include histology (predictive of the benefit of pemetrexed in nonsquamous NSCLC irrespective of the stage),[20] and genomic mutations in the *epithelial growth factor receptor* (EGFR), fusion oncogenes involving *anaplastic lymphoma kinase* (ALK) and rearrangements in the *ROS proto-oncogene 1* (ROS1). Patients with EGFR mutations, ALK-fusion, or ROS1 rearrangement benefit from *tyrosine kinase inhibitors* (TKIs).[21,22] A *tumor proportion score* (TPS) for the expression of *programmed death-ligand 1* (PD-L1) on 50% or more of tumor cells in NSCLC is predictive of patients who will benefit from first-line therapy with an *immune checkpoint inhibitor* (ICI) targeting *programmed death-1* (PD-1).[23] Genomic profiling of cytologic and histologic samples obtained from the primary tumor, lymph nodes, or metastatic lesions is standard practice, because this allows for the best selection of first-line treatment in patients with advanced NSCLC.

TREATMENT OF NON–SMALL CELL LUNG CANCER BY STAGE

This section presents discusses the treatment of NSCLC by stage; Table 77.1 presents an overview of treatment strategies for NSCLC.

STAGE I NON–SMALL CELL LUNG CANCER

In the most recent edition (eighth) of the TNM staging system for NSCLC,[24] stage I is broken down by size of tumor to stage IA (tumors ≤ 3 cm: ≤ 1 cm [T1a (eFig. 77.1A), > 1 cm but ≤ 2 cm [T1b], > 2 cm but ≤ 3 cm [T1c]) and stage IB, which includes tumors between 3 and 4 cm [T2a] (eFig. 77.1B), centrally located and/or involving the visceral pleura (eFig. 77.2A). All stage I tumors are completely surrounded by lung parenchyma greater than 2 cm away from the carina, do not invade the chest wall or parietal pleura, and do not have malignant lymph node or metastatic disease. Thus the TNM classification for stage I is either T1aN0M0, T1bN0M0, or T1cN0M0, (stage IA), or T2aN0M0 (stage IB).[24] Although stage I disease offers the best chance for long-term survival, only 16% of patients with NSCLC present with stage I disease.[4]

The current treatment for stage I lung cancer is surgery alone. The surgical procedure of choice is a lobectomy with mediastinal lymph node sampling. The patient must be a reasonable surgical candidate as determined primarily by cardiopulmonary reserve and secondarily by age and comorbidities. Patients with a postoperative percent predicted forced expiratory volume in 1 second or diffusion capacity less than 40% will have a higher morbidity and mortality following lung cancer surgery. Patients with borderline values preoperatively should be referred for a differential ventilation-perfusion scan for a better prediction of postoperative function. When there is still a question, a cardiopulmonary exercise test can be obtained. Compared with those with a maximum oxygen consumption greater than 20 mL/kg/min, patients with a maximum oxygen consumption between 11 and 19 mL/kg/min have a higher morbidity but no greater mortality and those with a maximum oxygen consumption less than 10 mL/kg/min have both a higher predicted morbidity and mortality.[25] Patients who are "close calls" for surgery should be evaluated by both a pulmonologist and a thoracic surgeon before making a decision on whether the patient is *operable*, meaning that

Table 77.1 Summary of Current Treatment Strategies for Non–Small Cell Lung Cancer

Stage	Surgery	Chemotherapy	Radiotherapy	Chemoradiotherapy	Comments
IA and IB	First line	Adjuvant—tumors ≥4 cm	First line*	No	Role of adjuvant chemotherapy for stage IB not clearly defined but should be considered in tumors ≥4 cm in size and/or high-risk features (vascular invasion, visceral pleural involvement)
IIA and IIB	First line	Adjuvant	No	No	5-year survival improvement with adjuvant chemotherapy about 5%
T3 due to multiple tumor nodules same lobe	Lobectomy to resect primary and satellite nodules				
T3 due to chest wall invasion	En bloc resection				
Superior sulcus tumors					Neoadjuvant chemoradiotherapy improves survival in this subset of stage IIB
IIIA	First line for N0-1	Adjuvant treatment in completely resected IIIA	Neoadjuvant or adjuvant in the setting of N2 nodes	First line for unresectable N2 disease Followed by consolidation immunotherapy	Combined chemotherapy ± radiotherapy followed by surgery is feasible in select N2 disease, but more data are needed to recommend routinely
IIIB and IIIC	No	No	No	First line Followed by consolidation immunotherapy	
IV	No	First line: systemic therapy†: ■ Chemotherapy ■ Targeted therapy ■ Immunotherapy ■ Chemotherapy and immunotherapy	Radiotherapy is used for palliation only	No	All stage IV adenocarcinomas should have mutational analysis, including *EGFR*, *ALK*-fusion, *ROS1*, and *KRAS* All stage IV NSCLC should be tested for PD-L1

*SBRT for patients who are medically unfit or who refuse surgery.
†First-line therapy in stage IV NSCLC is selected based on (1) histology: pemetrexed for nonsquamous cell, gemcitabine for squamous cell and bevacizumab is approved as an adjunct to chemotherapy in the first-line setting in patients with nonsquamous histology and no other contraindications; (2) presence of molecular target guides first-line therapy; (3) PD-L1 expression >50% used to select patients eligible for first-line pembrolizumab.

the patient can tolerate the planned operation. It is important to recognize that patients who are *resectable*, meaning they have a potentially resectable tumor, may not be operable, usually because the patient does not have the pulmonary reserve to tolerate a lobectomy (see Chapter 30).

Stage I tumors located close to the hilum may be amenable to bronchial or vascular sleeve resection as an alternative to bilobectomy or pneumonectomy if the patient does not have sufficient reserve to tolerate the larger resection. Use of video-assisted thoracoscopic surgery has been associated with better postoperative recovery including less pain, shorter length of stay, equivalent long-term survival, and improved quality of life compared to thoracotomy.[26,27]

Patients with T1 tumors less than 2 cm and who are surgically resectable but medically inoperable may be able to tolerate a sublobar resection (wedge resection for peripherally located tumors spanning multiple segments or segmentectomy) as opposed to a lobectomy or pneumonectomy. Margins and lymph node clearance must still be adequate. In the case of wedge resection, the locoregional recurrence rate is higher than that of an anatomic resection (i.e., segmentectomy or lobectomy), but the overall 5-year mortality is no different.[28] Segmentectomy may offer local control, the opportunity for prolonged disease free survival, and OS comparable to lobectomy while preserving lung parenchyma, and so should be offered to patients with inadequate pulmonary function to tolerate lobectomy or those with multiple primary tumors anticipated to need subsequent resection.[29] With segmentectomy, preoperative nodule localization and marking by navigational bronchoscopy can be used to increase the success of a negative margin.[30] Still, whenever possible, a lobectomy or greater anatomic resection is preferred over a lesser resection, primarily because the tumor may be found on pathologic examination to be greater than 2 cm in size or there may be unsuspected positive hilar nodes; both findings would warrant a larger resection than segmentectomy.

The 5-year survival by pathologic stage for surgically resected stage IA (T1a,b,c, N0, M0) NSCLC is 80–90%, whereas the survival for stage IB lung cancer is 73%.[24] Local adjuvant radiation for stage I, after either complete or incomplete resection of the tumor, has not been found to be of any benefit,[31] and adjuvant chemotherapy is associated with worse survival for patients with resected stage IA disease.[32,33] The role of adjuvant chemotherapy in resected stage IB (T2a >3–4 cm) is limited and has yet

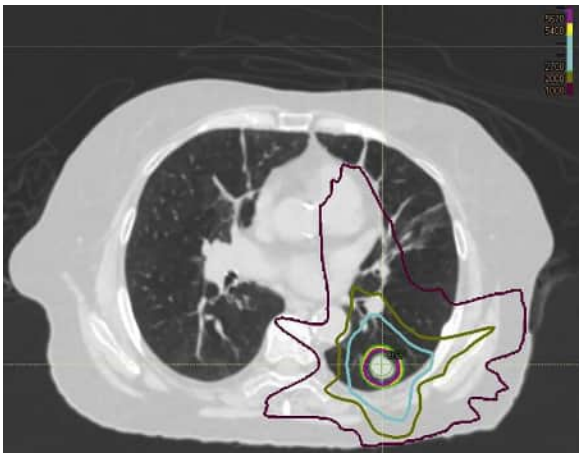

Figure 77.1 Stereotactic body radiotherapy planning. The image shows a typical stereotactic body radiotherapy plan for a peripheral lesion treated with 54 Gy in 3 fractions (yellow isodose line). Rapid dose falloff can be seen, with even a low isodose line (1000 cGy, purple) avoiding the spinal cord and esophagus.

to be defined. In a study of adjuvant chemotherapy in patients with stage IB NSCLC conducted by the Cancer and Leukemia Group B, significant improvement in PFS and OS was noted at 34 months. However, with a longer median follow-up of 74 months, differences in survival were not significant.[34] Subsequent exploratory analysis showed benefit for patients whose tumors were less than 4 cm in diameter (HR, 0.69).[34] This benefit has been reported by others,[35] and current National Comprehensive Cancer Network guidelines suggest adjuvant chemotherapy to treat patients with a tumor greater than 4 cm (particularly if it is poorly differentiated or shows vascular invasion or visceral pleural involvement).[36]

For patients who are deemed medically unfit or who refuse surgery, primary radiotherapy alone with curative intent is typically considered. Historically, nonsurgical candidates with early-stage lung cancer were treated with radiation using conventional fractionation (≈2 Gy per fraction for 6–7 weeks), *two-dimensional* (2D) techniques (without image guidance) and large radiation fields were used to account for tumor motion throughout the breathing cycle. With these relatively crude techniques, local control rates were only in the 30% range.[37] The approach of definitive radiation was further evaluated in a meta-analysis of 1 randomized and 35 nonrandomized trials.[38] The studies were heterogeneous, and the 5-year cancer-specific survival ranged between 13% and 39%. The authors concluded that, even in patients with severe emphysema, radiation therapy can be tolerated if careful planning with *three-dimensional* (3D) conformal techniques is undertaken. *Conformal* indicates that the radiation is designed in 3D to match the shape of the tumor, thereby allowing maximal targeting to the tumor with minimal injury to adjacent normal tissue. The Radiation Therapy Oncology Group conducted a series of dose escalation trials in the 1980s in an attempt to improve outcomes after definitive radiotherapy. Survival improved up to a dose of nearly 70 Gy, yet 2- year survival rates were actually lower at higher radiation doses, likely due to the pulmonary toxicity of high-dose radiation delivered in a nonconformal manner.[39] Consistent with this finding, comparisons of 2D versus 3D conformal radiation plans, of which the latter were based on CT, have demonstrated superior locoregional control with 3D conformal radiotherapy.[37]

More recently, *stereotactic body radiation therapy* (SBRT) has been introduced as a precise and accurate delivery method of highly conformal and dose-intensive radiation to small-volume targets. This method is also referred to as *stereotactic ablative body radiotherapy*. In contrast to conventionally fractionated radiotherapy, which ensures safety for normal body tissues by leveraging principles of radiobiology (small dose each day for many weeks), SBRT spares normal tissue by precise stereotactic localization, image guidance, and motion management to allow a *hypofractionated* course of treatment, in which 5 or fewer radiation treatments are given with larger doses of radiation delivered with each treatment. This technique allows delivery of a higher *biologic effective dose* (BED) with a typical radiotherapy plan (Fig. 77.1) than could previously be achieved using conventional radiotherapy methods.[40] Achieving a BED greater than 100 Gy results in improved local control of early-stage NSCLC, 92% versus 74% for patients receiving a BED less than 100 Gy.[41] Typical SBRT doses and fractionation for lung cancer (54 Gy in 3 fractions, 48 Gy in 4 fractions, and 50 Gy in 5 fractions) all have a BED greater than 100. In a single-arm phase II trial, patients with biopsy-proven stage I NSCLC deemed medically inoperable received SBRT with 60 Gy delivered in three fractions.[41] Long-term follow-up showed 5-year local control of 93%, lobar control 80%, distant failure rate of 31%, and OS 40%.[42] SBRT was typically well-tolerated with minimal toxicity (rates of grade 2 pneumonitis and chest wall pain < 10%).

In this SBRT study, however, the risk of complications was greater in *centrally located* tumors, defined as within 2 cm of the proximal tracheobronchial tree (six patients had treatment-related deaths, and four of those six had central lesions).[42] To improve the safety of SBRT for central lesions, subsequent studies have used a regimen of at least 5 fractions (in contrast to the 3-fraction regimen used for peripheral tumors). In a phase I/II dose escalation study, patients with biopsy-proven, medically inoperable, centrally located NSCLC were treated with 5-fraction SBRT ranging from 10 to 12 Gy delivered over 1.5 to 2 weeks.[43] Three-year local control was approximately 85% and dose-limiting *toxicity* rate in the first year was 7.2%; however, there were four deaths of patients in the higher dose per fraction cohorts—one due to esophageal ulcer and three due to bronchopleural hemorrhages.[43] As such, selection of dose for central lesions is vital to balance local control with risk of severe toxicities. For "ultracentral" tumors, which directly abut an organ at risk (trachea, mainstem bronchus or esophagus), more fractionated non-SBRT regimens (70 Gy in 10 fractions, 60 Gy in 12 fractions) are often used to mitigate toxicity. High local control rate with 60 Gy in 12 fractions has been reported in patients with tumors abutting the trachea or mainstem bronchus but with risk of severe toxicity, with 38% of patients developing a grade 3+ toxicity and 15% grade 5 pulmonary hemorrhage.[44] Thus patients with ultracentral tumors abutting major vessels and trachea are at risk for severe

toxicity even with moderately hypofractionated regimens (10–12 fractions).

STAGE II NON–SMALL CELL LUNG CANCER

Stage II NSCLC is divided into stage IIA T2bN0M0 (tumors >4 cm but ≤5 cm without involved nodes) (see eFig. 77.2B), and stage IIB includes either T3N0 tumors (>5 cm but ≤7 cm, invasion of chest wall or an ipsilobar satellite nodule) without lymph node involvement, or T1a–c or T2a–b tumors with hilar or peribronchial nodes (N1). The 5-year survivals for pathologic stage IIA and IIB are 65% and 56%, respectively.[24] Stage IIA NSCLC is quite uncommon, representing between 1% and 5% of patients treated in several surgical series.[45–48] Stage IIB NSCLC may represent up to 15% of surgically resected cases.[45,48] For stage IIA and IIB NSCLC, surgical therapy is the treatment of choice. NSCLC with invasion of structures such as the chest wall, (T3*inv*N0M0) (eFig. 77.3) is seen in about 5% of all NSCLC but represents about 45% of patients with T3 disease.[49] Adequate surgical treatment requires an en bloc resection of the affected nonvital structures and is designed to include lung, parietal pleura, visceral pleura, and parts of the chest wall, which could include the rib cage and the sternum, and results in a 5-year median survival of about 50%.[50,51] Surgery is also the primary treatment for tumors with satellite nodules in the same lobe (T3*satell*N0M0) and T3N0M0 superior sulcus (Pancoast) tumors.[24] A specific discussion of the evaluation and treatment of Pancoast tumor is discussed later in this chapter.

There is no benefit to postoperative radiotherapy in completely resected stage II and IIB NSCLC.[31] The value of adjuvant chemotherapy after surgery is discussed later (see "Stage IIIA") but, in short, adjuvant chemotherapy is recommended for all patients with resected stage II disease. Immunotherapy holds promise in early stage (stage I–II) NSCLC and is discussed further under "Immunotherapy."

STAGE III NON–SMALL CELL LUNG CANCER

The eighth edition of the TNM staging system expands stage III NSCLC into three subgroups: IIIA, IIIB, and IIIC,[24] which provides a better appreciation of the heterogeneity of stage III NSCLC. When applied retrospectively, each successive stage III subgroup is associated with incrementally shorter survival, ranging from 36% at 5 years for clinical stage IIIA disease to 13% for clinical stage IIIC disease.[24]

Stage IIIA

Stage IIIA NSCLC represents a diverse group of patients and includes those with N2 disease and patients with T3N1 and T4N0-1 disease.[24] The ability to achieve complete resection in stage III NSCLC may be limited by patient-related factors and by tumor characteristics such as large or invasive T4 tumors that cannot be completely resected with negative margins. For carefully selected T4N0-1M0 patients, surgery may be indicated with or without neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy (superior sulcus tumors) (eFig. 77.4).[52] The need for resection of the diaphragm, vertebrae, and even involved areas of the great vessels is no longer considered an absolute contraindication, and a multidisciplinary surgical approach should be considered in these cases. Individuals with T4N0-1 disease due to main carinal involvement have been treated with carinal resection with or without pulmonary resection. Carinal resection carries an operative mortality of 10–15% and 5-year survival of approximately 20% in carefully selected series. Patients who are T4N0 solely due to ipsilateral tumor nodules in a separate lobe (eFig. 77.5) have a 5-year survival of around 20% with surgery alone.[53]

There is no debate that a medically operable patient with T3N1, stage IIIA disease is best treated with surgical resection followed by adjuvant chemotherapy. Occasionally, after complete resection of the lymph nodes and the primary tumor, some patients are incidentally found to have occult N2 metastasis. These patients are best served by a resection of all known disease and consideration for adjuvant chemotherapy.[54] In patients with stage II or IIIA NSCLC who undergo complete resection, adjuvant chemotherapy is recommended with four cycles of a cisplatin-based *doublet* chemotherapy in which cisplatin is given along with a second agent.[32,33] The Lung Adjuvant Cisplatin Evaluation meta-analysis evaluated all stages of totally resected disease and observed a 5.4% overall 5-year survival benefit with adjuvant chemotherapy. The benefit was the greatest for patients with stage II and III disease and those with better PS.[32] The role of postoperative radiation therapy for patients with completely resected stage IIIA (N2) remains controversial; however, because local recurrence rates are very high, some nonrandomized trials suggest possible overall survival benefit from postoperative radiation therapy in patients with N2 disease.[55,56] In a trial, which randomized patients with completely resected stage IB–IIIA to adjuvant chemotherapy or observation, adjuvant radiotherapy was given at the discretion of the treating physicians.[57] In a subset analysis, receipt of adjuvant radiotherapy was associated with worsened OS in patients with N1 disease who received chemotherapy, but was associated with improved OS in patients with N2 involvement regardless of receipt of chemotherapy. A randomized phase III adjuvant radiotherapy trial is underway to evaluate postoperative radiation therapy in these patients.

It is less certain how best to treat patients when N2 (single or multiple station) metastases are documented before thoracotomy. This is a subset of patients who probably benefit the most when the treatment plan is discussed by a multidisciplinary team. Either definitive chemoradiotherapy or neoadjuvant chemotherapy followed by surgery is recommended over either surgery or radiation alone. These recommendations were largely influenced by the two cooperative group trials that evaluated the role of surgery in patients with N2 disease.[58,59] The European trial randomized patients with histologically proven N2 disease to radiotherapy or surgery after neoadjuvant chemotherapy with three cycles of a cisplatin doublet chemotherapy.[59] The MST was 16 months in the surgery arm and 17 months in the radiotherapy arm.[60] The 5-year survival in both arms was 16% and 14%, respectively, and was not significantly different. The North American trial also required pathologic proof of N2 disease and randomized patients to completion radiotherapy (to a cumulative dose of 60 Gy) or surgery

(either lobectomy or pneumonectomy with mediastinal nodal dissection/sampling) after neoadjuvant chemoradiotherapy of two cycles of etoposide plus cisplatin with concurrent thoracic radiotherapy of 45 Gy in 25 fractions over 5 weeks.[58] The MST was 24 and 22 months in the surgery and radiotherapy arms, respectively, with 5-year survivals of 27% and 20%, that were not statistically different. However, the PFS favored the surgery arm. A subset analysis showed that those requiring only a lobectomy (in contrast to a pneumonectomy) after neoadjuvant chemotherapy did better than a matched group receiving only chemoradiotherapy.[58] This was an unplanned subset analysis that weakens the strength of this analysis, though the findings mirror observations in practice that increasingly morbid surgical resection (pneumonectomy) may be poorly tolerated after neoadjuvant chemotherapy. Accordingly, the role of surgery for stage III with discrete N2 disease has not been definitively answered. For patients with stage IIIA disease who are deemed not to be candidates for surgery, the recommended treatment is concurrent chemoradiotherapy followed by consolidation therapy with the PD-L1 inhibitor durvalumab in those who have no evidence of disease progression after definitive treatment. This approach will be discussed in more detail in the next section.

Stage IIIB and Stage IIIC

Stage IIIB is also a heterogeneous group and includes T4N2M0 and T1a–c, T2a–bN3M0 patients. Stage IIIC (new in the eighth edition of TNM staging) includes patients with T3–4N3 disease.[24] The American College of Chest Physicians guidelines used the groupings of *infiltrative stage III* (N2/N3) tumors and stage III with discrete N2 involvement. In infiltrative stage III with N2/N3 involvement, the mediastinal nodes can no longer be clearly distinguished and measured (eFig. 77.6). These patients have extensive tumor infiltration in the mediastinum, which partially surrounds the major structures. In patients with unresectable stage IIIA and infiltrative stage III (N2/N3), good performance score, and minimal weight loss (≤10%), the recommended treatment with curative intent is concurrent chemoradiotherapy.[24,54]

Two multicenter trials concluded that concurrent chemoradiotherapy is superior to sequential therapy (chemotherapy followed by thoracic radiotherapy) in patients with unresectable stage IIIA, IIIB, and IIIC NSCLC.[60,61] Concurrent therapy, however, is associated with a higher rate of severe esophagitis than is sequential therapy. The recommended chemotherapy is a platinum-based regimen that includes etoposide, paclitaxel, or pemetrexed.[58,62] Three cooperative group trials of definitive chemoradiotherapy for unresectable stage III had an MST of 19 to 22 months with 2-year survivals of 40–45%.[58,62,63] Because randomized trials of chemoradiotherapy included both stage IIIA and IIIB disease participants and used the seventh edition of the TNM staging system, it is not possible to separate out the survival of stage IIIB or current IIIC patients specifically.[62,63] In an effort to improve OS in this population, a phase III trial randomized patients with unresectable stage III NSCLC to standard of care chemoradiotherapy (60 Gy in 2 Gy per fraction) versus dose-escalated chemoradiotherapy (74 Gy in 2 Gy per fraction).[64] Surprisingly, the dose-escalated group had worse survival (20 months vs. 29 months MST) than the control arm. Hypotheses for the inferiority of the high-dose arm include increased cardiac dose or worse local failure rates due to tighter treatment margins. There are no phase III randomized trials to date that demonstrate that neoadjuvant chemoradiotherapy followed by surgery for stage IIIB or IIIC disease results in prolonged survival compared with chemoradiotherapy alone.[54]

Unfortunately, most patients with Stage III NSCLC have disease progression after concurrent chemoradiotherapy, with approximately 15–30% of patients remaining alive at 5 years, which corresponds to an MST of no more than 28 months.[65] Although several studies have evaluated the role of adjuvant chemotherapy following concurrent chemoradiotherapy in stage III NSCLC, results are poor with MST ranging from 18 to 23 months.[66–68] More recently, incorporating consolidation therapy with immunotherapy in the treatment paradigm of stage III NSCLC has provided significant promise in survival improvement. Durvalumab is a selective, high-affinity, human IgG1 monoclonal antibody that blocks PD-L1 binding to PD-1 and CD80, thereby allowing T cells to recognize and kill tumor cells.[69,70] It is reported that chemoradiotherapy may up-regulate PD-L1 expression in tumor cells[71,72] and, as such, PD-L1 blockade may result in long-term immune response after chemoradiotherapy. The PACIFIC trial compared durvalumab (anti-PD-L1) to placebo in patients with stage III NSCLC without disease progression after treatment with definitive concurrent chemoradiotherapy.[73] Durvalumab resulted in significantly prolonged PFS compared to placebo, 16.8 months versus 5.6 months, with an HR for disease progression or death of 0.52. Subsequent OS analysis revealed durvalumab significantly improved OS at 24 months as compared with placebo, 66.3% versus 55.6%.[74] On the basis of these positive results, durvalumab is approved for consolidation therapy in unresectable stage III NSCLC patients without disease progression after concurrent chemoradiotherapy.

Occasionally, patients with stage III NSCLC may not qualify for definitive concurrent chemoradiotherapy. These patients can be treated with sequential chemotherapy and radiotherapy with consideration for consolidation immunotherapy. A recent study of patients with locally advanced (stage III disease, who were not candidates for surgery or chemoradiation) or advanced (stage IV) NSCLC (negative *EGFR* and *ALK*, and PD-L1 expression ≥1%) randomized to initial therapy with pembrolizumab versus platinum-based chemotherapy showed pembrolizumab resulted in better median OS, 16.7 versus 12.1 months (HR, 0.81).[75] Although the number of patients with locally advanced disease was small (n=160), subgroup analyses showed a trend toward benefit in these patients[75] and, as a result, pembrolizumab monotherapy was approved in April 2019 for patients with untreated stage III NSCLC who are not candidates for surgery or chemoradiation.

STAGE IV NON–SMALL CELL LUNG CANCER

Stage IV, metastatic or advanced NSCLC, is generally considered treatable but not curable. Approximately 57% of patients with NSCLC are diagnosed with metastatic disease for which the 5-year survival is only 4%.[4] The goal of therapy is to try to control the disease and palliate symptoms.

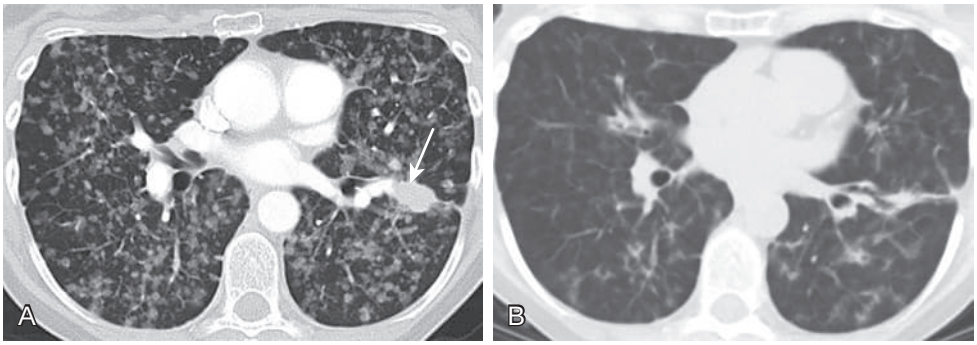

Figure 77.2 Adenocarcinoma of the lung with *ALK* translocation in a nonsmoking woman treated with alectinib. (A) Axial chest computed tomography (CT) displayed in lung windows shows a left lower lobe nodule consistent with adenocarcinoma (*arrow*) with widespread pulmonary metastases. (B) Axial CT following approximately 4.5 months alectinib therapy shows marked reduction in both the primary tumor and metastatic disease.

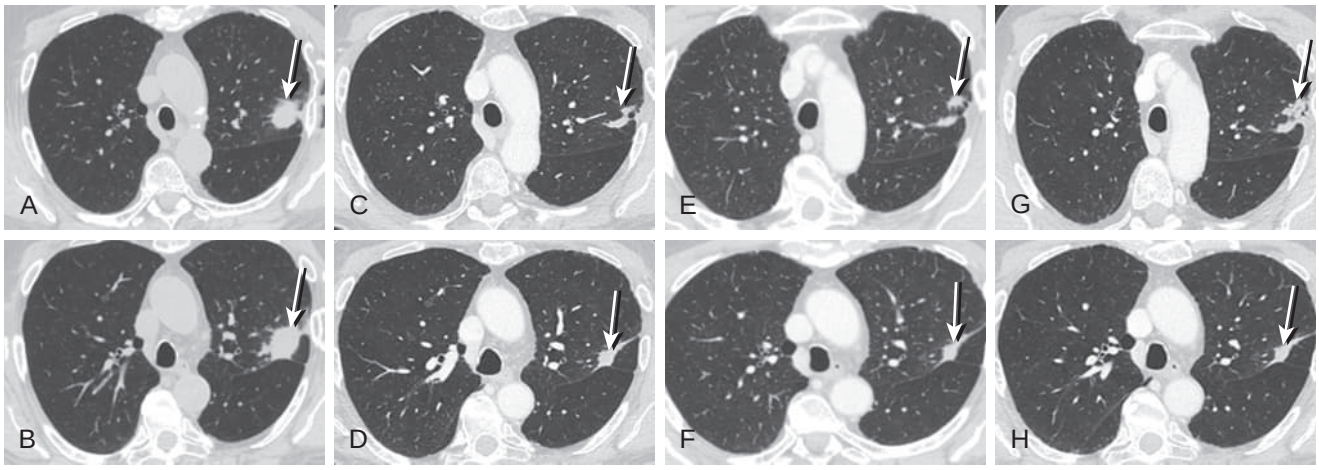

Figure 77.3 *EGFR*-mutated advanced adenocarcinoma of the lung treated with tyrosine kinase inhibitor with development of resistance. (A–B) Axial unenhanced chest computed tomography (CT) at presentation shows a poorly defined subpleural left upper lobe nodule *(arrows),* biopsy-proven to represent adenocarcinoma with *EGFR* mutation with exon 18 and 19 deletions. The lung cancer was stage IV and thus eligible for first-line targeted therapy. (C–D) Axial enhanced chest CT 8 months following presentation and just over 5 months following initiation of afatinib therapy shows reduction in size of the lesion *(arrows),* now with a more scarlike morphology, consistent with a positive response to therapy. (E–F) Axial enhanced chest CT 9 months after initiation of afatinib therapy shows that the main portion of the lesion (*arrow*, F), is similar to the first posttreatment CT (D), but nodularity is increasing along the cranial aspect of the lesion (*arrow*, *E*). (G–H) Axial enhanced chest CT 13 months following afatinib therapy was initiated shows continued growth in the nodularity along the cranial aspect of the lesion (*arrow*, G), while the main portion of the lesion remains stable (*arrow*, H). The patient had developed brain metastases at the time of this scan. (Courtesy Michael B. Gotway, MD.)

First-line treatment options for patients with advanced NSCLC now include chemotherapy, targeted therapy, and immunotherapy. Surgery and radiation can be used in selected cases to palliate symptoms. All patients should be offered access to palliative care services at the time of diagnosis.[76]

Identification of genetic alterations in oncogenes and tumor suppressor genes critical to tumor growth has led to the development of targeted therapies against these actionable mutations[77] and subsequent improvement in patient outcomes (Figs. 77.2 and 77.3). A recent study showed a 5-year survival rate among patients with *EGFR*-mutant metastatic lung adenocarcinoma treated with the TKIs erlotinib or gefitinib to be 14.6%.[78] (This 5-year survival rate can be compared to a 4% 5-year survival before the TKIs.[4]) The Lung Cancer Mutation Consortium demonstrated the potential for multiplex next-generation genomic sequencing in patients with advanced NSCLC and reported a driver mutation was detected in about 64% of genotyped cases.[79] The driver mutations identified include *KRAS* (25%), activating *EGFR* (15%), *ALK*-fusion (8%), *ROS-1* (2%), *BRAF* (2%), *HER2* (2%), *PIK3CA* (1%), and *MET* amplification (1%).[79]

Clinical practice guidelines promote the incorporation of biomarker testing in the diagnostic evaluation of lung cancer,[36,80] and recommend testing for *EGFR* mutations and *ALK* and *ROS1* in metastatic adenocarcinoma, large cell carcinoma, and NSCLC not otherwise specified (NSCLC where the pathologist cannot differentiate between squamous cell or adenocarcinoma). In addition, testing for *EGFR* and *ALK* should be considered in patients with metastatic squamous cell carcinoma or small cell cancer in patients with certain clinical criteria (young age, lack of smoking history) who are never-smokers.[36] The inclusion of additional genes (*HER2*, *MET*, *BRAF*, *KRAS*, and *RET*) is recommended for laboratories that perform next-generation genomic sequencing panels.[80] (See also Chapter 73.)

More recently, harnessing the power of the immune system via inhibition of immune checkpoints has shown significantly improved results and immunotherapy is now integrated into the clinical management of metastatic NSCLC.[81] Improved OS with immunotherapy using the immune checkpoint inhibitor nivolumab in the second-line setting in advanced NSCLCs has been reported, with an estimated 5-year OS rate of 15.6%.[82] Recently, exciting results of improved 5-year OS in a small number of patients with NSCLC treated with first-line pembrolizumab were reported: 15.7% in those with lower PD-L1 staining (TPS of 1–49%) and 29.6% in those

with higher staining (TPS of ≥50%).[83] PD-L1 testing is recommended in all patients with metastatic NSCLC.[36]

The key to realizing the benefits in survival outcomes in advanced NSCLC with precision oncologic therapy is critically dependent on performing genomic profiling and biomarker testing and using the results to guide initial treatment decisions in advanced NSCLC.

First-Line Chemotherapy

In 1995, a landmark meta-analysis evaluated nine randomized trials comparing platinum-based chemotherapy and best supportive care in advanced NSCLC.[84] With best supportive care, the MST was 4 months and the 1-year survival was 15%; with chemotherapy, there was an increase in the MST of 1.5 months and an increase in 1-year survival of 10%.[84] Subsequently, several randomized trials using platinum-based combination regimens demonstrated similar results and, although the survival advantage is modest, it is both clinically and statistically significant.[85] In the 1990s, a number of new chemotherapy agents were introduced, including paclitaxel, docetaxel, irinotecan, vinorelbine, and gemcitabine. Phase III trials incorporating these newer agents in combination with cisplatin have shown an MST of 7.9 months, and 1-year and 2-year survival rates of 33% and 11%, respectively, although no one combination is superior when using survival as the primary measure of outcome.[86] In addition, improved quality of life has been reported for those patients receiving chemotherapy versus best supportive care.[87]

Histology influences response to certain chemotherapeutic agents. A large phase III trial randomized patients to cisplatin plus pemetrexed or cisplatin plus gemcitabine. For the patients with adenocarcinoma, the survival was significantly better with the pemetrexed regimen (MST 12.6 months vs. 10.9 months). Conversely, squamous cell cancers had superior survival with the gemcitabine regimen (MST 10.8 months vs. 9.4 months).[88] Chemotherapy for stage IV NSCLC should be guided by histology and pemetrexed should be limited to patients with nonsquamous NSCLC.[36]

Bevacizumab, a monoclonal antibody that inhibits vascular endothelial growth factor, improves survival when added to platinum-based chemotherapy in some patients. In the ECOG Trial, 4599 patients with nonsquamous histology (bevacizumab is not recommended in squamous cell cancer due to risk of serious, potentially fatal hemorrhage) were randomized to treatment with carboplatin plus paclitaxel with or without bevacizumab. Bevacizumab was continued as maintenance therapy after six cycles of therapy in those responding to treatment or with stable disease.[89] Patients in the bevacizumab arm had a higher response rate (35% vs. 15%) and better survival (MST 12.3 months vs. 10.3 months; 2-year survival 44% vs. 15%). A meta-analysis of four randomized trials of NSCLC patients showed treatment with combination chemotherapy plus bevacizumab demonstrated increased PFS and OS compared with chemotherapy alone.[90]

In brief, treatment of stage IV NSCLC should be guided by histology, molecular pathology, age, comorbidities, PS, and of course, patient preferences. All patients with stage IV NSCLC with a good PS (ECOG 0–2) should be referred to a medical oncologist to discuss systemic therapy. In patients without an actionable mutation (*EGFR*, *ALK*, etc.) and with low PD-L1 expression, platinum-based doublet chemotherapy may be used as first-line therapy. Combination therapy with platinum-based chemotherapy and immunotherapy is emerging as a preferred strategy due to superior results over chemotherapy alone in patients with lower PD-L1 staining (PD-L1 < 50%) and PS 0-1. For PD-L1 staining greater than 50%, immunotherapy alone is the standard of care. This approach will be further discussed in the immunotherapy section.

Maintenance Chemotherapy

In patients with good PS (ECOG 0–2) and with stable or responding nonsquamous NSCLC, maintenance treatment with pemetrexed and/or bevacizumab has been shown to improve PFS and OS. Pemetrexed compared to placebo resulted in significantly improved OS with 22% reduction in the risk of death compared with the placebo group.[91,92] Maintenance therapy with bevacizumab is associated with improved PFS (4.4 vs. 2.8 months) and improved median OS (12.8 vs. 11.4 months) in comparison with placebo.[93] Routine maintenance chemotherapy for advanced squamous cell NSCLC has not been well established, although longer PFS has been reported with immediate versus delayed docetaxel (5.7 vs. 2.7 months) after first-line therapy.[94]

Second-Line Chemotherapy

Eventually, patients with metastatic NSCLC will progress after receiving first-line therapy, with or without maintenance therapy. For those patients who have a good PS (0–2), approved second-line chemotherapy options include docetaxel with or without ramucirumab (monoclonal antibody against vascular endothelial growth factor receptor 2) for all histologies, with pemetrexed for nonsquamous histology and the TKI afatinib for squamous histology.[95–97] Erlotinib represents a potential second- and third-line treatment option, especially in patients not suitable for immunotherapy or second-line chemotherapy, and has been shown in a phase III trial to result in superior survival versus placebo (6.7 vs. 4.7 months).[98] More recently, second-line immunotherapy has been approved for the treatment of metastatic NSCLC after progression on first-line therapy and will be discussed in more detail in the section on immunotherapy.

Targeted Therapy

Driver mutations result in downstream signaling that drives and sustains a tumor and, as opposed to the much more common *passenger* mutations, they render a tumor vulnerable to blockade of that single pathway (see Chapter 73). Driver mutations are detected in about 64% of genotyped NSCLCs,[4] are mutually exclusive of each other, and are more commonly found in adenocarcinoma, and in never-smokers or light smokers (<15 pack-years) but can also be found in smokers.[79,80] Development of drugs directly targeting a driver mutation (Table 77.2) led to the realization of personalized therapy in NSCLC and has resulted in improved PFS and OS in the subset of patients whose tumors harbor a driver mutation.

***EGFR* Mutations.** Activating mutations in the tyrosine kinase domain of EGFR include exon 19 deletions and exon 21 (L858R) substitutions and were the first to be described and to predict response to novel TKIs. Multiple

Table 77.2 Targeted Therapy for Metastatic NSCLC With Molecular Target

Biomarker	First-Line Therapy	Second-Line Therapy	Promising Therapies
EGFR mutations	Erlotinib Gefitinib Afatinib Osimertinib	Osimertinib (after first- or second-generation TKI if T790M)	
ALK-fusion	Crizotinib Alectinib Ceritinib	Lorlatinib Brigatinib	
ROS1	Crizotinib Entrectanib		Repotrectinib
BRAF		Dabrafenib/trametinib	
RET-fusions			LOXO-292 BLU-667
MET exon 14 mutation		Crizotinib	Capmatinib Savolitinib Tepotinib
HER2 dysregulation			Trastuzumab* Ado-trastuzumab*
$KRAS^{G12C}$ mutation			AMG510 MRTX849

*Off-label use.

studies have demonstrated that the phenotype most associated with response to the EGFR-TKIs gefitinib and erlotinib includes adenocarcinoma, never-smoker, female sex, and East Asian descent. Subsequent reports showed that these are the groups most likely to harbor the activating *EGFR* mutations.[99] In a landmark phase III trial in East Asia, patients with untreated stage IV NSCLC were randomized to gefitinib or platinum-based chemotherapy. Of the 437 patient samples tested, 60% were positive for an *EGFR* activating mutation. This subgroup had a significantly better response and PFS after gefitinib than after chemotherapy, and benefit was consistent across all age groups, genders, smoking status, and PS. The subgroup negative for mutations had improved response rates and PFS after chemotherapy.[100]

Multiple phase III trials comparing EGFR-TKIs to chemotherapy in patients with *EGFR*-activating mutations have been conducted. In general the response rate to an EGFR-TKI is 60–80%, the median PFS is 9 to 12 months, and the OS is approximately 2 years.[101] A meta-analysis including 13 studies observed a PFS advantage (HR, 0.43) in patients treated with an EGFR-TKI in the first-line setting.[102] Results were similar when the EGFR-TKI was used in the second-line setting in those with an activating *EGFR* mutation (HR, 0.34 for PFS). As a result of these and other studies, EGFR-TKIs (erlotinib, gefitinib, and afatinib) represent the standard of care in first-line treatment of patients with *EGFR*-mutated advanced NSCLC.

Although the majority of patients with *EGFR*-mutant NSCLC respond to TKIs, resistance will develop in most patients within 9 to 14 months of treatment (see Fig. 77.3).[103] Several mechanisms of resistance have been reported, including *HER2* amplification, *MET* amplification, small cell transformation and, most commonly (seen in more than 50% of patients), a secondary *EGFR* kinase domain mutation in exon 20, the T790M substitution.[104-106] Osimertinib, a third-generation EGFR-TKI, was developed to block *EGFR*-mutant receptors, including the T790M form, whether it arose de novo or as a resistance to prior TKI therapy. Osimertinib has significantly greater efficacy over platinum-based chemotherapy in patients with T790M mutations who progress during first-line treatment with an EGFR-TKI (including those with CNS metastases); with osimertinib, patients realized a median duration of PFS of 10.1 months versus 4.4 months with chemotherapy.[107] As a result of these promising findings, testing for T790M mutations is recommended in patients with *EGFR*-mutant adenocarcinoma who progress after first-line therapy, so they can be considered for osimertinib therapy.[36]

Osimertinib given as first-line therapy has been shown to improve PFS outcomes when compared with gefitinib or erlotinib. In a phase III trial of patients with treatment-naïve, *EGFR*-mutated advanced NSCLC randomized to osimertinib versus gefitinib or erlotinib, osimertinib demonstrated improvement in PFS (18.9 vs. 10.2 months) and duration of response (17.2 vs. 8.5 months).[108] First-line osimertinib is now considered one of the options for patients with metastatic *EGFR*-mutant NSCLC.

***ALK* Translocations.** The *ALK*-fusion gene is found in about 8% of NSCLC[79] and is the second most common driver mutation for which there is an effective TKI. In this mutation, fusion leads to abnormal *ALK* signaling and is opposed by TKIs that target the *ALK* tyrosine kinase. The efficacy of the first-generation ALK-TKI, crizotinib, was demonstrated in a phase I study of 143 patients with advanced-stage IV NSCLC with an *ALK*-fusion that showed an objective response rate of 61%, a median PFS of 9.7 months, and an estimated 12-month survival rate of 75%.[109] Subsequent randomized phase III trials comparing crizotinib to platinum-based chemotherapy as first-line treatment in advanced-stage NSCLC patients with an *ALK*-fusion demonstrated significantly longer PFS (ranging

from 7.7 to 10.9 vs. 3 to 7 months respectively).[22,110] While first-line treatment with crizotinib had been the standard of care for patients with *ALK*-fusion advanced stage NSCLC, the majority of patients eventually progress due to acquired resistance. In addition, crizotinib has negligible CNS penetration, which is unfortunate because *ALK*-fusion NSCLC commonly metastasizes to the brain.[111] The second-generation ALK inhibitors, ceritinib and alectinib, have excellent antitumor activity (see Fig. 77.2). A phase III trial comparing ceritinib to platinum-based chemotherapy in untreated *ALK*-fusion NSCLC resulted in a significant improvement in overall PFS (16.6 months vs. 8.1 months).[112] Furthermore, in patients with CNS metastases, the CNS response rate was superior with ceritinib (72.7%. vs. 27.3%).[112] Two randomized trials comparing first-line alectinib with crizotinib have demonstrated the superior efficacy of alectinib in *ALK*-fusion NSCLC.[113,114] The PFS in the alectinib group was 68.7% compared with 48.7% in the crizotinib group and the HR for disease progression or death was 0.47.[114] Only 12% of patients on alectinib progressed with CNS disease compared with 45% in the crizotinib group. Alectinib is currently the first-line TKI for *ALK*-fusion NSCLC patients.

ROS1. *ROS1* gene rearrangements are observed in approximately 2% of patients with adenocarcinoma of the lung.[4] Many TKIs approved for *ALK*-fusion NSCLC have shown activity in *ROS1*-positive tumors. Crizotinib is currently the standard of care for the treatment of *ROS1*-positive NSCLC.[115]

BRAF. The most common mutation in v-raf murine sarcoma viral oncogene homolog B1 (*BRAF*) is the V600E mutation, which is observed in about 2% of adenocarcinomas and is more common in smokers.[116] Although NSCLC patients with *BRAF*-V600E mutation respond to single-agent BRAF-TKIs, combining dabrafenib (a BRAF inhibitor) and trametinib (a MEK inhibitor) is recommended due to the enhanced efficacy.[117]

Other Targets. Additional mutations include *RET* fusions (2% of NSCLC),[118] *MET* exon 14 skipping mutation (3–4%), *HER2* dysregulation (2%),[4] and *KRAS*, which is the most common mutation, observed in approximately 32% of patients with adenocarcinoma.[4] Several ongoing clinical trials are evaluating the efficacy of TKI inhibitors in patients with *RET* fusions, *MET* mutations, and *HER2* dysregulation with promising results (see Table 77.2). Development of effective targeted therapy against *KRAS* has been disappointing until recently. Results from an ongoing phase I clinical trial with an inhibitor targeted at $KRAS^{G12C}$-mutated NSCLC are promising.[119]

Immunotherapy

Central and peripheral negative regulatory pathways known as immune checkpoints play a crucial role in down-regulating the immune system and protecting against excessive inflammatory responses and autoimmunity. These checkpoints are also used by cancer cells to suppress immune surveillance.[120,121] Immunotherapy targeting those checkpoints has dramatically changed the treatment paradigm in locally advanced and advanced NSCLC and shows promise in early-stage NSCLC and SCLC with extensive disease. Four ICIs have FDA approval in lung cancer: nivolumab and pembrolizumab, targeting the PD-1 receptor and atezolizumab and durvalumab, targeting the ligand PD-L1.[122] An immunohistochemistry-based test to determine PD-L1 expression is needed to guide decisions regarding first-line therapy with immunotherapy and should be routine for all patients with newly diagnosed NSCLC.[80] In addition, patient selection includes assessment of PS and importantly, evaluation for underlying comorbidities such as severe autoimmune disease, solid organ transplant, and interstitial lung disease, which can be associated with increased immune-related adverse events.[123,124]

Pembrolizumab has been established as first-line therapy in untreated patients with advanced NSCLC and PD-L1 expression of 50% or greater. A randomized study of patients with advanced NSCLC and PD-L1 50% or more without *EGFR* mutation or *ALK*-fusion comparing first-line pembrolizumab to platinum-based chemotherapy demonstrated pembrolizumab was associated with higher response rates (44.8% vs. 27.8%), PFS (10.3 vs. 6.7 months), and OS compared to platinum-based chemotherapy. As a result, pembrolizumab was approved as first-line therapy in squamous and nonsquamous advanced NSCLC.[125] An updated analysis revealed the median OS for pembrolizumab was 30 months compared to 14.2 months for chemotherapy (HR, 0.63).[126]

Several trials have evaluated the use of a combination of ICIs with platinum chemotherapy as a first-line regimen in NSCLC irrespective of PD-L1 expression. First-line pembrolizumab plus platinum-pemetrexed in patients with nonsquamous metastatic NSCLC demonstrated significant improvement in 12 months OS (69.2% vs. 49.4%) with similar toxicity profile, compared to chemotherapy plus placebo, irrespective of PD-L1 tumor expression.[127] Similarly, first-line pembrolizumab in combination with carboplatin-taxane in patients with metastatic squamous NSCLC improved survival compared with chemotherapy plus placebo (median OS of 15.9 months vs. 11.3 months).[128] Pembrolizumab in combination with platinum chemotherapy is now approved for first-line treatment in all patients with advanced NSCLC without *EGFR*/*ALK* alterations with PD-L1 tumor expression less than 50%.

Triple therapy with atezolizumab, bevacizumab, and platinum-based chemotherapy in patients with metastatic nonsquamous NSCLC without *EGFR*/*ALK* alterations improved median OS (19.2 vs. 14.7 months) compared with bevacizumab and platinum-based chemotherapy regardless of PD-L1 expression.[129] This triple combination is now approved as another option for first-line treatment for this patient population.

Second-Line Immunotherapy. Second-line therapy is given when first-line therapy either fails or stops working. In two large phase III trials of patients with advanced squamous or nonsquamous NSCLC whose disease had progressed on platinum-based chemotherapy, nivolumab (anti-PD-1), demonstrated improved survival over docetaxel.[130,131] In the trials of squamous cell NSCLC, nivolumab improved outcome in patients with previously treated, advanced squamous cell NSCLC (OS: 9.2 vs. 6.0 months; HR, 0.59).[130] In nonsquamous NSCLC, nivolumab improved outcome when compared to docetaxel (OS: 12.2 months vs. 9.4 months; HR 0.73).[131] As a result, nivolumab is approved

for second-line treatment of patients with advanced NSCLC who progress after first-line therapy.

The use of ICIs in the neoadjuvant setting in early-stage (stage I–IIIA) NSCLC holds promise. Even after curative intent surgical resection and adjuvant chemotherapy, relapse rates are high.[132] In a pilot study of patients with early-stage NSCLC, neoadjuvant nivolumab resulted in a major pathologic response in 45% of resected tumors and did not delay definitive surgery.[133] This approach is further being investigated in ongoing trials.

Adverse Effects. Immune-related adverse events may develop anywhere throughout the body (colitis, thyroiditis, diabetes, neuropathy, myositis, among others) but, in patients with lung cancer, immune-mediated pneumonitis, which may be life-threatening, is a particularly concerning complication. The reported incidence is about 19%.[134] Symptoms are nonspecific and include cough, dyspnea, wheezing, chest pain, and fever, with a range of imaging and pathologic correlates described.[14] Potential risk factors include tumor histology (e.g., risk may be higher with adenocarcinoma), combination therapy with ICIs, COPD, pulmonary fibrosis, autoimmune disease, and previous thoracic radiation.[123,124,134,135] Prompt recognition, withholding immunotherapy, and starting steroid therapy when indicated is essential.

OLIGOMETASTATIC DISEASE

Although metastatic NSCLC is a treatable disease, it has long been considered incurable. A subset of patients with metastatic NSCLC, however, has limited metastases and likely represents a distinct clinical group. This group of patients may possess a more indolent biology and may benefit from prolonged survival after definitive local treatment to all sites of active disease. In 1995, Hellman and Weichselbaum described the biologic spectrum of cancer extending from disease that remains localized, to disease that passes through many intermediate states before becoming systemic. Thus the number of metastatic lesions and sites of metastases may reflect the state of tumor development.[136] They defined oligometastases as "metastases limited to a single or a limited number of organs."[136] The authors subsequently proposed that the oligometastatic state is a distinct clinical entity of intermediate stages of limited metastatic capacity. The oligometastatic state may be more common than previously noted due to more sensitive detection with tools such as positron emission tomography and *magnetic resonance imaging* (MRI) and biomarkers such as circulating tumor DNA.[137]

While the eighth edition of the TNM staging system used M1b disease to identify this important group of patients,[138] the challenge remains that patients with oligometastatic disease represent a heterogenous group because there is currently no consensus on the appropriate cutoff to define the oligometastatic state. The number of metastatic lesions and organs involved in oligometastatic disease is likely cancer dependent and biologically determined.[139] Furthermore, the oligometastatic state can be further defined by number of metastases, organs involved, and rate of progression[140] (Table 77.3).

Table 77.3 Defining Oligometastic Disease

Terms	Definition
Oligometastases	Metastases limited to a single organ or a limited number of organs[176]
Oligometastatic disease	Solitary or few in number (1–5) usually confined to a single organ, more indolent biology and progression at existing sites without widespread metastases[177]
Synchronous	Detected at time of diagnosis of the primary tumor
Metachronous	Developed after treatment of the primary tumor (oligo-recurrent disease) Better prognosis
Oligoprogression	Progression of one or a limited number of metastases (generally five or fewer) while systemic therapy continues to control the primary site and most areas of metastatic disease (seen with acquired mutations to targeted therapy)[178]

Data supporting a curative-intent strategy in oligometastatic NSCLC have been limited to small retrospective studies including patients with 1 to 5 distinct metastases and showing that prognosis is more favorable when patients are treated aggressively with *local ablative therapies* (LAT) compared with palliative intent.[141] When the number of metastases is limited, it is theoretically possible to treat all detectable lesions with curative intent using LAT.[138] It is important to consider that a variety of therapeutic modalities can be explored for LAT, including surgery, SBRT, conventional/moderately hypofractionated radiotherapy, and radiofrequency ablative therapy (see Chapters 21 and 28).

A meta-analysis of 2176 patients with NSCLC and fewer than five metastatic lesions (60% had only metastatic brain lesions) showed that aggressive LAT of all sites of metastatic disease provides improved outcomes with median survival of 19 months and 5-year OS of 23.3%, although survival outcomes were highly variable.[142] In a subsequent meta-analysis of 757 NSCLC patients treated worldwide who had controlled disease at the primary site after definitive treatment and with five or fewer metastatic lesions treated with LAT to all sites of metastatic disease, survival and prognostic factors were evaluated and risk groups were defined by recursive partitioning analysis.[143] The median age was 61, majority had a good PS, 88% had no nodal disease, and the majority had a single brain or lung metastatic lesion (only 3% had multiorgan disease). Median OS was 26 months and 5- and 8-year OS was 29.4% and 23.4%, respectively.[143] Three risk groups were identified: (1) low risk, patients with metachronous disease with 5-year OS of 50%: (2) intermediate risk, patients with synchronous metastasis and no nodal disease with 5-year OS of 36%; and (3) high risk, patients with synchronous metastases and greater than N1 nodal disease with 5-year OS of 14%.[143]

In a recent phase II study patients with stage IV NSCLC with 1 to 3 metastatic lesions and no progression 3 months after first-line treatment were randomized to maintenance therapy or observation versus LAT to all sites of metastasis.[144] The trial was closed after 49 patients were randomized because of a significant benefit with LAT. Compared with maintenance therapy or observation, LAT resulted in a PFS of 14 months versus 4.6 months and an OS of 41.2 months versus 17 months and no increase in grade 3 or higher toxicity.[144] While results of this study are promising,

because of the limited prospective data available in this group of patients, more studies are needed and enrolling patients in clinical trials is recommended.

TREATMENT OF SMALL CELL LUNG CANCER

SCLC accounts for approximately 15% of all lung cancers; it has the strongest association with cigarette smoking and is rarely observed in never-smokers. It is the cell type most commonly associated with paraneoplastic syndromes such as the syndrome of inappropriate (excessive) antidiuretic hormone secretion, ectopic corticotropin secretion, Lambert-Eaton myasthenic syndrome, and sensory neuropathy.

SCLC usually presents as a centrally located mass in the hilum on chest radiograph (eFig. 77.7) and may be associated with obstructive pneumonia. In 5% or fewer cases, SCLC may present as a solitary pulmonary nodule/mass (eFig. 77.8). SCLC is generally staged according to the Veterans Administration Staging System and classified as *limited disease* (LD) or *extensive disease* (ED). LD is confined to one hemithorax, the mediastinum, and the ipsilateral supraclavicular lymph nodes, and the disease can be encompassed adequately in a safe radiation portal.[145] ED is any disease spread beyond these limits. Malignant pleural effusion or disease extending to the contralateral supraclavicular or hilar lymph nodes is generally considered to be ED. It has been proposed that the TNM staging system should also be used for SCLC. When SCLC has been staged via the TNM system, the clinical stage groupings of I to IV have been predictive of OS, and the findings have been validated in a cohort from the Surveillance Epidemiology and End Results registry[146] and the California Cancer Registry.[147] The survival rate for patients with LD with pleural effusions was intermediate between those with ED and LD without pleural effusions. Use of the TNM staging is most helpful in potentially resectable patients with T1–2NO disease. Accordingly, it would be advisable to use the TNM staging system both for tumor registries and for clinical trials to define patients with minimal disease.

In the unusual case in which SCLC presents as a small (T1–2) solitary nodule amenable to sublobar or lobar resection, the treatment of choice is surgical resection followed by adjuvant chemotherapy and, if nodal disease is found incidentally, possibly sequential thoracic radiotherapy. Careful preoperative staging should be performed in these individuals to rule out metastatic disease. Preresection mediastinoscopy should also be performed in all these patients being considered for resection with curative intent. If there are mediastinal node metastases, then surgery should be abandoned, and the patient treated with concurrent chemoradiotherapy as outlined later. The 5-year survival for a small T1–2 solitary SCLC nodule treated with surgery and adjuvant therapy is approximately 40–50%.[147,148]

Approximately one-third of patients with SCLC have LD at diagnosis. LD-SCLC has a response rate of 70–80% with standard chemotherapy and thoracic radiotherapy (eFig. 77.9), and a complete clinical response of 50–60%. Chemotherapy usually consists of a platinum-based regimen. The two most commonly used regimens are etoposide plus cisplatin or etoposide plus carboplatin. Chemotherapy beyond four to six cycles has not been shown to prolong survival. The National Comprehensive Cancer Network and American College of Chest Physicians guidelines recommend treatment with four to six cycles of platinum-based chemotherapy with either cisplatin or carboplatin plus either etoposide or irinotecan.[36,145] Multiple trials have evaluated a number of targeted agents but, to date, none has shown improved outcomes when added to standard treatment of SCLC.[149]

In a meta-analysis of trials with chemotherapy alone versus combined chemotherapy and thoracic radiotherapy, survival was significantly better with combined modality therapy. As a result of the exquisite radiosensitivity of SCLC, it was postulated that fractionating radiotherapy in smaller doses delivered twice daily might be more effective, albeit with a risk of greater acute toxicity. In a phase III trial, patients with LD-SCLC were randomized to receive concurrent chemotherapy with cisplatin/etoposide and 45 Gy radiotherapy delivered daily or 30 fractions delivered twice daily.[150] Although there was more toxicity due to esophagitis, the OS was significantly improved with twice-daily fractionation (5-year OS 16% vs. 26%) and, as such, this twice-daily regimen became standard of care. A more recent trial randomized patients with LD-SCLC to concurrent cisplatin plus etoposide with either 45 Gy radiotherapy delivered twice daily or 66 Gy in daily fractions.[151] Although the study was designed and powered to demonstrate superiority of the once-daily arm, no difference was found in the 2-year OS between the two groups or in toxicity (grade 3 esophagitis was 19% in both groups).[151] As such, twice-daily radiotherapy continues to be the standard of care in LD-SCLC (though once-daily treatment can be considered in situations where the logistics preclude twice-daily radiation).

A meta-analysis evaluated the timing of thoracic radiotherapy.[152] Early thoracic radiotherapy (<9 weeks from the start of chemotherapy) resulted in a 5.2% increase in 2-year survival. The interval from start of treatment to the end of radiotherapy was also identified as an important predictor of outcome.[153] Accordingly, data suggest that thoracic radiotherapy should begin early and be completed quickly.[145]

Patients with LD-SCLC who achieve complete remission after chemoradiotherapy have a 50% chance of developing intracranial metastasis within the next 2 years. A meta-analysis of seven randomized trials of *prophylactic cranial irradiation* (PCI) versus no PCI for patients in complete remission reported a 5.4% increase in absolute survival (20.7% vs. 15.3%) with PCI at 3 years.[154] The major questions raised by the meta-analysis concern the optimal dose of PCI and the neuropsychological sequelae. PCI at 25 Gy in 10 fractions[155] is recommended in patients with LD-SCLC who achieve a complete remission with initial therapy and has also been shown to result in a survival advantage in patients with ED-SCLC who achieve a complete or partial response to initial therapy.[156] However, the true benefit in the setting of ED-SCLC is now in question, because a Japanese randomized study has demonstrated no benefit to PCI if a postchemotherapy brain MRI shows an absence of brain metastases and MRI surveillance is performed.[157]

When patients relapse after initial therapy, the MST is 3 to 4 months. There are no cures with second-line therapy. If a patient has been off treatment for 6 months or longer, then it is reasonable to use the same agents that he or she received initially. If initial therapy did not include a platinum agent, then second-line therapy should use

a platinum-containing doublet. Currently the only drug approved for second-line treatment of SCLC by the FDA is single-agent topotecan.[145,155] Other single agents such as oral etoposide, paclitaxel, docetaxel, irinotecan, gemcitabine, and amrubicin are active but are not yet approved by the FDA for second-line treatment of SCLC. Amrubicin is commercially available and approved for second-line treatment in Japan but is not available in the United States. No molecularly targeted therapy has been approved for SCLC in either the first-line or second-line setting.

The addition of immunotherapy to platinum-based chemotherapy in ED-SCLC holds promise. A phase III trial randomized 403 patients with ED-SCLC to receive carboplatin/etoposide plus the anti-PD-L1 atezolizumab or to receive placebo plus atezolizumab. There was improved median OS and PFS in the group treated with chemotherapy plus atezolizumab, without increased toxicity.[158] Additional studies are ongoing.

PALLIATIVE CARE

Although much of this chapter is devoted to efforts to cure lung cancer, most patients will eventually succumb to their disease. Incorporating palliative care for patients with advanced lung cancer has been shown to improve quality of life and symptom management, reduce use of aggressive medical treatments at the end of life, and increase survival.[76] Current guidelines recommend referral to multidisciplinary palliative care teams within 8 weeks of initial diagnosis of advanced cancer.[159] While pulmonologists are adept at providing supportive care in the intensive care unit, caring for the ambulatory dying patient with lung cancer requires special consideration. There is a vast literature on ambulatory pain management, the use of interventional pulmonary techniques such as tumor ablation and stent placement to relieve malignant airway obstruction, and the use of hospice to provide end-of-life care in the home setting. With the tools now available to physicians, patients need not suffer debilitating cough, nausea, dyspnea, or pain. Pulmonologists are encouraged to provide "aggressive palliation" to lung cancer patients with the same conviction that they provide treatments for critically ill patients in the intensive care unit.[160]

SPECIAL CONSIDERATIONS IN LUNG CANCER

SUPERIOR SULCUS TUMORS AND PANCOAST SYNDROME

Pancoast syndrome is a constellation of symptoms and signs that include shoulder and arm pain along the distribution of the eighth cranial nerve trunk and first and second thoracic nerve trunks, Horner syndrome, and weakness and atrophy of the hand.[161–163] The underlying cause is usually local extension of an apical lung tumor located in the superior pulmonary sulcus (Pancoast tumor). Pancoast syndrome is present in approximately one-third of patients with superior sulcus tumors. The most common cause of this symptom complex is NSCLC; however, SCLC and a number of other types of tumors and infections may rarely present in this manner.[161] The most common initial symptom is shoulder pain, which is produced by tumor involvement of the parietal pleura, brachial plexus, vertebral bodies; and first, second, and third ribs. The pain may radiate along the upper back or shoulder into the axilla and along the distribution of the ulnar nerve. Patients are commonly treated for arthritis or bursitis of the shoulder for months before the correct diagnosis is determined. Horner syndrome consists of ptosis, miosis, and anhidrosis and is caused by the invasion of the paravertebral sympathetic chain and the inferior cervical (stellate) ganglion.[161] The intrinsic muscles of the hands may become weak and atrophied as the tumor progresses. With further extension through the intervertebral foramina, spinal compression and paraplegia may develop.

The chest radiograph may show an apical tumor, although, in some cases, a tumor can be identified only on chest CT (see eFig. 77.4A). If the diagnosis is suspected but the chest radiograph is negative, then a chest CT scan should be obtained. CT also provides additional information about the extent of the tumor and is especially helpful in identifying other pulmonary nodules and mediastinal adenopathy. MRI of the chest is considered to be superior for evaluating patients with superior sulcus tumors because of better assessment of invasion through the pleura and subpleural fat, better evaluation of plexus involvement (see eFig. 77.4B–C), and better definition of subclavian vessel involvement.[164] MR angiography may give the best assessment of vascular invasion of the subclavian vessels. Flexible fiberoptic bronchoscopy may be the first diagnostic test for apical tumors and has a diagnostic yield of approximately 50%.[165] TTNA has a very high diagnostic yield (>90%) even if the bronchoscopy is nondiagnostic.[166] Superior sulcus tumors are usually staged as T3N0M0 (stage IIB) or higher depending on size of the tumor (T3 or T4) and extent of lymph node involvement. In a large series from MD Anderson, 25% of patients were stage IIB, 22% were IIIA, and 53% were stage IIIB (T4 or N3).[167] Some patients who were stage IV at diagnosis were excluded from that report. It is estimated that one-third to one-half of all superior sulcus tumors have identifiable distant metastasis at diagnosis. In addition to the stage of disease and PS, other important poor prognostic factors include weight loss and vertebral body or supraclavicular involvement. The presence of N1 or N2 nodal involvement and incomplete resections have a worse prognosis.[168,169] In patients treated for localized disease (stage IIB or IIIB), the brain is the most common site of relapse.[169]

In the past, the most common treatment for localized superior sulcus tumors due to NSCLC was preoperative radiotherapy of 30 to 50 Gy followed by resection. This resulted in a 5-year survival of 25–35%. The current standard of practice is to perform neoadjuvant chemoradiotherapy followed by resection. This is based on results of the North America Intergroup Trial in which patients with a negative mediastinoscopy were treated with two cycles of etoposide plus cisplatin chemotherapy and concurrent thoracic radiotherapy (45 Gy in 5 wk). In the resected specimen, a pathologic complete response or minimal microscopic disease was identified in 66% of patients. The OS at 5 years was 44% and, for those with a complete resection, 54%.[169] In a phase II trial in Japan, chemotherapy with mitomycin, vindesine, and cisplatin with concurrent thoracic radiotherapy led to a 5-year survival of 56%.[170] Although the optimal regimen of treatment

has not been determined, a reasonable choice is that used in the Intergroup Trial study described earlier.

SUPERIOR VENA CAVA SYNDROME

A blockage of blood flow in the *superior vena cava* (SVC) results in SVC syndrome.[171] Lung cancer accounts for the vast majority of these cases in older adults.[172,173] In teenagers and young adults, SVC syndrome is usually due to non-Hodgkin lymphoma. Patients complain of dyspnea and a sensation of fullness in the head and/or light-headedness when bending over. They may also note facial swelling. Cough, pain, and dysphagia are less frequent symptoms. Physical examination findings included dilated neck veins, a prominent venous pattern on the chest, facial edema, and a plethoric appearance. The chest radiograph typically shows widening of the mediastinum or a right hilar mass. Occasionally, it may be normal. Dilated veins on the anterior chest wall and compression of the SVC may be demonstrated with CT with intravenous contrast. SVC syndrome is not generally a medical emergency, and patients should not be treated without a tissue diagnosis. Bronchoscopy or mediastinoscopy can be safely performed in the setting of SVC syndrome.[174] Because SCLC is chemosensitive, SVC syndrome due to SCLC is best treated with chemotherapy; generally, after treatment, symptoms start to resolve in 5 to 7 days.[175] NSCLC is best treated with concurrent chemoradiotherapy (see earlier discussion of treatment of stage IIIA/IIIB NSCLC), or radiotherapy alone in a patient presenting with SVC syndrome and distant metastatic disease. If there is a need for immediate relief of SVC obstruction, vascular stenting should be strongly considered. A Cochrane meta-analysis reported that SVC stents relieved obstruction in 95% of cases.[175] Stenting has been associated with a complication rate of 3–7%.

Key Points

- Stage I *non–small cell lung cancer* (NSCLC) is treated with surgery alone and, in those who are medically inoperable, stereotactic body radiation therapy is an alternative treatment option. Stage II NSCLC is treated with surgery followed by adjuvant chemotherapy. Stage III represents a heterogeneous group of patients. In carefully selected patients with stage IIIA disease, surgery may be indicated with or without neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy. Unresectable stage III disease is treated with a concurrent chemoradiotherapy followed by consolidation therapy with the immune checkpoint inhibitor, durvalumab. Treatment of stage IV NSCLC is determined by performance status, histology, molecular characterization, and PD-L1 expression and includes chemotherapy, targeted therapy, or immunotherapy alone or in combination with chemotherapy.
- It is imperative that metastatic adenocarcinoma, large cell carcinoma, and NSCLC not otherwise specified undergo molecular testing, preferably with next-generation sequencing, for *EGFR* mutations, ALK-fusion, *ROS1* translocations, and other actionable mutations for which targeted therapies are available or are being developed. Molecular characterization should also be considered in patients with metastatic squamous cell carcinoma who are never-smokers. Patients with actionable molecular targets respond better and have improved progression-free survival and overall survival when treated with targeted therapy.
- Immunotherapy plays a major role in the treatment of patients with stage III and IV NSCLC and has resulted in improved progression-free survival and overall survival. Immunotherapy also shows promise in early stage NSCLC and advanced stage small cell lung cancer.
- Localized small cell lung cancer (disease within one hemithorax that can be encompassed in a radiation port) is treated by chemoradiotherapy; extensive disease is treated with chemotherapy and immunotherapy.
- Patients with stage IV NSCLC who have limited metastases, considered oligometastatic disease, may benefit from definitive treatment to all sites of active disease.
- Immunotherapy-mediated pneumonitis is rare but potentially fatal and requires prompt recognition.

INTRODUCTION

Rare pulmonary tumors are defined as malignancies developed in the lung parenchyma with low prevalence and unusual histology and that are different from bronchogenic carcinomas, small and non–small cell lung carcinomas. Rare molecular subsets of non–small cell lung carcinomas, such as *ROS1*-, *RET*-, and *NTRK*-rearranged tumors, are then excluded from the definition, which is mostly based on histologic classification; even so, molecular alterations of therapeutic significance may be identified in rare pulmonary tumors.[1–4] In this setting, rare pulmonary tumors account for less than 1% of all primary lung tumors, whereas they correspond to more than 100 different histologic, molecular, clinical, radiologic, and prognostic entities.[1–4] Some rare lung tumors are specific to the lung, whereas others represent tumors more frequently diagnosed in other organs and are only rarely detected in the lungs, excluding metastases. It is estimated that about 60% of rare primary pulmonary tumors correspond to benign and low-grade lesions and that 40% are malignant.[1,2]

Rare pulmonary tumors are characterized by their low incidence but also by limited clinical and imaging descriptions, by the low number of experienced physicians for each tumor subtype, and by the absence of specific therapeutic data. Recognition of rare pulmonary tumors relies on characteristic clinical and radiologic signs, on a modified diagnostic and imaging strategy, and primarily on the determination of their primary or secondary nature. Of interest, some of those tumors may have a propensity to mimic lung carcinoma and benign orphan lung diseases because they may share clinical, imaging, pathologic, and even molecular features.[4,5] Pseudotumors have further been described in the lung, historically referring to any pseudoneoplasm, but they are now restricted to a specific heterogeneous group of diseases characterized by circumscribed fibrous tissue associated with inflammatory and myofibroblastic cells.[5–7]

The objective of this chapter is to provide the reader with a practical overview of rare pulmonary tumors, highlighting key concepts through the discussion of prototypic entities.

DEFINITION OF RARE PULMONARY TUMORS

Rare cancers are defined as those with an incidence rate less than 6 per 100,000 per year, as per the standard definition proposed in Europe[8]; these correspond to 198 different cancers and ultimately represent 24% of all new cancer cases diagnosed each year (www.rarecancerseurope.org). In the lung, rare tumors account for less than 1% of all lung malignancies and correspond to a wide array of histopathologic, molecular, clinical, and radiologic entities.[1–4] Prevalence ranges from merely uncommon lesions, such as carcinoids, which account for 0.15% of all primary lung tumors, to extremely unusual tumors, such as primary pulmonary melanoma, with fewer than 50 reported cases, even leading to debate about the actual primary pulmonary nature of those lesions. Overall, the most frequent rare malignant primary lung tumors are, in decreasing order of frequency, carcinoid, *mucosa-associated lymphoid tissue* (MALT) lymphoma, and sarcomatoid carcinomas.[1,9]

Most rare lung tumors develop from orthotopic tissues, constitutive of the normal lung parenchyma, or from hematopoietic tissues,[1,2] whereas tumors derived from ectopic tissues are even less frequent.[10] Some rare tumor subtypes arise specifically within the lung, whereas others, such as blastomas and perivascular epithelioid cell tumors, arise in many different tissues of the body, including the lung, and are infrequent wherever they are located. Furthermore, some primary tumors that are uncommon within the lung may be frequent in other locations, including lymph node lymphomas and soft tissue sarcomas, which present with specific histopathologic differentiation when originating in the lung, such as MALT lymphoma and angiosarcoma, respectively.

RARE MALIGNANT PRIMARY PULMONARY EPITHELIAL TUMORS

SARCOMATOID CARCINOMAS

Sarcomatoid carcinomas are a group of poorly differentiated non–small cell carcinomas containing a sarcomatous-like component corresponding to epithelial-mesenchymal transition. In addition to pneumoblastoma, four subtypes are recognized: (1) pleomorphic carcinoma, which corresponds either to the combination of adenocarcinoma, squamous cell carcinoma, or large cell carcinoma with spindle or giant cells; (2) spindle cell carcinoma, which consists exclusively of proliferating fascicular cells; (3) giant cell carcinoma, composed of highly pleomorphic mononucleated or multinucleated cells; and (4) carcinosarcoma, containing a mixture of carcinoma (frequently of epidermoid subtype) and poorly differentiated fibromatous sarcoma.[9,11,12]

Sarcomatoid carcinomas were historically defined in the 1999 World Health Organization classification. These tumors represent 0.3–1.3% of lung tumors, and their specific clinical and radiologic features are rarely reported and may be similar to that of *non–small cell lung cancer* (NSCLC). Sarcomatoid carcinomas develop mostly in men, at a mean age of 65 years at diagnosis.[11–14] Tobacco smoking is described in more than 80% of cases. Radiologic studies usually show a solitary voluminous peripheral heterogenous mass, possibly invading the chest wall in 60% of cases.[15,16] Vascular invasion is observed in 20% of cases. ^{18}*F-fluorodeoxyglucose* (FDG)-*positron emission tomography* (PET) scans show increased uptake.

Histopathologic diagnosis is challenging. The majority of patients present with advanced metastatic disease, and small biopsies are not usually representative of the tumor. In particular, the biopsies may not disclose both the epithelial and the sarcomatous components of the tumor, which is then misdiagnosed as lung cancer in more than 60% of cases.[1]

The sarcomatoid carcinomas, other than pneumoblastoma, are considered to be highly aggressive tumors with early metastatic spread,[17] possibly in unusual sites such as the esophagus, the peritoneum, the kidney, and the subcutaneous tissues. Median overall survival ranges from 6 to 20 months in surgical series.[11–17] The main prognostic factor is staging.[18]

Metastatic sarcomatoid carcinomas are often treated as other NSCLC, with platinum-based chemotherapy considered standard as first-line treatment. In pleomorphic carcinomas, cytotoxic agents (pemetrexed, gemcitabine, or vinorelbine) adapted to the histology of the carcinomatous component (adenocarcinoma versus squamous) may be used.[19] Expression of the immune checkpoint protein programmed cell death–ligand 1 is frequent, but there are only limited data available regarding the use of immune checkpoint inhibitors in the first-line setting.[20] Alternatively, chemotherapy has been reported to follow soft tissue sarcoma regimens.[21] In pleiomorphic carcinomas with an adenocarcinoma component, systematic screening for oncogenic alterations, such as *epidermal growth factor receptor (EGFR), BRAF,* and *MET* alterations, may predict the efficacy of targeted therapies.[22] *MET* alterations, including amplification and exon 14 skipping mutations, are reported in 10–40% of patients, predicting response to MET kinase inhibitors or antibodies.[23,24]

A separate molecularly defined entity within sarcomatoid carcinomas is the tumor with a deficiency of the chromatin remodeling complex SMARCA4 (BRG1).[25] As in the other sarcomatoid carcinomas, patients are usually smokers but are younger and present with larger tumors.[25] Histologically, rhabdoid features may be observed, thyroid transcription factor-1 expression is present, and there is a high tumor mutation burden. The majority of cases are metastatic at the time of diagnosis. Prognosis is poor because chemotherapy or any other standard systemic treatment is poorly effective; bromodomain-modulating agents are under investigation.

PNEUMOBLASTOMA

Pneumoblastoma is a biphasic tumor still classified among the sarcomatoid carcinoma group in the current World Health Organization classification, although corresponding to a separate clinical and biologic entity.[9] Pneumoblastoma contains both an epithelial well-differentiated component, showing tubular architecture resembling the normal fetal lung, and a mesenchymal undifferentiated stroma, defining the blastema-like configuration.[26] It has to be differentiated from pleuropulmonary blastoma, a tumor of early childhood related to other embryonic neoplasms, such as nephroblastoma and neuroblastoma.

Pneumoblastoma most frequently arises in patients age 30 to 45 years, with a marked female predominance (70% of cases) and frequent association with tobacco smoking.[26–28] Imaging shows a solitary circumscribed homogeneous mass,[29] often with cystic and necrotic features. FDG-PET scans show increased uptake. In many cases, the tumor is initially thought to be a bronchogenic carcinoma, and complete surgical resection with mediastinal lymph node dissection ensures both the initial diagnosis and the therapy.[26,27,29] Adjuvant treatment, mostly consisting of radiotherapy, has been reported in a few cases after incomplete resection or in patients with N2 mediastinal involvement, as for NSCLC.[26,30] In unresectable tumors, chemotherapy is based on protocols used for sarcomas, including doxorubicin and ifosfamide-based regimens. In

most recent reports, survival is better than in NSCLC, especially in completely resected cases.[26] Molecular analysis is proposed because oncogenic alterations, such as *ROS1* gene fusions, may be found that would predict the efficacy of targeted agents.[31]

MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinoma is the most frequent salivary gland–type tumor arising in the lung; other subtypes include adenoid cystic carcinoma and epithelial-myoepithelial carcinoma. Mucoepidermoid carcinoma is a mixed malignant tumor characterized by the presence of squamous cells, goblet mucin-secreting cells, and cells of intermediate type.[9,32] Identification of these three cellular subtypes in cytologic examination is pathognomonic. Tumors are classified as low-, intermediate-, and high-grade lesions depending on the mitotic index, the degree of cellular atypia, and the degree of necrosis. High-grade tumors contain predominantly squamous and intermediate cells and tend to infiltrate the lung parenchyma. In 60% of cases, molecular analysis may lead to the identification of *CRTC1-MAML2* gene fusions specific to mucoepidermoid carcinomas, which may be associated with better prognosis.[33]

Mucoepidermoid carcinoma in adults mostly develops between the third and fourth decades, with an equal sex distribution.[34] High-grade tumors (30% of cases) are usually diagnosed in older patients. Mucoepidermoid carcinoma is often associated with tobacco smoking. Symptoms, including dyspnea, cough, and hemoptysis, are related to the level of bronchial obstruction (eFig. 78.1). Metastases are found at time of diagnosis in 20% of cases, mainly in the liver, the bone, and the subcutaneous tissues (Fig. 78.1).[35] The lesion is solitary in 40–70% of cases. Hilar involvement is found only for high-grade lesions. There is increased uptake at FDG-PET scanning.[35] Proximal mucoepidermoid tumors can be diagnosed using endobronchial biopsy.

Treatment is historically the same as for NSCLC when the tumor is diagnosed at a limited stage, with extensive surgical resection, including mediastinal lymph node dissection.[32–35] High-grade lesions have often been reported to receive postoperative radiotherapy and chemotherapy, without clear benefit. Chemotherapy of metastatic tumors in most cases is based on cisplatin and/or 5-fluorouracil, as reported for head and neck carcinomas.[36] In cases with *MAML2* gene fusion, deregulation of the EGFR signaling pathway constitutes a rationale for the use of EGFR kinase inhibitors.[37] Prognosis is correlated with the grade of the lesion, the existence of nodal involvement, and the success of the initial surgical resection. Low-grade mucoepidermoid tumors present mostly in children and young adults, usually without hilar involvement, and have a 5-year survival ranging from 70–80%. High-grade tumors have a substantially worse prognosis because of their early disease progression and metastatic spread, with a 5-year survival of only 30–45%.

CARCINOIDS AND LARGE CELL NEUROENDOCRINE CARCINOMA

Carcinoid and large cell neuroendocrine carcinoma share common histopathologic features related to the neuroendocrine origin and correspond to four different clinical and prognostic entities: (1) low-grade typical carcinoids, (2) intermediate-grade atypical carcinoids, and (3) high-grade large and (4) small cell neuroendocrine carcinomas.[9] The *small cell lung carcinomas* (SCLCs) are frequent tumors, accounting for 15–20% of all primary lung malignancies. On the contrary, carcinoids and large cell neuroendocrine carcinomas account for 0.5–2% of lung tumors and are

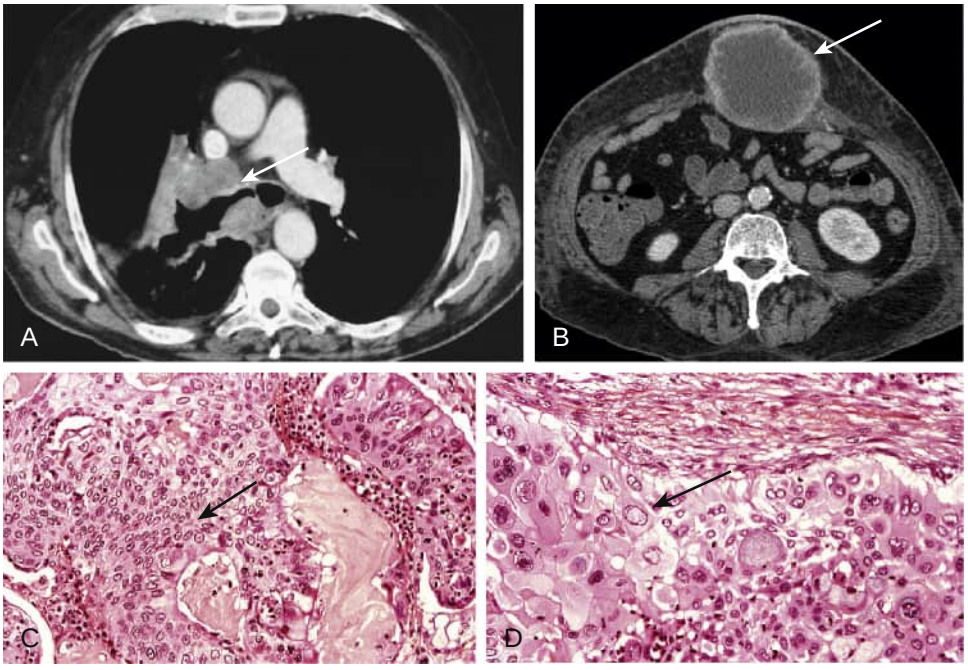

Figure 78.1 Primary pulmonary mucoepidermoid carcinoma. (A) The tumor is located in the right upper lobe and is invading the mediastinum (*arrow*). Radiologic imaging features are identical to those of non–small cell lung cancer. (B) A metastatic mass is discovered on clinical examination of the abdomen. Axial enhanced abdominal computed tomography confirms the location in the anterior abdominal wall (*arrow*). Histopathologic features: a mixture of squamoid (C) and mucin-secreting (D) cells (*arrows*). (C–D, Original magnification ×40.)

thus considered the most frequent lesions among the rare pulmonary tumors.

PATHOLOGIC FEATURES

These tumors share varying degrees of neuroendocrine morphologic features, including organoid nesting, the palisading and trabecular pattern, and rosette-like structures. Classification is mainly based on the mitotic index and the amount of necrosis.[9,38] *Typical* carcinoids exhibit a mitotic index of fewer than two mitoses per 10 high-power fields (2 mm^2), and the absence of necrosis in a tumor that is more than 5 mm in diameter. *Atypical* carcinoids exhibit a mitotic index ranging from 2 to 10, or areas of focal necrosis. Peripheral carcinoids may also be associated with small (<5 mm) neuroendocrine "tumorlets" and/or with diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, which may lead to obstructive lung disease[39] (eFig. 78.2). These lesions may correspond to early-stage in situ carcinoid proliferation. Large cell neuroendocrine carcinomas exhibit a mitotic index higher than 10 (ranging from 70–80 in most cases) and extensive necrosis. Unlike SCLCs, large cell carcinomas have large tumor cells, with moderate to abundant cytoplasm and frequently prominent nucleoli. Immunohistochemically, the expression of at least one neuroendocrine marker, including chromogranin, synaptophysin, or neural cell adhesion molecule (CD56), confirms the diagnosis. The pathologic classification also distinguishes large cell neuroendocrine carcinoma from NSCLC "with neuroendocrine differentiation," a pattern without specific prognostic or therapeutic implications.[40] Recent molecular analyses of large cell neuroendocrine carcinoma have identified two patterns, the first being related to NSCLC, with *KRAS*, *TP53*, and possibly *EGFR* and *BRAF* mutations, and the second being related to SCLC, with *RB1* alterations.[41]

CARCINOID TUMORS

Excluding SCLC, more than 80% of lung neuroendocrine tumors are carcinoids.[42] Carcinoids arise mostly in never-smokers (60–80% of cases). Carcinoids develop in the proximal airways in 60–70% of cases and may produce chronic cough, hemoptysis, and signs of bronchial obstruction. Peripheral carcinoids are asymptomatic, unless they are associated with diffuse hyperplasia of pulmonary neuroendocrine cells or diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH), producing bronchiolar obstruction in 50% of cases and possible airflow obstruction (see eFig. 78.2). Unlike carcinoids in extrathoracic locations, lung carcinoids are small lesions only rarely associated with liver metastases and do not generally produce the carcinoid or Cushing syndrome (<2% of cases).[43] CT shows a peripheral or proximal, circumscribed, solitary nodular lesion in 90% of cases,[42,44] often manifesting as a hilar or perihilar mass (eFig. 78.3). Carcinoid tumors may present as iceberg-like lesions, with a small amount of endobronchial growth (Fig. 78.2) and a prominent parenchymal mass. In some cases, carcinoid tumors may also present as endobronchial lesions, with or without lobar or segmental atelectasis (eFig. 78.4). Calcification (see eFig. 78.3C) may be observed in up to 30% of cases. Regional lymph node invasion is more frequent in atypical carcinoids (40–50% of cases vs. 10–15% of typical carcinoids) (eFig. 78.5), and the tumor-node-metastasis classification, although designed for NSCLC, has been used to stage carcinoids.[45] Although hypervascular (see eFig. 78.3B), carcinoids generally exhibit a low to moderate activity on FDG-PET scanning[46] (eFig. 78.6). Imaging for somatostatin receptors using indium-111–labeled octreotide (eFig. 78.7) is being replaced by gallium-68-DOTA-peptide-PET imaging, which allows three-dimensional analysis with higher sensitivity for diagnosis, staging, and follow-up.[47] The risk of hemorrhage after endobronchial biopsy is less than 1%.[48]

Surgery is the standard treatment for stage I–II and most stage III carcinoids, which account for 75% and 15% of cases, respectively. Typical carcinoids, with a low local recurrence rate, can be treated with limited resection with segmentectomy and regional lymph node dissection; resection followed by endobronchial anastomosis may be used for proximal tumors. This approach is associated with local control and survival rates identical to those after extensive procedures.[42,49] Endobronchial techniques, such as

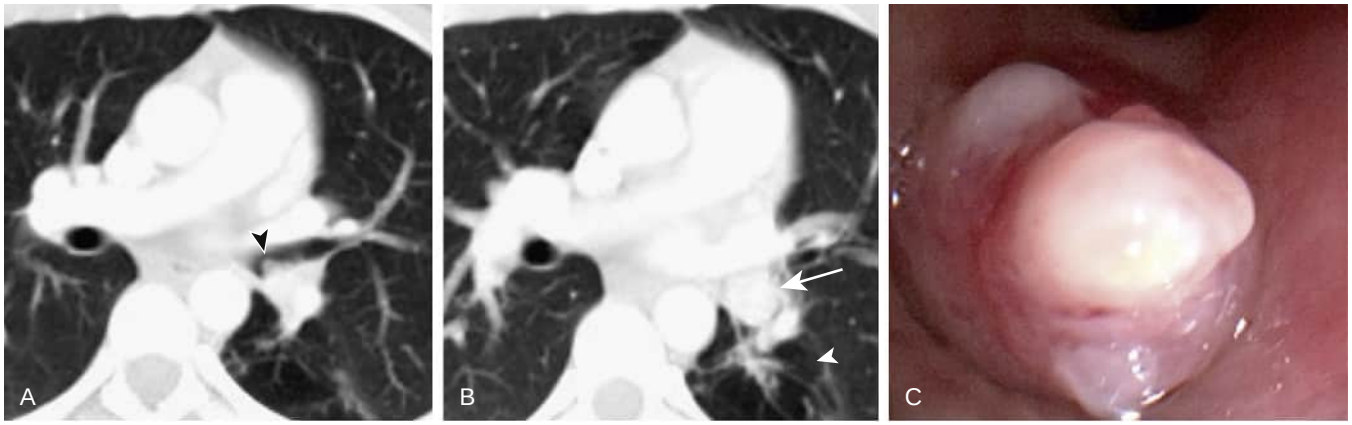

Figure 78.2 "Typical" carcinoid tumor: iceberg-like endobronchial mass. (A–B) Axial chest computed tomography displayed in lung windows in a 32-year-old woman with recurrent pneumonia shows a small portion of tumor protruding into the left mainstem bronchus (A, *arrowhead*), in a manner analogous to the small portion of an iceberg that protrudes above ocean water. There is complete obstruction of the left lower lobe bronchus (B, *arrow*). Left lower lobe postobstructive air trapping (B, *arrowhead*) is present. (C) Bronchoscopic image shows the left lower lobe lesion protruding into the left mainstem bronchus. (Courtesy Michael B. Gotway, MD.)

cryotherapy, have also been reported as an alternative approach for typical carcinoid but fail to ensure accurate counting of the mitotic index and therefore the confirmation of the subtype; this may be reserved for frail patients.[49] Atypical carcinoids, which have a higher local recurrence rate, usually require lobectomy and mediastinal lymph node dissection.[42] Lung carcinoids metastasize in less than 10% of cases; preoperative workup and follow-up should include systematic dedicated liver imaging.[50]

Carcinoids can exhibit quite different growth patterns, as shown in analyses of their molecular and growth characteristics.[50] In fact, some carcinoid tumors, usually with atypical features and high proliferation index, may present with metastases, poor outcome, and rapid progression; they have been defined as *supracarcinoid* tumors, a term that is debated but refers to a peculiar clinical entity. In the setting of metastatic or recurrent disease, cisplatin-based chemotherapy is ineffective, and management is tailored to the growth curve of the tumor lesions.[50] In patients with slow-growing, nonthreatening lesions, it is appropriate to watch and wait; to provide local treatment of oligometastases, which may lead to prolonged remission; or to use somatostatin analogues. In patients with rapidly progressive disease, everolimus may represent the best option.[50] In summary, the most significant prognostic factor is the histopathologic subtype, because 5-year survival rates of typical and atypical carcinoids are 87–98% and 56–73%, respectively.

LARGE CELL NEUROENDOCRINE CARCINOMA

The incidence of large cell neuroendocrine carcinoma has long been underestimated, probably because these tumors are often misdiagnosed as large cell undifferentiated carcinoma either on cytology or on tissue sections in the absence of immunostaining for neuroendocrine markers.[9,51] Large cell neuroendocrine carcinomas are strongly associated with tobacco smoking (90% of cases).[52,53] Clinical and radiologic (eFig. 78.8) features are similar to those of NSCLC and, in most reported series, treatment for early-stage tumors follows recommendations for NSCLC, including perioperative chemotherapy if recommended based on staging.[54] In advanced or metastatic disease, the chemotherapy regimen may be driven by mutation profiles; in the case of an NSCLC-like pattern, platinum-pemetrexed may lead to better outcomes but, in the case of a SCLC-like pattern, platinum-etoposide may be recommended.[55] Ultimately, overall survival is better than in SCLC, with stage being the most significant prognostic factor. Five-year survival rates in stages I–II, III, and IV are 52–88%, 20–45%, and 0–15%, respectively. Clinical trials with immune checkpoint inhibitors are ongoing.

PRIMARY PULMONARY LYMPHOMAS

Primary pulmonary lymphomas are historically strictly defined as lymphomas affecting one or both lungs, without evidence of extrapulmonary involvement at the time of diagnosis.[56–58] However, extrapulmonary lesions are actually found in up to 30% of cases when extensive workup is conducted.[57] Then, pulmonary lymphomas associated with small-sized satellite mediastinal and/or systemic nodes are regarded by clinicians as originating from the lung; similarly, large pulmonary lesions of lymphoma associated with single extrapulmonary lesions are regarded as primary pulmonary lymphoma.[58–61] Overall, primary pulmonary lymphomas are rare, representing 0.4% of all lymphomas. The most frequent subtype is MALT-type lymphoma. Other primary pulmonary lymphoma subtypes are mostly observed in immunocompromised patients. Lymphomatoid granulomatosis is a borderline primary pulmonary lymphoproliferative disorder.

MUCOSA-ASSOCIATED LYMPHOID TISSUE–TYPE LYMPHOMA

Pulmonary MALT lymphoma is referred to as nodal marginal-zone B cell lymphoma, with similar cytopathologic features to other MALT lymphomas, especially gastric lymphoma.[9] These low-grade lymphomas account for 70–90% of primary pulmonary lymphomas. At pathologic examination, MALT lymphoma appears as a diffuse infiltrate of small monomorphic lymphoid cells, with a typical lymphangitic growth pattern spreading along the bronchovascular bundles and interlobular septa and forming solid nodules that fill the alveolar spaces and obliterate the normal lung architecture (Fig. 78.3C–D). Immunohistochemistry forms the basis of the subtype classification, with the expression of the pan–B markers CD20 and CD79 and the absence of staining for CD5 and CD10.[9] The proliferation is monotypic, with surface and/or cytoplasmic expression of *immunoglobulin* (Ig) M and, less frequently, IgG and IgA (see Fig. 78.3E–F). Light chain restriction can be detected in the plasmacytic component using flow cytometry. MALT lymphomas are associated with unique chromosomal translocations, such as t(11;18)(q21,q21), resulting in a fusion of the *API2* and *MALT1* genes; t(1;14)(p22;q32), involving the *BCL10* and *IgH* genes—which is overall much less frequent, more specific to lung locations, and never found in high-grade lymphoma; and t(14;18)(q32;q21), involving the *IgH* and *MALT1* genes.[52,53,62] In cases with t(1;14) (*BCL10*/*IgH*) translocation, immunohistochemistry on paraffin-embedded tissues can detect the strong nuclear overexpression of BCL10. Amplification of the *IgH* gene from paraffin-embedded or cytologic samples with polymerase chain reaction–based assays was demonstrated to be a reliable method to detect monoclonality in greater than 60% of MALT lymphomas. Contrary to extrapulmonary MALT lymphomas, for which a strong relationship has been established with chronic bacterial inflammation related to *Helicobacter pylori* in the stomach and to *Chlamydia psittaci* in the ocular adnexa, no chronic infectious condition has been associated with pulmonary MALT lymphoma, although MALT is absent in the normal bronchial tree and is thought to develop only after long-term inflammation secondary to smoking or to an autoimmune condition.

Clinically, MALT lymphoma has mainly been observed in patients older than 45 years, with a slight male predominance, but it may also arise in younger patients with underlying immunosuppression, especially related to human immunodeficiency virus infection, or with inflammatory conditions such as Sjögren disease or

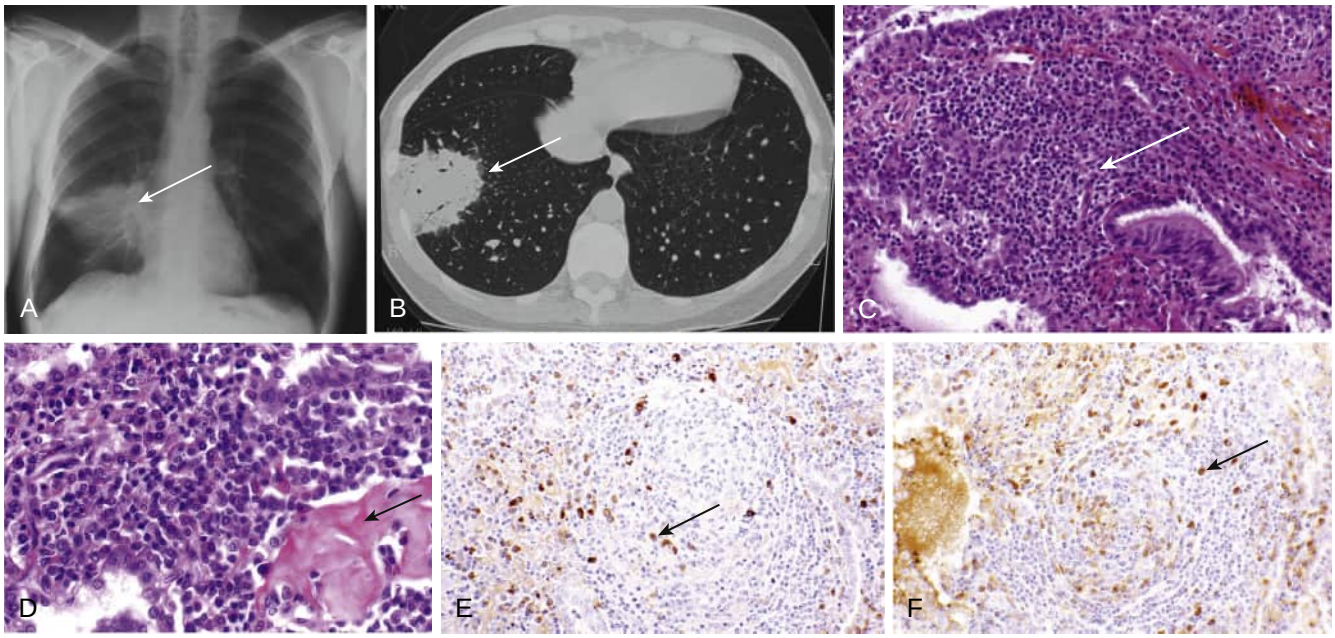

Figure 78.3 Primary pulmonary mucosa-associated lymphoid tissue lymphoma. Chest radiograph (A) and chest computed tomography (B) show a focus of consolidation in the right lower lobe (*arrows*) that persisted despite prolonged antibiotic therapy. (C) Pathologic examination of surgical biopsy showed proliferation of small-sized lymphoid cells infiltrating the bronchial wall. Note a bronchial epithelium encased by destructive lymphoid proliferation (*arrow*). (D) At high magnification, lymphoplasmacytic-like cells of the marginal zone lymphoma are associated with an amyloid deposit (*arrow*). (E) With *immunoglobulin* (Ig) lambda light chain immunostaining, there is a predominance of lambda chain plasma cells (lambda chain restriction; *arrow*). (F) With Ig mu heavy chain immunostaining, there is a predominance of IgM type in plasmacytic and plasma cells (*arrow*). (C, Hematoxylin eosin stain; original magnification ×40; D, original magnification ×100; E–F, original magnification ×40.)

rheumatoid arthritis, or in association with *Epstein-Barr virus* (EBV) infection.[56–65] Less than 50% of patients are symptomatic, with nonspecific symptoms, including cough, dyspnea, and chest pain. Unlike the situation with other lymphomas, systemic signs such as fever, swelling, and weight loss are uncommon. Association with IgM or IgG blood monoclonal gammopathy is observed in 30% of cases.

Radiologically, MALT lymphoma exhibits three imaging patterns on chest radiography and *computed tomography* (CT), which are challenging for differential diagnosis: (1) The most frequent and suggestive is the pneumonia-like alveolar consolidation with air bronchograms (see Fig. 78.3A–B), typically localized in the middle lobe; (2) a tumor-like appearance with a solitary circumscribed nodular opacity (30% of cases) (eFig. 78.9) and possible central air bronchogram; and (3) the "infiltrative" pattern with diffuse, poorly defined ground-glass opacities (eFig. 78.10), assumed to represent early-stage disease before tumor cells invade alveolar spaces.[56–66] The combination of a nodular opacity with peripheral peribronchovascular ground-glass attenuation halo is common. Pleural effusion is unusual. Multiple cystic lesions may be observed, which may be associated with light chain deposition disease. Hence differentiating MALT from infection, cancer, or interstitial diseases may be challenging, leading to frequent misdiagnosis if a complete workup is not conducted.

About one-third of MALT lymphomas are multifocal at the time of diagnosis, a presentation that may hamper the determination of the primary pulmonary origin of the disease.[67] Pulmonary MALT lymphomas are associated with tumor locations in the gastric mucosa in 10–20% of patients and in the bone marrow in 15–20% of patients. Gastroscopy and bone marrow biopsy are then recommended; FDG-PET imaging may not be sensitive enough to exclude extrathoracic disease. The Ann Arbor staging system, although not designed for extranodal lymphoma, may be applied in pulmonary MALT lymphoma, which would be staged as IE (one site, extranodal) in case of lung unilateral or bilateral involvement, IIE (two sites, both above the diaphragm, extranodal) in case of hilar or mediastinal lymph nodes, or IV in case of multiple sites.

Pathologic diagnosis actually requires a large, possibly surgical lung biopsy, because cytologic examination of bronchoalveolar lavage or fine-needle biopsy may show the CD20-positive B cell infiltration but fail to exclude differential diagnoses, such as reactional lymphoid proliferation, follicular bronchiolitis, or lymphoid interstitial pneumonia. *MALT1* gene rearrangements may be identified on bronchoalveolar lavage.[53,62]

Therapeutic options are based on the degree of tumor extension. Surgical resection ensures both the diagnosis and the treatment of nodular lesions, but MALT-type histology is usually unexpected when approaching a lesion thought to be NSCLC. In asymptomatic patients, a watch-and-wait attitude may be preferred to aggressive treatment. In the majority of patients, MALT lymphoma requires more aggressive management, and the standard of care is the combination of rituximab (an anti-CD20 antibody) with chlorambucil.[67] Several alternative options have been described, from single-agent therapy with chlorambucil, fludarabine, or rituximab to combined cytotoxic agents used for diffuse large B cell lymphomas.[68] Whether genomic profiles should drive the chemotherapy regimen is unclear,

even if rituximab alone may be effective in case of t(11;18) translocation.[69]

Prognosis of MALT lymphomas is usually excellent, with an indolent and localized prolonged course and response to chemotherapy. Historical series reported 5-year survival rates greater than 80%, and the more recent availability of rituximab may improve these results. Still, patients may present with recurrences leading to sequential treatment; parenchymal or bronchial sequelae may ensue, leading to chronic obstructive disease or pulmonary fibrosis. Local and systemic recurrences develop in about 50% of cases but are usually controllable with chemotherapy. Evolution to high-grade B cell lymphoma is seen in less than 5% of cases.[65,67] Young age at diagnosis is the most significant favorable prognostic factor.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis (LG), previously called "angiocentric lymphoma," is a malignant B cell angiocentric and angiodestructive lymphoproliferative disorder.[9,70] For a long time, LG was considered an inflammatory granulomatous disease owing to a presentation similar to other granulomatoses, such as granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis. Now, LG is recognized as a true EBV-related lymphoid malignancy. Differential diagnosis also includes allergic bronchopulmonary aspergillosis. The lung is the most frequent location, but the disease may also involve the brain, the skin, and the liver.[70–72]

Pathologically, LG forms multiple and confluent nodules composed of an atypical, angiocentric, and polymorphous lymphoid infiltration involving the vascular walls, from the subendothelium to the adventitial zones, with focal lumen obliteration. By immunohistochemistry, these lymphoid cells are characterized mostly as $CD4^+$ T lymphocytes, with scattered atypical cells of B phenotype.[9] Large B cells are infected with EBV in 65% of cases, a fact that correlates with the grade of the lesion. Pulmonary biopsy is required in most cases to exclude other granulomatoses.

LG arises in middle-aged patients between 40 and 50 years of age, with a male predominance.[70,71] Nearly all patients present with respiratory and systemic symptoms, consisting of cough, dyspnea, hemoptysis, chest pain, fever, and weight loss. Peripheral and mediastinal lymphadenopathy is absent. Prolonged immunosuppression is a frequent underlying condition. Hypereosinophilia may be observed in the blood and/or in the bronchioalveolar lavage. The typical radiologic presentation consists of multiple smooth bilateral nodules ranging from 2 to 10 cm, mainly localized in the lower lobes, exhibiting a peribronchovascular pattern, and mimicking multiple metastases (eFigs. 78.11 and 78.12). As in other granulomatoses, convergent nodules may migrate and form cavitated pseudotumoral masses.

LG is considered a low-grade or early-stage lymphoma, and a histopathologic grading system has been developed based on the degree of cellular atypia and necrosis, to predict the risk of evolution to high-grade lymphoma and to select patients for early aggressive treatment.[73] Chemotherapy based on the use of cyclophosphamide with high-dose steroids is the most frequently reported treatment. The additional use of rituximab has been reported.[72] The overall prognosis is grim, with a 5-year survival of 30–40% owing to progression to nodal diffuse aggressive lymphoma in 20–50% of patients.

OTHER LYMPHOMAS AND LYMPHOPROLIFERATIVE DISEASES

Other primary pulmonary malignant lymphoproliferative diseases are very rare and include high-grade, diffuse, large B cell lymphoma; intravascular large cell lymphoma; Hodgkin lymphoma; and plasmacytoma.

Primary pulmonary, diffuse, large B cell lymphoma is likely underrecognized owing to its rapid spread to mediastinal nodes and other extrathoracic sites, which may hide its pulmonary origin.[63] Primary pulmonary high-grade B cell lymphomas typically develop in immunocompetent patients in their sixth to seventh decade. Patients often present with marked respiratory and systemic symptoms. Radiologic studies usually show multiple well-defined rounded solid masses of various sizes, more frequently in the subpleural areas of the lower lobes (see eFigs. 90.33 to 90.35).[74] In younger patients, large B cell lymphoma may be caused by latent EBV infection, which may develop after drug-induced immunosuppression or after human immunodeficiency virus–related immunosuppression. In those patients, reduction of immunosuppression or active antiretroviral therapy, respectively, may lead to the near disappearance of primary pulmonary high-grade lymphomas. Chemotherapy is based on the same multi-agent regimens as those used in high-grade nodal lymphomas; new agents are under development.[75] The overall prognosis is much worse than for MALT lymphoma, with a 5-year survival less than 20%.

Intravascular large cell lymphoma is a variant of non-Hodgkin lymphoma, in which neoplastic lymphoid cells proliferate within the lumen of small- and intermediate-sized blood vessels, resulting in thrombotic and ischemic complications.[9] Clinical manifestations are multiple, but lymphadenopathy is usually absent. Pulmonary imaging features include bilateral ground-glass opacities and/or sometimes migratory atelectatic shadows (eFig. 78.13).

Primary pulmonary plasmacytoma is a solitary lesion composed exclusively of atypical monoclonal plasmocytes, possibly associated with amyloid deposition, without evidence of extrapulmonary myelomatous disease.[76] Again, the apparent decrease of the incidence of primary pulmonary plasmacytoma may be related to the increased sensitivity of biologic and imaging studies for the detection of primary extrapulmonary disease. Moreover, about one-third of patients operated on for pulmonary plasmacytoma were reported to present with multiple myeloma in following years.[76] Surgical resection is, however, recommended for solitary tumors, with a 5-year survival of 60%.[76]

PRIMARY PULMONARY SARCOMAS

Primary pulmonary sarcomas account for 20% of all primary rare lung malignancies and comprise (1) parenchymal lung sarcomas, which usually present as a lung mass, and (2) pulmonary vascular sarcomas, which include pulmonary

artery sarcomas and may mimic chronic pulmonary embolism, and small vessel sarcomas, which may produce interstitial lung disease.

PARENCHYMAL SARCOMAS

Primary lung parenchymal sarcomas show identical pathologic subtypes to those of their soft tissue counterparts, with a wide spectrum of differentiation from low to high grade. Leiomyosarcoma is the most frequent primary lung sarcoma,[77–79] followed by synovial sarcoma.

As in their soft tissue counterparts, pathologic diagnosis relies on morphologic and immunohistochemical features as well as identification of chromosomal translocations such as t(X;18)(p11.2;q11.2), pathognomonic of synovial sarcoma,[9] resulting in the fusion of two genes, *SYT-SSX1* and *SYT-SSX2*. Other subtypes include pleomorphic sarcoma as well as osteosarcoma and chondrosarcoma. Because most mesenchymal malignant tumors have a benign counterpart, pathologic examination must first evaluate the grade of the lesion, according to the three-grade system of the French Federation of Cancer Centers Sarcoma Group[80] and, second, rule out other epithelial tumors with sarcomatoid differentiation, such as sarcomatoid carcinoma, pneumoblastoma, or myofibroblastic tumors. Differential diagnosis also includes the very rare "benign" metastases from uterus (metastasizing leiomyoma) or bone (giant cell tumor).

Compared with their soft tissue counterparts, primary pulmonary sarcomas present in older patients, mainly in the sixth to eighth decade.[77–83] Clinical symptoms are nonspecific and usually consist of cough, dyspnea, and hemoptysis, depending on the size and the location of the lesions. Invasion of the chest wall may be frequent, leading to discussions about the primary parenchymal nature of the lesion. The incidence of radiation-induced sarcoma has decreased because cobalt-based radiotherapy has been abandoned. Unlike metastatic sarcoma, primary pulmonary sarcoma presents as a solitary lesion (eFigs. 78.14 and 78.15), with heterogeneous cystic, necrotic, or hemorrhagic features but with a well-defined circumference. Size ranges from 4 to 25 cm (Fig. 78.4A). FDG-PET scan shows increased uptake (see Fig. 78.4B and eFig. 78.15D) and may be used to rule out primary soft tissue sarcoma metastatic to the lung; attention should be paid to performing full-body (i.e., from skull to foot) scanning. Tumor progression is mainly local, and mediastinal lymph node invasion and systemic metastases are infrequent at the time of diagnosis (<2%).

Surgery is the most effective initial treatment, and complete resection is obtained in 80% of cases.[77–83] Strategies developed in soft tissue sarcoma may not be applicable to primary lung sarcomas; for example, neoadjuvant chemotherapy, based on anthracycline and ifosfamide, is commonly used in soft tissue locations but has been disappointing in primary lung tumors.[84] In the case of unresectable lesions, chemoradiation may be the best therapeutic strategy. As in soft tissue sarcoma, the chemotherapeutic drug trabectedin may be an option for second-line treatment. Prognosis mainly depends on the completeness of initial surgical resection, which, when combined with the grade of the lesion, is the best predictive factor of recurrence-free and overall survival. As is the case for all rare pulmonary tumors, surgery should be discussed in expert multidisciplinary teams. Overall 5-year survival varies from 30–50%.

VASCULAR SARCOMAS

Primary pulmonary vascular sarcomas include pulmonary artery sarcomas and small vessel sarcomas, that is, epithelioid hemangioendothelioma and its high-grade counterpart, angiosarcoma.[9]

Pulmonary artery sarcoma presents as an endoluminal polypoid or nodular mass, which spreads along the intima of the pulmonary artery. Histologic features consist of an undifferentiated spindle cell proliferation, with marked cellular pleomorphism and high mitotic index.[9] Leiomyosarcoma is the most frequent subtype (60% of cases).[85,86] Pulmonary artery sarcomas mainly develop in patients in their fifth to sixth decade.[85–87] Symptoms may mimic pulmonary embolism, with dyspnea, chest pain, cough, and hemoptysis. Failure of anticoagulants in this setting, as well as the presence of symptoms of weight loss and fever (in 40% of cases), may also suggest the diagnosis. Imaging findings also help differentiate between pulmonary artery sarcoma and pulmonary embolism. CT scanning may show a polypoid filling defect in the pulmonary artery, but, in contrast to thromboembolic disease, sarcoma forms a contiguously soft, smooth, tapering tissue, with possible

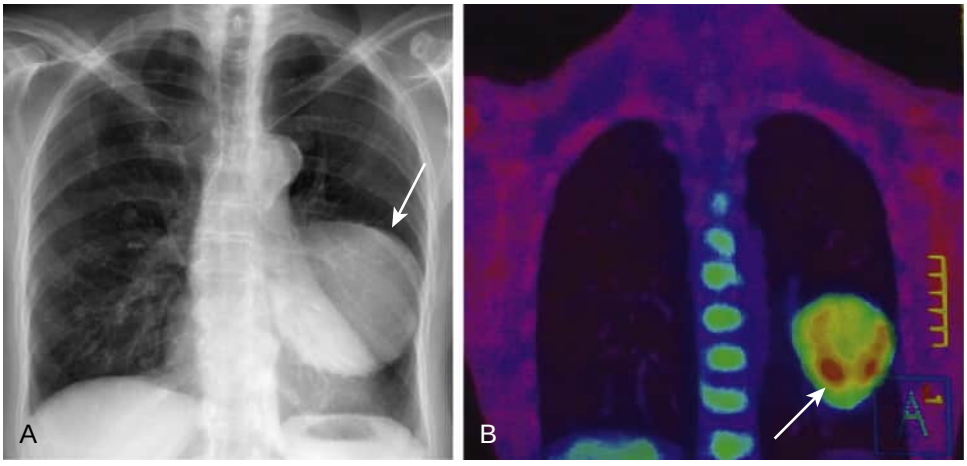

Figure 78.4 Primary pulmonary leiomyosarcoma. (A) Chest radiograph shows a large circumscribed homogeneous mass in the left lung (*arrow*). (B) Coronal positron emission tomography shows marked hypermetabolism within the lesion (*arrow*).

extravascular nodular spread in the parenchyma (40% of cases) (Fig. 78.5A, eFig. 78.16, and Video 78.1) and localized ground-glass opacities (see Fig. 78.5B).[86,87] Sarcoma also presents with a heterogeneous appearance, including areas of necrosis and hemorrhage, and with intense hyperactivity on FDG-PET scanning (see eFig. 78.16F–G). *Magnetic resonance imaging* (MRI) shows intermediate to mildly increased signal on T1-weighted images, often with heterogenous enhancement (eFig. 78.17), and T2-weighted images show intermediate to diminished signal relative to skeletal muscle. Furthermore, the intravascular mass may enhance, a feature not typically encountered with uncomplicated thromboembolic disease. Surgery is the only potentially curative treatment and, even if performed emergently in the setting of acute right-sided heart failure, allows resectability in 60–75% of cases[85–88] (see Fig. 78.5C). Heart and lung transplantation may be an alternative option for unresectable tumors but has rarely been reported. A slight improvement of overall survival has also been reported after adjuvant chemotherapy and/or radiotherapy. Contrary to soft tissue sarcoma, prognosis is mainly related to tumor location, because half of the patients die as a result of the progressive obstruction of the pulmonary trunk.[88] In case of recurrence, reoperation is feasible in 30% of cases; radiation therapy together with chemotherapy may be effective. However, in recent series, overall median survival is as low as 6 to 12 months (eFig. 78.18).[85–88]

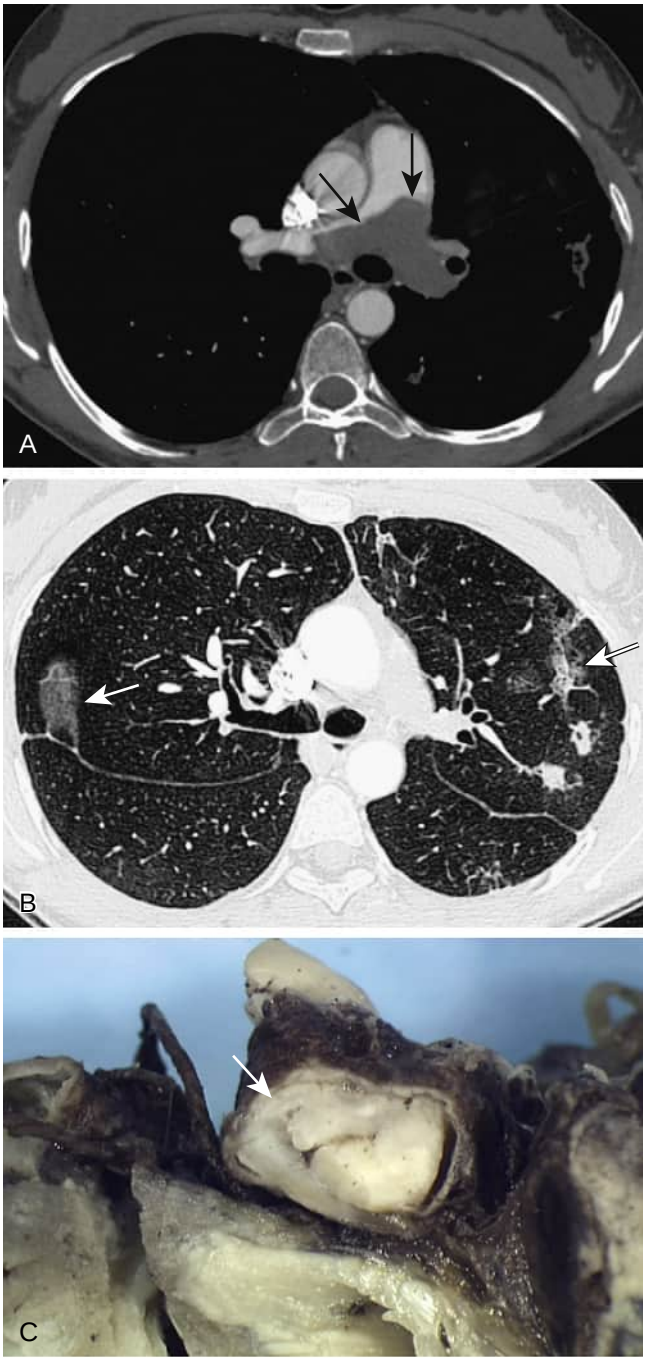

Figure 78.5 Pulmonary artery sarcoma. (A) Computed tomography displayed in soft tissue windows shows a mass filling the pulmonary artery lumen (*arrows*). (B) Computed tomography displayed in lung windows shows peripheral, irregular alveolar opacities (*arrows*) without pleural contact. (C) Specimen at pneumonectomy shows the infiltration of the pulmonary artery wall by the tumor (*arrow*).

Epithelioid hemangioendothelioma (EHE) is a low- to intermediate-grade mixed epithelioid, endothelial, and vascular tumor.[89–92] Lung is the most frequent extrahepatic location (10% of cases); EHE can also arise from the liver (63% of cases), the bone (8% of cases), and the skin (6% of cases).[89–92] EHE is characterized by polypoid nodules, with a central sclerotic paucicellular zone, growing into the alveolar spaces with an angiocentric distribution. Lymphangitic spread may mimic metastatic carcinoma. Around 90% of EHEs are caused by the fusion of *transcriptional coactivator with a PDZ-motif* (TAZ) with *calmodulin-binding transcription activator 1* (CAMTA1), a central nervous system–specific transcription activator; the 10% of EHEs that lack the *TAZ-CAMTA1* fusion instead have a fusion of *yes-associated protein* (YAP) and *transcription factor E3* (TFE3) genes *(YAP-TFE3)*.[93] EBV RNA sequences are detected in 90% of cases. Overlapping entities with IgG4-related disease have been described. Clinically, 80% of cases of EHE are diagnosed in white females.[89–92] The tumor is asymptomatic in 50% of cases; when present, symptoms are nonspecific and include pleuritic chest pain, nonproductive cough, dyspnea, and rarely hemoptysis. By CT imaging, EHE appears either with bilateral, slow-growing, perivascular, multiple nodules, usually located adjacent to small vessels or bronchi, or with predominant infiltrative ground-glass opacities (eFig. 78.19) with a micronodular pattern, mimicking carcinomatous lymphangitis. EHE nodules usually range from 3 to 50 mm, and their number varies from 10 to 20 lesions.[89–92] Nodules in patients with EHE may show increased uptake on FDG-PET scan. Although there are a few reports of spontaneous remission, the complete resection of all pulmonary nodules is the only curative treatment of EHE. Surgery remains effective even in cases of localized recurrence. In contrast, EHE is generally insensitive to chemotherapy (cisplatin based) or radiotherapy. Treatment with rituximab or antiangiogenic kinase inhibitors, such as sorafenib or bevacizumab, have been reported to be effective in isolated case reports.[94,95] In most cases, EHE is a slow-growing tumor that rarely metastasizes and is associated with a median survival of 5 to 6 years. Endobronchial spread, pleural effusion, and extended endovascular disease have been identified as unfavorable prognostic factors.

Angiosarcoma is a high-grade primary pulmonary vascular sarcoma considered a counterpart of EHE. However, no direct transformation from EHE to angiosarcoma has been reported yet.[96] Clinical features of angiosarcoma are similar to EHE, but massive hemoptysis is more frequent. Radiologic features of angiosarcoma include multiple nodules with a typical surrounding halo of ground-glass attenuation, with a specific cauliflower-like appearance on T2-weighted MRI.[97] This aspect may be shared by other disorders, including malignancies (e.g., adenocarcinoma with lepidic pattern [e.g., bronchioloalveolar carcinoma], metastatic sarcomas, choriocarcinoma, melanoma, lymphoma), infectious diseases (e.g., mycobacteriosis, aspergillosis, cytomegalovirus infection), granulomatosis with polyangiitis, and eosinophilic conditions. Distinguishing primary pulmonary angiosarcoma from extrathoracic angiosarcoma metastatic to the lung is crucial. Management of angiosarcoma is not established, because surgical resection is rarely possible owing to local and regional invasion, and because radiotherapy and chemotherapy are poorly effective, as seen for angiosarcoma in other locations. In immunocompromised patients, reduction of immunosuppressive agents may decrease the burden of the disease.

PSEUDOTUMORS AND BORDERLINE ENTITIES

Pseudotumors represent a wide range of etiologic, pathologic, and clinical-radiologic disorders that all share some degree of reactive inflammation and may present with some cancer-related biologic hallmarks. Pseudotumors may mimic the clinical and radiologic features of various intrathoracic diseases.

INFLAMMATORY MYOFIBROBLASTIC TUMOR

Inflammatory myofibroblastic tumor (IMT) is the most representative entity of the pulmonary pseudotumors[6,7,98] and encompasses a wide spectrum of lesions previously called inflammatory pseudotumor, fibroma, fibroxanthoma, fibrous histiocytoma, plasma cell/mast cell/solitary granuloma, plasma cell histiocytoma complex, or pseudosarcomatous tumor.

IMT appears as an intraparenchymatous well-circumscribed mass of variable size.[98–100] Histologically, the tumor is made of irregular proliferation of fibroblasts and myofibroblasts intermixed with an infiltrate of inflammatory cells, mainly lymphocytes and plasma cells. Three distinct histologic patterns are usually recognized[6,7,9,98–100]:

1. Plasma cell variant, also called the lymphoplasmacytic variant, which is composed of inflammatory myxoid proliferation with fascicles of spindled fibroblasts or myofibroblasts, abundant lymphocytes and plasma cells, and minimal fibrous connective tissue.
2. Fibrohistiocytic type, which appears as a compact spindle-cell pattern simulating fibrous histiocytoma characterized by a myxoid proliferation of fibroblasts and myofibroblasts associated with polyclonal plasma cells, xanthoma cells, and rare giant cells.
3. Organizing pneumonia-like type, which has a hypocellular pattern characterized by dense collagen with sparse spindle cells.

The proliferating myofibroblastic cells show no cellular atypia, no necrosis, and only rare mitotic figures. The myofibroblastic cells usually stain for vimentin and smooth muscle actin.

The concept of IMT as a proliferating neoplasm has been questioned.[7] More recently, clonal gene rearrangements have been observed,[101–103] especially involving the *anaplastic lymphoma kinase (ALK)* gene. *ALK* overexpression is observed in 40–70% of IMTs at immunohistochemistry, but *ALK* rearrangement is identified in less than 30% of pulmonary IMT cases and most frequently consists of t(1;2)(q21;p23) translocation, implicating the tropomyosin 3 gene.[101–103] Other translocations have been reported.[101–103] Given the oncogenic nature of *ALK* activation, these data lead some authors to consider IMT as a true malignant neoplasm; *ROS1* translocation has also been described.[103] Other elements further reinforce this concept, including the presence of vascular invasion, the local recurrence rate as high as 25%, and the existence of multifocal lesions.

IMT is also a consequence of immunologic disorders, which consist of EBV and human herpesvirus 8 infection of myofibroblastic cells[6,104] and, of more relevance, IgG4 expression in polyclonal plasma cells extracted from intrathoracic IMTs; such proliferation of IgG4-positive cells has also been associated with autoimmune disorders, including sclerosing pancreatitis and retroperitoneal and mediastinal fibrosis.[105] IMTs may then also be part of IgG4-related disease. Overlap exists between IMT, IgG4-related disorders, and prototypic high-grade inflammatory fibrosarcoma that exhibits prominent cellular atypias and necrosis.

Pulmonary IMTs usually appear before the fourth decade, accounting for more than 50% of pulmonary tumors in children.[6,98–100] IMT appears as a solitary, well-circumscribed, peripheral mass, ranging from 2 to 15 cm in size (Fig. 78.6 and eFig. 78.20). Contrary to its presentation at extrathoracic locations, the pulmonary IMT is usually solitary.[106] Calcifications are observed in 15% of cases. The usual stability

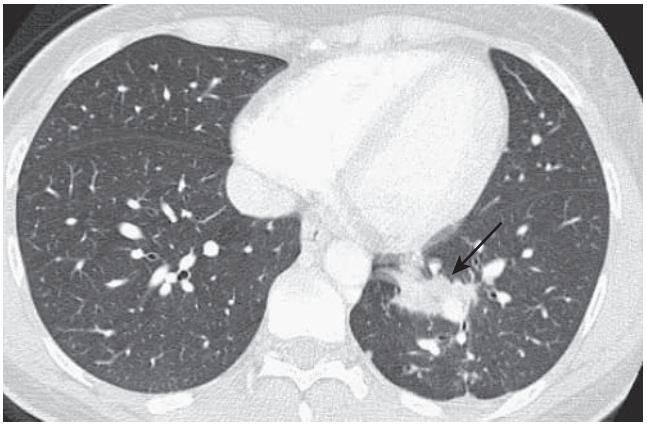

Figure 78.6 Inflammatory myofibroblastic tumor. Computed tomography performed for a 31-year-old man who presented with persistent cough and hemoptysis after infectious pneumonia. A poorly defined infiltrative-appearing opacity is present in the posterior and medial left lower lobe (*arrow*). Percutaneous transthoracic needle biopsy showed polymorphic inflammation without tumor cells.

in size over time is an important imaging feature. Mediastinal invasion is frequent; multifocal and bilateral IMTs are exceptional (eFig. 78.21) and are considered as overlapping forms of low-grade fibrosarcoma or malignant fibrous histiocytoma. IMTs are usually hypermetabolic on FDG-PET scan.

Even if historically considered a benign lesion with possible spontaneous regression, IMT is usually treated by surgical resection due to its tendency to grow, to provoke local complications, including hemoptysis and infection, and to relapse occasionally with lung/pleural and/or mediastinal invasion (15–25% of cases and 3–5% of cases, respectively).[107,108] The need for adjuvant treatment in case of incomplete resection has not been evaluated. In nonoperable patients, focal conformation radiotherapy or corticosteroids may represent an alternative. Corticosteroids are reported to induce objective responses in as many as 50% of cases, especially in predominantly plasma-cell and IgG4-positive tumors. In recurrent or multifocal lesions, chemotherapy may use the same regimens as for soft tissue sarcomas. ALK inhibitors are effective in case of *ALK*-rearranged IMT.[109]

RESPIRATORY TRACT PAPILLOMATOSIS

Some lesions thought to be benign may have a borderline presentation and outcome. One relevant example is recurrent respiratory papillomatosis. Papillomas usually present in the upper respiratory tract but may rarely spread to the lung parenchyma (<5% of cases).[110,111] Histologically, squamous papillomas are usually exophytic with an epithelial layer covering a central fibrovascular core that forms a frondlike architecture protruding into the lumen of the airway. Papillomas may exhibit imaging features similar to those of lung cancer, including heterogeneous, cavitating, or poorly defined masses.

Pulmonary papillomas may be solitary or multiple (eFigs. 78.22 to 78.25); if multiple, these are associated with multiple papillomas of the upper respiratory and aerodigestive tract. As in other locations, the pathogenesis of squamous papillomas is linked with *human papillomavirus* (HPV) infection, often acquired at birth.[112] Specifically, HPV type 11 infection has been reported to bear a high risk of transformation of papilloma to squamous cell carcinoma (Fig. 78.7 and see eFig. 78.25).[113] On a molecular basis, loss of the tumor suppressor genes *TP53, RB,* and *P21* has been reported in squamous cell carcinomas originating from papillomas. Mutation of the *HPV-11* gene with duplication of promoter and oncogene regions has been described in a case responding to vorinostat.[114] FDG-PET scanning may not be useful given the mild hypermetabolism of high-grade papillomas. Given this uncertain malignant potential and the difficult differential diagnosis with lung cancer, complete resection of papillomas is recommended if possible; complete resection may not be possible or may only be temporizing (see eFig. 78.25), in the setting of multiple and bilateral lesions (see Fig. 78.7 and eFigs. 78.22 to 78.24). The role of vaccines, antiangiogenic agents, and antiviral treatment in preventing evolution of pulmonary papillomas is unclear.

PULMONARY LANGERHANS CELL HISTIOCYTOSIS (See Chapter 95)

Pulmonary Langerhans cell histiocytosis (PLCH) is a heterogeneous disease defined by the proliferation of Langerhans cells, corresponding to CD1a-positive histiocytes exhibiting Birbeck granules on electron microscopy.[115–118] These cells of dendritic lineage derive from CD34-positive bone marrow stem cells. If the lung is the sole location of the disease, it is called pulmonary LCH. In less than 15% of cases, LCH is associated with multisystem disease, corresponding to acute disseminated LCH involving the lung, bone, skin, and pituitary gland.[117] The pathogenic concepts about LCH mostly involve an uncontrolled immune response to a yet undetermined stimulus, leading to the recruitment of Langerhans cells in the lung parenchyma. Smoking exposure is found in the majority of patients developing pulmonary LCH and is thought to stimulate this process in the bronchiolar epithelium.[119] The true nature of LCH remains elusive. Strongly favoring the hypothesis of a neoplastic disorder is the observation that Langerhans cells, isolated from patients with either pulmonary or disseminated LCH, are clonal[120] and may harbor activating *BRAF* mutations, as well as mutation of the *MAP2K1* pathway.[120–122] However, the limited proliferation of Langerhans cells, the absence of cellular atypia, the low number of Langerhans cells in high-stage lesions, and the possibility of spontaneous regression argue against a truly cancerous nature of LCH.

Pathologically, LCH lesions are made of Langerhans cells that proliferate and aggregate to form stellate nodules in the interstitium, with a bronchiolocentric pattern and linear distal and proximal spread. High-stage lesions are characterized by disappearance of Langerhans cells, increased amounts of fibrosis, and cavitation of the nodules leading to cyst formation.[115,116]

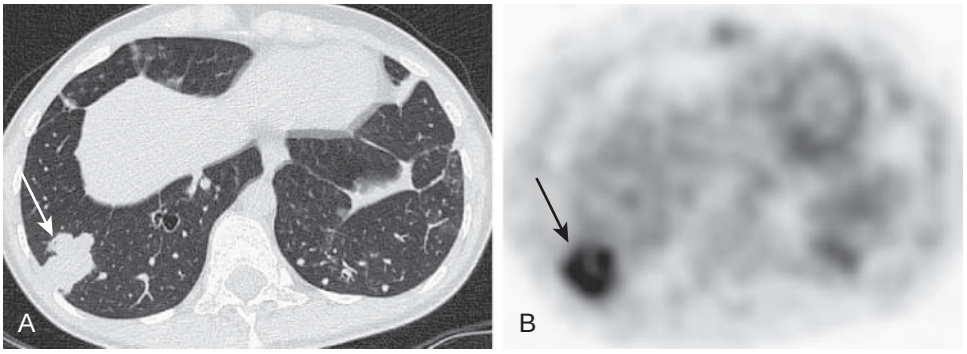

Figure 78.7 Pulmonary squamous cell carcinoma development in a patient with papillomatosis. (A) Chest computed tomography performed for a 32-year-old woman with a history of upper and lower respiratory tract papillomatosis and new complaints of worsening cough and weight loss shows a subpleural mass in the right lower lobe (*arrow*). A thin-walled cyst is also present within the right lower lobe, and small centrilobular nodules are seen in the left lower lobe. (B) Positron emission tomography shows increased metabolism. Percutaneous transthoracic needle biopsy showed squamous cell carcinoma.

Clinically, pulmonary LCH develops in young smokers who present with nonspecific respiratory symptoms, including dyspnea, cough, and chest pain. Pneumothorax may herald the disease in 15% of patients; 10–25% of patients are asymptomatic. The most typical imaging feature is the combination of pulmonary multiple cysts and micronodules sparing the lower zones of the lung. Nodules, ranging from 5 mm to 2 cm in size, are centrilobular and may be solid or cavitated (eFig. 78.26A–C) with smooth or irregular margins. LCH is an active process with predominant nodular aspect at early stages of the disease (see eFig. 78.26A–B), evolving to cavitated nodules, cysts of variable wall thickness (see eFig. 78.26C), and confluent cystic lesions over time (see eFig. 78.26D). Lesions of different age are usually observed. Rarely, pulmonary LCH presents as a single nodule, localized consolidation, or mediastinal disease. Increased uptake on FDG-PET scanning is frequent.

Smoking cessation may lead to regression in as many as 25% of patients. No other treatment has been confirmed to be useful in pulmonary LCH, which may also regress spontaneously. Patients with progressive or multiorgan disease may benefit from chemotherapy with cladribine, which produced a 75% objective response rate in a landmark study of 13 patients[123,124]; cladribine may also reduce the growth and development of cystic lesions. *BRAF* mutations are associated with resistance to chemotherapy but may predict the efficacy of RAF/MEK inhibitors. Supporting the neoplastic hypothesis, pulmonary LCH can recur after lung transplantation.

LESSONS LEARNED FOR THE MANAGEMENT OF RARE PRIMARY PULMONARY TUMORS

CLINICAL STRATEGY

When facing a pulmonary tumor lesion, the primary hypothesis for clinicians is that the lesion represents lung cancer, the main differential diagnosis of rare pulmonary malignancies. The absence of a tobacco-smoking history, especially in men, is more frequently seen for rare lung tumors and pseudotumors than for bronchogenic carcinoma (60% vs. 15%, respectively). Young age at diagnosis is another characteristic to consider because greater than 50% of rare tumors present before the fourth decade. Given the frequent initial suspicion of lung cancer, most patients undergo complete oncologic workup. FDG-PET scan is usually not helpful for differentiating rare primary lung tumors from NSCLC. Preoperative biopsies and intraoperative frozen sections may not be sufficiently representative of the tumor to ensure accurate histopathologic diagnosis, especially in biphasic or composite tumors, for which small-size samples may identify only one cellular component. Frozen specimen collection and storage is mandatory to preserve the tumor for additional analyses.

DISTINGUISHING PRIMARY TUMORS FROM METASTASES

In making the diagnosis of a rare primary lung tumor, one must also consider the fact that most lung tumors with unusual histology represent metastases from extrapulmonary tumors, not primary tumors. The main criteria favoring metastases include a prior history of extrathoracic tumor and the finding of multiple pulmonary lesions. The primary pulmonary nature of some rare tumors may be difficult to establish, either because of early systemic spread, as for EHE, which presents with synchronous pulmonary and hepatic lesions in 20% of cases or because of an ectopic origin, as for melanoma or Hodgkin disease, for which a primary pulmonary origin is highly controversial.

MOLECULAR PROFILING

Sophisticated molecular studies, including flow cytometry and genomic and cytogenetic analyses, may have a critical role in making the accurate diagnosis of rare pulmonary tumors because morphology may not be sufficient for classification and for evaluation of tumor grade. This is especially mandatory for lymphoma, IMT, or sarcomas. Systematic high-throughput genomic analyses, including DNA/RNA sequencing and possibly whole-exome sequencing, is also increasingly used to identify deregulated molecular pathways, which is not possible based on targeted, panel-based analyses designed for frequent tumors; this may lead to discussions of potential treatment strategies based on targeted agents.[125] Family history is of interest to understand possible predispositions and occupational/professional questionnaires to identify potential carcinogens; so far, limited data are available in those areas for rare pulmonary tumors.

TREATMENT PRINCIPLES

In many cases with a localized lesion in the lung parenchyma, initial surgical resection provides the correct diagnosis and the first step of the therapy. However, preoperative diagnosis remains important for specific subtypes, such as lymphoma, for which extensive resection is not warranted, and for sarcoma, which usually does not spread to the mediastinal lymph nodes and thus would not require nodal resection. Surgical biopsy may be required to obtain sufficient tissue material for extensive pathologic and molecular diagnoses, especially when clinical-radiologic presentation is not typical of neoplastic or non-neoplastic disease.

Finally, three main clinical scenarios may arise in the course of evaluation of patients with rare lung tumors:

1. Surgical resection of a tumor assumed to be lung cancer was complete, and pathologic examination disclosed an unusual histopathologic subtype, such as carcinoid or IMT. In this case, usually no adjuvant therapy is recommended; follow-up is adapted to fit the situation.
2. Specific clinical and radiologic signs led to recognition of a rare tumor, such as lymphoma or pulmonary artery sarcoma, followed by specific diagnostic and therapeutic management.
3. Surgery of a pulmonary mass initially thought to be lung cancer led to recognition of a rare tumor subtype for which the therapeutic and prognostic implications are unknown. In those cases, the decision for adjuvant treatment and follow-up is based either on a lung cancer

standard of care or on therapeutic strategies established for a similar tumor subtype in other locations, as is done for lymphoma and sarcoma.

In the absence of evidence-based recommendations, expert consensus is mandatory for selection of a specific therapeutic strategy, possibly based on strategies developed for lesions of similar histology arising in another anatomic location. As discussed, molecularly tailored treatment may be useful, and systematic high-throughput genomic analyses, including DNA/RNA sequencing, are recommended.[125] Also, these issues emphasize the need for multicenter collaboration to generate cohorts and to launch observational studies and clinical trials of rare lung tumors.

NETWORKS

More than their low frequency, the hallmarks of rare lung tumors may be the absence of comprehensive clinical data, the low number of specialized groups for the care of each tumor subtype, and the lack of specific therapeutic recommendations. More than 90% of rare lung tumor observations are published as case reports or small series including fewer than five patients.[1,7] Currently, only carcinoids and large cell neuroendocrine carcinoma, lymphomas, and some sarcomas, among the most frequent of the rare tumor subtypes, have been characterized regarding their clinical, molecular therapeutic, and prognostic features in large retrospective and prospective studies.

Meanwhile, patients with rare lung tumors, like many patients with cancer, tend to go through several stages of grief, including depression, uncertainty, hope, disappointment and, in most cases, physical degradation and social isolation. The rarity of the tumor may also enhance these feelings, owing to the relative lack of information and the increased feeling of isolation; the geographic disparity in access to specific care; the longer duration of the pretherapeutic workup; the involvement of multiple specialists; a feeling of injustice, especially in young and never-smoking patients; and the complex management undertaken in a state of uncertainty.[126] As a result, patients with rare lung tumors may not receive equal care and some may feel "orphaned," being incompletely integrated in the process of care of patients with the more frequent lung cancers.

Ultimately, the management of patients with rare pulmonary tumors requires continuous multidisciplinary expertise at each step of the disease. There has been a dramatic improvement in our knowledge in the last few years through the development of large databases, translational research programs, and clinical trials. Access to innovative strategies represents a major challenge because there is a lack of funding for clinical research in rare cancers, and their rarity precludes the design of robust clinical trials that could lead to specific approval of drugs. In this context, patient-centered initiatives, such as the establishment of dedicated networks, are warranted. International societies and patient advocacy groups provide infrastructure for global collaboration. There are many advantages to having strong regional groups working on the same issue; indeed, there may be regional differences in risk factors, susceptibility, management, and outcomes. The ability to address questions both regionally and globally is ideal to develop a full understanding of rare pulmonary tumors.

In Europe, the recent establishment of the European Reference Network EURACAN provides an infrastructure of more than 70 health care providers with a high level of multidisciplinary expertise for the diagnosis, management, and follow-up of patients with rare cancers, including rare thoracic tumors. The objectives of EURACAN include updating and assessment of current guidelines, development of educational programs, dissemination and communication with patients groups, and the establishment of research projects, from the diagnosis workup of the disease to the therapeutic strategies. Achieving the highest quality of patient care is the main objective of EURACAN, and a multidisciplinary tumor board is hosted by a pan-European online platform called the Clinical Patient Management System. The European network also provides an infrastructure for collaboration with diagnosis and pharmaceutical companies. One example may be the opening of dedicated cohorts in basket trials, in which patients with different tumors but with the same mutation or biomarker receive the same treatment. By using molecular characterization for assessing new drugs, the network allows a better identification of patients and facilitates the recruitment in the trials.

Key Points

- Rare lung tumors are mainly defined as uncommon lung tumors with unusual histology. Rare tumors account for less than 1% of all primary lung tumors, whereas they correspond to more than 100 different histologic entities.
- Rare lung tumors may mimic lung carcinoma or benign orphan lung diseases because they may share clinical, imaging, pathologic, and even molecular features. Awareness is the key to diagnosing rare pulmonary tumors.
- Some rare lung tumors are specific to the lung, whereas others represent tumors more frequently found in other organs and only rarely present in the lungs. Determining whether they are primary or metastatic is a major step in the diagnostic evaluation.
- The most frequent rare malignant primary lung tumors are—in decreasing order of frequency—carcinoid, mucosa-associated lymphoid tissue lymphoma, and sarcomatoid carcinomas.
- Sophisticated pathologic and molecular analyses studies have an increasingly critical role in diagnosis and in therapeutics. High-throughput sequencing is recommended for accurate diagnosis of tumors with complex histology and for deciphering molecular pathways of interest for targeted therapies.
- The management of patients with rare pulmonary tumors requires multidisciplinary expertise at every step of the disease. Dedicated networks are required to ensure high quality care and may provide an infrastructure for collaboration to improve diagnosis and treatment.

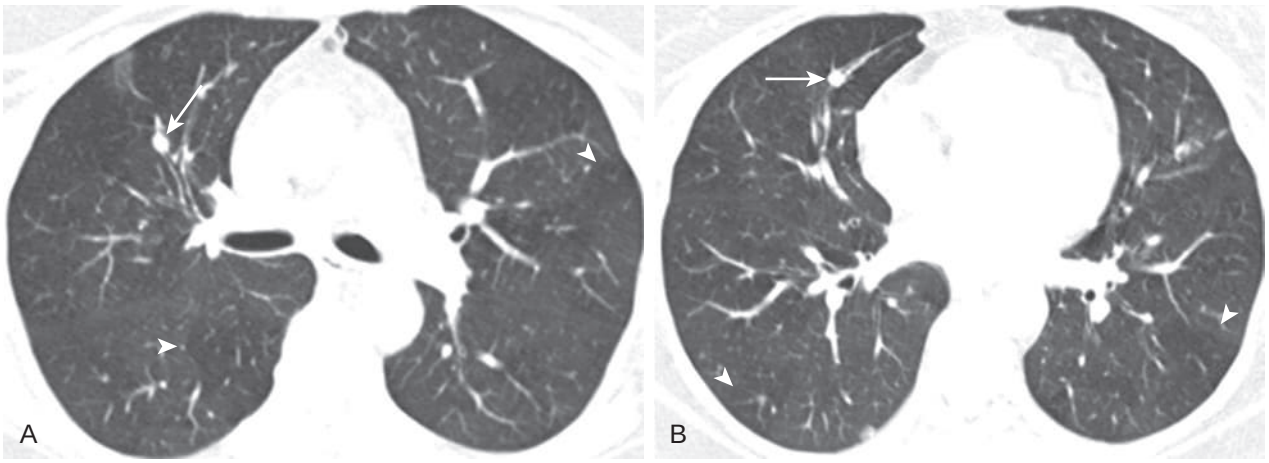
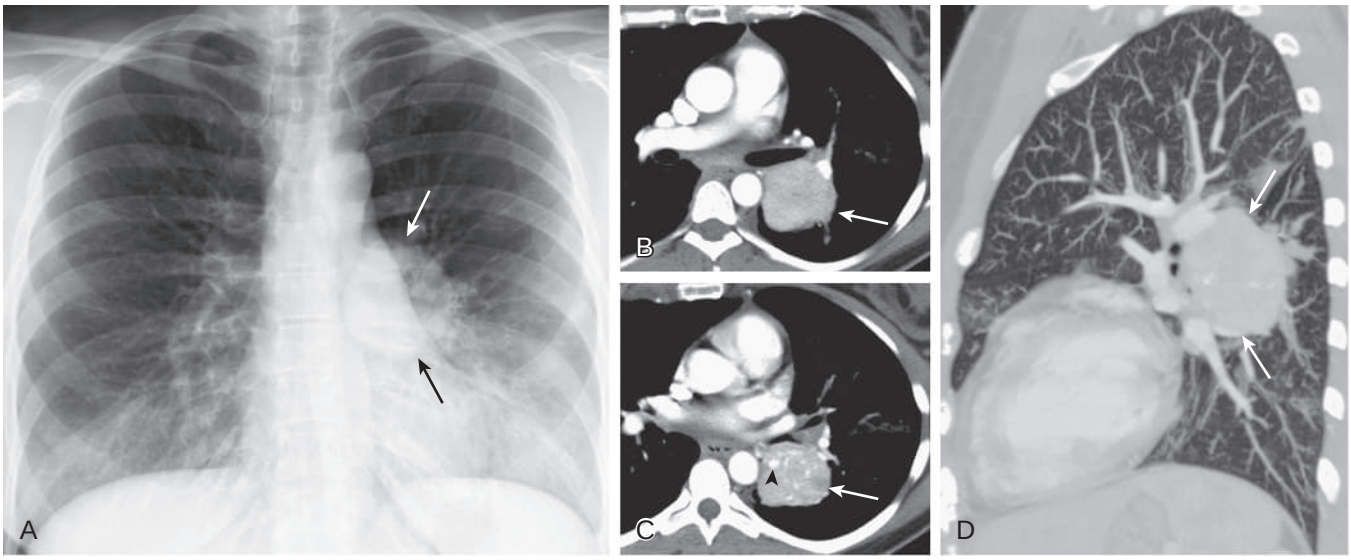
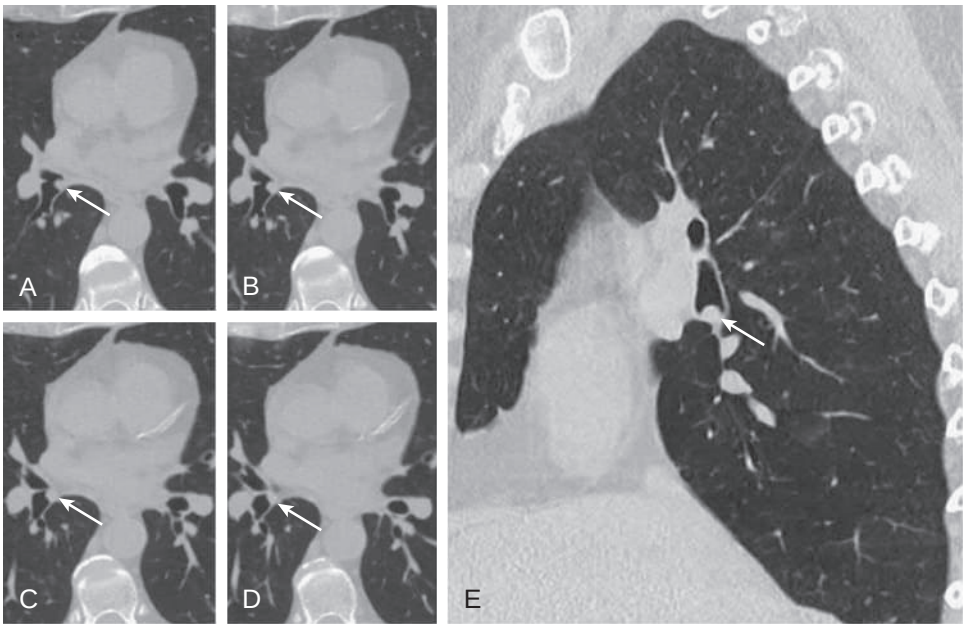
eFigure 78.1 Mucoepidermoid malignancy. Frontal (A) and lateral (B) chest radiographs in a young woman with mucoepidermoid malignancy show the classic chest radiographic appearance of left upper lobe collapse. Left para-aortic lymphadenopathy (C, *arrow*) is present. (C–E) Axial enhanced chest computed tomography scans displayed in soft tissue windows show left upper lobe collapse and reveal the obstructing lesion (D–E, *arrowhead*). (F) Coronal reformatted image displayed in an intermediate window again shows complete left upper lobe collapse and the obstructing lesion within the left upper lobe bronchus (*arrowhead*). (G–H) Bronchoscopic images show the mucoepidermoid tumor completely obstructing the left upper lobe bronchial orifice. (Courtesy Ewa Lupa-Laskus, MD, Arizona Pulmonary Specialists, Scottsdale, AZ.)



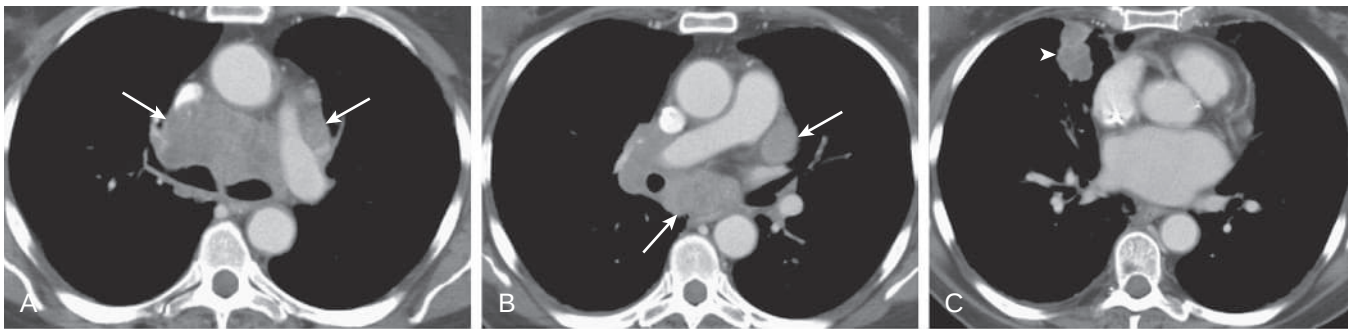
eFigure 78.2 Diffuse neuroendocrine cell hyperplasia. Axial unenhanced chest computed tomography through the middle (A) and lower (B) lungs shows multifocal bilateral inhomogeneous lung opacity with areas of mosaic perfusion manifesting as areas of low attenuation (*arrowheads*); these findings reflect the presence of small airway obstruction. Larger airway-associated nodules (*arrows*), reflecting carcinoid tumors, are present. (Courtesy Michael B. Gotway, MD.)



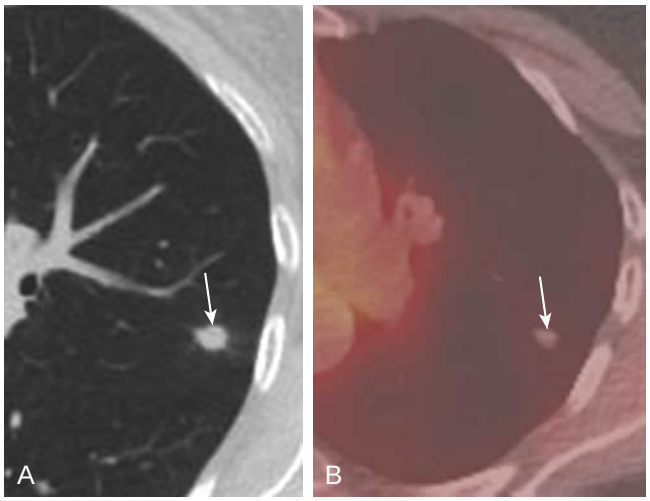
eFigure 78.3 "Typical" carcinoid tumor: hilar mass. (A) Frontal chest radiograph shows a circumscribed left hilar mass (*arrows*). (B–C) Enhanced axial chest computed tomography scans shown in soft tissue windows. (D) Sagittal lung window shows an enhancing mass (*arrows*) arising from and obstructing the left lower lobe bronchus. Calcification (*arrowhead*) is present within the mass. (Courtesy Michael B. Gotway, MD.)



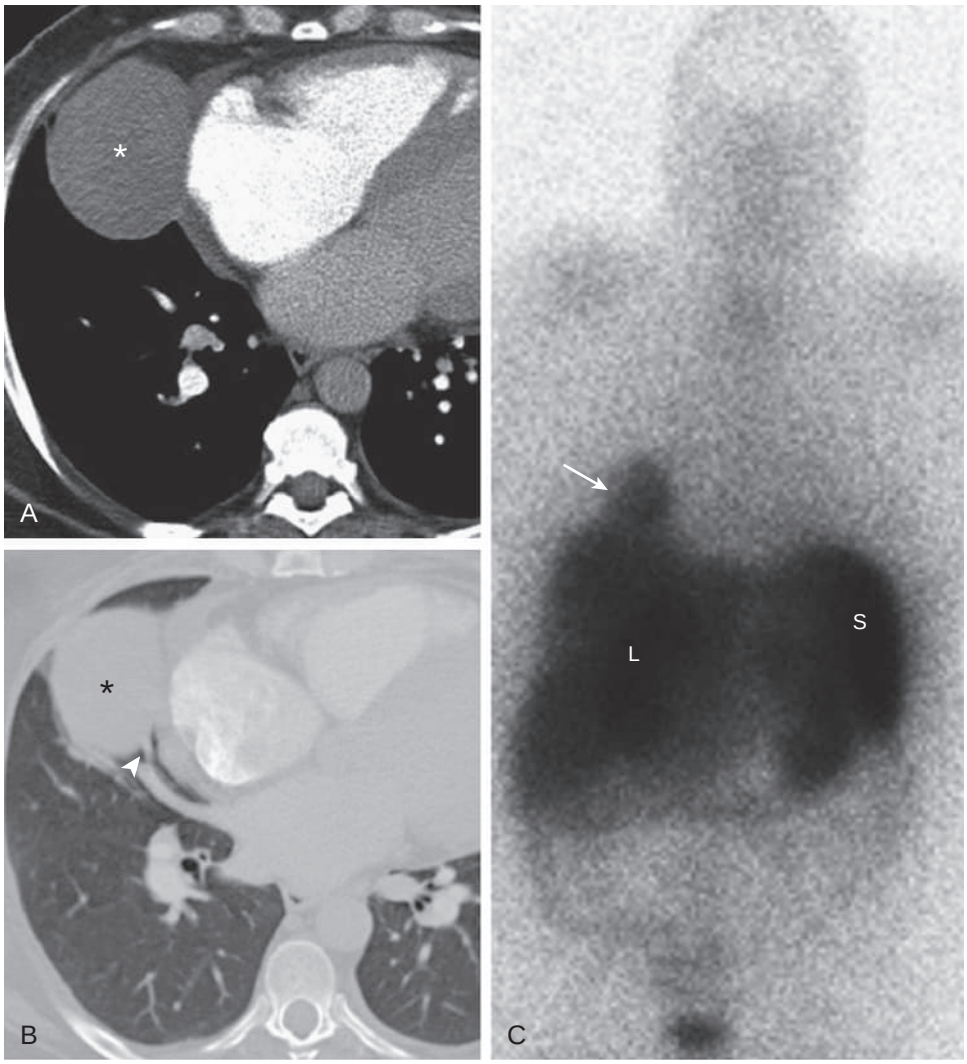
eFigure 78.4 "Typical" carcinoid tumor: endobronchial lesion without postobstructive changes. Axial (A–D) and sagittal (E) unenhanced chest computed tomography images show a small, circumscribed opacity (*arrows*) attached to the medial aspect of the cranial right lower lobe bronchus, unassociated with postobstructive pneumonia or atelectasis. Bronchoscopy and biopsy proved carcinoid tumor. (Courtesy Michael B. Gotway, MD.)



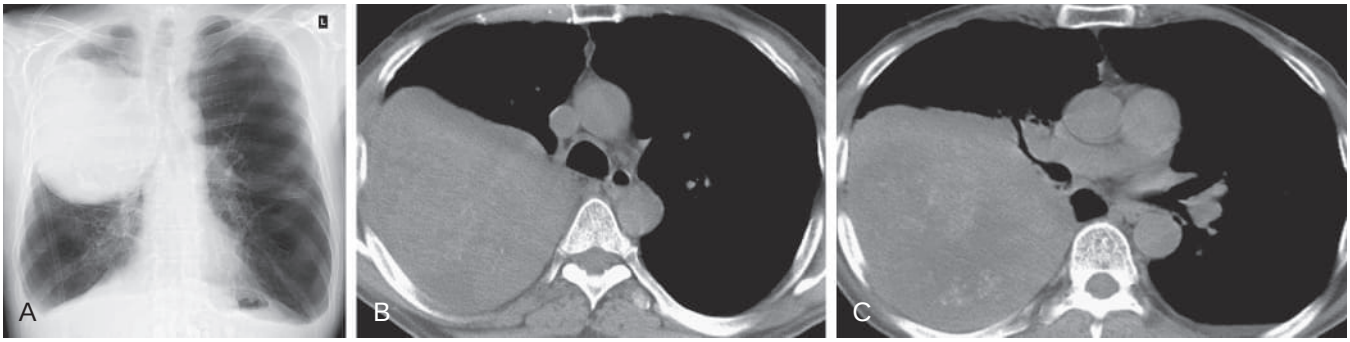
eFigure 78.5 "Atypical" carcinoid tumor. (A–C) Axial enhanced chest computed tomography scans displayed in soft tissue windows show extensive mediastinal lymph node enlargement (A–B, *arrows*) associated with a right middle lobe atypical carcinoid tumor (C, *arrowhead*). The appearance is indistinguishable from bronchogenic malignancy. (Courtesy Michael B. Gotway, MD.)



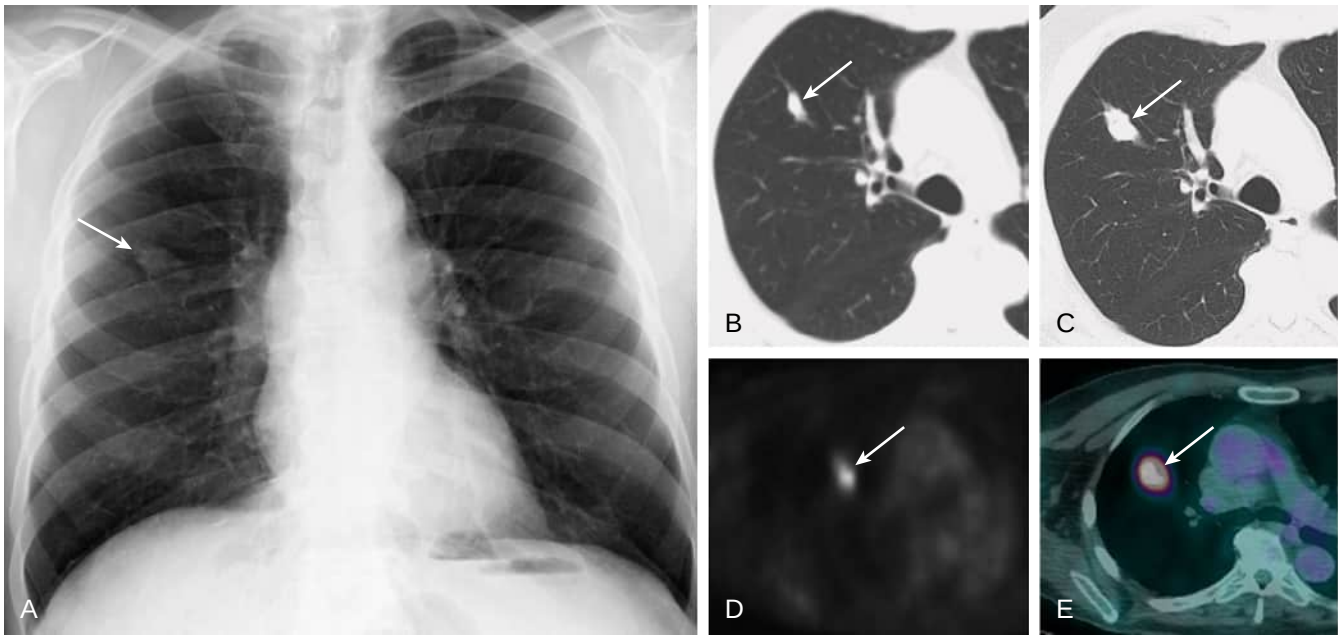
eFigure 78.6 "Typical" peripheral carcinoid tumor at computed tomography and ^{18}*F-fluorodeoxyglucose–positron emission tomography* (FDG-PET). (A) Axial unenhanced chest computed tomography scan displayed in lung windows shows a nonspecific, noncalcified, peripheral, somewhat spiculated left lung nodule (*arrow*). (B) Axial FDG-PET scan shows no tracer utilization within the nodule (*arrow*); compare to tracer activity within the mediastinal blood pool at the left aspect of the image. (Courtesy Michael B. Gotway, MD.)



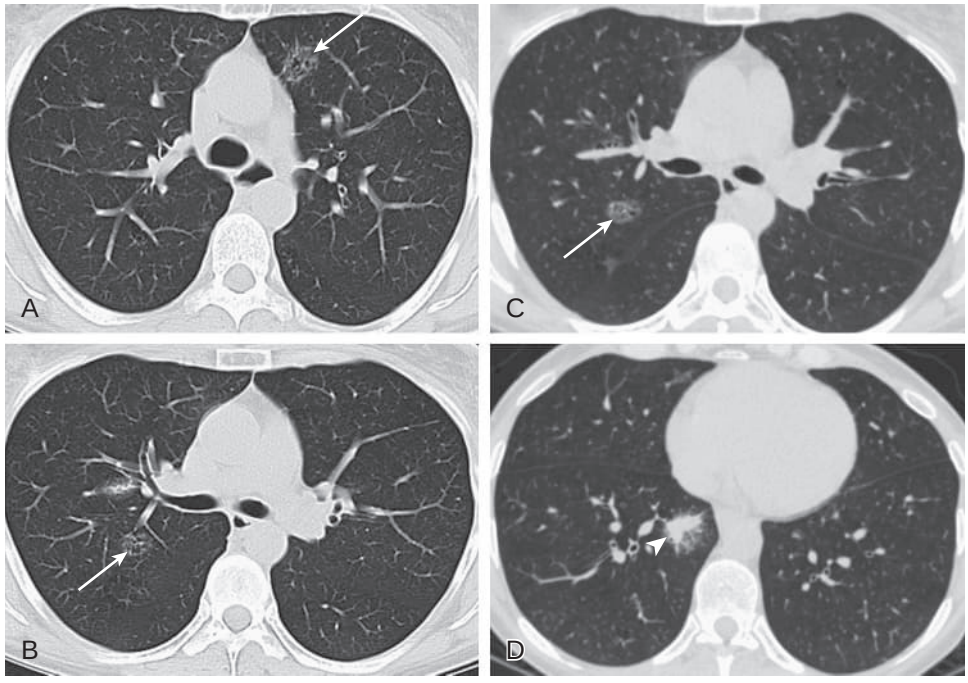
eFigure 78.7 "Typical" carcinoid tumor: somatostatin (octreotide) scintigraphy. Axial enhanced chest computed tomography scans displayed in soft tissue (A) and lung (B) windows show a circumscribed soft tissue mass (*asterisk*) in the right middle lobe, closely associated with bronchi (B, *arrowhead*), proven to represent typical carcinoid tumor. (C) Coronal planar octreotide scan shows tracer uptake within the right middle lobe lesion (*arrow*). Normal physiologic uptake is seen within the liver (L) and spleen (S). (Courtesy Michael B. Gotway, MD.)



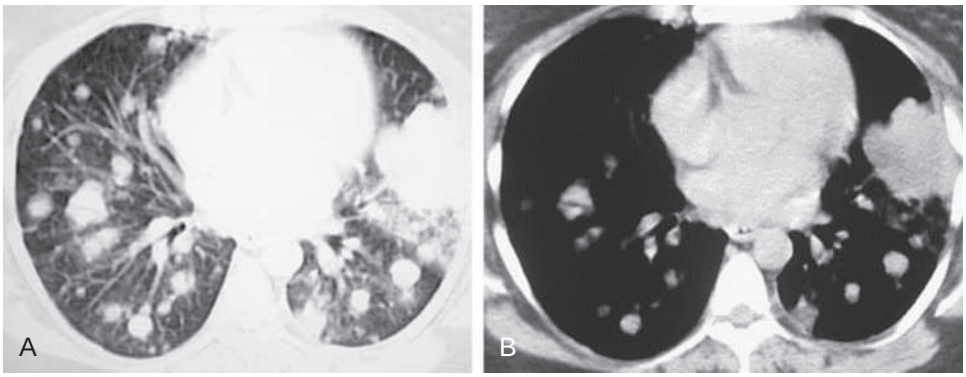
eFigure 78.8 Large cell neuroendocrine neoplasm. (A) Frontal chest radiograph in a patient with biopsy-proven large cell neuroendocrine neoplasm shows a large right upper lobe mass. (B–C) Axial chest computed tomography scans displayed in soft tissue windows show a heterogeneous right upper lobe mass with foci of faint internal hyperattenuation. The appearance is nonspecific and indistinguishable from bronchogenic malignancy. (Courtesy Michael B. Gotway, MD.)



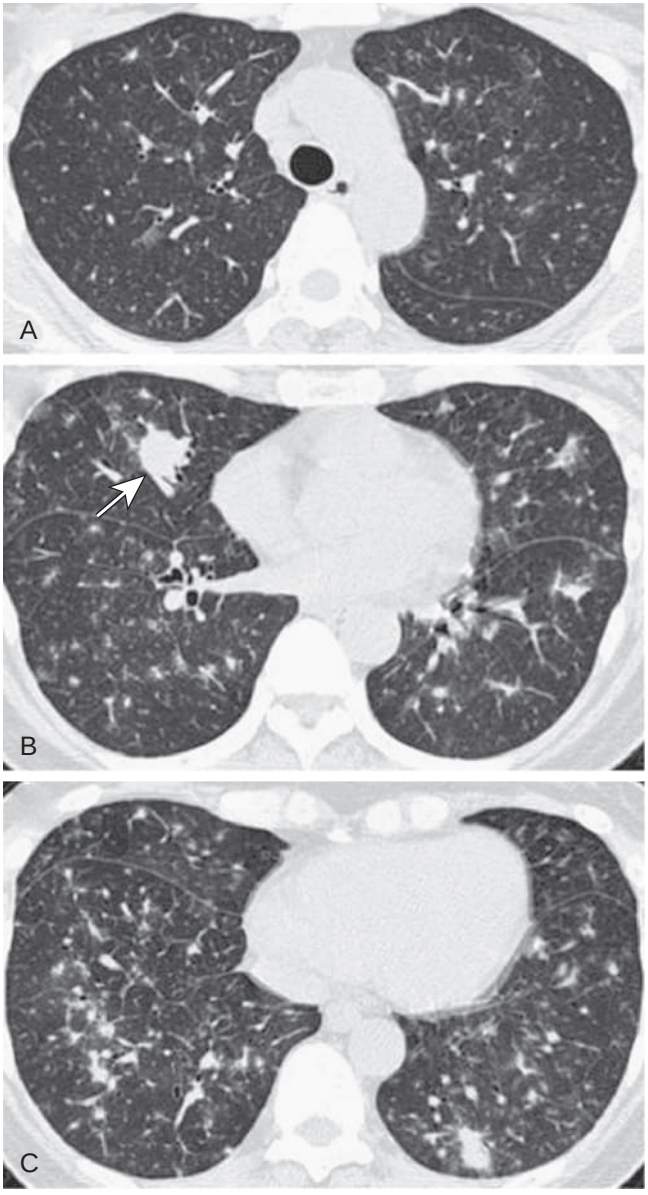
eFigure 78.9 Primary pulmonary mucosa-associated lymphoid tissue lymphoma: solitary pulmonary nodule. (A) Frontal chest radiograph shows a nonspecific, solitary, lobulated right upper lobe pulmonary nodule (*arrow*). (B–C) Axial enhanced chest computed tomography scans displayed in lung windows show rapid growth of the nodule (*arrows*) over a 3-month period. (D–E) *Positron emission tomography* (PET) and fused PET imaging obtained at nearly the same time as the computed tomography studies (B–C) show marked metabolic activity within the nodule (*arrows*). Percutaneous transthoracic fine-needle aspiration and core biopsy showed pulmonary mucosa-associated lymphoid tissue lymphoma. (Courtesy Michael B. Gotway, MD.)



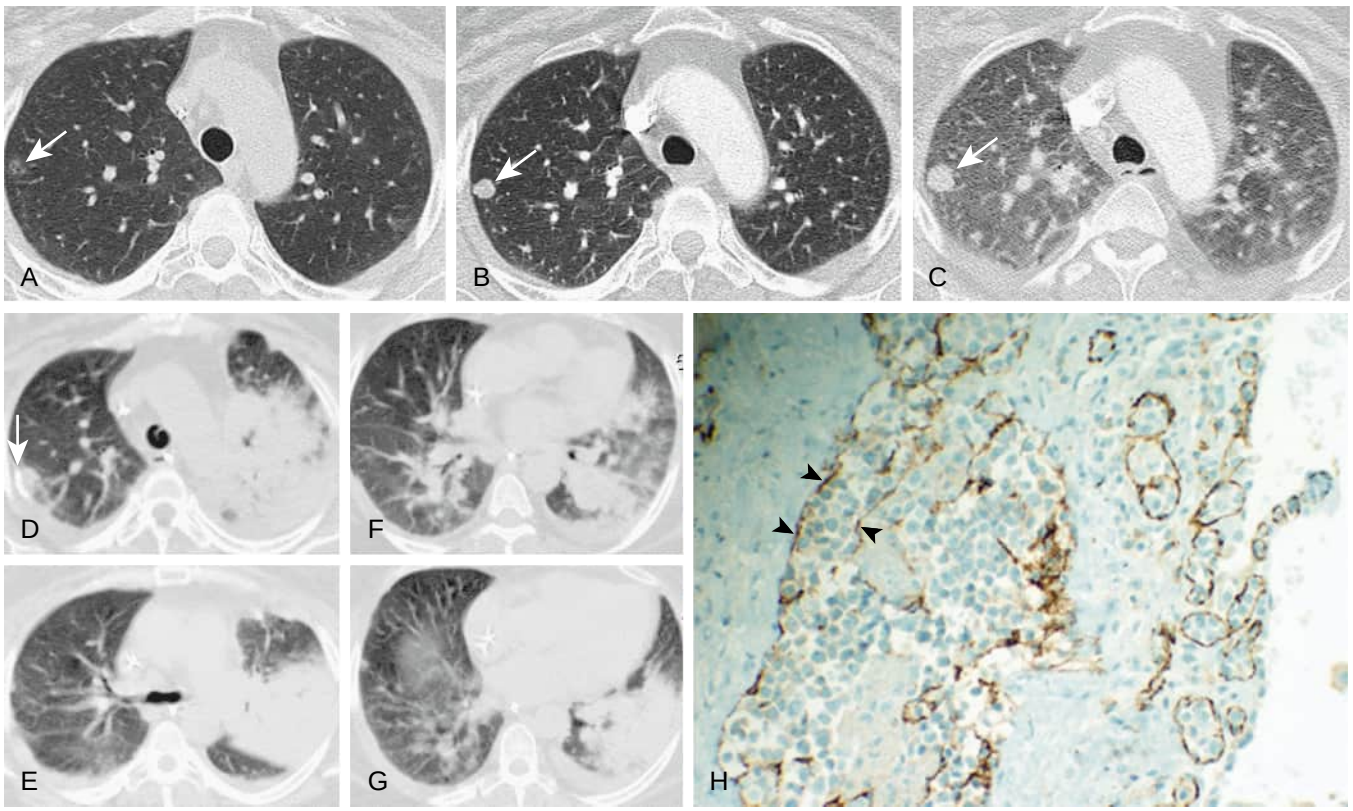
eFigure 78.10 Primary pulmonary mucosa-associated lymphoid tissue lymphoma: multiple nodules. (A–D) Axial chest computed tomography scans displayed in lung windows show multiple ground-glass opacity nodules (*arrows*) associated with small lucent foci. One right lower lobe nodule (*arrowhead*) shows a solid component. Percutaneous transthoracic fine-needle aspiration and core biopsy showed pulmonary mucosa-associated lymphoid tissue lymphoma. (Courtesy Michael B. Gotway, MD.)



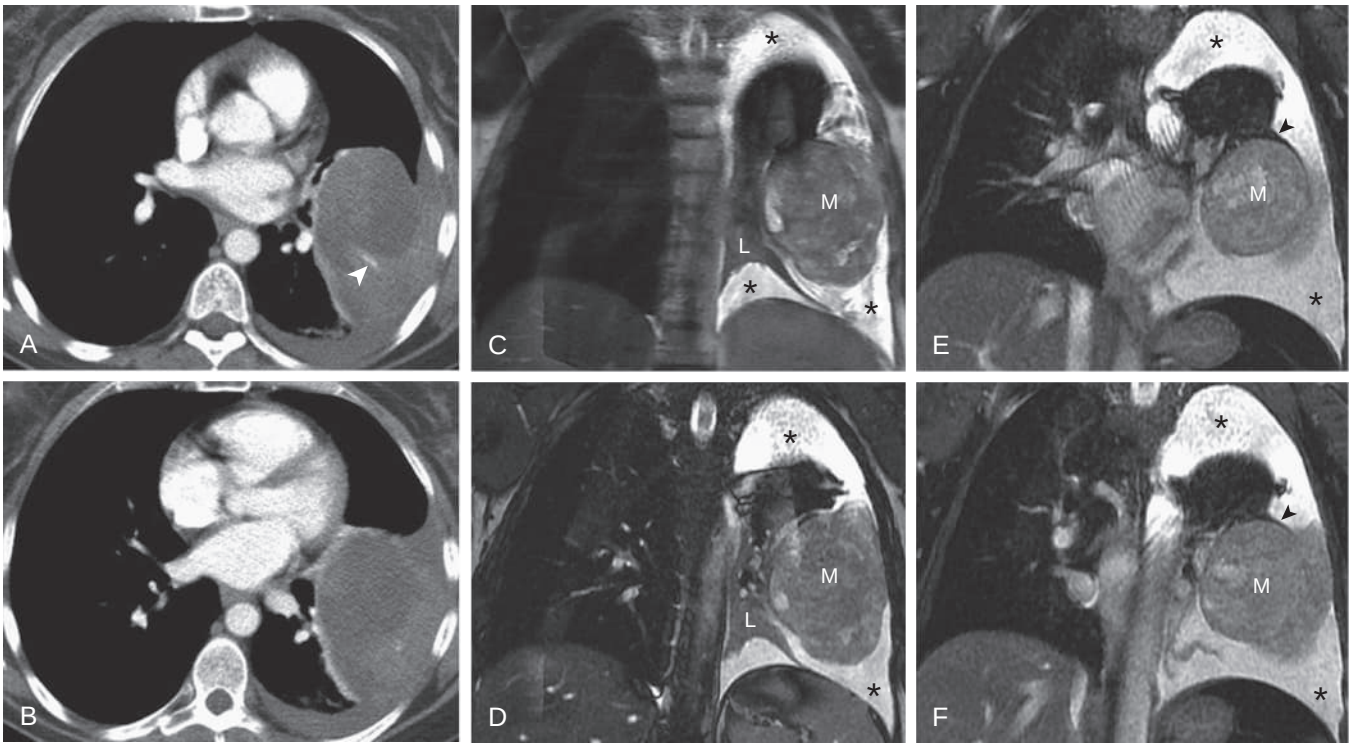
eFigure 78.11 Pulmonary lymphomatoid granulomatosis. Axial chest computed tomography scans displayed in lung (A) and soft tissue (B) windows show multiple, bilateral pulmonary nodules and a lingular mass, shown to represent pulmonary lymphomatoid granulomatosis at biopsy. (Courtesy Michael B. Gotway, MD.)



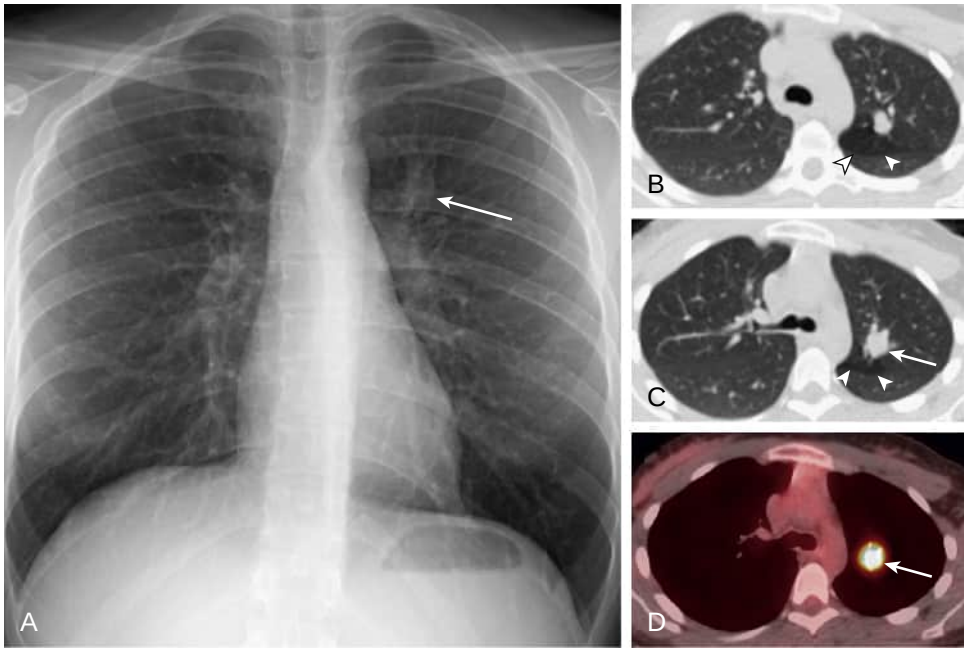
eFigure 78.12 Pulmonary lymphomatoid granulomatosis. (A–C) Axial chest computed tomography scans displayed in lung windows show multiple small nodules distributed along the bronchovascular bundles. A right middle lobe nodule (B, *arrow*) associated with an air bronchogram is present. Surgical lung biopsy showed pulmonary lymphomatoid granulomatosis. (Courtesy Michael B. Gotway, MD.)



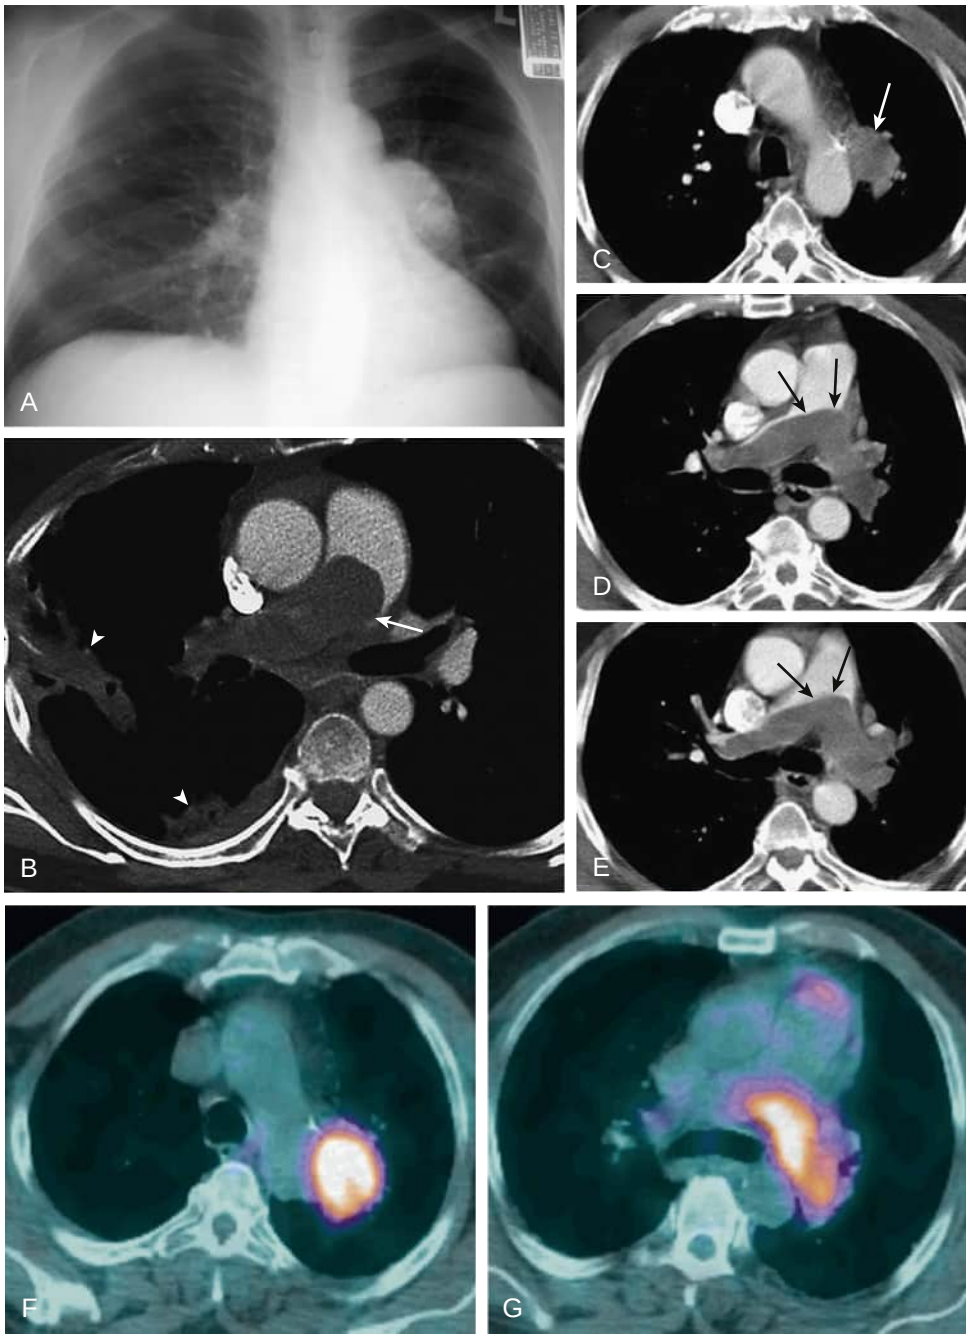
eFigure 78.13 Intravascular large cell lymphoma. (A–C) Axial chest computed tomography scans displayed in lung windows in a 46-year-old woman with sarcoidosis and systemic lupus erythematosus, who reported daily fever and progressive shortness of breath, shows a right upper lobe nodule (*arrow*) growing rapidly over a 2-month period. A corticosteroid therapy burst for 1 week was initiated in addition to the patient's baseline daily dose of 40 mg prednisone, but the patient's symptoms persisted after return to the baseline therapy. (D–G) Axial chest computed tomography scans after return to the baseline prednisone dose of 40 mg shows interval development of multiple, bilateral areas of consolidation and nodularity. A surgical lung biopsy of the right upper lobe nodule, evidenced by right upper lobe suture (*arrow*), was performed. (H) CD31 stain for endothelial cells outlines pulmonary vessels (*brown lined areas, arrowheads*). Note intravascular tumor cells consistent with diffuse, large B cell intravascular lymphoma. (H, Original magnification ×40.) (Courtesy Cristian Jivcu, MD, Cardio-Pulmonary Associates, Monterey, CA, and Michael B. Gotway, MD.)



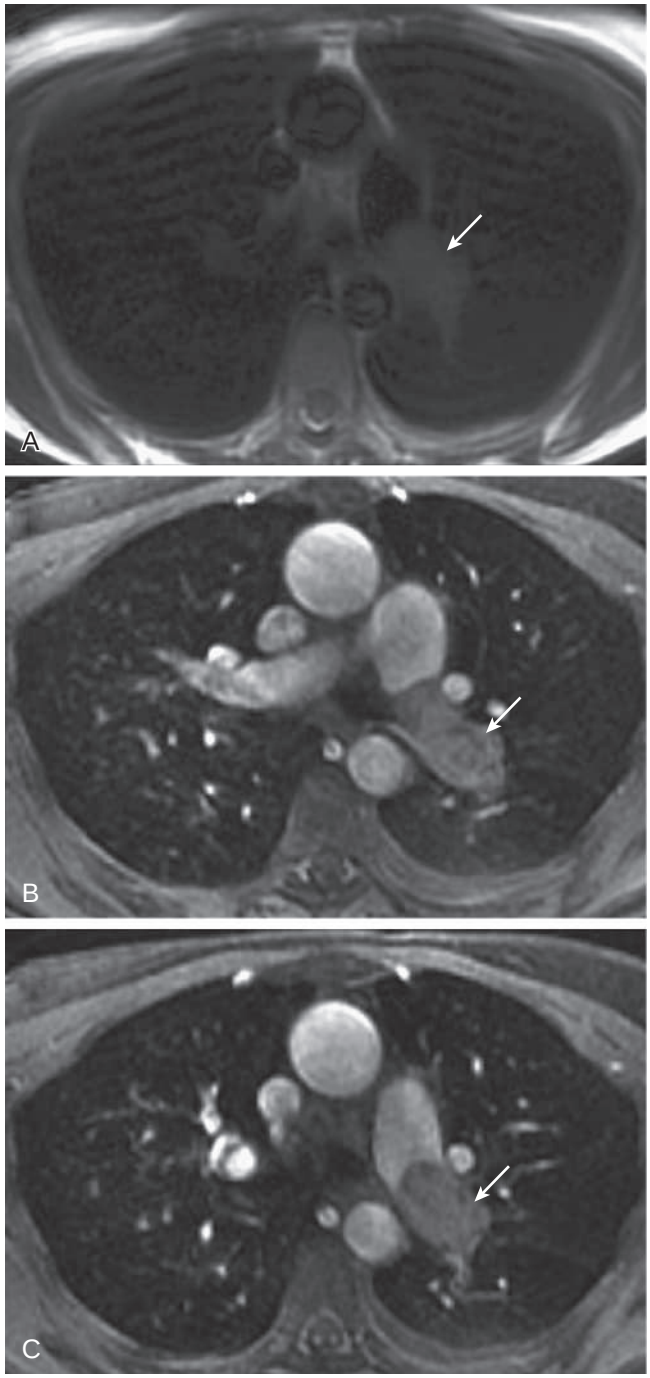
eFigure 78.14 Primary pulmonary leiomyosarcoma. (A–B) Axial enhanced chest computed tomography scans show a large peripheral lung mass associated with a small left pleural effusion. A prominent vessel (A, *arrowhead*) is seen within the mass. (C–F) Coronal magnetic resonance images show a heterogeneous mass (M) with intermediate signal intensity, which reflects the relatively cellular and fibrotic nature of the lesion, arising from the peripheral left lung (L). Some areas of cystic change (the hyperintense foci) are present within the mass. The pulmonary origin of the mass, rather than pleural origin, is suggested by the visible "claw" of lung tissue (E–F, *arrowheads*) surrounding a portion of the lesion. A moderate left pleural effusion (*asterisk*) is present. (Courtesy Michael B. Gotway, MD.)



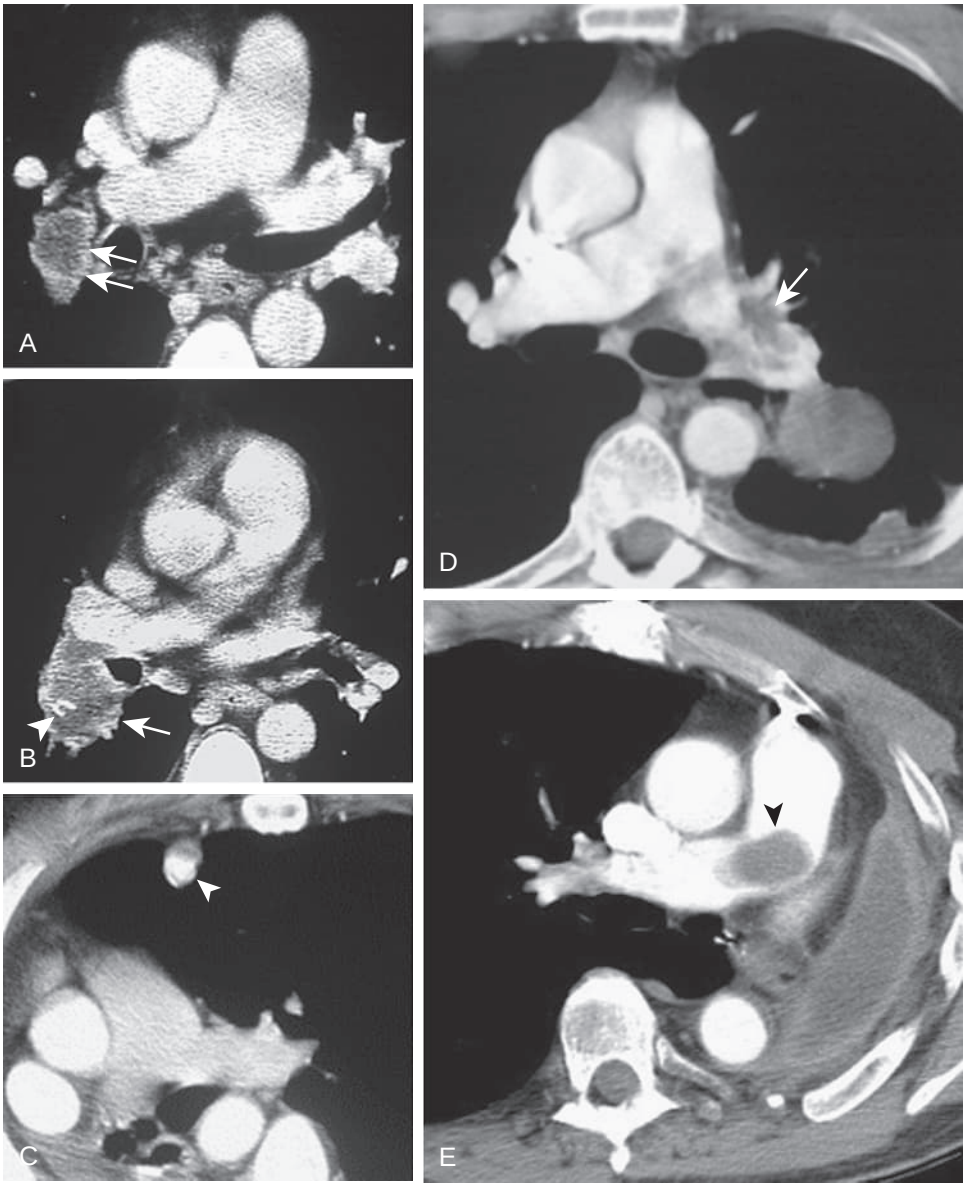
eFigure 78.15 Primary pulmonary leiomyosarcoma: endobronchial origin. (A) Frontal chest radiograph shows a poorly defined medial left upper lobe nodule (*arrow*). (B–C) Axial chest computed tomography scans displayed in lung windows show a circumscribed lesion (*arrow*) in the left upper lobe that could be traced to the apical-posterior segmental left upper lobe bronchus; note presence of hyperlucency distal to the lesion (*arrowheads*), representing postobstructive air trapping. (D) Fused axial positron emission tomography image shows intense metabolic activity within the lesion (*arrow*). (Courtesy Michael B. Gotway, MD.)



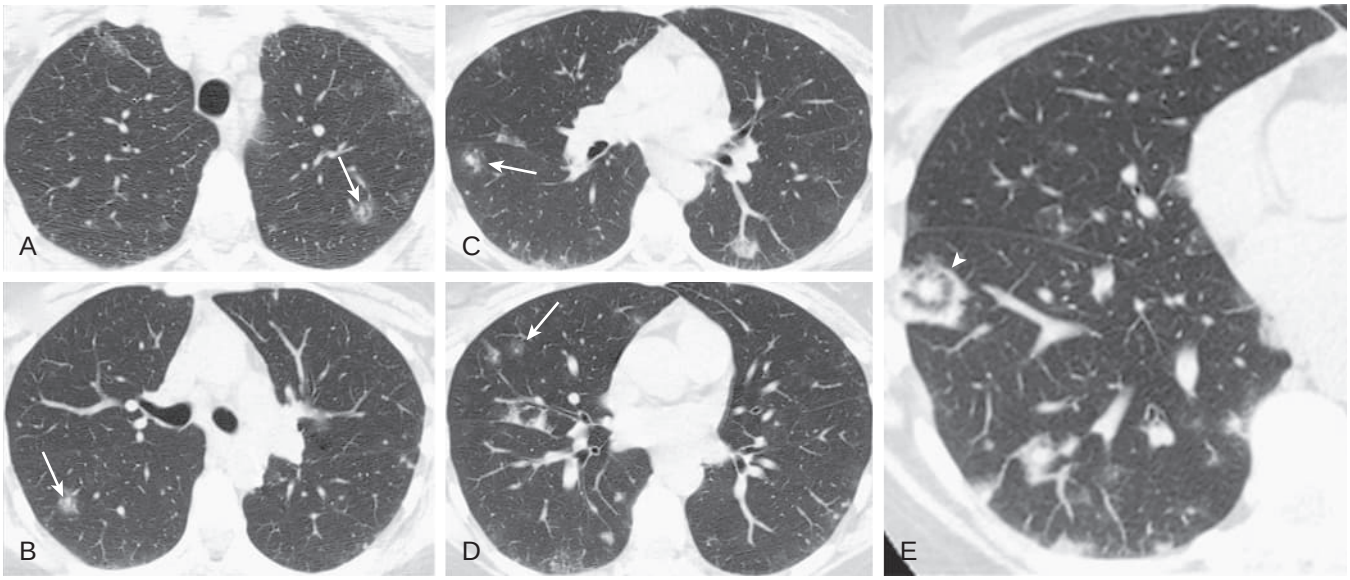
eFigure 78.16 Pulmonary artery sarcoma: imaging appearances. (A) Frontal chest radiograph shows a smoothly enlarged left pulmonary artery associated with left lung oligemia. Whereas pulmonary embolism can result in similar findings, emboli rarely produce findings of this magnitude. (B–E) Axial enhanced chest computed tomography scans in two patients show a large hypoattenuating lesion completely filling the right pulmonary artery (B, *arrow*), associated with pulmonary infarction (B, *arrowheads*). The second patient **(**C–E) shows a large lesion simulating a saddle pulmonary embolism (*arrows*). Both patients were hemodynamically stable and presented with subacute shortness of breath; such a presentation would be exceeding unlikely if pulmonary emboli were the cause of these large, obstructing central intravascular lesions. The full extent of the intravascular lesion and its resemblance to thromboembolic disease is demonstrated in Video 78.1. (F–G) Axial positron emission tomography scan (same patient as in C–E) shows intense hypermetabolic activity within the intravascular lesion, consistent with neoplasm. (Courtesy Michael B. Gotway, MD.)



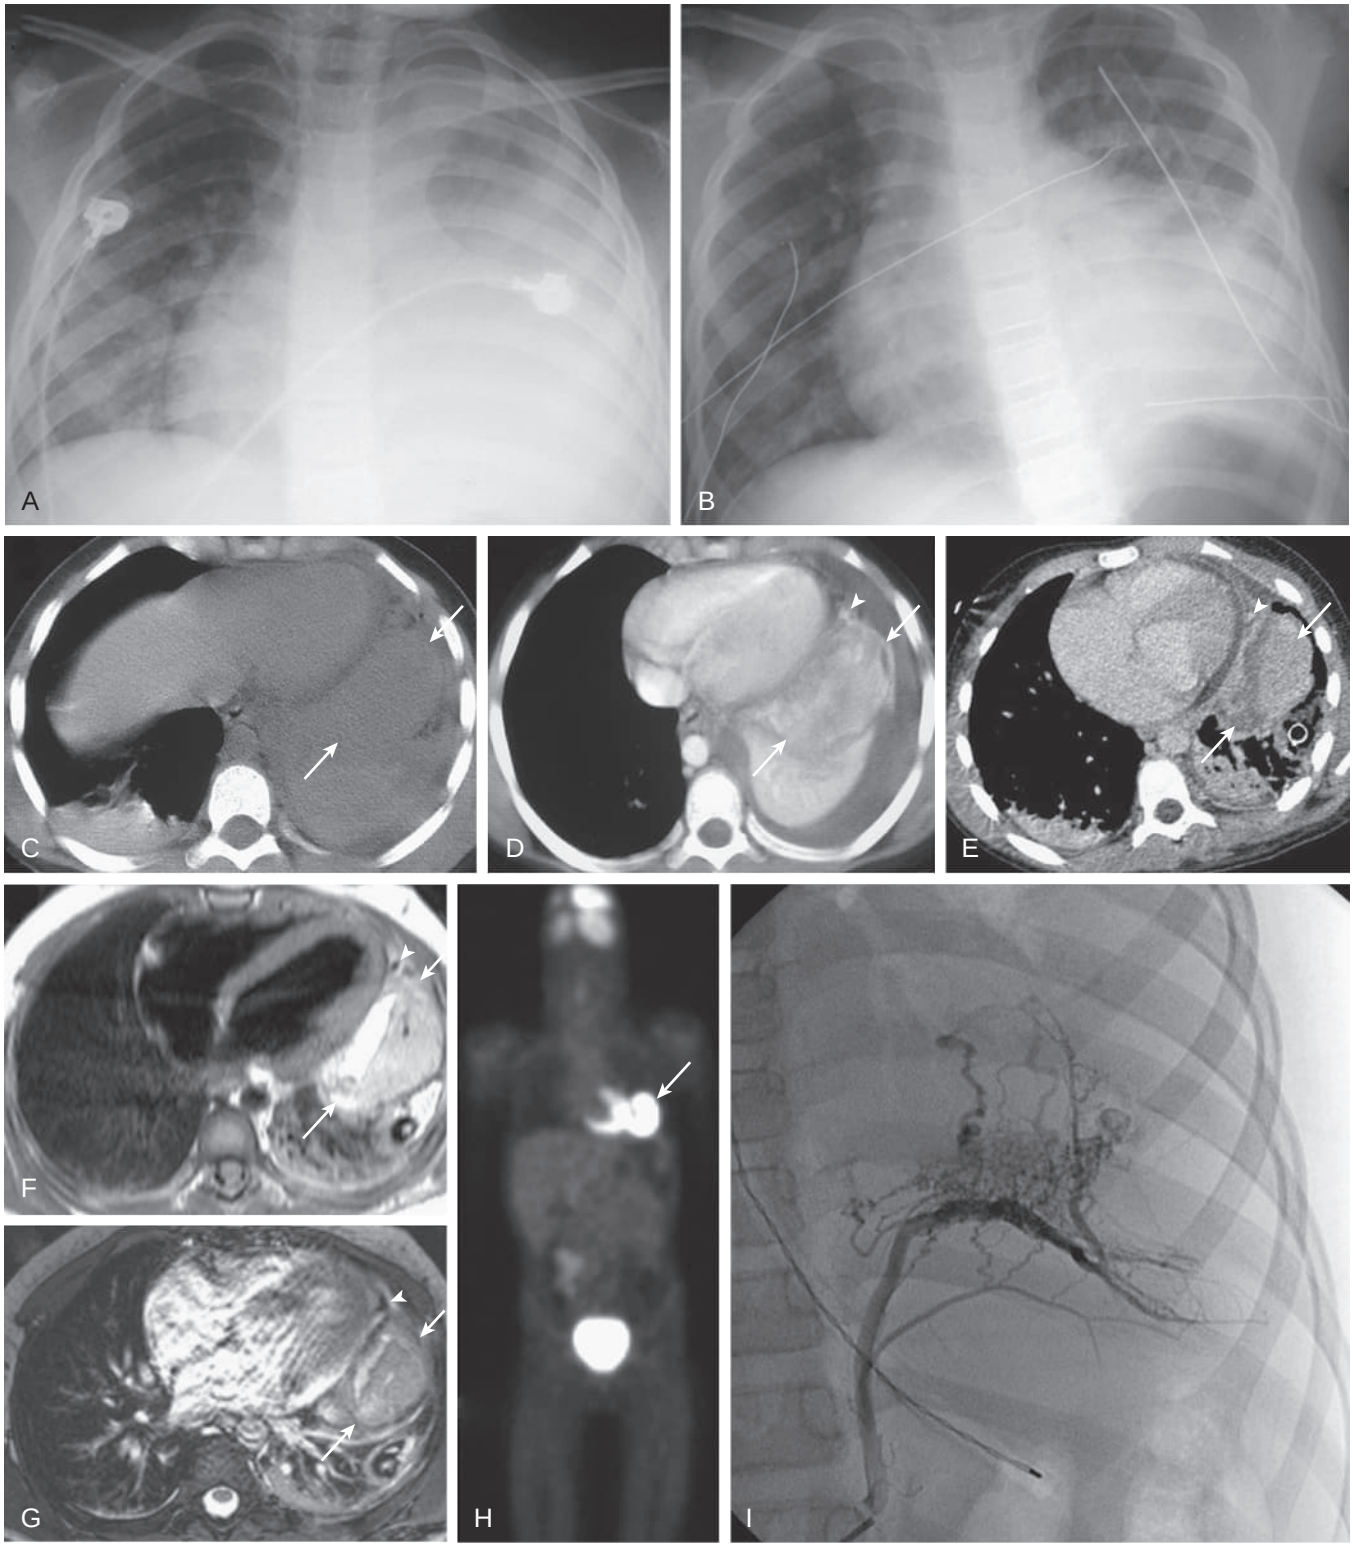
eFigure 78.17 Pulmonary artery sarcoma: magnetic resonance appearance. Axial double-inversion recovery T1-weighted image (A) and axial enhanced fast-spoiled gradient echo images (B–C) show a soft tissue mass (*arrows*) completely filling the left pulmonary artery. Note the faint internal enhancement visible within the intravascular lesion in part B. (Courtesy Michael B. Gotway, MD.)



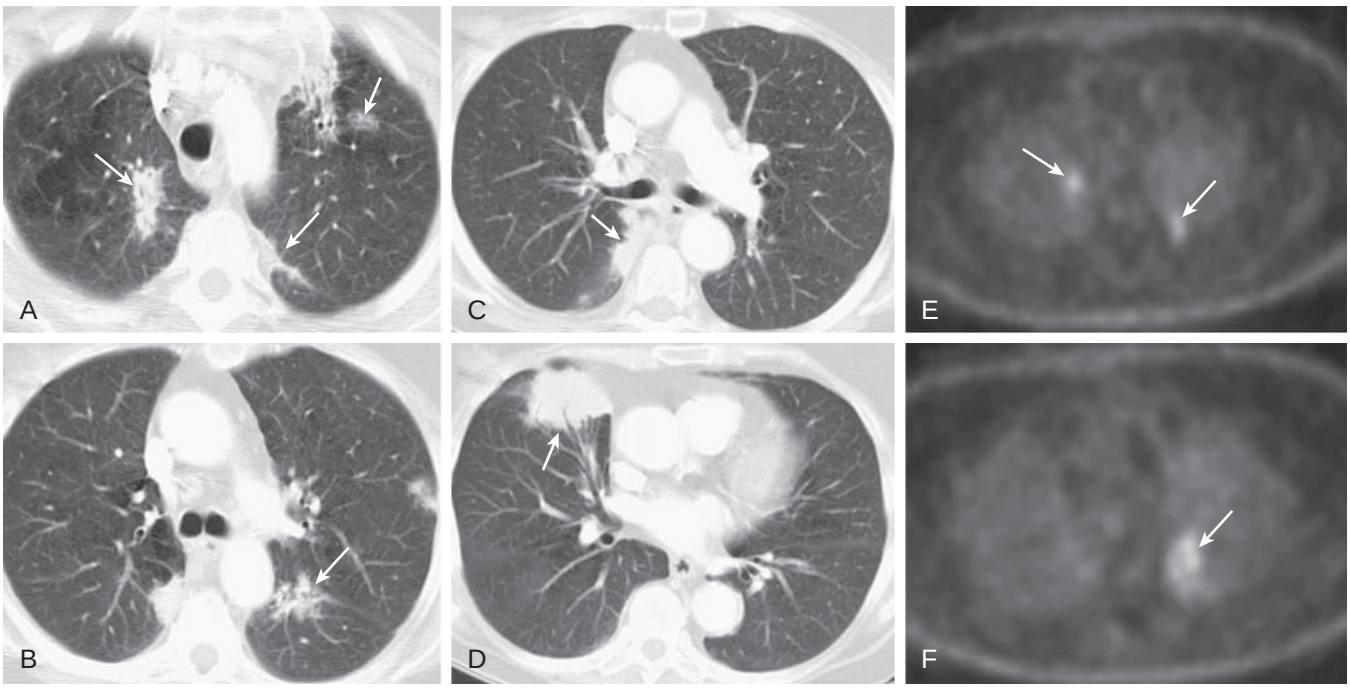
eFigure 78.18 Pulmonary artery sarcoma: tumor recurrence. (A–C) Axial enhanced chest computed tomography scans show right peribronchial lymph node enlargement (A, *double arrows*) associated with a tumor mass arising from the right lower lobe artery (B, *arrow*). Note the small focus of hyperattenuation present within the primary tumor (B, *arrowhead*). The lesion was an osteosarcoma arising with the pulmonary artery. Just over a year after right pneumonectomy, ossified metastatic nodules (C, *arrowhead*) appeared within the left lung. (D–E) In another patient, left pulmonary artery sarcoma (D, *arrow*) is seen, with recurrence (E, *arrowhead*) appearing 1 year after left pneumonectomy. (Courtesy Michael B. Gotway, MD.)



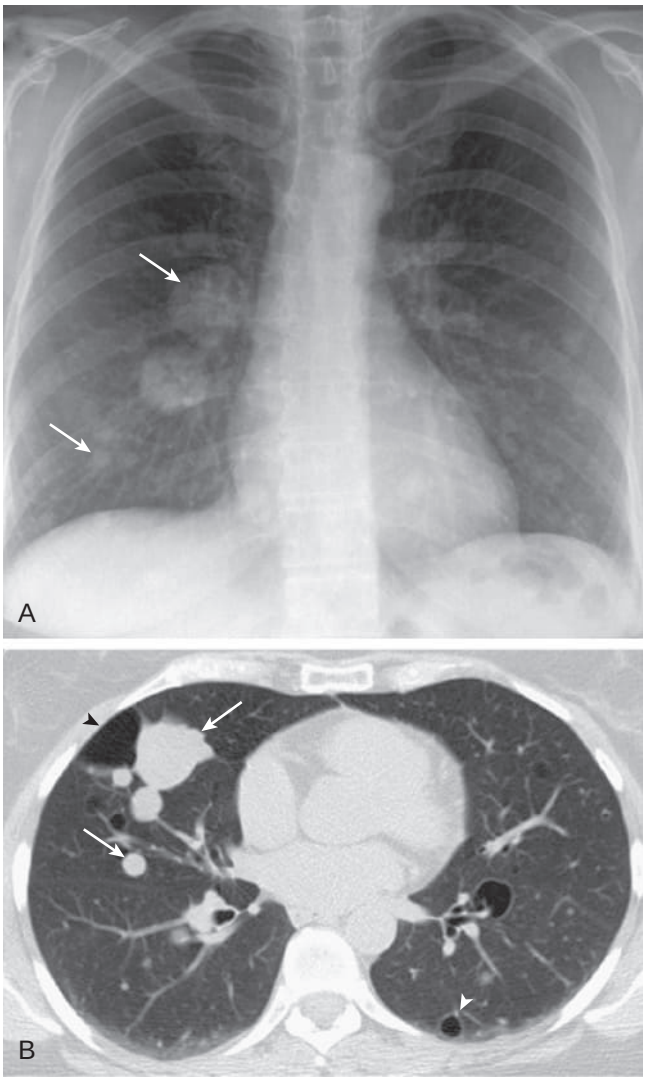
eFigure 78.19 Pulmonary hemangioendothelioma. (A–E) Axial chest computed tomography scans in a 39-year-old woman with cough and hemoptysis displayed in lung windows show multiple, bilateral, variably sized ground-glass opacity nodules with foci of solid nodular internal opacity centrally (*arrows*). One right lower lobe lesion shows peripheral consolidation surrounding ground-glass opacity with a centrally located solid nodular focus (E, *arrowhead*). Surgical lung biopsy proved pulmonary hemangioendothelioma. The lesions have been stable for 1 year during follow-up. (Courtesy Michael B. Gotway, MD.)



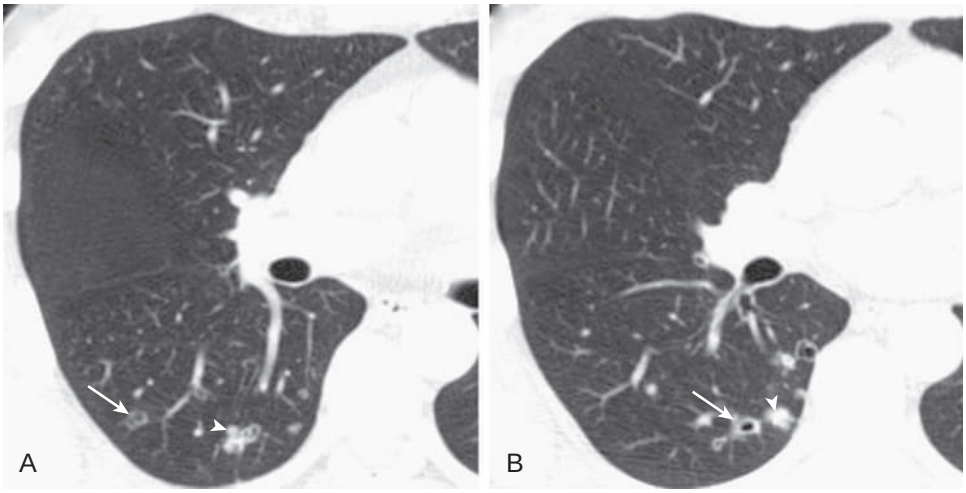
eFigure 78.20 Inflammatory myofibroblastic tumor. (A) Frontal chest radiograph obtained in an 8-year-old boy after being struck by an automobile shows a large left pleural effusion and basal predominant left lung opacity. (B) Frontal chest radiograph obtained after insertion of a surgical thoracostomy tube shows removal of the pleural fluid. During the placement of this tube, the surgeon noted a lesion in the left chest and obtained a small biopsy specimen, but profuse bleeding prevented further assessment. Axial unenhanced (C) and enhanced (D) chest computed tomography shows a left lower anterior chest mass (*arrows*); the mass shows intense enhancement after intravenous contrast administration. A large vessel (D, *arrowhead*) is present in the anterior mediastinum adjacent to the mass. (E) Axial enhanced multislice chest computed tomography again shows the mass (*arrows*) and prominent mediastinal vessel (*arrowhead*). This examination was obtained to search for aberrant systemic arterial supply on the assumption that the lesion might represent a sequestration. No systemic arterial supply arising from the thoracic aorta was seen, but the examination was not extended into the upper abdomen to evaluate the cranial abdominal aorta. Axial T1-weighted (F) and axial gradient echo (G) magnetic resonance images show that the mass (*arrows*) contains high signal in T1-weighted and intermediate to low signal on gradient echo imaging, consistent with hemorrhage. The hypointense structure in the mediastinum adjacent to the mass (*arrowhead*) represents a flow void within a large vessel. (H) Coronal positron emission tomography image shows intense metabolic activity within the lesion (*arrow*). (I) Coronal preoperative angiogram shows aberrant systemic arterial supply to the mass derived from the cranial abdominal aorta; this vessel was embolized to decrease intraoperative blood loss. Inflammatory myofibroblastic tumor was confirmed after surgical resection, and the lesion was noted to be highly vascular and to have invaded the mediastinum at surgery, with the venous drainage of the mass corresponding to the large anterior mediastinal vessel seen on computed tomography (D–E) and magnetic resonance imaging (F–G). (From Gotway MB, Dawn SK. An unusual cause of a pulmonary mass. *Clin Pulmon Med.* 2004;11:266–268.)



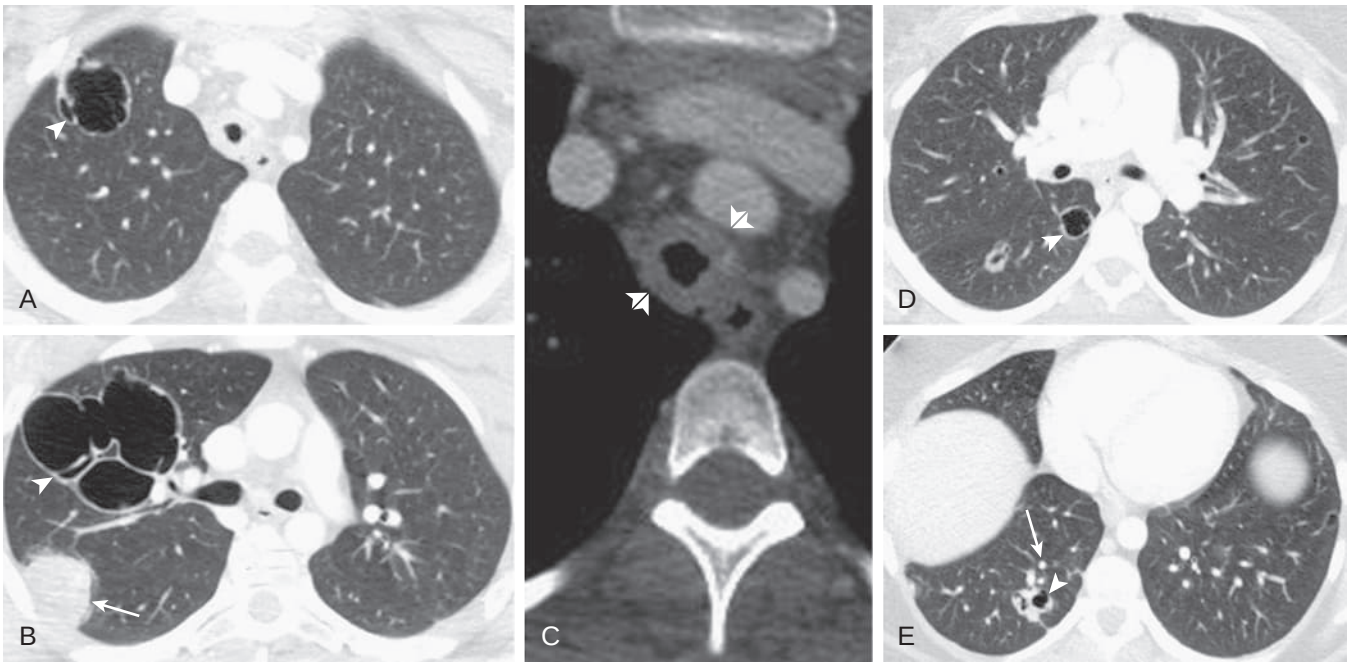
eFigure 78.21 Multicentric inflammatory myofibroblastic tumor. (A–D) Axial chest computed tomography scans displayed in lung windows show multiple, variably sized, poorly defined nodules (*arrows*). (E–F) Axial positron emission tomography images show mildly increased metabolic activity within several of the nodules (*arrows*). The imaging features are ultimately nonspecific, and surgical excision was required to establish the diagnosis. (Courtesy Michael B. Gotway, MD.)



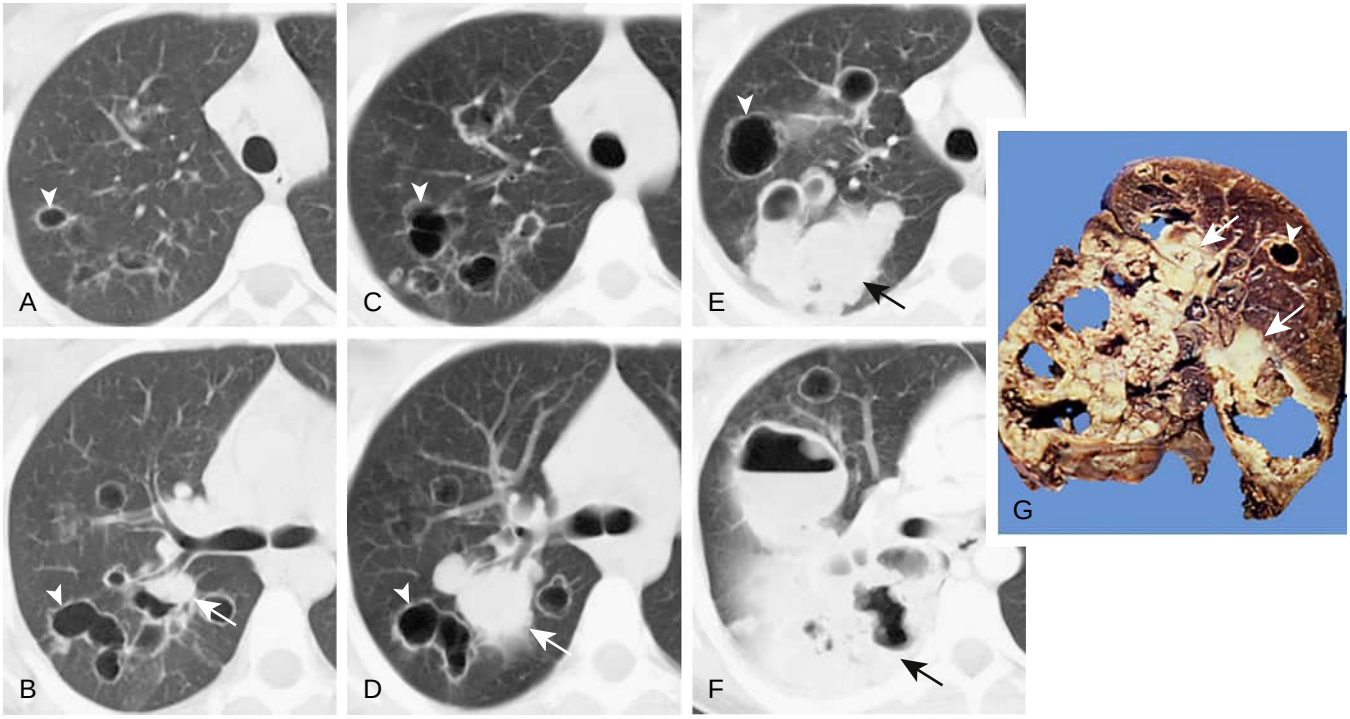
eFigure 78.22 Tracheobronchial papillomatosis: typical chest radiographic and computed tomography findings. (A) Frontal chest radiograph in a patient with tracheobronchial papillomatosis shows several variably sized nodules (*arrows*) bilaterally. (B) Axial chest computed tomography displayed in lung windows shows the typical combination of nodules (*arrows*) and cysts (*arrowhead*). (Courtesy Michael B. Gotway, MD.)



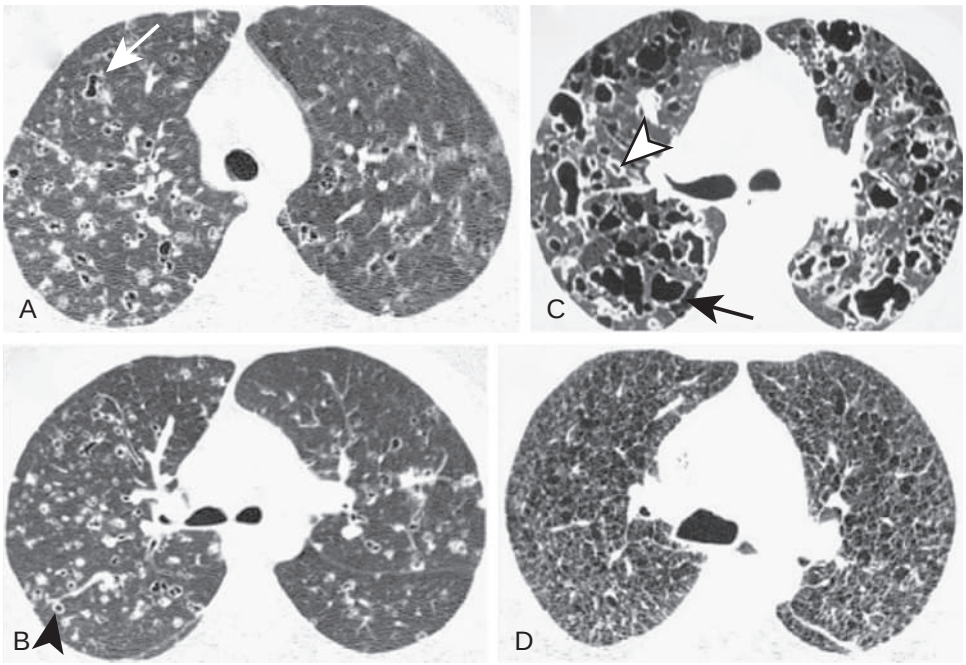
eFigure 78.23 Tracheobronchial papillomatosis: early disease. (A–B) Axial chest computed tomography scans displayed in lung windows show small centrilobular nodules (*arrowheads*) and thin-walled cavities (*arrows*) in the superior segment of the right lower lobe (a relatively dependent distribution). (Courtesy Michael B. Gotway, MD.)



eFigure 78.24 Tracheobronchial papillomatosis. (A–B, D–E) Axial chest computed tomography scans displayed in lung windows show relatively thin-walled, variably sized cysts (*arrowheads*) and nodules (*arrows*). (C) Axial enhanced chest computed tomography displayed in soft tissue windows shows circumferential tracheal wall thickening (*double arrowheads*). (Courtesy Michael B. Gotway, MD.)



eFigure 78.25 Tracheobronchial papillomatosis: progressive disease with malignant transformation. (A–F) Axial chest *computed tomography* (CT) images displayed in lung windows show progressive cyst and cavity enlargement with increasing nodularity related to the cyst walls. (A–B) Axial chest CT scans show mostly thin-walled cyst formation (*arrowheads*) with relatively mild nodularity (B, *arrow*). Axial chest CT scans obtained just over 1 year later shows enlarging cysts (C, *arrowheads*) and marked increase in nodular opacity related to the posterior segment right upper lobe bronchus (D, *arrow*). (E–F) Axial chest CT scans performed just over 2 years after A and B show further enlargement of pulmonary cysts and cavities (*arrowhead*), with marked increase in cavitary nodular right lung opacity (*arrows*). (G) Gross right lung specimen after pneumonectomy shows cystic change (*arrowhead*) with extensive cavitation with internal mural nodularity (*arrows*). The mural nodular opacity represents squamous cell carcinoma development. (Courtesy Michael B. Gotway, MD.)



eFigure 78.26 Langerhans cell histiocytosis. (A–B) Axial chest *computed tomography* (CT) scans displayed in lung windows performed in a 17-year-old patient show features consistent with relatively "early" Langerhans cell histiocytosis: numerous small nodules, some showing cavitation (B, *arrowhead*) and a few developing bizarrely shaped cysts (A, *arrow*). (C) Axial chest CT displayed in lung windows performed in a 30-year-old smoker shows features consistent with more developed Langerhans cell histiocytosis: prominent, bizarrely shaped cysts, with a few small, solid, and cavitating (*arrowhead*) nodules. (D) Axial chest CT displayed in lung windows performed in a 55-year-old smoker shows features consistent with relatively "late," or "burned-out," Langerhans cell histiocytosis: innumerable small cystic areas resembling pulmonary emphysema, which is often coexistent. (Courtesy Michael B. Gotway, MD.)

79 METASTATIC MALIGNANT TUMORS

DOUGLAS A. ARENBERG, MD, FACCP • RISHINDRA M. REDDY, MD

INTRODUCTION
Epidemiology
Clinical History
MECHANISM OF METASTASIS TO THE LUNG
DIAGNOSIS
Differential Diagnosis
Distinguishing Metastasis From Primary Lung Tumors
Pathology
Molecular Classification
Options for Obtaining a Tissue Diagnosis
TREATMENT
Multimodality Therapy of Potentially Curable Disease
Stereotactic Radiotherapy
Radiofrequency Ablation
Surgical Resection of Metastases
Palliative Care
SPECIAL CASES
Airway Metastasis
Vascular Embolic Metastasis
Pleural Metastases
KEY POINTS

INTRODUCTION

The lung is the most common site for metastasis of malignant tumors from other organs. Logic would suggest that this is because the lung alone receives the entire cardiac output. Indeed, this likely does play a role in the eventual seeding of the lungs when cancers metastasize by the hematogenous route. However, a more detailed understanding of the molecular mechanisms dictating organ-specific metastases has made it clear that specific properties of the primary tumor, as well as the microenvironment of both the tissue of origin and of the lung, all play a significant role in directing the process of metastasis to the lung. Paget[1] initially proposed what became known as the "seed and soil" hypothesis in 1889 based on his observations of the nonrandom nature of breast cancer metastasis. Although we can now begin to define mechanisms of organ-specific metastases at a molecular level,[2,3] and therapeutic tools specifically aimed at preventing metastases have been tested,[4] we still lack effective tools to exploit this emerging knowledge. This chapter reviews the epidemiology of lung metastasis, advances in the knowledge of the pathophysiology of metastasis, approaches to help distinguish metastasis from primary lung cancer, advances in diagnostic methods, and treatment options that vary from palliative therapy to curative surgery.

EPIDEMIOLOGY

Estimates of the incidence of lung metastasis among patients with cancer vary from 20–40%.[5,6] However, these estimates have limitations. Most series focus on a single tumor type as the origin of lung metastases. The incidence of lung metastasis also varies depending on the means used for detection and for follow-up; a lower incidence is reported if the metastases are detected because of respiratory symptoms, and it rises progressively if metastases are detected by routine surveillance with chest radiographs or *computed tomography* (CT) scans or from autopsy data. Not surprisingly, the detection of metastases for any given solid tumor type is greater when ^{18}F-fluorodeoxyglucose *positron emission tomography* (PET) scanning is used as a method of surveillance.[7] Although reports of the proportion of cancers that metastasize to the lung varies, the lung is always among the most common sites of metastasis of solid tumors.[5]

CLINICAL HISTORY

Lung metastases or pleural effusions can be the initial presenting finding of an extrathoracic cancer (*synchronous metastases*, discovered at the same time as the primary tumor), or they can manifest later after diagnosis of an extrathoracic malignancy (*metachronous metastases*). Metastases can be found incidentally in the course of follow-up of a prior malignancy or in the context of new pulmonary symptoms, which are more likely to happen when the metastatic lesion is in the central airways. Because of the large degree of reserve pulmonary function in most individuals, metastases to the periphery of the lung rarely produce symptoms, and patients with even a large metastatic tumor burden can present with minimal or no pulmonary symptoms. When nonspecific symptoms of cough, dyspnea, or chest pain or discomfort can be attributed to metastatic lesions, these symptoms usually result from a very large tumor burden (Fig. 79.1), extensive lymphatic infiltration, airway involvement, and/or a large pleural effusion. The first clue to the presence of lung metastasis most commonly comes from surveillance imaging in patients with known prior cancer. The most classic presentation of lung metastasis is the finding of multiple smooth, rounded nodules in the lower lobes. The finding of an incidental solitary pulmonary nodule as the first sign of an extrapulmonary neoplasm makes the distinction between metastasis and a primary lung tumor challenging. The physical examination is unlikely to disclose evidence of lung metastasis but, in the context of a solitary pulmonary nodule, the examination

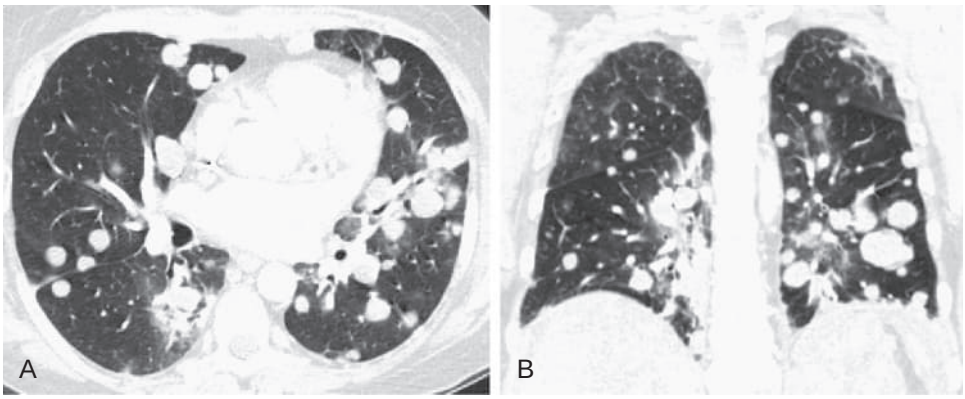

Figure 79.1 Typical appearance of metastatic disease. (A) Axial and (B) coronal thoracic computed tomography displayed in lung windows of a patient with innumerable rounded, lower lobe nodules and a prior history of melanoma. The appearance is typical of metastatic disease. The pretest probability of metastases is so high in such a case that the oncologist may not require a tissue confirmation.

should include a search for malignancy elsewhere in the body (e.g., breast or abdominal masses or enlarged lymph nodes). Rarely, a metastasis can affect the larger central airways and produce localized wheezing that an astute clinician discovers on auscultation. Malignant pleural fluid accumulation produces the physical findings of reduced breath sounds, dull percussion notes, and decreased tactile fremitus.

MECHANISM OF METASTASIS TO THE LUNG

Considering that the lung receives the entire cardiac output, it is perhaps surprising that lung metastases are not even more common among patients with cancer. However, studies show that most circulating cancer cells never form a clinically overt metastatic focus.[8–10] Anatomic access to the pulmonary circulation alone is therefore insufficient to result in clinically evident metastasis. Additional mechanisms must therefore account for the propensity of certain tumors to seed distant organs preferentially.

One of the main processes leading to metastasis involves expression of receptors that bind to ligands in metastatic sites. Chemokines are a group of small cytokines originally discovered as mediators of leukocyte trafficking. Chemokines mediate several important pathologic aspects of tumor biology, including angiogenesis, cell proliferation, invasion, and metastasis.[11] The pattern of constitutive expression of chemokine receptors on cancer cells combined with expression of the corresponding chemokine ligands in various organs may explain the organ-specific pattern of metastasis of a variety of common solid tumor types, including breast, prostate, and lung cancer.[12–14] For example, the chemokine receptors CXCR4 and CCR7 are highly expressed in human breast cancer cell lines, in primary breast tumor samples, and in their metastases. The corresponding ligands for the CXCR4 and CCR7 receptors, CXCL12 and CCL21, are constitutively expressed in organs to which these tumors commonly metastasize (lung, brain, bone, and lymph nodes).[14] In breast cancer cell lines, signaling through the receptors CXCR4 or CCR7 promotes in vitro migration and invasion. Most interestingly, antibodies or small molecule antagonists directed against CXCR4 significantly impaired metastasis of breast cancer cells to regional lymph nodes and lung in vivo. In addition, malignant melanoma, which has a metastatic pattern similar to that of breast cancer but also has a high incidence of skin metastases, showed high expression of the chemokine receptor CCR10 in addition to CXCR4 and CCR7. The ligand for CCR10 (*cutaneous T-cell–attracting chemokine* [CTACK/CCL27]) is highly expressed in normal dermis.[15] Chemokine receptors on cancer cells in concert with tissue-specific expression of their chemokine ligands appear to have a key role in determining the metastatic destination of circulating tumor cells.

Certain molecular processes may specifically increase lung vascular permeability to circulating tumor cells. In a mouse study, transforming growth factor-β was shown to prime breast cancer cells for lung-specific metastasis by up-regulation of the gene *angiopoietin-like 4* (*Angptl4*).[16] Transforming growth factor-β induction of *Angptl4* in breast cancer cells enhanced their subsequent retention in the lungs but not in bone. The investigators in this study showed that tumor cell–derived *Angptl4* disrupted the pulmonary microvascular cell-cell junctions, thereby increasing the permeability of lung capillaries and facilitating the passage of tumor cells into the lung parenchyma. In contrast, in the bone marrow sinusoids, which are normally the more leaky microvascular beds, this mechanism does not confer an advantage.[16]

Other processes may help support the metastatic cell in its lung microenvironment. In another mouse study, tumor cells were preceded into the metastatic niche by bone marrow–derived cells that express the type 1 vascular endothelial cell growth factor receptor. These investigators demonstrated that the receptor-expressing bone marrow–derived cells (1) arrived at the metastatic site before tumor cells, (2) accumulated in the target metastatic organ after either injection of tumor cells or treatment with tumor cell–conditioned media, and (3) established a premetastatic niche in a tumor-specific fashion (i.e., they established a permissive environment for metastasis in an organ-specific pattern that varied depending on the tumor type).[16a] Other investigators demonstrated that the protein metadherin is present on the surface of metastatic breast cancer cells and preferentially facilitated adherence to the pulmonary vascular endothelium.[17]

Although some processes enhance lung-specific metastasis, there are yet other mechanisms by which immune surveillance specifically inhibits lung metastasis. A study by Hanna and colleagues[18] showed that a certain subset of tissue resident monocytes, originally referred to as patrolling monocytes, specifically attenuated the establishment of metastatic foci in the lung in mice receiving experimental intravenous metastases.[19] In summary, tissue-specific metastases arise in a nonrandom fashion determined

by identifiable molecular mechanisms that involve both tumor-derived soluble factors and microenvironment-specific ligand-receptor interactions.

A further refinement in our understanding of the mechanisms of metastasis comes from a study that examined isolated efferent blood from primary tumors in mice. Primary tumors shed tumor fragments, or clusters, consisting of both malignant cells and host stromal fibroblasts. Importantly, the viability of circulating tumor cells was nearly twofold higher in these heterotypic tumor clusters as compared with single tumor cells shed from the primary tumor. These chaperone stromal fibroblasts survived, proliferated, and conferred a survival advantage in lung metastatic deposits. Selective depletion of carcinoma-associated fibroblasts from mice after primary tumor removal significantly inhibited the growth of metastatic deposits.[20] The study further demonstrated that human brain metastases, but not primary brain tumors, contained carcinoma-associated fibroblasts, a finding supporting the hypothesis that the fibroblasts enhanced the metastatic malignant process. This series of experiments, which required modern molecular techniques and cellular-lineage tracking, brought the field back full circle to Paget's seed and soil hypothesis. The study investigators pointed out that the tumor cells facilitated lung metastasis by "…bringing their own soil."[20] These advances are driving the search for new treatments to prevent cancer metastasis. Metastases are nearly universally responsible for cancer mortality and, as these molecular insights are exploited to develop novel strategies for prevention or treatment of metastases, survival *with* cancer (as opposed to a cure *for* cancer) is an attainable goal. Figure 79.2 illustrates some of the potential mechanisms behind tissue-specific metastasis to the lung from extrapulmonary malignancies.

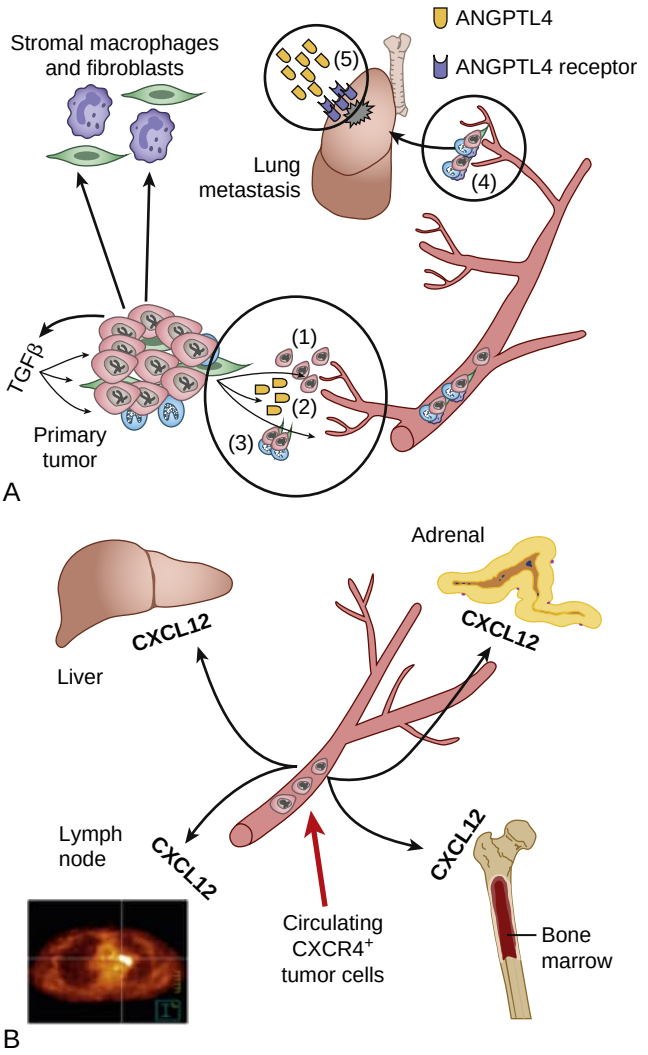

Figure 79.2 Illustration of molecular mechanisms that can drive lung specific metastasis from extrapulmonary malignancy. (A) The primary tumor can release *(1)* single tumor cells, *(2)* soluble substances such as *angiopoietin-like 4* (ANGPTL4), and *(3)* heterotypic tumor fragments, which have a survival advantage that renders them more likely to implant and survive in the lung *(4)*. In the lung, tumor-derived angiopoietin-like 4 creates a microvascular bed that is leaky and conducive to entry of tumor cells in the lung *(5)*. (B) Tumor cells bearing CXCR4, the receptor for the CXC chemokine *CXC chemokine ligand 12* (CXCL12), are preferentially attracted to organs that constitutively produce CXCL12. TGF-β, transforming growth factor-β.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Given the range of diagnostic and therapeutic options in cases of known or suspected lung metastasis, patient care is optimal when delivered within the context of a multidisciplinary team. For example, when deciding whether to perform a biopsy on a lung nodule by bronchoscopy or by using image guidance in a patient with a prior cancer, a chest physician is well served by speaking to the oncologist and/or the surgeon about available therapeutic options and how the results of a biopsy would alter those options. If a patient with a solitary nodule suspected to be an isolated lung metastasis is a surgical candidate, and complete resection is medically and technically feasible, a preoperative tissue diagnosis may not be necessary to undertake resection. Conversely, surgeons may prefer a preoperative tissue diagnosis to improve their discussion of risks, benefits, and alternatives with the patient. Surgeons may also prefer knowing whether a nodule is a metastasis or a primary lung cancer in planning the appropriate surgical procedure, whether a wedge resection, a lobectomy, or an anatomic segmentectomy. With the development of targeted therapy and immune checkpoint inhibitors, the role of and necessity for tissue diagnosis in patients with suspected lung metastases have also changed. Proceduralists and treating oncologists must communicate regarding the need for specific testing for mutations, oncogene rearrangements, or tissue staining to ensure that enough tissue is collected and is processed properly. For these and other reasons, management of these patients is best served by a multidisciplinary discussion.

In general, the patient with a prior history of cancer and a suspected lung metastasis should be managed with knowledge of several interacting factors: the type of prior cancer, its natural history, its propensity to cause lung metastasis, the potential effectiveness of systemic or radiation therapy, and the number and location of lung nodules. A decision to perform a biopsy should consider the likelihood of an alternative diagnosis and whether the results of the biopsy will change the management options.

The diagnostic possibilities for a lung nodule or multiple nodules in the patient with a history of cancer vary with the

type of prior cancer. For example, the implications of finding a cavitary nodule in a patient with prior leukemia after a bone marrow transplant are quite different from the same radiographic finding in an individual with prior head and neck cancer. In general, the differential diagnosis of a lung nodule in a patient with prior cancer includes the same diagnoses found in the general population, with the obvious exception that metastatic disease must be considered as well. Both primary malignant and benign causes, including infectious and noninfectious conditions, should be considered (Table 79.1).

DISTINGUISHING METASTASIS FROM PRIMARY LUNG TUMORS

When a nodule (or nodules) is discovered in a patient with a prior history of cancer, it is important to distinguish lung metastasis from a primary lung cancer because the treatment can be very different. Clues such as the type of prior cancer, radiologic characteristics of the nodule, and the pathologic analysis of biopsy material can be used to guide treatment decisions. Multiple pulmonary nodules with smooth borders located in the lower (dependent) lobes are most likely to be metastatic based on clinical grounds alone. When a single nodule is the only evidence of metastasis, recognizing it as metastatic can be more difficult. In some instances, the origin of the previous cancer can provide a clue to the likelihood of a metastasis versus a primary lung cancer. In a retrospective study of patients with single pulmonary nodules and a prior history of cancer, multiple factors were examined as possible predictors for metastasis, including the histologic characteristics of the original extrapulmonary neoplasm, the patient's age, and smoking history.[21] Of 161 patients with solitary pulmonary nodules, 81 (50%) were determined to have a primary lung cancer, a finding more common in patients with a prior history of cancer of the head and neck, bladder, breast, cervix, bile ducts, esophagus, ovary, prostate, or stomach. Fifty patients (31%) were determined to have metastasis, a finding more common in patients with salivary, thyroid, and adrenal tumors; melanoma; and sarcoma. Primary lung cancer and metastases were equally likely in patients with prior cancer of the colon, kidney, or uterus. In patients with prior lymphoma or leukemia, there was a high proportion of patients with a benign diagnosis (6 of 14), perhaps reflecting the predisposition of these patients to infections.[21] In total, 30 of 161 patients (19%) had benign nodules. The large percentage of benign diagnoses in this study by Quint and colleagues[21] (1994 to 1999) contrasts with a larger but much older study by Cahan and associates[22] (1940 to 1975) in which only 11 of 800 patients (1.3%) proved to have a benign diagnosis. The higher incidence of benign disease in the more recent study can probably be explained by two factors: the greater use of CT scanning and thus higher rate of detection of nodules in the more modern study and the fact that the earlier study was a surgical series in which patients with a high pretest probability of benign disease may have been excluded. A consistent finding in these two studies, representing nearly 40 years from two large centers, was the high proportion of patients with head and neck squamous or esophageal cancers who subsequently developed *primary* lung cancer. Of course, these aerodigestive cancers share common risk factors, and the presence of a smoking history increases the likelihood that a solitary lung nodule in someone with a prior extrapulmonary neoplasm will prove to be lung cancer. These older studies and more recent data[23] confirm that the histologic origin of previously diagnosed cancer can help predict the probability that a pulmonary nodule in a patient with a previously treated cancer is metastatic malignancy, a primary lung cancer, or a benign lesion (Table 79.2).

Table 79.1 Differential Diagnosis of Single or Multiple Pulmonary Nodules in Patients With Prior Cancer

MALIGNANT
Metastasis
Primary lung cancer
BENIGN

PATHOLOGY

When a nodule is found to be malignant, the etiology of the nodule can be assessed by comparing the pathologic features

Table 79.2 Probability of Metastasis in a Solitary Pulmonary Nodule Based on a Prior Diagnosis of Cancer

Origin of Prior Tumor	Probability of Metastasis	Probability of Primary Lung Cancer	Probability of Benign Etiology
Head and neck	+	++++	+
Bladder or prostate	+	+++	+
Esophagus, biliary, stomach	+	+++	+
Breast	++	+++	+
Endometrial	++	++	+
Colorectal	++	++	+
Salivary, adrenal, kidney, thyroid, thymus	++	++	+
Melanoma	+++	++	+
Sarcoma	+++	+	+
Germ cell, testicular	+++	+	+
Leukemia or lymphoma	–	+	+++

Relative likelihood of primary cancer, metastatic cancer, or a benign pulmonary nodule from very low (+) to very high (++++) and intermediate (++ or +++).

Data from Quint LE, Park CH, Iannettoni MD. Solitary pulmonary nodules in patients with extrapulmonary neoplasms. *Radiology.* 2000;217:257-261.

of the prior cancer and the lung nodule. The pathologist's approach begins with a knowledge of the prior cancer, its stage and grade (if applicable), and the pretest likelihood of lung metastasis from a tumor with such characteristics. The gross and microscopic patterns of the possible metastasis may be sufficiently similar to the original primary tumor that the diagnosis is rendered on morphologic criteria alone. If the histologic features are not sufficient to distinguish between metastasis and primary lung cancer,[24] immunohistochemical stains are used to help guide the diagnosis (Table 79.3). Lung adenocarcinoma can be identified by specific immunohistochemical markers, including cytokeratin 7, thyroid transcription factor 1 (see eFig. 21.2B), and napsin.[24,25] For example, cytokeratin 7 can be useful for distinguishing adenocarcinoma of the lung from colon cancer metastasis, with cytokeratin 7 favoring lung, and cytokeratin 20 favoring colon.[24] Thyroid transcription factor 1, a nuclear transcription protein expressed in embryonic and adult epithelial cells of the lung and thyroid,[26] is detected in 75% of lung adenocarcinomas, but it is rarely detected in other adenocarcinomas that commonly metastasize to the lungs, except for thyroid cancer.[26] Napsin is an aspartic proteinase present in lung and kidney epithelial cells, and a newer marker for lung adenocarcinoma with similar sensitivity but slightly greater specificity for lung origin than thyroid transcription factor 1. Markers specific for other tumors can of course be used to identify lesions as metastatic; for example, breast cancers can generally be identified if they maintain their original pattern of staining for estrogen receptor or Her-2/Neu, melanomas can be identified by S100 or HMB45 immunoreactivity, and renal carcinoma can be identified by immunostaining for the product of paired box gene 2 or 8. Thus, in instances where the metastatic lesion retains specific markers present in the primary tumor, these stains can be useful for identifying metastases. Squamous carcinoma presents a challenge when attempting to distinguish between a metastasis and a primary lung carcinoma because there are no markers currently capable of distinguishing between squamous tumors of lung origin and those arising from extrapulmonary epithelial tissues. In such situations, the diagnosis relies almost entirely on clinical judgment.

Table 79.3 Immunohistochemical Stains Useful for Distinguishing Primary Lung Cancer From Metastatic Cancer From an Extrapulmonary Primary Cancer

Cancer	Positive Markers	Negative Markers
Lung (adenocarcinoma)	CK7, TTF-1, SP-A, SP-B, napsin	CK20, PAX2, PAX8
Lung (squamous carcinoma)	CK5/6, p63, p40	*
Colon	CK20	TTF-1, napsin
Bladder (urothelium)	S100P, GATA3	TTF-1, napsin
Breast	ER, PR, Her2/Neu	TTF-1, napsin
Prostate	PSA, prostatic acid phosphatase	TTF-1, napsin
Melanoma	HMB45, S100, tyrosine hydroxylase	Cytokeratin†
Thyroid	TTF-1, thyroglobulin	Napsin
Germ cell	Alpha-fetoprotein	TTF-1, napsin
Renal cell	PAX2, PAX8, RCCma	TTF-1, napsin

*There are no accepted stains to distinguish between lung primary and metastatic squamous cancer.
†Fewer than 10% of melanoma metastases stain positively for cytokeratin.
CK, cytokeratin; ER, estrogen receptor; PAX, paired box gene; PR, progesterone receptor; PSA, prostate-specific antigen; RCCma, renal cell carcinoma marker; SP, surfactant protein; TTF, thyroid transcription factor.

MOLECULAR CLASSIFICATION

Progress in molecular characterization of tumors has provided tools to assist in determining the nature of a lung nodule. Giordano and colleagues[27] attempted to develop a molecular classification scheme to discriminate among adenocarcinomas of the lung, colon, and ovary. These investigators identified three groups of 20 differentially expressed genes that correctly identified the origins of all but two of 154 tumors.[27] Other groups of investigators have proposed classifiers for a broader representation of tumors in an effort to categorize the origin of tumors diagnosed as carcinoma of unknown primary. Tothill and colleagues[28] developed a gene array–based classifier, validated with real-time polymerase chain reaction on 229 samples of known origin (a training set). This gene classifier was then able to assign a "tissue of origin" in 9 of 11 cases of carcinoma with unknown primary.[28] The two specimens that the gene classifier failed to classify were squamous carcinomas. Subsequent review of the clinical course of the patients supported the assessment of the gene classifier.[28] In another study, a gene expression–based classifier was devised to distinguish metastases of head and neck squamous carcinoma from primary lung squamous cancer, a task made difficult by both the histologic similarity and the shared risks for both diseases. The expression levels of 10 genes were able to discriminate between tumors of the lung and of the upper aerodigestive origin with high accuracy in both the training and validation samples.[29]

Finding viral antigens may help identify the source of a malignancy. The role of oncogenic strains of *human papillomavirus* (HPV) in squamous carcinogenesis of the cervix and oropharyngeal mucosa had prompted studies to determine whether HPV was involved in the development of lung squamous carcinoma.[30] Investigators using both in situ hybridization and polymerase chain reaction–based genotyping found that, in 132 squamous lung carcinomas, only 5 (1.5%) contained the HPV genome. All five of these patients had prior diagnoses of HPV-related squamous carcinoma in a different tissue, and thus the HPV-positive tumors were considered to be metastatic.[31] This would suggest that the finding of HPV-associated squamous cancer in the lung may serve as an indicator of metastasis, particularly in the setting of a prior HPV-positive extrapulmonary malignancy. Other investigators have used combined characterization of p53 and HPV typing to distinguish metastatic head and neck squamous cancer from primary lung cancer.[32] Molecular techniques such as these may provide new ways of classifying tumors as primary or metastatic when such characterization is needed to determine the best means of treatment.

OPTIONS FOR OBTAINING A TISSUE DIAGNOSIS

A diagnosis may be confidently made without the need for a biopsy when a patient with a history of prior cancer

known to metastasize to the lungs presents with nodules with highly typical characteristics: multiple, new, or growing lower lobe pulmonary nodules with smooth borders. A diagnosis may also be possible without the need for a biopsy in the common situations where measurable diagnostic serum markers exist (e.g., cancer antigen 19-9, cancer antigen 125, carcinoembryonic antigen, alpha-fetoprotein, β-human chorionic gonadotropin, CYFRA21-1 [a fragment of cytokeratin 19]). However, for tumors other than those of germ cell origin, these epithelial markers are not sufficiently specific, and a biopsy is usually warranted to guide therapy. In all cases, before performing a lung biopsy, it is important to search for evidence of metastasis to other sites where a less-invasive biopsy may yield the diagnosis. This should begin with a thorough history and physical examination. In older series, many of the data on tissue biopsies were derived from surgical material, and this remains the gold standard because of the quantity of material available to the pathologist.[22] Surgery, generally video-assisted thoracoscopic surgery, can be used for diagnosis when it is also the appropriate definitive therapy for patients with completely resectable lung metastases from solid tumors. However, there are nonsurgical biopsy options, each with strengths and drawbacks that can be weighed to achieve the best balance of certainty, risk, and cost. Fiberoptic bronchoscopy, percutaneous CT-guided biopsy, and surgical resection are discussed here, with each successive option providing increased accuracy (sensitivity and negative predictive value) but also increased risk and cost.

Bronchoscopy

Fiberoptic bronchoscopy is particularly useful for accessing centrally located lesions and mediastinal lymph nodes. Endobronchial ultrasound–guided transbronchial needle aspiration of enlarged mediastinal lymph nodes is safe and has excellent diagnostic accuracy for malignant involvement of mediastinal lymph nodes (see Chapter 27). In patients with a prior history of cancer, the finding of mediastinal adenopathy still has a very broad differential diagnosis, including benign or inflammatory reactive adenopathy, and pathologic confirmation should almost always be pursued. Endobronchial ultrasound–guided transbronchial needle aspiration is an excellent diagnostic option in such cases.[33] The accuracy of standard bronchoscopy for lung parenchymal lesions declines rapidly as the distance from the main-stem bronchi increases, so that traditional transbronchial sampling techniques have less than 20% sensitivity for peripheral lung nodules.[34] The increasing use and availability of navigational bronchoscopy have allowed biopsy of small peripheral lung nodules with greater accuracy. A multicenter prospective registry study involving more than 1200 patients (with nodules of unknown etiology, including those suspected of representing primary and/or metastatic disease) and experienced navigational bronchoscopists showed a rate of diagnostic yield of 73%. A retrospective analysis of the *American College of Chest Physicians Quality Improvement Registry, Evaluation, and Education* (AQuIRE) by Ost and colleagues[35] showed a wider range of success with navigation bronchoscopy, so navigation bronchoscopy should be reserved for situations in which the available expertise and track record suggest a high probability of a diagnostic result. By using bronchoscopy, multiple samples can be taken from one area or from multiple different nodules in a single procedure without an appreciable increase in the risk for pneumothorax. Given the low risk of pneumothorax (1–5%) and of major bleeding, the chief risk of the bronchoscopic biopsy, even when combined with electromagnetic navigation and real-time radial-probe ultrasound, is that of a nondiagnostic biopsy.[36] In the future, newer robotic-guided bronchoscopy systems may offer the ability to perform biopsies on even smaller, more peripheral nodules with greater accuracy. Sputum cytology, although proven for primary lung cancer, has not been evaluated for its utility in diagnosing metastases.

Computed Tomography–Guided Biopsy (see Chapter 21)

CT-guided biopsy by experienced clinicians has excellent accuracy.[37] This approach has greater sensitivity than bronchoscopy, particularly for peripheral lesions. The sensitivity of CT-guided biopsy of lung nodules varies with the size of the lesion, with a 65–75% accuracy for smaller lesions (<1 cm diameter) and a greater than 95% sensitivity for lesions larger than 1.5 cm in diameter.[38–40] Larger size and a more peripheral location are associated with greater diagnostic accuracy[41] as well as lower risk.[42] Core biopsies can be obtained in addition to or instead of cytologic material (see Fig. 21.3). The major risk of CT-guided transthoracic needle biopsy is pneumothorax, with up to 35% of patients developing pneumothoraces and 10–15% requiring tube thoracostomy or catheter drainage.[43] The risk of pneumothorax appears to increase with the length of the needle tract, with the presence of obstructive lung disease,[41] or with smaller nodules.[42] Less common complications are identifiable only in larger retrospective series. Severe complications of CT-guided biopsy were quite rare. Of 6881 cases, 74 (0.75%) patients were reported with severe complications, including 6 patients with air embolism (see eFig. 21.6), 10 with tension pneumothorax, 6 with severe pulmonary hemorrhage, 9 with hemothorax (see eFig. 21.5), and 6 with seeding of the needle tract. Eight deaths were reported.[44] In general, therefore, CT-guided biopsies are safe and accurate for carefully selected peripheral lesions.

Surgery

Resection of a nodule has the greatest diagnostic yield and may provide both diagnosis and treatment in a single procedure. The selection of patients for whom nodule resection is appropriate is a matter of controversy. There is a lack of randomized data comparing surgical and nonsurgical treatment of lung metastasis, and the data from reported series on surgical treatment of lung metastases lack uniformity in selection criteria. The sensitivity of surgery for diagnosis is likely close to 100% given that it is the accepted gold standard for tissue diagnosis of lung lesions. However, very small lung lesions can be difficult for the surgeon to palpate and may be missed. The risks of surgery include those for general anesthesia in addition to the risks associated with lung resection. A patient's pulmonary function and physical status can also affect the decision whether to perform surgery because noninvasive therapeutic modalities (radiation and ablation) can be used for patients with a high surgical risk. Thoracoscopic surgery is discussed later and is the preferred option when surgery is required for diagnosis.

TREATMENT

MULTIMODALITY THERAPY OF POTENTIALLY CURABLE DISEASE

Treatment of lung metastasis is largely dictated by the tissue of origin (Fig. 79.3). In cases of curable cancers, patients with lung metastases should be treated with appropriate multimodal therapy. Germ cell tumors, neuroblastoma, gestational trophoblastic tumors, lymphoma, and osteosarcoma are included in this category. In patients with nonseminomatous germ cell tumors, resection of residual nodules or masses after systemic chemotherapy is an appropriate approach. In cases of testicular cancer, such residual masses remain after chemotherapy in approximately 40% of patients who had advanced disease but negative serum tumor markers at the conclusion of treatment.[45,46] When resected, approximately one-half of these masses contain only necrotic tissue, a further 25% show a mature teratoma, and the rest contain residual carcinoma. Long-term follow-up studies after chemotherapy suggest that 90% of patients found to have mature teratomas on resection and 50% of those with residual carcinomas are cured by "adjuvant" surgery.[45,46] In patients with other tumors, treatment options are mainly nonsurgical. For patients with lymphoma, for example, in whom treatment alternatives are more numerous and systemic therapy is necessary, biopsy rather than excision is more appropriate. These varied treatment options highlight the importance of undertaking the care of these patients with multidisciplinary input.

STEREOTACTIC RADIOTHERAPY

Often referred to as stereotactic ablative body radiotherapy or *stereotactic body radiotherapy* (SBRT), this mode of therapy is used to deliver a precise and high dose of radiation using a small number of fractions. SBRT combines multiple collimated radiation beams using stereotactic localization on a target lesion or lesions. The multiple lower-dose beams intersect at the target to focus a high dose of radiation at a carefully defined location and to minimize the dose to normal surrounding structures. This technique is gaining favor as a preferred means of local curative or ablative treatment where surgery is either technically or medically inadvisable. In the context of lung metastases, a growing body of evidence suggests that SBRT to treat known sites of metastases, in addition to other supportive care, may result in longer overall survival.[47,48] One study randomized 99 subjects in a 1:2 ratio to receive standard supportive care or supportive care with SBRT to known sites of metastases (up to five).[47] In this study, 53% of patients had lung metastases, and

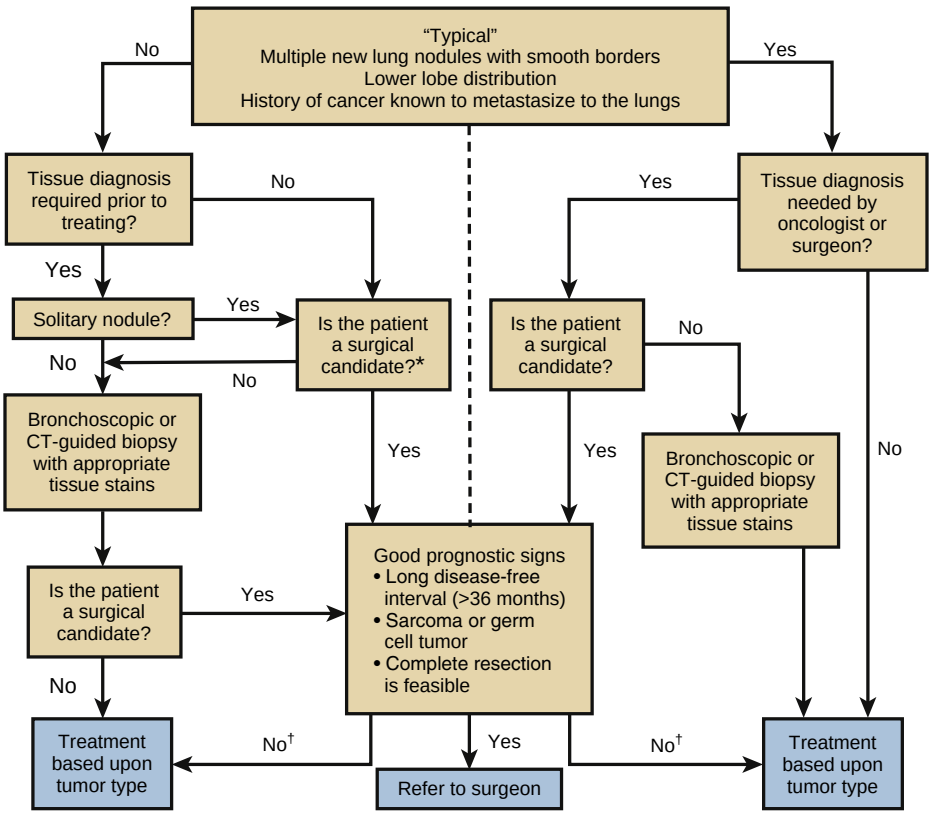

Figure 79.3 Suggested management algorithm for patients with known prior cancer and new lung nodule or nodules. Decisions take into account the typical or atypical appearance of a lung nodule in a patient with prior known cancer, the utility of a tissue diagnosis to the treating physicians, the physiologic fitness of the patient for surgery, and the known prognostic indicators for a favorable outcome after metastasectomy. Each patient should be managed individually, within the context of the skills and experience of local providers with the varied diagnostic and therapeutic options. *Patients at high risk for primary lung cancer may be considered for diagnostic lobectomy, when appropriate. †These are suggested criteria for surgical resection of lung metastases, and multidisciplinary teams should make this decision. Radiofrequency ablation or stereotactic ablative body radiotherapy may also be an excellent choice for these patients. CT, computed tomography.

overall survival was 28 months (95% confidence interval, 19 to 33) in the control group and 41 months (95% confidence interval, 26 to not reached) in the group that received SBRT. Additional prospective studies are ongoing to define the role of SBRT in treating oligometastatic disease.[49]

RADIOFREQUENCY ABLATION

Thermal ablation is a minimally invasive therapy that can be used for local cure or control of either primary or metastatic lung tumors. *Radiofrequency ablation* (RFA), which uses radiofrequency energy to generate frictional heating that leads to cell death, is the most commonly performed thermal ablation procedure used to treat lung tumors. Although the role of RFA is not as clearly defined as other options, the role of RFA in treating lung metastasis is gaining increased acceptance. Although RFA is more commonly performed to treat hepatic and renal tumors, it may be well suited to the lung because of its ability to concentrate thermal energy focally within tumor tissue with little or no energy spread to the adjacent aerated normal lung parenchyma.[51]

Smaller tumors, 3 cm or less in diameter, are more readily treated with RFA than are larger tumors.[52,53] Peripheral tumors surrounded by lung parenchyma and away from hilar structures can be safely treated with RFA (see Fig. 21.5 and eFig. 21.15).[54,55] However, more recent studies report that even tumors contiguous with certain vital structures, such as the thoracic aorta and pulmonary vessels, can be safely treated[56] because the cooling effect of the flowing blood may protect the large vessels from tissue damage. Multiple lesions in the same hemithorax can be treated at one sitting by experienced providers; however, because of the risk of pneumothorax (as high as 50% in one series[57]), bilateral lesions should not be treated during the same setting. Alternative ablative options include cryotherapy and microwave-mediated treatments, although these have not been as well studied as RFA.

SURGICAL RESECTION OF METASTASES

As measured by length of survival and quality of life, surgical resection of pulmonary metastases can be the appropriate choice. As metastasectomy has become more common, surgical registries have identified factors potentially associated with favorable outcomes. In general, the most consistent factor associated with improved survival is complete resection of all metastases. Incomplete resection is associated with survival rates that do not differ from rates in patients with no treatment at all. Another important favorable prognostic factor in numerous large series is a long disease-free interval between initial diagnosis of cancer and the discovery of lung metastasis.[58–60] Five-year survival was 33% when the disease-free interval was 0 to 11 months compared with 45% when the disease-free interval was more than 36 months.[61,62] Although a higher number of pulmonary metastases was once considered a poor prognostic factor, studies do not consistently find higher numbers of these metastases to predict poor outcomes. More accurate prognostic factors must be identified to improve selection of patients for metastasectomy. Suggested selection criteria for pulmonary metastasectomy, taken from various large series,[60,63,64] are shown in Table 79.4. In a retrospective analysis, selection of patients for pulmonary metastasectomy according to these criteria was associated with longer survival times.[60,65–68]

In 1991, the International Registry of Lung Metastases (comprising more than 5000 cases) was established to record and report on the long-term results of pulmonary metastasectomy according to the tissue of origin.[63] Patients with cancers that metastasize exclusively to the lungs have more favorable outcomes from pulmonary metastasectomy than do patients with cancers that metastasize more widely. Malignant diseases in patients with the greatest long-term survival after pulmonary metastasectomy include sarcomas, colorectal cancer, uterine or cervical tumors, head and neck cancer, breast cancer, testicular tumors, renal cell tumors, and melanoma (Table 79.5). Patients undergoing lung metastasectomy for osteosarcoma have some of the best results, but long-term survival after metastasectomy is not limited to patients with sarcoma.[63] Prolonged disease-free

Table 79.4 Suggested Criteria and Indications for Pulmonary Metastasectomy

ABSOLUTE CRITERIA
The patient must be able to tolerate the planned operative procedure.
The primary tumor is (or can be) controlled.
No extrapulmonary metastases exist; or, if present, they must be controllable.
Pulmonary metastases are completely resectable.
RELATIVE INDICATIONS
Pulmonary metastases are symptomatic (e.g. pneumothorax, hemoptysis).
Surgery is necessary to differentiate metastasis from primary lung cancer.
A long disease-free interval separated the metastasis from the primary cancer.

Data from Kondo H, Okumura T, Ohde Y, Nakagawa K. Surgical treatment for metastatic malignancies. Pulmonary metastasis: indications and outcomes. *Int J Clin Oncol.* 2005;10:81–85; and Kaifi JT, Gusani NJ, Deshaies I, et al. Indications and approach to surgical resection of lung metastases. *J Surg Oncol.* 2010;102:187–195.

Table 79.5 Tumor-Specific 5-Year Survival Rates Following Pulmonary Metastasectomy

Primary Malignancy	5-Year Survival (%)
Soft tissue sarcoma[72,86,87]	20–35
Osteosarcoma[88]	25–50
Melanoma[67,89]	5–33
Colorectal[70,90]	13–40
Testis (germ cell)[45,68]	50–80
Renal[71,91]	15–20
Breast[59,92,93]	25–50
Head and neck[69]	30

survival has been reported for patients with colon cancer, breast cancer, prostate cancer, and other malignancies.[58,66–72] Pulmonary metastasectomy for any cancer mandates adherence to certain surgical principles: complete resection must be possible, the primary tumor must be controlled, and there should be no other uncontrolled extrapulmonary metastases.

Surgical resection of pulmonary metastases requires careful planning and preparation. As with any lung resection, the number, location, and size of the lesion or lesions; the patient's pulmonary function; and the general condition of the patient must be considered, as must any evidence of local invasion or the prospects for response to systemic therapy. CT has high sensitivity and accuracy for localizing pulmonary nodules for resection. An emerging strategy is to mark small peripheral tumors before thoracoscopic resection by using guidewires, dye, radioactive tracers, or coils (see Fig. 21.6).[73,74] These markers can be placed either percutaneously or by bronchoscopy (typically using navigational bronchoscopy) before resection. Intraoperative localization of small, nonpalpable nodules can be aided with a sterile ultrasound or radioactivity probe in deflated lung.

In tumors avid for ^{18}F-fluorodeoxyglucose, PET scanning should be performed before pulmonary metastasectomy to exclude the presence of synchronous extrapulmonary metastasis. Increased activity on PET or lymph node enlargement seen on CT suggests the need for confirmation using less invasive biopsy techniques such as mediastinoscopy, transthoracic needle biopsy, and transbronchial needle biopsy (with or without endobronchial ultrasound). Apart from certain germ cell tumors (which may remain curable despite metastatic disease), the finding of synchronous metastasis outside the lung would be a contraindication to pulmonary metastasectomy.

Thoracotomy has been the most frequently used approach for unilateral metastasectomy, primarily because it enables the surgeon to palpate the lung for lesions. Similarly, sternotomy or a clamshell incision has been used for bilateral palpation and metastasectomy. To avoid the morbidity of a thoracotomy or sternotomy, alternate surgical approaches have been sought. Subxiphoid pulmonary metastasectomy has been described.[75] The subxiphoid approach permits palpation of both lungs without transecting large muscles or bone, but it can result in diaphragmatic hernias and has not been widely adopted. Thoracoscopy also allows minimally invasive resection of pulmonary metastases and has now become the gold standard approach. Initially, thoracoscopic pulmonary metastasectomy was criticized for its limited ability to permit palpation of the lungs to identify unknown metastases. However, as the resolution of CT scanning has improved, the likelihood of pulmonary nodules that can be palpated but not visualized on CT scan has decreased dramatically, thus improving the relative utility of thoracoscopic metastasectomy. In addition, instruments and techniques have evolved to allow enhanced visualization and even thoracoscopic palpation of lung parenchyma. Compared with thoracotomy, thoracoscopic metastasectomy has several advantages, including smaller incisions, less pain, earlier recovery, and fewer postoperative adhesions. The last advantage is especially important because repeat pulmonary metastasectomy may be indicated based on the same criteria as the initial metastasectomy.[62,63] Prior thoracotomy was considered a possible contraindication to future thoracoscopy, but the thoracoscopic take-down of adhesions after thoracotomy has proved to be feasible and well tolerated.[76] Indeed, more than 50% of patients who undergo complete pulmonary metastasectomy will develop recurrence. The probability of relapse is higher for sarcoma and melanoma than for epithelial or germ cell tumors. In the International Registry, repeat metastasectomy yielded 44% survival at 5 years and 29% at 10 years,[63] results comparable to those after initial metastasectomy. A retrospective, nonrandomized study comparing outcomes of patients who had undergone metastasectomy with open versus thoracoscopic approaches did not find differences in survival, although fewer complications and shorter hospital length of stay favored the thoracoscopic approach.[77] Thus, the approach for surgical resection should be carefully planned with respect to several criteria, including the number and location of lesions, the surgeon's experience, and the possible need for repeat metastasectomy.

Before any resection, all lung lesions should be identified to plan a resection that minimizes the loss of lung parenchyma. The extent of pulmonary resection is an important consideration. According to the registry data, metastasectomy was achieved by wedge resections in 67%, segmentectomy in 9%, and lobectomy or bilobectomy in 21%.[63] The operation should be planned to remove the least amount of lung parenchyma. Segmentectomy is increasingly favored over lobectomy for central lesions. Wedge resections for peripheral nodules should be the standard. Lymph node dissection is not encouraged given the low incidence of nodal involvement with pulmonary metastasis, associated morbidity, and the poor survival of patients with nodal metastasis regardless of resection. Pneumonectomy or extended resection was rarely used in the registry (3%) and should be reserved for special circumstances when there is acceptable surgical risk and a reasonable likelihood of long-term survival.[63]

The morbidity and mortality associated with pulmonary metastasectomy should be very low. Most series report less than 2% mortality and 10% morbidity.[63] The most common complications are persistent air leak and infection. Preoperative chemotherapy or radiation may increase the risk of respiratory failure after metastasectomy when high fractional concentrations of oxygen are used perioperatively.[46] Anesthesiologists should be alerted to a history of chest irradiation or chemotherapy (particularly with bleomycin used for germ cell tumors) and use the lowest possible fraction of inspired oxygen for these patients.

Most reports regarding the effectiveness of pulmonary metastasectomy have been retrospective. These nonrandomized and uncontrolled series introduce selection and lead-time bias. Reported survival rates of 30–40% at 5 years are encouraging, but the selection criteria used for surgical resection, as well as the nonrandomized design of these studies, must be considered when comparing treatment options. Additional studies are needed to define patients who will receive maximum benefit from metastasectomy. For example, molecular predictors of prognosis have been used in assessing treatment options for patients

with primary tumors, but this approach has been more difficult to incorporate into an algorithm (see Fig 79.3) for treating metastases because of the diversity of origins of primary tumors and the relatively small numbers reported in any given series of metastectomy.[78]

PALLIATIVE CARE

Unfortunately, most adults with pulmonary metastases from solid tumors have incurable disease, and palliative therapy is necessary. For selected cancers, palliative treatment may include radiotherapy, chemotherapy, hormonal, or biologic or targeted therapies. Agents chosen for palliative therapy should balance acceptable levels of toxicity with the expected degree of tumor response and symptom control. Radiation therapy for patients with radiosensitive tumors can provide rapid and effective symptom relief. For patients with endobronchial obstruction, endobronchial tumor ablation using rigid bronchoscopy, brachytherapy, laser, electrothermal cautery, or cryoprobes can be very effective for palliation (see Chapter 28). Because these approaches require specialized training, it is best to seek referral to a center with experience in such techniques when they are needed. Given that most centers may specialize in only one, or at most two, of these interventional methods, direct comparisons of the efficacy and safety of palliative interventions for malignant airway obstruction have not been reported. For patients with end-stage dyspnea, opiates and oxygen therapy may relieve symptoms. In general, for end-of-life care, social, emotional, and physical rehabilitation support measures, as well as hospice services, are valuable.

SPECIAL CASES

AIRWAY METASTASIS

Although rare, large airway involvement with endobronchial metastasis can produce very distressing symptoms of dyspnea and/or hemoptysis. Awareness of the clinical scenario along with available diagnostic and management strategies can be very helpful in palliating these patients. Reported series of patients with endobronchial metastasis are generally small, but they uniformly emphasize the utility of fiberoptic bronchoscopy for diagnosis, as well as interventional methods for symptom control and palliation. In addition to lung cancer, tumors that metastasize to the bronchi include colon, breast, renal cell carcinoma (eFig. 79.1), melanoma, and many others.[79] The tissue origin of airway metastases probably reflects the relative incidence of solid tumors in general rather than a biologic predisposition to seed the airway. Colon cancer can metastasize to the bronchi without involvement of the liver.[80] Radiation can be used for palliation in patients with airway obstruction due to radiosensitive tumors. Mechanical means, including stents, and endobronchial ablative methods (laser, cryoprobe, argon plasma coagulation or physical debridement) can be used for tumors that are relatively radioresistant. (see Chapter 28) These interventions require experienced thoracic surgeons or interventional pulmonologists who can also manage complications of these procedures.

VASCULAR EMBOLIC METASTASIS

A rare but dramatic presentation of lung metastasis is tumor embolism. When it is clinically evident, the symptoms are those of "subacute right heart failure" with dyspnea, edema, elevated jugular venous pressure, and auscultatory evidence of pulmonary hypertension and right ventricular failure. Antemortem diagnosis is difficult unless clinical suspicion is high. Tumor embolism has been reported as the initial presentation of extrapulmonary cancer or as a postmortem finding in those with no antemortem respiratory symptoms.[81] In a series of 214 selected autopsies, 89 patients had evidence of tumor emboli, and only 50 of these had clinical records indicating the presence of respiratory symptoms before death. However, in 29 of the 50 patients, tumor emboli were the recorded cause of death.[82] Tumors arising from the breast, liver, and pancreas accounted for more than 50% of the cases, but many tumor types were represented in this series.[81] Pulmonary arterial tumor emboli may affect larger pulmonary arteries, so-called macroscopic tumor embolization, which may be visible on thoracic CT (eFigs. 79.2 and 79.3). Small pulmonary arteries may also be affected by tumor embolization, a situation referred to as microscopic tumor embolization (eFig. 79.4). Thoracic CT findings (eFig. 79.4A–C) include small centrilobular opacities, possibly with branching configurations (simulating infection), smooth or nodular interlobular septal thickening, and areas of ground-glass opacity or parenchymal consolidation reflecting hemorrhage or infarction. When tumor embolism is suspected, cytologic examination of pulmonary capillary blood obtained through a wedged pulmonary arterial catheter is a possible diagnostic method.[83] Treatment options may be limited to anticoagulation and systemic chemotherapy. Surgical embolectomy is not possible in this setting.

PLEURAL METASTASES

Malignant pleural effusions are usually metastatic and are a significant cause of morbidity in patients with cancer (see Chapter 114). Diagnosis is typically straightforward and can be made in pleural fluid with cytology, though this may require more than one thoracentesis if initial cytology is negative. Flexible or rigid thoracoscopic examination of the pleural space is increasingly used to diagnose pleural metastasis. Metastatic disease to the pleura is incurable, and treatment is directed toward palliation of symptoms of dyspnea. In a randomized study, indwelling tunneled pleural catheters were superior to talc pleurodesis. However, there was no difference in validated quality of life metrics between the two groups, and blockage of the indwelling catheter was a common complication of the group treated with this approach.[84] Clinical practice guidelines have recommended that either indwelling catheters or talc pleurodesis can be used for palliation.[85] Indwelling pleural catheters are particularly useful when there is nonexpendable lung, and they can help dyspnea by reducing the expansion of the chest wall and returning the diaphragm to a more normal position.

Key Points

- Lung metastases are common and arise from most types of solid tumors.
- Metastases are nearly universally responsible for cancer mortality and, as these molecular insights are exploited to develop novel strategies for prevention or treatment of metastases, survival *with* cancer (as opposed to a cure *for* cancer) is an attainable goal.
- In addition to benign causes, a pulmonary nodule in a patient with prior cancer can be a metastasis or a primary lung cancer; the likelihood of metastasis will vary with the original type of cancer and risk factors for primary lung cancer.
- When clinical and/or histologic evaluation cannot distinguish primary lung cancer from a metastasis, immunohistochemistry for tumor-specific markers can be useful. Future directions will include molecular phenotyping.
- The choice of diagnostic method will be determined by the patient's status, the natural history of the prior cancer, the availability of specialized diagnostic methods, and the need, or lack thereof, for a tissue diagnosis before offering therapy.
- Ablation (e.g., radiofrequency, thermal, cryotherapy) is a potential therapeutic option when surgical resection, radiation therapy, or systemic therapy is not.
- Stereotactic body radiotherapy provides local curative or ablative treatment when surgery is either technically or medically inadvisable.
- Surgery for both diagnosis and treatment is appropriate in selected patients. The most important predictor of successful treatment is the ability to address by surgery, radiation, or other modality all visible and palpable lung nodules.

KEY POINTS

INTRODUCTION

Although in practice the terms "tumor" and "neoplasm" tend to be used interchangeably, there are important and substantial differences between them. A tumor may be regarded as any grossly mass-forming lesion, while a neoplasm is considered an abnormal proliferation of tissues, arising outside of physiologic control. Neoplasms may represent a clonal cell population or be heterogeneous and comprised of multiple cell types. As a result a tumor need not be a neoplasm and a neoplasm may not always be tumefactive. Examples include a localized variant of organizing pneumonia and bone marrow involvement by leukemia, respectively. This chapter reviews the salient clinical and pathologic features of benign lung neoplasms, collections of clonal cells, which generally do not invade or metastasize; these account for only a small fraction of resected lung tumors. Although rare, benign lung neoplasms might mimic more biologically aggressive lesions, posing diagnostic challenges for clinicians, radiologists, and pathologists alike. Localized, non-neoplastic conditions, such as granulomas and organizing pneumonia, that can radiographically resemble neoplasms are not discussed. In addition, rare primary lung tumors are discussed in Chapter 78. When there is overlap between benign and malignant behavior, some of the same entities are discussed in both chapters.

CLINICAL MANIFESTATIONS

Most benign lung tumors present as solitary pulmonary nodules, incidentally discovered on chest radiographs or *computed tomography* (CT) scans performed for other reasons. The majority of individuals are asymptomatic with occasional patients presenting with signs of airway obstruction, bleeding, or compression of surrounding structures. In some cases, a preoperative diagnosis may be possible using a combination of imaging data and transthoracic or endoscopic biopsy. In most cases, however, a diagnosis is recognized only after surgical resection of a lesion for which the possibility of malignancy could not be excluded.[1,2] The decision to proceed with surgical resection in a patient with an unexplained, solitary pulmonary nodule is complex and predicated on analysis of various risk factors, including any prior history of malignancy and radiographic characteristics of the lesion, among others. During the course of evaluation, patients may undergo ^{18}*F-fluorodeoxyglucose positron emission tomography* (FDG-PET) scan. Unfortunately PET scan cannot reliably discriminate between benign and malignant lung neoplasms in a patient with an indeterminate lesion. Therefore, it is rarely informative for patient management in this setting.[3,4] Finally, current recommended approaches to some patients with a solitary lung nodule include watchful waiting.[5,6] Prediction models for assessing the likelihood of malignancy[7–9] and Fleischner guidelines for the management of indeterminate pulmonary nodules[10] are helpful in suggesting watchful waiting for "low risk" nodules (<10% probability of malignancy). The approach to evaluation of a patient with an undiagnosed pulmonary nodule is discussed in detail in Chapter 41.

BENIGN EPITHELIAL LESIONS

PAPILLOMAS

Papilloma refers to a papillary neoplasm, consisting of epithelial-lined, arborizing, fibrovascular fronds (Fig. 80.1). Solitary papillomas are usually exophytic and protrude into conducting airways (eFig. 80.1 and Videos 80.1A–B). Given these features, symptomatic patients commonly present with symptoms due to airway obstruction or hemoptysis. Most solitary papillomas arise in large central airways; rarely, they can develop in smaller bronchioles and present as peripheral nodules.[11,12] Flieder and colleagues divided lung papillomas into three categories based upon the lining epithelium: squamous cell, glandular, and mixed types.[13] More recently, ciliated muconodular papillary tumor has also been described and considered by many to be a variant of glandular papilloma.[14] Of the subtypes, squamous lesions account for nearly 70% of reported cases. Squamous cell papillomas are found more frequently in men than women, and are more often associated with cigarette smoking and *human papillomavirus* (HPV) infection than the other subtypes.[13,15] Malignant transformation of solitary papillomas is very rare and limited to single case reports.[16,17] In the majority of cases initially interpreted as papillomas and later discovered to harbor a frankly malignant component

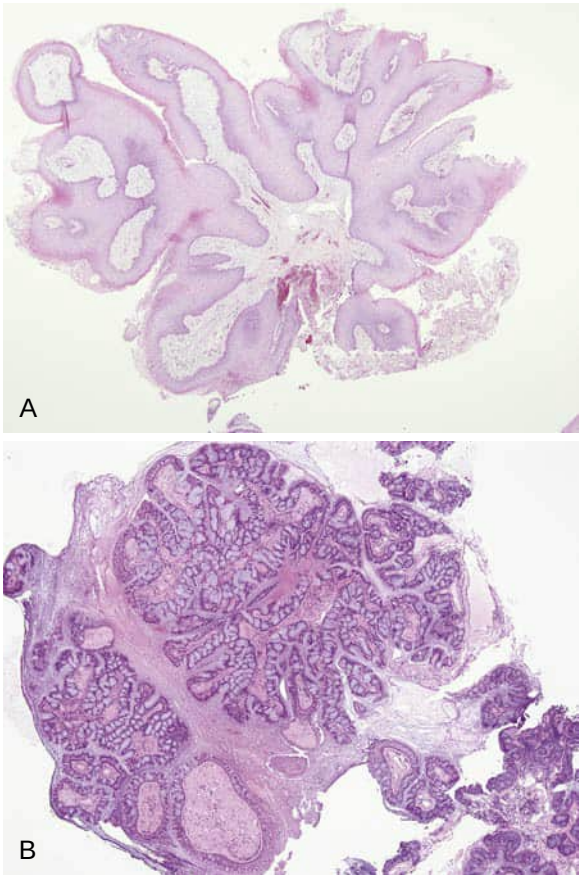

Figure 80.1 Papillomas. Low-magnification photomicrographs illustrate two different solitary endobronchial papillomas from adults. (A) Squamous papilloma showing papillary architecture with central connective tissue stalk covered by benign squamous epithelium with associated keratinous debris. (H&E stain; ×20 original magnification.) (B) Glandular papilloma lined by benign mucinous columnar cells with abundant extracellular mucus. (H&E stain; ×40 original magnification.)

on definitive excision, inadequate sampling at the time of biopsy likely accounts for this discrepancy rather than true malignant transformation. Most patients with solitary papillomas do well regardless of histologic type, and surgical resection is curative. Local recurrences are rare and limited to patients whose papilloma was not completely removed at the time of biopsy or who underwent subtotal bronchoscopic resection.[13] Cytology specimens obtained from these patients, including fine-needle aspirations and exfoliative respiratory specimens, are commonly reported as "atypical" and lack distinguishing cytomorphologic features to establish a diagnosis of benign papilloma with confidence[18]; therefore, endobronchial biopsy or surgical resection is often needed for accurate diagnosis.

Recurrent respiratory papillomatosis (RRP), also referred to as *juvenile laryngeal* or *laryngotracheal papillomatosis,* is a form of HPV-related papillomatosis. RRP is characterized by multiple papillomas that most commonly involve the larynx but can arise anywhere along the respiratory tract.[19] RRP was once considered a disease of children, usually presenting before age 5 years, but it is now recognized in adult patients as well.[20,21] HPV types 11 and/or 6 are implicated in virtually all cases. In children, infection is acquired perinatally through vertical transmission whereas, in adults, it

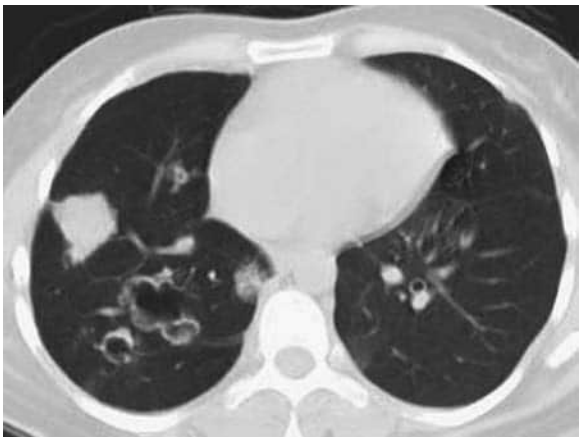

Figure 80.2 Recurrent respiratory papillomatosis. Axial computed tomography of a patient with recurrent respiratory papillomatosis involving her right lung. There are multiple nodules and opacities, the largest measuring 3 cm in greatest dimension. Some of the nodules appear cavitated. (Courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

may be related to new or latent infection.[22–24] Presenting symptoms include hoarseness, stridor, and dyspnea. Surgical excision or laser ablation are the mainstays of therapy for patients with symptomatic disease.[21] Although benign, recurrences are relentless and often necessitate multiple procedures. Squamous cell carcinoma, an infrequent complication, is most often observed in the setting of HPV-11 infection.[25,26]

Papillomas spread to the alveolar lung parenchyma in approximately 3% of patients with juvenile onset RRP. HPV type 11 is disproportionately represented in these patients. For example, HPV-11 is detected in 90% of patients with peripheral lung papillomas.[27] Parenchymal disease typically presents as multiple, asymptomatic radiographic nodules that may be cystic or solid (Figs. 80.2 and 80.3; see eFigs. 78.22 through 78.25).[27–30] The lesions can occasionally show high FDG avidity on PET scan. The histopathologic findings are unique, demonstrating tufts of benign squamous papillomas emanating from distal bronchioles with polypoid extensions into adjacent alveolar spaces (Fig. 80.4). The involved bronchioles are often ectatic, thus mimicking the appearance of cavitation on imaging studies.

Parenchymal lung involvement in patients with RRP is often associated with an aggressive clinical course. There is currently no effective medical therapy, but evidence suggests that HPV vaccination might offer one therapeutic strategy by decreasing disease burden and increasing the time between procedures.[31,32] About 15% of patients with parenchymal disease develop squamous cell carcinoma. The average age of cancer diagnosis is 23 years, with some patients dying of malignancy or progressive lung destruction from RRP (see Fig. 78.7 and eFig. 78.25).[27,33]

ADENOMAS

Whether arising in the peripheral lung or in the central lung as endobronchial lesions, adenomas of the lung are rare and comprise a morphologically heterogenous group of benign epithelial neoplasms. In the peripheral lung, four types are currently recognized, including sclerosing

Figure 80.3 Recurrent respiratory papillomatosis. Gross photograph of left lower lobe excised from a 19-year-old with multiple recurrences of respiratory papillomatosis. The patient had extensive papillomatosis involving his central airways and a large cystic cavity containing innumerable papillomas replacing much of his left lower lobe. (From Kerley SW, Buchon-Zalles C, Moran J, et al. Chronic cavitary respiratory papillomatosis. *Arch Pathol Lab Med*. 1989;113:1166–1169.)

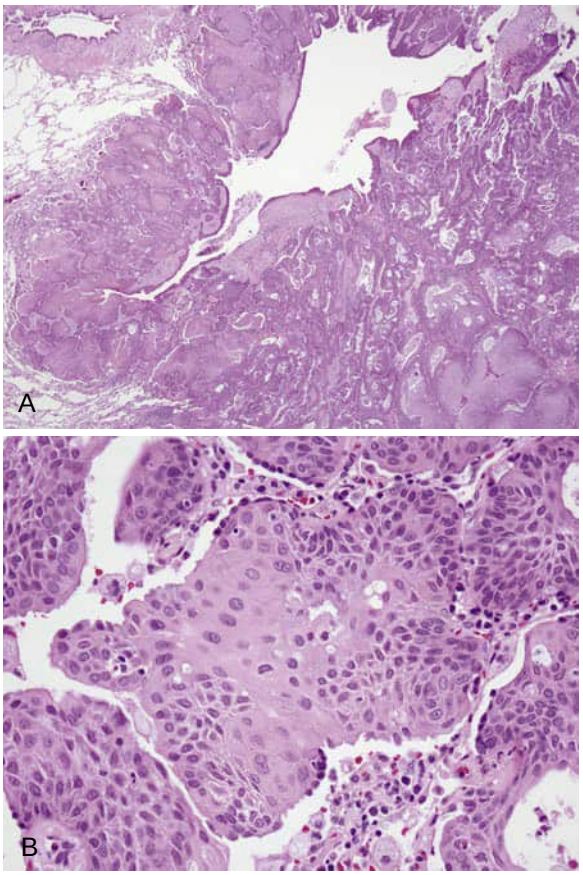

Figure 80.4 Recurrent respiratory papillomatosis. Photomicrographs illustrate lung involvement in a 40-year-old woman first diagnosed with recurrent respiratory papillomatosis at the age of 2 years. She underwent multiple resections of lung nodules starting in her second decade of life. (A) Low-magnification photomicrograph illustrates multiple benign papillomas within an ectatic bronchiole with a centrally dilated lumen. (H&E stain; ×20 original magnification.) (B) High-magnification photomicrograph illustrates cytologically bland, benign appearance of the lung papillomas. (H&E stain; ×400 original magnification.)

pneumocytoma, alveolar adenoma, papillary adenoma, and mucinous cystadenoma.

In the 1999 and 2004 versions of the *World Health Organization* (WHO) classification of lung tumors, *sclerosing pneumocytoma* (SP), historically referred to as sclerosing hemangioma, was considered to be in the "miscellaneous tumors" group, due to its uncertain histogenesis. Now, in the 2015 WHO classification, SP has been moved into the "adenomas" group because it is well recognized to be derived from incompletely differentiated respiratory epithelium.[34] SP has a female predominance, with women comprising up to 80% of patients in some studies. The mean age of diagnosis is the fifth decade of life, but SP has been reported in a wide age range, including children. Most patients are asymptomatic and incidentally discovered to have a solitary pulmonary nodule during imaging studies performed for unrelated problems.[35–41] Multiple lesions are rare but have been reported in up to 5% of patients.[42] CT findings are typically described as showing a well-circumscribed, subpleural, round to oval nodule with smooth margins and inhomogeneous enhancement; associated calcifications are present in about one third of patients (eFig. 80.2).[42–44] PET scans show significant FDG avidity (maximum standard uptake value [SUV_{max}] > 2.5) in half of cases.[45,46]

Resected SP are sharply circumscribed, peripheral nodules averaging 2 to 3 cm in diameter (Fig. 80.5). The histologic hallmark is intratumoral heterogeneity, resulting from both a mixture of cell types and highly variable growth patterns. Two populations of neoplastic epithelial cells are a characteristic feature, and include (1) surface cuboidal cells derived from pneumocytes or club cells and (2) pale stromal round cells with an incompletely differentiated respiratory epithelial phenotype.[37,47–51] Neoplastic cells are arranged in various growth patterns that often include a focally conspicuous sclerotic stroma that is often calcified (Fig. 80.6). Given the expression of the pneumocyte specific marker, TTF-1, by both surface and round cells and frequent papillary configuration, SP represents a potential diagnostic pitfall on fine-needle aspirates and may be misdiagnosed as lung adenocarcinoma.[52–54] "Metastatic" deposits in regional lymph nodes are rare and have no impact on the fundamentally benign behavior of these lesions; patients are considered cured by surgical management alone.[55–57]

Other types of adenomas involving the peripheral lung parenchyma, including alveolar adenoma, papillary adenoma, and mucinous cystadenoma, are even more rare. Of these, *alveolar adenoma* is the most common variant with the largest case series comprised of only 17 patients and the literature otherwise limited to single case reports.[58–63] The average age at diagnosis is between 50 and 55 years. Nearly all patients are asymptomatic at the time of diagnosis. Radiographically, alveolar adenomas present as well-circumscribed, peripheral nodules, averaging just over 2 cm in greatest dimension.[58,59] PET scans reportedly show alveolar adenomas as having no uptake or mild positivity.[60,61] Pathologically, alveolar adenomas are partially cystic nodules in which connective tissue septa are lined by cytologically bland epithelial cells (Fig. 80.7). The epithelial cells are derived from pneumocytes, while the stromal cells are undifferentiated fibroblasts; therefore, both epithelial and stromal components are regarded as neoplastic.[59,62] There is a single case report of papillary adenocarcinoma

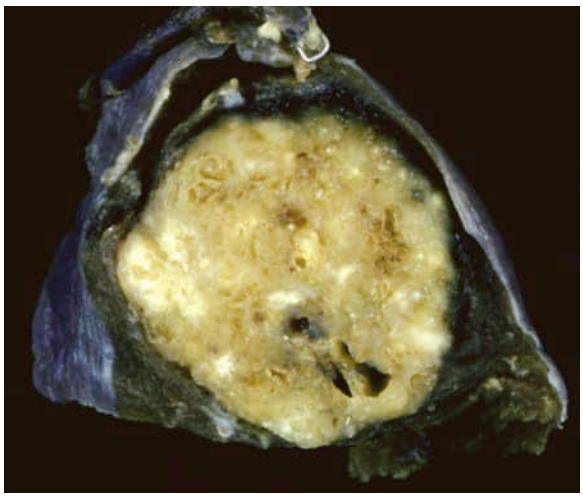

Figure 80.5 Sclerosing pneumocytoma. In this resected specimen, the lobulated nodule is well circumscribed and situated near the visceral pleura. The cut surface betrays the fundamentally heterogeneous nature of these neoplasms, showing a variegated pattern of pale brown and white with both solid and spongy areas.

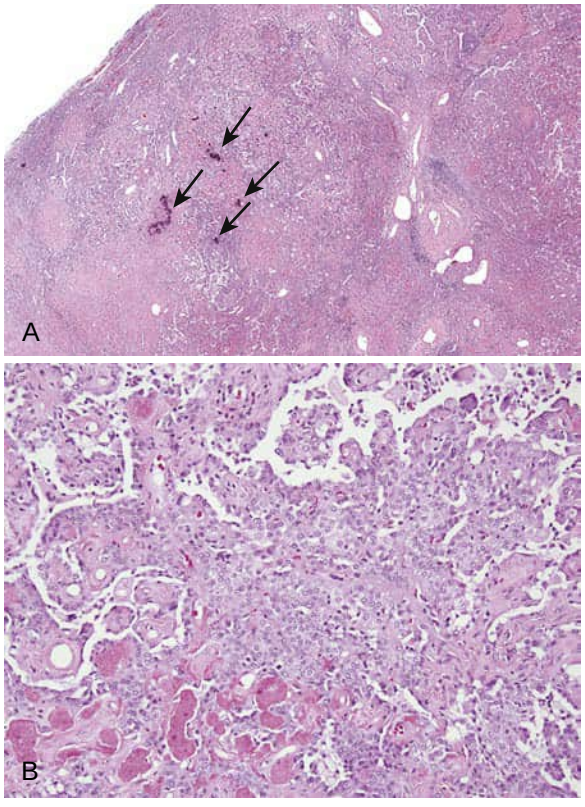

Figure 80.6 Sclerosing pneumocytoma. (A) Low-magnification photomicrograph shows the classic features of sclerosing pneumocytoma in which sclerotic zones with dense collagen deposition and focal calcifications *(arrows)* alternate with variably cellular regions. (H&E stain; ×2 original magnification.) (B) Higher-magnification photomicrograph shows solid and papillary growth patterns. The central area is solid and composed of the pale-staining round cells demonstrating a phenotype consistent with incompletely differentiated respiratory epithelium. (H&E stain; ×400 original magnification.)

arising within an alveolar adenoma; however, whether this case represents true malignant transformation of an alveolar adenoma or whether the two lesions are "true-true, unrelated" is unclear. As in other cases of alveolar adenoma, surgical resection alone was curative.[63]

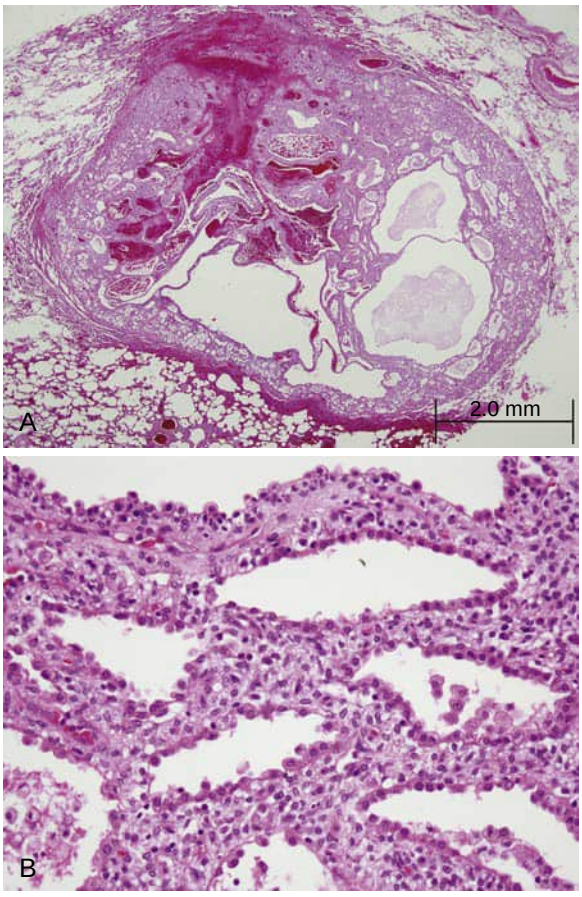

Figure 80.7 Alveolar adenoma. (A) Low-magnification photomicrograph shows a well-demarcated partially cystic mass in a peripheral lung biopsy. (H&E stain; ×20 original magnification.) (B) Higher-magnification photomicrograph illustrates connective tissue septa lined by bland pneumocytes. (H&E stain; ×400 original magnification.)

Papillary adenomas have been described in fewer than 25 patients.[64–70] Of these cases, nearly all patients underwent surgical resection for an asymptomatic solitary peripheral nodule and remained free of disease at follow-up. A single case report details multiple papillary adenomas in a 13-year-old boy with neurofibromatosis type 1; however, there is no established relationship with any specific gene mutation.[69,70] Histologically, papillary adenomas are circumscribed lesions composed of connective tissue fronds lined by cytologically bland type 2 pneumocytes (Fig. 80.8).

Mucinous cystadenoma is a rare lung neoplasm that overlaps with unequivocally malignant mucinous adenocarcinomas.[71–77] Gao and Urbanski proposed separating them into three histologically defined categories: mucinous cystadenoma, mucinous cystic tumor with atypia, and mucinous cystadenocarcinoma.[72] Histologically, benign tumors without atypia accounted for only 13% of reported patients, further emphasizing that this is an extremely rare neoplasm. Patients typically present with slowly growing, well-demarcated, peripheral lung masses that may or may not appear cystic.[73–76] All patients with histologically benign cystadenomas have remained free of disease after surgical resection.

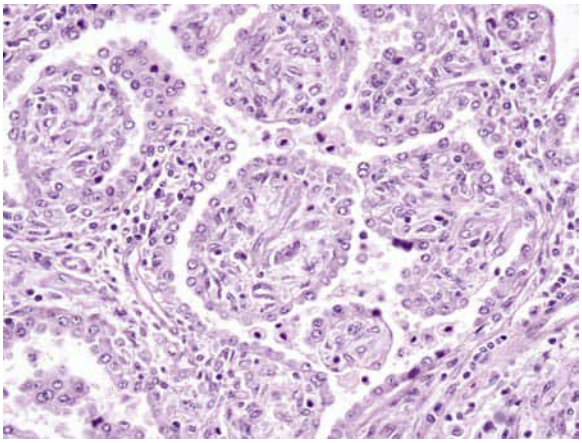

Figure 80.8 Papillary adenoma. High-magnification photomicrograph of a solitary peripheral lung nodule showing papillary connective tissue cores lined by bland cuboidal pneumocytes. (H&E stain; ×400 original magnification.)

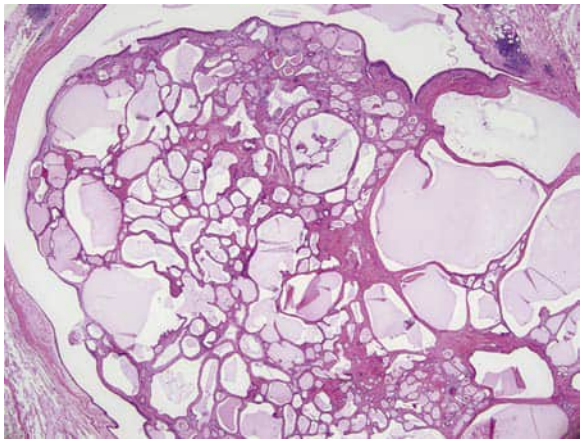

Figure 80.9 Endobronchial mucous gland adenoma. Low-magnification photomicrograph showing that the smooth surface is covered by ciliated respiratory epithelium, whereas the core comprises predominantly cystic spaces lined by variably attenuated columnar mucinous cells. (H&E stain; ×20 original magnification.)

Endobronchial adenomas include two entities analogous to salivary gland counterparts, mucous gland adenoma (cystadenoma), and pleomorphic adenoma, which presumably arise from bronchial submucosal seromucinous glands. As such, virtually all are located within the trachea and cartilaginous bronchi.

Mucous gland adenomas are rare benign tumors affecting a broad age range, including children. These lesions are often polypoid, endobronchial masses arising at the level of lobar or segmental bronchi, many times resulting in luminal obstruction.[78–81] When symptomatic, the most frequent complaints are cough, dyspnea, and wheezing, a combination of findings that can be misconstrued as asthma.[79,80] Chest radiographs may be normal, but more commonly show a solitary pulmonary nodule and/or postobstructive atelectasis or consolidation.[80,81] CT scans show a discrete nodule that may be accompanied by an air-meniscus sign, attesting to an endobronchial location.[81] Moderate PET avidity (SUV_{max} 4.9) is described in one case report.[82] Histologically, mucous gland adenomas are variably solid and cystic, and composed of cytologically bland columnar mucinous cells (Fig. 80.9). Surgical resection, which is often required for diagnosis, is curative.

Pleomorphic adenomas, also termed *benign mixed tumors,* are biphasic neoplasms composed of epithelial elements admixed with a myxoid or chondromyxoid stroma. They usually arise in major salivary glands with few documented cases arising within the lung. Primary pulmonary pleomorphic adenomas have been reported more commonly in women than men (ratio 2:1), with an average age at diagnosis of about 51 years. Cough is the most frequent presenting complaint and is sometimes associated with postobstructive pneumonia; however, one-third of patients are asymptomatic. Eighty percent are found within the larger central airways and appear as polypoid exophytic tumors.[83–86] Chest radiographs and CT scans show a solitary, well-circumscribed, solid mass without distinctive features. PET in a single patient showed high FDG avidity.[85,86] Complete surgical resection with tumor-free margins is curative. As can happen with their salivary gland counterparts, benign pleomorphic adenomas can undergo transformation to malignant carcinoma *(carcinoma ex pleomorphic adenoma)*.[87] Primary pleomorphic adenoma must be distinguished from so-called benign metastasizing pleomorphic adenoma, a term that refers to rare patients in whom histologically benign salivary gland tumors inexplicably metastasize to various sites, including the lung.[88–90]

MICRONODULAR PNEUMOCYTE HYPERPLASIA

Micronodular pneumocyte hyperplasia is an unusual proliferation of alveolar epithelium seen almost exclusively in patients with underlying tuberous sclerosis complex and/or lymphangioleiomyomatosis.[91–95] More than 85% of reported patients are women. Radiologic findings are characterized by scattered nodules that are occasionally numerous and distributed in a miliary fashion with or without the associated cystic changes of the lung parenchyma typical of lymphangioleiomyomatosis (eFig. 80.3).[92,94] The radiologic abnormalities correspond to ill-defined pale peripheral nodules seen either in isolation or in the setting of lymphangioleiomyomatosis (Figs. 80.10 and 80.11). Histologically, micronodular pneumocyte hyperplasia demonstrates circumscribed proliferations of bland pneumocytes cytologically identical to those seen in papillary adenomas, differing in that they are distributed along intact alveolar septa rather than along papillae (Fig. 80.12). These lesions are benign, hamartomatous proliferations that do not progress to carcinoma or require surgical management.

BENIGN NONEPITHELIAL LESIONS

HAMARTOMA AND RELATED LESIONS

Pulmonary hamartoma is the most common benign neoplasm in adults who undergo surgical resection and reportedly accounts for 8% of "coin lesions" seen on chest radiographs.[96–100] Histologically, pulmonary hamartomas are characterized by the presence of least two benign

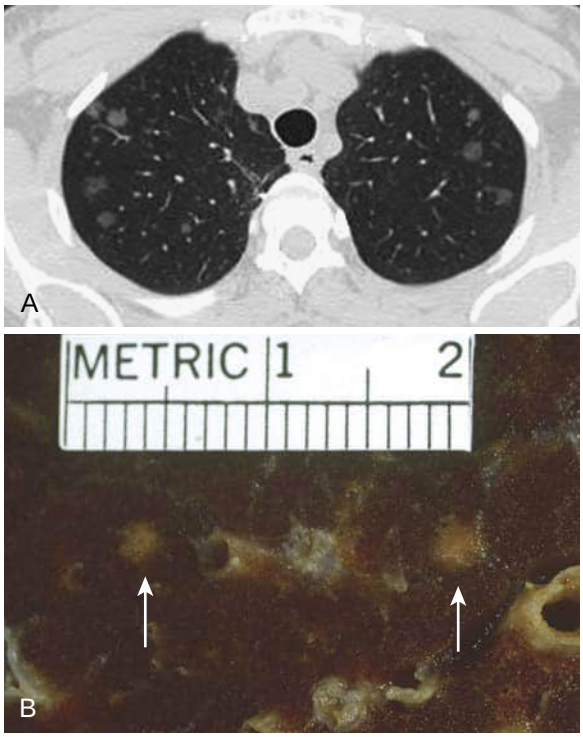

Figure 80.10 Micronodular pneumocyte hyperplasia in tuberous sclerosis complex without lymphangioleiomyomatosis. (A) Axial computed tomography of a 41-year-old woman with tubular sclerosis complex and micronodular pneumocyte hyperplasia shows multiple bilateral nodules characterized by ground-glass attenuation. (B) Photograph of autopsy lung specimen from another patient with tubular sclerosis complex and micronodular pneumocyte hyperplasia *(arrows)*. (A, Courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

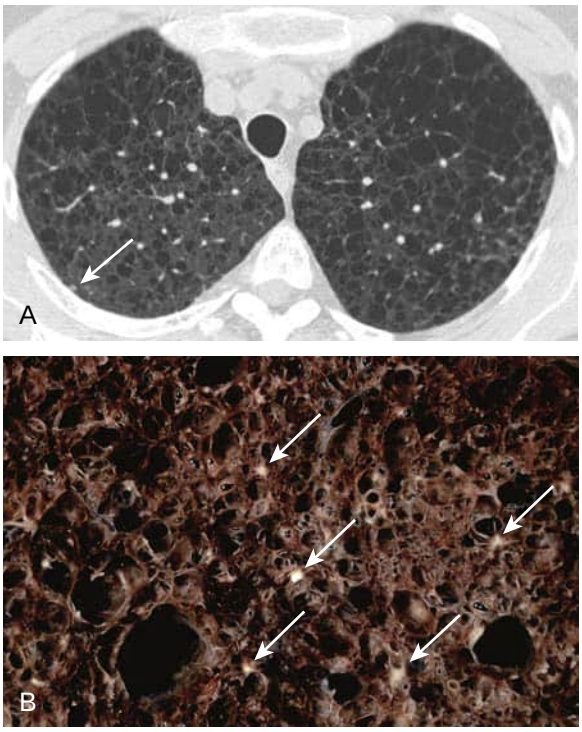

Figure 80.11 Micronodular pneumocyte hyperplasia associated with lymphangioleiomyomatosis. (A) Axial computed tomography scan of a 55-year-old woman with tuberous sclerosis complex and lymphangioleiomyomatosis and a right lung nodule *(arrow)* attributed to micronodular pneumocyte hyperplasia. (B) Photograph of a surgical lung specimen shows a combination of lymphangioleiomyomatosis and micronodular pneumocyte hyperplasia *(arrows)*. (A, Courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

mesenchymal elements (e.g., cartilage, adipose tissue, connective tissue, and smooth muscle) with entrapped, non-neoplastic respiratory epithelium. Although once regarded as a tumor-like malformation, molecular studies have since demonstrated translocations involving chromosomes 6p21 (gene *HMGA1*) or 12q14-15 (gene *HMGA2*), supporting pulmonary hamartoma as a true, acquired mesenchymal neoplasm.[99–101]

Pulmonary hamartomas develop more often in men than women with a peak incidence in the sixth or seventh decade of life. Patients are usually asymptomatic and incidentally discovered to have a solitary lung nodule, most commonly located within the peripheral, subpleural lung parenchyma. Endobronchial hamartomas (eFig. 80.4), which account for about 10% of cases, are the exception; these patients tend to present with obstructive pneumonia and less commonly hemoptysis and cough.[102–105] CT scans show a characteristic combination of calcifications and/or fat, the latter of which is particularly helpful in adding diagnostic specificity for pulmonary hamartomas (Fig. 80.13).[106,107] Pulmonary hamartomas are often negative on PET scans (SUV_{max} <1.5) with mild uptake correlating with larger lesion size.[45,108]

Pulmonary hamartomas usually manifest as well-circumscribed nodules, averaging 1.5 to 2 cm in diameter. A variegated cut surface reflects an admixture of stromal elements (Fig. 80.14). Mature hyaline cartilage is an almost universal component and is typically intermingled with mature fat, fibromyxoid tissue, and rare smooth muscle cells (Fig. 80.15). Any one of the stromal components can predominate, however, resulting in a histologic spectrum of neoplasms that includes *leiomyomas* and *lipomas*.[109–111] Entrapped non-neoplastic respiratory epithelium often results in a characteristically biphasic appearance, a phenomenon that contributes to relatively high rates of false-positive diagnoses of malignancy in fine-needle aspiration biopsies.[112] Although morphology alone is usually sufficient to establish a diagnosis of pulmonary hamartoma on core needle biopsies or surgical resection specimens, an HMGA2 immunohistochemical stain is now available to lend more diagnostic certainty in challenging cases.[113] Resection is curative with rare reports of recurrence or malignant transformation.[114,115]

Pulmonary chondroma is a purely cartilaginous benign lung neoplasm. Although rare cases of sporadic pulmonary chondromas have been described, most arise in patients affected by the Carney triad, a condition characterized by pulmonary chondromas, paragangliomas, and gastric stromal tumors. Pulmonary chondromas develop in three-fourths of patients with the Carney triad and multiple lung tumors are observed in about half of those cases.[116,117] Chondromas are distinct in being purely cartilaginous, devoid of the other stromal and epithelial elements characteristic of hamartoma.[117]

INFLAMMATORY MYOFIBROBLASTIC TUMOR

Inflammatory myofibroblastic tumors (IMTs) have been referred to by a variety of other terms, many of which likely

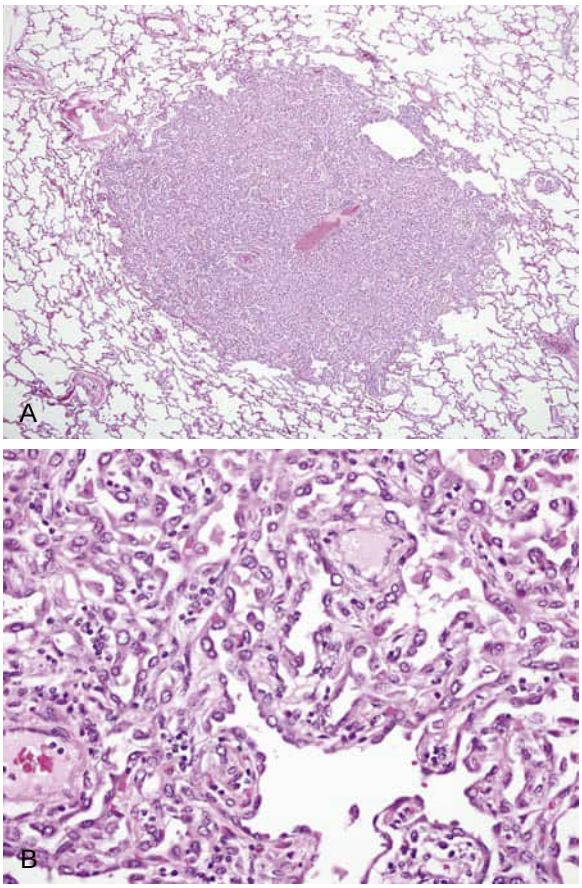

Figure 80.12 Micronodular pneumocyte hyperplasia. Histologic features are shown from the tuberous sclerosis complex patient also illustrated in Figure 80.10B. (A) Low-magnification photomicrograph shows a well-circumscribed nodule. (H&E stain; ×20 original magnification.) (B) High-magnification photomicrograph shows cytologically bland pneumocytes distributed along alveolar septa. (H&E stain; ×400 original magnification.)

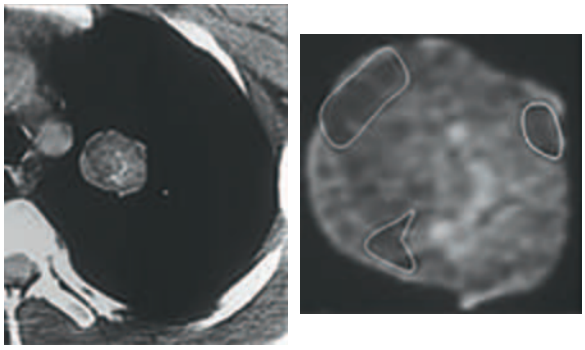

Figure 80.13 Pulmonary hamartoma. Axial computed tomography of a proven hamartoma shows a well-marginated nodule in which there is evidence of intratumoral fat and calcification *(left)*. This combination is characteristic but is seen in only about one-fourth of cases. The low attenuation foci representing fat within the lesion are outlined on the magnified image *(right)*.

represent a spectrum of neoplastic and tumor-like conditions that fall under the broad, descriptive category of "inflammatory pseudotumor." Within this heterogeneous group of lesions, IMT seems to represent a morphologically distinct neoplasm with consistent clonal rearrangements and low to intermediate grade biologic potential, which may recur and can rarely metastasize. Morphologically, IMT is characterized

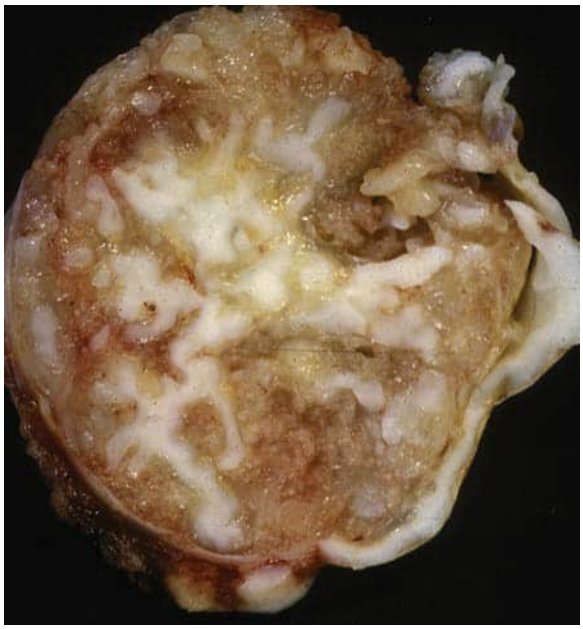

Figure 80.14 Pulmonary hamartoma. In this resected specimen, the cut surface of this well-circumscribed nodule shows glistening irregularly shaped cartilaginous islands alternating with pale yellow adipose tissue. The tumor was 4 cm in greatest dimension.

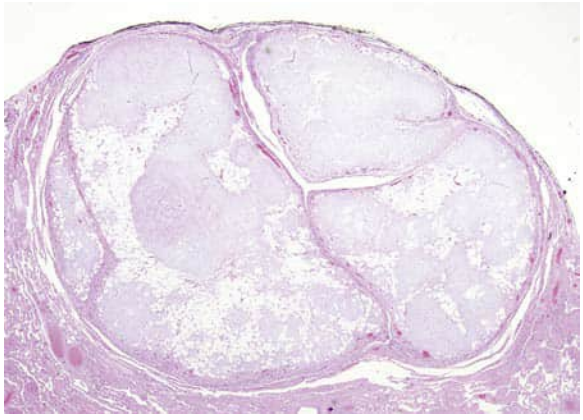

Figure 80.15 Pulmonary hamartoma. Low-magnification photomicrograph of a typical pulmonary hamartoma in which cartilaginous islands are interspersed with adipose tissue resulting in a lobulated appearance. (H&E stain; ×20 original magnification.)

by a proliferation of neoplastic myofibroblastic spindle cells, accompanied by a variably dense chronic inflammatory infiltrate comprised mainly of polyclonal plasma cells (Fig. 80.16). The most common molecular alteration involves translocation of the *ALK* gene locus (chromosome band 2p23) with various fusion partners.[118,119] *ROS1* gene rearrangements account for the majority of cases in which no *ALK* abnormality is detected.[118,120] ALK protein expression by immunohistochemistry is a particularly useful diagnostic tool in small biopsies, including fine-needle aspirates, which may show a spindle cell lesion with broad differential diagnosis that includes both reactive processes and/or malignant neoplasms.[121,122]

IMTs of the lung can arise in any age group but tend to be seen more frequently in children and young adults, with more than half of patients younger than 40 years at the

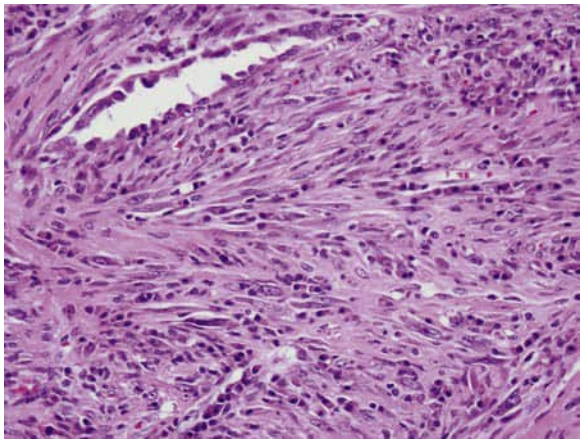

Figure 80.16 Inflammatory myofibroblastic tumor. High-magnification photomicrograph from the tumor illustrated in Figure 80.17. Neoplastic spindle cells are associated with a prominent infiltrate of plasma cells. Non-neoplastic respiratory epithelium *(upper left)* is surrounded by neoplastic spindle cells, resulting in a biphasic appearance, a common phenomenon in benign or low-grade nonepithelial tumors. (H&E stain; ×400 original magnification.)

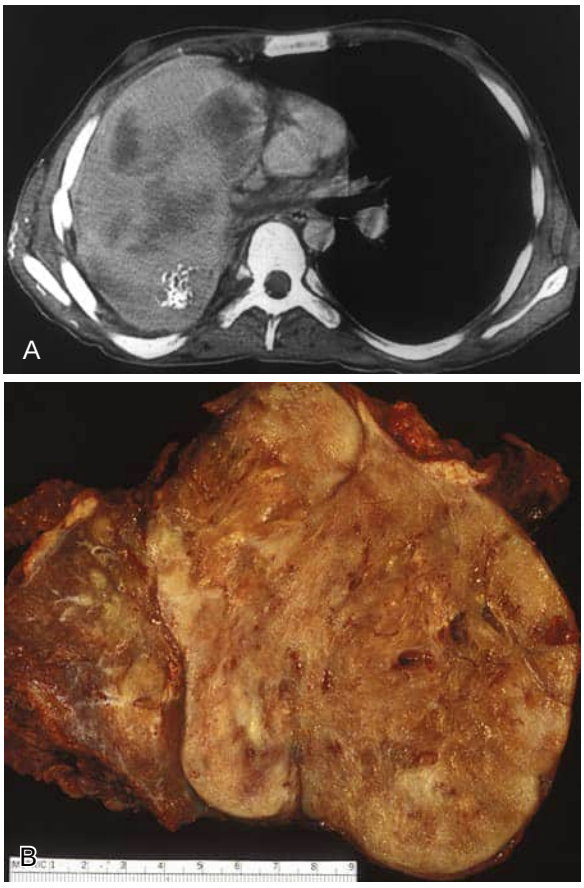

Figure 80.17 Inflammatory myofibroblastic tumor. Large Inflammatory myofibroblastic tumor in a 21-year-old man in whom an intrathoracic mass was first detected at the age of 10 years. (A) Axial computed tomography shows a large mass filling the right hemithorax with heterogeneous attenuation and calcification. (B) Photograph of right pneumonectomy specimen shows a large mass that, despite its size, was well circumscribed without invasion beyond lung parenchyma.

time of diagnosis. *ALK* overexpression and other described clonal gene rearrangements are seen almost exclusively in children and young adults, while tumors in older adults are often fusion-negative.[120,123–125] The absence of *ALK* expression has been associated with a greater risk for aggressive behavior, including distant metastasis.[123] Patients usually present with asymptomatic peripheral lung nodules, averaging 4 cm in greatest dimension.[126–128] Endobronchial tumors (eFig. 80.5) account for about 15% of cases and patients may present with symptoms of cough and dyspnea.[127,129] Chest imaging studies are frequently described as showing a well-circumscribed mass (eFig. 80.6), occasionally accompanied by calcifications, necrosis (Fig. 80.17), and cavitation.[126–128] IMTs can show increased uptake on PET CT (see eFigs. 78.20 and 78.21) and, in one study, accounted for the highest false-positive diagnosis of lung cancer of all benign pathologic entities.[130]

Most primary pulmonary IMTs are cured by surgical resection, with completeness of resection cited as the most significant prognostic factor.[126,131,132] As such, incomplete resection is associated with substantial risk of recurrence and rarely locally aggressive behavior and death.[123,133] In patients with large, unresectable tumors that harbor clonal gene rearrangements, targeted therapy with small molecule tyrosine kinase receptor inhibitors, crizotinib and ceritinib, has shown efficacy in inducing at least partial tumor regression.[134–137]

SOLITARY FIBROUS TUMOR

Solitary fibrous tumors (SFTs), formerly referred to as *localized fibrous mesotheliomas*, are mesenchymal neoplasms that frequently arise from the pleura. SFTs are not unique to the pleura, however, and have been described within the lung parenchyma (intrapulmonary SFT), mediastinum, and numerous extrathoracic sites.[138–142]

Pleural and intrapulmonary SFTs affect men and women equally, with a mean age of diagnosis in the sixth decade of life.[143–147] More than half of patients are symptomatic at the time of presentation with complaints of chest pain, shortness of breath, and/or cough; the severity of symptoms often correlates with tumor size and location. Clubbing has been reported in up to one-fifth of patients.[148] A paraneoplastic syndrome of hypoglycemia (Doege-Potter syndrome) is rare and results from tumor secretion of insulin-like growth factor-2.[149–153]

SFTs frequently measure over 10 cm in maximum dimension (range 1 to ≈40 cm) and are three times more likely to arise from the visceral than the parietal pleura (eFig. 80.7). Those arising from the visceral pleura are frequently pedunculated and attached to the lung surface by a connective tissue pedicle (Fig. 80.18A). Occasionally, SFTs arise within the fissures (Fig. 80.18B), resulting in a radiologic appearance difficult to distinguish from that of an intrapulmonary tumor (see eFig. 80.7). Parietal pleural lesions are more commonly sessile with a broad base of attachment to chest wall, diaphragm, or mediastinum. Regardless of whether the tumor is arising on the visceral or parietal pleura, chest imaging studies are often described as showing a lobulated, sharply delineated mass that compresses and displaces surrounding structures (Fig. 80.19, eFigs. 80.7 through 80.11, and Video 80.2). SFTs are characterized by heterogeneous attenuation and rich vascularization of the tumor resulting in enhancement with contrast administration (see eFigs. 80.8 and 80.10). Calcifications are occasionally present.[154–156]

Histologically, SFTs are variably cellular spindle cell neoplasms with a collagenous stroma and branching blood

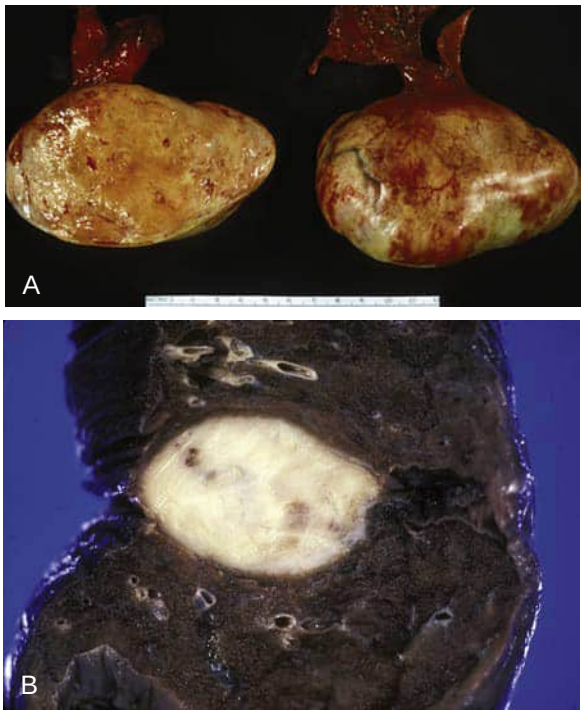

Figure 80.18 Solitary fibrous tumor. Resected solitary fibrous tumor (SFT) arising from the visceral pleura. (A) As demonstrated in this example, most visceral pleural SFTs are attached to the lung by a pedicle and are characterized by a smooth glistening surface *(right)* and an encapsulated homogeneous cut surface without necrosis *(left)*. (B) Less commonly, SFT arises within the fissures, as illustrated in this bilobectomy specimen.

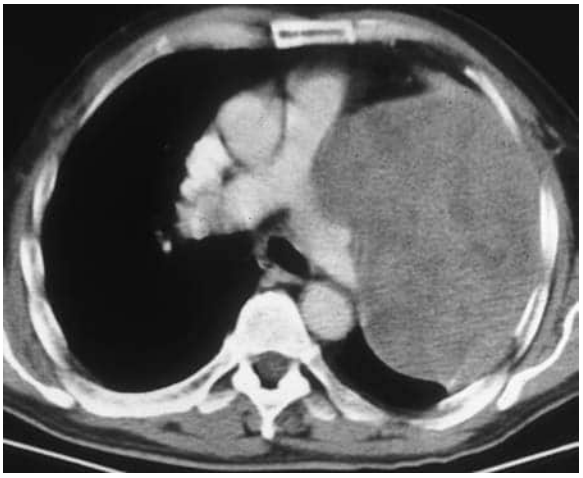

Figure 80.19 Solitary fibrous tumor. Axial computed tomography showing a large solitary fibrous tumor arising from the visceral pleura, nearly filling the left thorax. Together solitary fibrous tumor and inflammatory myofibroblastic tumor are the most likely diagnoses in patients who present with large benign intrathoracic tumors.

vessels. Malignant variants *(malignant SFT)* are more likely to have an invasive growth pattern, increasing cellularity with associated cytologic atypia, higher mitotic rates, and necrosis.[146] SFTs harbor a characteristic *NAB2-STAT6* gene fusion, resulting in overexpression of STAT6, an immunohistochemical finding helpful in distinguishing SFT from its histologic mimics, including in fine-needle aspirates.[157–160]

Most pleural and intrapulmonary SFTs behave as indolent neoplasms and patients are cured with complete surgical excision. A more aggressive course is seen in about 10% of patients, particularly those who undergo incomplete surgical resection or have histologically malignant tumors (eFigs. 80.12 and 80.13). Several risk stratification models have been proposed to predict the risk for recurrence, metastasis, and survival in patients with pleuropulmonary SFT, but, in the absence of indication for systemic therapy, surveillance for these patients remains the mainstay of clinical management.[161]

MENINGOTHELIAL-LIKE NODULES AND INTRAPULMONARY MENINGIOMA

Pulmonary *meningothelial-like nodules* (MLNs), historically termed *chemodectomas*, are a relatively common incidental finding in patients undergoing lung wedge resection for other reasons, usually for removal of a malignant tumor or less commonly for diagnosis of diffuse parenchymal lung disease. MLNs are more frequently seen in women than men and, in about half of patients, the nodules will be multiple.[162–165] A rare syndrome of multiple bilateral MLNs *(diffuse pulmonary meningotheliomatosis)* has been described in women who present in the sixth to eighth decade of life with multiple nodules seen on CT. Half of these patients report dyspnea and/or cough at presentation.[166] Microscopically, MLNs are composed of nests of epithelioid cells histologically and immunophenotypically indistinguishable from meningothelial cells of the central nervous system (Fig. 80.20). Despite this unexplained phenotypic overlap, molecular studies demonstrate significant differences between MLNs and conventional central nervous system meningiomas, raising the possibility that MLNs may be a reactive rather than neoplastic process.[167]

Primary *intrapulmonary meningiomas* are rare solitary lesions unrelated to MLN.[168–170] Men and women are affected equally and typically present in their mid-50s with an asymptomatic solitary lung nodule, averaging 3 cm in greatest dimension. Patients with multiple lesions should be presumed to have metastatic disease from a central nervous system primary until proven otherwise.[171,172] Rare cases of intrapulmonary meningioma show increased uptake on PET scan.[173] Complete surgical resection is curative in patients with WHO grade I meningiomas, while higher grade tumors have a greater risk of recurrence and/or locally aggressive behavior.[174]

OTHER RARE ENTITIES

Granular cell tumors, referred to in older literature as granular cell myoblastomas, are uncommon primary lung neoplasms that typically present as pedunculated or sessile endobronchial tumors (Fig. 80.21, eFig. 80.14).[175,176] Lesions are multiple in a fourth of patients. Symptoms are reported in half and result from airway obstruction. Pulmonary *granular cell tumors* are benign and can usually be managed with conservative excision.

PEComatous tumors refers to groups of tumors thought to arise from *perivascular epithelioid cells* (PECs). In the lung, these tumors may take several forms, including (1) a benign localized mass called *PEComa*, also referred to as *clear cell ("sugar")* tumor, or (2) a diffuse multicystic proliferation known as *lymphangioleiomyomatosis*.[34] PEComas usually present as asymptomatic solitary lung nodules.[177,178] Surgical resection is curative. Lymphangioleiomyomatosis is discussed in detail in Chapter 97.

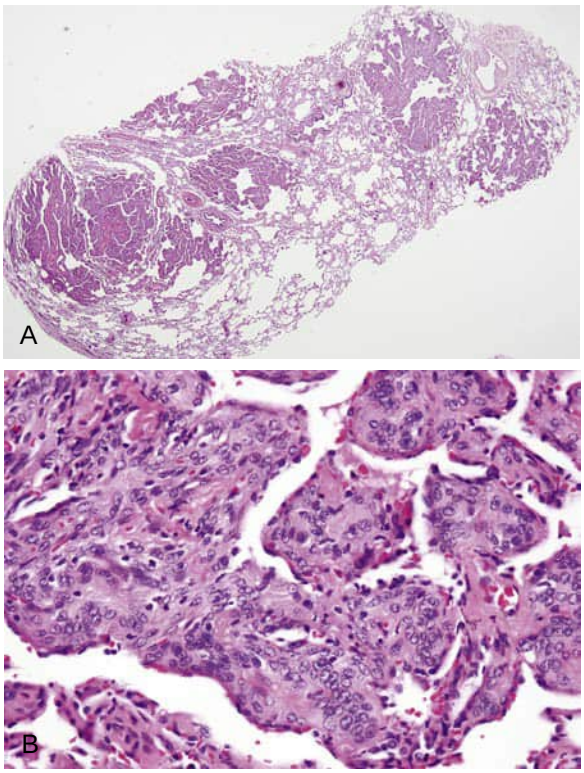

Figure 80.20 Multiple meningothelial-like nodules. Also called *diffuse pulmonary meningotheliomatosis,* the multiple nodules are shown in a surgical lung biopsy from a 56-year-old woman who presented with dyspnea. (A) At low magnification, multiple nodules are seen randomly distributed throughout the biopsy. (H&E stain; ×20 original magnification.) (B) At higher magnification, the nodules comprise bland meningothelial cells arranged in poorly formed nests and expanding the interstitium. (H&E stain; ×400 original magnification.)

Figure 80.21 Granular cell tumor. Cut surface of pneumonectomy specimen in which a granular cell tumor *(arrows)* partially obstructs the lower lobe bronchus.

Key Points

- Most benign lung neoplasms are incidentally discovered as asymptomatic, peripheral lung nodules in adult patients.
- Contrary to expectation, FDG-PET scans may be positive in benign lung tumors.
- Squamous cell papilloma is the most common type of papilloma and is associated with infection by HPV types 11 and/or 6.
- Pulmonary hamartoma is the most common benign neoplasm in patients who undergo resection; it has been shown to have translocations involving chromosomes 6p21 (gene *HMGA1*) or 12q14-15 (gene *HMGA2*).
- Inflammatory myofibroblastic tumor belongs to a heterogenous group of tumors broadly termed "inflammatory pseudotumor" but, within this group, it seems to represent a morphologically distinct neoplasm with common molecular alterations involving the *ALK* gene locus (chromosome band 2p23).
- Solitary fibrous tumors harbor a characteristic *NAB2-STAT6* gene fusion, resulting in overexpression of *STAT6*.
- Solitary fibrous tumor and inflammatory myofibroblastic tumor are the most likely diagnoses in patients who present with large intrathoracic tumors.
- For virtually all benign lung neoplasms, surgical resection is curative with recurrence most often associated with incomplete resection rather than malignant transformation.

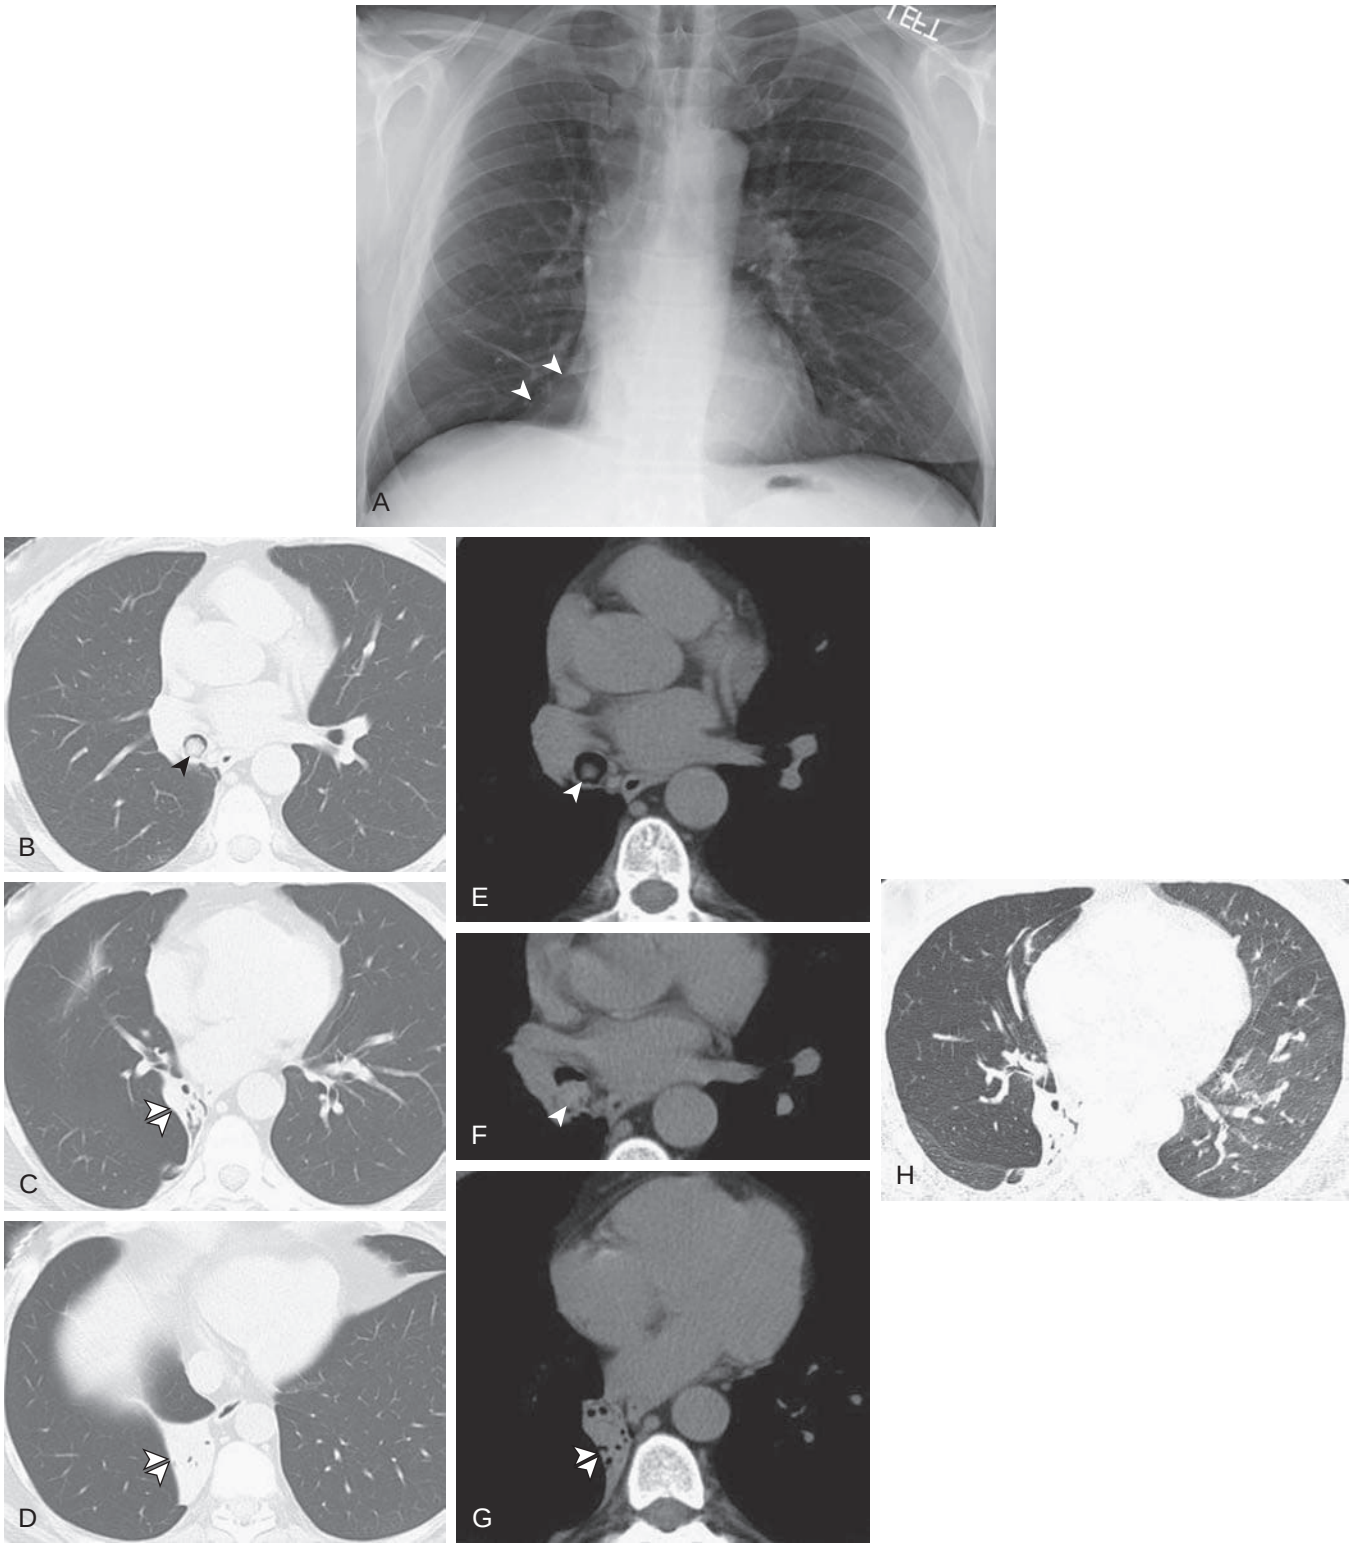
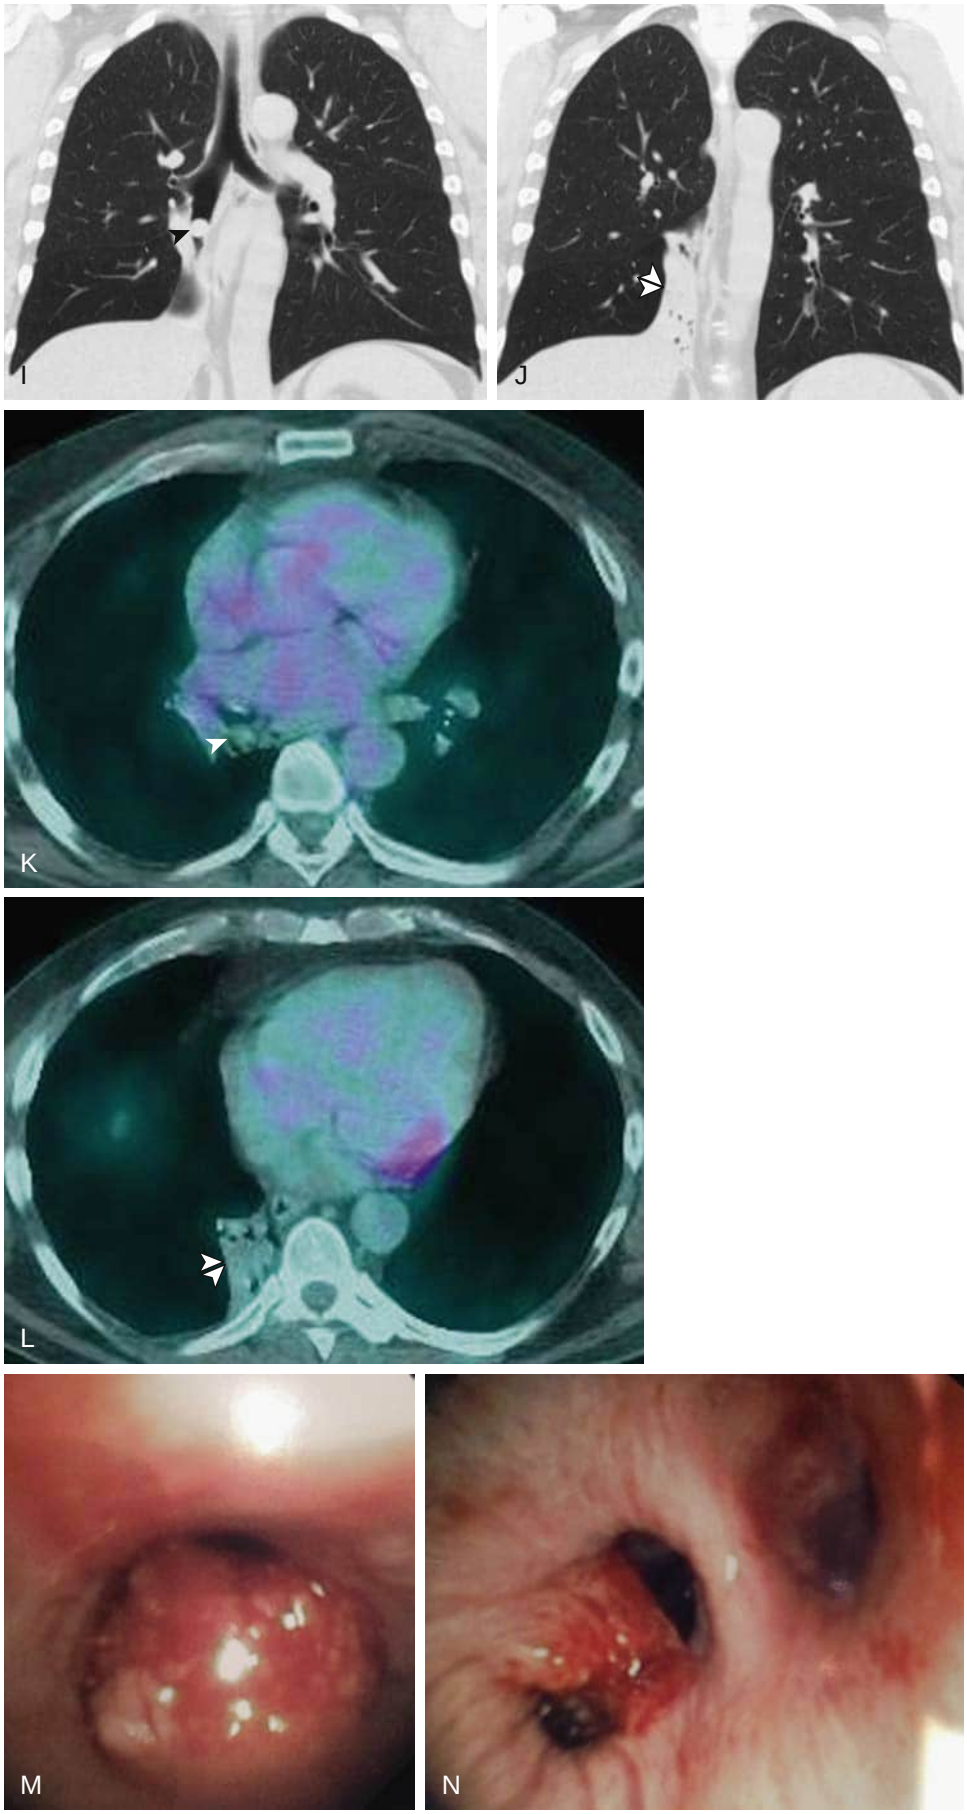
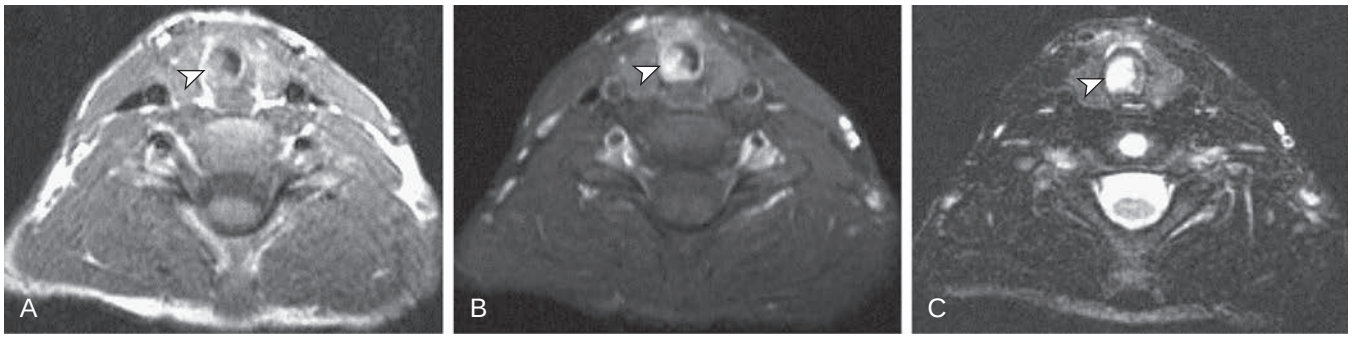
Axial chest computed tomography displayed in lung windows shows several thin-walled cysts *(arrowheads)* associated with small, nonspecific lung nodules *(arrows)*, the latter representing micronodular pneumocyte hyperplasia. (Courtesy Michael B. Gotway, MD.)



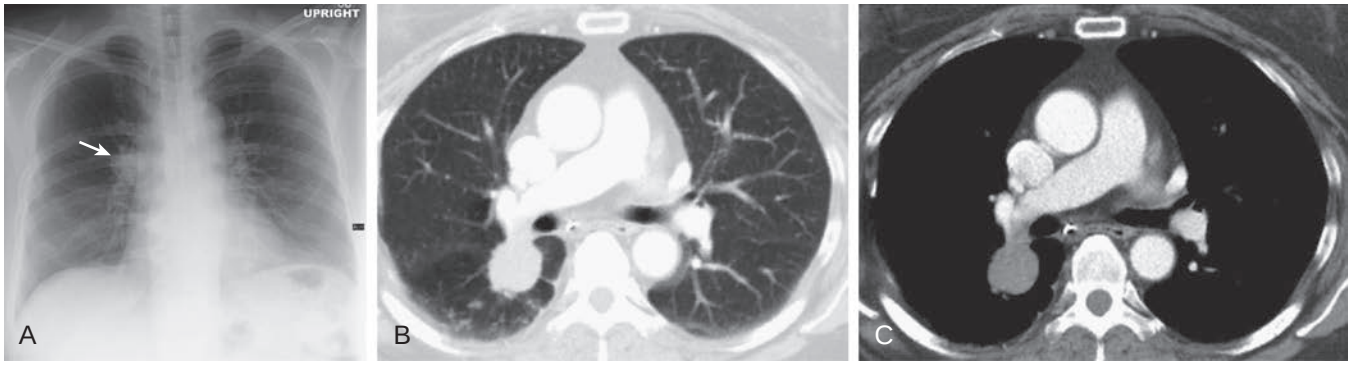
eFigure 80.4 Endobronchial hamartoma. (A) Frontal chest radiograph shows right lower lobe collapse, evidenced by medial and inferior retraction of the right major fissure *(arrowheads)*. Right lung volume is diminished overall compared with the left. Axial unenhanced chest computed tomography (CT) scans displayed in lung (B–D) and soft tissue (E–G) windows show a solid lesion residing within the bronchus intermedius (*arrowheads*, B, E, and F). Right lower lobe collapse (*double arrowheads*, C, D, and G) is present. (H) Axial high-resolution CT shows hyperinflation of the right middle lobe, partially compensating for the right lower lobe collapse.



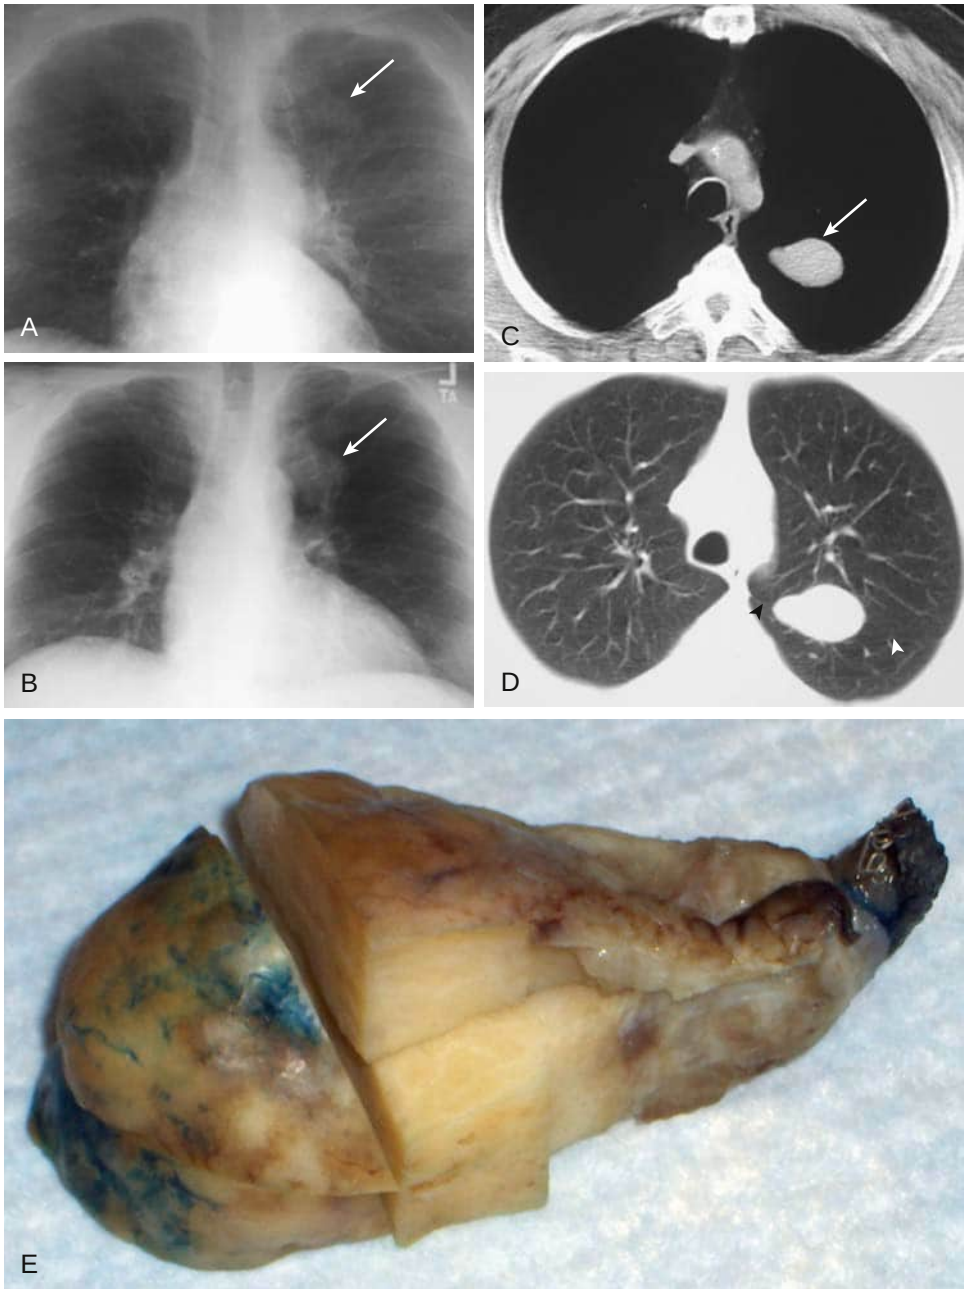
eFigure 80.4—cont'd (I–J) Coronal chest CT images show the endobronchial lesion *(arrowhead)* within the bronchus intermedius and the right lower lobe collapse *(double arrowheads)* to advantage. (K–L) Axial fused positron emission tomography-CT images show no significant tracer accumulation within the bronchus intermedius lesion *(arrowhead)* or the collapsed right lower lobe *(double arrowheads)*. Bronchoscopic images before (M) and after (N) treatment show decrease in size of the lesion, shown on biopsy to represent hamartoma. (Courtesy Andrew H. Goldstein, MD.)



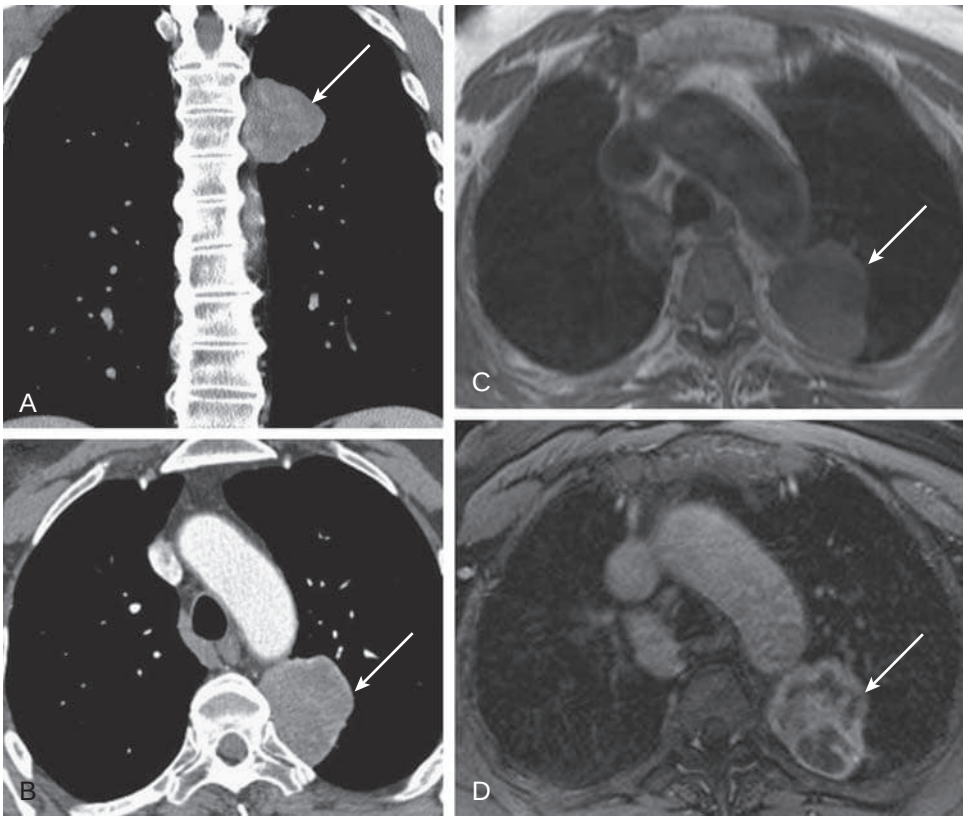
eFigure 80.5 Tracheal inflammatory myofibroblastic tumor. T1-weighted axial magnetic resonance (MR) images before (A) and after (B) intravenous gadolinium administration show an irregular lesion *(arrowheads)* arising from the right lateral tracheal wall. (C) Axial T2-weighted MR image shows high signal within the lesion *(arrowhead)*, consistent with fluid density. Biopsy showed inflammatory myofibroblastic tumor. (Courtesy Michael B. Gotway, MD.)



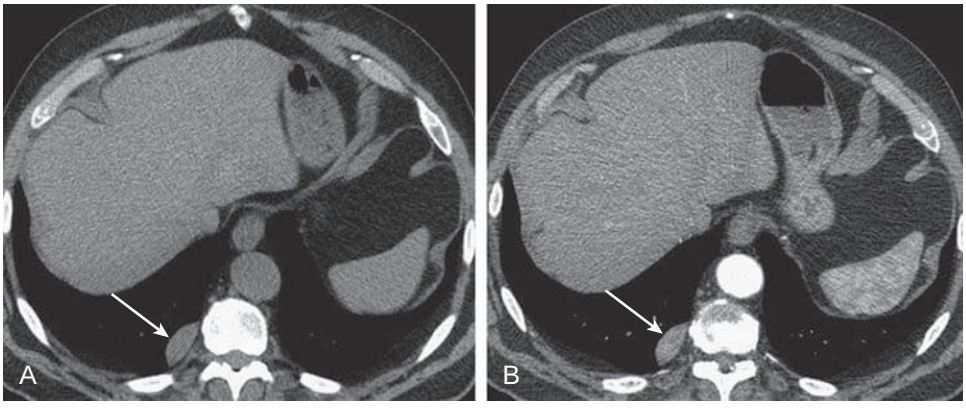
eFigure 80.6 Inflammatory myofibroblastic tumor. (A) Frontal chest radiograph shows a circumscribed nodule *(arrow)* projected over the right hilum. Axial contrast-enhanced chest computed tomography displayed in lung (B) and soft tissue (C) windows shows a finely lobulated superior segment right lower lobe nodule. Small satellite nodules were present more inferiorly. The appearance of the lesion is nonspecific. Biopsy showed inflammatory myofibroblastic tumor. (Courtesy Michael B. Gotway, MD; case courtesy Paul J. Conomos, MD, Arizona Pulmonary Specialists, Phoenix.)



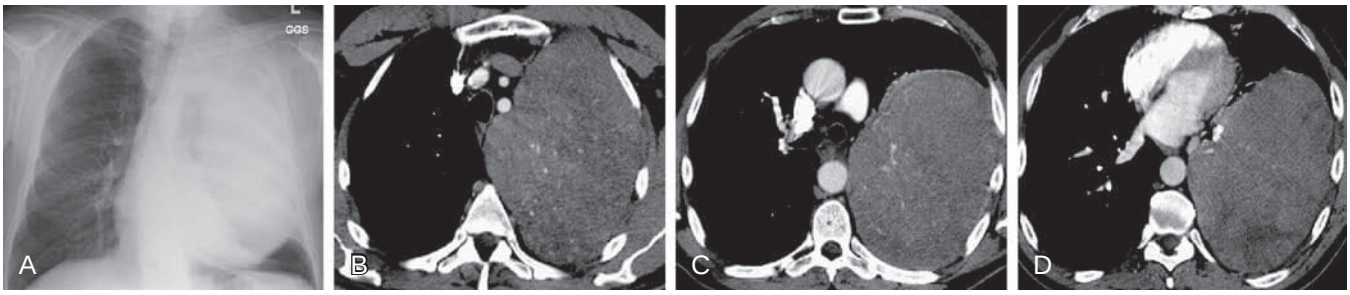
eFigure 80.7 Solitary fibrous tumor of the pleura: visceral pleural origin evident on imaging. (A) Frontal chest radiograph shows a poorly defined left upper lobe opacity *(arrow)*. (B) Repeat frontal chest radiograph 5 years after part A shows slow interval growth in the lesion *(arrow)*. Axial unenhanced chest computed tomography images displayed in soft tissue (C) and lung (D) windows shows a homogeneous, circumscribed, noncalcified lesion (*arrow*, C). On the lung window image (D), the lesion is clearly related to the left major fissure *(arrowheads)*. (E) Specimen following surgical resection was shown to be solitary fibrous tumor of the pleura. (A–D, Courtesy Michael B. Gotway, MD.)



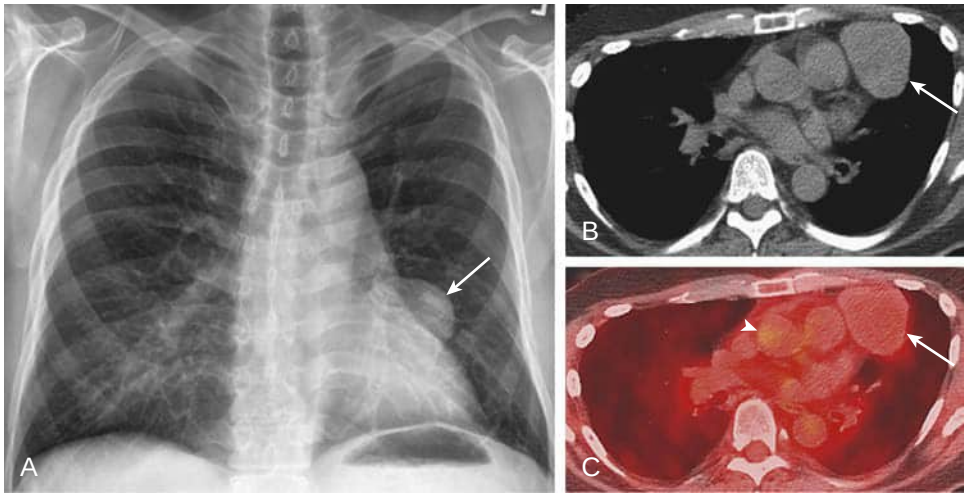
eFigure 80.8 Solitary fibrous tumor of the pleura. Coronal (A) and axial (B) contrast-enhanced chest computed tomography shows an enhancing lesion with extensive mediastinal pleural contact *(arrow)*, suggesting an extrapulmonary origin (see Video 80.2). (C) Axial T1-weighted magnetic resonance image before intravenous contrast administration. (D) Axial contrast-enhanced magnetic resonance image shows extensive peripheral lesion enhancement *(arrow)* as well as enhancement of the internal soft tissue septations within the lesion. Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)



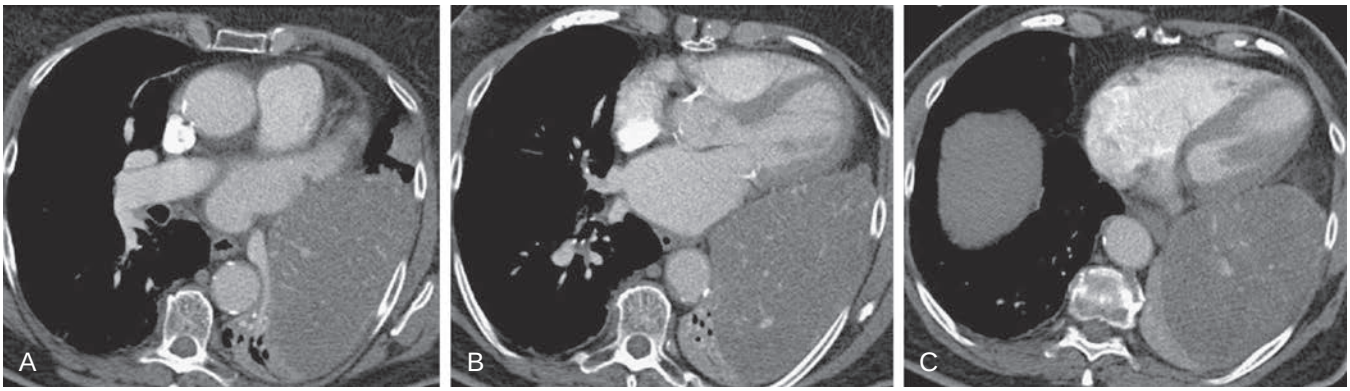
eFigure 80.9 Solitary fibrous tumor of the pleura. Unenhanced (A) and contrast-enhanced (B) chest computed tomography shows the typical appearance of an extrapulmonary lesion *(arrows)*: a circumscribed, lenticular- or oblong-shaped opacity creating obtuse margins with the chest wall. Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)



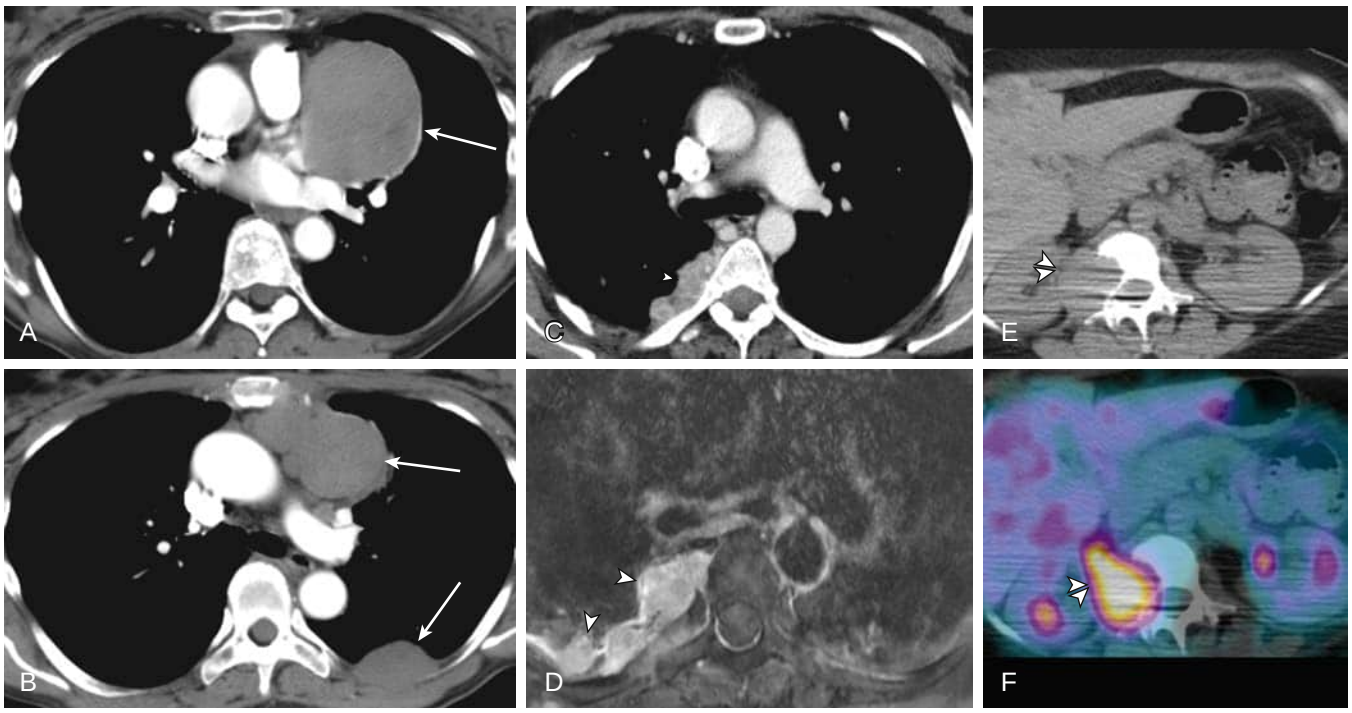
eFigure 80.10 Solitary fibrous tumor of the pleura; large. (A) Frontal chest radiograph shows near complete opacification of the left thorax with slight shift of the cardiomediastinal structures to the contralateral side. (B–D) Axial contrast-enhanced chest computed tomography shows a solid, vascularized lesion occupying much of the left thorax. The large size of the lesion makes determination of the organ of origin difficult, but solitary fibrous tumor of the pleura is a consideration, particularly when no overtly aggressive features, such as a large pleural effusion, rib destruction, or lymph node enlargement, are evident. Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)



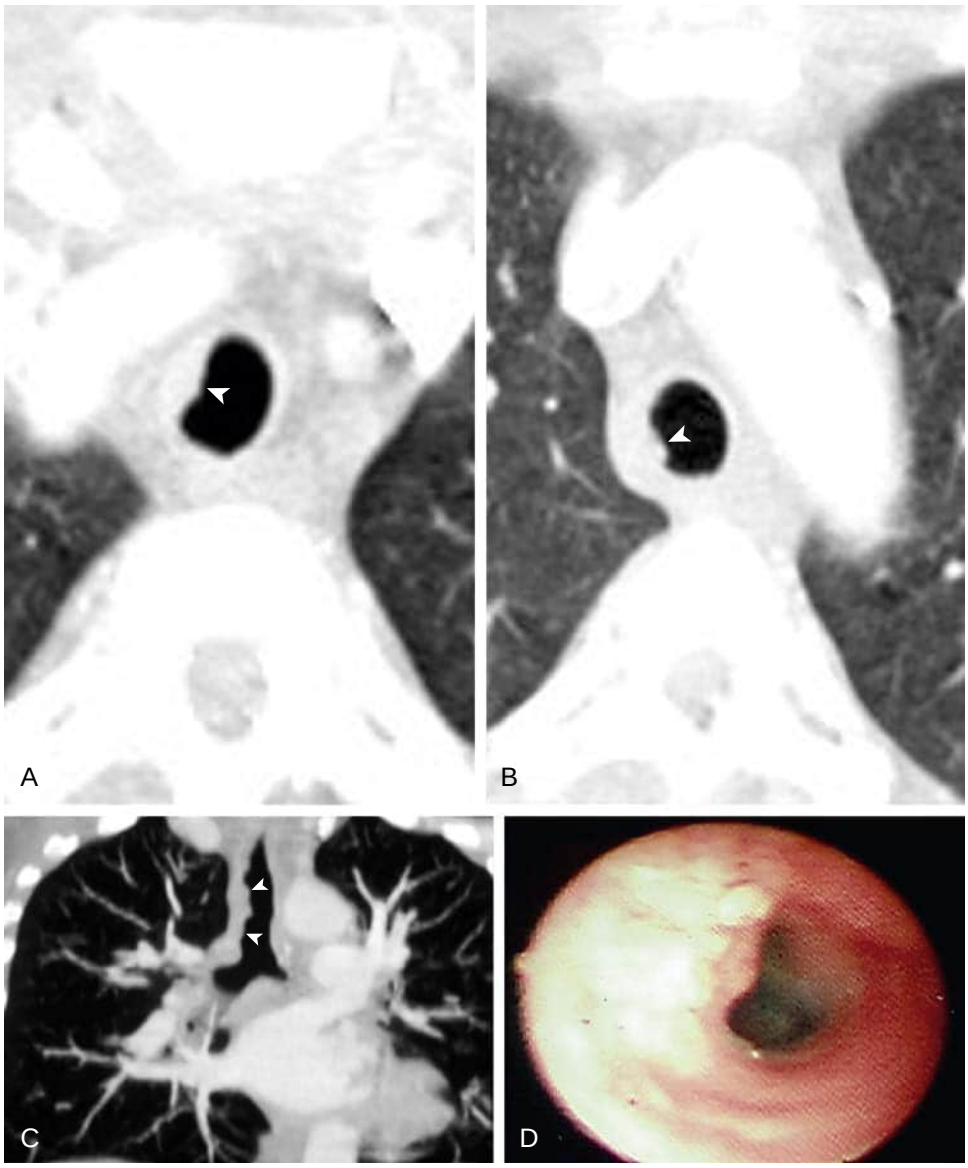
eFigure 80.11 Solitary fibrous tumor of the pleura. (A) Frontal chest radiograph shows a circumscribed mass *(arrow)* along the left heart border. The mediastinal contact, smoothly marginated character of the lesion, and obtuse angles of the lesion at its interface with the lung suggest an extrapulmonary origin. (B) Unenhanced chest computed tomography (CT) shows the lesion *(arrow)* has mildly inhomogeneous attenuation and significantly contacts the left mediastinum and pericardium. (C) Axial fused positron emission tomography-CT image shows little tracer accumulation within the lesion *(arrow)*: note the similarity in tracer uptake between the lesion *(arrow)* and mediastinal blood pool in the aorta *(arrowhead)*. Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)



eFigure 80.12 Malignant solitary fibrous tumor of the pleura. (A–C) Axial contrast-enhanced chest computed tomography shows a large, homogeneous, solid, vascularized left-sided mass with broad pleural surface contact. Biopsy showed features consistent with malignant fibrous tumor of the pleura. (Courtesy Michael B. Gotway, MD.)



eFigure 80.13 Malignant solitary fibrous tumor of the pleura. (A–B) Axial contrast-enhanced chest computed tomography (CT) displayed in soft tissue windows shows circumscribed and lobulated soft tissue masses *(arrows)* involving the mediastinal and posterior pleural surfaces, proven on biopsy to represent fibrous tumor of the pleura. Axial contrast-enhanced chest CT (C) and axial T2-weighted magnetic resonance imaging (D) show lobulated soft tissue masses *(arrowheads)* related to the right mediastinal and posteromedial pleural surfaces, again reflecting fibrous tumor of the pleura. Axial unenhanced chest CT (E) and fused positron emission tomography-CT image (F) show a metabolically active lesion involving L1, representing metastatic malignant fibrous tumor of the pleura. This patient originally had a right upper thoracic pleural fibrous tumor arising from the pleura resected in 1997. (Courtesy Diego Ruiz, MD, Palo Alto Medical Clinic, CA, and Michael B. Gotway.)



eFigure 80.14 Granular cell tumor of the trachea. Axial enhanced chest computed tomography (CT) (A–B) and coronal maximum intensity projection (C) performed as part of CT aortography in a patient with chest pain shows the incidental detection of a plaquelike lesion *(arrowheads)* along the right lateral tracheal wall. (D) Bronchoscopic image shows a lobulated lesion corresponding to the computed tomography abnormality. Biopsy proved malignant granular cell tumor. (A–C, Courtesy Michael B. Gotway, MD.)

INTRODUCTION

The one generalization about *venous thromboembolism* (VTE) free from controversy is that many aspects of this disorder remain controversial. There are multiple reasons why VTE continues to engender lively debate. Perhaps the major reason, notwithstanding recent substantial advances, is that a number of fundamental questions continue to exist regarding its pathogenesis, clinical presentation, diagnosis, and therapy.

VTE represents a potentially fatal disease process with a clinical presentation that is often silent or nonspecific and

for which a wide range of diagnostic techniques is available, many with technical and interpretive limitations. Although estimates vary widely, the best available information suggests that there are at least 1 to 5 million episodes of VTE annually in the United States.[1,2] The annual incidence of diagnosed acute *pulmonary embolism* (PE) is approximately 65 to 70 per 100,000.[3–5] Every year, based on discharge diagnosis codes, there are about 676,000 patients with *deep venous thrombosis* (DVT) and about 340,000 with PEs in the United States.[2] One in 12 persons aged 45 years or older will be diagnosed with VTE at some point in their lives, and the incidence increases exponentially through the sixth to ninth decades of life.[6]

Diagnosed cases likely underrepresent the true incidence of acute PE because they account for only those patients in whom the diagnosis was made correctly.[7] Autopsy series suggest that the true number of deaths from acute PE, including patients who died without the diagnosis being made, is at least threefold higher and could be as much as 10-fold higher than reported.[7-11] For this reason, it is likely that most PE-related deaths happen when PE is undiagnosed (and therefore untreated) during life.

Historically, about one in five patients who sustain a PE may die from it.[12] The overwhelming majority of these deaths do not appear to arise from therapeutic failure. The in-hospital mortality rate from acute PE is 2–5% once the diagnosis of embolism is confirmed and appropriate therapy initiated.[5,13,14] Notable exceptions are patients who initially present with hemodynamic impairment[14] and those with recurring PE despite therapy,[15] in whom mortality rates are much higher. Those circumstances notwithstanding, the majority of deaths related to embolism appear to arise from a failure to prevent the disease in at-risk patients and from a failure to make the diagnosis in those afflicted.[7,12]

The incidence of fatal PE declined from the 1970s through the 2000s[16,17] but, over the past 10 years, the number of PE-related deaths and the death rates in the U.S. population have gradually risen.[18] It is noteworthy that these statistics do not account for fatal PE not diagnosed clinically, as described earlier. Balancing these facts are some data that suggest that the increasing reliance on *computed tomographic pulmonary angiography* (CTPA) may be leading to overdiagnosis of PE in some populations.[19] Total admissions and hospital charges for PE have increased in the last 2 decades, which may reflect a trend of admitting patients with less severe PE, although that would not be supported by data showing that population-adjusted deaths during admission for PE have increased.[5] Despite the increase in PE-related hospitalizations, mortality from acute PE remains a substantial public health care problem, possibly because of the demographics of the aging population.[18,20]

Contributing to the debate surrounding VTE is the involvement of a wide range of medical disciplines in its prevention, diagnosis, and management. Thrombosis is not a discrete clinical subspecialty. The problem of VTE involves pulmonologists, cardiologists, hematologists, internists, specialists in vascular disease, radiologists, a range of surgical subspecialists, obstetricians, and others. Because specific prophylactic, diagnostic, and therapeutic strategies within one discipline may not necessarily be applicable to another, a perception of coherence in the clinical approach to this disease process often appears to be lacking.

Many of the long-standing controversies surrounding the natural history, diagnosis, and therapy of VTE have been partially or completely reconciled, resulting in substantial changes in the diagnostic and therapeutic approach to the disease. The persistence of a number of unresolved issues, and the emergence of still others, should not be a cause for cynicism. In the approach to the patient with suspected VTE, an understanding of what is unknown can prove invaluable to the decision-making process.

PATHOGENESIS AND RISK FACTORS

The triad of venous stasis, alterations in coagulation, and vascular injury identified by Virchow in 1856 as primary factors in the pathogenesis of VTE has been supported by a considerable amount of clinical and experimental evidence. Over the past several decades, severe abnormalities of the coagulation and fibrinolytic system, including isolated deficiencies of protein C, protein S, antithrombin III, and plasminogen, as well as the presence of a lupus anticoagulant, have been described and their association with first-time and recurrent VTE confirmed (Table 81.1).[21,22] In addition, there has been increasing recognition of less severe, but more common, inherited thrombophilic conditions capable of shifting the hemostatic balance toward thrombosis and mildly increasing the risk of venous thromboembolic events. They are especially notable among patients with thrombi in unusual locations, such as the upper extremities.[23] Although it is a subject of debate whether they increase the risk of recurrence slightly, the magnitude of the increase is unlikely to warrant changes in therapeutic strategies for patients with those thrombophilias, as discussed later.[6,24]

Factor V Leiden mutation, the most common of the inherited thrombophilic conditions, was first described in 1993 by Dahlback; it is the consequence of a single point mutation in the factor V gene (adenine for guanine) resulting in *activated factor V* (factor Va) with diminished sensitivity to the natural anticoagulant effect of activated protein C.[25] Approximately 5% of whites in Europe and North America are heterozygous for this genetic defect; lower rates of carrier frequency have been reported among Native American, African, and Asian populations.[26,27] Although initially suspected to present in the majority of patients with VTE, a large prospective study of unselected subjects detected the mutation in just over 10% of those who developed VTE.[28] Depending on the population involved, the heterozygous state carries between a twofold and 10-fold increase in lifetime risk for VTE.[6,29,30] Whereas the relative risk among patients homozygous for this mutation is likely much higher, only very small cohorts with this genotype have been followed prospectively, making estimates of absolute risk imprecise.[29–32]

Factor V Leiden mutation appears to be an important risk factor for VTE during pregnancy, in the postpartum

Table 81.1 Thromboembolic Risk Factors

HEREDITARY THROMBOPHILIAS
Protein C deficiency
Protein S deficiency
Antithrombin III deficiency
Factor V Leiden mutation
Prothrombin 20210 G → A variation
Hyperhomocysteinemia
Dysfibrinogenemia
Familial plasminogen deficiency
ACQUIRED SURGICAL PREDISPOSITIONS
Major thoracic, abdominal, or neurosurgical procedures requiring general anesthesia and lasting >30 min
Hip arthroplasty
Knee arthroplasty
Knee arthroscopy
Hip fracture
Major trauma
Open prostatectomy
Spinal cord injury
ACQUIRED MEDICAL PREDISPOSITIONS
Prior venous thromboembolism
Advanced age (>60 yr)
Malignancy
Congestive heart failure
Cerebrovascular accident
Nephrotic syndrome
Estrogen therapy
Pregnancy and the postpartum period
Obesity
Prolonged immobilization
Antiphospholipid antibody syndrome
Lupus anticoagulant
Inflammatory bowel disease
Paroxysmal nocturnal hemoglobinuria
Behçet syndrome

period, and during oral contraceptive use.[31–34] The risk of thrombosis in women who use oral contraceptives and are carriers of the factor V mutation is increased 30-fold compared to women who have neither of these risk factors.[35] However, because the absolute increase in VTE is modest, selective thrombophilia screening based on previous personal or family history of VTE is more cost-effective than universal screening.[32]

Normal prothrombin is overproduced in those with a sequence variation in the prothrombin gene (G20210A). This mutation was described in 1996 and is estimated to exist in approximately 2–4% of the population.[36] Heterozygous prothrombin G20210A is associated with a threefold to fourfold increased relative risk of lower extremity venous thrombosis.[36–38]

Hyperhomocysteinemia had been identified as a potential independent predisposition to VTE, but the evidence supporting its role is quite weak. Elevation of plasma homocysteine levels may be the result of genetic abnormalities, such as the methylene tetrahydrofolate reductase C677T gene polymorphism, nutritional deficiencies of vitamins (B_6, B_{12}, folate), clinical disorders (renal insufficiency, hypothyroidism, inflammatory bowel disease), or a combination of the three. Although retrospective, case-control studies suggested an association between hyperhomocysteinemia and VTE, the results were not consistently confirmed in prospective studies.[39,40] Specifically, there appears to be no association between the methylene tetrahydrofolate reductase C677T gene polymorphism and VTE and, at most, a weak association between elevated homocysteine levels and VTE.[41]

These three common genetic thrombophilias (factor V Leiden, prothrombin G20210A, and hyperhomocysteinemia) may act as independent risk factors for increasing thrombosis risk.[42,43] Although the relative risk for patients with multiple thrombophilic conditions may be higher than for patients with only one, the clinical implications of this possibility are uncertain.

The identification of these risk factors, and the likelihood that others exist, raises the possibility that screening to determine relative thromboembolic risk may be feasible in the future; however, a consensus for such an approach does not currently exist. Despite its prevalence in the general population, screening for factor V Leiden mutation is not advised because the overwhelming majority of patients with this abnormality will never experience a thromboembolic event. Furthermore, the absence of this abnormality should not influence the decision to provide prophylaxis to patients at clinical risk. In addition, there is no evidence that prolonged anticoagulation would be more beneficial for VTE patients with either factor V Leiden[44] or the prothrombin G20210A gene[45] than in VTE patients without these mutations.[24]

The long-term implications for patients with preexisting VTE who are homozygous for factor V Leiden or for prothrombin G20210A are controversial. Although early reports suggested that VTE patients homozygous for factor V Leiden had about twice the risk of recurrence than those who are heterozygous,[46,47] later studies reported no increase in risk for recurrence.[48,49] Studies suggesting higher recurrence for homozygotes differed regarding whether the recurrence risk was limited to provoked VTE (e.g., during subsequent pregnancies without prophylactic anticoagulation)[47] or whether it applied to spontaneous (unprovoked) recurrence.[46]

Similarly, reports have varied regarding whether patients with spontaneous (unprovoked) VTE who are heterozygous for both factor V Leiden and the prothrombin G20210A mutation are at higher risk for recurrence than similar patients without those mutations.[46–48] However, even if the association were to be confirmed, it would not establish a risk-benefit relationship for prolonged anticoagulation in patients with the combination of thrombophilic mutations.

For all the reasons stated, the benefits of screening for the common thrombophilias are controversial. Patient groups in whom screening is likely to yield positive results include those with a history of recurrent VTE or with a confirmed family history of thromboembolism, a first episode of thromboembolism at an early age, spontaneous venous thrombosis, thromboses in unusual anatomic sites, arterial thrombosis, and thromboembolism associated with pregnancy[50,51] or estrogen use. Whether screening should be performed before the initiation of oral contraceptive agents remains a matter of debate.[52,53] The relative risk of VTE is increased approximately fourfold in users of oral

contraceptives, although the increase in absolute risk is modest.[35,54] A policy of routine screening would deny effective contraception to a substantial number of women while preventing only a small number of PEs. A similar situation exists for pregnancy, in which the presence of factor V Leiden or the prothrombin G20210A mutation increases the relative risk of VTE but only slightly increases the absolute risk.[51]

In most patients, even those with an identified thrombophilic state, clinical conditions associated with venous stasis, intimal injury, or both serve as the basis for the thromboembolic event,[55] and adequate prophylaxis may mitigate that risk.[47] In hospitalized patients, the risk of VTE is not limited to patients undergoing surgical procedures; the risk in patients admitted with a wide range of acute medical problems is comparable to that seen in surgical patients.[56–58]

Major acquired risk factors include pelvic or lower extremity fractures, hip and knee surgery, a past history of VTE, acute paralytic stroke or spinal injury, major traumatic injury, open prostatectomy, and abdominal or pelvic surgery for malignant disease. Other factors that enhance risk include prolonged general anesthesia, advancing age, cardiac disease, pregnancy,[50] the postpartum state, the use of estrogen-containing hormone replacement therapy,[59] malignancy, nephrotic syndrome,[60] the presence of a lupus anticoagulant or antiphospholipid antibody, and prolonged immobilization.[61]

Risk factors may be multiplicative,[51,55] and chronic medical conditions not typically listed as thrombophilias may still substantially increase the risk of VTE. For example, the lifetime risk of VTE among patients with sickle cell disease or sickle cell trait is increased at least as high as it is among those with factor V Leiden,[6,62,63] and the risk of VTE during hospitalization is greatly increased in patients with sickle cell disease and sickle cell trait.[64] Patients with chronic liver disease have about twice the lifetime risk of VTE as the general population,[65] and hospitalized patients with cirrhosis have about twice the risk of VTE as other hospitalized patients,[66] despite elevated international normalized ratio values that might be incorrectly interpreted as protective and dissuade clinicians from using prophylaxis.[66–68] Obesity is known to increase the likelihood of VTE during critical illness.[69] It is additionally important to consider the diagnosis of PE in patients with acute exacerbations of COPD because the prevalence of PE in unexplained acute exacerbations of COPD is relatively high, with a pooled prevalence of 16.1% on a systematic review.[70]

Although the risk of posttreatment recurrence depends in part on whether the VTE was provoked by transient risk factors,[71] the distinction between provoked and unprovoked is not entirely dichotomous but, rather, represents a spectrum of risk for recurrence. For example, compared to unprovoked VTE, VTE provoked by a surgical event is one-tenth as likely to result in recurrence, whereas VTE provoked by a nonsurgical transient risk factor is more than half as likely to result in a posttreatment recurrence.[71] Furthermore, there is a great deal of heterogeneity among the nonsurgical provoking factors. For example, a strong risk factor such as acute necrotizing pancreatitis requiring hospitalization is more likely than not to result in VTE.[72] Air travel, on the other hand, is a relatively mild provoking factor, resulting in VTE after about 1 in every 100,000 flights shorter than 4 hours and 1 in every 4700 flights of longer duration.[73] Although the relative risk in fliers is increased compared to nonfliers, the absolute incidence is quite low[73,74] and, in about half of cases, associated with a coexisting risk factor that poses an even higher risk for VTE than the flight itself.[75]

The likelihood that a "provoking" factor was largely responsible for a VTE should weigh heavily in subsequent prognostic and treatment decisions. These types of considerations allow the development of a reasonable risk profile in an individual patient, a profile that should influence the use and intensity of prophylactic intervention.[55] See Chapter 82 for details on prophylaxis.

NATURAL HISTORY: DEEP VENOUS THROMBOSIS

Venous thrombi appear to originate either in the vicinity of a venous valve cusp, where eddy currents arise, or at the site of intimal injury.[76] Platelet aggregation and release of mediators initiate the sequence. With local accumulation of such factors, the coagulation cascade is activated and thrombus develops, composed primarily of fibrin and erythrocytes. As the thrombus extends, local fibrinolytic activity is enhanced. Thus, thrombus behavior becomes a dynamic process that may result in complete dissolution, partial resolution resulting in a variable degree of intimal narrowing and valvular damage, progressive proximal extension, or embolization. In more than half of patients, the venous wall suffers some degree of permanent scarring, which is visible on ultrasound[77]; if the venous wall scarring causes severe obstruction, collateral veins develop.

Extensive autopsy and clinical studies have established that some 90% of clinically apparent PEs arise from venous thrombosis in the deep veins of the lower extremities.[78] In fact, a conservative estimate is that at least one-third of DVT is complicated by symptomatic or asymptomatic PE.[79] Venous thrombi capable of embolization can also arise from other sites. Primary iliac or proximal femoral thrombi may develop in patients undergoing surgery involving the hip, and pelvic vein thrombosis may develop in patients undergoing pelvic or prostatic surgery. Axillosubclavian vein thrombosis may be spontaneous, resulting from congenital abnormalities of the thoracic outlet or may be related to indwelling central venous catheters, pulmonary artery catheters, or transvenous pacing wires.[80–82] Both peripherally inserted central catheters and midline venous catheters are also associated with venous thrombi.[83,84] In patients with dilated right heart chambers or pulmonary arteries, thrombi can form at those sites and embolize distally into the branches of the pulmonary artery. The prevalence of upper extremity DVT is about 3% in a large-scale VTE patient registry. Patients with DVT in the upper extremities were more likely to have a central venous catheter or active malignancy at the time of diagnosis and were less likely to be diagnosed with concomitant PE.[85]

The likelihood of embolism is influenced by the location of thrombi in the veins of the lower extremity. The majority of thrombi originate in the deep veins of the calf (i.e., *distal*) and those that remain limited to the calf veins do not usually result in PE.[86] However, 15–25% of symptomatic

isolated calf thrombi, if left untreated, will extend into the *proximal* deep veins, such as the popliteal vein, femoral vein (which was previously labeled by the misleading term "superficial femoral vein"), common femoral veins, and even more proximal veins.[87] One-third to one-half of patients with proximal extension develop symptomatic or asymptomatic PE.[15,79,88,89] For that reason, a small proportion of patients with distal DVTs are at risk for PE.[79,87,90–92] The risk of proximal DVT and PE after isolated calf DVT is higher in hospitalized patients and in those 60 years of age and older.[91] Symptomatic calf vein thrombosis also poses a risk for recurrence, although the risk is less than for proximal DVT.[87] In one series, about 1 in 10 patients with symptomatic isolated calf vein thrombosis experienced recurrence of VTE, and about half of those recurrences were in the form of proximal DVT or PE.[93]

This natural history of DVT has several important diagnostic and therapeutic implications. First, because the vast majority of emboli arise from thrombi in the veins in the lower extremity, diagnostic approaches to DVT can focus upon techniques that detect lower extremity DVT. Second, techniques that detect above-knee thrombi are of particular value. Finally, although it is true that calf-limited thrombi rarely embolize, many have incorrectly concluded from this information that symptomatic, calf-limited DVT represents a clinically irrelevant condition. As mentioned earlier, calf-limited thrombi may extend proximally, and patients with symptomatic calf vein thrombosis are at risk for PE and recurrence, albeit at a lower risk than proximal vein thrombosis.[87,94]

Although most above-knee thrombi represent extensions from calf thrombi, some do arise in the larger, proximal veins de novo. This appears to be restricted principally to patients with hip fracture or replacement, pelvic surgery (including prostatic resection), and other high inguinal pelvic trauma.

At any time during the thrombotic process, a portion or all of the thrombus can detach as an embolus. This risk is highest early in thrombus development before there is significant fibrinolysis or organization. Beyond this acute phase, the long-term outlook is influenced principally by the extent of residual venous obstruction and valvular damage. If significant obstruction or valvular damage persists, downstream stasis will be present, leading to a risk of recurrent DVT and development of the postphlebitic syndrome.[95,96]

NATURAL HISTORY: PULMONARY EMBOLISM

PE causes a number of consequences to gas exchange and other pulmonary functions.[97] Regional obstruction to pulmonary blood flow and diversion of the flow to unobstructed portions of the lung may alter the ventilation-perfusion balance in both the obstructed and the unobstructed regions.[98,99] In the regions with pulmonary vascular obstruction, alveolar dead space is created.[100] If a region's blood flow is severely obstructed, there may be bronchoconstriction in the airways distal to the area of obstruction as a result of alveolar hypocapnia.[101] This is probably uncommon in patients because they are free to inhale carbon dioxide–rich dead space air into the involved lung regions and because obstruction is rarely total. PE almost always leads to hyperventilation, the mechanism for which remains uncertain.

Hypoxemia is seen to some degree in about 85% of PE patients and is generally caused by the venous admixture due to areas of low ventilation/perfusion ratio or of shunt[98] (see also Chapter 44). Arterial hypoxemia may be worsened when acute increases in *right ventricular* (RV) afterload lower the cardiac output enough to widen the arteriovenous oxygen difference and decrease the oxygen saturation of mixed venous blood.[102] This lowering of the mixed venous oxygen content magnifies the effects of the normal venous admixture, thereby further lowering the resultant *arterial partial pressure of oxygen* (Pa_{O_2}). With more substantial PE, another potential mechanism for hypoxemia is right-to-left shunt, either intrapulmonary or intracardiac.[103] When embolic occlusion is sufficient to increase pulmonary artery pressure, hypoxic vasoconstrictive mechanisms can be overwhelmed, and perfusion may inappropriately increase in poorly ventilated or nonventilated lung regions. On occasion, embolic events massive enough to increase right atrial pressure may result in intracardiac right-to-left shunting through a patent foramen ovale. The final mechanism for hypoxemia relates to the loss of pulmonary surfactant.[104] Surfactant is not lost immediately; loss requires approximately 24 hours of total occlusion and lack of blood flow to develop. At that time or later, surfactant becomes depleted in the obstructed alveolar zones, resulting in atelectasis and edema. If the thrombus resolves, perfusion to this atelectatic region will contribute to hypoxemia.

Pulmonary infarction was once thought to be quite unusual with PE, but advanced CT scan imaging discloses subtle findings consistent with infarction in about 1 in 6 to 1 in 3 patients.[105,106] Still, infarction is uncommon, which is thought to be because the pulmonary parenchyma has three potential sources of oxygen: the pulmonary arteries, the bronchial arteries, and the conducting airways.[107] Of interest, pulmonary infarction is more frequent in the absence of preexisting cardiopulmonary disease and is more frequent in young patients than in elderly patients,[105,106] leading to longstanding speculation that elderly patients or those with preexisting disease may have established collateral flow that protects from infarction.

The cardiac and hemodynamic effects of embolism are related to three factors: the degree of reduction of the cross-sectional area of the pulmonary vascular bed, the preexisting status of the cardiopulmonary system, and the physiologic consequences of both hypoxic- and neurohumorally mediated vasoconstriction.[108–113] Mechanical obstruction of the pulmonary vascular bed by embolism accounts for most of the increase in pulmonary vascular resistance, although resistance is typically worsened by release of vasoconstrictive substances, such as endothelin, thromboxane A_2, and serotonin.[114,115] The combination acutely increases the workload on the RV, a chamber ill-equipped to deal with an acute elevation in pressure load.

In less severe cases, a number of compensatory events minimize adverse hemodynamic consequences. Pulmonary vessels are recruited and become distended, resulting in normal or near-normal pulmonary vascular resistance and pulmonary artery pressure. However, with greater extent

of pulmonary vascular obstruction, pulmonary vascular resistance is increased hyperbolically: It rises modestly as the remaining pulmonary vascular bed expands and recruits available vessels, but it increases precipitously as the vascular reserve is exhausted.[111,116]

PE is termed *submassive* if pulmonary artery resistance and pressure are increased and there are signs of RV strain but the patient is hemodynamically stable. Cardiac output is maintained by increases in heart rate and by increases in RV diastolic volume, which augment stroke volume (the Frank-Starling mechanism).[117] Maintaining cardiac output demands increased work from the RV, which in turn requires increased perfusion of the myocardium itself. The myocardial blood flow depends on the gradient between the coronary artery pressure and the pressure within the myocardium. Unfortunately, the myocardial pressure is greatly increased from the high pressure within the dilated RV lumen and the muscle wall tension required to maintain stroke volume against the pulmonary vascular obstruction.[118] Although a small amount of myocardial enzyme leak is evident clinically under those conditions,[119] the RV can maintain output without a substantial amount of myocardial ischemia. In patients without prior cardiopulmonary disease, the RV can generate mean pulmonary artery pressures of around 40 mm Hg and pulmonary artery systolic pressure of around 70 mm Hg.[110]

In patients with *preexisting* cardiopulmonary disease, the hemodynamic response to acute PE may be considerably different from that in patients without prior disease.[113] In patients without prior cardiopulmonary disease, there is a general relationship between the rise in pulmonary artery pressure and the pulmonary vascular obstruction, whereas in patients with prior cardiopulmonary disease, pulmonary artery pressures may rise disproportionately. As a result, severe pulmonary hypertension may develop in response to a relatively small reduction in pulmonary artery cross-sectional area.[120] In addition, evidence of RV hypertrophy (rather than RV dilation) associated with a mean pulmonary artery pressure greater than 40 mm Hg (pulmonary artery systolic pressure > ≈70 mm Hg) in a patient with suspected embolism should suggest an element of chronic pulmonary hypertension. Preexisting pulmonary hypertension could result from a potentially diverse group of etiologic possibilities (e.g., chronic thromboembolic pulmonary hypertension, left ventricular failure, or valvular disease).

PE is termed *massive* if the compensatory mechanisms are overwhelmed and cardiac output drops. In those cases, a perfect storm of conditions leads to RV failure and hemodynamic instability. Left ventricular diastolic filling is compromised by decreased inflow from the pulmonary circulation and, more importantly, by septal wall displacement from the dilated RV.[121] If the decompensation is severe enough to lower cardiac output and systemic blood pressure, the hypotension worsens the situation by decreasing the coronary perfusion pressure to the already tense RV.[118] The resulting hemodynamic instability can be self-perpetuating. RV ischemia/infarction lowers cardiac output further, which in turn worsens RV myocardial perfusion and magnifies the ischemia/infarction.[118] The mortality of massive PE is greatly increased over less severe manifestations.[122]

About 1 in 10 patients who initially present with submassive PE subsequently develop massive PE,[123,124] although the mechanism of the deterioration is a subject of some controversy. Hemodynamic instability may materialize in normotensive patients with submassive PE later during the day of presentation[124] or several days into treatment.[123] Mechanistically, deterioration reflects either acute recurrence, growth of pulmonary emboli despite appropriate therapy, or progressive RV failure and infarction despite unchanging (or improving) pulmonary vascular resistance. Acute recurrent PE is clinically demonstrable during the first several days of anticoagulant therapy in one-tenth[15] to one-fifth[122] of acute PE patients. If either the existing PE or the residual DVT (or both) are substantial, deterioration within the first few days could reflect a second embolization. Significant growth of emboli during this time frame seems unlikely because serial perfusion scans have disclosed at least some degree of resolution during the first week in almost all acute PE patients treated with anticoagulant therapy.[125] Progressive, continuous RV failure, if it happens, is uncommon because blood troponin levels reflecting RV ischemia peak within a few hours of presentation and then steadily decline over the subsequent hours and days.[126,127] Echocardiographic measurements of RV dysfunction likewise steadily improve over the first few days of therapy.[128]

Thromboemboli resolve in three phases: plasmin-mediated fibrinolysis, cellular infiltration with neutrophils, and monocyte-mediated remodeling with endothelial cells and fibroblasts. In the first phase, polymerized fibrin is degraded by plasmin into degradation products such as D-dimer. Although release of D-dimer into the plasma is evident in 80% of acute PE patients 1 week after diagnosis, it is present in only 40% after 1 month and 13% after 3 months.[129] After about 1 week, thrombus resolution becomes a neutrophil-mediated process dependent on a number of inflammatory cytokines.[130,131] Finally, a much slower phase of resolution is mediated by monocytes recruited from the circulating blood.[132,133] Monocytes[134] and endothelial progenitor cells[135] form channels within the clot to restore the lumen. Interleukin-8,[136] vascular endothelial growth factor,[134,137,138] and basic fibroblastic growth factor[137] stimulate angiogenesis and encourage thrombus resolution.[137,139] Residual lung perfusion defects reflect thrombi that have somehow avoided the full resolution process and have been instead remodeled into scar tissue.

Although there is a great deal of interpatient variability, resolution of PEs typically parallels our understanding of thrombus resolution biology. (The term *resolution* is used here to represent all the phases described in the preceding paragraph.) Resolution tends to be substantial during the first week, somewhat more gradual for the next 4 to 8 weeks, and then very slow thereafter.[100,125,140–144] Typically, about two-thirds of PE-related vascular obstruction resolves over the first month and, in about one-third of patients, resolution is complete by that time.[145] In terms of hemodynamic resolution, a stable pulmonary artery pressure is usually reached at around this time.[128] PEs typically recover more slowly over the subsequent 2 months.[146,147] Nevertheless, nearly one-third of patients with acute PE may have residual perfusion defects, which may be associated with a spectrum of symptoms, including dyspnea,

lower exercise tolerance, and higher pulmonary arterial pressures of various intensities.[148] About 10% of those patients will subsequently develop chronic thromboembolic disease.[149]

CLINICAL PRESENTATION

The most common symptoms and physical findings of venous thrombosis include swelling, pain, erythema, and warmth. "Classic" findings, such as the Homan sign (calf pain with flexion of the knee and dorsiflexion of the ankle), the Moses sign (pain with compression of the calf muscles forward against the tibia), or a palpable cord are infrequent and nonspecific.

As established by multiple investigations, the clinical diagnosis of venous thrombosis is imprecise.[78,150–153] In patients with clinical signs and symptoms suggestive of venous thrombosis, 60–80% will not have the diagnosis by objective testing. Furthermore, and even more disquieting, the majority of high-risk patients who are monitored and who develop DVT will not have signs or symptoms suggesting the diagnosis.[154] Algorithmic clinical models incorporating risk factors, symptoms, and physical signs have been shown to stratify *symptomatic* patients into risk categories, although not to a level in which clinical diagnosis, in the absence of objective testing, can be relied on either to confirm or exclude the diagnosis.[152,155] The differential diagnosis of DVT is extensive and includes cellulitis, arthritis, muscular injury or tear, neuropathy, arterial insufficiency, lymphedema, ruptured Baker cyst, superficial thrombophlebitis, and chronic venous insufficiency.

Similarly, the diagnosis of PE cannot be confirmed or excluded solely on clinical grounds.[156–158] However, recognition of the clinical signs and symptoms associated with PE is valuable because clinical findings and clinical suspicion represent an essential first step in the diagnostic pathway. Although a somewhat arbitrary classification, because presenting symptoms and signs of embolism frequently overlap, the presentation of PE can be categorized into one of three clinical syndromes: (1) isolated dyspnea, (2) pleuritic pain or hemoptysis, and (3) circulatory collapse.[159] Among patients without prior cardiopulmonary disease in the *Prospective Investigation of Pulmonary Embolism Diagnosis* (PIOPED) study, the syndrome of pleuritic pain or hemoptysis was the most common mode of presentation, seen in approximately 60% of patients; isolated dyspnea was noted in approximately 25% and circulatory collapse in 10%.

Overall, the most common presenting symptom of acute embolism is dyspnea.[158–160] However, even dyspnea is not ubiquitous and may be absent in one-fourth of PE patients.[160] Pleuritic chest pain is present in about two-thirds of patients, whereas hemoptysis is much less common. Less than half of patients have cough, leg swelling, or leg pain. Angina as a result of RV ischemia may also be present in the setting of massive embolism. Syncope or presyncope may also be a presenting complaint in major embolic occlusion,[161,162] although it is not consistently associated with a worse short-term outcome.[163,164]

The most common physical examination finding is tachypnea (respiratory rate > 20 breaths/min). Similar to the symptom of dyspnea, however, tachypnea is not universal and is absent in almost one-third of PE patients.[160] Clinical findings noted less frequently include inspiratory crackles, tachycardia, and an increased pulmonic component of the second heart sound (S_2). Fever may develop some hours after the event and often reaches, but rarely exceeds, 38.3°C. Although hemoptysis may be observed and even persist for days, it is usually quite modest in extent. Brisk hemoptysis is rare and is almost never the initial finding. With massive embolism, there may be evidence of RV overload or failure, such as a RV tap along the left sternal border and an accentuated pulmonary valve closure sound. If RV failure develops, there may be narrowed or fixed splitting of S_2, an S_3, and/or an S_4, elevated jugular venous pressure, and cyanosis. Careful examination of the legs may disclose signs suggestive of DVT (unilateral swelling and tenderness) in about 1 in 10 patients, although only about one-third of patients with those signs have demonstrable DVT.[165] However, although PE commonly originates from lower extremity DVT, clinically apparent venous thrombosis remains in only a small proportion of patients at the time of PE presentation.[160]

Obviously, these symptoms and signs are nonspecific. In the PIOPED study,[90,91] none of the presenting symptoms was capable of discriminating between patients with PE and those with other cardiopulmonary problems.[158,159] Also, in terms of presenting signs, only the presence of crackles, an S_4, and an increased pulmonic component of S_2 could differentiate between those with and without PE.[159,160,166] Furthermore, in patients with underlying cardiopulmonary disease, the presenting symptoms and signs frequently may be obscured by manifestations of chronic disease.[157]

It is also important to recognize that the clinical presentation of embolism has been characterized in trials composed of symptomatic patients, although it is known that many PEs do not produce symptoms. In prospective studies of high-risk patients with proximal DVT, PE can be documented in 40% of patients who had no symptoms of PE.[88,156,167] Unsuspected PE and incidental PE are found in about 2% of CT scans evaluating other cardiopulmonary pathology.[168]

It is likely that the frequency and severity of symptoms are influenced by the extent of embolic occlusion and the prior cardiopulmonary status of the patient. Small- or moderate-sized emboli may induce few or no symptoms in an otherwise normal individual.[168] In patients with preexisting cardiopulmonary disease, symptoms are more common and severe.[169]

Owing to the nonspecific presentation of PE, the differential diagnosis is varied and extensive, especially in hospitalized patients with coexisting cardiac or pulmonary disease. Common considerations include congestive heart failure, exacerbation of chronic lung disease, postoperative atelectasis, and viral pleurisy. PE presenting with fever, dyspnea, and chest radiographic abnormalities easily can be confused with a bacterial pneumonia. Fever and leukocytosis (rarely >15,000 cells/μL) are uncommon but well-described accompaniments of VTE.[170,171]

These precautionary statements regarding clinical diagnosis are not meant to suggest that the clinical presentation of VTE or PE cannot be used as a basis for clinical decision making. However, they are meant as a reminder that the clinical presentation of VTE and PE may often be atypical or

subtle and should serve only to generate a suspicion of that diagnosis. A reliance on symptoms and signs considered classic before making the decision to proceed to confirmatory testing may lead to underdiagnosis and unnecessary mortality.

DIAGNOSIS OF VENOUS THROMBOSIS

The proper diagnostic approach to VTE must take into account the central fact that venous thrombosis and PE are manifestations of the same disease process: venous thrombosis representing the source of PE, and PE representing a complication of venous thrombosis.

CLINICAL PREDICTION RULES

Perhaps the most important decision in the diagnostic approach to both venous thrombosis and PE is whether to pursue definitive diagnostic techniques or to exclude patients based on screening tests. The latter choice depends largely on Bayesian analysis, in which the pretest probability of the disease, calculated independently of a particular test result, is evaluated in combination with a test's likelihood ratio (derived from the sensitivity and specificity of that test) to estimate the posttest probability. The posttest probability can then be used as a basis for clinical judgment, either excluding the disease with a certain level of probability or supporting the need for additional diagnostic testing. This approach to diagnosis has proved especially useful for cost-effective medical practice.

Several clinical prediction rules for venous thrombosis based on data obtained during history taking and physical examination have been developed and validated.[172] The most commonly used one is the *Wells score,* which, in its current form (Table 81.2), includes 10 clinical characteristics capable of stratifying outpatients into two groups: "clinically unlikely" (score <2) or "clinically likely" (score ≥2).[173,174] The test was validated in numerous studies of outpatient populations with prevalences of DVT ranging from 5–39%. However, even in the outpatient settings in which the rule was tested, a low score alone is not capable of safely excluding DVT in patients in whom it is clinically suspected.[175] This is especially the case for men, patients outside primary care settings, those with previous DVT, and cancer patients, in whom the lowest possible score (−2) was still associated with a 5% probability of DVT.[175] For this reason, clinical prediction rules for patients suspected of having DVT are best combined with other objective data.

Table 81.2 Wells Clinical Model for Predicting the Pretest Probability of Deep Venous Thrombosis

Clinical Characteristic	Score
Active cancer (patient receiving treatment for cancer within the previous 6 mo or currently receiving palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within the previous 12 wk requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below the tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep venous thrombosis	1
Alternate diagnosis at least as likely as deep venous thrombosis	−2

Score	Clinical Assessment Probability
<2 points	Unlikely
≥2 points	Likely, cannot be ruled out

From Wells PS, Anderson DR, Rodger M, et al. Evaluation of D-dimer in the diagnosis of suspected deep vein thrombosis. *N Engl J Med.* 2003;349:1227–1235.

D-DIMER ASSAYS

Of all the available blood tests for VTE, the D-dimer assay has been subjected to the most rigorous clinical evaluation and has performed the best.[176–178] However, to appreciate the practical implications of the D-dimer assay, it is necessary to understand two inherent limitations. "D-dimer" is actually a heterogeneous mixture of fibrinogen derivatives, some (but not all) of which are the result of thrombosis and thrombolysis. The various commercially available tests use different antibodies that bind to different targets that may or may not be present on each D-dimer fragment. That means that the same sample may yield a variety of different D-dimer levels depending on the assays used.[176–178] Equally important is a critical distinction about mass/volume units used to report results. Because the antibodies detect only their specific targets, the "mass" is reported either as *fibrinogen equivalent units* ([FEU], the number of detections multiplied by the mass of an undigested fibrinogen molecule) or *D-dimer units* ([DDU], the number of detections multiplied by the presumed mass of a typical D-dimer fragment, which is half the mass of fibrinogen). To use D-dimer results diagnostically, the clinician must know which standards the local laboratory uses because, for example, 600 ng/mL FEU is the same as 300 ng/mL DDU. For both of these reasons, diagnostic cutoff values may be different among different laboratories.

D-dimer testing is highly sensitive but not specific; that is, elevated levels are present in nearly all patients with thromboembolism but also in a wide range of circumstances, including advancing age, pregnancy, trauma, infections, the postoperative period, inflammatory states, and malignancy. Therefore, the role of D-dimer testing is limited to one of exclusion of VTE. For the technical reasons just listed, D-dimer assay sensitivities can range from 80% to almost 100%.[176–178] The highly sensitive assays and cutoff levels are capable of excluding thromboembolism but are associated with such a high frequency of false-positive results that their clinical utility is limited. Less-sensitive assays and cutoff levels lack the ability to exclude thromboembolism in isolation but have been used successfully in combination with probability-derived clinical prediction rules to exclude

venous thrombosis in certain patients presenting with a low or intermediate clinical likelihood of the disease.[174,179]

A caveat of using D-dimer assays to rule out PE and DVT is that the normal levels of D-dimer in the blood increase as one ages. Multiple clinical studies have demonstrated a higher specificity in patients older than 50 years when age-adjusted D-dimer cutoff values (e.g., age × 10 μg/L FEU) were used rather than a single cutoff value (e.g., 500 μg/L FEU).[180] However, age-adjusted D-dimer cutoff values are subject to the same caveats discussed for single D-dimer cutoff values. For this reason, it is best for the clinician to refer to the local clinical laboratory (U.S. Food and Drug Administration–approved) table of age-adjusted cutoff values, which may differ among laboratories.[181]

COMBINATION OF PREDICTION RULES FOR DVT AND D-DIMER RESULTS

As expected with the Bayesian approach, the combination of independently ascertained clinical likelihood and objective blood test results is particularly useful. In most circumstances, for outpatients falling into the clinically unlikely category (Wells score <2), DVT is reliably excluded when the result of a sensitive D-dimer assay is below the cutoff values described in the previous section, thereby limiting the need for further workup.[174] The ability to exclude venous thrombosis in outpatients using a clinical prediction rule and negative results of a D-dimer assay has been confirmed in other studies.[175,182] The failure rate for the combination of a low Wells score and a low D-dimer is less than 2% in most outpatient populations, although somewhat higher failure rates have been observed for patients with a previous history of VTE and those with malignancy.[175] The fact that fewer than 10% of cancer patients suspected of having DVT fall into the "low score, low D-dimer" category further limits its usefulness in that population. Finally, it should be emphasized that clinical prediction rules constructed and validated in outpatients may not apply seamlessly to an inpatient population. Clinicians should retain the prerogative to perform further objective testing if, in their judgment, DVT remains a plausible risk.

CONTRAST VENOGRAPHY

Although it is rarely used in modern clinical settings, contrast venography (Fig. 81.1) is the gold standard by which many noninvasive techniques were validated.[183] Contrast venography has high sensitivity and specificity but has several shortcomings. It is not easy to interpret, especially in patients with a prior history of venous thrombosis. Venous cannulation may often be difficult and painful, especially in the presence of edema. Injection of contrast material has associated allergic and nephrotoxic risks. Last, it is expensive, and the procedure itself can unfortunately induce venous thrombosis.

Owing to these limitations, noninvasive studies capable of being performed on a sequential basis are much more common in clinical practice. Duplex ultrasonography is the most commonly used. *Magnetic resonance imaging* (MRI) and CT are capable of detecting thrombi, but their widespread use has been limited by cost, access and, in the case of CT, the need for contrast administration.

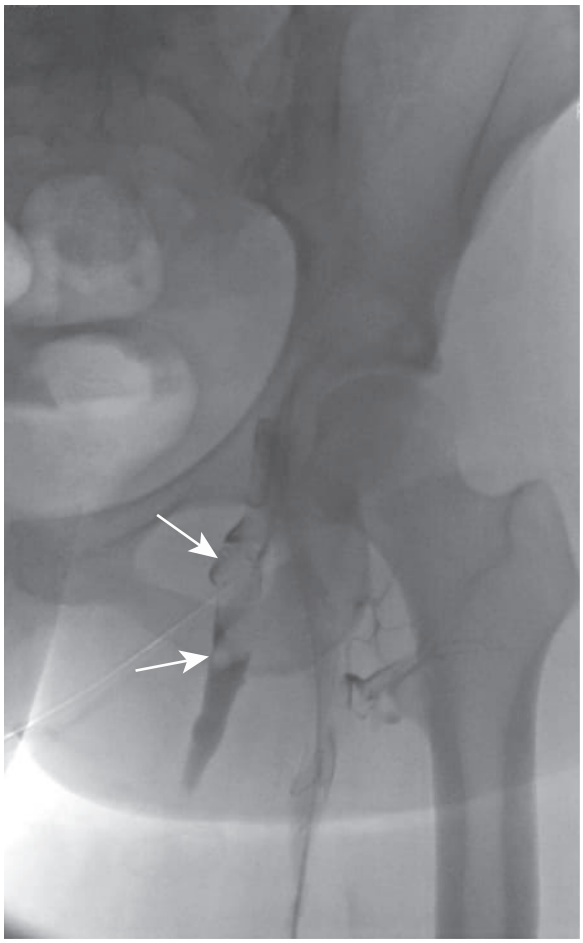

Figure 81.1 Contrast venography of deep venous thrombosis. Contrast venography performed during inferior vena cava filter placement in a patient with acute pulmonary embolism shows filling defects within the proximal femoral artery (*arrows*) representing deep venous thrombosis.

DUPLEX ULTRASONOGRAPHY

Duplex ultrasonography (i.e., the combination of Doppler venous flow detection and real-time B-mode imaging) has assumed a central role in the noninvasive diagnosis of symptomatic lower extremity DVT.[184] A number of criteria are used to diagnose venous thrombosis, the most reliable of which is the noncompressibility of a venous segment (Fig. 81.2 and Video 23.21). Secondary, less reliable criteria include the presence of echogenic material within the venous lumen (eFig. 81.1), venous distention, loss of phasic change with breathing, lack of response at the *common femoral vein* (CFV) to the Valsalva maneuver, lack of augmentation of flow at the CFV with compression of the calf, and diminished or absent color flow with color Doppler sonography (eFig. 81.2). The lack of color flow around a detected DVT is sometimes used to signify an "occlusive DVT," but that distinction has not been shown to influence the potential for PE or other clinical complications of DVT. The two signs showing a lack of increase in flow, either with Valsalva or with calf compression, can mean obstruction of veins between the site of increased pressure and the measured vein. The absence of an echogenic luminal mass cannot be considered useful in excluding the diagnosis of venous thrombosis because acute thrombus may not demonstrate echogenicity (eFig. 81.3).

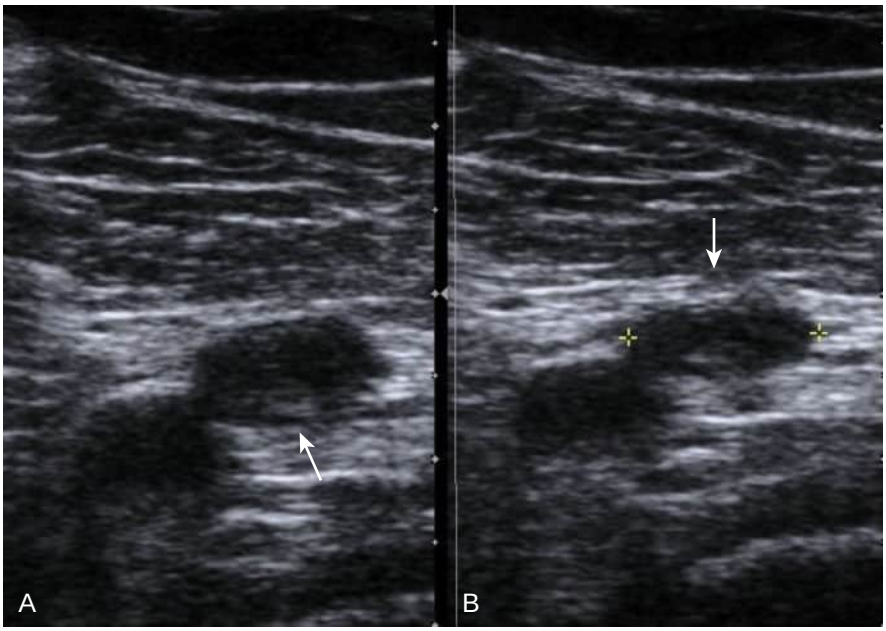

Figure 81.2 Compression ultrasonography for deep vein thrombosis. (A) Rest and (B) compression duplex ultrasonography demonstrates a noncompressible distal femoral vein containing an echogenic mass (*arrow*), consistent with venous thrombosis.

The sensitivity and specificity of duplex ultrasonography exceed 95% for symptomatic patients with proximal venous thrombosis, although asymptomatic and distal venous thrombi are harder to detect. Although simplified compression examinations limited to the symptomatic leg or to the common femoral and popliteal veins (rather than the entire lower extremity venous system) have been suggested, the time saved with such approaches is limited, and a number of isolated femoral vein or calf-limited thrombi may be overlooked.[185–187] Asymptomatic thrombi in the contralateral leg can be detected in approximately 5–10% of patients presenting with symptomatic acute venous thrombosis.[188] Although the detection of asymptomatic, contralateral thrombi has little impact on the immediate management of the patient, it may have long-term consequences when recurrence is suspected. A more prudent and comprehensive approach appears to be a complete examination extending from the inguinal ligament to the popliteal vein and examination of the contralateral extremity if thrombus is detected in the symptomatic leg.

Duplex ultrasonography is less accurate in the detection of symptomatic calf-limited thrombi (sensitivity ≈70%) and in asymptomatic proximal vein thrombi (sensitivity ≈50%), thereby limiting its utility as a screening study in high-risk populations.[189] When duplex ultrasonography is negative in patients with suspected venous thrombosis, a strategy of serial testing has proved to be effective in detecting proximal extension.[190]

MAGNETIC RESONANCE IMAGING

MRI techniques for detecting venous thrombosis include spin-echo magnetic resonance, gradient-recalled-echo magnetic resonance, and magnetic resonance venography. Preliminary reports suggest that MRI is at least as sensitive and specific as duplex ultrasonography.[191,192] A potential advantage of MRI is that the entire length of the venous system, including the pelvic veins, can be evaluated. Disadvantages associated with MRI include cost and limited access, as well as the expertise required to perform and interpret the studies properly.

COMPUTED TOMOGRAPHY

The role of CT as a stand-alone test for venous thrombosis is limited. The sensitivity and specificity of CT venography are comparable with those of ultrasonography but mandate contrast injection with its associated risks and radiation exposure. A diagnostic approach combining CT venography with CTPA, also called indirect CT venography because it does not require additional intravenous contrast, may have a role in patients undergoing evaluation for PE.[193,194] Potential advantages of CT venography, either direct or indirect, include the ability to visualize the pelvic veins (eFig. 81.4) and vena cava (eFig. 81.5). However, the additional scan adds radiation exposure to the pelvis, and nearly all coexisting DVTs discovered in clinical practice by CT venography could have been detected by duplex ultrasound.[195]

DIAGNOSIS OF PULMONARY EMBOLISM

As in the case of DVT diagnosis, clinical evidence is capable of raising the suspicion for PE, but it cannot be relied upon to confirm or exclude the diagnosis entirely. In the appropriate settings, however, clinical prediction rules in combination with noninvasive testing can identify a substantial number of patients in whom the risk is small enough that further diagnostic testing is unnecessary.

CLINICAL PREDICTION RULES

A number of standardized prediction rules for PE have been evaluated and published that range widely in their complexity. Simple, standardized prediction rules (Table 81.3) involve information that can be easily acquired even in an outpatient setting or the emergency department.[196,197]

Complicated prediction rules involve an increased number of clinical variables and require expert interpretation of radiography and *electrocardiography* (ECG) data.[198,199] Alternatively, the clinician may make a subjective ("gestalt") assessment of the probability of PE. So long as it is performed deliberately and independently of subsequent testing, the "gestalt" method appears to have comparable sensitivity to clinical prediction rules, when both are used in combination with sensitive D-dimer testing.[200]

The most commonly used clinical prediction score for acute PE is the *Wells score*, which assigns differential scores for risk factors for VTE (recent surgery or immobilization, previous VTE, malignancy), clinical signs and symptoms of PE and DVT (tachycardia, hemoptysis), and the absence of more likely alternative diagnoses (see Table 81.3).[201] A simplified Wells score, which uses 1 point for each item, appears to have similar accuracy.[202] As an alternative, the *revised Geneva score* uses only objective data (without a subjective evaluation for more likely diagnoses), but is considerably more complex.[203] The *Pulmonary Embolism Rule-Out Criteria* (PERC) is an 8-point clinical score applicable to emergency department patients in whom the diagnosis of

PE has already been judged as unlikely.[204,205] A modification of the Wells clinical decision rule, called the *YEARS algorithm*, combined an evaluation of three characteristics (clinical signs of DVT, hemoptysis, and whether PE is the most likely diagnosis) with a differential analysis of D-dimer concentrations. In patients with none of the characteristics, D-dimer of less than 1000 ng/mL safely excluded PE; in those with any (or all) of the characteristics, D-dimer less than 500 ng/mL was necessary to exclude PE.[206] Although not a randomized controlled trial, this study did demonstrate that this algorithm was safe and resulted in an absolute decrease of 14% in the number of CTPA examinations across all ages and subgroups.

Although such probability assessments, whether based on scores or overall clinical impression, are incapable of confirming or excluding the presence of PE entirely, they are capable of stratifying patients into categories of likelihood.[196,207] By combining low clinical probability with negative results of a noninvasive diagnostic technique, safe exclusion of embolism can be increased well beyond that achieved by the use of either method alone.[196,207] Clinically, the appropriate application of clinical prediction rules and D-dimer testing can substantially limit the number of patients who require thoracic imaging.[208–210]

D-DIMER TESTING

The utility of D-dimer testing in PE diagnostic pathways is limited by the same shortfalls as those encountered in venous thrombosis pathways: low specificity, which makes it most useful as an exclusionary technique in outpatients, and lack of standardization. However, studies have demonstrated that a normal D-dimer result can safely exclude embolism in patients with a low clinical probability of disease.[196,211,212] Although preliminary data suggest that a highly sensitive assay is capable of excluding embolism at all levels of clinical probability, these results require confirmation.[212]

The sensitivity of D-dimer is similar across age groups, but its specificity decreases markedly with age, which should be considered when interpreting D-dimer values.[213] A retrospective analysis of three large cohorts of patients derived the age-adjusted D-dimer cutoff value based on received operating characteristic curves and found that the clinical usefulness of this age-adjusted value in helping rule out PE, in conjunction with clinical prediction rules, was significantly improved for older patients.[214] When combined with an age-adjusted D-dimer cutoff, a simplified Wells clinical prediction rule worked as well as the original rule and provided a more simple two-tier model of risk (PE likely or PE unlikely).[202] This was prospectively validated by Righini[215] in ADJUST-PE (2014), a multicenter, multinational study that found use of an age-adjusted D-dimer cutoff was associated with a larger number of patients in whom PE could be considered ruled out. A failure rate of age-adjusted D-dimer was found to be 0.3% in this study in patients with low/intermediate or clinically unlikely risk assessment.

STANDARD LABORATORY EVALUATION

Routine laboratory studies cannot make the diagnosis of PE. Although none have the discriminatory power to confirm the diagnosis of embolism, they do provide valuable adjunctive information and support for therapeutic interventions and may confirm the presence of an alternative diagnosis.

The majority of patients with PE have abnormal chest radiographs.[216] However, these abnormalities are usually subtle, nonspecific, and therefore nondiagnostic (Fig. 81.3). In the PIOPED study,[160] the most common radiographic abnormalities were atelectasis and pulmonary opacities. There is some confusion about the diagnostic configuration of radiographic abnormalities due to embolism. Although usually abutting a pleural surface, the opacities can be of any shape, not necessarily wedge shaped. Although pleural effusions are seen in almost half of the patients, the majority of effusions are small and involve only blunting of the costophrenic angle.[158] Findings once considered specific for embolism, such as the *Westermark sign* (focal areas of avascularity, eFig. 81.6), the *Hampton hump* (pleural-based, wedge-shaped opacity, eFig. 81.7), and the *Fleischner sign* (prominence of the central pulmonary artery, eFig. 81.8), have not proved to have discriminatory value. In a patient with hypoxemia or pulmonary complaints, a normal chest radiograph may be quite useful in raising the index of suspicion of embolism and in excluding confounding diagnostic options. The major roles of chest radiography in suspected PE therefore are to exclude competing diagnoses and, if ventilation-perfusion (V/Q) scanning is anticipated, to evaluate the pulmonary parenchyma. Because pleural effusions associated with PE tend to be small, they are generally not amenable to thoracentesis. In the few patients in whom thoracentesis was performed, the effusions were found to be exudative with normal glucose levels and neutrophilic predominance.[217]

Likewise, ECG findings in PE, although frequent, are diverse and nonspecific.[218] The most common abnormalities include nonspecific tachycardia, T-wave inversions in the inferior leads, and abnormalities of the ST segment, although about one-fourth of patients have no ECG changes.[219] With more extensive occlusion, the ECG may reveal the more classic findings of right heart strain, including an $S_1Q_3T_3$ pattern, a pseudoinfarction pattern (Qr in V_1), a complete or incomplete right bundle-branch block, or right-axis deviation.[218,220] T-wave inversions on ECG are common among patients who require hospitalization for acute PE, and S-T segment deviation is common among those with dyspnea, hypotension, cardiogenic shock, and death (see "Risk Stratification" section later).[221] Rhythm disturbances other than sinus tachycardia are uncommon and usually confined to patients with underlying cardiac disease.[218]

Arterial blood gas analysis is helpful, although not definitive.[222] Arterial hypoxemia may be present, and the more massive the obstruction, the more severe the hypoxemia is likely to be. However, many other conditions also cause hypoxemia, and embolism often does not cause hypoxemia or even a widening of the alveolar-arterial P_{O_2} difference. Hypocapnia usually is present with embolism; hypercapnia, conversely, is rare. Hypercapnia appears with embolism only in patients with marked antecedent ventilatory limitation or when such limitation has been imposed because the patient is on controlled mechanical ventilation.

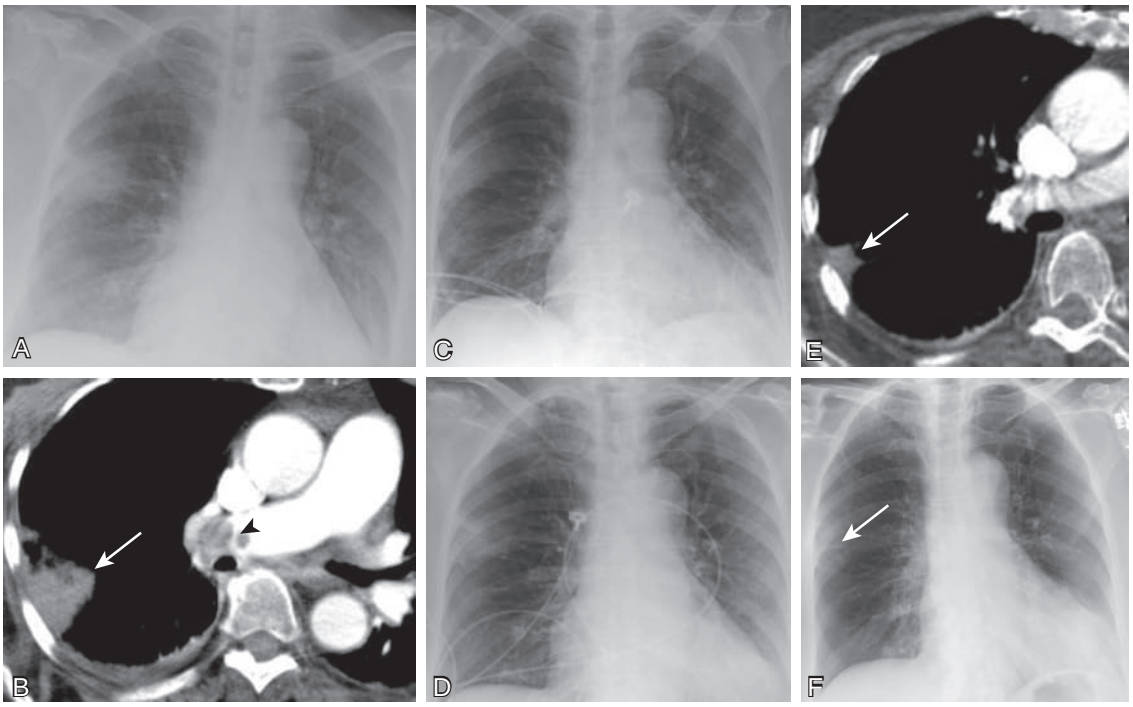

Figure 81.3 Chest radiographic findings in acute pulmonary embolism. (A) Frontal chest radiography at presentation shows a peripheral right upper lobe rounded opacity suggestive of pneumonia. (B) Computed tomography pulmonary angiography shows a right pulmonary arterial filling defect (*arrowhead*) consistent with acute pulmonary embolism. A right upper lobe subpleural wedge-shaped focus of consolidation (*arrow*) is consistent with infarction. (C) Frontal chest radiography obtained several days after presentation shows a more clearly wedge-shaped opacity in the right upper lobe. (D) Frontal chest radiography obtained 2 weeks after presentation shows the right upper lobe opacity is beginning to resolve. (E) Computed tomography pulmonary angiography about 2 weeks after presentation shows the right upper lobe infarct (*arrow*) has decreased in size. (F) Frontal chest radiography performed 5 weeks after presentation shows only linear opacity in the region of infarction (*arrow*), probably reflecting developing scar.

VENTILATION-PERFUSION SCANNING

V/Q lung scanning is typically performed with planar scintigraphic (two-dimensional) images that represent the number and size of lung perfusion defects and the absence or presence of corresponding defects in lung ventilation. The images are compared to differentiate primary vascular obstruction (mismatched defects) from primary parenchymal disorders that result in compensatory pulmonary vasoconstriction (matched defects). A related interpretation strategy relies on the shape and size of the perfusion defects compared to radiographically determined parenchymal lung disease.[223] PE can be diagnosed with either strategy, obviating the need for further studies in many cases.[224]

Despite its limitations, V/Q lung scanning remains a valuable step in the diagnosis of PE if it is interpreted appropriately.[160,225] First, a negative V/Q study (without perfusion defects) excludes the diagnosis of PE with the same degree of certainty as a negative pulmonary angiogram (Fig. 81.4) and has a similar negative predictive value as a negative pulmonary angiogram and negative high-quality CTPA.[226] This conclusion is illustrated by the results of two large prospective clinical trials comparing perfusion scanning to pulmonary angiography, the PIOPED study[160] (performed in the United States), and the *Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis* (PISA-PED) trial[227] (performed in Europe). In both trials, normal pulmonary perfusion scanning was a highly sensitive method for excluding the presence of PE. The value of a normal perfusion scan was not diminished even in a subset of patients who had a high pretest probability for PE[160] or who were critically ill.[228] This was re-demonstrated in a large retrospective study in which patients with normal lung perfusion scans with high clinical pretest probability underwent CTPA confirming the absence of pulmonary emboli, suggesting the negative predictive value of a normal lung perfusion scan approaches 100%.[229] The significance of a normal perfusion scan, as reported by the PIOPED and PISA-PED trials, is consistent with all published longitudinal studies.[230–232] A meta-analysis of diagnostic studies for

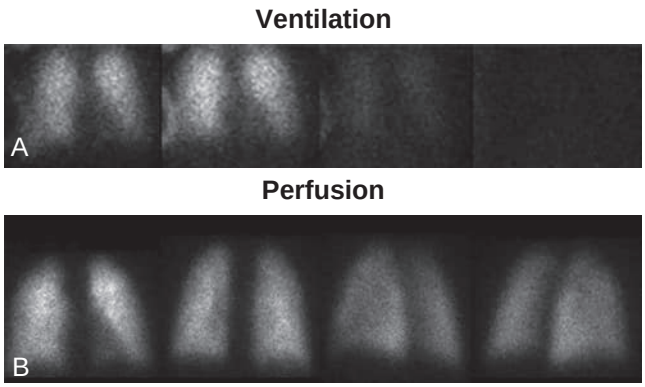

Figure 81.4 Normal ventilation-perfusion scintigraphy. (A) Posterior ventilation images using Tc-99m DTPA shows homogenous tracer distribution and rapid washout. (B) Perfusion imaging in the posterior (*left*), anterior (*middle left*), and oblique (*middle* and *far right*) projections using Tc-99m MAA shows homogenous tracer distribution. No ventilation-perfusion mismatches are present.

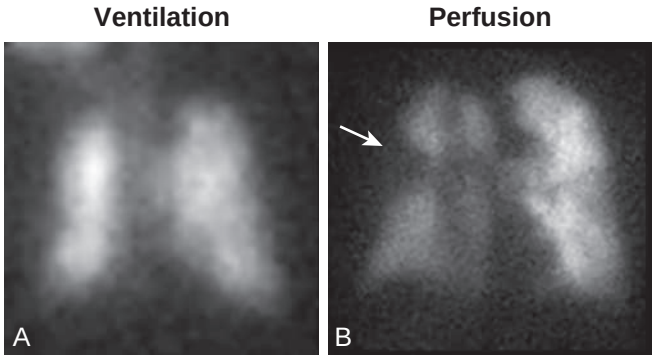

Figure 81.5 High-probability ventilation-perfusion scintigraphy. (A) Anterior ventilation study shows homogeneous tracer distribution. (B) Anterior perfusion study shows several perfusion defects, some clearly peripheral and wedged shaped (*arrow*), in areas of normal ventilation, representing ventilation and perfusion mismatching.

PE calculated the incidence of PE after a normal perfusion scan to be 0.3%.[233] A subsequent case series of consecutive patients followed clinically after objective testing for PE disclosed no pulmonary emboli in 188 patients who had normal perfusion scans.[234]

Conversely, a high-probability V/Q scan (one characterized by multiple, segmental-sized perfusion defects without matching ventilation defects) is associated with embolism in approximately 87% of patients; when coupled with a high clinical probability of embolism, the positive predictive value increased to 96% (Fig. 81.5).[160]

The utility of V/Q scanning is, unfortunately, limited by the fact that the overwhelming majority of patients with suspected embolism do not have scan findings that fall into a high-probability or normal category, the only categories that can be considered definitive.[160] In addition, a clinically significant percentage of patients with scan findings interpreted as "intermediate probability" (33%) or as "low probability" (16%) were subsequently demonstrated to have angiographic evidence of embolism.[160] Because of the latter finding, the term "low-probability scan" is misleading and potentially dangerous because of the frequency of PE in patients exhibiting this scan pattern.[235]

The diagnostic approach to PE in patients with underlying COPD is a particular challenge because the presentation of PE in this population may closely mimic an exacerbation of their underlying disease. Although the positive predictive value of a high-probability scan and the negative predictive value of a normal or near-normal scan in those patients are similar to that in the general population, the proportion of patients whose scans fall into a nondiagnostic category is much higher in patients with COPD than for those without COPD.[236] Given the limitations of V/Q scanning in this population, an approach using chest CTPA or *single-photon emission computed tomography* (SPECT)-V/Q as the initial objective diagnostic study would be appropriate (discussed later).

In critically ill patients in the intensive care unit with suspected PE, despite a large percentage having moderate to severely abnormal chest radiographs, PE may still be diagnosed by high-probability V/Q scan. Portable V/Q scan may be useful in this population with a high incidence of renal failure and hemodynamic instability making CTPA difficult to obtain.[237]

VENTILATION-PERFUSION SCANNING WITH SPECT

SPECT is a nuclear medicine technique that constructs three-dimensional tomographic perfusion and ventilation images from scintigraphic data, in a similar way that CT constructs tomographic images from transmitted x-rays.[238–240] The reported sensitivity of SPECT scanning for embolism has ranged from 62–100%, with a specificity ranging from 88–100%.[241] The tomographic images can identify perfusion defects in areas of the lung hard to visualize with planar V/Q scans because of interposing lung tissue (e.g., the medial basilar segments of the lower lobes).[242] As a result, SPECT-V/Q produces fewer nondiagnostic test results than planar V/Q, which removes one of the major limitations of planar V/Q testing. In fact, nondiagnostic results were reported in only 0.5–3% of SPECT-V/Q studies.[243–245]

SPECT-V/Q avoids the use of iodinated contrast required for CTPA,[246] which poses some risk of radiocontrast-induced nephropathy for older patients and for patients with preexisting renal insufficiency, especially when associated with diabetes mellitus.[247,248] In such patients, SPECT-V/Q may be preferred over CTPA. Another advantage of SPECT-VQ is that it delivers less radiation to breast tissue than CTPA typically delivers.[249] SPECT-V/Q has a high degree of agreement with CTPA in patients suspected of having acute PE.[244] Sensitivities and specificities for PE are typically in the 95–100% range.[244,250,251] Similar to studies with CTPA, the clinical outcomes of patients with negative SPECT-V/Q, in whom anticoagulation was not given, are excellent.[243,245,252] These findings suggest that SPECT-V/Q is highly sensitive for clinically important PE. SPECT-V/Q is less commonly used than other modalities for PE diagnosis, perhaps because the scanners are not present in every nuclear medicine department, and like all nuclear medicine studies, require specially trained personnel who are not always available.

COMPUTED TOMOGRAPHY PULMONARY ANGIOGRAPHY (See Also Chapter 20)

CTPA has substantially advanced the ability to diagnose PE. Unlike V/Q scanning, it provides the ability to visualize emboli directly and to detect parenchymal abnormalities that may support the diagnosis of embolism or provide an alternative basis for the patient's symptoms (Fig. 81.6; Video 81.1). The reported sensitivity of chest CT scanning for embolism has ranged from 57–100%, with a specificity ranging from 73–100%.[241] Factors responsible for this wide divergence relate to the proximal extent of vascular obstruction that can be detected and, in part, to advances in CT technology that allow higher resolution, dramatically faster scanning times, more peripheral visualization, and less motion artifact than that provided by earlier-generation scanners. Sensitivity and specificity of CT scanning for emboli involving the main and lobar pulmonary arteries exceeds 95%. Vascular involvement confined to segmental or subsegmental pulmonary vessels is associated with a lower sensitivity and specificity. In one series the sensitivity of CT scanning for subsegmental arteries reported by two readers ranged from 71–84% even after non-evaluable scans were excluded.[253] Isolated involvement of the subsegmental pulmonary arteries is not

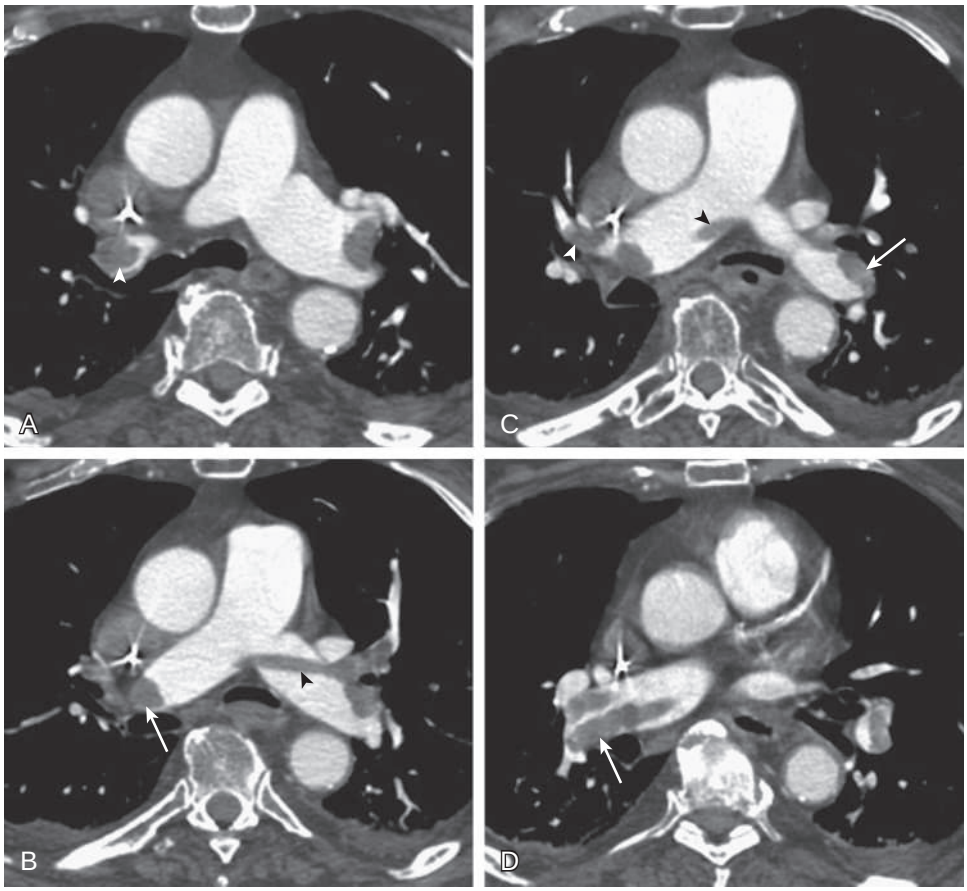

Figure 81.6 *Computed tomography pulmonary angiogram* (CTPA) showing pulmonary emboli. CTPA shows bilateral pulmonary emboli, including a "saddle" embolism (*black arrowheads,* B–C), right upper lobe emboli (*white arrowheads,* A–C), and interlobar emboli (*arrows,* B–D). See Video 81.1 for a clip from the full CT study.

unusual and, depending on the series, may be found in as few as 5% to as many as 30% of patients.[254–256] These findings suggest that filling defects consistent with embolism involving the main or lobar pulmonary arteries can be considered diagnostic of embolism. Depending on the characteristics of the image, defects involving the subsegmental arteries may be considered suggestive of embolism but should be supported by additional objective data.[257,258] The importance of treating patients with CTPA findings suggestive of exclusively subsegmental emboli has been questioned, especially in patients with good cardiopulmonary reserve and no coexisting DVT or persistent risk factors.[256,258] However, no large trials have yet demonstrated the safety of withholding anticoagulants in this patient population.[259,260]

Although CTPA has increased the number of diagnoses of acute PE,[261] it has inherent limitations. The technique requires infusion of intravascular iodinated contrast agents, which can cause the most common serious complications of testing. During CT scanning, the peripherally infused dye fills the lumen of the pulmonary arteries at the same time that the chest is imaged; CT scan images acquired outside that time frame are less accurate.[262] Emboli are detected as focal defects in pulmonary artery filling. When performed and interpreted expertly, CTPA scans are capable of identifying emboli in the segmental or larger pulmonary arteries, as does V/Q scanning.[263,264] However, certain areas, such as the hila, are prone to false positives. Reading emboli in these areas should be done with special care. Perhaps more important, as mentioned, CT scans have difficulty imaging emboli in subsegmental pulmonary arteries.[257,258] Smaller emboli may account for up to 20–30% of PEs[254,265] and represent the very cases in which V/Q scans are the most limited.[160]

The National Institutes of Health–funded PIOPED-2 study highlighted the strengths and limitations of CTPA.[194] Before enrolling the study population of 1090 patients, the investigators excluded 1350 patients because their abnormal creatinine levels reflected some degree of renal dysfunction, which would have increased the risk involved with the administration of contrast dye. An additional 272 patients were excluded because of a history of contrast dye allergy. During the performance of the trial, 6% of the scans were excluded because the images were of poor quality. Even after the inconclusive scans were disregarded, the sensitivity of the CTPA scans was only 83%, although it is difficult to be confident of the gold standard used to compare to CTPA. The PIOPED-2 investigators also excluded another 976 patients from the study because they had history of long-term anticoagulation therapy. This highlights another weakness of CTPA in that luminal filling defects remain long after an acute pulmonary embolic event, so the test cannot easily differentiate between chronic and acute VTE. This is clinically relevant because the rate of recurrence is about 7% during the 6 months after an acute PE and about 3% per year for the subsequent 5 years.[266]

Finally, CTPA can expose patients to clinically significant doses of radiation, and radiation doses may vary widely across countries and institutions.[241,267–271] Current clinical protocols deliver a radiation dose to the female breast ranging from 3 to 10 cGy per scan.[268,270,272] This dose is

especially concerning because most CTPA evaluations are negative, even when the criteria for scanning are rigorously followed.[194,225] In addition, because PE has a relatively high rate of recurrence, patients are commonly reimaged after their first episode. Younger women, who have a known elevated incidence of PE, are particularly at risk from radiation damage to breast and lungs[262] and represent a disproportionate number of patients who undergo CTPA.[273,274]

From a clinical (outcomes-based) perspective, CTPA and V/Q scanning have many similarities, and either can be used to exclude clinically significant PE in stable patients under many circumstances. Prospective outcome studies have demonstrated that withholding anticoagulant therapy in patients with a negative CTPA coupled with a negative lower extremity ultrasound study appears to be a safe strategy except in those patients who present with a high clinical likelihood of embolism.[275,276] Similarly, withholding anticoagulation from patients with non–high-probability findings on V/Q scan coupled with negative lower extremity studies is safe, except in those with inadequate cardiopulmonary reserve.[277,278] A randomized controlled trial comparing CTPA and V/Q for the management of suspected PE found the two studies to be comparable for excluding clinically significant PE.[225] Specifically, the study disclosed no difference in outcome among patients in whom anticoagulation was withheld based on the combination of a negative CTPA and negative leg studies compared with patients in whom anticoagulation was withheld based on the combination of a non–high-probability V/Q scan and negative leg studies or on a normal V/Q scan (without the need for leg studies). Although the value of either study alone (without leg studies) had been controversial,[279] prospective series using modern techniques have disclosed the safety of withholding anticoagulants in patients in whom either CTPA[280] or SPECT-V/Q[281] have ruled out PE. However, it should be emphasized that the outcome studies were done on relatively stable patients. Those with instability or poor cardiopulmonary reserve may require a higher degree of diagnostic certainty to rule out PE.[278]

ECHOCARDIOGRAPHY

Echocardiography may serve a valuable role in the diagnostic approach to PE when RV compromise is suspected. In addition, in some circumstances, the detection of unexplained RV volume (eFig. 81.9A) or pressure overload might suggest the possibility of embolism and lead to confirmatory testing (eFig. 81.9B). A distinct echocardiographic pattern involving akinesia of the mid–free RV wall with apical sparing has been described known as the McConnell sign (Video 81.2).[282,283] Direct visualization of RV chamber emboli is uncommon but possible (Video 81.3). Properly performed *transesophageal* echocardiography may disclose proximal emboli that involve the pulmonary trunk and the right and left main pulmonary arteries.[284] Transesophageal echocardiography has also proven valuable in the evaluation of competing diagnostic possibilities, such as RV infarction, endocarditis, pericardial tamponade, and aortic dissection, in patients with unexplained shock and evidence of elevated central venous pressure.

Echocardiography is not necessary in most cases of low-risk PE.[285] The characteristic findings of RV hypokinesis, dilation, or elevated estimated end-systolic pressure are nonspecific and found in only about half of patients with PE.[286,287] It may be diagnostically useful in patients with suspected massive PE who have no other plausible explanation for RV abnormalities and are unable to be diagnosed by other means. Its most common use, however, is to evaluate evidence of pulmonary hypertension and RV dysfunction in patients with confirmed diagnoses of PE who are hemodynamically unstable.[288] For example, *tricuspid annular plane systolic excursion* (TAPSE) reflects RV systolic function. Among high-risk acute PE patients, even those who are hemodynamically stable, the finding of a decreased TAPSE was associated with elevated systolic pulmonary artery pressures and higher mortality risk.[289] However, there is a great deal of inconsistency among clinicians regarding the use of echocardiography in PE, and higher use is not associated with decreases in PE-related mortality.[290]

CONCURRENT LOWER EXTREMITY VENOUS EVALUATION

Because the majority of PEs arise from the deep veins of the lower extremities, the detection of lower extremity proximal vein thrombosis in a patient suspected of embolism, although not confirming PE, is strongly suggestive of that diagnosis and has an equivalent therapeutic implication. Positive ultrasound findings without symptoms or signs referable to the lower extremities should be interpreted judiciously, especially in patients with low pretest probability of PE, because even a highly specific test can yield false-positive results in some circumstances.[291] Lower extremity ultrasonography has a very low yield in patients without leg symptoms or without risk factors strongly suggestive of thromboembolism.[165,292] Conversely, it is typically positive in only about 10–20% of patients with suspected embolism and in 50% of patients with proven embolism.[293] Therefore, a negative ultrasound finding cannot exclude the diagnosis of PE. Indirect CT venography (see eFig. 81.4) as an adjunct to chest CTPA appears to be capable of detecting femoropopliteal thrombosis with the same accuracy as duplex ultrasonography, while also detecting pelvic and abdominal thrombosis.[193,194] However, the combined CT technique is technically complicated because it must be performed within 2 minutes of the CTPA to use the same contrast injection.[194] It also significantly increases the amount of pelvic radiation exposure to the patient.[267,268,294]

PULMONARY ANGIOGRAPHY

Angiography is uncommonly used due to the utility and availability of the less invasive methods discussed, but it can be considered in patients in whom the diagnosis has not been confirmed or excluded using noninvasive techniques or when the results of diagnostic testing are at such odds with the clinical impression as to warrant the risk of the procedure. Pulmonary angiography can be performed quite safely if certain safeguards are observed and experienced personnel are involved. Because it involves right heart catheterization, it has the additional advantage of providing hemodynamic data.

Like contrast venography, however, pulmonary angiography has a number of limitations as a gold standard. It is invasive and not without risk, especially in patients with acute RV failure. However, experience has demonstrated that the perception of risk associated with angiography outweighs the actual risk.[295,296] Angiography must be performed in a special facility, which may require transport to another hospital. In some institutions, the logistical problems involved are modest; in others, they are substantial. The other limitation is interpretation. The interpretation of pulmonary angiograms is heavily influenced by three factors: the location of the thromboembolic obstruction, the quality of the images, and the experience of the interpreters. Only two angiographic findings are diagnostic of acute embolism: a filling defect and an abrupt cutoff of a vessel (Fig. 81.7). Technical adequacy of the angiogram is essential for accurate identification of both. Flow artifacts can falsely suggest a filling defect. It is essential that good vessel opacification be obtained and that the filling defects be identified as present on a sequence of images.

Although concern about risk should not deter pulmonary angiography, there are noteworthy limitations on its performance and value. Still, it is a rather odd commentary on medical thinking that few would advise against performance of a coronary angiogram in a patient with coronary thrombosis or ischemia because of risk; yet the question of risk often deters pulmonary angiography in a patient in whom embolism is suspected. Given that the case-fatality rate of undiagnosed and untreated embolism exceeds that of myocardial infarction, it is not clear why this disparity exists; it should not exist, given equal competence in the performance and interpretation of these two procedures.

DIAGNOSTIC APPROACH TO PULMONARY EMBOLISM: SUMMARY

A large array of diagnostic techniques is available for patients with suspected VTE. What the clinician at the bedside must understand and accept is that multiple approaches are possible and that a stepwise diagnostic strategy, rather than any single diagnostic technique, may be necessary to confirm or exclude the diagnosis (Fig. 81.8). The initiating point for the diagnostic pathway begins with clinical suspicion, and a subsequent rational approach is essential and potentially lifesaving. Withholding anticoagulation in a patient who has had an embolic event places that patient at risk for recurrent, potentially lethal events; instituting empirical anticoagulant therapy in a patient who has not had an embolic event will involve unnecessary hospitalization and therapy, places the patient at risk for hemorrhagic complications, and establishes a "preexisting" condition that may adversely affect future health care. Finally, the clinician must understand that the use of a clinical prediction rule derived from an outpatient population might have a very different predictive value when applied to a less healthy inpatient population.

MASSIVE PULMONARY EMBOLISM

Massive PE accounts for less than 5% of all diagnosed cases of PE.[5,297] The more than a 15-fold increase in mortality of massive PE in comparison to less severe PE justifies a separate consideration of the diagnostic and therapeutic approach to this problem.[122,298] The definition of massive PE should be based on hemodynamic instability rather than purely anatomic size of the embolus.[299–301] Although anatomically extensive emboli have a greater likelihood of being associated with hemodynamic compromise, they do not all lead to circulatory insufficiency, and the clot burden observed on CTPA is a poor predictor of mortality.[120] Irrespective of the extent of vascular obstruction, patients with PE who present with shock have a several-fold higher mortality rate than more stable PE, regardless of the type of intervention.[14]

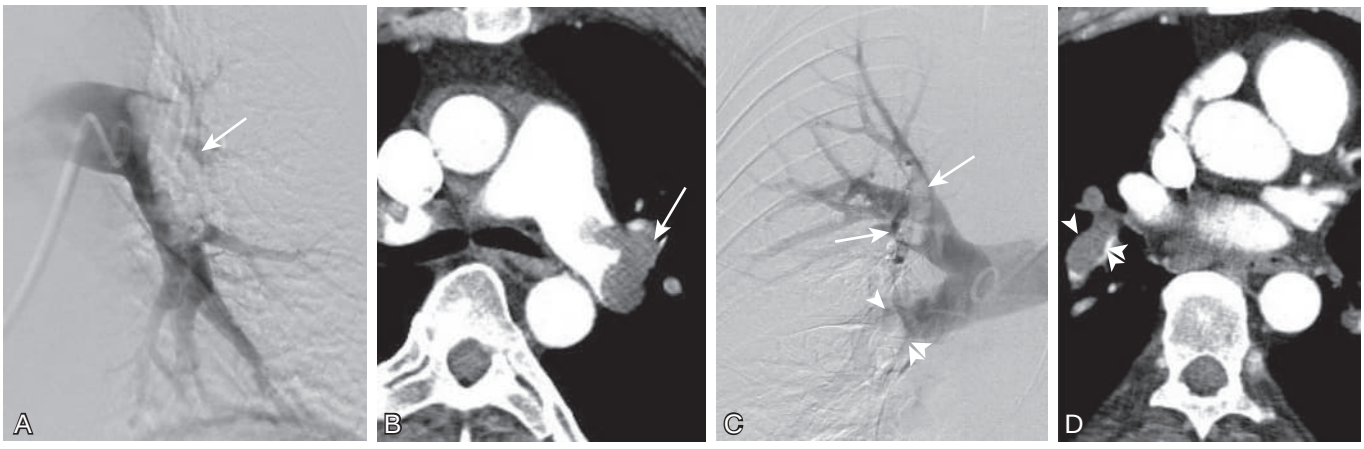

Figure 81.7 Catheter angiographic findings of pulmonary embolism with *computed tomography* (CT) correlation. (A) Catheter digital pulmonary angiography performed via an injection in the left pulmonary artery shows a large intraluminal filling defect within the left pulmonary artery (*arrow*) representing pulmonary embolism. (B) CT pulmonary angiography shows the corresponding left pulmonary arterial embolism (*arrow*). (C) Catheter digital pulmonary angiography performed via an injection in the right pulmonary artery shows several intraluminal filling defects (*arrows*) consistent with acute pulmonary embolism. The right lower lobe artery shows an abrupt vascular cutoff (*single arrowhead*), nearly occlusive, with a thin rim of contrast-opacified blood extending around the right lower lobe embolism along its medial border (*double arrowheads*). (D) CT pulmonary angiography shows the corresponding right lower lobe nearly occlusive pulmonary arterial embolism (*arrowhead*) with the thin stream of contrast extending along the medial border of the embolus (*double arrowheads*).

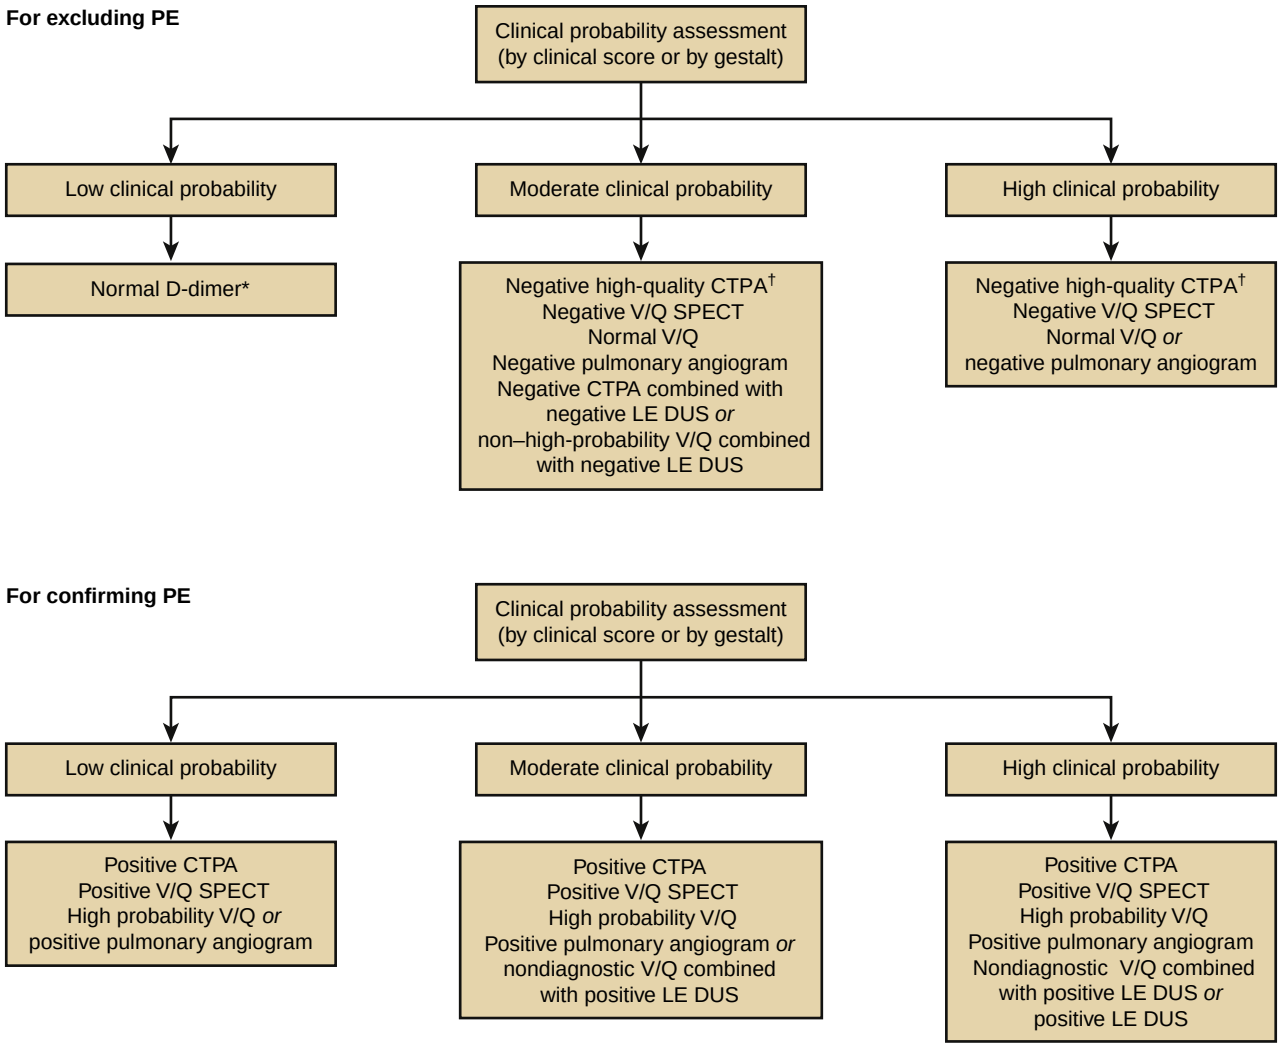

Figure 81.8 Diagnostic strategies capable of excluding or confirming the diagnosis of pulmonary embolism. Depending on the assessed clinical probability, the tests and their results can be used either to exclude or to confirm a diagnosis of pulmonary embolism. CTPA, computed tomographic pulmonary angiography; DUS, Doppler ultrasound; LE, lower extremity; V/Q, ventilation-perfusion scan; V/Q SPECT, ventilation-perfusion scan performed with a SPECT (single-photon emission computerized tomography) protocol. *The limits of normal for D-dimer are best appreciated when the patient's age is taken into account (see text).†Artifacts may interfere with the sensitivity of CTPA, especially in scanners with four or fewer detectors (see text).

RISK STRATIFICATION

The risk of mortality and significant morbidity from acute PE is substantially influenced by the patient's premorbid conditions and clinical presentation.[302] Clinical scoring systems can identify well patients who are at low risk for mortality and who may therefore require less monitoring. However, scoring systems alone typically are not capable of identifying patients at such high risk of PE-related mortality that specialized interventions (fibrinolytics, inferior vena cava filters, embolectomy, etc.) are warranted. The *Pulmonary Embolism Severity Index* (PESI), a risk stratification scoring system derived from patients' demographic characteristics (gender and age), incorporates coexisting illnesses (cancer, heart failure, and chronic lung disease) and physical findings related to cardiopulmonary status (heart rate, systolic blood pressure, respiratory rate, temperature, mental status, and oxygenation).[303,304] The PESI divides PE patients into five distinct classes of risk, and the mortality associated with each class has been shown to be remarkably consistent across several validation populations.[303,304] Mortality is typically 0–1.6% for class I, 2.0–3.5% for class II, 6.5–7.7% for class III, 10.4–12.2% for class IV, and 17.9–24.5% for class V.[303,304] A *simplified version of the PESI score* (sPESI, see Table 82.3), including only age, cancer, chronic cardiopulmonary disease, heart rate, systolic blood pressure, and oxyhemoglobin saturation levels, appears to perform just as well as the more complicated one.[305] An alternative scoring system called the *Bova score* is a 7-point system representing combinations of variables significantly associated with risk of PE-related complications within 30 days, including death from PE, hemodynamic collapse, and recurrent nonfatal PE. The variables include elevated cardiac troponin, tachycardia, RV dysfunction, and hypotension. Patients categorized into low, intermediate, and high-risk groups with this score had acute PE-related mortality of 1.7%, 5.0%, and 15.5%, respectively.[306,307] Regardless of the scoring system used, clinical judgment is paramount. A patient with a low PESI score who nonetheless appears severely ill should be monitored according to clinical judgment, rather than by the score itself.[304]

The ECG provides some information helpful for risk stratification. Increased risk of circulatory collapse and death is seen in patients with the $S_1Q_3T_3$ pattern of RV strain; right bundle-branch block; inverted T waves in the inferior, right sided, or precordial chest leads; S-T segment elevation in aVR; prolonged Q-T interval; Qr pattern in V_1; and tachycardia or atrial fibrillation.[308–313] Widespread T wave inversions predict increased mortality and complications from acute PE,[309] as does the combination of ischemic findings and clinical risk.[312]

Short-term mortality risk in PE is strongly related to the presence of systemic hypotension, a potentially fatal manifestation of RV dysfunction. Systemic hypotension represents the perfect storm of ischemia-related cardiac dysfunction, increased resistance against RV outflow, and hemodynamic instability. For this reason, transthoracic echocardiography[314] and biochemical markers, such as serum troponin[315] or serum brain natriuretic peptide[316] levels, have been investigated as a means of evaluating RV function in patients with embolism. Clinical studies have suggested that, whereas these techniques are reasonably capable of distinguishing patients with a good prognosis from those at risk for death and other adverse events, they lack the predictive power to warrant clinical decision making exclusively on the basis of a single test.[317–319] Moreover, it has not been conclusively established that the potential risks of a more aggressive therapeutic approach (thrombolytics, embolectomy, etc.) in all "high-risk" patients, the majority of whom have a satisfactory outcome when treated with anticoagulation therapy alone, justifies the potential benefit.[320]

OTHER PREDICTORS OF MORTALITY

Other predictors of mortality may reflect the presence of comorbid disease in addition to the effects of PE itself. For example, pleural effusion detected on CT scan at the time of diagnosis of acute PE is associated with increased mortality,[321,322] regardless of whether the effusions were ipsilateral or contralateral to the PE locations.[322] Likewise, hypoalbuminemia[323] and hyponatremia[324] in PE patients are associated with higher mortality, possibly because they reflect coexisting renal disease or malignancy. Renal dysfunction itself in the presence of PE is a poor prognostic factor[325,326] and is associated with a higher incidence of RV injury[327,328] and death.[270]

Bleeding events understandably increase the risk of death in acute PE patients.[270] High red blood cell distribution width, a measure of the variation of red blood cell size, is also associated with mortality,[329,330] although whether that observation reflects recent blood loss or other coexisting conditions is unknown. Other hematologic markers associated with high PE-related mortality, such as high platelet to lymphocyte and high neutrophil to lymphocyte ratios,[331,332] may reflect increased inflammation and thrombogenesis.[333,334]

PULMONARY EMBOLISM DURING PREGNANCY

VTE is a leading cause of maternal mortality.[335] However, PE is confirmed in only about 5% of CTPA scans in pregnant women,[336,337] whereas other findings to explain their symptoms are found in an additional 12% of scans.[337] Because the scans entail the potential risk of radiation exposure to the fetus,[294] a diagnostic approach that limits that exposure is warranted. Therefore, duplex ultrasonography is an appropriate initial diagnostic approach.

Unfortunately, the D-dimer assay and other assays of thrombotic activity are far less useful as screening tools for VTE in pregnant and postpartum women than in the general population. Plasma D-dimer levels in healthy women increase markedly and to variable degrees during pregnancy.[338] The normal increase in plasma D-dimer and other hemostatic markers precludes a specific cutoff value from distinguishing between those with and without VTE.[339–342] However, the combination of low clinical prediction scores and low D-dimer is likely to enable the identification of pregnant women at low enough risk for PE that further workup is not necessary. Specifically, the YEARS algorithm (see the "Clinical Prediction Rules" section), modified for pregnant (not postpartum) women by mandating lower extremity duplex ultrasound in those with leg symptoms, safely excluded PE across all trimesters of pregnancy.[343] The algorithm avoided the need for CTPA in 32% of patients in the third trimester and 65% of patients in the first trimester.[343]

If PE cannot be safely excluded, the diagnostic evaluation should proceed as previously described based on the clinical assessment probability and using CTPA, V/Q scanning, or SPECT-V/Q as the next diagnostic technique. CTPA has a comparable accuracy to planar V/Q for pregnancy-associated PE but may deliver a higher dose of maternal radiation, with wide ranges reported in the literature that may increase with body mass index (1–20 mSv for CTPA vs. 0.9–5.9 mSv for V/Q).[262,344–348] Because of the physiologic changes associated with pregnancy, rates of inconclusive studies for either CTPA or V/Q scanning may be relatively high.[349] Specifically with CTPA, inconclusive studies in pregnant women have been found to be related to motion artifact and low attenuation of the pulmonary artery.[350] Both CTPA and V/Q scanning result in risk of fetal radiation exposure below the safety threshold of 100 mm Gy associated with fetal radiation complications.[349] CTPA may result in less fetal radiation exposure than V/Q scanning[268,351]; however, the breast-absorbed radiation to proliferating breast tissue is significantly higher from CTPA and the long-term implications of this with respect to maternal breast cancer risk remain unknown.[344,346,348] Shielding can be used to reduce radiation to the breast tissue (see Fig. 129.3 and Chapter 129). In the future, MRI may be used to image the pelvic and lower extremity veins and pulmonary arteries; although it would avoid radiation exposure, its accuracy for diagnosis of VTE is not currently known.

RECURRENT PULMONARY EMBOLISM AND DEEP VENOUS THROMBOSIS

The risk of recurrent VTE depends on factors such as the nature of the initial thromboembolic event (spontaneous or associated with a defined clinical circumstance), the type of

initial event (DVT or PE),[352,353] the presence of an ongoing predisposition (either clinical or hereditary), the severity of the initial event,[354] plasma markers reflecting ongoing thrombosis,[355] and residual vascular scars at the thrombotic sites.[356]

Patients whose VTE was associated with clearly defined strong and reversible provoking factors that have subsequently resolved can likely be managed with a short (3- to 6-month) course of therapy with minimal risk of recurrence.[357,358] However, the clinician must evaluate both the strength and the reversibility of provoking factors when evaluating the risk of recurrence because they can vary markedly. For example, VTE provoked by surgery has a recurrence rate of 0.7% per patient-year, whereas VTE provoked by nonsurgical factors has a recurrence rate of 4.2% per patient-year. By comparison, unprovoked VTE has a recurrence rate of 7.4% per patient-year.[71]

Patients without clearly defined strong and reversible provoking factors for thromboembolism (unprovoked VTE) have about a 30–50% risk of recurrence during the subsequent 10 years.[359,360] Recurrence rates are higher in patients with a history of more than one episode of idiopathic DVT or PE[361]; the presence of certain irreversible acquired or hereditary risk factors that strongly predispose toward VTE (active cancer,[362] antiphospholipid antibody syndrome,[363] and hereditary deficiencies of antithrombin III, protein C, or protein S[364]); the presence of extensive residual venous thrombosis[96]; and the presence of extensive residual V/Q scan or CT scan defects.[148,365,366] Although the presence of the heterozygous factor V Leiden mutation or the prothrombin gene mutation individually does not appear to increase the absolute risk of recurrence substantially,[24] the presence of the homozygous factor V Leiden mutation or the heterozygous factor V Leiden mutation in combination with the prothrombin gene mutation does appear to be associated with an increased recurrence risk.[30]

Among unprovoked VTE without the specific risk factors listed in the previous paragraph, a reasonable estimate of recurrence risk may be estimated by various scoring systems (Table 81.4). The *DASH score* is based on the posttreatment D-dimer level, age, sex, and presence or absence of hormone therapy associated with the VTE.[367] The *HERDOO2 system* estimates women (only) at low risk for recurrence if they have no more than one of the following: postthrombotic signs (*h*yperpigmentation, *e*dema, or *r*edness), elevated posttreatment *D*-dimer levels, *o*besity, or *o*lder age.[368] The *Vienna scoring system* constructs a nomogram for risk based on male sex, proximal versus distal DVT, PE versus distal DVT, and elevated posttreatment D-dimer.[356]

A standard for repeating noninvasive testing of either the lungs or the deep veins of the lower extremities at the anticipated time of anticoagulant discontinuation does not exist. Although the cost implications would be substantial, such an approach would be beneficial in establishing a new baseline study that could be used for comparison in the event thromboembolic recurrence was suspected and in identifying patients with pulmonary vascular obstruction of sufficient extent to place them at risk for the development of chronic thromboembolic pulmonary hypertension.

Table 81.4 Prediction of VTE Recurrence in Patients With Prior Unprovoked VTE

LONG-TERM CONSEQUENCES OF PULMONARY EMBOLISM

After a PE, embolic material in the pulmonary arteries either resolves by fibrinolysis or is remodeled into organized scars. The extent of remodeling and the severity of the resulting vascular obstruction varies among patients; in some, lung perfusion is rapidly restored,[80] although the resolution in the first week is typically incomplete. Embolic remodeling probably continues at a slower pace for the next 1 to 2 months.[247,248] Residual defects commonly persist beyond this period, suggesting that the emboli have been remodeled into permanent vascular scar.[55,74–79,249] Factors associated with poor resolution include large initial PE,[369] unprovoked PE,[370] abnormal fibrinogen subtypes,[369] and elevated fibrinogen levels.[370] Incomplete resolution after acute PE is an important clinical problem.[266,371] An array of chronic manifestations, with considerable overlap, has been described by various authors:

persistent acute pulmonary artery filling defects, residual pulmonary vascular obstruction, post-PE dyspnea, post-PE exercise limitation, post-PE syndrome, chronic thromboembolic disease, and *chronic thromboembolic pulmonary hypertension* (CTEPH) (see also Chapter 86).

Persistent pulmonary artery filling defects refer to intravascular filling defects observed on pulmonary artery contrast studies (CTPA or angiogram).[372–374] Although CTPA findings resolve rapidly in most patients,[145] persistent filling defects have been observed in about 15% of CTPA scans after acute PE and about 50% of scans performed after massive PE.[372,373] About half of those scans disclose central filling defects or complete occlusions similar in appearance to the original PE, another third disclose eccentric defects contiguous with the vessel wall at the site of acute PE, and the remainder disclose filling defects that contain channels of contrast material that suggest recanalization.[372] Acute proximal pulmonary artery PE is more likely to result in persistent pulmonary artery filling defects than distal PE.[372,375] Because of the potential for chronic filling defects to mimic recurrent acute PE, the latter is most confidently diagnosed in patients with prior PE if acute-appearing defects are disclosed in new previously uninvolved regions, such as the contralateral lung or in arteries separate or more proximal than the original PE.[376]

Residual pulmonary vascular obstruction refers to findings on V/Q scan (planar or SPECT) of persistent unmatched perfusion defects.[100,125,140–142,144,377–382] About one-third of acute PE patients will have residual pulmonary vascular occlusion in 10% or more of the lung regions (i.e., in at least two lung segments).[148] In follow-up after acute PE, residual pulmonary vascular obstruction (on V/Q) is about twice as common as persistent pulmonary artery filling defects (on CTPA).[372] SPECT may be more sensitive than planar V/Q for identifying chronic perfusion defects.[383,384]

Residual pulmonary vascular obstruction is associated with respiratory symptoms,[381] hypoxemia[100,140,377] gas exchange deficits,[100,385,386] exercise intolerance,[387] and other serious clinical consequences.[100,140,377,381,385–388] Residual pulmonary vascular obstruction is also associated with an increased risk of CTEPH.[148]

In a substantial proportion of patients, there is post-PE dyspnea and reduced quality of life,[389,390] although it cannot be assumed that such symptoms reflect incomplete resolution of the thromboemboli themselves.[391] Post-PE exercise limitation is a related term that typically implies abnormal results on an objective exercise test.[391,392] Post-PE syndrome is a term used to describe dyspnea or deteriorated quality of life after PE, combined with objective evidence of either cardiac or pulmonary dysfunction (e.g., on echocardiography[393] or cardiopulmonary exercise testing[393,394]). Of interest, a reasonable proportion of patients who fit the definition of post-PE syndrome do not have residual pulmonary vascular obstruction, so their symptoms may reflect comorbid diseases or exercise-limiting conditions, such as obesity or deconditioning.[391,392,395,396]

In many cases, however, post-PE dyspnea is associated with residual pulmonary vascular obstruction on V/Q scan[148] or persistent pulmonary artery filling defects on CTPA.[373] Residual pulmonary vascular obstruction is associated with exertional dyspnea and increased alveolar dead space ventilation and RV dysfunction.[148,397–399] Residual vascular obstruction increases alveolar dead space ventilation in CTEPH, which correlates with severity.[399] Residual vascular obstruction also increases pulmonary arterial resistance and impedes RV stroke volume reserve.[397,398] It may be prudent to evaluate post-PE dyspnea patients with cardiopulmonary exercise testing. V/Q scanning (SPECT or planar) may be used in those with cardiopulmonary dysfunction to search for residual pulmonary vascular occlusion.

CTEPH results from intravascular scar tissue that develops and obstructs the pulmonary arteries sufficiently to cause pulmonary hypertension.[149,400] It arises in a small percentage of "all-comers" after acute PE[388,401–408] but in about one-sixth of patients with residual pulmonary vascular occlusion.[148] The pulmonary hypertension from CTEPH causes significant morbidity and mortality, as described in Chapter 86. CTEPH is distinguished from acute PE on the basis of its chronic presentation, including evidence of pulmonary hypertension and radiographic findings (e.g., intravascular webs, pulmonary artery retraction or dilation, bronchial artery dilation, RV hypertrophy, and interventricular septum flattening[409]). *Chronic thromboembolic disease* is a more recent term used to describe patients with similar findings but in whom pulmonary hypertension is not evident on tests performed at rest, although exercise may induce elevated pulmonary artery pressures or other pathophysiologic changes.[410]

Other forms of embolism are described at ExpertConsult.com.

Key Points

- *Pulmonary embolism* (PE) continues to be a common yet underrecognized cause of morbidity and mortality.
- Most deaths from PE are due to a failure to prevent the disease in at-risk patients and to a failure to make the diagnosis.
- Deep venous thrombosis is best diagnosed by a consideration of clinical probability, D-dimer as a screening test, and then lower extremity Doppler ultrasound.
- Clinical suspicion for PE is the first and most critical step in the diagnosis. Clinical decision rules help determine which patients merit further workup.
- Because D-dimers are highly sensitive but not specific for thromboembolism, the role of D-dimer testing is mainly one of exclusion.
- Recurrence of venous thromboembolic disease is a function of many factors, primarily whether there is an ongoing predisposition to thrombosis.
- Massive PE causes hemodynamic compromise as result of right heart ischemia and failure, caused by increased demand for work, high intraventricular pressures and low systemic blood pressure leading to poor coronary perfusion.
- Long-term outcomes after PE include recurrence as well as a risk of chronic dyspnea.
- The optimal method to screen for and work up prolonged symptoms such as dyspnea after acute PE remains uncertain.

OTHER FORMS OF EMBOLISM

Because the lungs receive all of the blood flow returned from the venous system, the pulmonary vascular bed serves as a "sieve" for all particulates entering the venous blood and is the first vascular bed to be exposed to any toxic substance injected intravenously. As a result of its strategic position, the pulmonary vascular bed is therefore exposed to a wide variety of potentially obstructing and injurious agents.

SCHISTOSOMIASIS

Among such agents, the most common on a worldwide basis, although not within the United States, is schistosomiasis. This parasitic disorder may cause pulmonary hypertension by three mechanisms: anatomic obstruction by the organism itself, an intense inflammatory vasculitic response to the components of the organism, and the development of portopulmonary hypertension. In endemic areas, schistosomal disease is the most common cause of RV dysfunction. Limited data suggest that cardiopulmonary schistosomiasis is seen most often in *Schistosoma mansoni* infection. This form of RV dysfunction is always seen with concomitant schistosomal liver disease because the liver is always involved, usually quite extensively, before the lung. The premortem diagnosis of cardiopulmonary schistosomiasis depends on serology and the detection of schistosomal ova in stool or urine along with evidence of hepatic fibrosis and pulmonary hypertension. Treatment with praziquantel can eradicate schistosomal infections with minimal toxicity. However, cardiopulmonary manifestations are not likely to be reversible once chronic fibrosis develops (see Chapter 58).[411]

AIR EMBOLISM

An increasingly common form of nonthrombotic embolism in the United States is air embolism.[412] The increasing frequency of the problem reflects the wide variety of invasive surgical and medical procedures now available, the broad use of indwelling central venous catheters, the use of positive-pressure ventilation with high levels of positive end-expiratory pressure, and the frequency of thoracic and other forms of trauma.[413] The simple inadvertent transection or disconnection of a large-bore *intravenous* (IV) catheter (eFig. 81.10), particularly in the jugular or subclavian vein, can result in ingress of substantial quantities of air. Air bubbles enter the pulmonary vascular bed and, if the air bolus is large enough, can travel from the pulmonary arteries to the pulmonary veins through microvascular shunts and be distributed diffusely throughout the body.[414]

Physiologic consequences of pulmonary air embolism include an abrupt rise in pulmonary artery pressure. Increased permeability (noncardiogenic) pulmonary edema may develop, lung compliance falls, and hypoxemia ensues. The symptoms of air embolism are variable and nonspecific and may include alterations in sensorium, chest pain, dyspnea, or a sense of impending doom. These and other consequences appear to be due to two phenomena: actual lodging of the bubbles in capillary beds, which interferes with nutrient supply to the affected organs, and the formation of platelet-fibrin aggregates, creating diffuse microthrombi.[415] Thrombocytopenia may be seen as a consequence of this latter event. The most serious consequences result from cerebral or coronary artery air embolism, and the severity of the consequences depending upon the volume of air that gains access to the venous circulation.[412]

The best approaches to air embolism are prevention and early detection. Treatment consists of measures designed to restore blood flow and to promote reabsorption of the intravascular air. Measures designed to restore flow include patient positioning (Trendelenburg position with the left side down), removal of air through central venous catheters or direct needle aspiration, and closed-chest cardiac massage. Measures designed to increase absorption include the use of 100% oxygen and the institution of hyperbaric oxygen therapy as early as possible.[416–418] By using such aggressive measures, mortality from air embolism has been dramatically reduced.[419]

FAT EMBOLISM

Another reasonably frequent and dramatic form of nonthrombotic embolism is fat embolism. A rather characteristic syndrome follows entry of neutral fat into the vascular system creating mechanical emboli and focal ischemia, resulting in a triad of symptoms consisting of respiratory distress, petechiae, and altered mental status. There is a variable lag time of 12 to 72 hours in the onset of the syndrome after the inciting event.[420]

By far the most common inciting event is traumatic fracture of marrow-containing long bones; the incidence of fat embolism rises with the number of fractures. However, orthopedic procedures and trauma to other fat-laden tissues (e.g., fatty liver) occasionally are followed by the same syndrome.

The reasons for the variability in incidence of the syndrome after apparently comparable injuries are not clear. Perhaps variations in incidence and severity relate to the amount of fat released. The pathophysiologic consequences appear to derive from two events: (1) actual vascular obstruction by neutral particles of fat and (2) the injurious effects of free fatty acids released by the action of lipases on the neutral fat.[421] The latter effect is probably the more important, causing a diffuse vasculitis with leakage from cerebral, pulmonary, and other vascular beds.[422]

The diagnosis of fat embolism syndrome is a clinical one suggested by the onset of dyspnea, neurologic abnormalities, petechiae, and fever in the proper clinical context (see Fig. 127.2 and eFig. 127.2). Petechiae, typically distributed over the head, neck, anterior chest, and axillae, are present in only 20–50% of cases.[423] Therefore, their absence should not preclude consideration of the disease. No laboratory test is diagnostic of the syndrome.

Although a variety of treatments have been suggested (e.g., IV ethanol, albumin, dextran, heparin), none has proved effective. There is some evidence to suggest that corticosteroid therapy might prevent the onset of fat embolism syndrome after an inciting event, but controlled studies are sparse, and the topic remains controversial.[424] Supportive treatment, including mechanical ventilatory support, when necessary, is the primary approach and, with meticulous supportive care, survival among most cases of fat embolism is common.[425] However, severe fat embolism syndrome, manifested by widespread opacities on chest CT and acute respiratory distress syndrome, is often life-threatening.[426]

AMNIOTIC FLUID EMBOLISM (See Chapter 129)

Another special form of embolism is *amniotic fluid embolism* (AFE), a rare but unpredictable and potentially catastrophic complication of pregnancy with an incidence of approximately 1 in 40,000 pregnancies and accounting for 5–15% of all maternal deaths.[427] This disorder may arise during or after delivery when amniotic fluid gains access to uterine venous channels and, from there, to the pulmonary and general circulations. The delivery may be either spontaneous or by cesarean section; there are case reports of AFE after therapeutic abortion. Unexpectedly and suddenly, the patient may have severe respiratory distress, cyanosis, hypotension, and often cardiovascular collapse. Most cases develop during labor (see Fig. 129.5), but delayed onset of symptoms up to 48 hours after delivery has been reported.[428] Increased risk for AFE is associated with induction of labor, multiparity, advanced maternal age, ethnic minority status, cesarean delivery, placental abnormalities, eclampsia, polyhydramnios, cervical lacerations, uterine rupture, premature placental separation, fetal death, and meconium staining of amniotic fluid.[429,430]

Amniotic fluid contains particulate materials that may cause pulmonary vascular obstruction (see Fig. 129.4), but the major pathogenetic mechanism of the syndrome remains uncertain. Animal models suggest that physical obstruction of the pulmonary capillaries by amniotic fluid is not the main mechanism of AFE.[430] Pulmonary vasoconstriction and increased pulmonary vascular resistance appear to be the drivers of hemodynamic collapse during AFE, leading initially to RV collapse followed by left ventricular failure.[431] Amniotic fluid does have thromboplastic activity that leads to extensive fibrin deposition in the lung vasculature and, occasionally, in other organs. As a consequence of fibrin deposition, a severe consumptive coagulopathy develops, including marked hypofibrinogenemia and thrombocytopenia. After the acute event, there often is an enhanced fibrinolytic state consistent with disseminated intravascular coagulation.[432]

The diagnosis of AFE is based on a compatible clinical picture. Although various forms of therapy have been suggested (e.g., antifibrinolytic agents, such as aminocaproic acid, cryoprecipitate, factor VIIA, pulmonary vasodilators), the best approach is supportive.[430] Even in the setting of aggressive supportive measures, however, maternal mortality is in the range of 20–60%, with many survivors suffering from long-term neurologic disability.[427,433]

SEPTIC EMBOLISM

Septic embolism is another special disorder that, unfortunately, is also increasing in frequency owing to widespread injection drug use and the expanding use of indwelling IV catheters. Previously, septic embolism was almost exclusively a complication of septic pelvic thrombophlebitis secondary to both septic abortion and postpuerperal uterine infection. Although these conditions still lead to septic emboli, injection drug use is now by far the more common cause.[434] An increasingly common cause is iatrogenic: infections secondary to indwelling catheters inserted for a variety of diagnostic or therapeutic purposes.[435,436]

Microscopically, septic phlebitis consists of purulent material admixed with fibrin thrombus. Embolization can result in obstruction of small pulmonary vessels, but the major consequence is pulmonary infection. Characteristically, imaging shows peripherally distributed pulmonary nodular opacities that undergo cavitation (eFig. 81.11). An increasing number of such opacities develop over periods of hours to a few days. Symptoms and signs include a septic temperature course, dyspnea, cough, pleuritic chest pain, and hemoptysis. Initial treatment consists of appropriate antimicrobial drugs. If an indwelling catheter is suspected to be the source of the infection, it should be removed. If there is not a prompt response to this regimen, surgical isolation of the septic vein, if present, should be considered. The role of systemic anticoagulation remains uncertain. Endocarditis may complicate septic phlebitis, or mimic it, particularly in IV drug users.

OTHER EMBOLI

A wide variety of other materials may lodge in the lung, which in effect acts as a sieve for the entire cardiac output.[437] Cancer cells, of course, often find their way into and adhere to the pulmonary vessels; on occasion, tumor emboli (admixtures of thrombus with cells) can lodge in the pulmonary circulation and mimic bland embolization (see eFigs. 79.2 and 79.3). Trophoblastic tissue can escape the uterus and lodge in the pulmonary circulation during evacuation of a molar pregnancy or during hysterectomy for an invasive mole. After head trauma, brain tissue has been found in the lungs; the same is true of liver cells after abdominal trauma and of bone marrow after cardiopulmonary resuscitation. In rare instances, iatrogenic emboli can arise from injection therapy (e.g., treatment of gastric varices) or even procedures such as vertebroplasty (eFigs. 81.12 and 81.13).

In sickle cell disease, pulmonary artery thrombi, either from thromboembolism or from in situ thrombosis, are found in 10–20% of patients with acute chest syndrome.[438] During the acute chest syndrome, pulmonary artery thrombosis may present without clinical findings suggestive of PE, so clinicians would be wise to have a high index of suspicion for this complication. Patients with sickle cell disease may also develop pulmonary artery hypertension.[439] (See Chapter 127 for information about sickle cell disease.)

Finally, in this era of injection drug use, noninfectious vasculitic-thrombotic complications are being seen with increasing frequency. Particulate and irritant drug carriers (e.g., talc [see eFig. 99.17], and cellulose [see eFig. 99.16]), and occasionally, the drugs themselves, may cause vascular inflammation and secondary thrombosis.[440] More common, uptake of the talc into the pulmonary interstitium results in fibrosis and advanced emphysema.[441–443]

Mercury, both orally ingested and embolized through the absorption via the gastrointestinal tract and intravenously injected, may embolize to the lungs. Mercury can be used as a homeopathic remedy for pain,[444] injected in the setting of deliberate suicide attempt, for improving athletic or sexual performance, or in the setting of concomitant IV drug abuse. Mercury emboli may have a dramatic radiographic appearance but rarely cause significant respiratory symptoms or decrease in pulmonary function by spirometry.[445]

KEY POINTS

INTRODUCTION

Prophylaxis (i.e., primary prophylaxis) and treatment of pulmonary thromboembolism are best achieved with drugs. The primary difference between prophylaxis and treatment is the dosages of anticoagulants used: treated patients receive a higher dosage. This chapter briefly describes the rationales for prophylaxis and treatment and then focuses on the details of each.

PROPHYLAXIS

Because most pulmonary thromboembolism originates in the deep veins, particularly of the lower extremities, the term *venous thromboembolism* (VTE) is often used to describe both *deep venous thrombosis* (DVT) and *pulmonary embolism* (PE). This chapter uses these three terms. Three predisposing factors—hypercoagulability, stasis, and venous injury or inflammation (known as Virchow's triad)—may each contribute to a clot that becomes clinically evident as DVT or PE.

Persons at elevated risk for VTE include the following: patients with lower extremity trauma or surgery, with (total knee replacement) or without (total hip replacement) an intraoperative tourniquet; other patients undergoing prolonged procedures, inpatient or outpatient; lengthy periods of relative immobility (e.g., airplane "economy class syndrome"); diagnosed or undiagnosed high-risk inherited (e.g., homozygous prothrombin gene mutation) or acquired (e.g., antiphospholipid antibody syndrome) thrombophilia; certain cancers (e.g., lung, brain, pancreas, leukemia); and hormonal manipulations (e.g., high-dose fertility injections, hormonal therapy for prostate cancer, certain oral contraceptives).

Because objective tests (e.g., lower extremity venograms and contrast-assisted chest computed tomography) have repeatedly shown that DVT and PE may manifest in patients without symptoms or signs, "primary" VTE drug prophylaxis is undoubtedly administered to some patients who already have established thrombosis.[1] The effect of prophylactic treatment (i.e., low-dose antithrombotic therapy) in these patients is likely partial prevention of clot extension and new clot formation, while endogenous lysing mechanisms resolve the thrombi.

There are two categories of VTE prophylaxis: drug and mechanical. Antithrombotic drugs administered at prophylaxis dosages nonetheless carry risks, such as bleeding, heparin-induced thrombocytopenia, drug interactions interfering with other important therapies, and others. Mechanical prophylaxis, which includes intermittent pneumatic compression and early ambulation, is generally less effective than medical prophylaxis but carries fewer serious risks. Risks include skin injury from improperly applied intermittent pneumatic compression and a potential increase in falls.

BIOAVAILABILITY OF SUBCUTANEOUS ANTICOAGULANTS

The plasma availability for VTE prophylaxis of subcutaneously injected anticoagulants can depend on the patient's other clinical features. A study of mechanically ventilated intensive care unit patients on vasopressors, similar intensive care unit patients not on vasopressors, and surgical ward patients on neither ventilators nor vasopressors, all receiving once-daily subcutaneous prophylactic

nadroparin (a *low-molecular-weight heparin* [LMWH]), measured blood anti–factor Xa levels just before and 3, 4, 6, 8, and 12 hours after a nadroparin dose on the third day of dosing. The patients not receiving vasopressor therapy had expected and satisfactory mean levels of nadroparin at each time point. In contrast, the patients receiving vasopressor therapy had mean nadroparin levels 25–33% of the expected level at each time point, presumably because of peripheral vasoconstriction.[2]

In a 2019 study of adding mechanical prophylaxis to subcutaneous drug prophylaxis in intensive care unit patients that found no added benefit beyond drug prophylaxis alone,[3] only 66% of study participants were on artificial ventilation, and only 35% were receiving vasopressor therapy. Hence, although there is certainty that the bioavailability of subcutaneous drug prophylaxis is markedly reduced in patients receiving vasopressor therapy, an effective countermeasure is not known.

DIFFERING PHILOSOPHIES OF VENOUS THROMBOEMBOLISM PROPHYLAXIS

There are two opposing philosophies to determine which persons warrant VTE prophylaxis. One is *personalized risk stratification*, exemplified by the Caprini[4] risk assessment score for surgical patients and the Geneva Risk and Padua Prediction[5] scores for medical inpatients. The other approach is nearly *universal application within patient groups*,[6] almost akin to society's approach to infant immunization. Proponents of the second approach argue that it simplifies decision-making and recognizes that hospitalization itself is the risk factor provoking prophylaxis consideration. Each approach allows exceptions.

To the extent possible, physicians can share with patients their view of prophylaxis for that individual. We think VTE prophylaxis should be recommended to each patient absent a contraindication. The timing of initiation, duration, drug, and dosage should provide maximum VTE risk protection without undue risk.

VENOUS THROMBOEMBOLISM PROPHYLACTIC DRUGS

Unfractionated Heparin

Unfractionated heparin (UFH) is a mixture of glycosaminoglycans purified from pig intestine. A tanker-truck of pig intestines yields about 8 pounds of UFH. Despite its biologic origin, it is classified as a drug and is standardized by a range of component molecular-weight molecules and activities of anti–factor Xa and anti–factor IIa. Factor Xa is factor X activated by either tissue factor complexed with factor VII (extrinsic pathway) or factor VIII complexed with factor IX (intrinsic pathway). Factor IIa is thrombin, the cleavage-activated product of prothrombin, factor II. Both anti–factor Xa and anti–factor IIa components of UFH have antithrombotic activity. The anti–factor IIa activity of UFH is primarily through binding to catalyze antithrombin, but UFH also has antithrombotic activity in low-antithrombin states, perhaps mostly through its anti–factor Xa molecules. The most sensitive assay for heparin is the anti–factor Xa level, but this level is rarely measured during prophylactic use.

UFH was the first VTE prophylactic drug proven effective, as shown in a study of surgical patients in 1972. When given subcutaneously at 5000 units 2 hours preoperatively and every 8 hours postoperatively for 7 days, autopsy-proven fatal PE was identified in 2 of 2045 patients (0.09%) in the UFH group and in 16 of 2074 (0.8%) in the control group.[7] Currently, UFH prophylaxis is not commonly begun before surgery but is instead given every 8 or 12 hours during the risk period, usually until hospital discharge, assuming reasonable hemostasis. A 2011 meta-analysis showed nonsignificant differences between the two dosing interval regimens for PE, DVT, death, and bleeding.[8]

Subcutaneous UFH is slowly and incompletely absorbed into the circulation, with the circulating amount dependent on the subcutaneously injected dosage; 5000 units UFH administered subcutaneously shows only 15–20% of the area under the curve of activity (measured as anti–factor Xa level) of 5000 units intravenous UFH, with a peak anti–factor Xa level of 0.13 units/mL, and it falls below detection after 4 hours.[9] However, a higher subcutaneous dosage seems to saturate the subcutaneous injection site, and more drug becomes evident in plasma. When 35,000 units UFH is injected subcutaneously in divided doses over 24 hours, more than 90% reaches the plasma. This is the apparent explanation for the treatment efficacy of high-dose subcutaneous UFH and approximate equivalent prophylactic efficacy of 7500 units UFH subcutaneously compared with an LMWH[10]; if more subcutaneous UFH is given, more will find its way into the circulation.

The metabolism and elimination of subcutaneous UFH are complex. Some UFH remains at the injection site. UFH reaching the circulation is partially nonspecifically bound by plasma proteins (acute phase reactants and others) and endothelial cells; these endothelial cells release bound UFH molecules over time. In the liver, reticuloendothelial cells take up and metabolize UFH.

Disadvantages of UFH prophylaxis include bleeding, *heparin-induced thrombocytopenia* (HIT), and heparin resistance. Routine prophylaxis with UFH, as with other antithrombotic drugs, results in an increased frequency of surgical wound hematoma and other bleeding, depending on surgical and patient-specific factors. HIT, seen in an estimated 3% of overall UFH recipients,[11] results from formation of antibodies to complexes of heparin and *platelet factor 4* (PF4); the antibody-heparin-PF4 complex then activates platelets, thus leading to thrombocytopenia and occasionally life-threatening thrombosis. The onset of HIT is usually after 4 to 5 days of UFH administration, but it can rarely begin 1 or 2 days after a single dose.[12] Heparin resistance refers to impaired *activated partial thromboplastin time* (aPTT) elevation despite treatment-level dosing, due to binding and neutralization of UFH by PF4 and plasma proteins, resulting in reduced UFH efficacy.

Low-Molecular-Weight Heparins

Multiple LMWHs (e.g., enoxaparin, dalteparin, nadroparin, tinzaparin) are used in different venues for VTE prophylaxis and treatment. Each is derived from UFH, which is digested to provide smaller fragments of mean molecular weight of approximately 5000 daltons, rather than a mean of approximately 15,000 daltons for UFH. The smaller molecular size

of LMWH provides several therapeutic advantages and a disadvantage. The first advantage is that there is more than 90% absorption of all dosages from subcutaneous injection sites, thereby leading to predictable dose-proportional plasma drug levels. Second, LMWH has minimal nonspecific protein binding in tissue or plasma, so that administered doses are both absorbed and bioactive. Third, LMWH has approximately one-tenth the frequency of causing HIT as UFH, or approximately 3 per 1000 patients.[11] The sole disadvantage of LMWH, besides increased cost compared with UFH, is its nearly total renal elimination. As a consequence, it accumulates in patients with renal insufficiency, who already have impaired hemostasis. Daily LMWH prophylactic dosing in patients with more than minor renal-related impaired hemostasis increases bleeding risk if blood anti–factor Xa levels are not checked and LMWH dosing adjusted or if the patient is not switched to UFH prophylaxis.

LMWHs for prophylaxis are given in fixed dosages or, for two of these drugs, are adjusted for actual body weight. Although LMWHs are all similar, they were developed with different approaches that led to quite differing dosing schemes. The two LMWH prophylactic drugs commonly used in the United States and Canada are enoxaparin, given in a fixed milligram dosage without respect to body weight, and dalteparin, given in a fixed dosage in anti–factor Xa units. Another LWMH, nadroparin, is dosed in units by body weight category or at a fixed dosage, and a fourth, tinzaparin, is dosed in units by actual body weight. Some patients with higher VTE risk situations are given LMWH twice daily in a higher overall dosage than for lower-risk situations. LMWH prophylaxis dosing after hospital discharge is currently given for patients after hip and knee replacement and is used by some higher-risk persons intermittently, such as for long airplane rides.

Fondaparinux

Fondaparinux, also called ultra-LMWH and pentasaccharide, is a synthesized molecule of approximately 1700 daltons molecular weight. Its most important current clinical property is its effectiveness as treatment for HIT,[13] in spite of its ability, like that of UFH and LMWH, to stimulate generation of anti-PF4 antibodies. Despite its generation of PF4 antibodies, fondaparinux molecules are so small that the anti-PF4 antibody bridging and binding are not sufficient to degranulate platelets and cause the HIT syndrome. Therefore, fondaparinux is an excellent treatment for HIT because of its rapid onset of action and effective sustained antithrombotic activity. Absorption from a subcutaneous injection of 2.5 mg, the prophylactic dose, is complete, and elimination is nearly entirely renal, with a prolonged half-life of approximately 18 hours. There is an approximately 20% increase in steady-state blood level with identical daily doses that is reached and stabilized after approximately 5 days in persons with normal renal function; in patients with renal impairment, blood levels may continue to rise.

Oral Anticoagulants

Vitamin K Antagonists. Vitamin K antagonists, or warfarin in the United States and several other countries, was originally used for inpatient, and later extended to outpatient, prophylaxis by some practitioners after lower extremity joint replacement because of several attractive qualities: (1) it took warfarin several days to develop its full antithrombotic effect, thus allowing wound hemostasis to improve; (2) it was orally administered, unlike injected UFH or LMWH; (3) it could be monitored by existing prevalent methods (international normalized ratio) to prevent an overly intense antithrombotic effect; (4) other than bleeding risk, it is quite safe; and (5) it is inexpensive. Warfarin is now uncommonly used because *direct-acting oral anticoagulants* (DOACs) have been extensively studied for the same joint replacement indications and have been judged safe and effective. Warfarin is much less expensive (in the United States) if prophylaxis is to be prolonged (e.g., 5 weeks after discharge). The international normalized ratio target for warfarin in these limited prophylactic indications is not fully settled; some orthopedists target 2.5 (normal, 0.8-1.2), whereas others target a lower range.

Dabigatran (a Direct Oral Anticoagulant). Dabigatran is a direct inhibitor of thrombin. It is *U.S. Food and Drug Administration* (FDA) approved for prophylaxis solely in hip replacement patients, with a half-dose (110 mg) taken 2 hours after awakening from surgery and a full dose (220 mg) taken once daily beginning the next morning for 28 to 35 days. After oral absorption, dabigatran's bioavailability is only 4–7%, irrespective of food intake. A peak level is reached at 2 hours, and the low prophylactic dose effect is nearly gone by 24 hours. There is no significant accumulation with once-daily dosing in patients with normal renal function; because of the drug's renal elimination, drug levels rise with renal insufficiency. Only 35% protein bound, dabigatran can be cleared by dialysis. The prophylactic dose (220 mg once daily) is lower than the treatment dose for VTE and prevention of thromboembolism in patients with nonvalvular atrial fibrillation (150 mg twice daily). The manufacturer reported a statistically significant increased frequency of myocardial infarction compared with warfarin treatment in dabigatran-dosed patients, a finding seen with other direct thrombin inhibitors.[14,15] Hence, among DOACs, dabigatran is a less preferred prophylactic agent. Dabigatran does have a specific antibody antidote,[16] an advantage among DOACs, and is associated with less intracranial bleeding than warfarin. Overdose with hemorrhage can be treated with the antibody antidote and hemodialysis.

In clinical trials, dabigatran was noninferior for VTE prevention to the LMWH enoxaparin, subcutaneously 40 mg/day, the most commonly administered dose in Europe, but inferior to 30 mg subcutaneously every 12 hours, the common North American dose at the time.[17] VTE events were nearly all asymptomatic (>99%) and detected by contrast venography. Bleeding rates were similar.

Rivaroxaban (a Direct Oral Anticoagulant). Rivaroxaban is a direct inhibitor of factor Xa. It is FDA approved for VTE prophylaxis in patients with hip (dosed for 35 days) and knee (dosed for 12 days) replacements, at 10 mg once daily starting 6 to 10 hours after surgery ends and hemostasis is ensured. Absorption and bioavailability are 80–100% at this low dose, although, at higher treatment dosages, they are reduced unless the drug is taken with food to maximize bioavailability (reasons for this are not well understood). Rivaroxaban reaches a peak level in 2 to 4 hours and is measurable in plasma for 16 to

27 hours after ingestion, hence the once-daily dosing for prophylaxis. It has 50% renal elimination and substantial hepatic metabolism, so *significant renal or liver impairment is a relative contraindication to use*. A short-acting competitive inhibitor of rivaroxaban and other anti–factor Xa antithrombotic drugs, andexanet alfa, is an antidote[18] given by infusion; however, it is expensive and not readily available. Restoring depleted clotting factors (including fibrinogen), platelets, and red blood cells, and administering *factor VIII inhibitory bypass activity* (FEIBA), which is sometimes used in patients with hemophilia, can be useful strategies while awaiting the antidote or metabolic elimination of rivaroxaban in a bleeding patient. On prophylactic dosage, the prothrombin time may or may not be prolonged, and the degree of prolongation is not a reliable predictor of rivaroxaban blood level.[19]

Joint Replacement. In clinical trials, rivaroxaban 10 mg/day was superior to the European enoxaparin regimen, 40 mg once daily subcutaneously, in patients undergoing hip and knee replacement for preventing "major VTE," a composite of asymptomatic proximal DVT and symptomatic confirmed DVT and PE. Symptomatic VTE developed in 1% of enoxaparin-treated patients.[20]

Internal Medicine. Rivaroxaban prophylaxis for 45 days was compared with placebo in approximately 12,000 discharged internal medicine patients who were assessed to be at high risk for VTE. Rates of symptomatic VTE or VTE-related death were similar in both groups, at approximately 1%. Clinically relevant bleeding was noted in 2% of rivaroxaban recipients compared with 0.6% of placebo recipients. A previous randomized double-blind trial of medical inpatients compared 10 days of subcutaneous enoxaparin 40 mg once daily with 35 days of rivaroxaban 10 mg. For the first 10 days, symptomatic VTE and clinically relevant bleeding were equivalent. Over 35 days, of those patients receiving only 10 days of enoxaparin, 2% had symptomatic VTE or VTE-related death compared with 1% of patients receiving 35 days of rivaroxaban. However, clinically relevant bleeding was 2.5 times more frequent in rivaroxaban recipients over the first 10-day period compared with the overall 35-day period (4% vs. 1.7%, respectively).[21] A subsequent placebo-controlled study showed no significant difference in efficacy or major bleeding.[22] In 2019, a subgroup reanalysis for regulatory authorities combining subgroup patients from both studies led to U.S. regulatory approval.

Cancer. Prophylaxis with rivaroxaban 10 mg/day for 6 months was compared with placebo in high–VTE risk ambulatory patients with cancer. There was no significant difference in symptomatic VTE overall (approximately 4% in each group) or during the period of randomized treatment (1% for rivaroxaban, 3% for placebo—approximately one-half of patients had discontinued treatment by 6 months), but there were fewer overall VTEs detected in the rivaroxaban group during randomized prophylactic treatment. Clinically relevant bleeding was more frequent in the rivaroxaban group, at 5%, versus 3% in placebo patients.[23]

Apixaban (a Direct Oral Anticoagulant). Another anti–factor Xa drug, apixaban, is begun 12 to 24 hours after hip or knee replacement surgery at 2.5 mg every 12 hours and is continued for 35 days (hip) and 12 days (knee). With or without simultaneous food administration, levels peak at 3 to 4 hours. Bioavailability is approximately 50% and the half-life is approximately 10 hours, close to the time of receiving the next apixaban dose. Thus, although rivaroxaban has a higher peak and lower trough with once-daily dosing, apixaban delivers closer to a steady-state level. There is no known clinical advantage of one property compared with the other. Andexanet alfa is an effective inhibitor antidote to apixaban,[18] as for rivaroxaban, similarly requiring repeat infusions to maintain inhibitory activity. The same approaches to controlling hemorrhage as described for rivaroxaban can be used. In general, antithrombotic activity of apixaban is somewhat reduced compared with rivaroxaban dosing for the same indication[18] (e.g., VTE prophylaxis); for this reason, its lower peak levels, and perhaps its twice-daily dosing, it may be more advantageous to use in patients with increased bleeding risk. As with dabigatran and rivaroxaban, the frequency of intracerebral hemorrhage is reduced compared with similarly effective warfarin dosage.[24]

Joint Replacement. Approximately 1% of hip and knee replacement patients had symptomatic VTE during the trials' observation period, with similar frequencies in the apixaban (40 mg subcutaneously once daily) and enoxaparin (30 mg subcutaneously twice daily) groups.[25] In these recently operated patients, there was a similar extent of clinically relevant bleeding in all treatment groups, at 3–5%.

Betrixaban (a Direct Oral Anticoagulant). Betrixaban is a longer-acting anti–factor Xa drug that is FDA approved for internal medicine patients for VTE prophylaxis of 35 to 42 days' duration, during and after hospitalization. Oral bioavailability is 35% and is reduced by approximately one-half if the drug is taken with food, even within 6 hours of eating. Its half-life is nearly 24 hours. Betrixaban is given at a loading dose of 160 mg, then 80 mg once daily on subsequent days; with this approach, it reaches steady state within 2 to 3 days. Betrixaban can be neutralized by infusion of the antidote andexanet alfa.[26] Because it is only 60% protein bound, an alternative or additional neutralizing therapy is hemodialysis. Betrixaban is metabolized primarily by non–cytochrome P liver enzymes; only 10–15% is eliminated in the urine.

In its sole large clinical trial in hospitalized medical patients, once daily betrixaban for 5 to 6 weeks compared with subcutaneous enoxaparin 40 mg for the first 6 to 14 days reduced the symptomatic VTE rate from 1.5–0.9%. There was an approximate doubling of clinically significant bleeding events in the betrixaban group of 3% compared with 1.6% in the inpatient-only enoxaparin group.[27]

Aspirin. Aspirin, long-recognized for its antiplatelet arterial antithrombotic properties through cyclooxygenase-1 inhibition of thromboxane A_2 production, was also identified early as a DVT prophylactic drug. Platelet activation propagates thrombin generation and thrombosis. Aspirin was found to be approximately as effective as warfarin and superior to placebo in reducing proximal DVT in patients undergoing surgery for hip fracture (9%, 11%, and 30%, respectively).[28] Noncoated oral aspirin is 40–50% absorbed, reaching peak blood levels in 30 minutes, but with a half-life of only 20 minutes. Its effect is prolonged, however, because it irreversibly acetylates circulating platelets; new platelets last 8 to 10 days. The best daily dose of aspirin is uncertain, but less than 300 mg/day produces fewer side effects than higher doses,

without lower efficacy. Some diabetic patients and persons with a high body mass index have more rapid platelet turnover; in these patients, 100 mg aspirin twice daily ensured full inhibition of cyclooxygenase 1.[29] Aspirin at 81 to 100 mg twice daily should be maximally effective in all patients.

Large clinical trials of aspirin for VTE prophylaxis have been limited to patients undergoing hip replacement and hip fracture surgery; these patients had a significant approximately 30% reduction in symptomatic DVT and nonfatal PE compared with patients receiving placebo.[30] Aspirin recipients (160 mg once daily for 35 days) had slightly more clinically relevant bleeding episodes but no more fatal bleeding episodes or reoperations resulting from bleeding. Patients undergoing hip replacement[31] who received 10 days of LMWH (dalteparin 5000 units subcutaneously) and patients undergoing hip and knee replacement[32] who received 5 days of rivaroxaban 10 mg once daily, in separate studies, were then randomized to continue that therapy or switch to 81 mg oral aspirin once daily. In both studies, the patients who transferred to aspirin prophylaxis had outcomes that were nearly identical to those in the comparison group.

Aspirin treatment is so prevalent that some inferences may be drawn from its bystander appearances in other-purposed clinical trials. In a rivaroxaban VTE prophylaxis study of high-VTE risk, discharged medical patients receiving 10 mg rivaroxaban or placebo for 45 days (described earlier), approximately one-half of the patients were taking aspirin up to 162 mg/day. The frequency of symptomatic VTE or VTE-related death in the aspirin-only group and the rivaroxaban-only group was identical, 0.9%, with nearly 3000 patients in each group.[33] Major bleeding was rare in both groups, at 0.2–0.3%; clinically relevant bleeding was not reported. Aspirin use was not randomized, and aspirin users should be assumed to have been self-selected as tolerant to its effects. Overall, aspirin is likely a less potent thromboprophylactic agent than those described earlier, but it may be sufficient for average- and low-risk outpatients in whom prophylaxis is desired.

MECHANICAL PROPHYLAXIS

Options for mechanical prophylaxis include externally applied devices, ambulation, and *inferior vena cava* (IVC) filters. Graduated compression stockings, *intermittent pneumatic compression* (IPC; knee high or thigh high), venous foot pumps, and early ambulation are mechanical. Their primary role is VTE prophylaxis in patients for whom bleeding risk is so high that the aforementioned drug prophylaxis is contraindicated. These devices can also be applied to unoperated lower extremities during operations that carry VTE risk. Mechanical prophylactic devices can be harmful in the following circumstances: if they are improperly applied and thus cause underlying skin, muscle, or vascular injury, if their use impedes ambulation, or if they are ordered in lieu of more effective antithrombotic drugs but are used for only a short time. Interpreting published studies of these approaches is difficult because there is no blinding, and adherence to device use during the study is variable (<50% adherence in one study and as low as 20% in another). Reviews and meta-analyses acknowledging such limitations conclude that some externally applied devices such as IPCs may prevent as many as 16 symptomatic VTEs per 1000 patients undergoing hip and knee replacement or hip fracture surgery.[34]

Fewer studies have been published in hospitalized internal medicine patients, and these studies are inconclusive regarding the benefit of graduated compression stockings (knee high vs. thigh high) and IPC. A 2019-reported intensive care unit–based comparison of IPC added to UFH or LMWH prophylaxis found no difference in symptomatic or asymptomatic VTE.[3] PE was diagnosed in 1% of patients in each group. An earlier study comparing compression stockings alone with IPC added to compression stockings in intensive care unit patients found double the number of patients with asymptomatic distal DVT in patients without IPC but no difference in day 6 outcome in patients with asymptomatic proximal DVT or symptomatic VTE.[35] A larger clinical trial in patients with fresh stroke or transient ischemic attack compared thigh-high IPC with no prophylaxis for 30 days. A total of 67% of patients were taking aspirin or clopidogrel. By day 8, 12% of patients without IPC had duplex ultrasound–proven proximal DVT compared with 8.5% of patients assigned to IPC, a 33% reduction that was significant. There was a borderline significant 18% reduction in death at 30 days.[36]

Considered together, the data suggest that, in orthopedic surgical and medical patients with a contraindication to antithrombotic prophylactic drugs, IPC offers some protection. Conditions should be optimized: a battery-powered rather than corded electric device should be used to optimize compliance, thigh-high devices may be best, there should be regular attention to protecting the skin, and drug prophylaxis should be used when considered safe. Ambulation when safe should be added to every prophylactic regimen.

Vena Cava Interruption

Retrievable IVC filters for primary prevention of PE are primarily used in patients undergoing bariatric surgery at particularly high VTE risk (perhaps 25% of such patients in the United States) and those with serious trauma who may (or may not) have a contraindication to drug prophylaxis. A randomized trial comparing retrievable IVC filter insertion within 72 hours of trauma with no filter insertion resulted in no difference in a composite outcome of symptomatic PE or deaths over a 90-day period. All patients received IPC to uninjured legs. However, among patients whose bleeding risk was too high to receive anticoagulant prophylaxis before day 7, there were fewer PEs in IVC filter recipients at 14 days. These investigators concluded that this latter subgroup could be good candidates for retrievable IVC filters.[37] Although retrievable IVC filters are generally effective in the short term, placement and particularly retrieval involve significant risk of complications—filter migration, filter penetration, tilting, thrombosis—and many filters are never retrieved. As many as 5% of penetration cases require surgery.[38] If IVC filters are used for prophylaxis, they should be limited to temporary use in bariatric and trauma patients.

MANAGEMENT OF PROPHYLAXIS

Table 82.1 presents patient-related categories and recommended approaches to VTE prophylaxis.

We recommend using effective prophylaxis during risk periods unless contraindicated (universal application within patient groups), rather than risk assessing each

Table 82.1 Prophylaxis for Venous Thromboembolism

Patient Category	Prophylaxis	Comment
Internal medicine inpatients	UFH 5000 U SC q8hr or q12hr*	Monitor platelets daily for HIT
	LMWH (e.g., enoxaparin 40 mg SC every morning)	Accumulates with renal insufficiency; HIT less likely, but monitor platelets every 2 days
	Intermittent pneumatic compression	Battery operated, thigh high optimal Use when drug prophylaxis contraindicated
	Retrievable IVC filter	Use when drug prophylaxis contraindicated Expert removal when no longer needed
ICU patients receiving vasopressor therapy	LMWH (e.g., enoxaparin 40 mg SC every morning with intermittent pneumatic compression)	LMWH accumulates with renal insufficiency; optimal IPC thigh high; can monitor anti–factor Xa peak blood levels 3–4 hr after dosing, increase dose if needed to reach 0.25 anti–factor Xa unit/mL
Hip or knee replacement patients	Apixaban 2.5 mg PO 12–24 hr after surgery, then q12hr for 35 days (hip) or 12 days (knee)	
	Rivaroxaban 10 mg PO 6–10 hr after surgery with hemostasis, then daily for 5 days; follow with 81 mg aspirin PO daily for 30 days (after hip replacement) or 9 days (after knee replacement)	Alternatively, rivaroxaban could be continued for the entire duration
	LMWH beginning day after surgery (e.g., enoxaparin 30 mg SC q12hr; dalteparin 5000 U SC daily; tinzaparin 75 U/kg daily) continued for 14 days after knee replacement or 28 days after hip replacement	Could consider stopping SC LMWH after 10 days and starting aspirin 81 mg daily for the remainder of prophylaxis
	Intermittent pneumatic compression	Battery operated, thigh high optimal Use when drug prophylaxis contraindicated, or continue for at least 6 hr after drug prophylaxis was begun
General surgery patients	UFH 5000 U SC q12hr or q8hr after hemostasis	Monitor daily platelets for HIT; start with IPC during surgery, thigh high and bilateral; can discontinue 6 hr after drug prophylaxis is underway
	LMWH (enoxaparin 40 mg SC daily, dalteparin 2500 U SC daily) during hospitalization, after hemostasis	Accumulates with renal insufficiency; HIT less likely, but monitor platelets at least every 2 days; start with IPC during surgery, thigh high and bilateral; can discontinue 6 hr after drug prophylaxis is underway
	Intermittent pneumatic compression	Start during surgery, thigh high and bilateral, until after UFH or LMWH prophylaxis is at least 6 hr underway; continue if drug prophylaxis is contraindicated until contraindication remits
Abdominal or pelvic cancer surgery, high–VTE risk patients	LMWH (enoxaparin 40 mg SC daily, dalteparin 2500 U SC daily) after hemostasis	Accumulates with renal insufficiency; HIT less likely, but monitor platelets at least every 2 days; start with IPC during surgery, thigh high and bilateral, and can discontinue 6 hr after drug prophylaxis is underway; consider extending prophylaxis for 30 days
	UFH 5000 U SC q8hr for 30 days, after hemostasis	Monitor daily platelets for HIT; transition to LMWH for outpatient extended prophylaxis
	Intermittent pneumatic compression	Start during surgery, thigh high and bilateral, until after UFH or LMWH prophylaxis is at least 6 hr underway; continue if drug prophylaxis is contraindicated until contraindication remits
Major trauma patients without intracranial trauma	LMWH (e.g., enoxaparin 40 mg daily) or UFH SC q12hr or q8hr	Start with IPC during surgery, thigh high and bilateral, until after UFH or LMWH prophylaxis is at least 6 hr underway; continue if drug prophylaxis is contraindicated until contraindication remits; LMWH accumulates with renal insufficiency; monitor platelets daily for UFH, every 2 days for LMWH
	Intermittent pneumatic compression	Start during surgery, thigh high and bilateral, unless contraindicated; use in patients for whom drug prophylaxis is contraindicated until contraindication remits
	Consider IVC retrievable filter for trauma patients with or without intracranial trauma who cannot receive drug prophylaxis before day 7 after trauma	Data inconclusive and some risks with IVC filters
Intracranial trauma and/or surgery patients	Intermittent pneumatic compression	Start as soon as possible, thigh high and bilateral; start UFH 5000 units SC q12hr, with platelet monitoring daily, when or if hemostasis and conditions permit

Continued

Table 82.1 Prophylaxis for Venous Thromboembolism—cont'd

Patient Category	Prophylaxis	Comment
Bariatric surgery patients[39]	LMWH (e.g., enoxaparin 40 mg SC q12hr beginning 3 hr before surgery) for 4 wk	May increase intraoperative and postoperative bleeding; accumulation with renal insufficiency; IPC during surgery and postoperatively until fully ambulatory
	UFH 5000 U SC q8hr beginning 3 hr before surgery, for 4 wk	May increase intraoperative and postoperative bleeding; early daily platelet count monitoring followed by close clinical and appropriate laboratory surveillance after discharge; IPC during surgery and postoperatively until fully ambulatory
Outpatients with indwelling central venous catheters	Consider LMWH (e.g., enoxaparin 40 mg SC once daily)	Accumulates with renal insufficiency; increases bleeding risk; may not alter 3-mo mortality; probably superior to low-dose warfarin

*Selection of dosing every 8 hours or every 12 hours should be based on assessment of underlying risk of VTE and bleeding.[41]
HIT, heparin-induced thrombocytopenia; IPC, intermittent pneumatic compression; ICU, intensive care unit; IVC, inferior vena cava; LMWH, low-molecular-weight heparin; PO, orally; SC, subcutaneously; UFH, unfractionated heparin; VTE, venous thromboembolism.

individual to determine whether to use VTE prophylaxis (personalized risk stratification).

Inpatients should generally receive VTE drug prophylaxis unless contraindicated; mechanical prophylaxis can be used until the contraindication remits. Selected groups warrant primary prophylaxis (hip and knee replacement patients). Physicians must be aware of drug prophylaxis risks and monitor accordingly. Maximizing safe ambulation is a part of all VTE prophylaxis strategies.

Patients with a history of VTE are at higher than average VTE risk and particularly warrant prophylaxis. If they are undergoing elective surgery, they need a surgeon comfortable with providing drug prophylaxis. On nonsurgical admissions, these patients need the most effective, safe prophylaxis possible, with close monitoring for complications.

PROPHYLAXIS IN COVID-19 PATIENTS AND SUSPECTS

Numerous reports of coagulopathy, including elevated D-dimer, thrombocytopenia, prolonged aPTT, decreased fibrinogen, objectively diagnosed PE and DVT, and microthromboses at autopsy have characterized cases of COVID-19 in China and the United States.[39,40] Although there is limited evidence, adopting the approach of administering drug thromboprophylaxis unless contraindicated seems wise. Some clinicians recommend higher-dose prophylaxis, as was administered early in North America to joint replacement recipients (e.g., enoxaparin 30 mg subcutaneously every 12 hours rather than 40 mg once daily), if the D-dimer level of the patient with COVID-19 is high and continues to rise or remain elevated. Because thrombocytopenia is not uncommon, using LMWH initially to reduce the HIT risk seems prudent. However, given that progressive renal insufficiency appears common in patients with COVID-19, reducing the frequency of dosing, measuring anti–factor Xa level at peak (4 hours after subcutaneous injection) for a target of 0.2 to 0.35, and switching to UFH may be necessary in these patients to minimize bleeding complications.

TREATMENT OF PULMONARY EMBOLISM

OVERVIEW

Acute PE is a potentially fatal disorder, especially when effective treatment is delayed.[42,43] As such, PE requires prompt diagnosis and effective treatment. Most deaths attributable to PE result from acute *right ventricular* (RV) failure caused by the initial obstruction of blood flow through the pulmonary arteries or from recurrent PE when the diagnosis or treatment of PE is delayed. Death from recurrent PE is uncommon once therapeutic anticoagulation is begun.[44-46]

Treatment of acute PE requires assessment of the risks and benefits of all interventions for each patient. The physician must respond to changes in the patient's condition that alter the risks or benefits of treatment. Understanding the pathophysiology of acute PE is essential.

PATHOPHYSIOLOGY (See Chapter 81)

Acute PE compromises both the circulatory system and the respiratory system.[47]

Circulatory Compromise

Embolic obstruction of the pulmonary arterial tree is the principal cause of circulatory compromise. In the absence of preexisting pulmonary vascular disease, recruitment and distention of pulmonary arteries preserve normal mean pulmonary artery pressure, pulmonary vascular resistance, and cardiac output until more than 25% of the pulmonary arterial tree is obstructed.[48] However, severe embolic obstruction (>50% pulmonary arterial tree) or less severe embolic obstruction combined with preexisting pulmonary vascular disease causes hemodynamic compromise.[47,49-57]

Pulmonary arterial vasoconstriction may combine with vascular obstruction to cause circulatory compromise. Alveolar hypoxia, serotonin and thromboxane released from platelets, and endothelin released from endothelial cells each may contribute to pulmonary vasoconstriction in patients with acute PE.[54,55,58,59]

Increased mean pulmonary artery pressure and pulmonary vascular resistance increase RV afterload. In general, without RV hypertrophy from preexisting pulmonary vascular disease, the right ventricle is unable to generate a mean pulmonary artery pressure higher than 40 mm Hg (RV systolic pressure >70 mm Hg), and cardiac output falls even with catecholamine-induced increases in heart rate and stroke volume.[48,53] Acute right-sided heart failure increases RV end-diastolic pressure and volume, RV wall tension, and myocyte stress. Systemic hypotension and increased RV end-diastolic pressure decrease the pressure gradient, thus reducing blood flow through the coronary arteries and producing RV ischemia.

Respiratory Compromise

Embolic obstruction of the pulmonary arterial tree is also the principal cause of respiratory compromise. Although pulmonary artery obstruction creates dead-space ventilation,[60] compensatory hyperventilation of perfused lung units eliminates carbon dioxide and, in the absence of previous cardiopulmonary disease, acute PE rarely causes hypercarbic respiratory acidosis.[61]

Mild arterial hypoxemia, easily reversed by low-flow oxygen, is common after PE. Redistribution of preserved cardiac output through patent lung vessels creates lung units with low ventilation-to-perfusion ratios.[62,63] Furthermore, investigators have reported qualitative and quantitative changes in pulmonary surfactant following acute PE.[64] Loss of surfactant contributes to alveolar collapse and pneumoconstriction and creates lung units with low ratios of ventilation to perfusion.[65,66]

More severe arterial hypoxemia, refractory to low-flow oxygen, results from right-to-left shunting of venous blood through the lungs, the heart, or both. Right-to-left intrapulmonary shunting can arise in the setting of alveolar hemorrhage, pulmonary edema, and/or atelectasis.[67] Intracardiac shunting usually takes place when venous blood flows from the right atrium to the left atrium through a patent foramen ovale when right-sided heart failure causes right atrial pressure to exceed left atrial pressure.[68] In the setting of a right-to-left shunt, reduction of mixed venous oxygen saturation, resulting from reduced delivery of oxygen to tissues, worsens arterial hypoxemia.[69] (See Chapter 44.)

INITIAL MANAGEMENT OF SUSPECTED PULMONARY EMBOLISM

The initial management of a patient with symptoms or signs that suggest acute PE involves coordination of diagnostic testing, assessment of the patient's risks for morbidity, including major bleeding and mortality, and initiation of treatment (Fig. 82.1).

Pulmonary Embolism Suspected in a Patient With Hypotension, Shock, or Cardiac Arrest

Patients who present with undifferentiated hypotension, shock, or cardiopulmonary arrest are especially challenging (Fig. 82.2). They are often too unstable to transport for imaging studies, and clinicians must use point-of-care tests. Bedside ultrasonography is useful to detect acute RV failure (see Video 24.9), PE in the main pulmonary arteries, PE in transit (Fig. 82.3, Video 81.3), or DVT. However, bedside ultrasonography has limitations. RV free wall hypokinesis with relatively normal contraction of the RV apex (McConnell's sign) is not entirely sensitive or specific for acute PE,[74-82] transesophageal echocardiography can detect only large PE in proximal pulmonary arteries, PE in transit is rarely identified,[83-87] and lower extremity compression ultrasonography detects DVT in less than 50% of patients with acute PE.[88-91] (See Videos 82.1 and 81.2 for McConnell's sign.) These limitations of bedside testing sometimes force clinicians to treat patients with undifferentiated shock or cardiopulmonary arrest for suspected PE without diagnostic confirmation.[92]

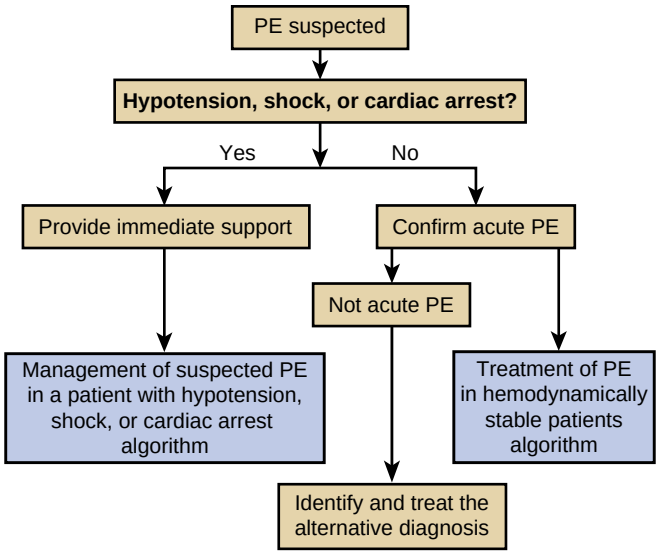

Figure 82.1 The initial management of a patient with symptoms or signs suggesting acute pulmonary embolism. Decision making involves coordination of diagnostic testing, assessment of the patient's risks for morbidity, mortality, and risk for major bleeding, and initiation of treatment. Patients presenting with hypotension, shock, or cardiac arrest require immediate supportive care (see Fig. 82.2), whereas hemodynamically stable patients require prompt confirmation or exclusion of *pulmonary embolism* (PE) combined with judicious initiation of therapy based on individual patient characteristics (see Figure 82.4).

Patients with hypotension, shock, or cardiopulmonary arrest require immediate respiratory and cardiovascular support. Oxygen is essential to reverse arterial hypoxemia, which contributes to RV ischemia, and to reverse hypoxic pulmonary vasoconstriction of pulmonary arterioles. Positive airway pressure is useful to treat intrapulmonary shunting caused by pulmonary edema or alveolar collapse, but positive airway pressure may worsen intracardiac shunting through a patent foramen ovale by increasing pulmonary vascular resistance.[93]

Most experienced clinicians avoid endotracheal intubation, if possible, because narcotics or sedatives depress cardiac function and reduce systemic vascular resistance, thereby leading to hypotension and hemodynamic collapse.[94] Continuous positive airway pressure may allow treatment of arterial hypoxemia without intubation.[95] However, intubation may be necessary when arterial hypoxemia resulting from pulmonary edema and/or pulmonary hemorrhage cannot be reversed by noninvasive means. Care must be taken to avoid hemodynamic instability during tracheal intubation by using anesthetic agents such as etomidate that do not inhibit sympathetic tone or depress myocardial function.

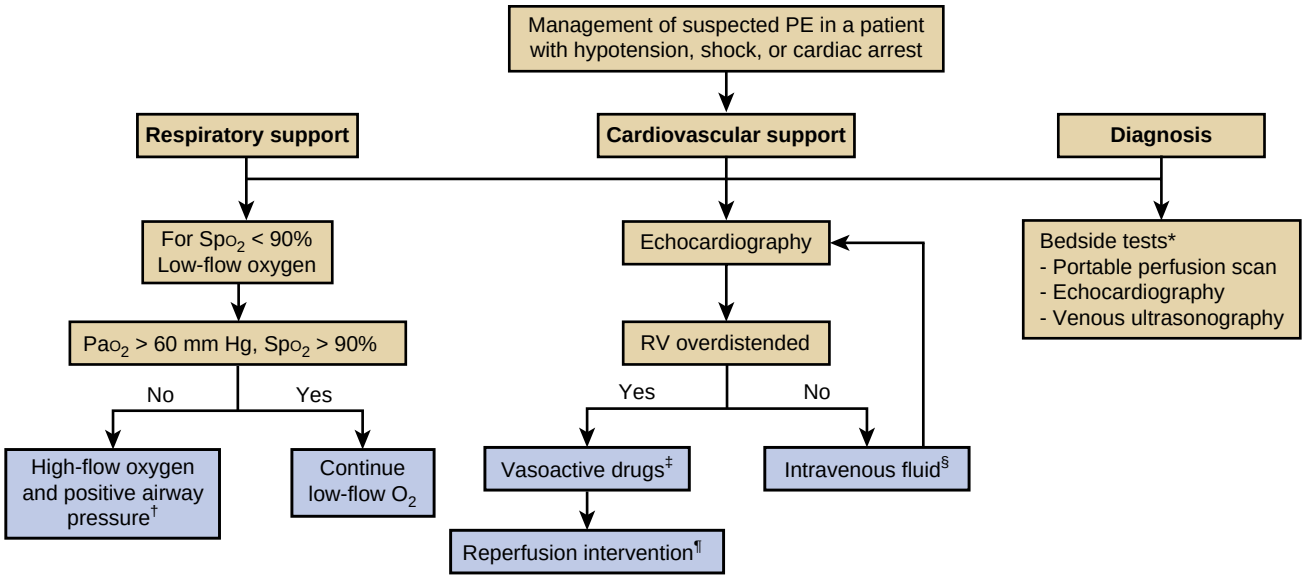

Figure 82.2 Management of a patient with suspected pulmonary embolism and hypotension. Hypotension (defined by systolic blood pressure < 90 mm Hg), shock, and cardiac arrest represent a life-threatening spectrum of hemodynamic compromise, and these conditions often limit diagnostic options. At times, thrombolysis must be tried even though the diagnosis of *pulmonary embolism* (PE) is unproven. *A bedside echocardiogram can support the diagnosis of acute pulmonary embolism (e.g., McConnell's sign) or can provide another diagnosis (e.g., pericardial tamponade), and venous ultrasonography can show deep venous thrombosis. ¶Reperfusion interventions include thrombolysis, surgical embolectomy, and catheter-based treatment. The choice of reperfusion strategy depends on patient-related factors (e.g., bleeding risk and hemodynamic stability) and the institutional resources that can be mobilized (e.g., cardiovascular surgical team). †Suspect right-to-left shunting of venous blood when low-flow oxygen is insufficient. Provide high-flow oxygen. Assess the location of shunting (e.g., atelectasis and/or shunt through the foramen ovale). Provide positive airway pressure with mask ventilation and avoid intubation, if possible, for intrapulmonary shunt, and monitor and manage adverse effects of positive airway pressure on cardiac output. ‡A list of vasoactive drugs is provided in Table 82.2 and is discussed in the text. §Intravenous fluids should be titrated carefully to avoid overdistention of the right ventricle (RV). Pao_2, arterial partial pressure of oxygen; Spo_2, oxygen saturation as measured by pulse oximetry.

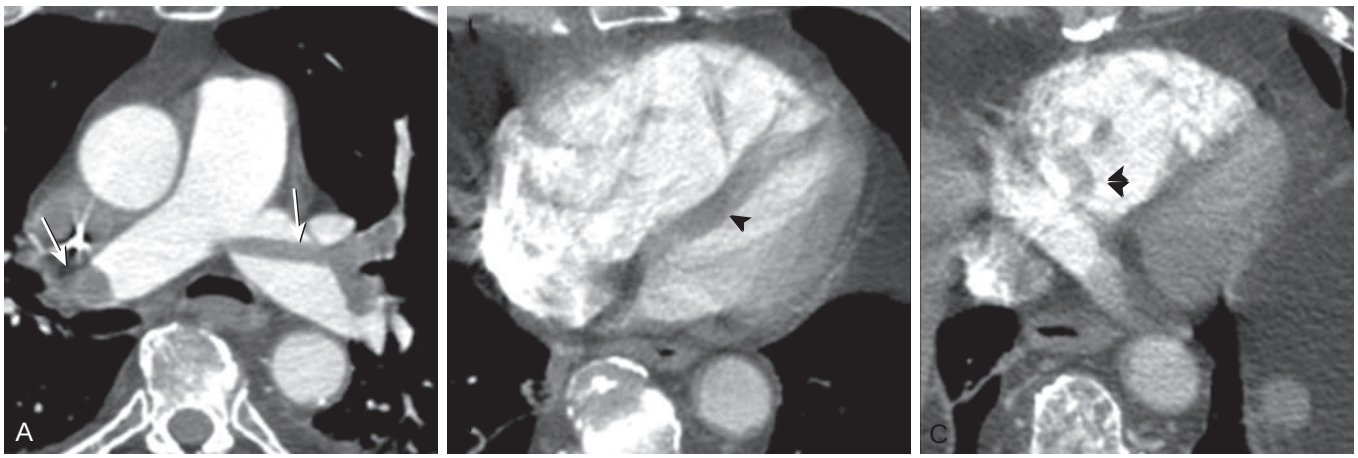

Figure 82.3 Pulmonary embolism in transit. Acute pulmonary embolism with right ventricular embolus and right ventricular strain is seen on computed tomography pulmonary angiography. (A) Imaging through the main pulmonary arterial bifurcation shows a saddle pulmonary embolism (*arrows*). (B) At the level of the tricuspid valve, right ventricular enlargement with leftward bowing of the ventricular septum (*arrowhead*), consistent with elevated right heart pressures, is noted. (C) At the caudal margin of the tricuspid valve and inferior right ventricle, a linear filling defect (*double arrowhead*) is present, representing emboli caught on the papillary muscle and chordae tendineae of the right ventricle. (Courtesy Michael B. Gotway, MD.)

Cardiovascular support involves the judicious administration of intravenous fluids with or without vasoactive agents.[96] The goal of intravenous fluid administration is optimal RV preload to support perfusion of critical organs. Intravenous fluids can improve hemodynamics in patients with acute PE.[97] However, excessive fluid administration may increase RV end-diastolic pressure and, in the setting of low systemic blood pressure, may reduce coronary artery blood flow to the right ventricle. Excessive intravenous fluid also may increase RV wall stress and exacerbate ischemia.[98] A direct comparison of intravenous fluid administration with norepinephrine in an animal model of acute PE demonstrated that even small volumes of intravenous fluid caused RV dysfunction, whereas norepinephrine improved cardiac output.[99,100] Given the physiologic differences of individual patients, administration of intravenous fluids with or without vasoactive agents requires careful monitoring and assessment of each patient's response. Echocardiographic measurement of the ratio of RV to left ventricular end-diastolic axial diameter

Table 82.2 Vasoactive Medications Used to Support Patients With Pulmonary Embolism

Vasoactive Drug	Mechanism	Clinical Effects
Epinephrine	Stimulates α_1, β_1, and β_2 receptors	Increases myocardial contractility and CO
Norepinephrine	Stimulates α_1 and β_1 receptors	Increases myocardial contractility, CO, and coronary flow; use for hypotension to increase coronary flow to RV; high doses may increase PVR
Phenylephrine	Stimulates α_1 receptors	Increases SVR
Dobutamine	Stimulates β_1 receptors	Increases myocardial contractility and CO; increases HR
Dopamine (low dose)	Dopaminergic	Increases myocardial contractility and CO; caution: increases CO and worsens V/Q
Dopamine (high dose)		Increases SVR
Isoproterenol	Stimulates β_1 and β_2 receptors	Increases CO and decreases SVR
Nitric oxide	Vasodilates pulmonary arterioles	Decreases PVR
Milrinone	PDE3 inhibitor	Increases myocardial contractility; decreases SVR
Vasopressin	Stimulates V_1 receptors	Increases SVR; dilates coronary, pulmonary, and cerebral arteries
Levosimendan	Calcium sensitizer	Increases myocardial contractility (no clinical trial data)

CO, cardiac output; HR, heart rate; PDE, phosphodiesterase; PVR, pulmonary vascular resistance; RV, right ventricle; SVR, systemic vascular resistance; V/Q, ventilation-perfusion.

may guide intravenous fluid administration until the ratio is greater than 1.0, whereupon inotropic support replaces fluid administration.[96]

The initial management of shock or cardiac arrest may also require the use of vasoactive medications. Vasopressors differ in their effects on RV function, heart rate, and pulmonary and systemic vascular resistance (Table 82.2).[101] In the absence of well-designed clinical trials, approaches to the choice and dosing of vasopressors differ, with some authors favoring norepinephrine,[102] others favoring dobutamine or dopamine,[94,98] and others advising norepinephrine for hypotensive patients and dobutamine for normotensive patients who have a reduced cardiac index.[103] Assessment of the hemodynamic response to the initial vasoactive medication is essential, so that alternatives can be initiated if blood pressure and perfusion of critical organs are not restored promptly.

The role of thrombolytic therapy for undifferentiated shock or cardiac arrest remains controversial. A randomized double-blind trial of thrombolysis during resuscitation for out-of-hospital cardiac arrest reported no difference in survival at 30 days.[104] However, clinicians have described bolus thrombolysis leading to successful resuscitation of patients with a high pretest probability of PE.[92] These observations suggest that clinicians should avoid thrombolysis for witnessed out-of-hospital cardiac arrest, but they should consider bolus thrombolysis when patients with a high probability for acute PE have cardiopulmonary arrest before diagnostic testing can be completed.

Pulmonary Embolism Suspected in a Patient Without Hypotension, Shock, or Cardiac Arrest

Confirmation of acute PE with specific diagnostic tests is necessary because the clinical manifestations of acute PE are nonspecific, and anticoagulant or thrombolytic therapy increases the risk for major bleeding.[70,71] Computed tomography pulmonary angiography is the preferred imaging modality to confirm PE and to differentiate acute PE from less common abnormalities such as chronic thromboembolic disease and pulmonary artery sarcoma.[72] Correct diagnosis avoids therapeutic misadventures such as the use of thrombolytic therapy to treat these other entities.

When there are no contraindications to anticoagulation, experts recommend initiation of antithrombotic therapy before diagnostic confirmation of PE on the basis of the pretest probability of PE and the time needed to complete diagnostic tests.[73] Specific recommendations for preemptive anticoagulation in this setting include (1) anticoagulation in patients with a high pretest probability of PE before diagnostic testing, (2) anticoagulation in patients with an intermediate pretest probability of PE before tests anticipated to take more than 4 hours to complete, and (3) anticoagulation in patients with a low pretest probability of PE before tests anticipated to take more than 24 hours to complete.

Preemptive anticoagulation reduces delays in treating PE and decreases the risk for recurrent PE. However, preemptive anticoagulation introduces the risk of anticoagulant-induced harm in patients without PE, and it does not address management of patients with either a high risk of bleeding or a contraindication to anticoagulants when delays in completion of diagnostic tests are anticipated. These issues can be addressed by ensuring timely assessment and confirmation of PE in hemodynamically stable patients before initiating treatment.

INITIAL MANAGEMENT OF CONFIRMED PULMONARY EMBOLISM

The initial management of patients with confirmed acute PE requires a clear understanding of the rationale for treatment and evidence basis for management decisions (Fig. 82.4). Treatment is directed at clinically important end points, including death from PE, prevention of recurrent VTE, and avoidance of major or clinically relevant bleeding, rather than intermediate end points such as reversing arterial hypoxemia. Rigorous clinical trials provide the foundation for most management decisions.

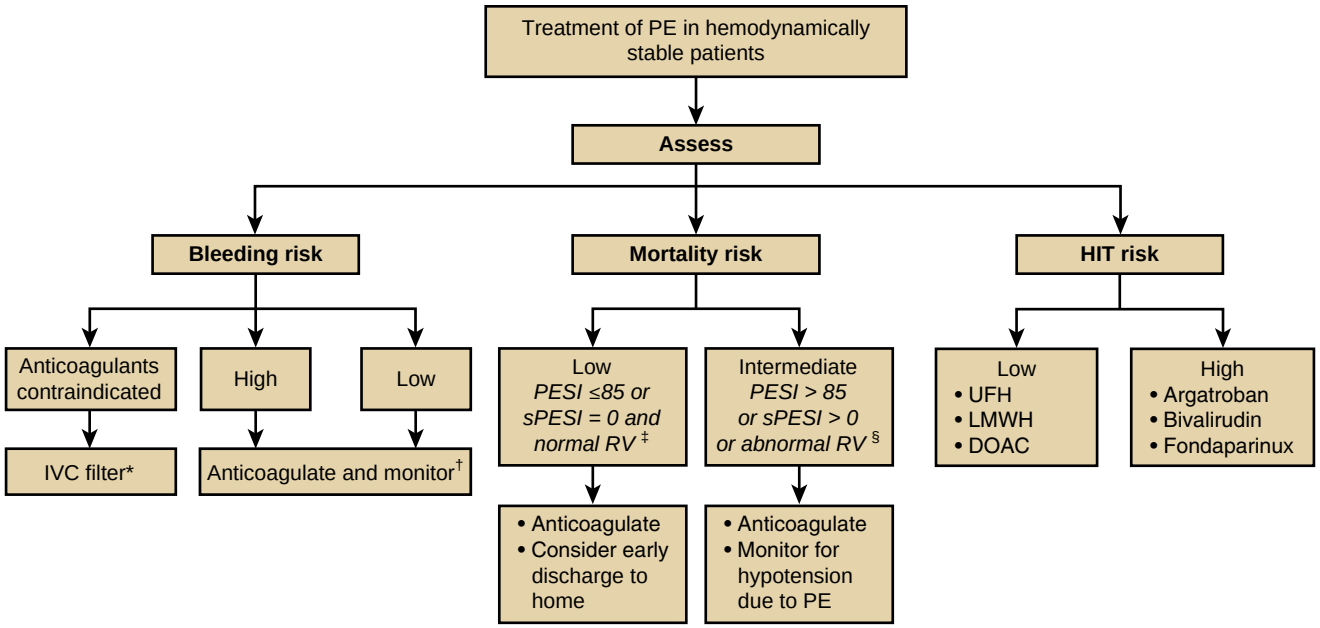

Figure 82.4 Treatment of *pulmonary embolism* (PE) in hemodynamically stable patients. Decisions require assessment of bleeding risk, mortality risk, and risk of *heparin-induced thrombocytopenia* (HIT). *Consider echocardiography to rule out pulmonary embolism in transit (if not already done) before *inferior vena cava* (IVC) filter placement. †See Tables 82.4 and 82.7 for assessment of bleeding risk and recommendations for anticoagulation in patients at high risk for major bleeding. ‡No abnormality of the *right ventricle* (RV) is detected on initial diagnostic testing (e.g., computed tomography pulmonary angiography, echocardiography, troponin). §Obtain an echocardiogram and biomarker test (e.g., troponin or natriuretic peptides) if not done previously. DOAC, direct oral anticoagulant; LMWH, low-molecular-weight heparin; PESI, pulmonary embolism severity index; sPESI, simplified PESI; UFH, unfractionated heparin.

Table 82.3 Simplified Pulmonary Embolism Severity Index (sPESI)[105]*

Variable	Score
Age > 80 yr	1
History of cancer	1
Chronic cardiopulmonary disease	1
Pulse ≥ 110 beats/min	1
Systolic blood pressure < 100 mm Hg	1
Arterial oxygen saturation < 90%	1

*If no variable is met, the mortality risk is considered low. Any score of 1 or more indicates high risk.

Assessment of Pulmonary Embolism Mortality Risk

Assessment of the risk of death from PE is an essential initial step in the management of patients with confirmed acute PE. The risk of death from PE is high for patients who present with hypotension or shock. Death from PE is rare when hemodynamically stable patients with PE receive appropriate therapy.[46] Many patients with PE have advanced comorbidities such as metastatic cancer or severe heart failure, and most deaths within 12 months of acute PE result from these comorbid conditions rather than from PE.[46] Recognition of comorbid conditions with a poor prognosis often negates aggressive intervention to prevent death from PE. In the absence of terminal comorbidities, several algorithms exist to guide management on the basis of the risk of death from acute PE.[103]

Prognostic models offer validated methods to assess mortality risk and guide management. The *pulmonary embolism severity index* (PESI) provides a score to predict 30-day mortality for patients with acute PE who do not present with hypotension or shock. In 2010, investigators reported a simplified version of the original PESI score (sPESI) to facilitate the use of a risk score in clinical practice (Table 82.3).[105] sPESI uses six variables instead of the 11 variables of the original PESI score, with each variable receiving a binary score of 0 or 1, which are then summed for a total score ranging from 0 to 6. An sPESI of 0 combined with a sensitive troponin assay maintains high accuracy in identifying PE patients with a low 30-day mortality risk.[106] Any score of 1 or more indicates high 30-day mortality risk.

Rarely patients with an sPESI score of 0 may have features of increased mortality risk such as the ratio of RV to left ventricular axial diameters greater than 1.0 on computed tomography pulmonary angiography, elevated troponin, or echocardiographic evidence of RV dysfunction on studies done as part of their initial evaluation. Such patients warrant additional testing (e.g., echocardiography and biomarker levels), if not already performed, which may support reclassification to an intermediate mortality risk.

Hemodynamic effects of acute PE, not the appearance of the emboli on imaging studies, are the best predictors of PE mortality.[98] Most algorithms propose that clinicians use systolic blood pressure to differentiate patients with a high risk of death from PE (hypotension defined by systolic blood pressure lower than 90 mm Hg for 15 minutes or longer or a drop of 40 mm Hg or more with end-organ hypoperfusion) from patients with a low risk of death from PE.[98,107] In contrast, the appearance of PE on imaging studies does not predict mortality. For example, most patients who present with "saddle emboli" are hemodynamically stable, and

they usually recover when treated with anticoagulants alone.[108]

An important subpopulation of patients with PE but without hypotension requires special attention because their risk of death from PE falls into an intermediate category (i.e., neither high nor low). These patients have systolic blood pressure higher than 90 mm Hg and evidence of acute RV strain on echocardiography with or without elevated cardiac troponin or natriuretic peptide levels, and they may decompensate abruptly. In the *Pulmonary Embolism International Thrombolysis* (PEITHO) study, 28 of 499 (5.6%) patients with RV strain detected on echocardiography and elevated troponin levels either died or became hypotensive during the first week of treatment.[107] For this reason, patients with RV strain with or without elevated troponin levels require monitoring to detect and treat hypotension resulting from RV failure.[107,109]

Assessment of Bleeding Risk

Assessment of risk for major bleeding in a patient with PE represents another critical step before administration of an anticoagulant or thrombolytic medication. Absolute contraindications to anticoagulants (Table 82.4) and to thrombolytics (Table 82.5) are established when the risk for major bleeding exceeds the benefit of these therapies. In the absence of absolute contraindications, the bleeding risk of anticoagulant or thrombolytic therapy can be estimated from observations reported from pivotal clinical trials.[107,110] Such estimates of the risk for major bleeding may be subject to adjustment on the basis of individual patient characteristics. Additional risk factors include (1) advanced age (>75 years); (2) previous bleeding (if not associated with a reversible cause) or anemia, (3) active cancer, (4) previous stroke, (5) chronic liver or kidney disease, (6) use of antiplatelet or nonsteroidal anti-inflammatory drugs, (7) other serious acute or chronic illness, and (8) poor anticoagulation control. Furthermore, clinicians sometimes must make difficult decisions because the expected benefits of anticoagulation or thrombolysis do not clearly exceed the risk of major bleeding.

Some experienced clinicians choose to give low-dose UFH intravenously without a bolus, although this approach remains unproven. This approach engenders the risk of recurrent VTE because it takes longer to achieve a therapeutic anticoagulant effect. Other clinicians recommend the incorporation of the patient's values into treatment decisions when the risks of major bleeding and recurrent thromboembolism are comparable.[73]

Table 82.4 Contraindications to Anticoagulation

Absolute*	Relative†
Difficult to control active bleeding	Intracranial or intraspinal tumor
Platelet count < 25,000/mL	Aortic dissection
Intracranial bleeding in the last 30 days	Active gastrointestinal bleeding in the last 7 days
	Platelet count < 50,000/mL
	Major surgery‡

*Do not give anticoagulants if any absolute contraindications are present.
†Anticoagulation is strongly discouraged in the presence of relative contraindication(s), but clinicians can assess risk, benefits, and individual patient preferences when they make shared decisions with patients in these difficult circumstances.
‡Major surgery represents a relative contraindication based on the location of the surgery, the time elapsed since the surgical procedure, the degree of hemostasis achieved, and the risk posed by bleeding.

Table 82.5 Contraindications to Thrombolysis

Absolute	Relative
Prior intracranial hemorrhage	History of chronic, severe, poorly controlled hypertension
Structural cerebrovascular lesion	History of ischemic stroke more than 3 mo previously
Known intracranial neoplasm	Traumatic or prolonged (>10 min) cardiopulmonary resuscitation
Ischemic stroke within 3 mo	Major surgery in the past 3 wk
Suspected arterial dissection	Major bleeding in the past 4 wk
Active bleeding or bleeding diathesis	Noncompressible vascular puncture
Significant head trauma within 3 mo	Recent invasive procedure
	Pregnancy or first week postpartum
	Active peptic ulcer
	Pericarditis or pericardial fluid
	Current use of an anticoagulant
	Age > 75 yr
	Diabetic retinopathy

Assessment of Risk for Heparin-Induced Thrombocytopenia

Assessment of the risk for HIT is also necessary before treatment with UFH or an LMWH. Strong risk factors for HIT include the duration of heparin therapy (>5 days), the heparin product (UFH > LMWH > fondaparinux), the clinical setting (surgical and trauma patients at highest risk), and the patient's sex (female > male). A past history of HIT with thrombosis contraindicates initiation of UFH or an LMWH, and it provides justification for anticoagulation with argatroban, bivalirudin, or fondaparinux.[111] Guideline authors recommend intravenous argatroban to treat VTE in patients with HIT and renal insufficiency. Limited evidence suggests that DOACs such as rivaroxaban and apixaban are effective and safe options for treating HIT in selected patients with HIT-induced thrombosis.[112]

Assessment to Determine the Site of Pulmonary Embolism Treatment

Before 2011, hospitalization for the treatment of acute PE was recommended routinely,[113] although randomized clinical trials, completed in 1996, demonstrated that selected patients with symptomatic proximal DVT could be managed safely without a long hospitalization.[114-116] More recent evidence suggests that selected low-risk patients with acute PE can be managed safely with early hospital discharge or without hospitalization.[117-121] However, a Cochrane Database systematic review concluded that only low-quality evidence was available from two published randomized controlled trials on outpatient versus inpatient management of low-risk patients with PE.[122] For this reason, guideline algorithms recommend that clinicians consider early discharge or outpatient treatment for carefully selected patients on the basis of risks (e.g., mortality,

recurrent thromboembolism, bleeding) as well as individual patients' circumstances (e.g., home environment, access to health care, need for pain control). Current algorithms suggest the use of validated risk assessment scores such as the PESI or sPESI score.[103] The Hestia criteria integrate PE severity, comorbidities, and the feasibility of home treatment. If the answer to even one questions is "yes," then the patient cannot be discharged early. In a single-arm management trial that used these criteria to select candidates for home treatment, the 3-month rate of recurrent VTE was 2.0% (0.8–4.3%) in patients with acute PE who were discharged within 24 hours.[120]

Hospitalization remains necessary for most patients with PE. When feasible, tertiary care settings with specialized resources are chosen for patients with an intermediate or high risk for morbidity and mortality from PE or its treatment. Many of these patients require admission to monitored settings with rapid access to reperfusion strategies such as thrombolysis or pulmonary embolectomy.

Telemedicine and Pulmonary Embolism Response Teams

Health care delivery continues to evolve rapidly. The emergence of telemedicine may allow selected patients with PE to receive inpatient monitoring and treatment without immediate transfer to a tertiary care facility.[123] In some institutions, PE response teams direct the initial management of patients with acute PE.[124] PE response teams can offer rapid access to multidisciplinary expertise and skills necessary for a comprehensive assessment of the patient, followed by implementation of a decisive treatment plan.

Initial Treatment of the Patient With Confirmed Pulmonary Embolism and Hypotension, Shock, or Cardiac Arrest

Patients with PE and hypotension, shock, or cardiac arrest require immediate hemodynamic and respiratory support (see Fig. 82.2), combined with treatment to relieve obstruction of the pulmonary arteries.[103] Current reperfusion strategies include thrombolysis and embolectomy.

Systemic Thrombolysis. Systemic thrombolysis is indicated for patients with hypotension, shock, or cardiac arrest resulting from acute PE, provided there is not an absolute contraindication (see Table 82.5). Patients who have stabilized after hypotension require careful monitoring, but previous hypotension, in and of itself, is not an indication for systemic thrombolysis.[109]

Thrombolytic agents lyse thromboemboli more rapidly than endogenous fibrinolysis accompanied by anticoagulation.[125-136] In the setting of life-threatening acute PE, accelerated clot dissolution provided by systemic thrombolysis may be lifesaving,[137] and it justifies the increased risk for major bleeding, especially intracranial hemorrhage, associated with systemic thrombolysis. Current evidence-based guidelines recommend peripheral infusion of 100 mg recombinant tissue plasminogen activator over 2 hours for hypotensive patients and a bolus infusion (0.6 mg/kg up to a maximum of 50 mg recombinant tissue plasminogen activator over 15 minutes) for patients with imminent or full cardiac arrest caused by acute PE.[126,131,134,138]

In contrast, decisions about systemic thrombolysis for patients with acute PE who have an intermediate mortality risk are among the most difficult that a clinician must make. The potential benefit of systemic thrombolysis for normotensive patients with an intermediate mortality risk may not outweigh the risk of intracranial hemorrhage when compared with anticoagulation alone. The PEITHO study randomly assigned 1006 normotensive PE patients with RV dysfunction and myocardial injury to treatment with tenecteplase and heparin or placebo and heparin.[107] Although tenecteplase reduced the primary end point of hemodynamic collapse within 7 days of randomization (2.6% tenecteplase vs. 5.6% placebo), tenecteplase increased the rate of intracranial bleeding (2.0% tenecteplase vs. 0.2% placebo). The all-cause 7-day mortality was low (1.2% tenecteplase vs. 1.8% placebo), and systemic thrombolysis did not alter long-term survival, RV dysfunction on echocardiography, or persistent dyspnea.[139]

Results from PEITHO suggest that patients who meet PEITHO criteria (i.e., patients with PE who are normotensive with RV dysfunction on echocardiography and biochemical evidence of myocardial injury) benefit most from initial anticoagulation with UFH and careful monitoring for hypotension from PE as an indication for systemic thrombolysis, rather than immediate thrombolysis, and this is our recommendation for treating these patients. The PEITHO study also clearly demonstrated the need for new approaches to reduce major bleeding associated with systemic thrombolysis.

Low-Dose Thrombolysis. Low-dose thrombolysis represents an approach to maintain efficacy and reduce the rate of major bleeding complications observed with full-dose thrombolytic regimens when treating life-threatening PE.[134,140] A 2018 retrospective analysis compared propensity score-matched PE cohorts treated with half-dose alteplase with those treated with full-dose alteplase and found no difference in hospital mortality, cerebral hemorrhage, or other major bleeding.[141] Without additional data from well-designed clinical trials, low-dose thrombolysis remains unproven for the treatment of life-threatening PE.

Catheter-Directed Therapies. Catheter-directed therapies aim to establish reperfusion in the setting of life-threatening PE while avoiding the major bleeding complications of systemic thrombolysis. Patients with hypotension from PE and absolute contraindications to thrombolysis may be treated with pigtail or balloon-tipped catheters to fragment PEs or aspiration catheters to suction PEs.

Catheter embolectomy provides an alternative treatment when thrombolysis is contraindicated, unavailable, or has already failed in patients with hypotension, shock, or cardiac arrest from acute PE. This approach also avoids the risks of surgery for patients unlikely to tolerate surgical embolectomy. Investigators have reported several catheter embolectomy techniques.[98,142-149] No randomized controlled trial has compared systemic thrombolysis with catheter-directed thrombolysis, and we do not have comparative data about the choice of catheters, adjunctive thrombolysis, and anticoagulation management in these patients. Thus, this therapy relies on available expertise and

Table 82.6 Trials of Ultrasound-Assisted Catheter-Directed Thrombolysis for Acute Pulmonary Embolism

Reference	Trial	N	Method/Result	Safety
Kucher et al.[185]	ULTIMA	59	RCT in which CDT compared with systemic anticoagulation reduced RV/LV at 24 hr more than UFH alone	0 ICH
Piazza et al.[186]	SEATTLE II	150	Single-arm cohort study finding that USCDT reduced RV/LV at 48 hr	0 ICH
Kuo et al.[187]	PERFECT	54	Registry study finding that MT with CDT reduced PA pressure	1 ICH
Engelberger et al.[188]		52	Retrospective study finding that USCDT reduced mean PA pressure	0 ICH
Tapson et al.[189]	OPTALYSE	101	RCT comparing 4 USCDT regimens in which USCDT reduced RV/LV at 48 hr, but with 1 ICH	1 ICH

CDT, catheter-directed thrombolysis; ICH, intracranial hemorrhage; LV, left ventricle; MT, mechanical thrombectomy; PA, pulmonary artery; RCT, randomized clinical trial; RV, right ventricle; UFH, unfractionated heparin; USCDT, ultrasound-assisted catheter-directed thrombolysis.

resources. However, experts recommend (1) discontinuation of catheter embolectomy once hypotension is reversed and (2) removal of clot only in the main or lobar pulmonary arteries to minimize the risk of perforation or dissection of pulmonary arteries.[98]

In the absence of absolute contraindications to thrombolysis, investigators have attempted direct infusions of thrombolytic drugs into the pulmonary artery or the combination of mechanical fragmentation of PE with local infusion of thrombolytic drugs to improve the benefit of thrombolysis and reduce the risk of major bleeding. In 1988, a randomized clinical trial demonstrated no difference in PE outcomes between a direct infusion of recombinant tissue plasminogen activator into the pulmonary artery and intravenous recombinant tissue plasminogen activator.[150] More recently, investigators have reported experiences with ultrasound-assisted catheter-directed thrombolysis, but all main results are physiologic or anatomic rather than patient-centered outcomes (Table 82.6).

For now, the relative safety and efficacy of all catheter-directed therapies remain to be demonstrated in well-designed clinical trials. However, these approaches deserve consideration for patients with life-threating acute PE who are not candidates for systemic thrombolysis or surgical embolectomy.

Surgical Embolectomy. Surgical embolectomy is an option for patients with hypotension, shock, or cardiac arrest resulting from acute PE who are not candidates for thrombolysis.[151] Embolectomy may also be best for selected patients with mobile intracardiac thrombi when thrombolysis is contraindicated or unsuccessful or when thrombolysis poses a greater risk to the patient than surgical embolectomy.

Reports describe variable survival following surgical embolectomy.[152-155] Patient selection likely accounts for much of the variation in surgical outcomes, although surgical techniques such as limiting extraction to visible clot without blind instrumentation and avoidance of fibrillatory arrest, cardioplegia, and aortic cross-clamping may also contribute to improved survival.[98]

Extracorporeal Membrane Oxygenation or Percutaneous Right Ventricular Assist. Extracorporeal membrane oxygenation and percutaneous RV assist have been reported as life-sustaining treatments that may lead to good outcomes in patients with PE refractory to other therapies.[151,156] Extracorporeal membrane oxygenation has primarily been used in the setting of near cardiac arrest and prolonged hypotension despite volume infusion, vasopressor, and inotropic therapy. The same is true of RV assist (e.g., with Impella PR, a percutaneous microaxial pump providing temporary hemodynamic support).[156] Both extracorporeal membrane oxygenation and percutaneous RV assist require relatively large-bore vascular access by experienced staff. Major hemorrhage is a risk for both extracorporeal membrane oxygenation and percutaneous RV assist but, in settings where they are already used for cardiogenic failure and/or overwhelming respiratory failure, the expertise may exist to deploy such techniques in otherwise treatment-refractory patients.

Initial Treatment of the Patient With Confirmed Pulmonary Embolism Without Hypotension, Shock, or Cardiac Arrest

Anticoagulation. Anticoagulants provide effective initial (day 1 to day 7), long-term (day 7 to 3 months), and extended (beyond 3 months) treatment of PE. The choice of anticoagulant and the anticoagulant dose should match the more intense thrombotic state during the early stages and reductions in the thrombotic state during the long-term and extended stages of treatment. Additional individual patient-related factors also influence the choice of anticoagulants.

In the absence of contraindications, prompt administration of therapeutic doses of an anticoagulant regimen with proven efficacy is indicated. UFH, LMWH, fondaparinux, and direct inhibitors of factor Xa or thrombin are effective.[157,158] Clinical trials have demonstrated the efficacy and safety of these anticoagulants.[159] The choice of anticoagulant and dose often reflects specific clinical circumstances (Table 82.7). For example, UFH is preferable to factor Xa inhibitors for patients with PE who are at increased risk for PE mortality and who may therefore need thrombolysis or embolectomy. UFH also is preferable for patients with renal failure. Other examples include the following: the use of LMWH in patients with liver disease and coagulopathy, in whom oral anticoagulants are contraindicated; avoidance of dabigatran in patients with coronary artery disease, gastrointestinal bleeding, and/or dyspepsia;

Table 82.7 Anticoagulant Treatments for Acute Pulmonary Embolism

Clinical	Initial*	Long-Term*	Extended*
Unstable	UFH† (5+ days)	DOAC or warfarin‡	DOAC or warfarin‡
High risk for bleed§	UFH† (5+ days)	DOAC or warfarin‡	DOAC or warfarin‡
Stable, cancer	Dalteparin 200 IU/kg/day‖ (1 mo)	Dalteparin 150 IU/kg/day	Dalteparin 150 IU/kg/day
Stable, cancer	Enoxaparin 1 mg/kg/bid‖	Enoxaparin 1 mg/kg/bid	Enoxaparin 1 mg/kg/bid
Stable, cancer	Enoxaparin 1 mg/kg bid (7 days)	Edoxaban 60 mg/day¶	Edoxaban 60 mg/day¶
Stable, no cancer	Apixaban 10 mg bid (7 days)	Apixaban 5 mg bid	Apixaban 2.5 mg bid
Stable, no cancer	Rivaroxaban 15 mg bid (21 days)	Rivaroxaban 20 mg qd	Rivaroxaban 20 mg qd
Stable, no cancer	Enoxaparin 1 mg/kg bid (5–7 days)	Dabigatran 150 mg bid	Dabigatran 150 mg bid

*Initial anticoagulant period from day 1 to day 5 to 7 of treatment, followed by long-term anticoagulation from day 5 to 7 to 3 months, with anticoagulation extended beyond 3 months when the risk of recurrent PE exceeds the risk of major bleeding.
†UFH dosed according to a standardized protocol[164]; monitor for HIT.
‡If oral vitamin K antagonist (e.g., warfarin) treatment is planned, begin with 4 to 5 mg once daily and transition entirely to warfarin after all the following criteria are satisfied: (1) at least 5 days of UFH or LMWH; (2) INR > 2.0 for two determinations; (3) PE symptoms and PE-related hypoxemia significantly improved, then monitor INR; and (4) adjust dose to maintain INR in range of 2.0 to 3.0.
§High risk for bleeding as defined by Kearon and colleagues.[73] Some experts advise intravenous UFH 400 U/hr without a bolus and observe for bleeding/hemostasis. After 6 hours with hemostasis, increase to 600 U/hr with continued observation. Keep aPTT < 50 seconds and anti–factor Xa level < 0.5 U/mL. If hemostasis is maintained, then slowly increase UFH dose over 24 hours to 800 U/hr.
‖LMWHs accumulate with renal dysfunction. Titrate doses to produce anti–factor Xa levels of 0.4 to 0.85 U/mL and monitor for HIT.
¶Edoxaban 30 mg once daily for creatinine clearance 15 to 50 mL/min or body weight < 60 kg.
aPTT, activated partial thromboplastin time; bid, twice daily; DOAC, direct oral anticoagulant; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; qd, once daily; UFH, unfractionated heparin.

and the use of an LMWH, apixaban, or edoxaban (a direct inhibitor of factor Xa) for patients with cancer.[160-162]

Unfractionated Heparin. Continuous intravenous UFH provides highly effective treatment of acute VTE.[42] However, proper dosing and monitoring of UFH are essential to prevent recurrent VTE. Approaches not based on a protocol often deliver inadequate doses of UFH.[163] Prompt initiation of continuous intravenous UFH according to dosing protocols proven to achieve a therapeutic anticoagulant effect reduces the risk of recurrent VTE dramatically. Hull and colleagues[43] reported a 15-fold increase in the rate of recurrent VTE in patients who did not have a therapeutic anticoagulant effect within 24 hours of the start of continuous intravenous UFH. A common protocol initiates therapy with an 80-unit UFH/kg bolus, followed by continuous infusion of 18 units UFH/kg/hr, with monitoring of the aPTT and subsequent UFH doses guided by protocol.[164] An aPTT higher than 1.5 times the upper limit of normal provides therapeutic anticoagulation and corresponds to 0.3 to 0.7 unit/mL measured by anti–factor Xa assay. Anti–factor Xa levels, rather than aPTT, guide UFH dose adjustment for patients with circulating lupus anticoagulants or heparin resistance (defined as a requirement for >40,000 units UFH /day).[165]

Low-Molecular-Weight Heparins. LMWHs are at least as effective and safe as UFH for the initial treatment of most patients with acute PE that is not life-threatening. However, LMWHs should not be used to treat PE in patients with unstable renal function or renal failure. Conversely, LMWHs are preferable to UFH, followed by warfarin, for patients with cancer because of improved efficacy in the prevention of recurrence with comparable safety.[160]

Fondaparinux. Fondaparinux is effective and safe to treat acute PE initially.[166] The therapeutic dose depends on the patient's weight (5 mg, 7.5 mg, and 10 mg subcutaneously daily for patients who weigh less than 50 kg, 50 to 100 kg, and more than 100 kg, respectively), and fondaparinux must be given for at least 5 days. Like LMWH, fondaparinux should be avoided in patients with renal failure.

Direct Inhibitors of Factor Xa or Thrombin. DOACs are as effective as vitamin K antagonists for long-term treatment of VTE and are associated with less frequent and less severe bleeding.[157,158] Furthermore, DOACs offer treatment without routine coagulation monitoring, rapid onset and offset of action, and few drug-drug interactions.

Rivaroxaban, a direct inhibitor of factor Xa, is FDA approved for treatment of PE at an initial dose of 15 mg twice daily for 21 days, followed by a reduced dose of 20 mg daily during the long-term and extended phase of treatment. Impaired renal or liver function may alter excretion or metabolism of rivaroxaban and is a relative contraindication to its use. Furthermore, abrupt discontinuation of rivaroxaban in patients with PE and concomitant atrial fibrillation increases the risk of stroke.

Apixaban, a direct inhibitor of factor Xa, is FDA approved for treatment of PE at an initial dose of 10 mg twice daily for 7 days, followed by 5 mg twice daily for 3 months. A dose of 2.5 mg twice daily may be used for extended anticoagulation. Apixaban, 5 mg twice daily, provides effective extended treatment for VTE in patients with advanced cancer.[162]
