Get the most out of your **Gray's Anatomy**
FORTY-SECOND EDITION

Included in your purchase is a rich variety of BONUS electronic content, to supplement and enhance the printed book.

Look out for this icon, indicating where there is related further electronic text, images, tables, labelled imaging or video material.

In addition, you can access 21 'Gray's Commentaries': especially written (electronic only) articles on new and emerging topics related to anatomy. This icon highlights where one relates directly to a topic in the printed book. Chapters 80 and 81 (electronic only) contain descriptions of the systematic anatomy of the peripheral nervous system and vascular system, respectively.

For an extended historical bibliography, all references from the thirty-eighth edition (which includes all references cited in earlier editions, up to and including the thirty-eighth edition) are also available in the e-book that accompanies *Gray's Anatomy*.

Don't miss out on any of this additional electronic content – see the inside front cover for your access instructions.

COVER IMAGE

The cover image for this edition is a cinematically rendered 3D reconstruction of a normal heart from a contrast-enhanced computed tomography (CT) coronary angiography study performed at the Royal Papworth Hospital, Cambridge, UK. Image reconstruction and post-processing was performed on a SIEMENS syngo.via Frontier workstation by Dr Julia Sun (Clinical Fellow in Radiology, Royal Papworth Hospital) with further editing by Dr Jonathan Weir-McCall (Honorary Consultant Radiologist, Royal Papworth Hospital) and Dr Tom Turmezei (Consultant Radiologist, Norfolk and Norwich University Hospital).

PREFACE

A common definition of a preface is that it is '*an introduction to a book, typically stating its subject, scope or aims*'. It is often the only place where an author or editor speaks directly to their readership, and in this respect, a preface is akin to an actor breaking the conceptual 'fourth wall' in the theatre or on film. In the Preface to the first edition in 1858 Henry Gray wrote that '*This Work is intended to furnish the Student and Practitioner with an accurate view of the Anatomy of the Human Body, and more especially the application of this science to Practical Surgery*'. Subsequent editions of *Gray's Anatomy* not only upheld that intention, but developed it, in order to embrace and engage a wider readership.

The first two editors to succeed Gray were Timothy Holmes (1863–1880) and Thomas Pickering Pick (1883–1905). They both wondered in their Prefaces whether it was appropriate to include findings from the burgeoning discipline of anatomical science in a book intended specifically for students of surgery: '*so long as the Examining Bodies do not exact a knowledge of this branch of science as a necessary part of Medical Education, it would be unwise to encumber the pages of a work designed specifically for students with matter which, however interesting and valuable in itself, could hardly be regarded as essential*' (Holmes, 3rd edition, 1863). Pickering Pick pointed out that microscopical anatomy had been revised in the 10th edition '*in order to keep pace with the ever-increasing activity of research in the branch of the science of Anatomy*' (1883), and while not intending the 13th edition for the 'scientific anatomist', he was anxious not '*to disparage, for an instant, the study of Philosophical or Scientific Anatomy*' (1893).

Future editions slowly assimilated findings in the fields of cell biology, embryology, neuroanatomy and imaging: just as the discipline it describes has evolved, so a book originally intended for students of surgery has morphed into the great reference book that is published today. Our current view of the detailed internal landscape of the body, from molecular to whole body and from conception onwards, owes much to the enormous technological advances that have taken place in the last half century. Our 'anatomical gaze' has been enlightened by progress in bioinformatics, molecular biology, experimental genetics, light and electron microscopy, diagnostic imaging (including X-rays, magnetic resonance imaging, computed tomography and ultrasonography), and the use of 'soft' perfusion techniques and frozen–thawed, unembalmed cadavers for dissection-based studies and surgical training. That gaze is not only informed by, but also informs, the design and negotiation of minimally invasive surgical access routes to structures and regions that were once regarded as inaccessible 'tiger territories'. The momentum created by these changes powered the radical modernizing revisions seen in the 36th to 38th editions under the editorship of Roger Warwick and Peter Williams: '*The discipline of Anatomy has changed out of all recognition because it is no longer just "Descriptive and Applied"*' (Editorial team, Preface to the 38th edition, 1995), and has continued to drive subsequent editions.

Terminological disputes have long entertained anatomists: '*one cynic has commented that anatomists would rather use each other's toothbrushes than employ their terminology*' (Tansey 1995).[1] Henry Gray's anatomical terminology in the first edition can be little different from the language he used when teaching and operating at St George's Hospital: his words were written long before the publication of the *Basle Nomina Anatomica* (BNA) in 1895. The exasperated comments of TB Johnston, in his Preface to the 25th edition, have a familiar ring almost 90 years later: '*It is my earnest hope that before another edition of this work is published, the question of terminology will have been settled and an unproductive subject will have ceased to occupy attention*' (Johnston 1932). These hopes have not been entirely satisfied. An early attempt to reconcile differing terminologies in *Gray's Anatomy* was described as 'stultifying' (Tansey 1995).[1] The text of the 42nd edition of *Gray's Anatomy* is almost entirely *Terminologia Anatomica* 2-compliant.[2] However, on occasion the preferred term that is used is a synonym that may not be TA2-compliant: it has been chosen either because it is the agreed term in the relevant clinical consensus document or, as my editors frequently remind me, because it enjoys widespread clinical usage, whereas the TA-compliant term does not.[3] Wherever this occurs, all terms are included at first meeting, with synonyms in parentheses.

The use of eponyms is contentious: detractors argue that they are inherently inaccurate, non-scientific and often undeserved, while proponents point out that eponyms are deeply embedded in the anatomical and clinical literature and that they remind us of the giants on whose shoulders we stand. On balance, I believe that *Gray's Anatomy* is an appropriate repository for anatomical eponyms: they are cited in parentheses on first usage of a preferred term in the text and an updated list of eponyms is available in the e-book for reference purposes. I recognize the irony in the exclusion of Henry Vandyke Carter's name from the eponymous title of *Gray's Anatomy*, particularly since Carter's drawings invariably attracted praise: '*those excellent images which have … contributed so materially to smooth the thorny path of the student of human anatomy*' (Carter's obituary, BMJ May 15 1897); '*The splendid illustrations in Gray have long been known as the most effective and intelligible presentations of anatomical structure ever produced …*' (Preface to the American 15th edition, 1901).

As a general rule, the orientation of diagrams and photographs throughout the book has been standardized to show the left side of the body, irrespective of whether a lateral or medial view is presented. Transverse sections have been drawn from below to facilitate comparison with axial clinical images: the conventional 'top down' orientation has been retained in diagrams in Section 3 (neuroanatomy). Clinicopathological examples have been selected where the pathology is either a direct result, or a consequence, of the anatomy, or where the anatomical features are instrumental in the diagnosis/treatment/management of the condition. Unless otherwise indicated, the photomicrographs illustrate human histology and embryology.

In the Preface to the 39th edition I explained that the editorial team had decided that, in order to provide the greatest benefit to clinicians, *Gray's Anatomy* would better mirror their daily practice if anatomy was described in the way that they use it, i.e. regionally. That said, including regional and systematic descriptions of topographical anatomy has remained my goal and I am therefore delighted that the anatomy of the nervous and vascular and lymphatic systems is included in the online version of the 42nd edition (in Chapters 80 and 81).

Neel Anand, Marco Catani, Pat Collins, Alan Crossman, Michael Gleeson, Alistair Ross, Shane Tubbs, Richard Tunstall, Caroline Wigley and Stephanie Woodley brought a wealth of scholarship and experience as anatomists, cell biologists, research scientists, educators and clinicians to their roles as Section Editors. They recognize that a knowledge of clinically relevant and evidence-based anatomy is essential for safe and effective clinical practice across all specialisms. It is with great pleasure that I thank them for their dedication and enthusiastic support, both in selecting and interacting with the authors in their Sections and in meeting Elsevier's deadlines, despite the ever-increasing demands on their time from their university and/or clinical managers. Richard

[3]Jeppson PC, Balgobin S, Washington BB et al 2018 Recommended standardized terminology of the anterior female pelvis based on a structured medical literature review. Am J Obstet Gynecol 219:26–39.

Tunstall and Caroline Wigley also worked closely with many authors to update the text and artworks for evidence-based surface anatomy and microstructure, respectively, across Sections 3 to 9. Tom Turmezei has been an enthusiastic 'go to' editor for sourcing images throughout the book: Tom and his team have produced a superb collection of additional labelled images (see **Bonus imaging collection**). Owen Arthurs and his colleagues at Great Ormond Street Hospital provided microCT images for Section 2 (Embryogenesis and development). Over a hundred highly experienced clinicians and anatomists have contributed new text and/or artworks, original micrographs or other images to individual chapters and I thank them all for their input – as ever, it has been an enriching experience to read their revisions.

I offer my sincere thanks to the editorial team at Elsevier, under the leadership of Jeremy Bowes, for their guidance, professionalism, good humour and unfailing support at all times. I particularly thank Trinity Hutton, Joanna Souch, Julie Taylor and Elaine Leek, for being at the end of a phone or available by e-mail whenever I needed advice or support. I thank the artists who have worked to produce new artworks under Richard Tibbitts' leadership, continuing the tradition of Henry Vandyke Carter, the first great illustrator of *Gray's Anatomy*.

I dedicate my work on this edition of *Gray's Anatomy* to my daughters, Helen and Caroline.

Susan Standring
February 2020

PROFESSOR EMERITUS KARL ZILLES (1944–2020)

It was with great sadness that we learned that Professor Emeritus Karl Zilles, who co-authored the updated chapter on the cerebral hemispheres (Chapter 32), died while the proofs of this edition of *Gray's Anatomy* were being finalized. He was an outstanding neuroscientist and '*…his dedication, rigor, and scientific approaches have been transformative in the field of neuroanatomy…*' (Zaborszky 2020). The quantitative histological methods that he developed have played a significant role in bridging the gap between classical post-mortem neuroanatomy and neuroimaging of the living human brain.

Karl Zilles graduated in medicine from the Johann-Wolfgang-Goethe University in Frankfurt in 1971 and received a PhD in Anatomy from the Medical School of Hannover in 1977. He became full Professor of Anatomy and Neuroanatomy at the University of Cologne in 1981 and was Director of the prestigious Cécil and Oscar Vogt Institute for Brain Research at Heinrich Heine University in Düsseldorf from 1991 to 2012 and the Institute of Neurosciences and Medicine at the Forschungszentrum in Jülich from 1998 to 2012.

During a long and highly productive career, Karl Zilles explored the structural, molecular and functional organization of the marsupial, rodent, non-human primate and human cerebral cortices. Very early, he introduced TV cameras connected to a microscope for extracting quantitative morphometric parameters from histological sections (Zilles et al 1978). The realization of the existence of significant inter-individual differences in brain architecture led him to propose and establish the use of 3D cytoarchitectonic probabilistic maps of cortical areas (Amunts et al 1999, Schormann et al 1995). The rapid development of *in vivo* neuroimaging methods combined with a quantitative probabilistic approach to cytoarchitectonic brain mapping produced reference atlases and digital databases for the precise localization of cortical areas and functions in the human brain (Zilles and Amunts 2010).

He developed a method for the quantitative autoradiograpical analysis of the laminar and regional distribution of multiple transmitter receptors. He introduced neurotransmitter fingerprints, which reflect the balance between different receptors and neurotransmitter systems that characterize each cortical area. He demonstrated that receptor fingerprints differ across species and between healthy and diseased brains, and therefore represent a very powerful tool to study the molecular architecture of each area under different conditions (Zilles et al 1986, Zilles and Palomero-Gallagher 2017).

In the last 15 years, Karl Zilles and his collaborators introduced an ultra-high resolution method for axon and white matter fibre visualization based on polarized light imaging (Axer et al 2011). Future developments and applications of this technique will offer an invaluable tool with which to describe the organization of neural connections in the brain and to validate current descriptions of white matter tracts based on *in vivo* diffusion MRI tractography.

To his students, collaborators and friends, Professor Karl Zilles was an inspirational and encouraging figure, always ready to converse and write about neuroanatomy, history of neuroscience, epistemology, philosophy and ethics: he will be deeply missed.

ACKNOWLEDGEMENTS

Elsevier and the *Gray's Anatomy* 42nd edition editorial team would like to offer sincere thanks to the Department of Radiology at the Norfolk and Norwich University Hospital, Norwich, UK, for their support in sourcing and preparing over 140 superb new radiological imaging figures for this edition. Guided by Imaging Editor Dr Tom Turmezei, these include cutting-edge images that showcase the impact of radiology on anatomical education, harnessing different modalities and image processing techniques to show living internal human anatomy in detail. In particular, we would like to thank consultant radiologists Tariq Ali, Phyllis Mezue and Iztok Caglic; musculoskeletal radiology clinical fellow Elliott Rees; and radiology trainees Julia Sun, Ramona-Rita Barbara, Fatma Eminaga, Amr Moussa, Nathan Chan and Emily Pearlman.

The following images were sourced by the Department of Radiology at the Norfolk and Norwich University Hospital:

HISTORICAL INTRODUCTION

Gray's Anatomy is now more than 160 years old. The book is a rarity in textbook publishing in having been in continuous publication on both sides of the Atlantic Ocean since 1858, an exceptionally long era for a textbook. Of course, the volume now is very different from the one Mr Henry Gray first created with his colleague Dr Henry Vandyke Carter in mid-Victorian London. In this introductory essay, I shall explain the long history of *Gray's*, from those Victorian days right up to today.

The shortcomings of existing anatomical textbooks probably impressed themselves on Henry Gray when he was still a student at St George's Hospital Medical School, near London's Hyde Park Corner, in the early 1840s. He began thinking about creating a new anatomy textbook a decade later, while war was being fought in the Crimea. New legislation was being planned that would establish the General Medical Council (1858) to regulate professional education and standards.

Gray was 28 years old, and a teacher himself at St George's. He was very able, hard-working and highly ambitious, already a Fellow of the Royal Society and of the Royal College of Surgeons. Although little is known about his personal life, his was a glittering career so far, achieved while he served and taught on the hospital wards and in the dissecting room (**Fig. 1**) (Anon 1908).

Gray shared the idea for the new book with a talented clinical colleague on the teaching staff at St George's, Henry Vandyke Carter, in November 1855. Carter was from a family of Scarborough artists, and was himself a talented artist and experienced microscopist (**Fig. 2**). He had produced fine illustrations for Gray's scientific publications before, but could see that this idea was a much more complex project. Carter recorded in his diary:

> *'Little to record. Gray made proposal to assist by drawings in bringing out a Manual for students: a good idea but did not come to any plan … too exacting, for would not be a simple artist'* (Carter 1855).

Neither of these young men was interested in producing a pretty book, or an expensive one. Their purpose was to supply an affordable, accurate teaching aid for people like their own students, who might soon be required to operate on real patients, or on soldiers injured at Sebastopol or some other battlefield. The book they planned together was a practical one, designed to encourage youngsters to study anatomy, help them pass exams and assist them as budding surgeons. It was not simply an anatomy textbook, but a guide to dissecting procedure, and to the major operations.

Gray and Carter belonged to a generation of anatomists ready to infuse the study of human anatomy with a new, and respectable, scientificity. Disreputable aspects of the profession's history, acquired during the days of body-snatching, were assiduously being forgotten. The Anatomy Act of 1832 had legalized the requisition of unclaimed bodies from workhouse and hospital mortuaries, and the study of anatomy (now with its own Inspectorate) was rising in respectability in Britain. The private anatomy schools that had flourished in the Regency period were closing their doors, and the major teaching hospitals were erecting new, purpose-built dissection rooms (Richardson 2000).

The best-known student works when Gray and Carter had qualified were probably Erasmus Wilson's *Anatomist's Vade Mecum*, and *Elements of Anatomy* by Jones Quain. Both works were small – pocket-sized – but Quain came in two thick volumes. Their small pages of dense type, and even smaller illustrations, were somewhat daunting, seeming to demand much nose-to-the-grindstone effort from the reader.

The planned new textbook's dimensions and character were serious matters. Pocket manuals were commercially successful because they appealed to students by offering much knowledge in a small compass. But pocket-sized books had button-sized illustrations. Knox's *Manual of Human Anatomy*, for example, was only 6 inches by 4 (15 × 10 cm) and few of its illustrations occupied more than one-third of a page. Gray and Carter must have discussed this matter between themselves, and with Gray's publisher, JW Parker & Son, before decisions were taken about the size and girth of the new book, and especially the size of its illustrations. While Gray and Carter were working on the book, a new edition of *Quain's* was published; this time it was a 'triple-decker' – in three volumes – of 1740 pages in all.

The two men were earnestly engaged for the following 18 months in work for the new book. Gray wrote the text, and Carter created the illustrations; all the dissections were undertaken jointly. Their working days were long – all the hours of daylight, eight or nine hours at a stretch – right through 1856, and well into 1857. We can infer from the

Fig. 1 Henry Gray (1827–1861) is shown here in the foreground, seated by the feet of the cadaver. The photograph was taken by a medical student, Joseph Langhorn. The room is the dissecting room of St George's Hospital Medical School in Kinnerton Street, London. Gray is shown surrounded by staff and students. When the photo was taken, on 27 March 1860, Carter had left St George's, to become Professor of Anatomy and Physiology at Grant Medical College, in Bombay (nowadays Mumbai). The second edition of *Gray's Anatomy* was in its proof stages, to appear in December 1860. Gray died just over a year later, in June 1861, at the height of his powers.

Fig. 2 Henry Vandyke Carter (1831–1897). Carter was appointed Honorary Physician to Queen Victoria in 1890. (Self portrait painted while Carter was in India, courtesy of Professor Susan Standring.)

warmth of Gray's appreciation of Carter in his published acknowledgements that their collaboration was a happy one.

> *'The Author gratefully acknowledges the great services he has derived in the execution of this work, from the assistance of his friend, Dr. H. V. Carter, late Demonstrator of Anatomy at St George's Hospital. All the drawings from which the engravings were made, were executed by him,* (Gray 1858).

With all the dissections completed, and Carter's inscribed woodblocks at the engravers, Gray took six months' leave from his teaching at St George's to work as a personal doctor for a wealthy family. It was probably as good a way as any to get a well-earned break from the dissecting room and the dead-house (Nicol 2002).

Carter sat the examination for medical officers in the East India Company, and sailed for India in the spring of 1858, when the book was still in its proof stages. Gray had left a trusted colleague, Timothy Holmes, to see it through the press. Holmes's association with the first edition would later prove vital to its survival. Gray looked over the final galley proofs, just before the book finally went to press.

THE FIRST EDITION

The book Gray and Carter had created together, *Anatomy, Descriptive and Surgical*, appeared at the very end of August 1858, to immediate acclaim. Reviews in *The Lancet* and the *British Medical Journal* were highly complimentary, and students flocked to buy.

It is not difficult to understand why it was a runaway success. *Gray's Anatomy* knocked its competitors into a cocked hat. It was considerably smaller and more slender than the doorstopper with which modern readers are familiar. The book held well in the hand, it felt substantial, and it contained everything required. To contemporaries, it was small enough to be portable, but large enough for decent illustrations: 'royal octavo' – 9½ × 6 inches (24 × 15 cm) – about two-thirds of modern A4 size. Its medium-size, single-volume format was far removed from *Quain's*, yet double the size of Knox's *Manual*.

Simply organized and well designed, the book explains itself confidently and well; the clarity and authority of the prose are manifest. But what made it unique for its day was the outstanding size and quality of the illustrations. Gray thanked the wood engravers Butterworth and Heath for the 'great care and fidelity' they had displayed in the engravings, but it was really to Carter that the book owed its extraordinary success.

The beauty of Carter's illustrations resides in their diagrammatic clarity, quite atypical for their time. The images in contemporary anatomy books were usually 'proxy-labelled': dotted with tiny numbers or letters (often hard to find or read) or bristling with a sheaf of numbered arrows, referring to a key situated elsewhere, usually in a footnote, which was sometimes so lengthy it wrapped round on to the following page. Proxy labels require the reader's eye to move to and fro: from the structure to the proxy label to the legend and back again. There was plenty of scope for slippage, annoyance and distraction. Carter's illustrations, by contrast, unify name and structure, enabling the eye to assimilate both at a glance. We are so familiar with Carter's images that it is hard to appreciate how incredibly modern they must have seemed in 1858. The volume made human anatomy look new, exciting and accessible.

The first edition was covered in a brown bookbinder's cloth embossed all over in a dotted pattern, and with a double picture-frame border. Its spine was lettered in gold blocking:

GRAY'S
ANATOMY

with 'DESCRIPTIVE AND SURGICAL' in small capitals underneath. *Gray's Anatomy* is how it has been referred to ever since. Carter was given credit with Gray on the book's title page for undertaking all the dissections on which the book was based, and sole credit for all the illustrations, though his name appeared in a significantly smaller type, and he was described as the 'Late Demonstrator in Anatomy at St George's Hospital' rather than being given his full current title, which was Professor of Anatomy and Physiology at Grant Medical College, Bombay. Gray was still only a Lecturer at St George's and he may have been aware that his words had been upstaged by the quality of Carter's anatomical images. He need not have worried: Gray is the famous name on the spine of the book.

Gray was paid £150 for every thousand copies sold. Carter never received a royalty payment, just a one-off fee at publication, which may have allowed him to purchase the long-wished-for microscope he took with him to India.

The first edition print-run of 2000 copies sold out swiftly. A parallel edition was published in the United States in 1859, and Gray must have been deeply gratified to have to revise an enlarged new English edition in 1859–60, though he was surely saddened and worried by the death of his publisher, John Parker junior, at the young age of 40, while the book was going through the press. The second edition came out in the December of 1860 and it too sold like hot cakes.

The following summer, in June 1861, at the height of his powers and full of promise, Henry Gray died unexpectedly at the age of only 34. Gray had contracted smallpox while nursing his nephew. A new strain of the disease was more virulent than the one with which Gray had been vaccinated as a child; the disease became confluent, and Gray died in a matter of days.

Within months, the whole country would be pitched into mourning for the death of Prince Albert. The creative era over which he had presided – especially the decade that had flowered since the Great Exhibition of 1851 – would be history.

THE BOOK SURVIVES

Anatomy Descriptive and Surgical could have died too. With Carter in India, the death of Gray, so swiftly after that of the younger Parker, might have spelled catastrophe. Certainly, at St George's there was a sense of calamity. The grand old medical man Sir Benjamin Brodie, Sergeant-Surgeon to the Queen, and to whom *Anatomy* had been dedicated, was a great supporter of Gray and cried forlornly: 'Who is there to take his place?' (Anon 1908).

But old JW Parker ensured the survival of *Gray's* by inviting Timothy Holmes, the doctor who had helped proof-read the first edition, and who had filled Gray's shoes at the medical school, to serve as Editor for the next edition. Other long-running anatomy works, such as that of Quain, remained in print in a similar way, co-edited by other hands (Quain 1856).

Holmes (1825–1907) was another gifted St George's man, a scholarship boy who had won an exhibition to Cambridge, where his brilliance was recognized. He was a Fellow of the Royal College of Surgeons at 28. John Parker junior had commissioned him to edit *A System of Surgery* (1860–64), an important essay series by distinguished surgeons on subjects of their own choosing. Many of Holmes's authors remain important figures, even today: John Simon, James Paget, Henry Gray, Ernest Hart, Jonathan Hutchinson, Charles-Édouard Brown-Séquard and Joseph Lister. Holmes had lost an eye in an operative accident, and he had a gruff manner that terrified students, yet he published a lament for young Parker that reveals him capable of deep feeling (Holmes 1860).

John Parker senior's heart, however, was no longer in publishing. His son's death had closed down the future for him. The business, with all its stocks and copyrights, was sold to Messrs Longman and Parker retired to the village of Farnham, where he later died.

With Holmes as editor, and Longman as publisher, the immediate future of *Gray's Anatomy* was assured. The third edition appeared in 1864 with relatively few changes, Gray's estate receiving the balance of his royalty after Holmes was paid £100 for his work.

THE MISSING OBITUARY

Why no obituary appeared for Henry Gray in *Gray's Anatomy* is curious. Gray had referred to Holmes as his 'friend' in the preface to the first edition, yet it would also be true to say that they were rivals. Both had just applied for a vacant post at St George's, as Assistant Surgeon. Had Gray lived, it is thought that Holmes may not have been appointed, despite his seniority in age (Anon 1908).

Later commentators have suggested, as though from inside knowledge, that Holmes's 'proof-reading' included improving Gray's writing style. This could be a reflection of Holmes's own self-regard, but there may be some truth in it. There can be no doubt that, as Editor of seven subsequent editions of *Gray's Anatomy* (third to ninth editions, 1864–1880), Holmes added new material, and had to correct and compress passages, but it is also possible that, back in 1857, Gray's original manuscript had been left in a poor state for Holmes to sort out. In other works, Gray's writing style was lucid, but he always seems to have paid a copyist to transcribe his work prior to submission. The original manuscript of *Gray's Anatomy*, sadly, has not survived, so it is impossible to be sure how much of the finished version had actually been written by Holmes.

It may be that Gray's glittering career, or perhaps the patronage that unquestionably advanced it, created jealousies among his colleagues, or that there was something in Gray's manner that precluded affection, or that created resentments among clever social inferiors like Carter and Holmes, especially if they felt their contributions to Gray's brilliant career were not given adequate credit. Whatever the explanation, no reference to Gray's life or death appeared in *Gray's Anatomy* itself until the twentieth century (Howden et al 1918).

A SUCCESSION OF EDITORS

Holmes expanded areas of the book that Gray himself had developed in the second edition (1860), notably in 'general' anatomy (histology) and 'development' (embryology). In Holmes's time as Editor, the volume grew from 788 pages in 1864 to 960 in 1880 (ninth edition), with the histological section paginated separately in roman numerals at the front of the book. Extra illustrations were added, mainly from other published sources.

The connections with Gray and Carter, and with St George's, were maintained with the appointment of the next editor, T. Pickering Pick, who had been a student at St George's in Gray's time. From 1883 (tenth edition) onwards, Pick kept up with current research, rewrote and integrated the histology and embryology into the volume, dropped Holmes from the title page, removed Gray's preface to the first edition, and added bold subheadings, which certainly improved the appearance and accessibility of the text. Pick said he had *'tried to keep before himself the fact that the work is intended for students of anatomy rather than for the Scientific Anatomist'* (thirteenth edition, 1893).

Pick also introduced colour printing (in 1887, eleventh edition) and experimented with the addition of illustrations using the new printing method of half-tone dots: for colour (which worked) and for new black-and-white illustrations (which did not). Half-tone shades of grey compared poorly with Carter's wood engravings, still sharp and clear by comparison.

What Henry Vandyke Carter made of these changes is a rich topic for speculation. He returned to England in 1888, having retired from the Indian Medical Service full of honours, and in 1890 he was made Honorary Physician to Queen Victoria. Carter had continued researching throughout his clinical medical career in India, and became one of India's foremost bacteriologists/tropical disease specialists before there was really a name for either discipline. He made some important discoveries, including the fungal cause of mycetoma, which he described and named, and he was a key figure in confirming scientifically in India some major international discoveries, such as Hansen's discovery of the cause of leprosy, Koch's discovery of the organism causing tuberculosis and Laveran's discovery of the organism that causes malaria. Carter married late in life, and his wife was left with two young children when he died in Scarborough in 1897, aged 65. Like Gray, he received no obituary in the book, but unlike Gray, Carter received an obituary in the *British Medical Journal* that celebrated not only his achievements in India but also *'those excellent illustrations for Gray's Anatomy which have … contributed so materially to smooth the thorny path of the student of human anatomy'* (BMJ 1897).

When Pick was joined on the title page by Robert Howden (a professional anatomist from the University of Durham) in 1901 (fifteenth edition), the volume was still easily recognizable as the book Gray and Carter had created. Although many of Carter's illustrations had been revised or replaced, many others still remained. Sadly, though, an entire section (embryology) was again separately paginated, because its revision had taken longer than anticipated. *Gray's Anatomy* had grown, seemingly inexorably, and was now quite thick and heavy: 1244 pages, weighing 5 lb 8 oz/2.5 kg. Both co-editors, and perhaps also its publisher, were dissatisfied with it.

KEY EDITION: 1905

Serious decisions were taken well in advance of the next edition, which turned out to be Pick's last with Howden. Published 50 years after Gray had first suggested the idea to Carter, the 1905 (sixteenth) edition was a landmark one.

The period 1880–1930 was a difficult time for anatomical illustration, because the new techniques of photo-lithography and half-tone were not as yet perfected, and in any case could not provide the bold simplicity of line required for a book like *Gray's*, which depended so heavily on clear illustration and clear lettering. Recognizing the inferiority of half-tone illustrations by comparison with Carter's wood-engraved originals, Pick and Howden courageously decided to jettison the second-rate half-tones altogether. Most of the next edition's illustrations were either Carter's, or old supplementary illustrations inspired by his work, or newly commissioned wood engravings or line drawings, intended 'to harmonize with Carter's original figures'. They successfully emulated Carter's verve. Having fewer pages and lighter paper, the 1905 (sixteenth edition) weighed less than its predecessor, at 4 lb 11 oz/2.1 kg. Typographically, the new edition was superb.

Howden took over as sole editor in 1909 (seventeenth edition) and immediately stamped his personality on *Gray's*. He excised 'Surgical' from the title, changing it to *Anatomy Descriptive and Applied*, and removed Carter's name altogether. He also instigated the beginnings of an editorial board of experts for *Gray's*, by adding to the title page 'Notes on Applied Anatomy' by AJ Jex-Blake and W Fedde Fedden, both St George's men. For the first time, the number of illustrations exceeded one thousand. Howden was responsible for the significant innovation of a short historical note on Henry Gray himself, nearly 60 years after his death, which included a portrait photograph (1918, twentieth edition).

THE NOMENCLATURE CONTROVERSY

Howden's era, and that of his successor TB Johnston (of Guy's), was overshadowed by a cloud of international controversy concerning anatomical terminology. European anatomists were endeavouring to standardize anatomical terms, often using Latinate constructions, a move resisted in Britain and the United States. *Gray's* became mired in these debates for over 20 years. The attempt to be fair to all sides by using multiple terms doubtless generated much confusion amongst students, until a working compromise was at last arrived at in 1955 (thirty-second edition, 1958).

Johnston oversaw the second retitling of the book (in 1938, twenty-seventh edition): it was now, officially, *Gray's Anatomy*, finally ending the fiction that it had ever been known as anything else. *Gray's* suffered from paper shortages and printing difficulties in World War II, but successive editions nevertheless continued to grow in size and weight, while illustrations were replaced and added as the text was revised.

Between Howden's first sole effort (1909, seventeenth edition) and Johnston's last edition (1958, thirty-second edition), *Gray's* expanded by over 300 pages – from 1296 to 1604 pages, and almost 300 additional illustrations brought the total to over 1300. Johnston also introduced X-ray plates (1938) and, in 1958 (thirty-second edition), electron micrographs by AS Fitton-Jackson, one of the first occasions on which a woman was credited with a contribution to *Gray's*. Johnston felt compelled to mention that she was 'a blood relative of Henry Gray himself', perhaps by way of mitigation.

AFTER WORLD WAR II

The editions of *Gray's* issued in the decades immediately following World War II give the impression of intellectual stagnation. Steady expansion continued in an almost formulaic fashion, with the insertion of additional detail. The central historical importance of innovation in the success of *Gray's* seems to have been lost sight of by its publishers and editors: Johnston (1930–1958, twenty-fourth to thirty-second editions), J Whillis (co-editor with Johnston, 1938–1954), DV Davies (1958–1967, thirty-second to thirty-fourth editions) and F Davies (co-editor with DV Davies 1958–1962, thirty-second to thirty-third editions). *Gray's* had become so pre-eminent that perhaps complacency crept in, or editors were too daunted or too busy to confront the 'massive undertaking' of a root and branch revision (Tansey 1995). The unexpected deaths of three major figures associated with *Gray's* in this era, James Whillis, Francis Davies and David Vaughan Davies – each of whom had been ready to take the editorial reins – may have contributed to retarding the process. The work became somewhat dull.

KEY EDITION: 1973

DV Davies had recognized the need for modernization, but his unexpected death left the work to other hands. Two Professors of Anatomy at Guy's, Roger Warwick and Peter Williams, the latter of whom had been involved as an indexer for *Gray's* for several years, regarded it as an honour to fulfil Davies's intentions.

Their thirty-fifth edition of 1973 was a significant departure from tradition. Over 780 pages (of 1471) were newly written, almost a third of the illustrations were newly commissioned, and the captions for the illustrations were freshly written throughout. With a complete

re-typesetting of the text in larger double-column pages, a new index and the innovation of a bibliography, this edition of *Gray's* looked and felt quite unlike its 1967 (thirty-fourth edition) predecessor, and much more like its modern incarnation.

This 1973 edition departed from earlier volumes in other significant ways. The editors made explicit their intention to try to counter the impetus towards specialization and compartmentalization in twentieth-century medicine, by embracing and attempting to reintegrate the complexity of the available knowledge. Warwick and Williams openly renounced the pose of omniscience adopted by many textbooks, believing it important to accept and mention areas of ignorance or uncertainty. They shared with the reader the difficulty of keeping abreast in the sea of research, and accepted with a refreshing humility the impossibility of fulfilling their own ambitious programme.

Warwick and Williams's 1973 edition had much in common with Gray and Carter's first edition. It was bold and innovative – respectful of its heritage, while also striking out into new territory. It was visually attractive and visually informative. It embodied a sense of a treasury of information laid out for the reader (Williams and Warwick 1973). It was published simultaneously in the United States (the American *Gray's* had developed a distinct character of its own in the interval), and sold extremely well there (Williams and Warwick 1973).

The influence of the Warwick and Williams edition was forceful and long-lasting, and set a new pattern for the following quarter-century. As has transpired several times before, wittingly or unwittingly, a new editor was being prepared for the future: Professor Susan Standring (of Guy's and subsequently King's College London), who created the new bibliography for the 1973 edition of *Gray's*, went on to serve on the editorial board, and has served as Editor-in-Chief for the last three editions before this one (2005–2016, thirty-ninth, fortieth and forty-first editions). These editions are important for different reasons.

For the thirty-ninth edition, the entire content of *Gray's* was reorganized, from systematic to regional anatomy. This great sea-change was not just organizational but historic, because, since its outset, *Gray's* had prioritized bodily systems, with subsidiary emphasis on how the systems interweave in the regions of the body. Professor Standring explained that this regional change of emphasis had long been asked for by readers and users of *Gray's*, and that new imaging techniques had raised the clinical importance of regional anatomy (Standring 2005). The change was facilitated by an enormous collective effort on the part of the editorial team and the illustrators. The subsequent and current editions, now also containing a substantial online-only component including an imaging library, consolidate that momentous change (see **Table 1**).

THE DOCTORS' BIBLE

Neither Gray nor Carter, the young men who – by their committed hard work between 1856 and 1858 – created the original *Gray's Anatomy*, would have conceived that so many years after their deaths their book would not only be a household name, but also be regarded as a work of such pre-eminent importance that a novelist half a world away would rank it as cardinal – alongside the Bible and Shakespeare – to a doctor's education (Sinclair Lewis 1925, Richardson 2008). From this forty-second edition of *Gray's Anatomy*, we can look back to appraise the long-term value of their efforts. We can discern how the book they created triumphed over its competitors, and has survived pre-eminent. *Gray's* is a remarkable publishing phenomenon. Although the volume now looks quite different to the original, and contains so much more, its kinship with the *Gray's Anatomy* of 1858 is easily demonstrable by direct descent, every edition updated by Henry Gray's successor. Works are rare indeed that have had such a long history of continuous publication on both sides of the Atlantic, and such a useful one.

ANATOMICAL NOMENCLATURE

Anatomy is the study of the structure of the body. Conventionally, it is divided into topographical (macroscopic or gross) anatomy (which may be further divided into regional anatomy, surface anatomy, neuroanatomy, endoscopic and imaging anatomy); developmental anatomy (embryogenesis and subsequent organogenesis); and the anatomy of microscopic and submicroscopic structure (histology).

Anatomical language is one of the fundamental languages of medicine. The unambiguous description of thousands of structures is impossible without an extensive and often highly specialized vocabulary. Ideally, these terms, which are often derived from Latin or Greek, should be used to the exclusion of any other, and eponyms should be avoided. In reality, this does not always happen. Many terms are vernacularized and, around the world, synonyms and eponyms still abound in the literature, in medical undergraduate classrooms and in clinics and operating theatres. The 2nd edition of the *Terminologia Anatomica*,[1] drawn up by the Federative Committee on Anatomical Terminology (FCAT) and newly published in 2019, continues to serve as our reference source for the terminology for macroscopic anatomy, and the text of the 42nd edition of *Gray's Anatomy* is almost entirely TA2-compliant. However, where terminology is at variance with, or, more likely, is not included in, the TA, the alternative term used either is cited in the relevant consensus document or position paper, or enjoys widespread clinical usage. Synonyms and eponyms are given in parentheses on first usage of a preferred term and not shown thereafter in the text; an updated list of eponyms and short biographical details of the clinicians and anatomists whose names are used in this way is available in the e-book for reference purposes (see Preface, p. ix, for further discussion of the use of eponyms).

When medical students begin dissection classes they are often surprised by the range of anatomical variation that they encounter amongst the cadavers in the laboratory. As they progress to clinical examination and study their patients' X-ray, CT, MRI or ultrasound images, they encounter further variations that prompt the age-old question, 'what is normal, and what is beyond the range of anatomical normality?' The interested reader is directed to *Bergman's Comprehensive Encyclopedia of Human Anatomic Variation*, which 'attempts to capture many of the known variants of the human form'.[2]

PLANES, DIRECTIONS AND RELATIONSHIPS

To avoid ambiguity, all anatomical descriptions assume that the body is in the conventional 'anatomical position', i.e. standing erect and facing forwards, upper limbs by the side with the palms facing forwards, and lower limbs together with the toes facing forwards (**Fig. 1**). Descriptions are based on four imaginary planes – median, sagittal, coronal and horizontal – applied to a body in the anatomical position. The median plane passes longitudinally through the body and divides it into right and left halves. The sagittal plane is any vertical plane parallel with the median plane; although often employed, 'parasagittal' is therefore redundant and should not be used. The coronal (frontal) plane is orthogonal to the median plane and divides the body into anterior (front) and posterior (back). The horizontal (transverse) plane is orthogonal to both median and sagittal planes. Radiologists refer to transverse planes as (trans)axial; convention dictates that axial anatomy is viewed as though looking from the feet towards the head.

Structures nearer the head are superior, cranial or (sometimes) cephalic (cephalad), whereas structures closer to the feet are inferior; caudal is most often used in embryology to refer to the hind end of the embryo. Medial and lateral indicate closeness to the median plane, medial being closer than lateral; in the anatomical position, the little finger is medial to the thumb, and the great toe is medial to the little toe. Specialized terms may also be used to indicate medial and lateral. Thus, in the upper limb, ulnar and radial are used to mean medial and lateral, respectively; in the lower limb, tibial and fibular (peroneal) are used to mean medial and lateral, respectively. Terms may be based on embryological relationships; the border of the upper limb that includes the thumb, and the border of the lower limb that includes the great toe are the pre-axial borders, whilst the opposite borders are the post-axial borders. Various degrees of obliquity are acknowledged using compound terms, e.g. posterolateral.

When referring to structures in the trunk and upper limb, we have freely used the synonyms anterior, ventral, flexor, palmar and volar, and posterior, dorsal and extensor. We recognize that these synonyms are not always satisfactory, e.g. the extensor aspect of the leg is anterior with respect to the knee and ankle joints, and superior in the foot and digits; the plantar (flexor) aspect of the foot is inferior. Dorsal (dorsum) and ventral are terms used particularly by embryologists and neuroanatomists; they therefore feature most often in Sections 2 and 3.

Distal and proximal are used particularly to describe structures in the limbs, taking the datum point as the attachment of the limb to the trunk (sometimes referred to as the root), such that a proximal structure is closer to the attachment of the limb than a distal structure. However, proximal and distal are also used in describing branching structures, e.g. bronchi, vessels and nerves. External (outer) and internal (inner) refer to the distance from the centre of an organ or cavity, e.g. the layers of the body wall, or the cortex and medulla of the kidney. External and internal can also describe rotation that is lateral or medial, respectively, e.g. at the hip or shoulder joints. Superficial and deep are used to describe the relationships between adjacent structures. Ipsilateral refers to the same side (of the body, organ or structure), bilateral to both sides, and contralateral to the opposite side.

Teeth are described using specific terms that indicate their relationship to their neighbours and to their position within the dental arch; these terms are described on page 646.

[1] *Terminologia Anatomica 2* (2019) is the joint creation of the Federative Committee on Anatomical Terminology (FCAT) and the Member Associations of the International Federation of Associations of Anatomists (IFAA).

CHAPTER
1 Basic structure and function of cells

CELL STRUCTURE

General characteristics of cells

The shapes of mammalian cells vary widely depending on their interactions with each other, their extracellular environment and internal structures. Their surfaces are often highly folded when absorptive or transport functions take place across their boundaries. Cell size is limited by rates of diffusion, either that of material entering or leaving cells, or that of diffusion within them. Movement of macromolecules can be much accelerated and also directed by processes of active transport across the plasma membrane and by transport mechanisms within the cell. According to the location of absorptive or transport functions, apical microvilli (**Fig. 1.1**) or basolateral infoldings create a large surface area for transport or diffusion.

Motility is a characteristic of most cells, in the form of movements of cytoplasm or specific organelles from one part of the cell to another. It also includes: the extension of parts of the cell surface such as pseudopodia, lamellipodia, filopodia and microvilli; locomotion of entire cells, as in the amoeboid migration of tissue macrophages; the beating of flagella or cilia to move the cell (e.g. in spermatozoa) or fluids overlying it (e.g. in respiratory epithelium); cell division; and muscle contraction. Cell movements are also involved in the uptake of materials from their environment (endocytosis, phagocytosis) and the passage of large molecular complexes out of cells (exocytosis, secretion).

Epithelial cells rarely operate independently of each other and commonly form aggregates by adhesion, often assisted by specialized intercellular junctions. They may also communicate with each other, either by generating and detecting molecular signals that diffuse across intercellular spaces, or more rapidly by generating interactions between membrane-bound signalling molecules. Cohesive groups of cells constitute tissues, and more complex assemblies of tissues form functional systems or organs.

Most cells are between 5 and 50 µm in diameter: e.g. resting lymphocytes are 6 µm across, red blood cells 7.5 µm and columnar epithelial cells 20 µm tall and 10 µm wide (all measurements are approximate). Some cells are much larger than this: e.g. megakaryocytes of the bone marrow and osteoclasts of the remodelling bone are more than 200 µm in diameter. Neurones and skeletal muscle cells have relatively extended shapes, some of the former being over 1 m in length.

Cellular organization

Each cell is contained within its limiting plasma membrane, which encloses the cytoplasm. All cells, except mature red blood cells, also contain a nucleus that is surrounded by a nuclear membrane or envelope (see Fig. 1.1; **Fig. 1.2**). The nucleus includes: the genome of the cell contained within the chromosomes; the nucleolus; and other subnuclear structures. The cytoplasm contains cytomembranes and several membrane-bound structures, called organelles, which form separate

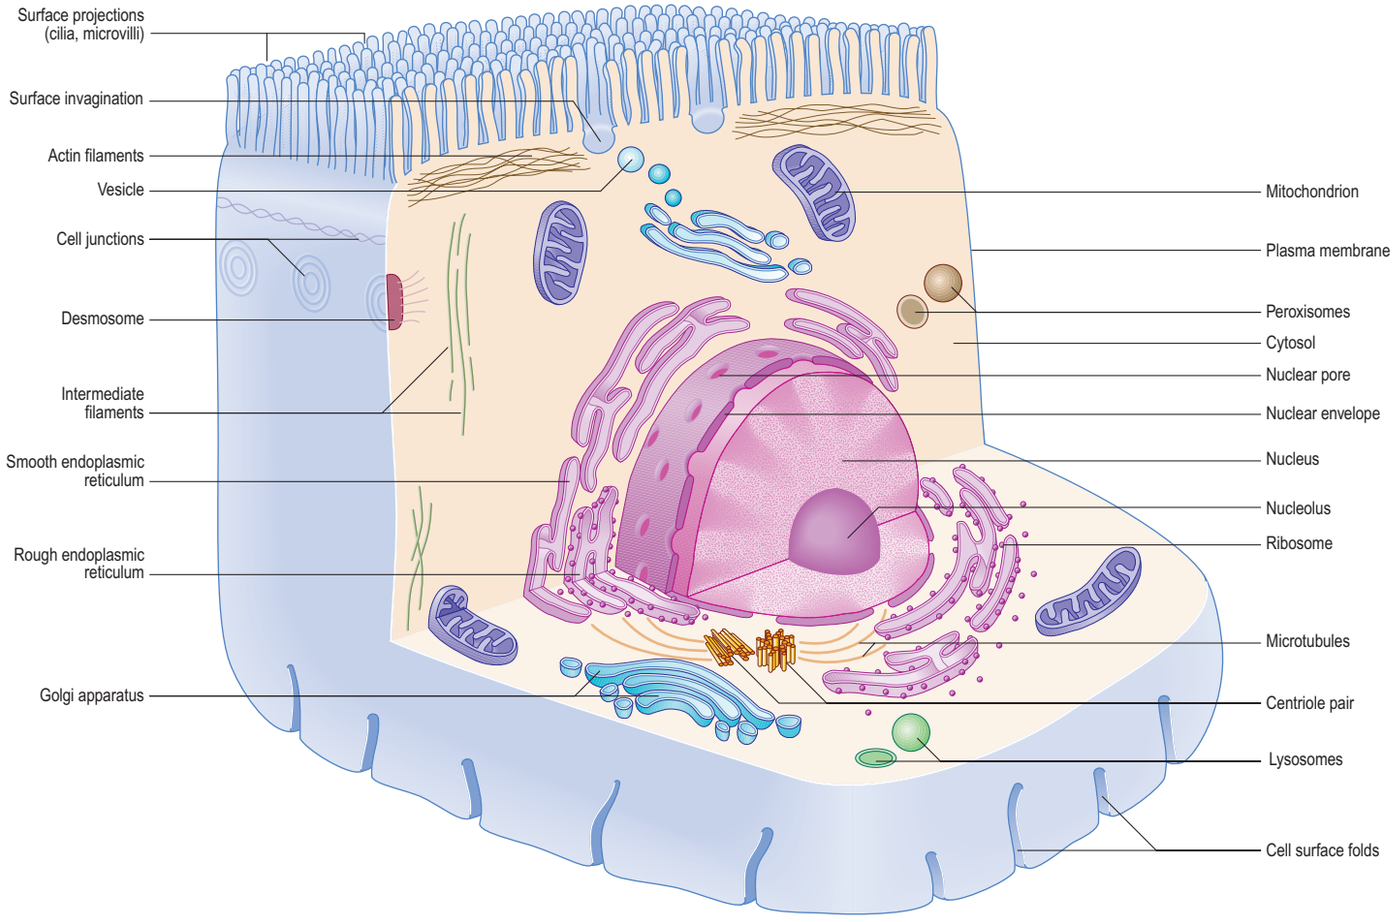

Fig. 1.1 The main structural components and internal organization of a generalized cell.

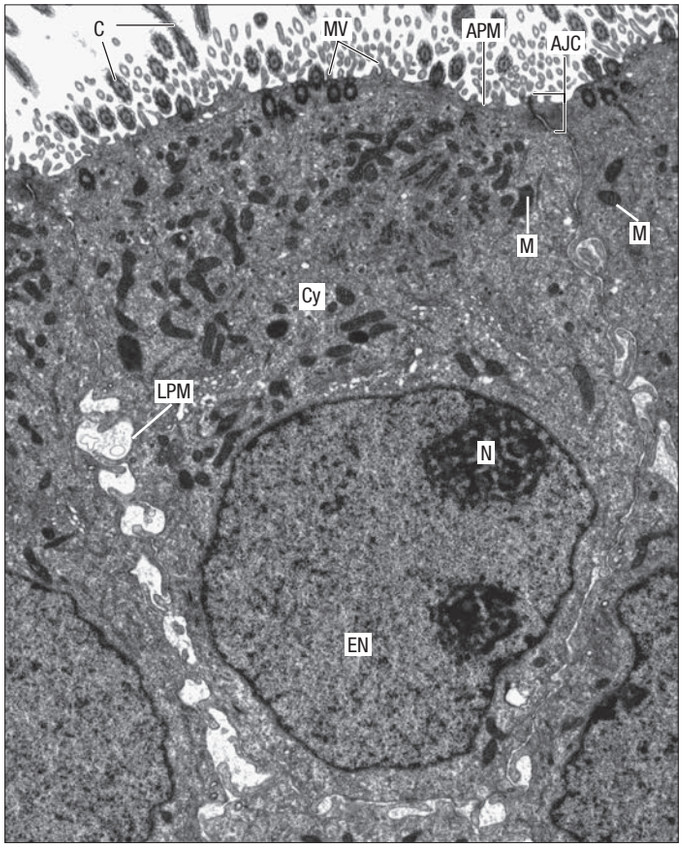

Fig. 1.2 The structural organization and some principal organelles of a typical cell. This example is a ciliated columnar epithelial cell from human nasal mucosa. The central cell, which occupies most of the field of view, is closely apposed to its neighbours along their lateral plasma membranes. Within the apical junctional complex, these membranes form a tightly sealed zone (tight junction) that isolates underlying tissues from, in this instance, the nasal cavity. Abbreviations: AJC, apical junctional complex; APM, apical plasma membrane; C, cilia; Cy, cytoplasm; EN, euchromatic nucleus; LPM, lateral plasma membrane; M, mitochondria; MV, microvilli; N, nucleolus. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

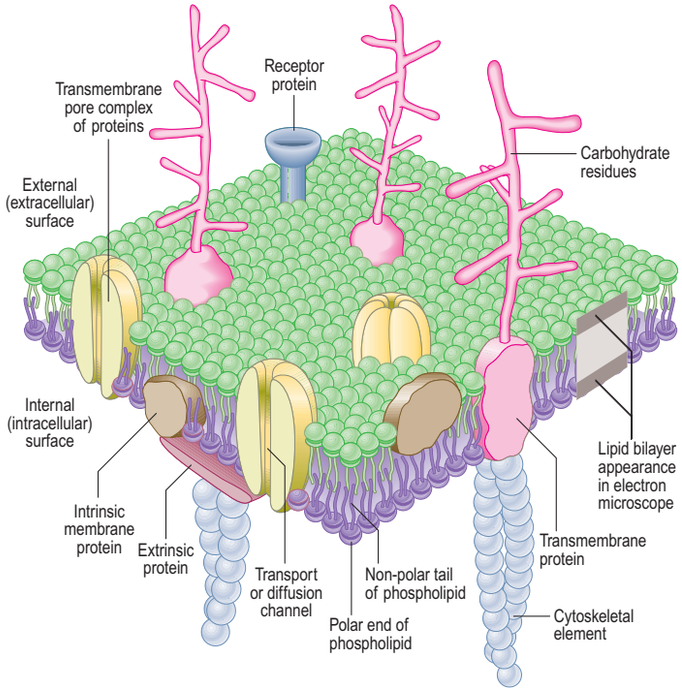

Fig. 1.3 The molecular organization of the plasma membrane, according to the fluid mosaic model of membrane structure. Intrinsic or integral membrane proteins include diffusion or transport channel complexes, receptor proteins and adhesion molecules. These may span the thickness of the membrane (transmembrane proteins) and can have both extracellular and cytoplasmic domains. Transmembrane proteins have hydrophobic zones, which cross the phospholipid bilayer and allow the protein to 'float' in the plane of the membrane. Some proteins are restricted in their freedom of movement where their cytoplasmic domains are tethered to the cytoskeleton.

and distinct compartments within the cytoplasm. Cytomembranes include the rough and smooth endoplasmic reticulum and Golgi apparatus, as well as vesicles derived from them. Organelles include lysosomes, peroxisomes and mitochondria. The nucleus and mitochondria are enclosed by a double-membrane system; lysosomes and peroxisomes have a single bounding membrane. There are also non membrane-bound structures, called inclusions, which lie free in the cytosolic compartment. They include glycogen aggregates and pigments (e.g. lipofuscin). In addition, ribosomes and several filamentous protein networks, known collectively as the cytoskeleton, are found in the cytosol. The cytoskeleton determines general cell shape and supports specialized extensions of the cell surface (microvilli, cilia, flagella). It is involved in the assembly of specific structures (e.g. centrioles) and controls cargo transport in the cytoplasm. The cytosol contains many soluble proteins, ions and metabolites.

Plasma membrane

Cells are enclosed by a distinct plasma membrane, which shares features with the cytomembrane system that compartmentalizes the cytoplasm and surrounds the nucleus. All membranes are composed of lipids (mainly phospholipids, cholesterol and glycolipids) and proteins, in approximately equal ratios. Plasma membrane lipids form a lipid bilayer, a layer two molecules thick. The hydrophobic ends of each lipid molecule face the interior of the membrane and the hydrophilic ends face outwards. Most proteins are embedded within, or float in, the lipid bilayer as a fluid mosaic. Some proteins, because of extensive hydrophobic regions of their polypeptide chains, span the entire width of the membrane (transmembrane proteins), whereas others are only superficially attached to the bilayer by lipid groups. Both are integral (intrinsic) membrane proteins, as distinct from peripheral (extrinsic) membrane proteins, which are membrane-bound only through their association with other proteins. Carbohydrates in the form of oligosaccharides and polysaccharides are bound either to proteins (glycoproteins) or to lipids (glycolipids), and project mainly into the extracellular domain (Fig. 1.3).

Combinations of biochemical, biophysical and biological techniques have revealed that lipids are not homogeneously distributed in membranes, but that some are organized into microdomains in the bilayer, called 'detergent-resistant membranes' or lipid 'rafts', rich in sphingomyelin and cholesterol. The ability of select subsets of proteins to partition into different lipid microdomains has profound effects on their function, e.g. in T-cell receptor and cell–cell signalling. The highly organized environment of the domains provides a signalling, trafficking and membrane fusion environment.

In the electron microscope, membranes fixed and contrasted by heavy metals such as osmium tetroxide appear in section as two densely stained layers separated by an electron-translucent zone – the classic unit membrane. The total thickness of each layer is about 7.5 nm. The overall thickness of the plasma membrane is typically 15 nm. Freeze–fracture cleavage planes usually pass along the hydrophobic portion of the bilayer, where the hydrophobic tails of phospholipids meet, and split the bilayer into two leaflets. Each cleaved leaflet has a surface and a face. The surface of each leaflet faces either the extracellular surface (ES) or the intracellular or protoplasmic (cytoplasmic) surface (PS). The extracellular face (EF) and protoplasmic face (PF) of each leaflet are artificially produced during membrane splitting. This technique has also demonstrated intramembranous particles embedded in the lipid bilayer; in most cases, these represent large transmembrane protein molecules or complexes of proteins. Intramembranous particles are distributed asymmetrically between the two half-layers, usually adhering more to one half of the bilayer than to the other. In plasma membranes, the intracellular leaflet carries most particles, seen on its face (the PF). Where they have been identified, clusters of particles usually represent channels for the transmembrane passage of ions or molecules between adjacent cells (gap junctions).

Biophysical measurements show the lipid bilayer to be highly fluid, allowing diffusion in the plane of the membrane. Thus proteins are able to move freely in such planes unless anchored from within the cell. Membranes in general, and the plasma membrane in particular, form boundaries selectively limiting diffusion and creating physiologically distinct compartments.

Transport across cell membranes

Most biological molecules cannot diffuse through the phospholipid bilayer. Specific transport proteins, such as carrier proteins and channel proteins, mediate the selective passage of molecules across the membrane, thus allowing the cell to control its internal composition. Molecules (such as oxygen and carbon dioxide) can cross the plasma membrane down their concentration gradients by dissolving first in the phospholipid bilayer and then in the aqueous environment at the cytosolic or extracellular side of the membrane. This mechanism, known as passive diffusion, does not involve membrane proteins. Lipid and lipid-soluble (e.g. steroid) substances can also cross the bilayer.

Other biological molecules (such as glucose, charged molecules and small ions H+, Na+, K+ and Cl–) are unable to dissolve in the hydrophobic interior of the phospholipid bilayer. They require the help of specific transport proteins (**Fig. 1.4**) and channel proteins, which facilitate the passage or facilitated diffusion of most biological molecules. Facilitated diffusion requires carrier proteins, which can bind specific molecules to be transported, or channel proteins, which form open gates through the membrane. Carrier proteins transport sugars, amino acids and nucleosides. Channel proteins are ion channels involved in the rapid transport of ions (faster transport than that mediated by carrier proteins), are highly selective of molecular size and electrical charge, and are not continuously open. Ligand-gated channels open 'gates' in response to the binding of a signalling molecule, whereas voltage-gated channels open in response to changes in electric potential across the membrane. Similar to passive diffusion, facilitated diffusion of biological molecules is determined by concentration and electrical gradients across a membrane.

There are three types of transport protein: uniporter, symporter, and antiporter (see Fig. 1.4). Uniporter transport proteins can be either channel proteins or carrier proteins. They are involved in facilitated diffusion and carry a single molecule at a time from one side of the membrane to the other along its concentration gradient. Symporter and antiporter transport proteins are involved in active transport, where the transporter utilizes energy, in the form of adenosine triphosphate (ATP) to mobilize molecules against their concentration gradient in order to maintain the correct concentrations of ions and molecules in cells. Symporter transport proteins are co-transporters (such as the glucose–sodium co-transporter): they carry two molecules simultaneously or sequentially in the same direction. Antiporter transport proteins, such as the sodium–potassium pump, carry two molecules simultaneously or sequentially in the opposite direction to each other.

Translocation of proteins across intracellular membranes

Proteins are generally synthesized on ribosomes in the cytosol or on the rough endoplasmic reticulum: a few are made on mitochondrial ribosomes. Once synthesized, many proteins remain in the cytosol, where they carry out their functions. Others, such as integral membrane proteins or proteins for secretion, are translocated across intracellular membranes for post-translational modification and targeting to their destinations. This is achieved by the signal sequence, an addressing system contained within the protein sequence of amino acids, which is recognized by receptors or translocators in the appropriate membrane. Proteins are sorted by their signal sequence (or set of sequences that become spatially grouped as a signal patch when the protein folds into its tertiary configuration), in order that they are recognized by and enter the correct intracellular membrane compartment.

Plasma membrane proteins also provide surfaces for the attachment of enzymes; sites for the receptors of external signals, including hormones and other ligands; and sites for the recognition and attachment of other cells. Internally, plasma membranes can act as points of attachment for intracellular structures, in particular those concerned with cell motility and other cytoskeletal functions. Cell membranes are synthesized by the rough endoplasmic reticulum in conjunction with the Golgi apparatus.

Cell coat (glycocalyx)

The external surface of a plasma membrane differs structurally from internal membranes in that it possesses an external, fuzzy, carbohydrate-rich coat, the glycocalyx, composed of the carbohydrate portions of glycoproteins and glycolipids embedded in the plasma membrane (see Fig. 1.3). The cell coat forms an integral part of the plasma membrane, projecting as a diffusely filamentous layer 2–20 nm or more from the lipoprotein surface.

The precise composition of the glycocalyx varies with cell type; many tissue and cell type-specific antigens are located in the coat, including the major histocompatibility complex of the immune system and, in the case of erythrocytes, blood group antigens. The glycocalyx therefore plays a significant role in organ transplant compatibility. The glycocalyx found on the apical microvilli of enterocytes, the cells forming the lining epithelium of the intestine, consists of enzymes involved in the digestive process. Intestinal microvilli are cylindrical projections (1–2 μm long and about 0.1 ts} μm in diameter) forming a closely packed layer called the brush border that increases the absorptive function of enterocytes (see Fig. 1.26).

Cytoplasm

Compartments and functional organization

The cytoplasm consists of the cytosol and two cytomembrane systems, the endoplasmic reticulum and Golgi apparatus, all enclosed by the cell or plasma membrane. The cytosol is a gel-like material made up of colloidal proteins such as enzymes, carbohydrates and small protein molecules, together with ribosomes and ribonucleic acids. The cytoplasm also contains membrane-bound organelles (lysosomes, peroxisomes and mitochondria), membrane-free inclusions (glycogen and pigments) and the cytoskeleton. The nuclear contents, the nucleoplasm, are separated from the cytoplasm by the nuclear envelope.

Endoplasmic reticulum

The endoplasmic reticulum is a system of interconnecting membrane-lined channels within the cytoplasm (**Fig. 1.5**). These channels take various forms, including cisternae (flattened sacs), tubules and vesicles. The membranes divide the cytoplasm into two major compartments. The intramembranous compartment, or cisternal space, is where secretory products are stored or transported to the Golgi complex and cell exterior: it is continuous with the perinuclear space.

Structurally, the channel system can be divided into rough or granular endoplasmic reticulum (RER), which has ribosomes attached to its outer, cytosolic surface, and smooth or agranular endoplasmic reticulum (SER), which lacks ribosomes. The functions of the endoplasmic reticulum vary greatly and include the synthesis, folding and transport of proteins; the biosynthesis and transport of phospholipids and

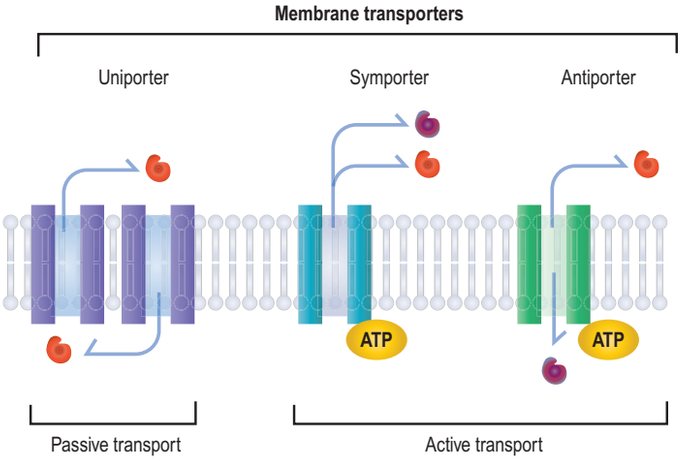

Fig. 1.4 Transporter proteins. Uniporter transport proteins are involved in facilitated diffusion (passive transport without an energy source). They carry a single molecule at a time from one side of the membrane to the other along its concentration gradient. Symporter and antiporter transport proteins are involved in active transport. In active transport, unlike passive transport, the transporter utilizes energy, in the form of adenosine triphosphate (ATP) to mobilize molecules against their concentration gradient. Symporter transport proteins are co-transporters (such as the glucose–sodium co-transporter); they carry two molecules simultaneously or sequentially in the same direction. Antiporter transport proteins, such as the sodium–potassium pump, carry two molecules simultaneously or sequentially in the opposite direction. (With permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

The glycocalyx plays a significant role in maintenance of the integrity of tissues and in a wide range of dynamic cellular processes, e.g. serving as a vascular permeability barrier and transducing fluid shear stress to the endothelial cell cytoskeleton (Weinbaum et al 2007). Disruption of the glycocalyx on the endothelial surface of large blood vessels precedes inflammation, a conditioning factor of atheromatosis (e.g. deposits of cholesterol in the vascular wall leading to partial or complete obstruction of the vascular lumen).

steroids; the degradation of glycogen; and the maintenance of calcium homeostasis. Endoplasmic reticulum (ER)-associated degradation (ERAD) is part of the cellular protein quality control system and is responsible for the clearance of misfolded proteins from the ER for cytosolic proteasomal degradation.

In general, RER is well developed in cells that produce abundant proteins, whereas SER is abundant in steroid-producing cells and muscle cells. The sarcoplasmic reticulum is a variant of the endoplasmic reticulum in muscle cells: it is involved in calcium storage and release for muscle contraction. For further reading on the endoplasmic reticulum, see Bravo et al (2013).

Smooth endoplasmic reticulum

The smooth endoplasmic reticulum (**Fig. 1.5A**) is associated with carbohydrate metabolism and many other metabolic processes, including detoxification and synthesis of lipids, cholesterol and steroids. The membranes of the smooth endoplasmic reticulum serve as surfaces for the attachment of many enzyme systems, e.g. the enzyme cytochrome P450, which is involved in important detoxification mechanisms and is thus accessible to its substrates, which are generally lipophilic. The smooth endoplasmic reticulum in hepatocytes (which are able to store glycogen) contains the enzyme glucose-6-phosphatase, which converts glucose-6-phosphate to glucose, a step in gluconeogenesis. The membranes also cooperate with the rough endoplasmic reticulum and the Golgi apparatus to synthesize new membranes; the protein, carbohydrate and lipid components are added in different structural compartments.

Rough endoplasmic reticulum

The rough endoplasmic reticulum is a site of protein synthesis; its cytosolic surface is studded with ribosomes (**Fig. 1.5B**). Ribosomes only bind to the endoplasmic reticulum when proteins targeted for secretion begin to be synthesized. Most proteins pass through its membranes and accumulate within its cisternae, although some integral membrane proteins, e.g. plasma membrane receptors, are inserted into the rough endoplasmic reticulum membrane, where they remain. After passage from the rough endoplasmic reticulum, proteins remain in membrane-bound cytoplasmic organelles such as lysosomes, become incorporated into new plasma membrane, or are secreted by the cell. Some carbohydrates are also synthesized by enzymes within the cavities of the rough endoplasmic reticulum and may be attached to newly formed protein (glycosylation). Vesicles are budded off from the rough endoplasmic reticulum for transport to the Golgi as part of the protein-targeting mechanism of the cell

Ribosomes, polyribosomes and protein synthesis

Ribosomes are macromolecular machines that catalyse the synthesis of proteins from amino acids; synthesis and assembly into subunits takes place in the nucleolus and includes the association of ribosomal RNA (rRNA) with ribosomal proteins translocated from their site of synthesis in the cytoplasm. The individual subunits are then transported into the cytoplasm, where they remain separate from each other when not actively synthesizing proteins. Ribosomes are granules approximately 25 nm in diameter, composed of rRNA molecules and proteins assembled into two unequal subunits. The subunits can be separated by their sedimentation coefficients (S) in an ultracentrifuge into larger 60S and smaller 40S components. These are associated with 73 different proteins (40 in the large subunit and 33 in the small), which have structural and enzymatic functions. Three small, highly convoluted rRNA strands (28S, 5.8S and 5S) make up the large subunit, and one strand (18S) is in the small subunit.

A typical cell contains millions of ribosomes. They may form groups (polyribosomes or polysomes) attached to messenger RNA (mRNA), which they translate during protein synthesis for use outside the system of membrane compartments, e.g. enzymes of the cytosol and cytoskeletal proteins. Some of the cytosolic products include proteins that can be inserted directly into (or through) membranes of selected organelles, such as mitochondria and peroxisomes. Ribosomes may be attached to the membranes of the rough endoplasmic reticulum (see Fig. 1.5B).

In a mature polyribosome, all the attachment sites of the mRNA are occupied as ribosomes move along it, synthesizing protein according to its nucleotide sequence. Consequently, the number and spacing of ribosomes in a polyribosome indicate the length of the mRNA molecule and hence the size of the protein being made. The two subunits have separate roles in protein synthesis. The 40S subunit is the site of attachment and translation of mRNA. The 60S subunit is responsible for the release of the new protein and, where appropriate, attachment to the endoplasmic reticulum via an intermediate docking protein that directs the newly synthesized protein through the membrane into the cisternal space.

Protein synthesis on ribosomes may be suppressed by a class of RNA molecules known as small interfering RNA (siRNA) or silencing RNA. These molecules are typically 20–25 nucleotides in length and bind (as a complex with proteins) to specific mRNA molecules via their complementary sequence. This triggers the enzymatic destruction of the mRNA or prevents the movement of ribosomes along it. Synthesis of the encoded protein is thus prevented. Their normal function may have antiviral or other protective effects; there is also potential for developing artificial siRNAs as a therapeutic tool for silencing disease-related genes.

Golgi apparatus (Golgi complex)

The Golgi apparatus is a distinct cytomembrane system located near the nucleus and the centrosome. It is particularly prominent in secretory cells and can be visualized when stained with silver or other metallic salts. Traffic between the endoplasmic reticulum and the Golgi apparatus is bidirectional and takes place via carrier vesicles derived from the donor site that bud, tether and fuse with the target site. Carrier vesicles in transit from the endoplasmic reticulum to the Golgi apparatus (anterograde transport) are coated by coat protein complex II (COPII), whereas COPI-containing vesicles function in the retrograde transport route from the Golgi apparatus (reviewed in Spang (2013)).

Golgins are long coiled-coil proteins attached to the cytoplasmic surface of cisternal membranes, forming a fibrillar matrix surrounding the Golgi apparatus to stabilize it; they have a role in vesicle trafficking (Witkos and Lowe 2015). The Golgi apparatus has several functions: it links anterograde and retrograde protein and lipid flow in the secretory pathway; it is the site where protein and lipid glycosylation occurs; and it provides membrane platforms to which signalling and sorting proteins bind.

Ultrastructurally, the Golgi apparatus (**Fig. 1.6A**) displays a continuous ribbon-like structure consisting of a stack of several flattened membranous cisternae, together with clusters of vesicles surrounding its surfaces. Cisternae differ in their enzymatic content and activity. Small transport vesicles from the rough endoplasmic reticulum are received at one face of the Golgi stack, the convex *cis*-face (entry or forming surface). Here, they deliver their contents to the first cisterna in the series by membrane fusion. The protein is transported from the edges of this cisterna to the next cisterna by vesicular budding and then fusion, and this process is repeated across medial cisternae until the final cisterna at the concave *trans*-face (exit or condensing surface) is reached. Here, larger vesicles are formed for delivery to other parts of the cell.

The *cis*-Golgi and *trans*-Golgi membranous networks form an integral part of the Golgi apparatus (**Fig. 1.6B**). The *cis*-Golgi network is a region of complex membranous channels interposed between the rough endoplasmic reticulum and the Golgi *cis*-face, which receives and transmits vesicles in both directions. Its function is to select appropriate proteins synthesized on the rough endoplasmic reticulum for delivery by vesicles to the Golgi stack, while inappropriate proteins are shuttled back to the rough endoplasmic reticulum.

The *trans*-Golgi network, at the other side of the Golgi stack, is also a region of interconnected membrane channels engaged in protein sorting. Here, modified proteins processed in the Golgi cisternae are packaged selectively into vesicles and dispatched to different parts of the cell. The packaging depends on the detection, by the *trans*-Golgi network, of particular amino acid signal sequences, leading to their enclosure in membranes of appropriate composition that will further modify their contents, e.g. by extracting water to concentrate them (vesicles entering the exocytosis pathway) or by pumping in protons to acidify their contents (lysosomes destined for the intracellular sorting pathway). The membranes contain specific signal proteins that may allocate them to microtubule-based transport pathways and allow them to dock with appropriate targets elsewhere in the cell, e.g. the plasma membrane in the case of secretory vesicles. Vesicle formation and budding at the *trans*-Golgi network involves the addition of clathrin on their external surface, to form coated pits.

Within the Golgi stack proper, proteins undergo a series of sequential chemical modifications by Golgi resident enzymes synthesized in the rough endoplasmic reticulum. These include glycosylation (changes in glycosyl groups, e.g. removal of mannose, addition of *N*-acetylglucosamine and sialic acid); sulphation (addition of sulphate groups to glycosaminoglycans); and phosphorylation (addition of phosphate groups). Some modifications serve as signals to direct proteins and lipids to their final destination within cells, including lysosomes and plasma membrane. Lipids formed in the endoplasmic reticulum are also routed for incorporation into vesicles.

Exocytic (secretory) pathway

Secreted proteins, lipids, glycoproteins, small molecules such as amines, and other cellular products destined for export from the cell are

transported to the plasma membrane in small vesicles released from the *trans*-face of the Golgi apparatus. This pathway is either constitutive, in which transport and secretion occur more or less continuously, as with immunoglobulins produced by plasma cells, or it is regulated by external signals, as in the control of salivary secretion by autonomic neural stimulation. In regulated secretion, the secretory product is stored temporarily in membrane-bound secretory granules or vesicles. Exocytosis is achieved by fusion of the secretory vesicular membrane with the plasma membrane and release of the vesicle contents into the extracellular domain. In polarized cells, e.g. most epithelia, exocytosis occurs at the apical plasma membrane. Glandular epithelial cells secrete into a duct lumen, as in the pancreas, or on to a free surface, such as the lining of the stomach. In hepatocytes, bile is secreted across a very small area of plasma membrane forming the wall of the bile canaliculus. This region, the apical plasma membrane, is the site of exocrine secretion, whereas secretion of hepatocyte plasma proteins into the blood stream is targeted to the basolateral surfaces facing the sinusoids. Packaging of different secretory products into appropriate vesicles takes place in the *trans*-Golgi network. Delivery of secretory vesicles to their correct plasma membrane domains is achieved by sorting sequences in the cytoplasmic tails of vesicular membrane proteins.

Endocytic (internalization) pathway

The endocytic pathway begins at the plasma membrane and ends in lysosomes (see below) involved in the degradation of the endocytic cargo through the enzymatic activity of lysosomal hydrolases. Endocytic cargo is internalized from the plasma membrane to early endosomes and then to late endosomes. Late endosomes transport their cargo to lysosomes, where the cargo material is degraded following fusion and mixing of contents of endosomes and lysosomes. Early endosomes derive from endocytic vesicles (clathrin-coated vesicles and caveolae). Once internalized, endocytic vesicles shed their coat of adaptin and clathrin, and fuse to form an early endosome, where the receptor molecules release their bound ligands. Membrane and receptors from the early endosomes can be recycled to the cell surface as exocytic vesicles.

Clathrin-dependent endocytosis occurs at specialized patches of plasma membrane called coated pits: this mechanism is also used to

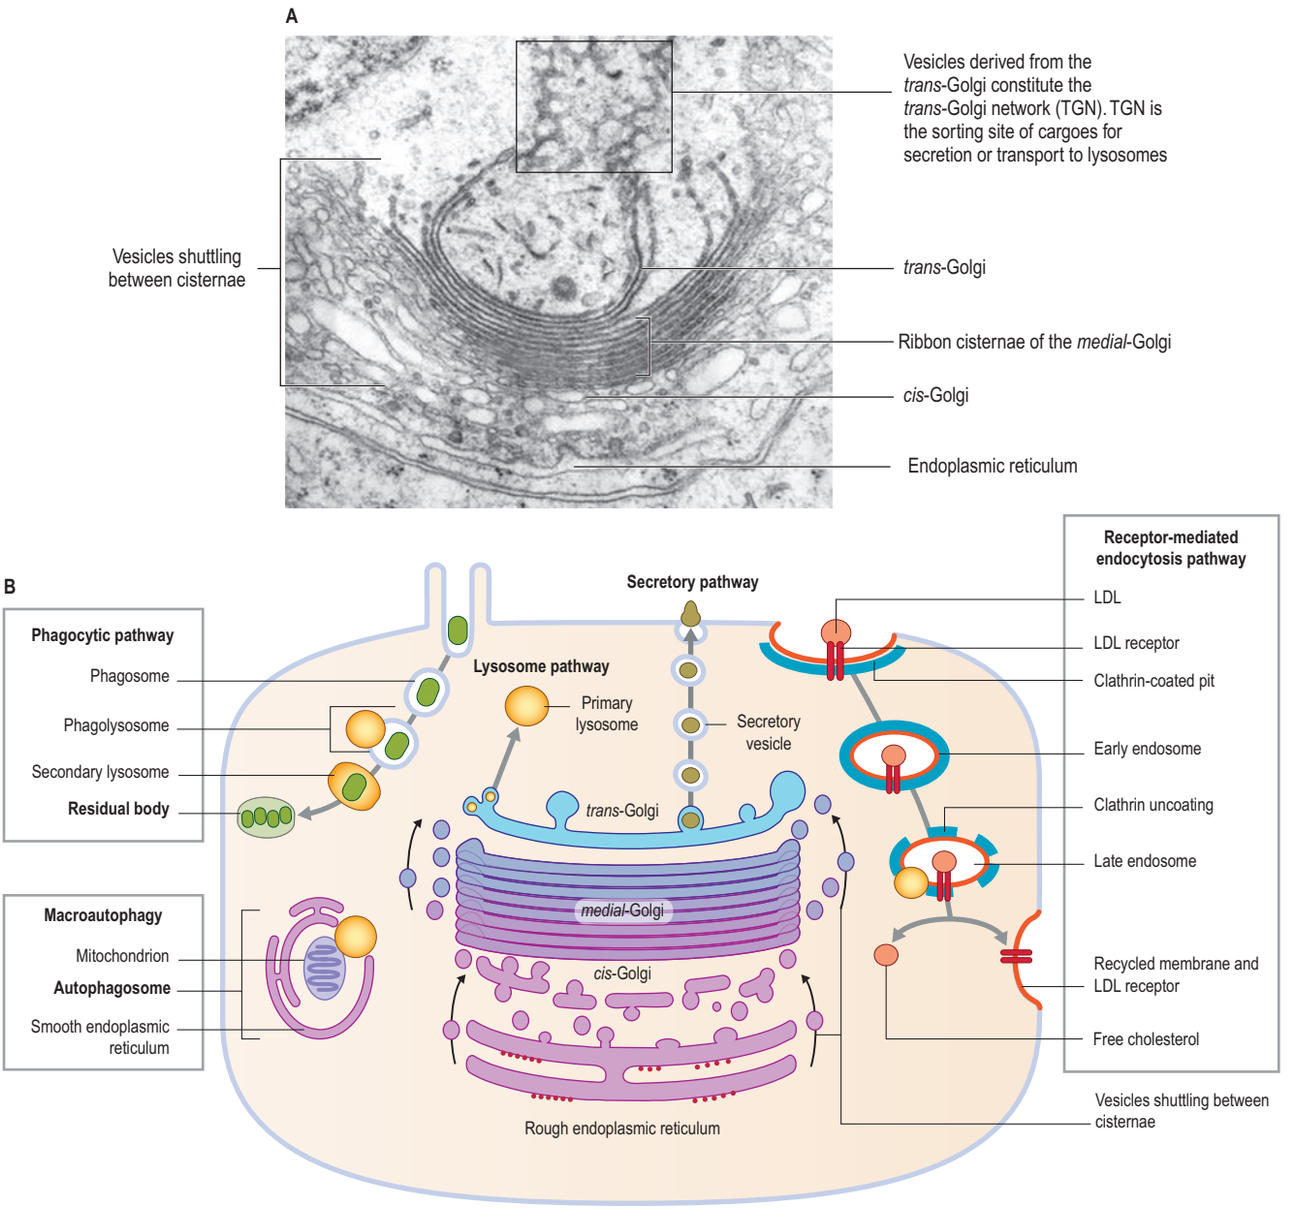

Fig. 1.6 A, The Golgi apparatus consists of four major functionally distinct compartments. Products derived from the endoplasmic reticulum enter the Golgi apparatus at the *cis*-Golgi. Cargoes exit at the *trans*-Golgi. The *medial*-Golgi is a stack of ribbon-like cisternae interposed between the *cis*-Golgi and the *trans*-Golgi. Cargoes destined for transport to lysosomes or secretion (exocytosis) are sorted in the *trans*-Golgi network (TGN). **B**, There are three major pathways for the intracellular degradation of materials. Extracellular particles can be taken up by phagocytosis and receptor-mediated endocytosis. Aged intracellular components are degraded by macroautophagy, a non-selective process. The Golgi apparatus releases vesicles for secretion or lysosome-containing vesicles that remain in the cell. Lysosomes are organelles that contain about 40 types of hydrolytic enzymes active in an acidic environment (pH approximately 5.0).

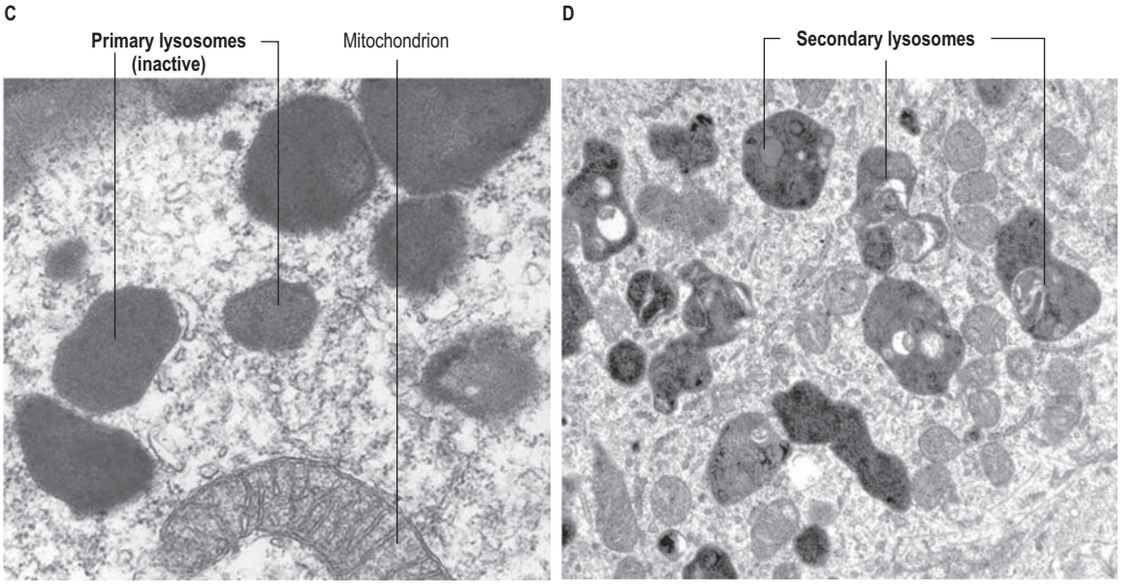

Fig. 1.6, cont'd C, Primary lysosomes are inactive storage sites for hydrolytic enzymes. **D**, Secondary lysosomes are engaged in degradation and contain remnants of the degraded structures. (A, C and D with permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

internalize ligands bound to surface receptor molecules and is also termed receptor-mediated endocytosis. Caveolae are structurally distinct pinocytotic vesicles most widely used by endothelial and smooth muscle cells, where they are involved in transcytosis, signal transduction and possibly other functions. In addition to late endosomes, lysosomes can also fuse with phagosomes, autophagosomes and plasma membrane patches for membrane repair. Lysosomal hydrolases process or degrade exogenous materials (phagocytosis or heterophagy) as well as endogenous material (autophagy). Phagocytosis consists of the cellular uptake of invading pathogens, apoptotic cells and other foreign material by specialized cells. Lysosomes are numerous in actively phagocytic cells, e.g. macrophages and neutrophil granulocytes, where they are responsible for destroying phagocytosed particles, e.g. bacteria. These cells may contain phagosomes, vesicles that potentially contain a pathogenic microorganism and that may fuse with several lysosomes.

Specialized cells of the immune system, antigen-presenting cells (APCs), degrade protein molecules (antigens) transported by the endocytic pathway for lysosomal breakdown, and expose their fragments to the cell exterior to elicit an immune response, that is mediated initially by helper T cells.

Late endosomes receive lysosomal enzymes from primary lysosomes (**Fig. 1.6C**) derived from the Golgi apparatus after late endosome–lysosome membrane tethering and fusion followed by diffusion of lysosomal contents into the endosomal lumen. The pH inside the fused hybrid organelle, now called a secondary lysosome, is low (about 5.0): this activates lysosomal acid hydrolases to degrade the endosomal contents. The products of hydrolysis are either passed through the membrane into the cytosol, or they may be retained in the secondary lysosome (**Fig. 1.6D**). Secondary lysosomes may grow considerably in size by vesicle fusion to form multivesicular bodies; the enzyme concentration may increase greatly to form large lysosomes.

Lysosomes

Lysosomes are membrane-bound organelles 80–800 nm in diameter, often with complex inclusions of material undergoing hydrolysis (secondary lysosomes). Two classes of protein participate in lysosomal function, namely soluble acid hydrolases and integral lysosomal membrane proteins. Each of the 60 or more known acid hydrolases (including proteases, lipases, carbohydrases, esterases and nucleases) degrades a specific substrate. There are about 25 lysosomal membrane proteins participating in the acidification of the lysosomal lumen, protein import from the cytosol, membrane fusion and transport of degradation products to the cytoplasm. Material that has been hydrolysed within secondary lysosomes may be completely degraded to soluble products, e.g. amino acids, which are recycled through metabolic pathways. However, degradation is usually incomplete and some debris remains. A debris-laden vesicle is called a residual body or tertiary lysosome (see Fig. 1.6B), and may be passed to the cell surface, where it is ejected by exocytosis; alternatively, it may persist inside the cell as an inert residual body. Considerable numbers of residual bodies can accumulate in long-lived cells, often fusing to form larger dense vacuoles with complex lamellar inclusions. As their contents are often darkly pigmented, this may change the colour of the tissue; e.g. in neurones, the end-product of lysosomal digestion, lipofuscin (neuromelanin or senility pigment), gives ageing brains a brownish-yellow coloration. Lysosomal enzymes may also be secreted – often as part of a process to alter the extracellular matrix, as in osteoclast-mediated erosion during bone resorption. For further reading on lysosome biogenesis, see Saftig and Klumperman (2009).

Lysosomal dysfunction

The transcription factor EB (TFEB) is responsible for regulating lysosomal biogenesis and function, lysosome-to-nucleus signalling and lipid catabolism (for further reading, see Settembre et al (2013)). If there is a failure of any of the actions of lysosomal hydrolases, of the lysosome acidification mechanism or of lysosomal membrane proteins, there is progressive lysosomal dysfunction in several tissues and organs. This may be due to faulty degradation and recycling of extracellular substrates delivered to lysosomes by the late endosome or the defective degradation and recycling of intracellular substrates by autophagy.

Lysosomal storage disorders (LSDs) are a consequence of lysosomal dysfunction. Approximately 60 different types of LSD have been identified on the basis of the type of material accumulated in cells (such as mucopolysaccharides, sphingolipids, glycoproteins, glycogen and lipofuscins).

Peroxisomes

Peroxisomes are small (0.2–1 μm in diameter) membrane-bound organelles present in most mammalian cells. They contain more than 50 enzymes responsible for multiple catabolic and synthetic biochemical pathways, in particular the β-oxidation of very-long-chain fatty acids (>C22) and the metabolism of hydrogen peroxide (hence the name peroxisome). Peroxisomes may be derived from pre-existing peroxisomes that divide by fission. Alternatively, they may arise *de novo* by budding as pre-peroxisomal vesicles from the endoplasmic reticulum and possibly from mitochondria (Farré et al 2019). All matrix proteins and some peroxisomal membrane proteins are synthesized by cytosolic ribosomes and contain a peroxisome targeting signal that enables them to be imported by proteins called peroxins (Braverman et al 2013, Theodoulou et al 2013).

Peroxisomes often contain crystalline inclusions composed mainly of high concentrations of the enzyme urate oxidase. Oxidases use molecular oxygen to oxidize specific organic substrates (such as L-amino acids, D-amino acids, urate, xanthine and very-long-chain fatty acids) and produce hydrogen peroxide that is detoxified (degraded) by peroxisomal catalase. Peroxisomes are important in the oxidative detoxification of various substances taken into or produced within cells. They are particularly numerous in hepatocytes.

LSDs are characterized by severe neurodegeneration, mental decline, and cognitive and behavioural abnormalities. Autophagy impairment caused by defective lysosome–autophagosome coupling triggers a pathogenic cascade by the accumulation of substrates that contribute to neurodegenerative disorders, including Parkinson's disease, Alzheimer's disease, Huntington's disease and several tau-opathies. In Tay–Sachs disease (GM2 gangliosidosis), a faulty β-hexosaminidase A leads to the accumulation of the glycosphingolipid GM2 ganglioside in neurones, causing death during childhood. In Danon disease, a vacuolar skeletal myopathy and cardiomyopathy with neurodegeneration in hemizygous males, lysosomes fail to fuse with autophagosomes because of a mutation of the lysosomal membrane protein LAMP-2 (lysosomal-associated membrane protein-2).

Peroxin mutation is a characteristic feature of Zellweger syndrome (craniofacial dysmorphism and malformations of brain, liver, eye and kidney; cerebrohepatorenal syndrome). Neonatal leukodystrophy is an X-linked peroxisomal disease affecting mostly males, caused by deficiency in β-oxidation of very-long-chain fatty acids.

The build-up of very-long-chain fatty acids in the nervous system and suprarenal glands determines progressive deterioration of brain function and suprarenal insufficiency (Addison's disease). For further reading, see Braverman et al (2013).

Mitochondria

Mitochondria appear in the light microscope as long, thin structures in the cytoplasm of most cells, particularly those with a high metabolic rate, e.g. secretory cells in exocrine glands. In the electron microscope, mitochondria usually appear as round or elliptical bodies 0.5–2.0 µm long (Fig. 1.7), consisting of an outer mitochondrial membrane; an inner mitochondrial membrane, separated from the outer membrane by an intermembrane space; cristae, infoldings of the inner membrane that harbour ATP synthase to generate ATP; and the mitochondrial matrix, a space enclosed by the inner membrane and numerous cristae. The permeability of the two mitochondrial membranes differs considerably: the outer membrane is freely permeable to many substances because of the presence of large non-specific channels formed by proteins (porins), whereas the inner membrane is permeable to only a narrow range of molecules. The presence of cardiolipin, a phospholipid, in the inner membrane may contribute to this relative impermeability.

Mitochondria are the principal source of chemical energy in most cells. They are the site of the citric acid (Krebs') cycle and the electron transport (cytochrome) pathway by which complex organic molecules are finally oxidized to carbon dioxide and water. This process provides the energy to drive the production of ATP from adenosine diphosphate (ADP) and inorganic phosphate (oxidative phosphorylation). The various enzymes of the citric acid cycle are located in the mitochondrial matrix, whereas those of the cytochrome system and oxidative phosphorylation are localized chiefly in the inner mitochondrial membrane. The intermembrane space houses cytochrome *c*, a molecule involved in activation of apoptosis.

The number of mitochondria in a particular cell reflects its general energy requirements; e.g. in hepatocytes there may be as many as 2000, whereas in resting lymphocytes there are usually very few. Mature erythrocytes lack mitochondria altogether. Cells with few mitochondria generally rely largely on glycolysis for their energy supplies. These include some very active cells, e.g. fast-twitch skeletal muscle fibres, which are able to work rapidly but for only a limited duration. Mitochondria are distributed within a cell according to regional energy requirements, e.g. near the bases of cilia in ciliated epithelia, in the basal domain of the cells of proximal convoluted tubules in the renal cortex (where considerable active transport occurs) and around the proximal segment, called the middle piece, of the flagellum in spermatozoa. In living cells, mitochondria constantly change shape and intracellular position; they multiply by growth and fission, and may undergo fusion.

Mitochondria may be involved in tissue-specific metabolic reactions, e.g. various urea-forming enzymes are found in liver cell mitochondria. Moreover, a number of genetic diseases of mitochondria affect particular tissues exclusively, e.g. mitochondrial myopathies (skeletal muscle) and mitochondrial neuropathies (nervous tissue).

The mitochondrial matrix is an aqueous environment. It contains a variety of enzymes, and strands of mitochondrial DNA with the capacity for transcription and translation of a unique set of mitochondrial genes (mitochondrial mRNAs and transfer RNAs, mitochondrial ribosomes with rRNAs). The DNA forms a closed loop, about 5 µm across and several identical copies are present in each mitochondrion. The ratio between its bases differs from that of nuclear DNA; the RNA sequences also differ in the precise genetic code used in protein synthesis. At least 13 respiratory chain enzymes of the matrix and inner membrane are encoded by the small number of genes along the mitochondrial DNA (mtDNA). The great majority of mitochondrial proteins are encoded by nuclear genes and made in the cytosol, then inserted through special channels in the mitochondrial membranes to reach their destinations. Their membrane lipids are synthesized in the endoplasmic reticulum.

Mitochondrial ribosomes are smaller and quite distinct from those of the rest of the cell in that they (and mitochondrial nucleic acids) resemble those of bacteria. This similarity underpins the theory that mitochondrial ancestors were oxygen-utilizing bacteria that existed in a symbiotic relationship with eukaryotic cells unable to metabolize the oxygen produced by early plants.

It has been shown that mitochondria are of maternal origin because the mitochondria of spermatozoa are not generally incorporated into the ovum at fertilization. As mitochondria are formed only from previously existing ones, it follows that all mitochondria in the body are descended from those in the cytoplasm of the ovum. Thus mitochondria (and mitochondrial genetic variations and mutations) are passed only through the female line. For further information on mitochondrial genetics and disorders, see Chinnery and Hudson (2013).

Mitochondrial replacement therapies

Available with the *Gray's Anatomy* e-book

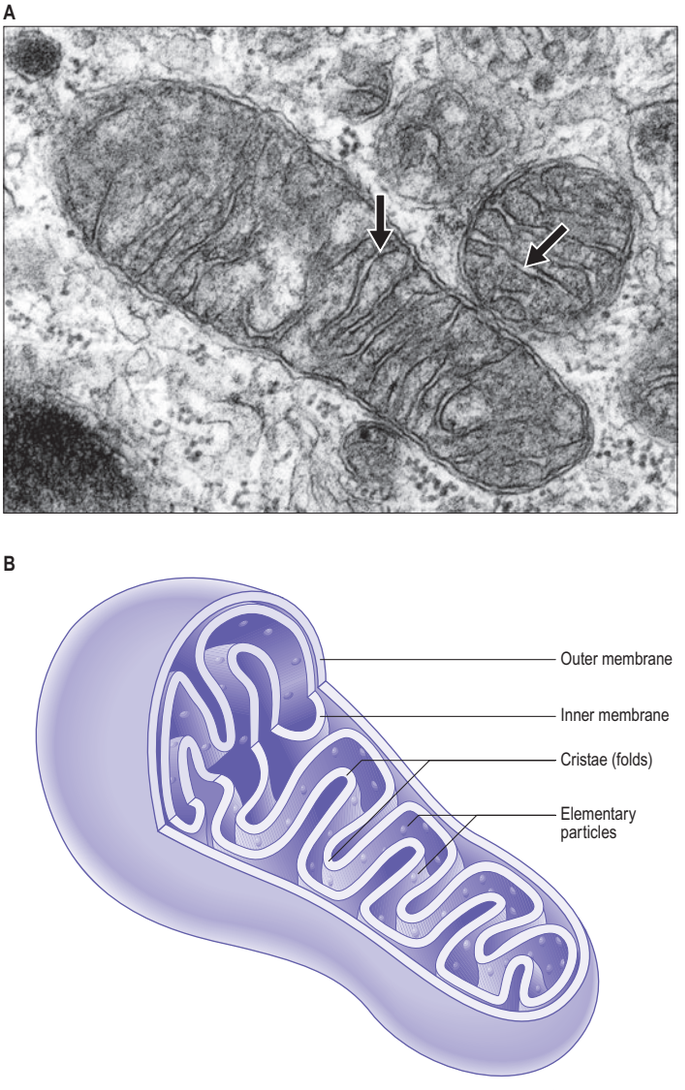

Fig. 1.7 A, Mitochondria in human cardiac muscle. Cytosolic inclusions

The aqueous cytosol surrounds the membranous organelles described above. It also contains various non-membranous inclusions, including free ribosomes, components of the cytoskeleton, and other inclusions, such as storage granules (e.g. glycogen), pigments (such as lipofuscin granules, remnants of the lipid oxidative mechanism seen in the suprarenal cortex).

Lipid droplets

Lipid droplets are spherical bodies of various sizes found within many cells, but are especially prominent in the adipocytes (fat cells) of adipose connective tissue. They do not belong to the Golgi-related vacuolar system of the cell. Lipid droplets, suspended in the cytosol, are surrounded by perilipin proteins, which regulate lipid storage and lipolysis. (See Smith and Ordovás (2012) for further reading on obesity and perilipins.) In cells specialized for lipid storage, the vacuoles reach 80 µm or more in diameter. They function as stores of chemical energy, thermal insulators and mechanical shock absorbers in adipocytes. In many cells, they may represent end-products of other metabolic pathways, e.g. in steroid-synthesizing cells, where they are a prominent feature of the cytoplasm. They may also be secreted, as in the alveolar epithelium of the lactating breast.

Cristae are abundant in mitochondria within cardiac muscle cells and in steroid-producing cells (in the suprarenal cortex, corpus luteum and Leydig cells). The protein, steroidogenic acute regulatory protein (StAR), regulates the synthesis of steroids by transporting cholesterol across the outer mitochondrial membrane. A mutation in the gene encoding StAR causes defective suprarenal and gonadal steroidogenesis.

Mitochondrial replacement therapies have been developed to resolve mitochondrial disorders of maternal origin, e.g. by transplantating the pronucleus from an egg containing mutant mtDNA from a carrier mother to an enucleated egg from an unaffected donor (Fig. 1.8). This procedure can be performed after in vitro fertilization using sperm from the intended father. Soon after fertilization, the haploid maternal and paternal nuclei are assembled as a pronucleus. Because it is difficult to distinguish between male and female pronuclei, pronuclear transfer (PNT) involves transplantation of both the maternal and paternal pronuclei, clearly visualized by light microscopy. mtDNA resides within mitochondria, separately from the genes housed in each cell nucleus. Since mitochondria are inherited only through the maternal germline, mutated mitochondria are thus replaced with normal mitochondria from enucleated oocytes provided by the unaffected donor. An alternative procedure involves transfer of the nuclear genetic material from the affected female (maternal spindle transfer, MST) into an enucleated donor egg with normal mitochondria, prior to fertilization.

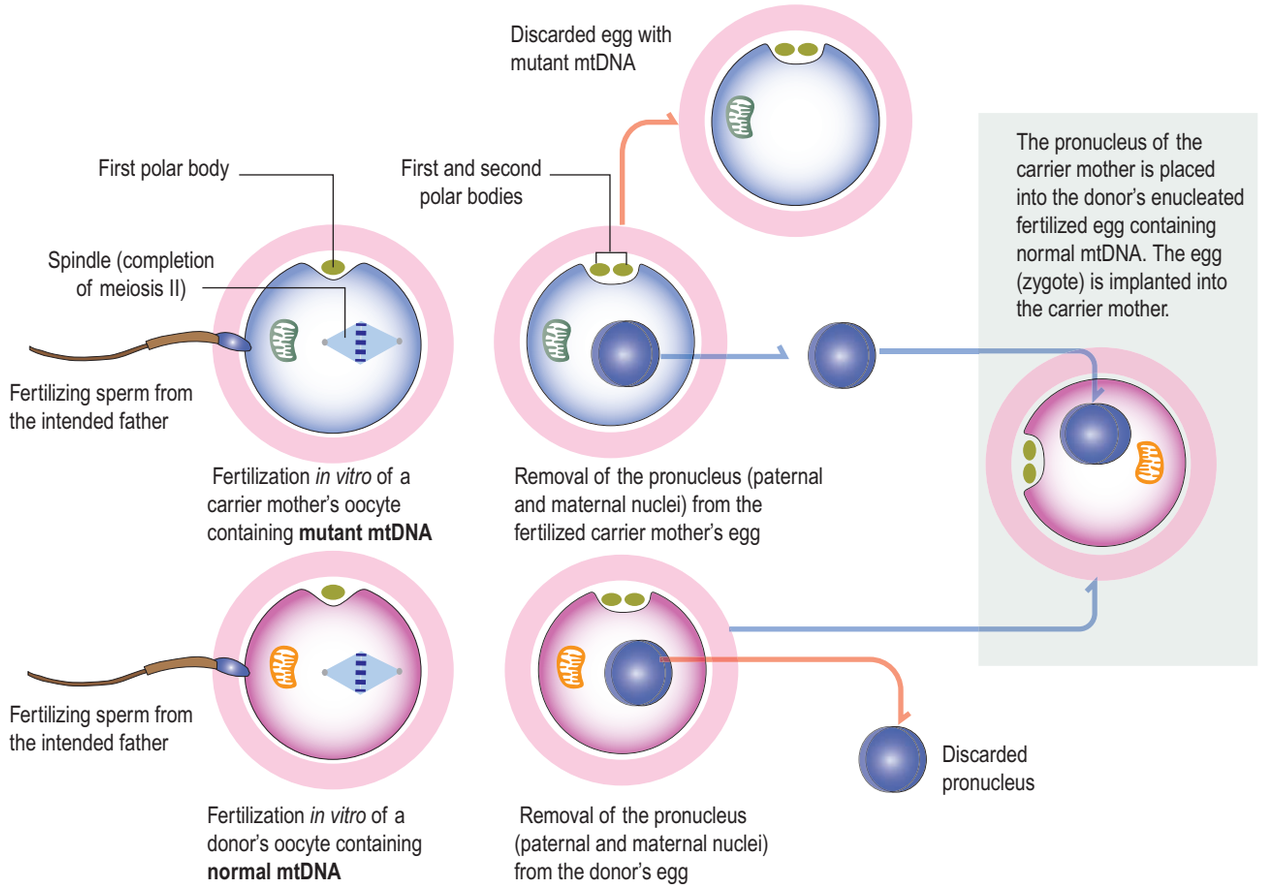

Fig. 1.8 Mitochondrial replacement by pronuclear transfer. Mitochondrial DNA (mtDNA) is transmitted by the mother (maternal inheritance). Both males and females can be affected by mitochondrial diseases, but males do not transmit the disorder to their offspring. One mitochondrial replacement therapy involves the transplantation of the pronucleus from an egg containing mutant mtDNA from a carrier mother to an enucleated egg from an unaffected donor. This can be performed after in vitro fertilization using sperm from the intended father. Cell signalling

Cellular systems in the body communicate with each other to coordinate and integrate their functions, through a variety of processes known collectively as cell signalling, in which a signalling molecule produced by one cell is detected by another, almost always by means of a specific receptor protein molecule. The recipient cell transduces the signal, which it most often detects at the plasma membrane, into intracellular chemical messages that change cell behaviour.

The signal may act over a long distance, e.g. endocrine signalling through the release of hormones into the blood stream, or neuronal synaptic signalling via electrical impulse transmission along axons and subsequent release of chemical transmitters of the signal at synapses or neuromuscular junctions. A specialized variation of endocrine signalling (neurocrine or neuroendocrine signalling) occurs when neurones or paraneurones (e.g. chromaffin cells of the suprarenal medulla) secrete a hormone into interstitial fluid and the blood stream. Alternatively, signalling may occur at short range through a paracrine mechanism, in which cells of one type release molecules into the interstitial fluid of the local environment, to be detected by nearby cells of a different type that express the specific receptor protein.

Neurocrine cell signalling uses chemical messengers found also in the central nervous system, which may act in a paracrine manner via interstitial fluid or reach more distant target tissues via the blood stream. Cells may generate and respond to the same signal. This is autocrine signalling, a phenomenon that reinforces the coordinated activities of a group of like cells, which respond together to a high concentration of a local signalling molecule. The most extreme form of short-distance signalling is contact-dependent (juxtacrine) signalling, where one cell responds to transmembrane proteins of an adjacent cell that bind to surface receptors in the responding cell membrane. Contact-dependent signalling also includes cellular responses to integrins on the cell surface binding to elements of the extracellular matrix. Juxtacrine signalling is important during development and in immune responses. These different types of intercellular signalling mechanism are illustrated in Fig. 1.9.

Signalling molecules and their receptors

The majority of signalling molecules (ligands) are hydrophilic and so cannot cross the plasma membrane of a recipient cell to effect changes inside the cell unless they first bind to a plasma membrane receptor protein. Ligands are mainly proteins (usually glycoproteins), polypeptides or highly charged biogenic amines. They include classic peptide hormones of the endocrine system; cytokines, which are mainly of haemopoietic cell origin and involved in inflammatory responses and tissue remodelling (e.g. the interferons, interleukins, tumour necrosis factor, leukaemia inhibitory factor); and polypeptide growth factors (e.g. the epidermal growth factor superfamily, nerve growth factor, platelet-derived growth factor, the fibroblast growth factor family, transforming growth factor beta and the insulin-like growth factors). Polypeptide growth factors are multifunctional molecules with more widespread actions and cellular sources than their names suggest. They and their receptors are commonly mutated or aberrantly expressed in certain cancers. The cancer-causing gene variant is termed a transforming oncogene and the normal (wild-type) version of the gene is a cellular oncogene or proto-oncogene. The activated receptor acts as a transducer to generate intracellular signals, which are either small diffusible second messengers (e.g. calcium, cyclic adenosine monophosphate or the plasma membrane lipid-soluble diacylglycerol), or larger protein complexes that amplify and relay the signal to target control systems.

Some signals are hydrophobic and able to cross the plasma membrane freely. Classic examples are the steroid hormones, thyroid hormones, retinoids and vitamin D. Steroids, for instance, enter cells non-selectively, but elicit a specific response only in those target cells that express specific cytoplasmic or nuclear receptors. Light stimuli also cross the plasma membranes of photoreceptor cells and interact intracellularly, at least in rod cells, with membrane-bound photosensitive receptor proteins. Hydrophobic ligands are transported in the blood stream or interstitial fluids, generally bound to carrier proteins, and they often have a longer half-life and longer-lasting effects on their targets than do water-soluble ligands.

A separate group of signalling molecules that are able to cross the plasma membrane freely is typified by the gas, nitric oxide. The principal target of short-range nitric oxide signalling is smooth muscle, which relaxes in response. Nitric oxide is released from vascular endothelium as a result of the action of autonomic nerves that supply the vessel wall, causing local relaxation of smooth muscle and consequent dilation of the vessel. This mechanism is responsible for penile erection. Nitric oxide

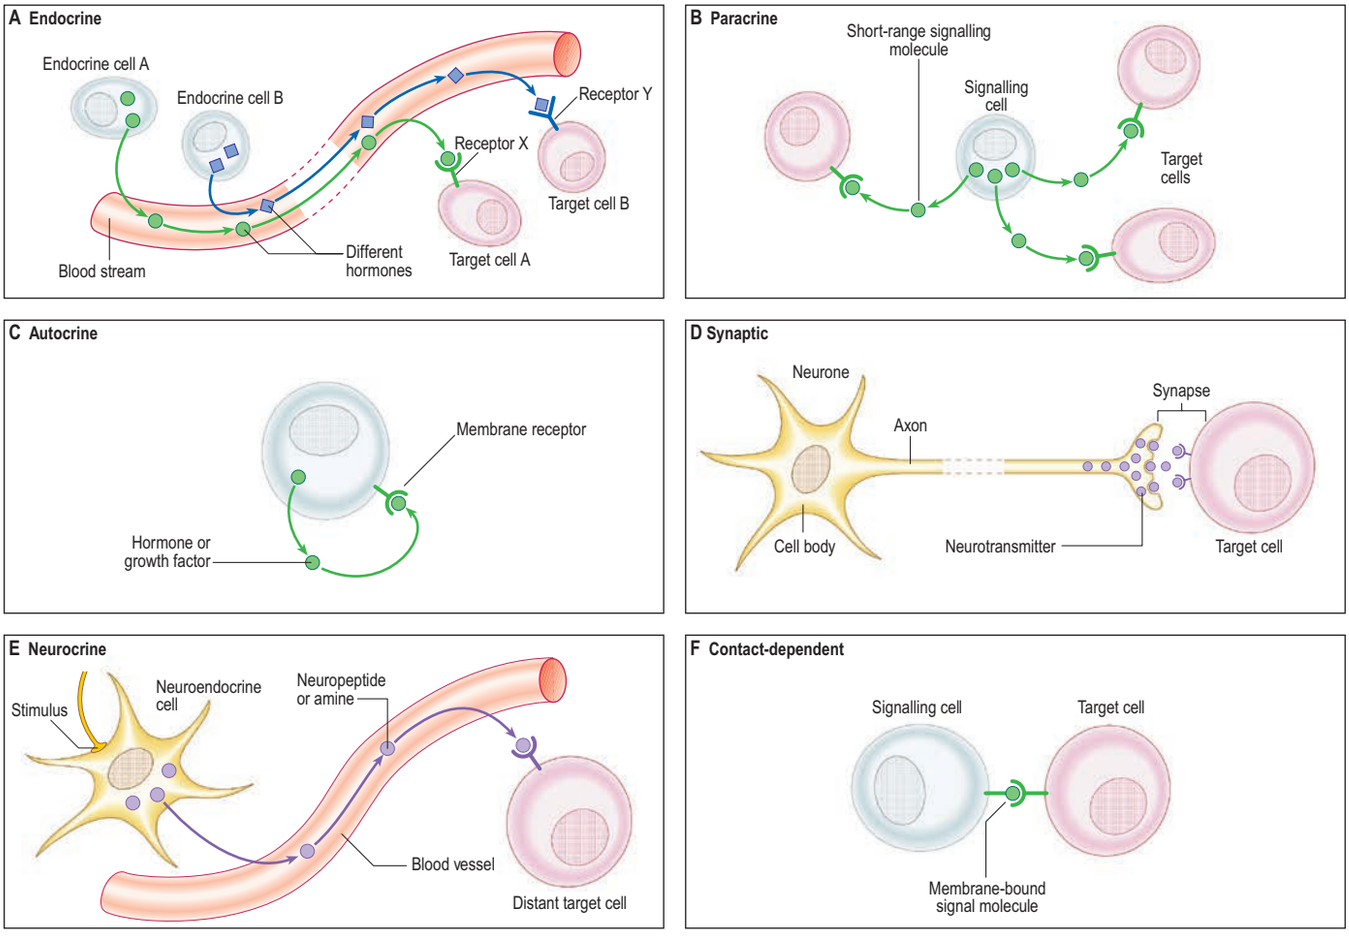

Fig. 1.9 The different modes of cell–cell signalling.

is unusual among signalling molecules in having no specific receptor protein; it acts directly on intracellular enzymes of the response pathway.

Receptor proteins

There are some 20 different families of receptor proteins, each with several isoforms responding to different ligands. The great majority of these receptors are transmembrane proteins. Members of each family share structural features that indicate either shared ligand-binding characteristics in the extracellular domain or shared signal transduction properties in the cytoplasmic domain, or both. There is little relationship either between the nature of a ligand and the family of receptor proteins to which it binds and activates, or the signal transduction strategies by which an intracellular response is achieved. The same ligand may activate fundamentally different types of receptor in different cell types.

Cell surface receptor proteins are generally grouped according to their linkage to one of three intracellular systems: ion channel-linked receptors; G-protein coupled receptors; or receptors that link to enzyme systems. Other receptors do not fit neatly into any of these categories. All the known G-protein-coupled receptors belong to a structural group of proteins that pass through the membrane seven times in a series of serpentine loops: these receptors are thus known as seven-pass transmembrane receptors or, because the transmembrane regions are formed from α-helical domains, as seven-helix receptors. The best known of this large group of phylogenetically ancient receptors are the odorant-binding proteins of the olfactory system; the light-sensitive receptor protein, rhodopsin; and many of the receptors for clinically useful drugs. A comprehensive list of receptor proteins, their activating ligands and examples of the resultant biological function is given in Pollard et al (2016).

Major signalling pathways

Most cell surface receptors stimulate intracellular target enzymes to transmit and amplify a signal upon ligand binding. A signalling pathway can activate a series of intracellular targets located downstream of the receptor, in particular the activity of intracellular proteins, or, like neurotransmitter receptors, control the flow of water (aquaporins) and electrolytes across ligand-gated ion channels located on the plasma membrane. An amplified signal can be propagated to the nucleus to regulate gene expression in response to an external cell stimulus.

The cyclic adenosine monophosphate (cAMP) pathway is a major intracellular signalling pathway. For example, there is an increase in the intracellular concentration of cAMP when adrenaline (epinephrine) binds to its receptor. Adrenaline breaks down glycogen into glucose before muscle contraction. cAMP is formed from ATP by the action of the enzyme adenylyl cyclase and degraded to adenosine monophosphate (AMP) by the enzyme cAMP phosphodiesterase. This mechanism led to the concept of a first messenger (adrenaline) mediating a cell-signalling effect by a second messenger, cAMP.

Signalling pathways play important roles in embryonic and fetal development, body axis patterning, cell migration and cell proliferation. They all contain components subject to diverse regulatory steps and crosstalk mechanisms and some use different downstream effectors activated by specific transcription factors. The following signalling pathways have clinical relevance: the JAK–STAT, Hedgehog (Hh), Wingless (Wnt) and transforming growth factor (TGF)-β signalling pathways. For example, erythropoietin stimulates the development of the erythroid lineage (red blood cell formation) in bone marrow by a mechanism that involves the JAK–STAT pathway (**Fig. 1.11**).

Cytoskeleton

The cytoskeleton is a three-dimensional network of filamentous intracellular proteins of different shapes, sizes and composition distributed throughout the cytoplasm. It provides mechanical support, maintains cell shape and rigidity, and enables cells to adopt highly asymmetric or irregular profiles. It plays an important part in establishing structural polarity and different functional domains within a cell. It also provides mechanical support for permanent projections from the cell surface (see below), including persistent microvilli and cilia, and transient processes, such as the thin finger-like protrusions called filopodia (0.1–0.3 μm) and lamellipodia (0.1–0.2 μm). Filopodia consist of parallel bundles of actin filaments and have a role in cell migration, wound healing and neurite growth. The protrusive thin and broad lamellipodia, found at the leading edge of a motile cell, contain a branched network of actin filaments.

The cytoskeleton restricts specific structures to particular cellular locations. For example, the Golgi apparatus is near the nucleus and endoplasmic reticulum, and mitochondria are near sites of energy requirement. In addition, the cytoskeleton provides tracks for intracellular transport (e.g. shuttling vesicles and macromolecules, called cargoes, among cytoplasmic sites), the movement of chromosomes during cell division (mitosis and meiosis) or movement of the entire cell during embryonic morphogenesis or the chemotactic extravascular migration of leukocytes during homing. Examples of highly developed and specialized functions of the cytoskeleton include the contraction of the sarcomere in striated muscle cells and the bending of the axoneme of cilia and flagella.

The catalogue of cytoskeletal structural proteins is extensive and still increasing. The major filamentous structures found in non-muscle cells are microfilaments (7 nm thick), microtubules (25 nm thick) and intermediate filaments (10 nm thick). Other important components are proteins that bind to the principal filamentous types to assemble or disassemble them, regulate their stability or generate movement. These include actin-binding proteins such as myosin, which in some cells can assemble into thick filaments, and microtubule-associated proteins. Pathologies involving cytoskeletal abnormalities include ciliopathies (resulting from the abnormal assembly and function of centrioles, basal bodies and cilia); neurodegenerative diseases (a consequence of defective anterograde transport of neurotransmitters along microtubules in axons); and sterility (determined by defective or absent microtubule-associated dynein in axonemes, e.g. Kartagener's syndrome).

Actin filaments (microfilaments)

Actin filaments are flexible filaments, 7 nm thick (**Fig. 1.13A**). Within most cell types, actin constitutes the most abundant protein and in some motile cells its concentration may exceed 200 μM (10 mg protein per ml cytoplasm). The filaments are formed by the ATP-dependent polymerization of actin monomer (with a molecular mass of 43 kDa) into a characteristic string of beads in which the subunits are arranged in a linear tight helix with a distance of 13 subunits between turns (Dominguez 2010). The polymerized filamentous form is termed F-actin (filamentous actin) and the unpolymerized monomeric form is known as G-actin (globular actin). Each monomer has an asymmetric structure. When monomers polymerize, they confer a defined polarity on the filament: the plus or barbed end favours monomer addition, and the minus or pointed end favours monomer dissociation.

Treadmilling designates the simultaneous polymerization of an actin filament at one end and depolymerization at the other end to maintain its constant length.

See Bray (2001) for further reading.

Actin-binding proteins

A wide variety of actin-binding proteins are capable of modulating the form of actin within the cell. These interactions are fundamental to the organization of cytoplasm and to cell shape. The actin cytoskeleton is organized as closely packed parallel arrays of actin filaments forming bundles or cables, or loosely packed criss-crossed actin filaments forming networks (**Fig. 1.14A**). Actin-binding proteins hold together bundles and networks of actin filaments. Actin-binding proteins can be grouped into G-actin (monomer) binding proteins and F-actin (polymer) capping, cross-linking and severing proteins. Actin-binding proteins may have more than one function.

Capping proteins bind to the ends of the actin filament either to stabilize an actin filament or to promote its disassembly (see Fig. 1.13A).

Cross-linking or bundling proteins tie actin filaments together in longitudinal arrays to form bundles, cables or core structures. The bundles may be closely packed in microvilli and filopodia, where parallel filaments are tied tightly together to form stiff bundles orientated in the same direction. Cross-linking proteins of the microvillus actin bundle core include fimbrin and villin.

Other actin-bundling proteins form rather looser bundles of filaments that run antiparallel to each other with respect to their plus and minus ends. They include myosin II, which can form cross-links with ATP-dependent motor activity, and cause adjacent actin filaments to slide on each other in the striated muscle sarcomere, and either change the shape of cells or (if the actin bundles are anchored into the cell membrane at both ends), maintain a degree of active rigidity. Filamin interconnects adjacent actin filaments to produce loose filamentous gel-like networks composed of randomly orientated F-actin.

F-actin can branch. The assembly of branched filamentous actin networks involves a complex of seven actin-related proteins 2/3 (Arp2/3) that is structurally similar to the barbed end of actin.

See Rotty et al (2013) for further reading.

Branched actin generated by the Arp2/3 protein complex localizes at the leading edge of migrating cells, lamellipodia and phagosomes (required for the capture by endocytosis and phagocytosis of particles and foreign pathogens by immune cells). Formin can elongate pre-existing actin filaments by removing capping proteins at the barbed end.

The adrenaline receptor is linked to adenylyl cyclase by G protein, which stimulates cyclase activity upon adrenaline binding. In the adrenaline-dependent regulation of glycogen metabolism, the intracellular signalling effects of cAMP are mediated by the enzyme cAMP-dependent protein kinase (or protein kinase A). In its inactive form, protein kinase A is a tetramer composed of two regulatory subunits (to which cAMP binds) and two catalytic subunits. Binding of cAMP results in the dissociation of the catalytic subunits. Free catalytic subunits can phosphorylate serine residues on target proteins (Fig. 1.10).

This pathway links a protein with tyrosine kinase activity (JAK) to a transcription factor (STAT) that becomes activated by this event. STAT (Signal Transducers and Activators of Transcription) proteins are transcription factors with an SH2 domain. They are present in the cytoplasm in an inactive state. Stimulation of a receptor by ligand binding recruits STAT proteins, which bind to the cytoplasmic portion of the receptor-associated JAK protein tyrosine kinase through their SH2 domain and become phosphorylated. Phosphorylated STAT proteins then dimerize and translocate into the nucleus, where they activate the transcription of target genes (Fig. 1.11).

The Hh signalling pathway (Fig. 1.12A) is involved in switching Gli (Glioma) factors from transcriptional repressors into activators in the cytoplasm to allow Hh-specific transcriptional events. Hh proteins bind to the receptor PTCH1 (PaTCHed Homologue 1) and then signal through SMO (SMOothened), a transmembrane protein, to regulate gene transcription by repressing or activating Gli3, the transcription factor. If SMO is not present, Sufu (SUppressor of FUsed) permits the truncated Gli3 repressor to block Hh-specific gene expression. If SMO is present, activated full-length Gli2A translocates to the cell nucleus to regulate Hh-specific gene expression (the expression of cyclin D, cyclin E, Myc and Patched). Hh ligands include Sonic (Shh), Indian (Ihh) and Desert (Dhh). Dysfunctions of the Hh signalling pathway include Gorlin syndrome, basal cell carcinoma in the skin and medulloblastoma.

The Wingless (Wnt) signalling pathway (Fig. 1.12B) relies on Wnt proteins controlling tissue organization and body-axis formation during embryogenesis and the regulation of stem cells in adult tissue. Wnt protein binding to FZD (frizzled) receptor is regulated by several interacting proteins, including leucine-rich repeat containing G protein-coupled receptor (Lgr) 5 or 6; R-spondin (Rspo) 1 to 4 and E3 ubiquitin ligase enzyme (Znrf3 or Rnf43). In the absence of Rspos, the ubiquitin ligase catalyses FZD degradation, thus preventing Wnt protein binding. Rspo prevents enzyme activity, FZD receptors accumulate and Wnt signalling increases. β-catenin then translocates to the nucleus and stimulates the transcription of Wnt target genes by interacting with the co-activators LEF1 (Lymphoid Enhancer-binding Factor 1) and TCF (T Cell Factor) 1, TCF3 and TCF4 (not shown in Fig. 1.12B). In the β-catenin independent pathway, Wnt protein induces G protein-coupled phosphatidylinositol to activate protein kinase C (PKC). Wnt signalling has direct implications for regenerative medicine and Wnt-associated cancers. Regeneration, in contrast to repair, is a steady-state condition, for example of the normal epidermis and the gastrointestinal lining. The possibility of restoring function to damaged tissue following disease, injury or ageing depends on its capacity for tissue repair.

TGF-β signalling is associated with the bone morphogenetic protein (BMP) signalling pathway (Fig. 1.12C). BMPs are members of the TGF-β superfamily and regulate cell growth, differentiation and development in a wide range of biological processes by activating SMAD transcription factor proteins.

BMP/TGF-β ligands induce the dimerization and then heteromerization of serine/threonine receptor kinases and phosphorylation of the cytoplasmic signalling molecules SMAD2 and SMAD3 for the TGF-β pathway, or SMAD1/5/8 for the BMP pathway. The common SMAD4 transducer translocates to the nucleus. Activated SMADs regulate several biological processes by cell-specific modulation of transcription. TGF-β is a tumour suppressor of premalignant cells but enhances invasion and metastasis of more advanced carcinomas. Mutations of *SMAD4* genes are frequent in gastrointestinal and pancreatic tumours. For further reading on cell signalling pathways, see Kierszenbaum and Tres (2019).

Septins are emerging as a novel cytoskeletal element because of their filamentous organization and association with actin filaments and microtubules. They are guanosine triphosphate (GTP)-binding proteins that form hetero-oligomeric complexes (see Mostowy and Cossart 2012 for additional information).

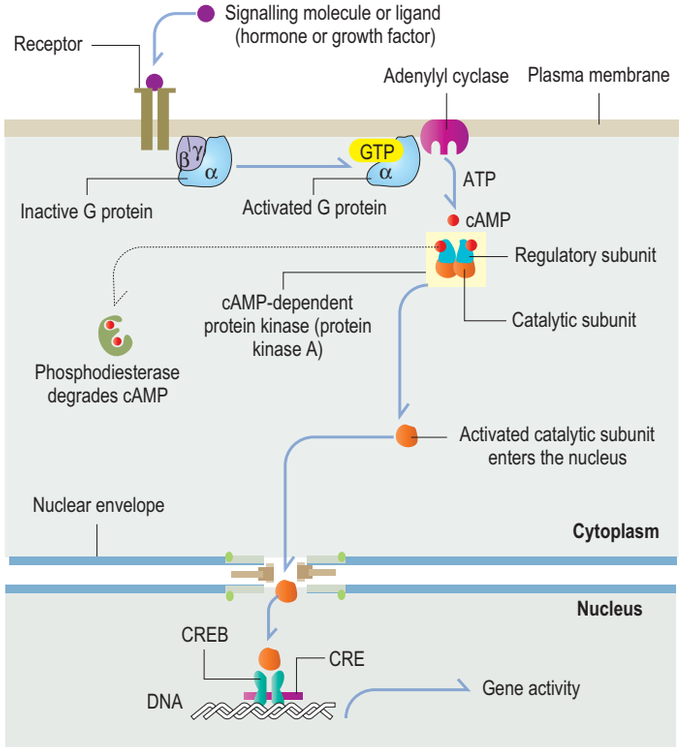

Fig. 1.10 The cAMP signalling pathway. Ligand binding to a cell receptor leads to the activation of adenylyl cyclase by the guanosine triphosphate (GTP)-bound G protein subunit to form cAMP from ATP. cAMP, the second messenger, binds to the regulatory subunits of cAMP-dependent protein kinase (protein kinase A) and releases the catalytic subunits. cAMP is eventually degraded by a cAMP-dependent phosphodiesterase. The activated catalytic subunit translocates into the nucleus and phosphorylates the transcription factor CREB (CRE-binding protein) bound to the cAMP response element (CRE): specific gene expression of inducible genes occurs. (With permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

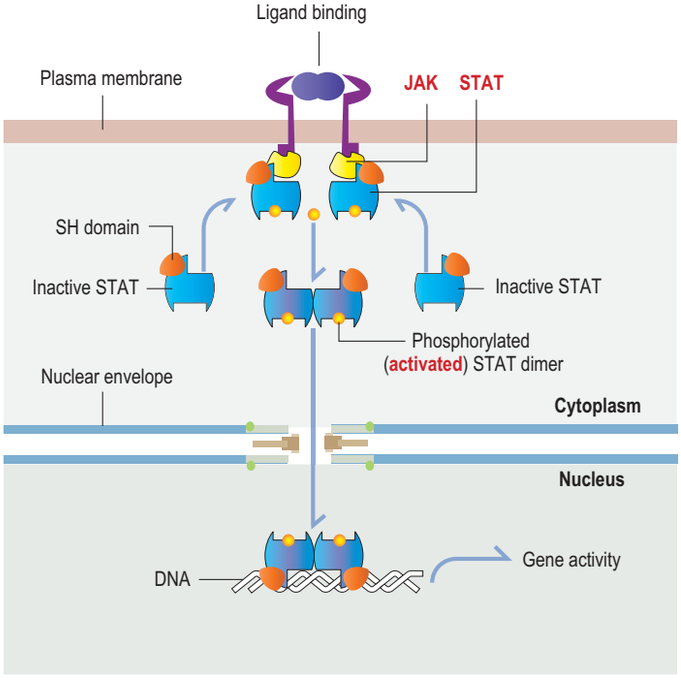

Fig. 1.11 The JAK–STAT signalling pathway. Ligand binding to a receptor leads to the attachment of the inactive transcription factor STAT, present in the cytosol, to the receptor-associated JAK protein tyrosine kinase via their SH2 domains. Phosphorylated STAT dimerizes and translocates to the nucleus where it activates transcription of target genes (With permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

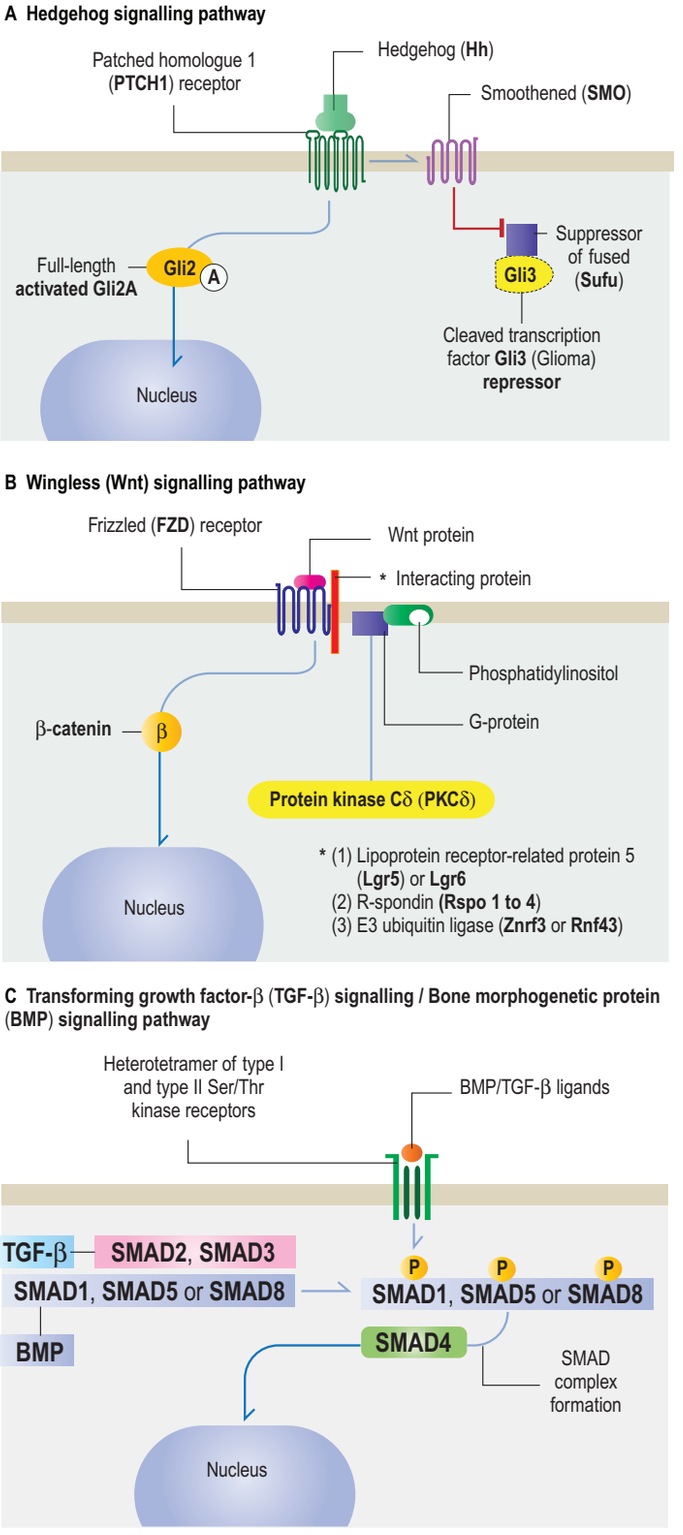

Fig. 1.12 A, The Hedgehog (Hh) signalling pathway. Hh proteins bind to the receptor PTCH1 and then signal through SMO, a transmembrane protein, to regulate gene transcription by repressing or activating Gli3, a transcription factor. If SMO is not present, Sufu permits the truncated Gli3 repressor to block Hh-specific gene expression. If SMO is present, activated full-length Gli2A translocates to the cell nucleus to regulate Hh-specific gene expression. Hh ligands include Sonic (Shh), Indian (Ihh) and Desert (Dhh) hedgehog proteins. **B**, The Wingless (Wnt) signalling pathway. Wnt protein binding to FZD receptor is regulated by interacting proteins (*): Leucine-rich repeat containing G protein-coupled receptor (Lgr) 5 or 6; R-spondin (Rspo) 1 to 4 and E3 ubiquitin ligase enzyme (Znrf3 or Rnf43). In the absence of Rspos, the ubiquitin ligase catalyses FZD degradation and so prevents Wnt protein binding. Rspo prevents enzyme activity, FZD receptors accumulate and Wnt signalling increases; β-catenin translocates to the nucleus and stimulates the transcription of Wnt target genes. **C**, The transforming growth factor-β (TGF-β) signalling/Bone morphogenetic protein (BMP) signalling pathway. BMP/TGF-β ligands induce the dimerization and then heteromerization of serine/threonine receptor kinases and phosphorylation of the cytoplasmic signalling molecules SMAD2 and SMAD3 for the TGF-β pathway, or SMAD1/5/8 for the BMP pathway. The common SMAD4 transducer translocates to the nucleus. Activated SMADs regulate several biological processes by cell-specific modulation of transcription. This polarity can be visualized in negatively stained images by allowing F-actin to react with fragments containing the active head region of myosin. Myosins bind to filamentous actin at an angle to give the appearance of a series of arrowheads pointing towards the minus end of the filament, with the barbs pointing towards the plus end.

It involves the addition of ATP-bound G-actin monomers at the barbed end (fast-growing plus end) and removal of ADP-bound G-actin at the pointed end (slow-growing minus end). Actin filaments grow or shrink by addition or loss of G-actin monomer at both ends. Essentially, actin polymerization *in vitro* proceeds in three steps: nucleation (aggregation of G-actin monomers into a 3–4-monomer aggregate), elongation (addition of G-actin monomers to the aggregate) and a dynamic steady state (treadmilling). Specific toxins (e.g. cytochalasins, phalloidins and lantrunculins) bind to actin and affect its polymerization. Cytochalasin D blocks the addition of new G-actin monomers to the barbed end of F-actin; phalloidin binds to the interface between G-actin monomers in F-actin, thus preventing depolymerization; and lantrunculin binds to G-actin monomers, blocking their addition to an actin filament.

Profilin and thymosin β4 are G-actin binding proteins. Profilin binds to G-actin bound to ATP; it inhibits addition of G-actin to the slow-growing (pointed) end of F-actin but enables the fast-growing (barbed) end to grow faster and then dissociates from the actin filament. In addition, profilin participates in the conversion of ADP back to the ATP–G-actin bound form. Thymosin β4 binds to the ATP–G-actin bound form, preventing polymerization by sequestering ATP–G-actin into a reserve pool.

Members of the F-actin capping protein family are heterodimers consisting of an α subunit (CPα) and a β subunit (CPβ) that cap the barbed end of actin filaments within all eukaryotic cells. Gelsolin has a dual role: it severs F-actin and caps the newly formed barbed end, blocking further filament elongation.

Fascin is an additional cross-linking protein. Villin is also a severing protein, causing the disassembly of actin filaments and the collapse of the microvillus.

In the presence of activated nucleation promotion factors, such as Wiskott–Aldrich syndrome protein (WASP) and WASP family verprolin-homologous protein (WAVE, also known as SCAR), the Arp2/3 protein complex binds to the side of an existing actin filament (mother filament) and initiates the formation of a branching actin daughter filament at a 70° angle relative to the mother filament utilizing G-actin delivered to the Arp2/3 complex site.

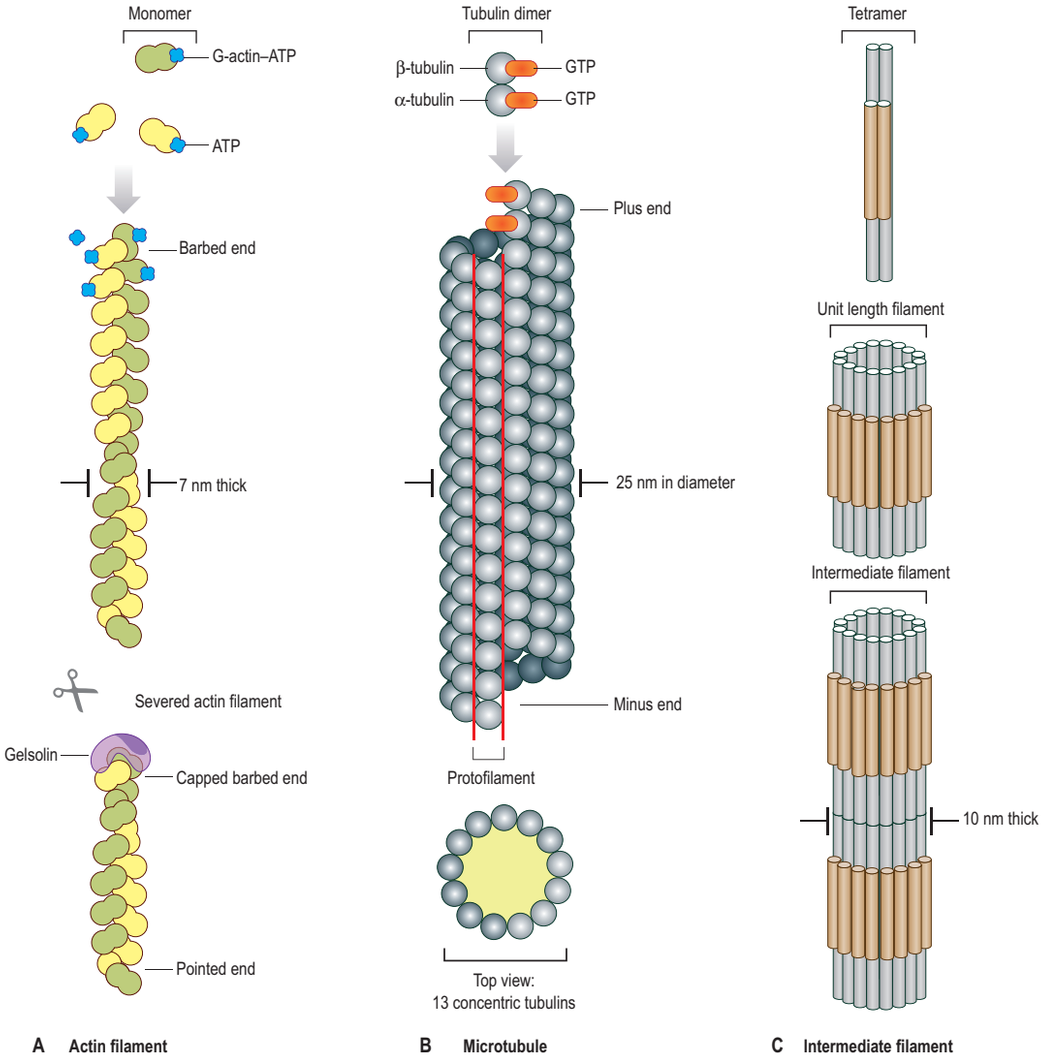

Fig. 1.13 Structural and molecular features of cytoskeletal components. **A**, The actin filament (F-actin) is a 7 nm thick polymer chain of ATP-bound G-actin monomers. F-actin consists of a barbed (plus) end, the initiation site of F-actin, and a pointed (minus) end, the dissociation site of F-actin. F-actin can be severed and capped at the barbed end by gelsolin. **B**, The microtubule is a 25 nm diameter polymer of GTP-bound α-tubulin and GTP-bound β-tubulin dimers. The dimer assembles at the plus end and depolymerizes at the minus end. A linear chain of α-tubulin/β-tubulin dimers is called a protofilament. In the end-on (top) view, a microtubule displays 13 concentrically arranged tubulin subunits. **C**, Tetrameric complexes of intermediate filament subunits associate laterally to form a unit length filament consisting of eight tetramers. Additional unit length filaments anneal longitudinally and generate a mature 10 nm thick intermediate filament.

Other classes of actin-binding protein link the actin cytoskeleton to the plasma membrane either directly or indirectly through a variety of membrane-associated proteins. The latter may also create links via transmembrane proteins to the extracellular matrix. Best known of these is the family of spectrin-like molecules, which can bind to actin and also to each other and to various membrane-associated proteins to create supportive networks beneath the plasma membrane. Tetramers of spectrin α and β chains line the intracellular side of the plasma membrane of erythrocytes and maintain their integrity by their association with short actin filaments at either end of the tetramer.

Class V myosins (see below) are unconventional motor proteins transporting cargoes (such as vesicles and organelles) along actin filaments. Class I myosins are involved in membrane dynamics and actin organization at the cell cortex, thus affecting cell migration, endocytosis, pinocytosis and phagocytosis. Tropomyosin, an important regulatory protein of muscle fibres, is also present in non-muscle cells, where its function may be primarily to stabilize actin filaments against depolymerization.

Myosins, the motor proteins

The myosin family of microfilaments is often classified within a distinct category of motor proteins. Myosin proteins have a globular head region consisting of a heavy and a light chain. The heavy chain bears an α-helical tail of varying length. The head has an ATPase activity and can bind to and move along actin filaments – the basis for myosin function as a motor protein. The best-known class is myosin II, which occurs in muscle and in many non-muscle cells. Its molecules have two heads and two tails, intertwined to form a long rod. The rods can bind to each other to form long, thick filaments, as seen in striated and smooth muscle fibres and myoepithelial cells. Myosin II molecules can also assemble into smaller groups, especially dimers, which can cross-link individual actin microfilaments in stress fibres and other F-actin arrays. The ATP-dependent sliding of myosin on actin forms the basis for muscle contraction and the extension of microfilament bundles, as seen in cellular motility or in the contraction of the ring of actin and myosin around the cleavage furrow of dividing cells. There are a number of known subtypes of myosin II; they assemble in different ways and have different dynamic properties. In skeletal muscle the myosin molecules form bipolar filaments 15 nm thick. Because these filaments have a symmetric antiparallel arrangement of subunits, the midpoint is bare of head regions. In smooth muscle the molecules form thicker, flattened bundles and are orientated in random directions on either face of the bundle. These arrangements have important consequences for the contractile force characteristics of the different types of muscle cell.

Related molecules include the myosin I subfamily of single-headed molecules with tails of varying length. Functions of myosin I include the movements of membranes in endocytosis, filopodial formation in neuronal growth cones, actin–actin sliding and attachment of actin to membranes as seen in microvilli. As indicated above, molecular motors of the myosin V family are implicated in the movements of cargoes on actin filaments. So, for example, myosin Va transports vesicles along F-actin tracks in a similar manner to kinesin and cytoplasmic dynein-related cargo transport along microtubules. Each class of motor protein has different properties, but during cargo trafficking they often function together in a coordinated fashion. (See Hammer and Sellers 2012 for further reading on class V myosins.)

Other thin filaments

A heterogeneous group of filamentous structures with diameters of 2–4 nm occurs in various cells. The two most widely studied forms, titin and nebulin, constitute around 13% of the total protein of skeletal muscle (Ch. 5). They are amongst the largest known molecules and have subunit weights of around 10^6; native molecules are about 1 μm in length. Their repetitive bead-like structure gives them elastic properties that are important for the effective functioning of muscle, and possibly for other cells.

Microtubules

Microtubules are polymers of tubulin with the form of hollow, relatively rigid cylinders, approximately 25 nm in diameter and of varying length (up to 70 μm in spermatozoan flagella). They are present in most

Spectrin-related molecules are present in many other cells. For instance, fodrin is found in neurones and dystrophin occurs in muscle cells, linking the contractile apparatus with the extracellular matrix via integral membrane proteins. Proteins such as ankyrin (which also binds actin directly), vinculin, talin, zyxin and paxillin connect actin-binding proteins to integral plasma membrane proteins such as integrins (directly or indirectly), and thence to focal adhesions (consisting of a bundle of actin filaments attached to a portion of a plasma membrane linked to the extracellular matrix).

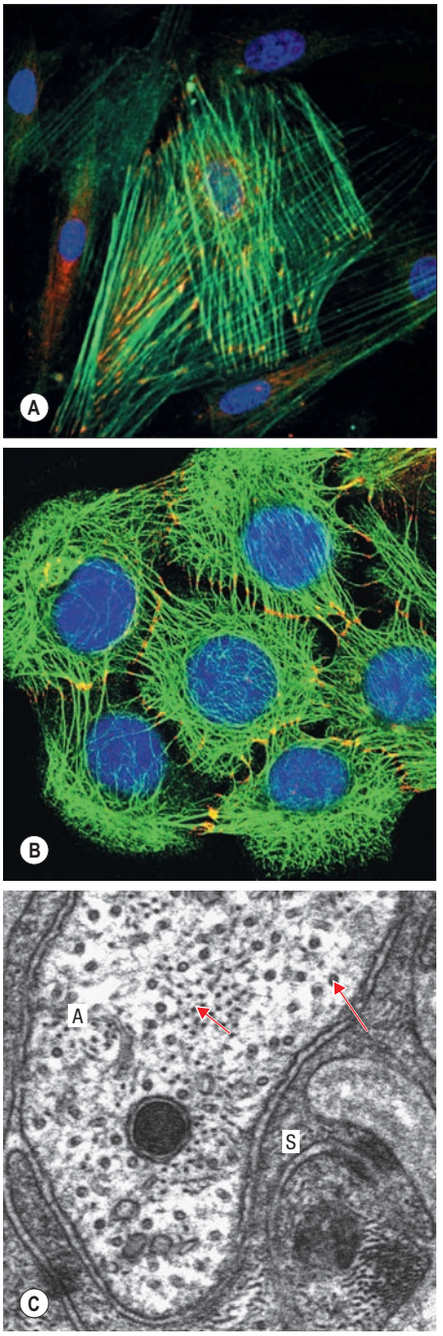

Fig. 1.14 The cytoskeleton. **A**, An immunofluorescence micrograph of α-actin microfilaments (green) in human airway smooth muscle cells in culture. The actin-binding protein, vinculin (red), is localized at the ends of actin filament bundles; nuclei are blue. **B**, An immunofluorescence micrograph of keratin intermediate filaments (green) in human keratinocytes in culture. Desmosome junctions are labelled with antibody against desmoplakin (red). Nuclei are stained blue (Hoechst). **C**, An electron micrograph of human nerve showing microtubules (small, apparently hollow structures in cross-section, long arrow) in a transverse section of an unmyelinated axon (A), engulfed by a Schwann cell (S). Neuronal intermediate filaments (neurofilaments) are the solid, electron-dense profiles, mainly in transverse section (short arrow). (A, Courtesy of Dr T Nguyen, Professor J Ward, Dr SJ Hirst, King's College London. B, Courtesy of Professor Dr WW Franke, German Cancer Research Centre, Heidelberg. C, Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

cell types, being particularly abundant in neurones, leukocytes and blood platelets. Microtubules are the predominant constituents of the mitotic spindles of dividing cells and also form part of the axoneme of cilia, flagella and centrioles.

Microtubules consist of tubulin dimers and microtubule-associated proteins. There are two major classes of tubulin: α- and β-tubulins. Before microtubule assembly, tubulins are associated as dimers with a combined molecular mass of 100 kDa (50 kDa each). Each protein subunit is approximately 5 nm across and is arranged along the long axis in straight rows of alternating α- and β-tubulins, forming protofilaments (Fig. 1.13B). Typically, 13 protofilaments (the number can vary between 11 and 16) associate in a ring to form the wall of a hollow cylindrical microtubule (Fig. 1.14C). Each longitudinal row is slightly out of alignment with its neighbour, so that a spiral pattern of alternating α and β subunits appears when the microtubule is viewed from the side. There is a dynamic equilibrium between the dimers and assembled microtubules: dimeric asymmetry creates polarity (α-tubulins are all orientated towards the minus end, β-tubulins towards the plus end). Tubulin is added preferentially to the plus end; the minus end is relatively slow-growing. Microtubules frequently grow and shrink at a rapid and constant rate, a phenomenon known as dynamic instability, in which growing tubules can undergo a 'catastrophe', abruptly shifting from net growth to rapid shrinkage. The primary determinant of whether microtubules grow or shrink is the rate of GTP hydrolysis. Tubulins are GTP-binding proteins; microtubule growth is accompanied by hydrolysis of GTP, which may regulate the dynamic behaviour of the tubules. Microtubule growth is initiated at specific sites, the microtubule-organizing centres, of which the best known are centrosomes (from which most cellular microtubules polymerize) and the centriole-derived basal bodies (from which cilia grow). Microtubule-organizing centres include a specialized tubulin isoform known as γ-tubulin that is essential for the nucleation of microtubule growth.

Various drugs (e.g. colcemid, vinblastine, griseofulvin, nocodazole) cause microtubule depolymerization by binding the soluble tubulin dimers and so shifting the equilibrium towards the unpolymerized state. Microtubule disassembly causes a wide variety of effects, including the inhibition of cell division by disruption of the mitotic spindle. Conversely, the drug paclitaxel (taxol) is a microtubule depolymerization inhibitor because it stabilizes microtubules and promotes abnormal microtubule assembly. Although this can cause a peripheral neuropathy, paclitaxel is widely used as an effective chemotherapeutic agent in the treatment of breast and ovarian cancer.

Microtubule-associated proteins

Various proteins that can bind to assembled tubulins may be concerned with structural properties or associated with motility. One important class of microtubule-associated proteins (MAPs) consists of proteins that associate with the plus ends of microtubules. They regulate the dynamic instability of microtubules as well as interactions with other cellular substructures. Structural MAPs form cross-bridges between adjacent microtubules or between microtubules and other structures such as intermediate filaments, mitochondria and the plasma membrane. Microtubule-associated proteins found in neurones include: MAPs 1A and 1B, which are present in neuronal dendrites and axons; MAPs 2A and 2B, found chiefly in dendrites; and tau, found only in axons. MAP 4 is the major microtubule-associated protein in many other cell types. Structural microtubule-associated proteins are implicated in microtubule formation, maintenance and disassembly, and are therefore of considerable significance in cell morphogenesis, mitotic division, and the maintenance and modulation of cell shape.

Transport-associated microtubule-associated proteins are found in situations in which movement occurs over the surfaces of microtubules, e.g. cargo transport, bending of cilia and flagella, and some movements of mitotic spindles. They include a large family of motor proteins, the best known of which are the dyneins and kinesins. Another protein, dynamin, is involved in endocytosis. The kinetochore proteins assemble at the chromosomal centromere during mitosis and meiosis. They attach (and thus fasten chromosomes) to spindle microtubules; some of the kinetochore proteins are responsible for chromosomal movements in mitotic and meiotic anaphase.

All of these microtubule-associated proteins bind to microtubules and either actively slide along their surfaces or promote microtubule assembly or disassembly. Kinesins and dyneins can simultaneously attach to membranes such as transport vesicles and convey them along microtubules for considerable distances, thus enabling selective targeting of materials within the cell. Such movements occur in both directions along microtubules. Kinesin-dependent motion is usually towards the plus ends of microtubules, e.g. from the cell body towards the axon terminals in neurones, and away from the centrosome in other cells. Conversely, dynein-related movements are in the opposite direction, i.e. to the minus ends of microtubules. The transport of cargoes along microtubules is the means by which neurotransmitters are delivered along axons within synaptic vesicle precursors towards neuronal synapses (anterograde axonal transport, utilizing kinesins) and membrane-bound vesicles are returned for recycling to the neuronal soma (retrograde axonal transport, utilizing dyneins).

Dyneins also form the arms of peripheral microtubules in cilia and flagella, where they make dynamic cross-bridges to adjacent microtubule

pairs. When these tethered dyneins try to move, the resulting shearing forces cause the axonemal array of microtubules to bend, generating ciliary and flagellar beating movements. Kinesins form a large and diverse family of related microtubule-stimulated ATPases. Some kinesins are motors that move cargo and others cause microtubule disassembly, whilst still others cross-link mitotic spindle microtubules to push the two centriolar poles apart during mitotic prophase. See Bray (2001) for further reading.

Centrioles, centrosomes and basal bodies

Centrioles are microtubular cylinders 0.2 µm in diameter and 0.4 µm long (Fig. 1.15). They are formed by a ring of nine microtubule triplets linked by a number of other proteins. At least two centrioles occur in all animal cells that are capable of mitotic division (eggs, which undergo meiosis instead of mitosis, lack centrioles). See Gönczy (2012) for further reading on the structure and assembly of the centriole. They usually lie close together, at right angles or, most usually, at an oblique angle to each other (an arrangement often termed a diplosome), within the centrosome, a densely filamentous region of cytoplasm at the centre of the cell. The centrosome is the major microtubule-organizing centre of most cells; it is the site at which new microtubules are formed and the mitotic spindle is generated during cell division.

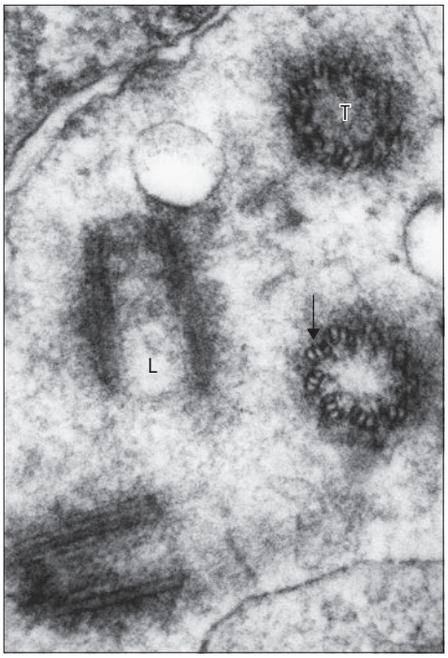

Fig. 1.15 A duplicated pair of centrioles in a human carcinoma specimen. Each centriole pair consists of a mother and daughter, orientated approximately at right angles to each other so that one is sectioned transversely (T) and the other longitudinally (L). The transversely sectioned centrioles are seen as rings of microtubule triplets (arrow). (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

Centriole biogenesis is a complex process (Fig. 1.16) At the beginning of the S phase (DNA replication phase) of the cell cycle (see below), a new daughter centriole forms at right-angles to each separated maternal centriole. Each mother–daughter pair forms one pole of the next mitotic spindle, and the daughter centriole becomes fully mature only as the progeny cells are about to enter the next mitosis. Because centrosomes are microtubule-organizing centres, they lie at the centre of a network of microtubules, all of which have their minus ends proximal to the centrosome.

The microtubule-organizing centre contains complexes of γ-tubulin that nucleate microtubule polymerization at the minus ends of microtubules. Basal bodies are microtubule-organizing centres that are closely related to centrioles, and are believed to be derived from them. They are located at the bases of cilia and flagella, which they anchor to the cell surface. The outer microtubule doublets of the axoneme of cilia and flagella originate from two of the microtubules in each triplet of the basal body.

Intermediate filaments

Intermediate filaments are about 10 nm thick and are formed by a heterogeneous group of filamentous proteins. In contrast to actin filaments and microtubules, which are assembled from globular proteins with nucleotide-binding and hydrolysing activity, intermediate filaments consist of filamentous monomers lacking enzymatic activity. Intermediate filament proteins assemble to form linear filaments in a three-step process. First, a pair of intermediate filament protein subunits, each consisting of a central α-helical rod domain of about 310 amino acids flanked by head and tail non-α-helical domains of variable size, form a parallel dimer through their central α-helical rod domains coiled around each other. The variability of intermediate filament protein subunits resides in the length and amino-acid sequence of the head and tail domains, thought to be involved in regulating the interaction of intermediate filaments with other proteins. Second, a tetrameric unit is formed by two antiparallel half-staggered coiled dimers. Third, eight tetramers associate laterally to form a 16 nm thick unit length filament (ULF). Individual ULFs join end to end to form short filaments that continue growing longitudinally by annealing to other ULFs and existing filaments. Filament elongation is followed by internal compaction leading to the 30 nm thick intermediate filament (Figs 1.13C, 1.14B). The tight association of dimers, tetramers and ULFs provides intermediate filaments with high tensile strength

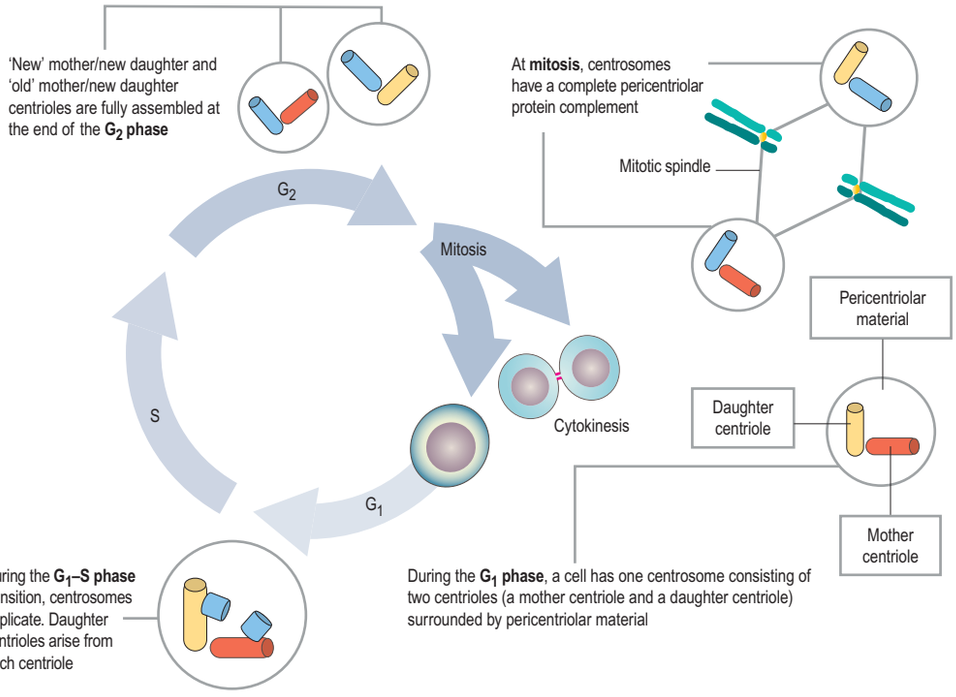

Fig. 1.16 A centriolar pair consists of a mother and a daughter centriole that duplicates once every cell cycle in preparation for cell division. Each centriole generates a daughter centriole, which means that there are two new daughter centrioles. The previous daughter centriole becomes the 'new' mother and the previous mother centriole remains as the 'old' mother centriole, i.e. an 'old' mother centriole is connected to one of the new daughter centrioles and a 'new' mother centriole is linked to the other new daughter centriole. (Adapted with permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

The association of membrane vesicles with dynein motors means that certain cytomembranes (including the Golgi apparatus) concentrate near the centrosome. This is relevant because the microtubules provide a means of targeting Golgi vesicular products to different parts of the cell.

and resistance to stretching, compression, twisting and bending forces. In contrast to actin filaments and microtubules, intermediate filaments are non-polar (because of the antiparallel alignment of the initial tetramers) and do not bind nucleotides (as in G-actin and tubulin dimers), and ULFs anneal end to end to each other (in contrast to the polarized F-actin and microtubules, with one end, the plus end, growing faster than the other end, the minus end). See Herrmann et al (2007) for further reading.

Intermediate filaments are found in different cell types and are often present in large numbers, either to provide structural strength where it is needed (see Figs 1.14B, 1.14C) or to provide scaffolding for the attachment of other structures. Intermediate filaments form extensive cytoplasmic networks extending from cage-like perinuclear arrangements to the cell surface. Intermediate filaments of different molecular classes are characteristic of particular tissues or states of maturity and are therefore important indicators of the origins of cells or degrees of differentiation, as well as being of considerable value in histopathology.

Intermediate filament proteins have been classified into five distinct types on the basis of their primary structure and tissue-specific expression. Of the different classes of intermediate filaments, keratin (cytokeratin) proteins are found in epithelia, where keratin filaments are always composed of equal ratios of type I (acidic) and type II (basic to neutral) keratins to form heteropolymers. About 20 types of each of the acidic and basic/neutral keratin proteins are known. For further reading on keratins in normal and diseased epithelia, see Pan et al (2012). Within the epidermis, expression of keratin heteropolymers changes as keratinocytes mature during their transition from basal to superficial layers. Genetic abnormalities of keratins are known to affect the mechanical stability of epithelia. For example, the disease epidermolysis bullosa simplex is caused by lysis of epidermal basal cells and blistering of the skin after mechanical trauma. Defects in genes encoding keratins 5 and 14 produce cytoskeletal instability leading to cellular fragility in the basal cells of the epidermis. When keratins 1 and 10 are affected, cells in the spinous (prickle) cell layer of the epidermis lyse, and this produces the intraepidermal blistering of epidermolytic hyperkeratosis. See Porter and Lane (2003) for further reading.

Type III intermediate filament proteins, including vimentin, desmin, glial fibrillary acidic protein and peripherin, form homopolymer intermediate filaments. Vimentin is expressed in mesenchyme-derived cells of connective tissue and some ectodermal cells during early development; desmins in muscle cells; glial fibrillary acidic protein in glial cells; and peripherin in peripheral axons. Type IV intermediate filaments include neurofilaments, nestin, syncoilin and α-internexin. Neurofilaments are a major cytoskeletal element in neurones, particularly in axons (see Fig. 1.14C), where they are the dominant protein. Neurofilaments (NF) are heteropolymers of low (NF–L), medium (NF–M) and high (NF–H) molecular weight (the NF–L form is always present in combination with either NF–M or NF–H forms). Abnormal accumulations of neurofilaments (neurofibrillary tangles) are characteristic features of a number of neuropathological conditions. Nestin resembles a neurofilament protein, which forms intermediate filaments in neurectodermal stem cells in particular. The type V intermediate filament group includes the nuclear lamins A, lamin B1 and lamin B2 lining the inner surface of the nuclear envelope of all nucleated cells. Lamin C is a splice variant of lamin A. Lamins provide a mechanical framework for the nucleus and act as attachment sites for a number of proteins that organize chromatin at the periphery of the nucleus. They are unusual in that they form an irregular anastomosing network of filaments rather than linear bundles. See Burke and Stewart (2013) for further reading.

Nucleus

The nucleus (see Figs 1.1–1.2) is generally the largest intracellular structure and is usually spherical or ellipsoid in shape, with a diameter of 3–10 μm. Conventional histological stains, such as haematoxylin or toluidine blue, detect the acidic components (phosphate groups) of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) in cells and tissue sections. DNA and RNA molecules are said to be basophilic because of the binding affinity of their negatively charged phosphate groups to basic dyes such as haematoxylin. A specific stain for DNA is the Feulgen reaction.

Nuclear envelope

The nucleus is surrounded by the nuclear envelope, which consists of an inner nuclear membrane (INM) and an outer nuclear membrane (ONM), separated by a 40–50 nm perinuclear space that is spanned by nuclear pore complexes (NPCs). The perinuclear space is continuous with the lumen of the endoplasmic reticulum. The ONM has multiple connections with the endoplasmic reticulum, with which it shares its membrane protein components. The INM contains its own specific integral membrane proteins (lamin B receptor and emerin, both providing binding sites for chromatin bridging proteins). A mutation in the gene encoding emerin causes X-linked Emery–Dreifuss muscular dystrophy (EDMD), characterized by skeletal muscle wasting and cardiomyopathy.

The nuclear lamina, a 15–20 nm thick, protein-dense meshwork, is associated with the inner face of the INM. The major components of the nuclear lamina are lamins, the type V intermediate filament proteins consisting of A-type and B-type classes.

The nuclear lamina reinforces the nuclear membrane mechanically, determines the shape of the nucleus and provides a binding site for a range of proteins that anchor chromatin to the cytoskeleton. Nuclear lamin A, with more than 350 mutations, is the most mutated protein linked to human disease. These are referred to as laminopathies, characterized by nuclear structural abnormalities that cause structurally weakened nuclei, leading to mechanical damage. Lamin A mutations cause a surprisingly wide range of diseases, from progeria to various dystrophies, including an autosomal dominant form of EDMD. A truncated farnesylated form of lamin A, referred to as progerin, leads to defects in cell proliferation and DNA damage of mesenchymal stem cells and vascular smooth muscle cells. Affected patients display cardiovascular disease and die at an early age. Mice lacking lamin B1 and lamin B2 survive until birth; however, neuronal development is compromised when lamin B1 or lamin B2 is absent. Overexpression of lamin B1 is associated with autosomal dominant leukodystrophy characterized by gradual demyelination in the central nervous system. See Worman (2012) and Burke and Stewart (2013) for additional reading on lamins and laminopathies.

Condensed chromatin (heterochromatin) tends to aggregate near the nuclear envelope during interphase. At the end of mitotic and meiotic prophase (see below), the lamin filaments disassemble by phosphorylation, causing the nuclear membranes to vesiculate and disperse into the endoplasmic reticulum. During the final stages of mitosis (telophase), proteins of the nuclear periphery, including lamins, associate with the surface of the chromosomes, providing docking sites for membrane vesicles. Fusion of these vesicles reconstitutes the nuclear envelope, including the nuclear lamina, following lamin dephosphorylation. See Simon and Wilson (2011) for further reading on the nucleoskeleton.

The transport of molecules between the nucleus and the cytoplasm occurs via specialized nuclear pore structures that perforate the nuclear membrane (**Fig. 1.17A**). They act as highly selective directional molecular filters, permitting proteins such as histones and gene regulatory proteins (which are synthesized in the cytoplasm but function in the nucleus) to enter the nucleus, and molecules that are synthesized in the nucleus but destined for the cytoplasm (e.g. ribosomal subunits, transfer RNAs and messenger RNAs) to leave the nucleus.

Ultrastructurally, nuclear pores appear as disc-like structures with an outer diameter of 130 nm and an inner pore with an effective diameter for free diffusion of 9 nm (**Fig. 1.17B**). The nuclear envelope of an active cell contains up to 4000 such pores. The nuclear pore complex has an octagonal symmetry and is formed by an assembly of more than 50 proteins, the nucleoporins. The inner and outer nuclear membranes fuse around the pore complex (see Fig. 1.17A). Nuclear pores are freely permeable to small molecules, ions and proteins up to about 17 kDa. See Raices and D'Angelo (2012) for further reading on nuclear pore complex composition. Most proteins that enter the nucleus do so as complexes with specific transport receptor proteins known as importins. Importins shuttle back and forth between the nucleus and cytoplasm. Binding of the cargo to the importin requires a short sequence of amino acids known as a nuclear localization sequence (NLS), and can either be direct or take place via an adapter protein. Interactions of the importin with components of the nuclear pore move it, together with its cargo, through the pore by an energy-independent process. A complementary cycle functions in export of proteins and RNA molecules from the nucleus to the cytoplasm using transport receptors known as exportins.

A small GTPase called Ras-related nuclear protein (Ran) regulates the import and export of proteins across the nuclear envelope.

For further reading on the Ran pathway and exportins/importins, see Clarke and Zhang (2008) and Raices and D'Angelo (2012).

Chromatin

DNA is organized within the nucleus in a DNA–protein complex known as chromatin. The protein constituents of chromatin are the histones and the non-histone proteins. Non-histone proteins are an extremely heterogeneous group that includes structural proteins, DNA and RNA polymerases, and gene regulatory proteins. Histones are the most abundant group of proteins in chromatin, primarily responsible for the packaging of chromosomal DNA into its primary level of organization, the nucleosome. There are four core histone proteins – H2A, H2B, H3 and H4 – which vary in amino acid sequence and post-translational modifications

A-type lamins include lamin A (interacting with emerin), lamin C, lamin C2 and lamin AΔ10 encoded by a single gene (*LMNA*). Lamin A and lamin C are the major A-type lamins expressed in somatic cells, whereas lamin C2 is expressed in testis. B-type lamins include lamin B1 and lamin B2 (expressed in somatic cells), and testis-specific lamin B3. Lamin B1 is encoded by the *LMNB1* gene; lamin B2 is encoded by the *LMNB2* gene.

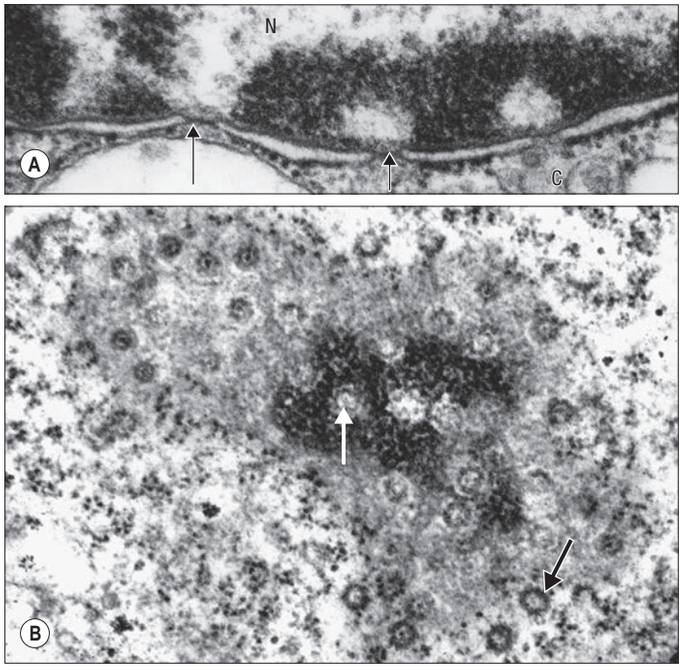

Fig. 1.17 **A**, The nuclear envelope with nuclear pores (arrows) in transverse section, showing the continuity between the inner and outer phospholipid layers of the envelope on either side of the pore. The fine 'membrane' appearing to span the pore is formed by proteins of the pore complex. Note that the chromatin is less condensed in the region of nuclear pores. Abbreviations: N, nucleus; C, cytoplasm. **B**, Nuclear pores seen '*en face*' as spherical structures (arrows) in a tangential section through the nuclear envelope. The appearance of the envelope varies in electron density as the plane of section passes through different regions of the curved double membrane, which is interrupted at intervals by pores through the envelope (see also Fig. 1.1). The surrounding cytoplasm with ribosomes is less electron dense. Human tissues. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

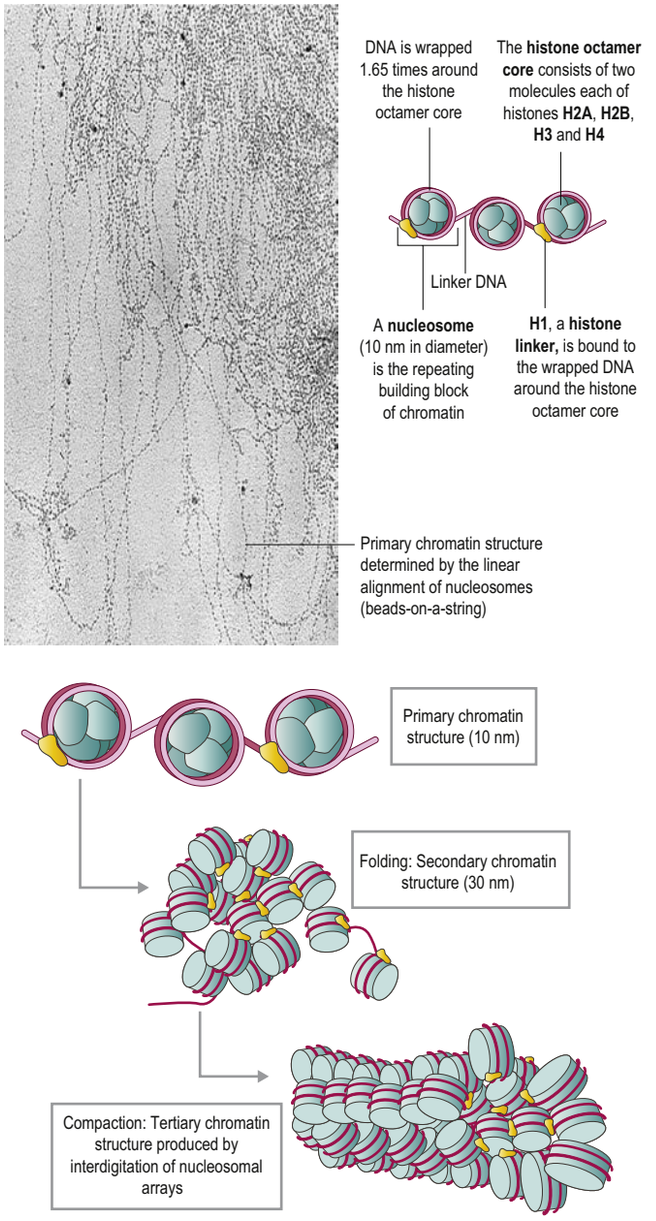

Fig. 1.18 The nucleosome is the repeating building block of chromatin and consists of DNA wrapped around a histone core. Each nucleosome contains two molecules of each histone H2A, H2B, H3 and H4. Histone variability has an effect on the condensation of the chromatin fibre and the interaction of nucleosomes with non-histone proteins. Nucleosomes connected in a linear array by a short DNA segment (linker DNA) form the primary structure of chromatin. The side-by-side interaction of the primary chromatin structure (electron micrograph, left) determines a secondary order of folding. The interaction between secondary chromatin fibres producing tertiary structures accounts for the compact chromatin state seen in the condensed metaphase chromosome and in heterochromatin. (Adapted with permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier. Copyright 2019.)

(including acetylation, methylation and phosphorylation). They combine in equal ratios to form a compact octameric nucleosome core. A fifth histone, H1, is involved in further compaction of the chromatin (**Fig. 1.18**). The DNA molecule (one per chromosome) winds twice around each nucleosome core, taking up 145–147 base pairs. This packaging organizes the DNA into a chromatin fibre 10 nm in diameter, and imparts to this form of chromatin the electron microscopic appearance of beads on a string, in which each bead is separated by a variable length of DNA, typically about 35 nucleotide pairs long. The nucleosome core region and one of the linker regions constitute the nucleosome proper, which is typically about 200 nucleotide pairs in length. However, chromatin rarely exists in this simple form and is usually packaged further into a 30 nm thick fibre, involving a single H1 histone per nucleosome, which interacts with both DNA and protein to impose a higher order of nucleosome packing. Usually, 30 nm thick fibres are further coiled or folded into larger domains. Individual domains are believed to decondense and extend during active transcription. In a typical interphase nucleus, euchromatin (nuclear regions that appear pale in appropriately stained tissue sections, or relatively electron-lucent in electron micrographs; see Fig. 1.2) is likely to consist mainly of 30 nm fibres and loops, and contains the transcriptionally active genes. Transcriptionally active cells, such as most neurones, have nuclei that are predominantly euchromatic. See Luger et al (2012) for further reading on the nucleosome and chromatin structure.

Heterochromatin (nuclear regions that appear dark in appropriately stained tissue sections or electron-dense in electron micrographs) is characteristically located mainly around the periphery of the nucleus, except over the nuclear pores (see Fig. 1.17A), and adjacent to the nucleolus (see Fig. 1.2). It is a relatively compacted form of chromatin in which the histone proteins carry a specific set of post-translational modifications, including methylation at characteristic residues. This facilitates the binding of specific heterochromatin-associated proteins. Heterochromatin includes non-coding regions of DNA, such as centromeric regions, which are known as constitutive heterochromatin. DNA becomes transcriptionally inactive in some cells as they differentiate during development or cell maturation, and contributes to heterochromatin; it is known as facultative heterochromatin. The inactive X chromosome in females is an example of facultative heterochromatin and can be identified in the light microscope as the deeply staining Barr body often located near the nuclear periphery or a drumstick extension of a nuclear lobe of a mature multilobed neutrophil leukocyte.

In transcriptionally inactive cells, chromatin is predominantly in the condensed, heterochromatic state, and may comprise as much as 90% of the total. Examples of such cells are mature neutrophil leukocytes (in which the condensed chromatin is present in a multilobular, densely staining nucleus) and the highly condensed nuclei of orthochromatic erythroblasts (late-stage erythrocyte precursors). In most mature cells, a mixture of the two occurs, indicating that only a proportion of the DNA is being transcribed. A particular instance of this is seen in the B lymphocyte-derived plasma cell, in which much of the chromatin is in the condensed condition and is arranged in regular masses around the perimeter of the nucleus, producing the so-called 'clock-face' nucleus (see Figs 4.6, 4.12). Although this cell is actively transcribing, much of

its protein synthesis is of a single immunoglobulin type, and consequently much of its genome is in an inactive state.

During mitosis, the chromatin is further reorganized and condensed to form the much-shortened chromosomes characteristic of metaphase. This shortening is achieved through further levels of close packing of the chromatin. The condensed chromosomes are stabilized by protein complexes known as condensins. Progressive folding of the chromosomal DNA by interactions with specific proteins can reduce 5 cm of chromosomal DNA by 10,000-fold, to a length of 5 µm in the mitotic chromosome.

Chromosomes and telomeres

The nuclear DNA of eukaryotic cells is organized into linear units called chromosomes. The DNA in a normal human diploid cell contains 6×10^9 nucleotide pairs organized in the form of 46 chromosomes (44 autosomes and 2 sex chromosomes). The largest human chromosome (number 1) contains 2.5×10^8 nucleotide pairs, and the smallest (the Y chromosome) 5×10^7 nucleotide pairs.

Each chromosomal DNA molecule contains a number of specialized nucleotide sequences that are associated with its maintenance. One is the centromeric DNA region. During mitosis, a disc-shaped structure composed of a complex array of proteins, the kinetochore, forms as a substructure at the centromeric region of DNA to which kinetochore microtubules of the spindle attach. Another region, the telomere, defines the end of each chromosomal DNA molecule. Telomeres consist of hundreds of repeats of the nucleotide sequence $(TTAGGG)_n$. The very ends of the chromosomes cannot be replicated by the same DNA polymerase as the rest of the chromosome, and are maintained by a specific enzyme called telomerase, which contains an RNA subunit acting as the template for lengthening the TTAGGG repeats. See Nandakumar and Cech (2013) for further reading on the recruitment of telomerase to telomeres. Thus telomerase is a specialized type of polymerase known as a reverse transcriptase that turns sequences in RNA back into DNA. The number of tandem repeats of the telomeric DNA sequence varies. The telomere appears to shorten with successive cell divisions because telomerase activity reduces or is absent in differentiated cells with a finite lifespan. In mammals, telomerase is active in the germ-cell lineage and in stem cells, but its expression in somatic cells may lead to or prompt cancer. A lack of telomere maintenance determines the shrinking of telomeres in proliferating cells to the point when cells stop dividing, a condition known as replicative senescence. See Sahin and DePinho (2012) for further reading on telomeres and progressive DNA damage.

The role of the telomere in ageing and cell senescence is further discussed at the end of this chapter.

Karyotypes: classification of human chromosomes

A number of genetic abnormalities can be directly related to the chromosomal pattern. The characterization or karyotyping of chromosome number and structure is therefore of considerable diagnostic importance. The identifying features of individual chromosomes are most easily seen during metaphase, although prophase chromosomes can be used for more detailed analyses.

Lymphocytes separated from blood samples, or cells taken from other tissues, are used as a source of chromosomes. Diagnosis of fetal chromosome patterns is generally carried out on samples of amniotic fluid containing fetal cells aspirated from the uterus by amniocentesis, or on a small piece of chorionic villus tissue removed from the placenta. Whatever their origin, the cells are cultured *in vitro* and stimulated to divide by treatment with agents that stimulate cell division. Mitosis is interrupted at metaphase with spindle inhibitors. The chromosomes are dispersed by first causing the cells to swell in a hypotonic solution, then the cells are gently fixed and mechanically ruptured on a slide to spread the chromosomes. They are subsequently stained in various ways to allow the identification of individual chromosomes by size, shape and distribution of stain (**Fig. 1.19**). General techniques show the obvious landmarks, e.g. lengths of arms and positions of constrictions. Banding techniques demonstrate differential staining patterns, characteristic for each chromosome type. Fluorescence staining with quinacrine mustard and related compounds produces Q bands, and Giemsa staining (after treatment that partially denatures the chromatin) gives G bands (see Fig. 1.19A). Other less widely used methods include: reverse Giemsa staining, in which the light and dark areas are reversed (R bands); the staining of constitutive heterochromatin with silver salts (C-banding); and T-banding to stain the ends (telomeres) of chromosomes. Collectively, these methods permit the classification of chromosomes into numbered autosomal pairs in order of decreasing size, from 1 to 22, plus the sex chromosomes.

A summary of the major classes of chromosome is given in **Table 1.1**.

Methodological advances in banding techniques improved the recognition of abnormal chromosome patterns. These include a reciprocal translocation between chromosomes 9 and 22, the latter being characteristically short and known as the Philadelphia (Ph^1) chromosome; it

TABLE 1.1 Summary of the major classes of chromosome

Group	Features
1–3 (A)	Large metacentric chromosomes
4–5 (B)	Large submetacentric chromosomes
6–12 + X (C)	Metacentrics of medium size
13–15 (D)	Medium-sized acrocentrics with satellites
16–18 (E)	Shorter metacentrics (16) or submetacentrics (17, 18)
19–20 (F)	Shortest metacentrics
21–22 + Y (G)	Short acrocentrics; 21, 22 with satellites, Y without

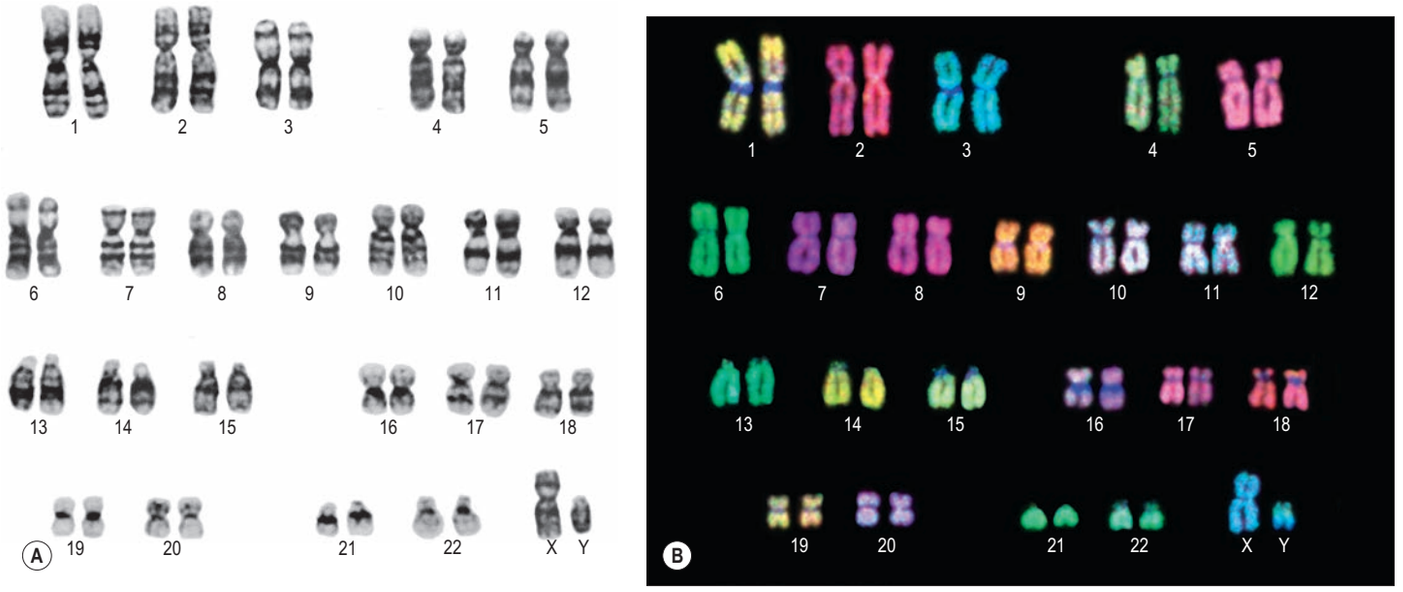

Fig. 1.19 Chromosomes from normal males, arranged as karyotypes. **A**, G-banded preparation. **B**, Preparation stained by multiplex fluorescence *in situ* hybridization to identify each chromosome. (Courtesy of Dr Denise Sheer, Cancer Research UK.)

Telomerase has been associated with ageing and cell senescence because a gradual loss of telomeres may lead to tissue atrophy, stem cell depletion and deficient tissue repair or regeneration. Mutations causing loss of function of telomerase or the RNA-containing template have been associated with dyskeratosis congenita (characterized by abnormal skin pigmentation, nail dystrophy and mucosal leukoplasia), aplastic anaemia and pulmonary fibrosis.

is a hallmark of chronic myeloid leukaemia and some cases of acute lymphoblastic leukaemia.

The use of *in situ* hybridization with fluorescent DNA probes specific for each chromosome (see Fig. 1.19B) permits the identification of even very small abnormalities.

Nucleolus

Nucleoli are a prominent feature of an interphase nucleus (see Fig. 1.2). They are the site of most of the synthesis of ribosomal RNA (rRNA) and assembly of ribosome subunits. Nucleoli organize at the end of mitosis and consist of repeated clusters of ribosomal DNA (rDNA) genes and processing molecules responsible for producing ribosome subunits. The initial step of the assembly of a ribosome subunit starts with the transcription of rDNA genes by RNA polymerase I. The rDNA genes, arranged in tandem repeats called nucleolar organizing regions (NORs), are located on acrocentric chromosomes. There are five pairs of acrocentric chromosomes in humans. The initial 47S rRNA precursor transcript is cleaved to form the mature 28S, 18S and 5.8S rRNAs, assembled with the 5S rRNA (synthesized by RNA polymerase III outside the nucleolus) and coupled to small nucleolar ribonucleoproteins and other non-ribosomal proteins to form 60S (containing 28S rRNA, 5.8S rRNA and 5S rRNA) and 40S (containing 18S rRNA) preribosome subunits. These are then exported to the cytoplasm across nuclear pores as mature ribosome subunits. About 726 human nucleolar proteins have been identified by protein purification and mass spectrometry. For further reading on nucleolar functions, see Boisvert et al (2007).

Ribosomal biogenesis occurs in distinct subregions of the nucleolus, visualized by electron microscopy. The three nucleolar subregions are fibrillar centres (FCs), dense fibrillar components (DFCs) and granular components (GCs). Transcription of the rDNA repeats takes place at the FC–DFC boundary; pools of RNA polymerase I reside in the FC region; processing of transcripts and coupling to small nucleolar ribonucleoproteins take place in DFC; and the assembly of ribosome subunits is completed in the GC region.

The nucleolus is disassembled when cells enter mitosis and transcription becomes inactive. It reforms after nuclear envelope reorganization in telophase, in a process associated with the onset of transcription in nucleolar organizing centres on each specific chromosome, and becomes functional during the G_1 phase of the cell cycle. An adequate pool of ribosome subunits during cell growth and cell division requires steady nucleolar activity to support protein synthesis. Several DNA helicases, a conserved group of enzymes that unwind DNA, accumulate in the nucleolus under specific conditions such as Bloom's syndrome (an autosomal recessive disorder characterized by growth deficiency, immunodeficiency and a predisposition to cancer) and Werner's syndrome (an autosomal recessive condition characterized by the early appearance of various age-related diseases).

CELL DIVISION AND THE CELL CYCLE

During prenatal development, most cells undergo repeated division (**Video 1.1**) as the body grows in size and complexity. As cells mature, they differentiate structurally and functionally. Some cells, such as neurones, lose the ability to divide. Others may persist throughout the lifetime of the individual as replication-competent stem cells, e.g. cells in the haemopoietic tissue of bone marrow. Many stem cells divide infrequently, but give rise to daughter cells that undergo repeated cycles of mitotic division as transit (or transient) amplifying cells. Their divisions may occur in rapid succession, as in cell lineages with a short lifespan and similarly fast turnover and replacement time. Transit amplifying cells are all destined to differentiate and ultimately to die and be replaced, unlike the population of parental stem cells, which self-renews.

Patterns and rates of cell division within tissues vary considerably. In many epithelia, such as the crypts between intestinal villi, the replacement of damaged or ageing cells by division of stem cells can be rapid. Rates of cell division may also vary according to demand, as occurs in the healing of wounded skin, in which cell proliferation increases to a peak and then returns to the normal replacement level. The rate of cell division is tightly coupled to the demand for growth and replacement. Where this coupling is faulty, tissues either fail to grow or replace their cells, or they can overgrow, producing neoplasms.

The cell cycle is an ordered sequence of events, culminating in cell growth and division to produce two daughter cells. It generally lasts a minimum of 12 hours, but in most adult tissues can be considerably longer, and is divided into four distinct phases, which are known as G_1 (for gap 1), S (for DNA synthesis), G_2 (for gap 2) and M (for mitosis). The combination of G_1, S and G_2 phases is known as interphase. M is the mitotic phase, which is further divided into four phases (see below). G_1 is the period when cells respond to growth factors directing the cell to initiate another cycle; once made, this decision is irreversible. It is also the phase in which most of the molecular machinery required to complete another cell cycle is generated. Centrosomes duplicate during S phase in preparation for mitosis. Cells that retain the capacity for proliferation, but which are no longer dividing, have entered a phase called G_0 and are described as quiescent even though they may be quite active physiologically. Growth factors can stimulate quiescent cells to leave G_0 and re-enter the cell cycle, whereas the proteins encoded by certain tumour suppressor genes (e.g. the gene mutated in retinoblastoma, *Rb*) block the cycle in G_1. DNA synthesis (replication of the genome) occurs during S phase, at the end of which the DNA content of the cell has doubled. During G_2, the cell prepares for division; this period ends with the onset of chromosome condensation and breakdown of the nuclear envelope. The times taken for S, G_2 and M are similar for most cell types, and occupy 6–8, 2–4 and 1–2 hours respectively. In contrast, the duration of G_1 shows considerable variation, sometimes ranging from less than 2 hours in rapidly dividing cells to more than 100 hours, within the same tissue.

The passage of a cell through the cell cycle is controlled by proteins in the cytoplasm: cyclins and cyclin-dependent kinases (Cdks; **Fig. 1.21**). Cyclins include G_1 cyclins (D cyclins), S-phase cyclins (cyclins E and A) and mitotic cyclins (B cyclins). Cdks, protein kinases, which are activated by binding of a cyclin subunit, include G_1 Cdk (Cdk4), an S-phase Cdk (Cdk2) and an M-phase Cdk (Cdk1). Cell cycle progression is driven in part by changes in the activity of Cdks. Each cell cycle stage is characterized by the activity of one or more Cdk–cyclin pairs. Transitions between cell cycle stages are triggered by highly specific proteolysis by the 26S proteasome of the cyclins and other key components. The targets for proteolysis are marked for destruction by E3 ubiquitin ligases, which decorate them with polymers of the small protein ubiquitin, a sign for recognition by the 26S proteasome.

To give one example, the transition from G_2 to mitosis is driven by activation of Cdk1 by its partners, the A- and B-type cyclins; the characteristic changes in cellular structure that occur as cells enter mitosis are largely driven by phosphorylation of proteins by active Cdk1-cyclin A and Cdk1-cyclin B. Cells exit from mitosis when an E3 ubiquitin ligase, the anaphase promoting complex, also called cyclosome (APC/C), marks the cyclins for destruction. In addition, APC/C prompts

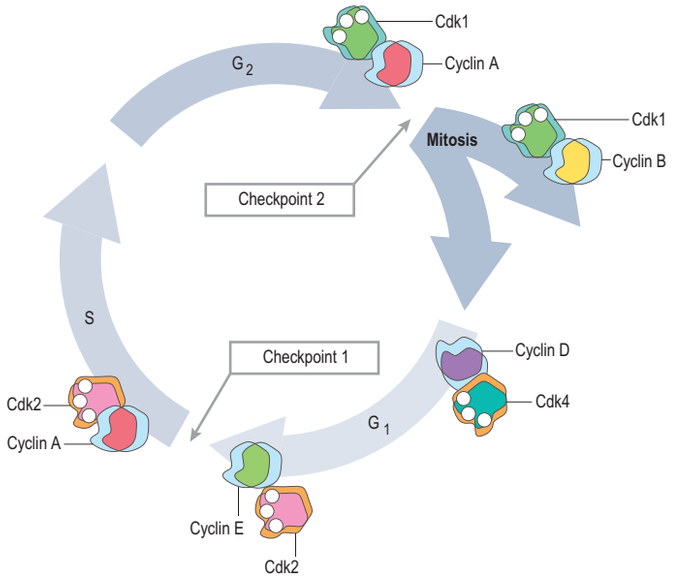

Fig. 1.21 The cell cycle consists of an interphase (G_1 phase, S phase and G_2 phase) followed by mitosis. The cyclin D/Cdk4 complex assembles at the beginning of G_1; the cyclin E/Cdk2 complex assembles near the end of G_1 as the cell is preparing to cross checkpoint 1 to start DNA synthesis (during S phase). The cyclin A/Cdk2 complex assembles as DNA synthesis starts. Completion of G_2 is indicated by the assembled cyclin A/Cdk1 complex. A cell crosses checkpoint 2 to initiate mitosis when the cyclin B/Cdk1 complex assembles. The cyclin B/Cdk1 complex is degraded by the 26S proteasome and an assembled cyclin D/Cdk4 marks the start of the G_1 phase of a new cell cycle. For details, see text. (Adapted with permission from Kierszenbaum AL, Tres LL Histology and Cell Biology: An Introduction to Pathology, 5th ed. Elsevier, Mosby. Copyright 2019.)

In this translocation, the ABL1 (cABL) cellular oncogene on chromosome 9 is relocated to a region adjacent to the *BCR* (break-point cluster) gene on chromosome 22. The resulting fusion gene codes for a hybrid protein with constitutively active tyrosine kinase signalling function. This drives uncontrolled proliferative activity in affected cells (Fig. 1.20).

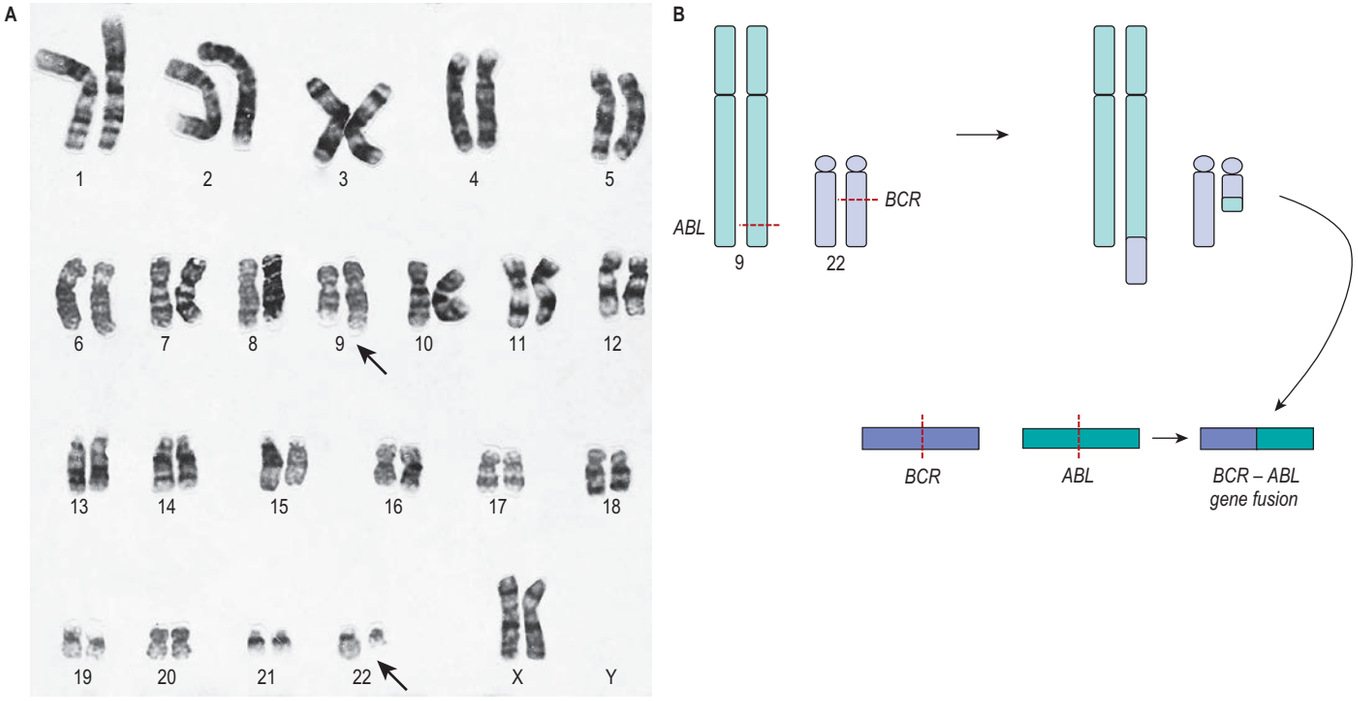

Fig. 1.20 **A**, G-banded karyotype of chronic myeloid leukaemia (CML) cells, showing a reciprocal translocation between chromosome 9 (creating the longer 9q+ chromosome) and chromosome 22. The shorter chromosome 22 is characteristic of CML and is known as the Philadelphia (Ph^1) chromosome. **B**, Representation of the Philadelphia translocation which creates a fusion gene (*BCR–ABL*). See text for details. (Courtesy of Professor Denise Sheer, Queen Mary University of London.)

the degradation of the mitotic cyclin B and the destruction of cohesins, thus allowing sister chromatids to separate.

There are important checkpoints in the cell cycle (see Fig. 1.21). Checkpoint 1 requires G_1 cyclins to bind to their corresponding Cdks to signal the cell to prepare for DNA synthesis. S-phase promoting factor (SPF; cyclin A bound to Cdk2) enters the nucleus to stimulate DNA synthesis. Checkpoint 2 requires M-phase promoting factor (mitotic cyclin B bound to M-phase Cdk1) to trigger the assembly of the mitotic spindle, breakdown of the nuclear envelope, arrest of gene transcription and condensation of chromosomes. During metaphase of mitosis, M-phase promoting factor activates APC/C, which determines the breakdown of cohesins, the protein complex holding sister chromatids together. Then, at anaphase, separated chromatids move to the opposite poles of the spindle. Finally, B cyclins are destroyed following their attachment to ubiquitin, targeting them for destruction by the 26S proteasome. As G_1 starts, cyclins D, bound to Cdk4, start preparation for a new cell cycle.

Quality control checkpoint 2 operates to delay cell-cycle progression when DNA has been damaged by radiation or chemical mutagens. Cells with checkpoint defects, such as loss of the protein p53, which is a major negative control element in the division cycle of all cells, are commonly associated with the development of malignancy. An example is Li Fraumeni syndrome, where a defective *p53* gene leads to a high frequency of cancer in affected individuals. In cells, p53 protein binds DNA and stimulates another gene to produce p21 protein, which interacts with Cdk2 to prevent S-phase promoting activity. When mutant p53 can no longer bind DNA to stimulate production of p21 to stop DNA synthesis, cells acquire oncogenic properties. The *p53* gene is an example of a tumour suppressor gene. For further reading on *p53* mutations and cancer, see Muller and Vousden (2013).

Mitosis and meiosis

Mitosis is the process that results in the distribution of identical copies of the parent cell genome to the two daughter somatic cells. In meiosis, the divisions immediately before the final production of gametes halve the number of chromosomes to the haploid number, so that at fertilization the diploid number is restored. Moreover, meiosis includes a phase in which exchange of genetic material occurs between homologous chromosomes. This allows a rearrangement of genes to take place, which means that the daughter cells differ from the parental cell in both their precise genetic sequence and their haploid state. Mitosis and meiosis are alike in many respects, and differ principally in chromosomal behaviour during the early stages of cell division. In meiosis, two divisions occur in succession, without an intervening S phase. Meiosis I is distinct from mitosis, whereas meiosis II is more like mitosis.

Mitosis

New DNA is synthesized during the S phase of the cell cycle interphase. This means that the amount of DNA in diploid cells has doubled to the tetraploid value by the onset of mitosis, although the chromosome number is still diploid. During mitosis, this amount is halved between the two daughter cells, so that DNA quantity and chromosome number are diploid in both cells. The cellular changes that achieve this distribution are conventionally divided into four phases called prophase, metaphase, anaphase and telophase (**Figs 1.22–1.23**; see Video 1.1) .

Prophase

During prophase, the strands of chromatin, which are highly extended during interphase, shorten, thicken and resolve themselves into recognizable chromosomes. Each chromosome is made up of duplicate chromatids (the products of DNA replication) joined at their centromeres. Outside the nucleus, the two centriole pairs begin to separate, and move towards opposite poles of the cell. Parallel microtubules are assembled between them to create the mitotic spindle, and others radiate to form the microtubule asters, which come to form the spindle poles or mitotic centre. As prophase proceeds, the nucleoli disappear, and the nuclear envelope suddenly disintegrates to release the chromosomes, an event that marks the end of prophase.

Prometaphase–metaphase

As the nuclear envelope disappears, the spindle microtubules extend into the central region of the cell, attaching to the chromosomes, which subsequently move towards the equator of the spindle (prometaphase). The spindle consists of kinetochore microtubules attached to the kinetochore, a multiprotein structure assembled at the centromeric DNA region, and polar microtubules, which are not attached to chromosomes but instead overlap with each other at the centre of the cell. The grouping of chromosomes at the spindle equator is called the metaphase or equatorial plate. The chromosomes, attached at their centromeres, appear to be arranged in a ring when viewed from either pole of the cell, or to lie linearly across this plane when viewed from above. Cytoplasmic movements during late metaphase effect the approximately

equal distribution of mitochondria and other cell structures around the cell periphery.

Anaphase

By the end of metaphase every chromosome consists of a pair of sister chromatids attached to opposing spindle poles by bundles of microtubules associated with the kinetochore. The onset of anaphase begins with the proteolytic cleavage by the enzyme separase of a key subunit of protein complexes known as cohesins. The latter hold the replicated sister chromatids together to resist separation even when exposed to microtubule-dependent pulling forces. Proteolytic cleavage releases the cohesion between sister chromatids, which then move towards opposite spindle poles while the microtubule bundles attached to the kinetochores shorten and move polewards. At the end of anaphase the sister chromatids are grouped at either end of the cell, and both clusters are diploid in number. An infolding of the cell equator begins, deepening during telophase as the cleavage furrow.

Telophase

During telophase the nuclear envelopes reform, beginning with the association of membranous vesicles with the surface of the chromosomes. Later, after the vesicles have fused and the nuclear envelope is complete, the chromosomes decondense and the nucleoli reform. At the same time, cytoplasmic division, which usually begins in early anaphase, continues until the new cells separate, each with its derived nucleus. The spindle remnant now disintegrates. While the cleavage furrow is active, a peripheral band or belt of actin and myosin appears in the constricting zone; contraction of this band is responsible for furrow formation.

Failure of disjunction of chromatids, so that sister chromatids pass to the same pole, may sometimes occur. Of the two new cells, one will have more, and the other fewer, chromosomes than the diploid number. Exposure to ionizing radiation promotes non-disjunction and may, by chromosomal damage, inhibit mitosis altogether. A typical symptom of radiation exposure is the failure of rapidly dividing epithelia to replace lost cells, with consequent ulceration of the skin and mucous membranes.

Mitosis can also be disrupted by chemical agents, particularly vinblastine, paclitaxel (taxol) and their derivatives. These compounds either disassemble spindle microtubules or interfere with their dynamics, so that mitosis is arrested in metaphase.

Meiosis

There are two consecutive cell divisions during meiosis: meiosis I and meiosis II (Fig. 1.24). Details of this process differ at a cellular level for male and female lineages.

Meiosis I

Prophase I

Meiotic prophase I is a long and complex phase that differs considerably from mitotic prophase and is customarily divided into five substages, called leptotene, zygotene, pachytene, diplotene and diakinesis. There are three distinctive features of male meiotic prophase that are not seen during mitotic prophase: the pairing, or synapse, of homologous chromosomes of paternal and maternal origin to form bivalent structures; the organization of nucleoli by autosomal bivalents; and significant non-ribosomal RNA synthesis by autosomal bivalents (in contrast to the transcriptional inactivity of the XY chromosomal pair) (see Tres 2005). In the female, meiotic prophase I starts during fetal gonadogenesis, is arrested at the diplotene stage, and resumes at puberty. In the male, meiosis starts at puberty.

Leptotene stage During leptotene, homologous chromosomes (maternal and paternal copies of the same chromosome), replicated in a preceding S phase and each consisting of sister chromatids joined at the centromere (see above), locate one another within the nucleus, and the process of genetic recombination is initiated. Cytologically, chromosomes begin to condense, appearing as individual threads that are attached via their telomeres to the nuclear envelope. They often show characteristic beading throughout their length.

Zygotene stage During zygotene, the homologous chromosomes initiate pairing or synapsis, during which they become intimately associated with one another. Synapsis may begin near the telomeres at the inner surface of the nuclear membrane, and during this stage the telomeres often cluster to one side of the nucleus (a stage known as the bouquet because the chromosomes resemble a bouquet of flowers). The pairs of synapsed homologues, also known as bivalents, are linked together by a tripartite ribbon, the synaptonemal complex, which consists of two lateral dense elements and a central, less dense, linear element.

The sex chromosomes also start to synapse during zygotene. In males, with distinct X and Y chromosomes, synapsis involves a region of shared DNA sequence known as the pseudoautosomal region. The XY bivalent adopts a special condensed structure, known as the sex vesicle, which becomes associated later at pachytene with migratory nucleolar masses originating in the autosomal bivalents.

Chromosome behaviour in meiosis is intimately linked with the process of genetic recombination. This begins during leptotene, as homologous chromosomes first locate one another at a distance. Synapsis, stabilized by the synaptonemal complex, facilitates recombination, as sites of genetic exchange are turned into specialized structures known as chiasmata, which are topological crossing-over points that hold homologous chromosomes together.

Pachytene stage When synapsis is complete for all chromosomes, the cell is said to be in pachytene. Each bivalent looks like a single thick structure, but is actually two pairs of sister chromatids held together by the synaptonemal complex. Genetic recombination between non-sister chromatids is completed at this point, with sites where it has occurred (usually one per chromosome arm) appearing as recombination nodules in the centre of the synaptonemal complex.

Diplotene stage During diplotene, the synaptonemal complex disassembles and pairs of homologous chromosomes, now much shortened, separate, except where crossing over has occurred (chiasmata): this process is called disjunction. At least one chiasma forms between each homologous pair, exchanging maternal and paternal sequences; up to five have been observed. In the ovaries, primary oocytes become diplotene by the fifth month *in utero* and each remains at this stage until the period before ovulation (up to 50 years).

Diakinesis Diakinesis is the prometaphase of the first meiotic division. The chromosomes, still as bivalents, become even shorter and thicker. They gradually attach to the spindle and become aligned at a metaphase plate. In eggs, the spindle forms without centrosomes. Microtubules first

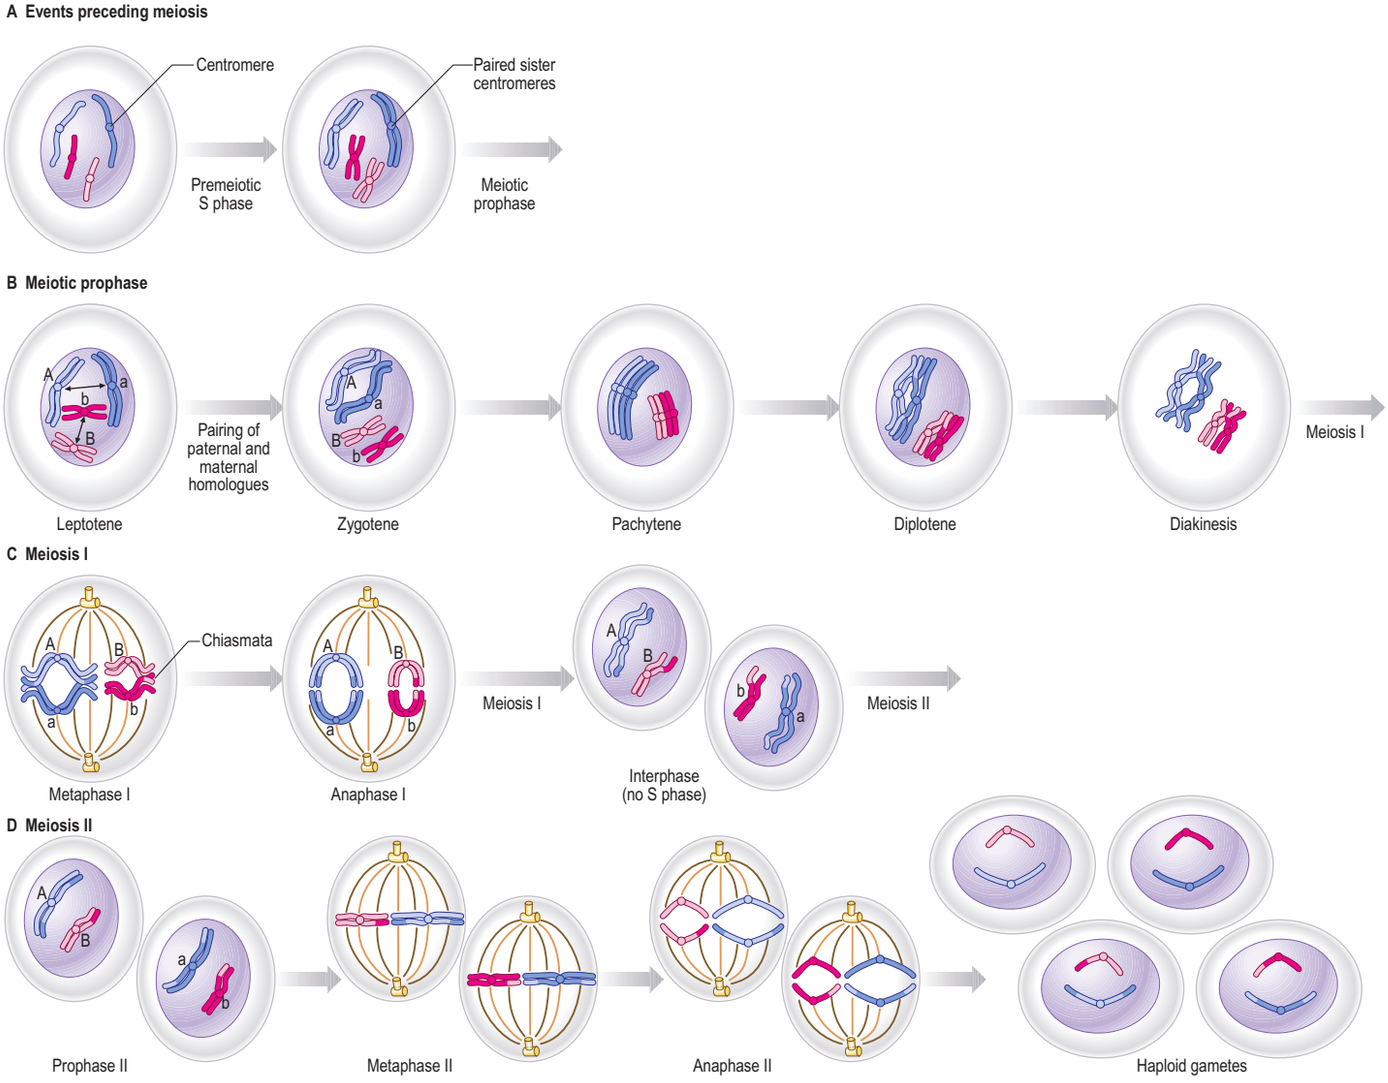

Fig. 1.24 The stages in meiosis, depicted by two pairs of maternal and paternal homologues (dark and pale colours). DNA and chromosome complement changes and exchange of genetic information between homologues are indicated.

nucleate and are stabilized near the chromosomes; the action of various motor molecules eventually sorts them into a bipolar spindle. Perhaps surprisingly, this spindle is as efficient a machine for chromosome segregation as the spindle of mitotic cells with centrosomes at the poles.

Metaphase I

Metaphase I resembles mitotic metaphase, except that the bodies attaching to the spindle microtubules are bivalents, not single chromosomes. They become arranged so that the homologous pairs occupy the equatorial plane of the spindle. The centromeres of each pair of sister chromatids function as a single unit, facing a single spindle pole. Homologous chromosomes are pulled towards opposite spindle poles, but are held paired at the spindle midzone by chiasmata. Errors in chromosome segregation (non-disjunction) lead to the production of aneuploid progeny. Most human aneuploid embryos are non-viable and this is the major cause of fetal loss (spontaneous abortion), particularly during the first trimester of pregnancy. The most common form of viable aneuploid progeny in humans is Down's syndrome (trisomy for chromosome 21): the prevalence exhibits a dramatic increase with maternal age.

Anaphase and telophase I

Anaphase I of meiosis begins with the release of cohesion between the arms of sister chromatids, much as it does during mitosis. As positioning of bivalent pairs is random, assortment of maternal and paternal chromosomes in each telophase nucleus is also random. Critically, sister centromeres, and thus chromatids, do not separate during anaphase I.

During meiosis I, cytoplasmic division occurs by specialized mechanisms. In females, the division is highly asymmetric, producing one egg and one tiny cell known as a polar body. In males, the process results in production of spermatocytes that remain joined by small cytoplasmic bridges.

Meiosis II

Meiosis II commences after only a short interval during which no DNA synthesis occurs. The centromeres of sister chromatids remain paired, but rotate so that each one can face an opposite spindle pole. Onset of anaphase II is triggered by loss of cohesion between the centromeres, as it is in mitosis. This second division is more like mitosis, in that chromatids separate during anaphase, but, unlike mitosis, the separating chromatids are genetically different (the result of genetic recombination). Cytoplasmic division also occurs and thus, in the male, four haploid cells, interconnected by cytoplasmic bridges, result from meiosis I and II.

CELL POLARITY AND DOMAINS

Epithelia are organized into sheets or glandular structures with very different environments on either side. The cells they contain actively transfer macromolecules and ions between the two surfaces and are thus polarized in structure and function. Polarized cells, particularly in epithelia, are generally subdivided into domains that reflect the activities that occur within them. The free surface, e.g. facing the intestinal lumen or airway, is the apical surface: its adjacent cytoplasm is the apical cell domain, where the cell interfaces with a specific body compartment (or, in the case of the epidermis, with the outside world). The apical surface is therefore specialized to act as a barrier, restricting access of substances from this compartment to the rest of the body. Specific components are selectively absorbed from, or added to, the external compartment by the active processes of active transport and endocytosis inwardly or exocytosis and secretion outwardly, respectively. The apical surface is often covered with microvilli, small protrusions of the cell surface which increase the surface area, particularly for absorption.

The surface of the cell opposite to the apical surface is the basal surface; its associated cytoplasm is the basolateral cell domain. In a single-layered epithelium, this surface faces the basal lamina. The other cell surfaces are known as the lateral cell surfaces: the lateral and basal surfaces often perform similar functions and their shared cellular domain is termed the basolateral domain. Cells actively transport substances, such as digested nutrients from the intestinal lumen or endocrine secretions, across their basal (or basolateral) surfaces into the subjacent connective tissue matrix and the blood capillaries that run within it. Dissolved non-polar gases (oxygen and carbon dioxide) diffuse freely between the cell and the blood stream across the basolateral surface. Apical and basolateral surfaces are separated by a tight intercellular seal, the tight junction (occluding junction, zonula adherens), which prevents the passage of even small ions through the space between adjacent cells, and thus maintains the difference between environments on either side of the epithelium.

Cell surface apical differentiations

The surfaces of many different types of cell are specialized to form structures that project from the surface. These projections may permit movement of the cell itself (flagella), or of fluids across the apical cell surface (cilia), or increase the surface area available for absorption (microvilli). Infoldings of the basolateral plasma membrane also increase the area for transport across this surface of the cell. In most non-dividing epithelial cells, the centriole-derived basal body gives rise to a non-motile primary cilium, which has an important mechanosensory role.

Cilia and flagella

Cilia and flagella are motile, hair-like projections of the cell surface. They create currents in the surrounding fluid or movements of the cell to which they are attached, or both. There are two categories of cilia: single non-motile primary cilia and multiple motile cilia. Primary cilia are non-motile but can detect physical and biochemical signals. Motile cilia are present in large numbers on the apical domains of the epithelia of the upper respiratory tract and oviducts, and beat in a wave-like motion to generate fluid movement. Cilia also occur, in modified form, at the dendritic endings of olfactory receptor cells, vestibular hair cells (kinocilia), and the photoreceptor rods and cones of the retina. Flagella have a primary function in cell locomotion. They are found on single cell eukaryotes and on spermatozoa, which each possess a single flagellum 70 µm long.

A cilium or flagellum has a shaft (0.25 µm diameter) that constitutes most of its length, a tapering tip and a basal body at its base, lying within the surface cytoplasm of the cell (**Fig. 1.25**). Other than at its base, the entire structure of a cilium is covered by plasma membrane. The core of a cilium is the axoneme, a cylinder of nine microtubule doublets surrounding a central pair of single microtubules (see Fig. 1.25). Ciliogenesis of primary and motile cilia involves distinct steps. A centriole-derived basal body migrates to the apical cell domain and axonemal microtubule doublets emerge from its distal region (the transition zone). The continued elongation of the cilium requires the import and intraciliary transport of tubulin dimers to the distal tip by bidirectional motor-driven proteins of the intraflagellar transport (IFT) complex. The constant length of cilia is maintained by a steady-state balance between tubulin turnover and the addition of new tubulin dimers at the ciliary tip.

Several filamentous structures are associated with the 9+2 doublet microtubule of the axoneme in the shaft of a cilium or flagellum. They include radial spokes that extend inwards from the outer doublet microtubules towards the central pair, surrounded by an inner sheath (see Fig. 1.25). The outer doublet microtubules bear two rows of tangential dynein arms attached to the complete A subfibre of the doublet (consisting of 13 protofilaments), that point towards the incomplete B subfibre of the adjacent doublet (consisting of 10–11 protofilaments). Adjacent doublets are also linked by thin nexin filaments. Tektins are scaffolding filamentous proteins that extend along the axonemal microtubules.

In motile cilia, arrays of dynein arms with ATPase activity cause outer microtubule doublets to move past one another, resulting in a large-scale bending motion: microtubules do not change in length. Movements of cilia and flagella are broadly similar. In addition to the axoneme, spermatozoan flagella have outer dense fibres and a fibrous sheath surrounding the axoneme. Flagella move by rapid undulation, passing from the attached to the free end. There is an additional helical component to this motion in human spermatozoa. In cilia, the beating is planar but asymmetric. In the effective stroke, the cilium remains stiff except at its base, where it bends to produce an oar-like stroke. During the recovery stroke that follows, the bend passes from base to tip, returning the cilium to its initial position for the next cycle. The activity of groups of cilia is usually coordinated so that the bending of one is rapidly followed by the bending of the next and so on, resulting in long travelling waves of metachronal synchrony that pass over the tissue surface in the same direction as the effective stroke. Ciliary motion is important in clearing mucus from airways, moving eggs along oviducts, and circulating cerebrospinal fluid in brain ventricles. In the node of the developing embryo, cilium-driven flow is essential for determining left–right visceral asymmetry (developing patterning). Cilia also have a sensory function, determined by the presence of receptor and channel proteins on the ciliary membrane, thus primary cilia in the collecting ducts of the uriniferous tubule sense the flow of urine and also modulate duct morphogenesis. Cilia are essential for signalling through the Hedgehog pathway, a mechanism involved in organizing the body plan, organogenesis and tumorigenesis in vertebrates. For additional reading on Hedgehog signalling and primary cilia, see Briscoe and Thérond (2013).

There is a group of genetic diseases in which cilia beat either ineffectively or not at all, e.g. Kartagener's immotile cilia syndrome. Affected cilia exhibit deficient function or a lack of dynein arms. Males are typically sterile because of the loss of spermatozoan motility, and half have an alimentary tract that is a mirror image of the usual pattern (*situs inversus*), because it rotates in the opposite direction during early development. Defects in ciliary motility disrupt airway mucus clearance, leading to chronic sinusitis and bronchiectasis. Defects in sensory cilia determine polycystic kidney disease, anosmia and retinal degeneration.

Intraflagellar and intraciliary transport mechanisms

In addition to anterograde and retrograde motor proteins, the assembly and maintenance of all cilia and flagella involves the participation of non-membrane-bound macromolecular protein complexes called IFT particles that are localized along the polarized microtubules of the axoneme, beneath the ciliary and flagellar membranes (reviewed in Scholey (2008)). IFT particles consist of two protein subcomplexes: IFT-A (required for retrograde transport of cargoes from the tip of the axoneme to the cell body for turnover) and IFT-B (participates in intraciliary/intraflagellar anterograde transport of cargoes from the cell body to the tip of the axoneme, a step essential for the assembly and maintenance of cilia and flagella). The movement of IFT proteins along microtubules is catalysed by kinesin-2 (towards the ciliary tip; anterograde direction) and cytoplasmic dynein-2 motor proteins (towards the cell body; retrograde direction). A cargo may include axonemal components, ciliary/flagellar membrane proteins (including the BBSome, for Bardet–Biedl syndrome, an obesity/retinopathy ciliopathy) and ciliary signal transduction proteins. For further reading on the BBSome, see Jin and Nachury (2009) and Ye et al (2018). For further reading on ciliogenesis, see Baldari and Rosenbaum (2010) and on IFT, see Hao and Scholey (2009).

The transport of the BBSome in cilia occurs in association with anterograde IFT-B and retrograde IFT-A particles.

Microvilli

Microvilli are finger-like cell surface extensions usually 0.1 µm in diameter and up to 2 µm long (**Fig. 1.26**).

When arranged in a regular parallel series, as typified by the absorptive surfaces of the epithelial enterocytes of the small intestine and the proximal convoluted tubule of the nephron of the kidneys, microvilli acquire a fuzzy appearance like the bristles of a paintbrush (termed brush border or striated border at the light microscope level).

Microvilli are covered by plasma membrane and supported internally by closely packed bundles of actin filaments linked by cross-bridges of the actin-bundling proteins, fascin and fimbrin. Other bridges composed of myosin I and calmodulin connect the filament bundles to the plasma membrane. At the tip of each microvillus, the free ends of microfilaments are inserted into a dense mass that includes the protein, villin. The actin filament bundles of microvilli are embedded in the apical cytoplasm amongst a meshwork of transversely running actin filaments stabilized by spectrin to form the terminal web, which is underlain by keratin intermediate filaments. The web is anchored laterally to the tight junctions and zonula adherens of the apical epithelial junctional complex. Myosin II and tropomyosin are also found in the terminal web, which may explain its contractile activity.

Microvilli greatly increase the area of cell surface (up to 40 times), particularly at sites of active absorption. In the small intestine, they have a very thick cell coat or glycocalyx, which reflects the presence of integral membrane glycoproteins, including enzymes concerned with digestion and absorption. Irregular microvilli, filopodia, are also found on the surfaces of many types of cell, particularly free macrophages and fibroblasts, where they may be associated with phagocytosis and cell motility. For further reading on the cytoskeleton of microvilli, see Brown and McKnight (2010).

Long and branching microvilli are called stereocilia, an early misnomer, because they are not motile and lack microtubules: an appropriate

Ciliopathies, many related to the defective sensory and/or mechanical function of cilia, include retinal degeneration and polycystic kidney disease, Bardet–Biedl syndrome, Jeune syndrome (asphyxiating thoracic dystrophy), respiratory disease and defective determination of the left–right axis. The seven-protein complex designated BBSome is a component of the basal body and participates in the formation of the primary cilium by regulating the export and/or import of ciliary proteins (see Fig. 1.25).

During ciliogenesis, IFT requires the anterograde kinesin-2 motor and the retrograde IFT-dynein motor to transport IFT particles–cargo complexes in opposite directions along the microtubules, from the basal body to the tip of the ciliary axoneme and back again (intraciliary transport). IFT is not restricted to the microtubules of cilia and flagella. During development of the spermatid tail, IFT particles–motor protein–cargo complexes appear to utilize microtubules of the manchette, a transient microtubule-containing structure, to deliver tubulin dimers and other proteins by intramanchette transport (Kierszenbaum et al 2011). IFT also occurs along the modified cilium of photoreceptor cells of the retina. Mutations in IFT proteins lead to the absence of cilia and are lethal during embryogenesis.

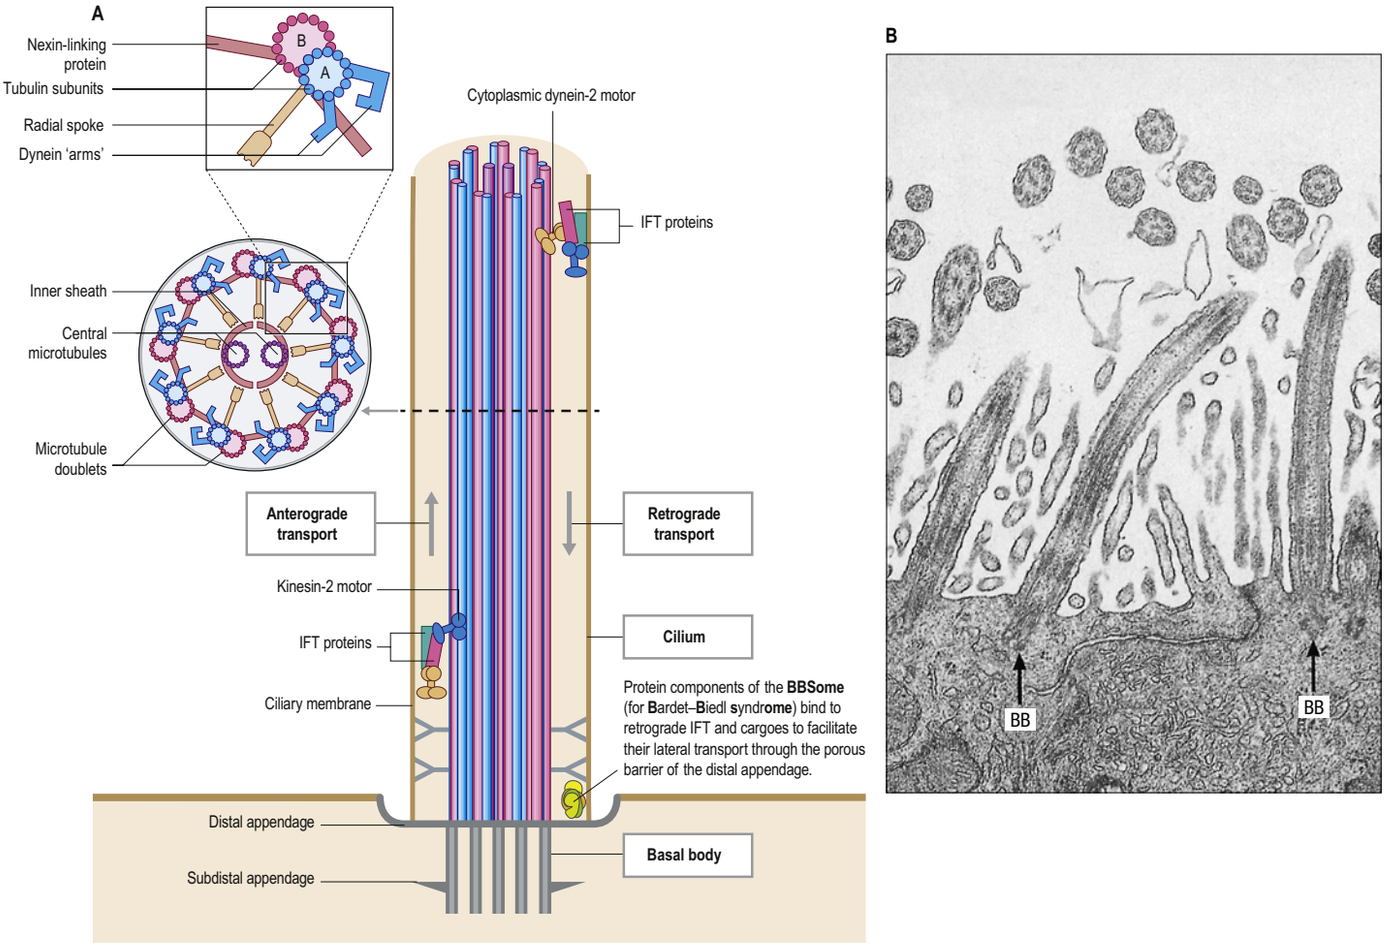

Fig. 1.25 **A**, The structure of a cilium shown in transverse (left) and longitudinal (right) section. A and B are subfibres of the peripheral microtubule doublets (see text); the basal body is structurally similar to a centriole, but with microtubule triplets. The cilium is formed and maintained by the transport of tubulins along the axoneme mediated by proteins of the intraflagellar transport (IFT) system. IFT trafficking from the base of the cilium to the tip (anterograde transport; to the microtubule plus end) is mediated by kinesin-2 motor proteins mobilizing IFT protein complexes. Cytoplasmic dynein-2 motor proteins participate in retrograde transport (to the microtubule minus end; base of the cilium). IFT proteins form a platform for transporting cargo between the base and tip of the cilium. Proteins of the Hedgehog signalling pathway participate in intraciliary and intraflagellar transport (not shown). Disruption of the kinesin-2 motor or IFT proteins blocks cilia formation. Basal body proteins influence ciliary trafficking: they include components of the BBSome, named after their association with Bardet-Biedl syndrome (BBS). BBSome proteins, bound to ciliary proteins, facilitate their crossing through the distal appendage. All motile and non-motile cilia extend from a basal body consisting of a microtubule triplet and distal and subdistal appendages. Distal appendages (also known as transition fibres) and Y-shaped structures anchor and connect the basal body to the base of the ciliary membrane. **B**, The apical region of respiratory epithelial cells, showing the proximal parts of three cilia sectioned longitudinally, anchored into the cytoplasm by basal bodies (BB). Other cilia project out of the plane of section and are cut transversely, showing the '9+2' arrangement of microtubules. B, With permission from Young B, Heath JW Wheater's Functional Histology, 4th ed. Elsevier, Churchill Livingstone. Copyright 2000.)

name is stereovilli. They are found on cochlear and vestibular receptor cells, where they act as sensory transducers, and also in the absorptive epithelium of the epididymis.

Intercellular junctions

The basolateral region of the plasma membrane of epithelial cells establishes junctions with adjacent cells and with structural components of the extracellular matrix. Intercellular junctions are resilient and dynamic, and prevent epithelial tissues from dissociating into their component cells. In adults, the epidermis withstands imposed deformations because of the interplay of two components of intercellular junctions, the junctional cytoskeleton and cell adhesion molecules (Fig. 1.27). The establishment and maintenance of cell polarity in an epithelial layer depends on two circumferential apical belts, the tight junctions and the zonulae adherentes, running in parallel to each other and associated with F-actin. These two belts control epithelial permeability and determine epithelial cell polarity. The apical cell domain resides above the belts; the basolateral cell domain resides below the belts. Desmosomes (maculae adherentes) are a third class of spot-like intercellular adhesion. In contrast to tight junctions and the zonulae adherentes, desmosomes do not form belts and link instead to intermediate filaments. The hemidesmosome, anchoring epithelial cells to the basal lamina, also links to intermediate filaments. Gap junctions are unique: they provide direct connection between adjacent cells and are not linked to the cytoskeleton. Molecular aspects of cell adhesion molecules will be considered first and then integrated with the junctional cytoskeleton to define specific structural and molecular aspects of different intercellular junctions.

Cell adhesion molecules

Cell adhesion molecules are transmembrane or membrane-anchored glycoproteins that bridge the intercellular space from the plasma membrane to form adhesive contacts. There are a number of molecular subgroups, which are broadly divisible on the basis of their dependence on calcium for function. Calcium-dependent cell adhesion molecules include cadherins and selectins. Calcium-independent cell adhesion

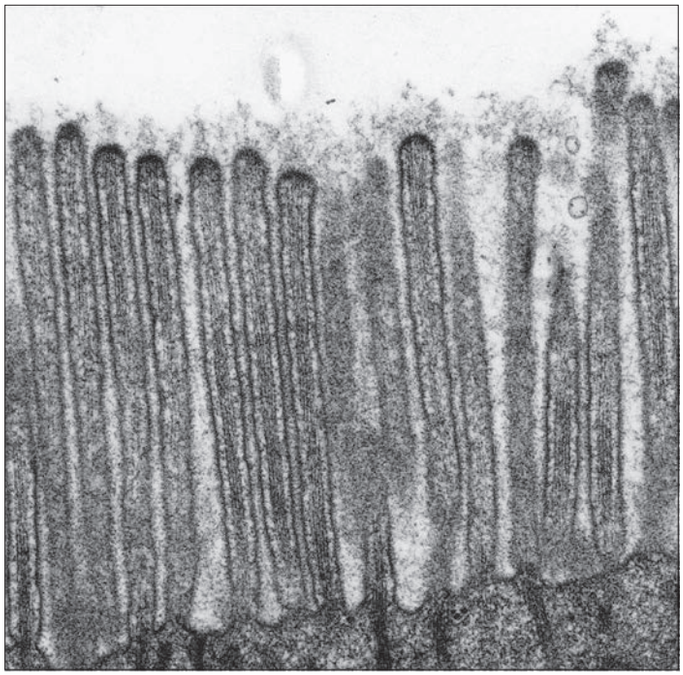

Fig. 1.26 Microvilli sectioned longitudinally in the striated border of an intestinal absorptive cell in a human duodenal biopsy specimen. Actin filaments fill the cores of the microvilli and insert into the apical cytoplasm. A prominent glycocalyx (formed by the extracellular domains of plasma membrane glycoproteins) is seen as a fuzzy coat at the tips of and between microvilli; it includes enzymes concerned with the final stages of digestion. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

molecules include the immunoglobulin-like superfamily of cell adhesion molecules (Ig-CAMs), including nectins, and integrins, the only cell adhesion molecules consisting of two subunits (α and β subunits).

Calcium-dependent cell adhesion molecules: cadherins and selectins

Cadherins are single-pass transmembrane glycoproteins, with five heavily glycosylated calcium-binding external domains and an intracellular catenin-binding cytoplasmic tail. Catenins are intracellular proteins linking cadherins to F-actin in the zonula adherens. The extracellular segment of cadherins participates in calcium-dependent homophilic *trans*-interactions in which a cadherin molecule on one cell binds to an identical cadherin molecule on an adjacent cell. After binding, cadherins cluster laterally (*cis*-interaction) at cell–cell junctions to form a zipper-like structure that stabilizes tight adhesion between cells.

Different cell types possess different members of the cadherin family, e.g. N-cadherins in nervous tissue, E-cadherins in epithelia and P-cadherins in the placenta. Two further members of the cadherin family are the desmogleins and the desmocollins. Cadherins are present in maculae adherentes and desmosomes but not in tight junctions or hemidesmosomes (see below). Alterations in the expression of cadherins in the epidermis produce pathological conditions such as blisters and ulcerations. See Brieher and Yap (2013) for further reading on cadherins and their associated cytoskeleton.

As with cadherins, selectins are calcium-dependent. In contrast to cadherins, selectins do not establish homophilic *trans*-interactions. Instead, they bind to carbohydrates and belong to the group of lectins. Each selectin has an extracellular carbohydrate recognition domain (CRD) with binding affinity to a specific oligosaccharide attached to a protein or lipid. The molecular configuration and binding affinity of the CRD to carbohydrate moieties is calcium-dependent. Selectins participate in the homing of leukocytes circulating in blood towards tissues by extravasation across the endothelium. For additional reading on the significance and mechanism of homing, see Girard et al (2012).

Three major types of selectin are L-selectin (for lymphocytes), E-selectin (for endothelial cells) and P-selectin (for platelets).

Calcium-independent cell adhesion molecules: Ig-CAMs, nectins and integrins

Ig-CAMs are cell-surface glycoproteins with an extracellular domain characterized by a variable number of immunoglobulin-like loops. Most Ig-CAMs have a transmembrane domain; others are attached to the cell surface by a glycophosphatidyl inositol (GPI) anchor. As in cadherins, Ig-CAMs establish homophilic interactions contributing to cell–cell adhesion, although in a calcium-independent manner. The cytoplasmic tail of Ig-CAMs also interacts with cytoskeletal components such as F-actin, ankyrins and spectrin. Ig-CAMs can directly or indirectly bind growth factor receptors and control their internalization.

Different types are expressed in different tissues. Neural cell adhesion molecules (N-CAMs) are found on a number of cell types but are expressed widely by neural cells. Intercellular adhesion molecules (ICAMs) are expressed on vascular endothelial cells. Cell adhesion molecule binding is predominantly homophilic, although some use a heterophilic mechanism, e.g. vascular intercellular adhesion molecule (VCAM), which can bind to integrins.

Nectins and nectin-like molecules (Necls) are members of the Ig-CAM superfamily (see Takai et al (2008) for further reading on nectins and Necls). They have an extracellular domain with three Ig-like loops, a transmembrane segment and a cytoplasmic tail. The nectins and Necls consist of four and five members, respectively. These are present in the belt-like tight junctions and zonula adherens.

The nectin–afadin complex initiates the formation of a zonula adherens; after cell–cell contacts are formed between adjacent cells, cadherins are recruited to these contact sites. Afadin and α-catenin interact with one another and also with F-actin through adaptor proteins.

Integrins mediate cell–extracellular matrix and cell–cell interactions, and integrate extracellular signals with the cytoskeleton and cellular signalling pathways. Because integrins can be activated by proteins binding to their extracellular or their intracellular domains, they can function in a bidirectional fashion by transmitting information from either outside-in (cues from the extracellular environment) or inside-out (cues from the intracellular environment) of the cell. The integrin family of proteins consists of α subunits and β subunits forming transmembrane heterodimers. The amino-acid sequence arginine–glycine–aspartic acid, or RGD motif, on target ligands (such as fibronectin, laminin and other extracellular matrix proteins) has binding affinity to the extracellular binding head of integrins. For further reading on properties of integrins and their ligands, see Barczyk et al (2010).

Specialized intercellular junctions

Specialized cell–cell junctions are the hallmark of all epithelial tissues. There are two major categories: symmetric junctions and asymmetric junctions. Symmetric junctions may be subdivided into three types: tight junctions (also known as occluding junctions or zonulae occludentes); anchoring junctions (including zonulae adherentes, or belt desmosomes, and maculae adherentes, or spot desmosomes); and communication junctions, represented by gap junctions. Tight junctions and anchoring junctions are components of the epithelial apical junctional complex. Hemidesmosomes are asymmetric junctions (see Fig. 1.27).

Tight junctions (occluding junctions, zonulae occludentes)

Tight junctions are the most apical component of the epithelial apical junctional complex. The main functions of tight junctions are the regulation of the paracellular permeability of the epithelial layer and the formation of an apical–basolateral intramembrane diffusion barrier, the hallmark of epithelial cell polarity. Tight junctions form a continuous belt (zonula) around the cell perimeter, near the apical domain of epithelial cells, and are connected to the actin cytoskeleton. At the site of the tight junction, the plasma membranes of adjacent cells come into close contact, so that the space between them is obliterated. Freeze-fracture electron microscopy shows that the contact between these membranes is represented by branching and anastomosing sealing strands of protein particles on the P (protoplasmic) face of the lipid bilayer (**Figs 1.27A, 1.27B**). A tight junction contains numerous proteins: occludins and claudins, members of the tetraspanin family of proteins, containing four transmembrane domains, two loops and two cytoplasmic tails – occludins and tetraspanins provide the molecular basis for the formation of the branching and anastomosing strands seen in freeze-fracture preparations; the afadin–nectin complex and junctional adhesion molecules (JAMs), each forming *cis*-homodimers and interacting with each other through their extracellular domains (forming *trans*-homodimers) – nectins and JAMs are members of the immunoglobulin superfamily, and the afadin component of the afadin–nectin complex interacts with F-actin; and cytosolic zonula occludens proteins 1, 2 and 3 (ZO-1, ZO-2 and ZO-3). ZO-1 protein is associated with afadin and the intracellular domain of JAMs. All three ZO proteins facilitate the reciprocal interaction of occludins, claudins and JAMs with F-actin. Defects in paracellular magnesium permeability and reabsorption in kidneys occur when there is a mutation in claudin 16 and claudin 19 (renal magnesium wasting).

The cytoplasmic tail recruits proteins of the catenin complex: β-catenin is the first to be recruited. The cadherin–β-catenin complex rapidly recruits α-catenin which binds directly to F-actin and coordinates the activity of actin-nucleating proteins and actin-binding partners (such as vinculin and α-actinin) to provide the dynamic forces that modulate cell–cell adhesion: p120-catenin binds to the cytoplasmic tail of cadherin and becomes a positive regulator of cadherin function.

Homing, a process that also enables thymus-derived T cells (Ch. 4) to home in on lymph nodes, consists of two phases. In the first, selectin phase, carbohydrate ligands on the surface of leukocytes adhere loosely to selectins present on the surface of endothelial cells. During the second, cooperative sequential integrin phase, strong adhesion permits the transendothelial migration of leukocytes into the extravascular space in cooperation with cell adhesion molecules of the Ig-CAM superfamily.

Nectins can interact homophilically or heterophilically with other nectins to mediate, primarily, adhesion. The intracellular domain of nectins binds to the cytoplasmic adaptor protein afadin, which links to actin, whereas Necls interact with scaffolding proteins but not to afadin. Necls are involved in a large variety of cellular functions, including axon–glial interaction, Schwann cell differentiation and myelination.

In humans there are about 18 α-subunit subtypes and 8 β-subunit subtypes, and 24 integrin heterodimers. The subunits are associated by non-covalent interactions and consist of an extracellular ligand-binding head, two multidomain segments, two single-pass transmembrane segments and two cytoplasmic tails. Upon binding of extracellular ligands, integrins undergo a conformational change (integrin activation), that allows the recruitment of several cytoplasmic F-actin activator proteins (such as talin, vinculin, α-actinin and kindlins) to their short cytoplasmic domain, forming a protein complex that interacts with the actin cytoskeleton.

The actin-binding protein talin binds the cytoplasmic domain of integrin β subunit and activates integrins. Vinculin interacts with talin and α-actinin and cross-links two filaments of actin. Kindlins, named after the gene mutated in Kindler's syndrome, a skin blistering disease, interact with talin to activate integrins.

The protein complex also promotes the recruitment and activation of several protein kinases (such as focal adhesion kinase), leading to the activation of signalling pathways essential for cellular activities such as cell migration, proliferation, survival and gene expression.

Genetic mutations in integrins or integrin regulators have been associated with Glanzmann's thrombasthenia (caused by mutations in integrin β3 subunit); the immunodeficiency disorder leukocyte adhesion deficiency types I and III (determined by mutations in integrin β2 subunit and kindlin 3, respectively); and skin diseases (caused by mutations in kindlin 1 and integrin α2, α6 and β3 subunits). Integrins are essential in the leucocyte homing process, following the selectin phase, and are also involved in tumour progression and metastasis.

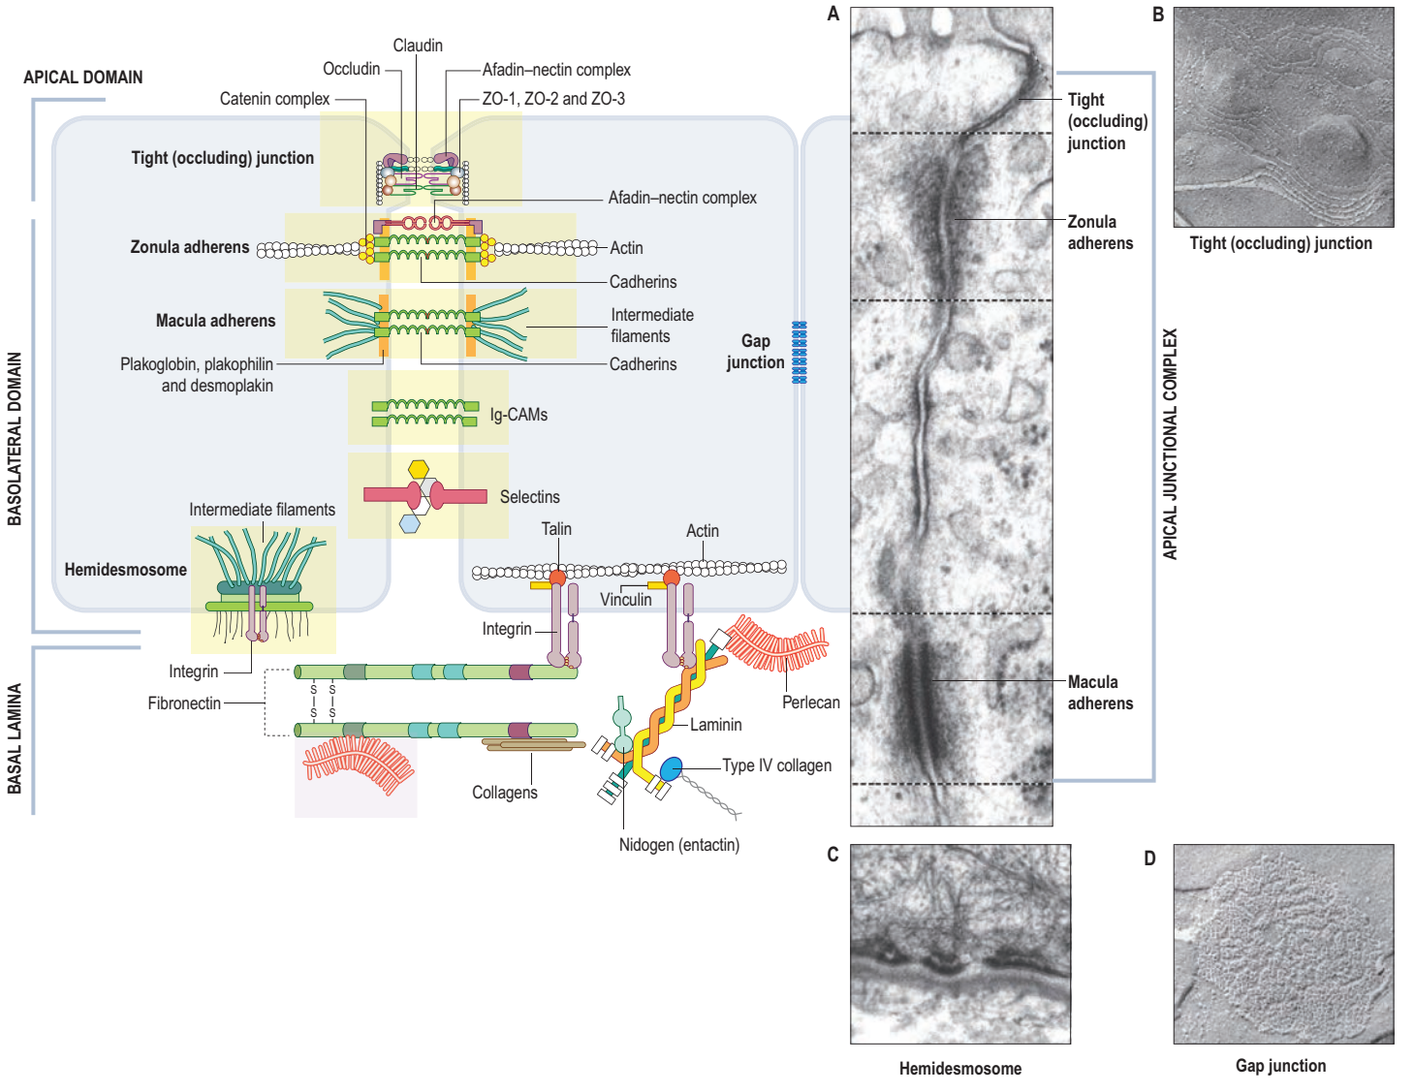

Fig. 1.27 Intercellular junctions: the apical junctional complex and other junctional specializations, illustrating the protein components of each junction and of the basal lamina. An anastomotic network of contacts between adjacent cell membranes forms a tight occluding junction. Basal plasma membrane is attached to a basal lamina at a hemidesmosome. In a gap junction, numerous channels (pores within connexons) are clustered to form a plaque-like junctional region between adjacent plasma membranes. (**A** and **C** are transmission electron micrographs; **B** and **D** are freeze-fractured preparations.) **A**, An apical junctional complex. **B**, A tight junction. **C**, A hemidesmosome. **D**, A gap junction. Anchoring junctions

In contrast to tight junctions, zonulae adherentes and maculae adherentes are characterized by the presence, along the cytosolic sides of the plasma membranes of adjacent epithelial cells, of symmetric dense plaques connected to each other across the intercellular space by cadherins. They differ in that F-actin is associated with plaques in zonulae adherentes and intermediate filaments are linked to plaques in maculae adherentes.

Zonula adherens (belt desmosome)

A zonula adherens is a continuous belt-like zone of adhesion parallel and just basal to a tight junction and also encircling the apical perimeter of epithelial cells. Calcium-dependent cell adhesion molecules (members of the desmoglein and desmocollin families of cadherins) are key components of a zonula adherens. In addition to the cadherin–catenin complex, a zonula adherens also houses the afadin–nectin complex.

Essentially, two molecules, cadherins and afadin, link to the actin cytoskeleton. In cultured cells, nectins appear to initiate the formation of a zonula adherens before the involvement of cadherins.

A specific component of a zonula adherens is a cytoplasmic dense plaque attached to the cytosolic side of the plasma membrane. It consists of desmoplakin, plakophilin and plakoglobin proteins (the latter is also known as γ-catenin). A similar plaque is seen in a macula adherens or spot desmosome (see below).

Fascia adherens

A fascia adherens is similar to a zonula adherens, but is more limited in extent and forms a strip or patch of adhesion, e.g. between smooth muscle cells, in the intercalated discs of cardiac muscle cells and between glial cells and neurones. The junctions involve cadherins attached indirectly to actin filaments on the inner side of the membrane.

Desmosomes (maculae adherentes)

Desmosomes are limited, plaque-like areas of particularly strong intercellular contact. In epithelial cells, they may be located subjacent to the tight junction and zonula adherens belts, forming collectively the epithelial apical junctional complex (see Fig. 1.27A). The intercellular gap is approximately 25 nm; it is filled with electron-dense filamentous material (the intercellular cadherins) running transversely across it and is also marked by a series of densely staining bands (the cytoplasmic dense plaques) running parallel to the cell surfaces. Adhesion is mediated by

calcium-dependent cadherins, desmogleins and desmocollins. Within the cells on either side, each cytoplasmic dense plaque underlies the plasma membrane and consists of the proteins plakophilin, desmoplakin and plakoglobin (γ-catenin), into which the ends of intermediate filaments are inserted. The type of intermediate filament depends on the cell type, e.g. keratins are found in epithelia and desmin filaments are found in cardiac muscle cells. Desmosomes form strong anchorage points, likened to spot-welds, between cells subject to mechanical stress, e.g. in the prickle cell layer of the epidermis, where they are extremely numerous and large.

Hemidesmosomes

Hemidesmosomes are asymmetric anchoring junctions found between the basal side of epithelial cells and the associated basal lamina. The latter is a component of the basement membrane and contains laminin, an integrin ligand. The other component of the basement membrane is the reticular lamina, a collagen-containing layer produced by fibroblasts that also contains fibronectin, another integrin ligand. Hemidesmosomes resemble a single-sided desmosome, anchored on one side to the plasma membrane, and on the other to the basal lamina and adjacent collagen fibrils (**Fig. 1.27C**). The plaque has distinct proteins not seen in the plaques of a zonula adherens or a macula adherens: BPAG1 (bullous pemphigoid antigen 1), a member of the plakin family, and BPAG2 (bullous pemphigoid antigen 2), which possesses an extracellular collagenous domain. BPAG1 and BPAG2 were initially detected in patients with bullous pemphigoid, an autoimmune blistering disease. On the cytoplasmic side of the dense plaque there is a less dense plate into which keratin filaments are inserted, where they interact with the protein plectin associated with integrin α6β4. Hemidesmosomes use integrins and anchoring filaments (laminin 5) as their adhesion molecules anchored to the basal lamina, whereas desmosomes use cadherins.

Focal adhesion plaques

Less highly structured attachments with a similar arrangement exist between many other cell types and their surrounding matrices, e.g. between smooth muscle cells and their matrix fibrils, and between the ends of skeletal muscle cells and tendon fibres. The smaller, punctate adhesions resemble focal adhesion plaques, which are regions of local attachment between cells and the extracellular matrix. They are typically situated at or near the ends of actin filament bundles (stress fibres), anchored through intermediary proteins to the cytoplasmic domains of integrins. In turn, these are attached at their external ends to collagen or other filamentous structures in the extracellular matrix. They are usually short-lived; their formation and subsequent disruption are part of the motile behaviour of migratory cells. See Geiger et al (2009) for further reading on focal adhesions.

Gap junctions (communicating junctions)

Gap junctions resemble tight junctions in transverse section, but the two apposed lipid bilayers are separated by an apparent gap of 3 nm, which is bridged by a cluster of transmembrane channels (connexons). Each connexon is formed by a ring of six connexin proteins whose external surfaces meet those of the adjacent cell in the middle. A minute central pore links one cell to the next (**Fig. 1.27D**). Larger assemblies of many thousands of channels are often packed in hexagonal arrays. Gap junctions occur between numerous cells, including hepatocytes and cardiac myocytes.

AGEING, CELLULAR SENESCENCE, CANCER AND APOPTOSIS

Ageing is a universal feature of biological organisms, defined by a gradual decline over time in cell and tissue function that often, but not always, decreases the longevity of an individual. The hallmarks of ageing are reviewed in Kubben and Misteli (2017).

Cellular senescence is defined by an irreversible arrest in cell proliferation when cells experience DNA damage at telomeres and a decrease in mitogenic signalling. In contrast to reversibly arrested quiescent cells in G_0 of the cell cycle, senescent growth arrest is irreversible; cells in this state cannot be stimulated to proliferate by known stimuli and cannot be prompted to re-enter the cell cycle by physiological mechanisms. For further reading on senescence and the cell cycle, see Chandler and Peters (2013). Senescent cells can cause or foster degenerative diseases. In old age, cellular senescence in humans determines typical pathologies, including atherosclerosis leading to stroke, osteoporosis, macular degeneration, cardiopulmonary and renal failure, and neurodegenerative diseases such as Alzheimer's and Parkinson's disease.

Senescent cells undergo changes in gene expression, which result in the secretion of proinflammatory cytokines, growth factors and proteases, activities that collectively define a senescence-associated secretory phenotype capable of triggering angiogenesis, inflammatory responses, stem cell renewal and differentiation, and which may also determine resistance to cancer chemotherapy. Senescent cells can be identified histochemically by their expression of either senescence-associated β-galactosidase, a lysosomal marker which is overexpressed in these cells, or the tumour suppressor protein $p16^{INK4a}$, which promotes the formation of senescence-associated chromatin. For further reading on ageing, cellular senescence and cancer, see Campisi (2013).

Cellular senescence can be caused by a disruption of metabolic signalling pathways, derived from mitogens and proliferation factors, and the activation of tumour suppressors, combined with telomere shortening and genomic damage. See Sahin and DePinho (2012) and Kubben and Misteli (2017) for further reading.

Cellular senescence suppresses tumorigenesis because cell proliferation is required for cancer development. However, senescent cells can stimulate the proliferation and malignant progression of adjacent premalignant cells by the release of senescence-inducing oncogenic stimuli. Cancer cells must harbour mutations to prevent telomere-dependent and oncogene-induced senescence, such as in the p53 and p16-retinoblastoma protein pathways. See Kubben and Misteli (2017) for further reading on the pathogenesis of premature ageing and ageing-associated diseases.

Apoptosis

Cells die as a result of either tissue injury (necrosis) or the internal activation of a 'suicide' programme (apoptosis) in response to extrinsic or intrinsic cues. Apoptosis (programmed cell death) is defined by the controlled demolition of cellular constituents and the ultimate uptake of apoptotic cell fragments by other cells to prevent immune responses. Some senescent cells become resistant to cell-death signalling, i.e. they are apoptosis-resistant. In effect, senescence blocks growth of damaged or stressed cells, whereas apoptosis quickly disposes of them. Apoptosis is a central mechanism controlling multicellular development. During morphogenesis, apoptosis mediates activities such as the separation of the developing digits, and plays an important role in regulating the number of neurones in the nervous system (the majority of neurones die during development). Apoptosis also ensures that inappropriate or inefficient T cells are eliminated in the thymus during clonal selection.

The morphological changes exhibited by necrotic cells are very different from those seen in apoptotic cells. Necrotic cells swell and subsequently rupture, and the resulting debris may induce an inflammatory response. Apoptotic cells shrink, their nuclei and chromosomes fragment, forming apoptotic bodies, and their plasma membranes undergo conformational changes that act as a signal to local phagocytes. The dead cells are removed rapidly, and as their intracellular contents are not released into the extracellular environment, inflammatory reactions are avoided; the apoptotic fragments also stimulate macrophages to release anti-inflammatory cytokines.

Apoptosis and cell proliferation are intimately coupled; several cell cycle regulators can influence both cell division and apoptosis. The signals that trigger apoptosis include withdrawal of survival factors or exposure to inappropriate proliferative stimuli. Three main routes to the induction of apoptosis have been established (**Fig. 1.28**). Two, the Fas ligand (FasL) pathway and the granzyme B pathway, are extrinsic, whereas the mitochondrial route is intrinsic. The FasL pathway involves binding of FasL to death receptors on the plasma membrane and recruitment of adaptor proteins, such as the Fas-associated death domain proteins, followed by the recruitment and activation of caspase 8. The granzyme B pathway involves creation of a perforin plasma membrane channel enabling the caspase-like granzyme B to enter the cell. The intrinsic mitochondrial route involves the release of cytochrome *c* from the space between the inner and outer mitochondrial membranes into the cytosol. Extrinsic and intrinsic pathways work cooperatively in the subsequent activation of a family of initiator-effector proteases, known as caspases (cysteine aspartic acid-specific proteases), which are present in healthy cells as inactive precursor enzymes or zymogens. Activation of caspases 3, 6 and 7 mediates apoptosis by initiating a cascade of degradative processes that target major constituents of the cell cytoskeleton, producing membrane blebbing, a distinctive feature of apoptosis caused by cytosolic and nuclear fragments flowing into the developing apoptotic bodies. Caspase cleavage inactivates many systems that normally promote damage repair and support cell viability, and activates a number of proteins that promote the death and disassembly of the cell. For further reading on apoptosis, see Taylor et al (2008).

The ends of the chromosomes, or telomeres, become shorter and more dysfunctional with each DNA replication round. Telomere shortening has been shown to activate DNA damage responses, leading to mitochondrial dysfunction (a decrease in production of ATP and an increase in reactive oxygen species) and the activation of p53, which induces growth arrest, apoptosis and senescence of stem cells and progenitor cells. p53 interconnects with different longevity metabolic signalling pathways, including the insulin, insulin-like growth factor I (IGFI) and mammalian target of rapamycin (mTOR) pathways, which are known to regulate lifespan by increasing the expression of genes involved in stress resistance and energy balance. Mutations in TERC (the RNA component of telomerase) and TERT (the catalytic component of telomerase) are found in patients with dyskeratosis congenita (an example of a premature ageing syndrome), a bone marrow failure syndrome classically associated with a triad of mucocutaneous features: nail dystrophy, oral leukoplakia and abnormal reticulate skin pigmentation. Other important contributors to cell senescence are dysregulated autophagy and lack of disposal of misfolded proteins by the ubiquitin–26S proteasome machinery. These responses are collectively designated telomere-initiated cellular senescence.

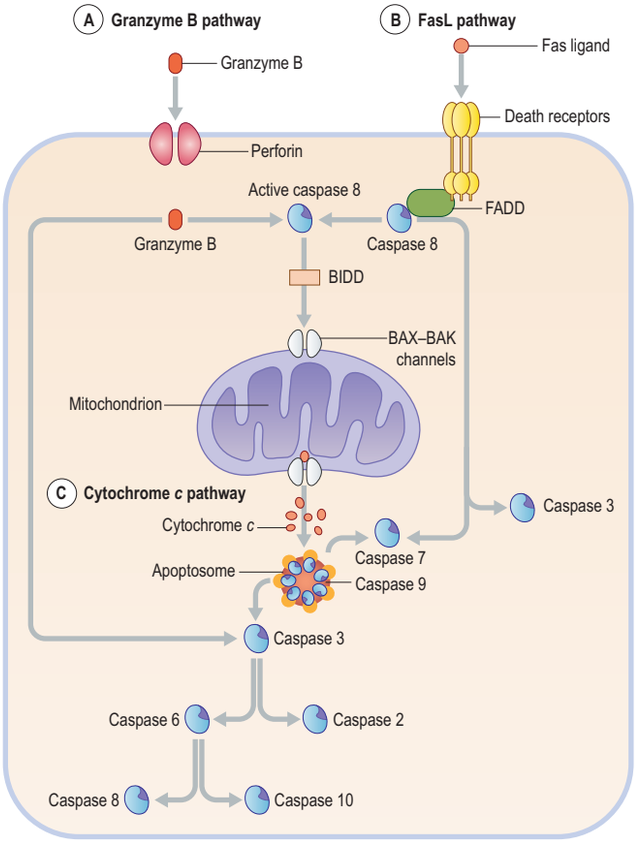

Fig. 1.28 Caspase activation pathways during apoptosis. **A**, The granzyme B extrinsic pathway activates caspase 8 and caspase 3 following entry of granzyme B across the plasma membrane pore-forming protein, perforin. This pathway is observed in cytotoxic T cells or natural killer cells for delivery of the protease granzyme B to target cells. **B**, The Fas ligand (FasL) extrinsic pathway is initiated by binding of FasL to clustered transmembrane death receptors that recruit adaptor proteins, such as the Fas-associated death-domain protein (FADD), to their intracellular domain which in turn recruits and aggregates caspase 8 molecules, which become activated. Activated caspase 8 activates caspase 7 and caspase 3. **C**, The cytochrome *c* intrinsic pathway is initiated when granzyme B or activated caspase 8 causes the proteolytic truncation of the protein BIDD (BH3-interacting domain death agonist) that penetrates a mitochondrion through BAX–BAK (BCL-2 associated X protein–BCL-2 antagonist killer) channel proteins on the outer mitochondrial membrane, causing the release of cytochrome *c*. Cytochrome *c* enables the assembly of the apoptosome (consisting of seven molecules of apoptosis protease-activating factor-1 (APAF1) and seven molecules of caspase 9), which in turn activates caspase 3 and caspase 7. Finally, the proteolytic activation cascade of caspase 6, caspase 2, caspase 8 and caspase 10 executes cell deconstruction.

Intracellular proteolytic mechanisms

The intracellular degradation of organelles and residual or misfolded proteins can be mediated by the autophagy pathway, the ubiquitin-proteasome pathway and the mitophagy signalling pathway (Fig. 1.29). The autophagy pathway involves the sequestration of cytoplasmic components within autophagosomes. Progressive dysfunction of autophagy is likely to lead to ageing. The ubiquitin-proteasome pathway utilizes a catalytic multi-subunit structure, the 26S proteasome, that recognizes ubiquitinated proteins for degradation. This pathway (Fig. 1.29B) directs the degradation of proteins that have already accomplished a specific function (such as specific cyclins during the cell cycle) or proteins that have folded incorrectly because of faulty translation or are encoded by defective genes. The mitophagy signalling pathway (Fig. 1.29C) specifically eliminates damaged mitochondria to maintain normal cell function.

The apoptosis pathway is concerned with the turnover of entire cells. While apoptosis and the ubiquitin-proteasome activities take place in the cytosol, autophagy occurs within a sealed compartment, the autophagosome, with the assistance of lysosomes. Defects in mitochondrial function are the cause of reactive oxidative stress and specific neurodegenerative disorders, such as some familial forms of Parkinson's disease.

The autophagy pathway (Fig. 1.29A) is a self-degradation and cytoprotective process involved in the turnover of cytoplasmic organelles as an adaptation to declining nutrient resources or as a form of cell death (when the intensity and duration of stress are excessive). The process of autophagy starts with the phagophore, a cytomembrane derived from the endoplasmic reticulum, Golgi or plasma membrane. The phagophore expands, surrounds and encloses a cytoplasmic component (such as a mitochondrion) that is captured within a double membrane structure, the autophagosome. Autophagy is a cellular cleansing and recycling pathway; apoptosis often occurs in the same cell, when autophagy precedes apoptosis.

The 26S proteasome is a multicatalytic protease found in the cytosol and the nucleus that degrades intracellular proteins conjugated to a polyubiquitin chain by an enzymatic cascade. The 26S proteasome consists of several subunits arranged into two 19S polar caps, where protein recognition and adenosine 5′-triphosphate (ATP)-dependent target processing occur, flanking a 20S central barrel-shaped structure with an inner proteolytic chamber (Tomko and Hochstrasser 2013). The 26S proteasome participates in the removal of misfolded or abnormally assembled proteins, the degradation of cyclins involved in the control of the cell cycle, the processing and degradation of transcription regulators, cellular-mediated immune responses, and cell cycle arrest and apoptosis.

The mitophagy signalling pathway involves two enzymes: Parkin, a ubiquitin ligase that is located in the cytoplasm in an inactive form, and PINK1, a protein kinase, associated with the outer mitochondrial membrane. In response to mitochondrial damage, PINK1 recruits and activates Parkin: activated Parkin exerts its ubiquitin ligase activity by transferring polyubiquitin to proteins attached to the outer mitochondrial membrane. Ubiquitin-tagged proteins are recognized by the proteasomal proteolytic machinery to initiate mitochondrial degradation. The goal of the Parkin–PINK1 complex is to eliminate defective mitochondria. If the Parkin–PINK1 complex is defective, dysfunctional mitochondria are not cleared and cell function is compromised. Parkinson's disease is an example of a neurodegenerative disease caused by mitochondrial dysfunction determined by mutations in the ubiquitin ligase Parkin and protein kinase (PINK1). There is a clear difference between the lysosome-based autophagy pathway and the ubiquitin-proteasome-based mitophagy signalling pathway that is recruited in the removal of aged or damaged mitochondria.

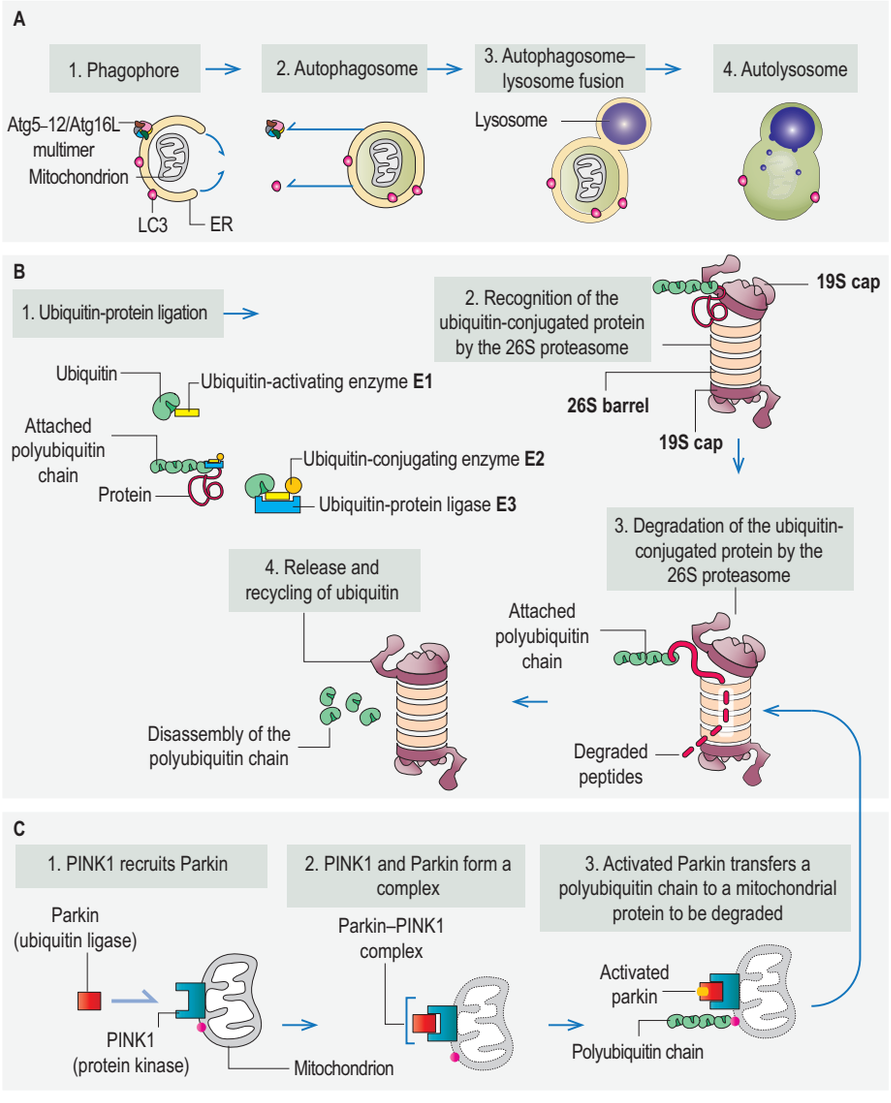

Fig. 1.29 A, The autophagy pathway. 1. Assembly of a phagophore involves a membrane of the endoplasmic reticulum (ER), the conjugation of Atg (autophagy)5–Atg12 proteins interacting with Atg16L, and the insertion of LC3 (light chain 3). 2. The presence of LC3 in the extended and fused membranes of the autophagosome facilitates enclosure of a mitochondrion for degradation. The Atg5–12/Atg16L multimeric complex and some LC3 are then recycled. 3. A lysosome fuses with the autophagosome: LC3 remains associated with double membrane-containing autophagosomes. 4. The mitochondrion is proteolytically degraded within the autolysosome by hydrolytic lysosomal enzymes. Note that the autolysosome (autophagolysosome) has a single membrane. **B**, The ubiquitin-proteasome pathway. 1. The degradation process is initiated by the attachment of ubiquitin to a protein targeted for degradation. Ubiquitin-activating enzyme E1 attaches the first ubiquitin molecule to the target protein, followed by the construction of an attached polyubiquitin chain involving ubiquitin-conjugating enzyme E2 and ubiquitin-ligating enzyme E3. 2. The polyubiquitin chain-tagged protein is recognized by the 26S proteasome which consists of two 19S polar caps flanking a 25S barrel. An open 19S cap is the entry site to the 25S barrel. 3. Protein degradation takes place within the 26S barrel. 4. The polyubiquitin chain disassembles and the ubiquitin components recycle when protein degradation is completed. **C,** Mitophagy. 1. In contrast to the autophagy pathway, no autophagosome is assembled to degrade a mitochondrion. Instead, the ubiquitin ligase Parkin (like E3 in the ubiquitin-proteasome pathway) is recruited by the protein kinase PINK1 that is present in the outer membrane of a mitochondrion, close to a target protein for degradation. 2. A Parkin–PINK1 complex is formed. 3. Activated Parkin transfers a polyubiquitin chain to a mitochondrial protein to initiate the degradation process. The 26S proteasome, called into action, degrades the polyubiquitin-conjugated protein, leading to the destruction of the mitochondrion. CHAPTER 2

Integrating cells into tissues

Cells evolved as single, free-living organisms, but natural selection favoured more complex communities of cells, multicellular organisms, where groups of cells specialize during development to carry out specific functions for the body as a whole. This allowed the emergence of larger organisms with greater control over their internal environment and the evolution of highly specialized organic structures such as the brain. The human body contains more than 200 different cell types, sharing the same genome but with different patterns of gene expression.

Some cells in the body are essentially migratory, but most exist as cellular aggregates in which individual cells carry out similar or closely related functions in a coordinated manner. These aggregates are termed tissues, and can be classified into a fairly small number of broad categories on the basis of their structure, function and molecular properties. On the basis of their structure, most tissues are divided into four major types: epithelia, connective or supporting tissue, muscle and nervous tissue. Epithelia are continuous layers of cells with little intercellular space, which cover or line surfaces, or have been so derived. In connective tissues, the cells are embedded in an extracellular matrix, which, typically, forms a substantial and important component of the tissue. Muscle consists largely of specialized contractile cells. Nervous tissue consists of cells specialized for conducting and transmitting electrical and chemical signals and the cells that support this activity.

There is molecular evidence that this structure-based scheme of classification has validity. Thus the intermediate filament proteins characteristic of all epithelia are keratins (Pan et al 2012); those of connective tissue are vimentins; those of muscle are desmins; and those of nervous tissue are neurofilament and glial fibrillary acidic proteins. However, cells such as myofibroblasts, neuroepithelial sensory receptors and ependymal cells of the central nervous system have features of more than one tissue type. Despite its anomalies, the scheme is useful for descriptive purposes; it is widely used and will be adopted here.

In this chapter, two of the major tissue categories, epithelia and general connective and supporting tissues, will be described. Specialized skeletal connective tissues, i.e. cartilage and bone, together with skeletal muscle, are described in detail in Chapter 5 as part of the musculoskeletal system overview. Smooth muscle and cardiac muscle are described in Chapter 6. Nervous system tissues are described in Chapter 3. Specialized defensive cells, which also form a migrant population within the general connective tissues, are considered in more detail in Chapter 4, with blood, lymphoid tissues and haemopoiesis.

EPITHELIA

The term epithelium is applied to the layer or layers of cells that cover the body surfaces or line the body cavities that open on to it. The fate of embryonic epithelial populations is illustrated in Fig. 12.3. Epithelia function generally as selective barriers that facilitate, or inhibit, the passage of substances across the surfaces they cover. In addition, they may: protect underlying tissues against dehydration, chemical or mechanical damage; synthesize and secrete products into the spaces that they line; and function as sensory surfaces. In this respect, many features of nervous tissue can be regarded as those of a modified epithelium and the two tissue types share an origin in embryonic ectoderm.

Epithelia (**Fig. 2.1**) are predominantly cellular and the little extracellular material they possess is limited to the basal lamina. Intercellular junctions, which are usually numerous, maintain the mechanical cohesiveness of the epithelial sheet and contribute to its barrier functions. A series of three intercellular junctions forms a typical epithelial junctional complex: in sequence from the apical surface, this consists of a tight junctional zone, an adherent (intermediate) junctional zone and a region of discrete desmosome junctions. Epithelial cell shape is most usually polygonal and partly determined by cytoplasmic features such as secretory granules. The basal surface of an epithelium lies in contact with a thin layer of filamentous protein and proteoglycan termed the basal lamina, which is synthesized predominantly by the epithelial cells. The basal lamina is described on p. 35.

Epithelia can usually regenerate when injured. Indeed, many epithelia continuously replace their cells to offset cell loss caused by mechanical abrasion (reviewed in Blanpain et al 2007). Blood vessels do not penetrate typical epithelia and so cells receive their nutrition by diffusion from capillaries of neighbouring connective tissues. This arrangement limits the maximum thickness of living epithelial cell layers. Epithelia, together with their supporting connective tissue, can often be removed surgically as one layer, which is collectively known as a membrane. Where the surface of a membrane is moistened by mucous glands it is called a mucous membrane or mucosa (see p. 41), whereas a similar layer of connective tissue covered by mesothelium is called a serous membrane or serosa.

Classification

Epithelia can be classified as unilaminar (single-layered, simple), in which a single layer of cells rests on a basal lamina; or multilaminar, in which the layer is more than one cell thick. The latter includes: stratified squamous epithelia, in which flattened superficial cells are constantly replaced from the basal layers; urothelium (transitional epithelium), which serves special functions in the urinary tract; and other multilaminar epithelia such as those lining the largest ducts of some exocrine glands, which, like urothelium, are replaced only very slowly under normal conditions. Seminiferous epithelium is a specialized multilaminar tissue found only in the testis.

Unilaminar (simple) epithelia

Unilaminar epithelia are further classified according to the shape of their cells, into squamous, cuboidal, columnar and pseudostratified types. Cell shape may, in some cases, be related to cell volume. Where little cytoplasm is present, there are generally few organelles and therefore there is low metabolic activity and cells are squamous or low cuboidal. Highly active cells, e.g. secretory epithelia, contain abundant mitochondria and endoplasmic reticulum, and are typically tall cuboidal or columnar. Unilaminar epithelia can also be subdivided into those that have special functions, such as those with cilia, numerous microvilli, secretory vacuoles (in mucous and serous glandular cells) or sensory features. Myoepithelial cells, which are contractile, are found as isolated cells associated with glandular structures, e.g. salivary and mammary glands.

Squamous epithelium

Simple squamous epithelium is composed of flattened, tightly apposed, polygonal cells (squames). This type of epithelium is described as tessellated when the cells have complex, interlocking borders rather than straight boundaries. The cytoplasm may in places be only 0.1 μm thick and the nucleus usually bulges into the overlying space (**Fig. 2.2A**). These cells line the alveoli of the lungs, where their surface area is huge and cytoplasmic volume correspondingly large, and they also form the outer capsular wall of renal corpuscles, the thin segments of the renal tubules and various parts of the inner ear. Because it is so thin, simple squamous epithelium allows rapid diffusion of gases and water across its surface; it may also engage in active transport, as indicated by the presence of numerous endocytic vesicles in these cells. Tight junctions (occluding junctions, zonulae occludentes) between adjacent cells ensure that materials pass primarily through cells, rather than between them.

Cuboidal and columnar epithelia

Cuboidal and columnar epithelia consist of regular rows of cylindrical cells (**Figs 2.2B–C**). Cuboidal cells are approximately square in vertical section, whereas columnar cells are taller than their diameter, and both are polygonal when sectioned horizontally. Commonly, microvilli are found on their free surfaces, considerably increasing the absorptive area, e.g. in the epithelia of the small intestine (columnar cells with a striated border of very regular microvilli), the gallbladder (columnar cells with a brush border of microvilli); proximal convoluted tubules of the kidney (large cuboidal to low columnar cells with brush borders); and the

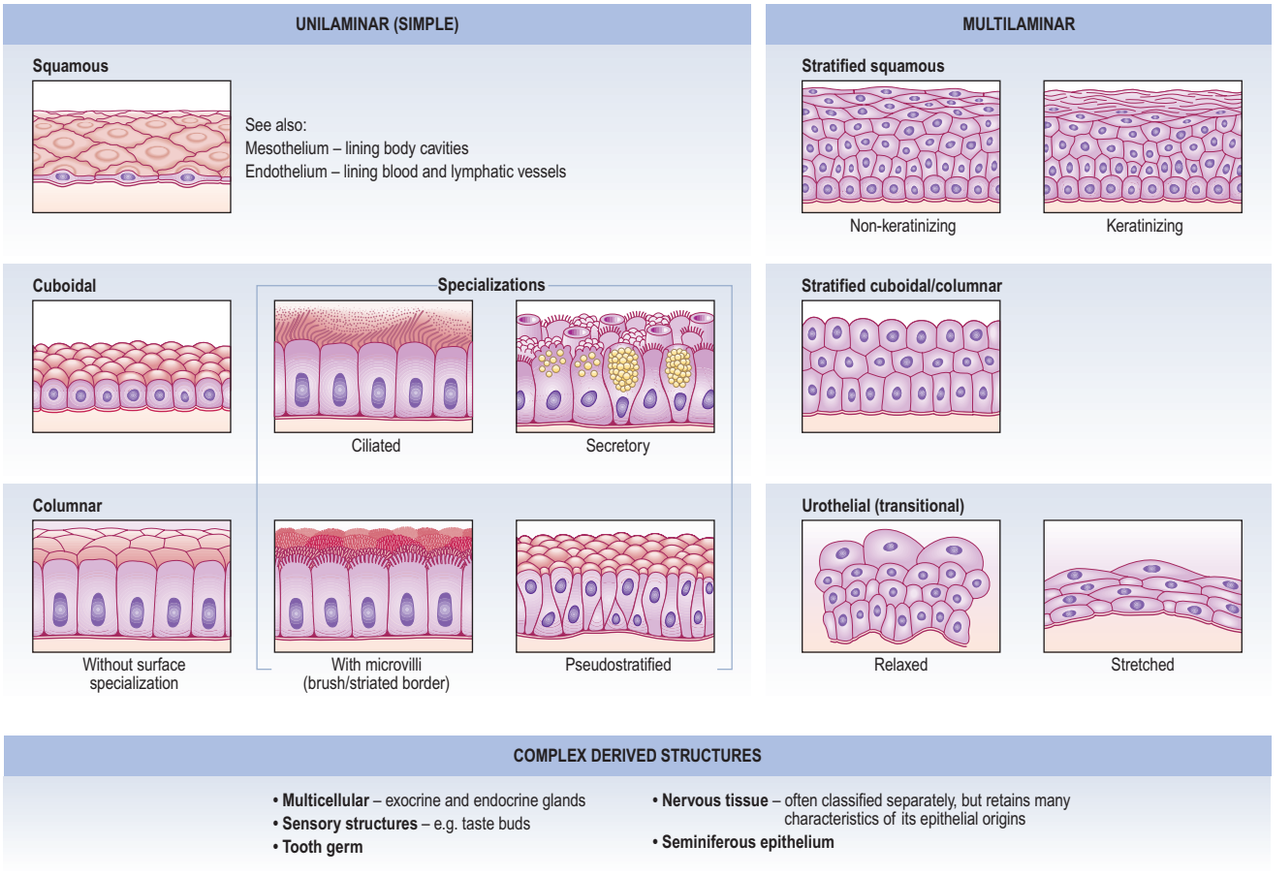

Fig. 2.1 Classification of epithelial tissues and cells.

epididymis (columnar cells with extremely long microvilli, erroneously termed stereocilia).

Ciliated columnar epithelium lines most of the respiratory tract, except for the lower pharynx and vocal folds, and is pseudostratified (Fig. 2.2D) as far as the larger bronchioles. It also lines some of the tympanic cavity and auditory tube, the uterine tube and the efferent ductules of the testis. Submucosal mucous glands and mucosal goblet cells secrete mucus on to the luminal surface of much of the respiratory tract, and cilia sweep a layer of mucus, trapped dust particles and so on from the lung towards the pharynx in the mucociliary rejection current, which clears the respiratory passages of inhaled particles. Cilia in the uterine tube assist the passage of oocytes and fertilized ova to the uterus.

Some columnar cells are specialized for secretion, and aggregates of such cells may be described as glandular tissue. Their apical domains typically contain mucus- or protein-filled (zymogen) vesicles, e.g. mucin-secreting and chief cells of the gastric epithelium. Where mucous cells lie among non-secretory cells, e.g. in the intestinal epithelium, their apical cytoplasm and its secretory contents often expand to produce a characteristic cell shape, and they are known as goblet cells (see Fig. 2.2D). For further details of glandular tissue, see p. 33, and for the characteristics of mucus, see p. 42.

Pseudostratified epithelium

Pseudostratified epithelium is a single-layered (simple) columnar epithelium in which nuclei lie at different levels in a vertical section (see Fig. 2.2D). All cells are in contact with the basal lamina throughout their lifespan, but not all cells extend through the entire thickness of the epithelium. Some constitute an immature basal cell layer of smaller cells, which are often mitotic and able to replace damaged mature cells. Migrating lymphocytes and mast cells within columnar epithelia may also give a similar, pseudostratified appearance because their nuclei are found at different depths. Much of the ciliated lining of the respiratory tract is of the pseudostratified type, and so is the sensory epithelium of the olfactory area.

Sensory epithelia

Sensory epithelia are found in special sense organs of the olfactory, gustatory and vestibulocochlear receptor systems. All of these contain sensory cells surrounded by supportive non-receptor cells. Olfactory receptors are modified neurones and their axons pass directly to the brain, but the other types are specialized epithelial cells that synapse with terminals of afferent (and sometimes efferent) nerve fibres.

Myoepithelial cells

Myoepithelial cells (sometimes termed basket cells) are fusiform or stellate in shape (Fig. 2.3), contain actin and myosin filaments, and contract when stimulated by nervous or endocrine signals. They surround the secretory portions and ducts of some glands, e.g. mammary, lacrimal, salivary, prostate and sweat glands, and lie between the basal lamina and the glandular or ductal epithelium. Their contraction assists the initial flow of secretion into larger conduits. Ultrastructurally, myoepithelial cells are similar to smooth muscle cells in the arrangement of their actin and myosin, but differ from them because they originate, like the glandular cells, from embryonic ectoderm or endoderm. They can be identified immunohistochemically on the basis of the co-localization of myofilament proteins (which signify their contractile function; Fig. 2.4) and keratin intermediate filaments (which accords with their epithelial lineage) (Balachander et al 2015).

Multilaminar (stratified) epithelia

Multilaminar epithelia are found at surfaces subjected to mechanical damage or other potentially harmful conditions. They can be divided into those that continue to replace their surface cells from deeper layers, designated stratified squamous epithelia, and others in which replacement is extremely slow except after injury.

Stratified squamous epithelia

Stratified squamous epithelia are multilayered tissues in which the formation, maturation and loss of cells is continuous, although the rates of these processes can change, e.g. after injury. New cells are formed in the most basal layers by the mitotic division of stem cells and transit (or transient) amplifying cells. The daughter cells move more superficially, changing gradually from a cuboidal shape to a more flattened form, and are eventually shed from the surface as a highly flattened squame. Typically, the cells are held together by numerous desmosomes to form strong, contiguous cellular sheets that provide protection to the underlying tissues against mechanical, microbial and chemical damage. Stratified

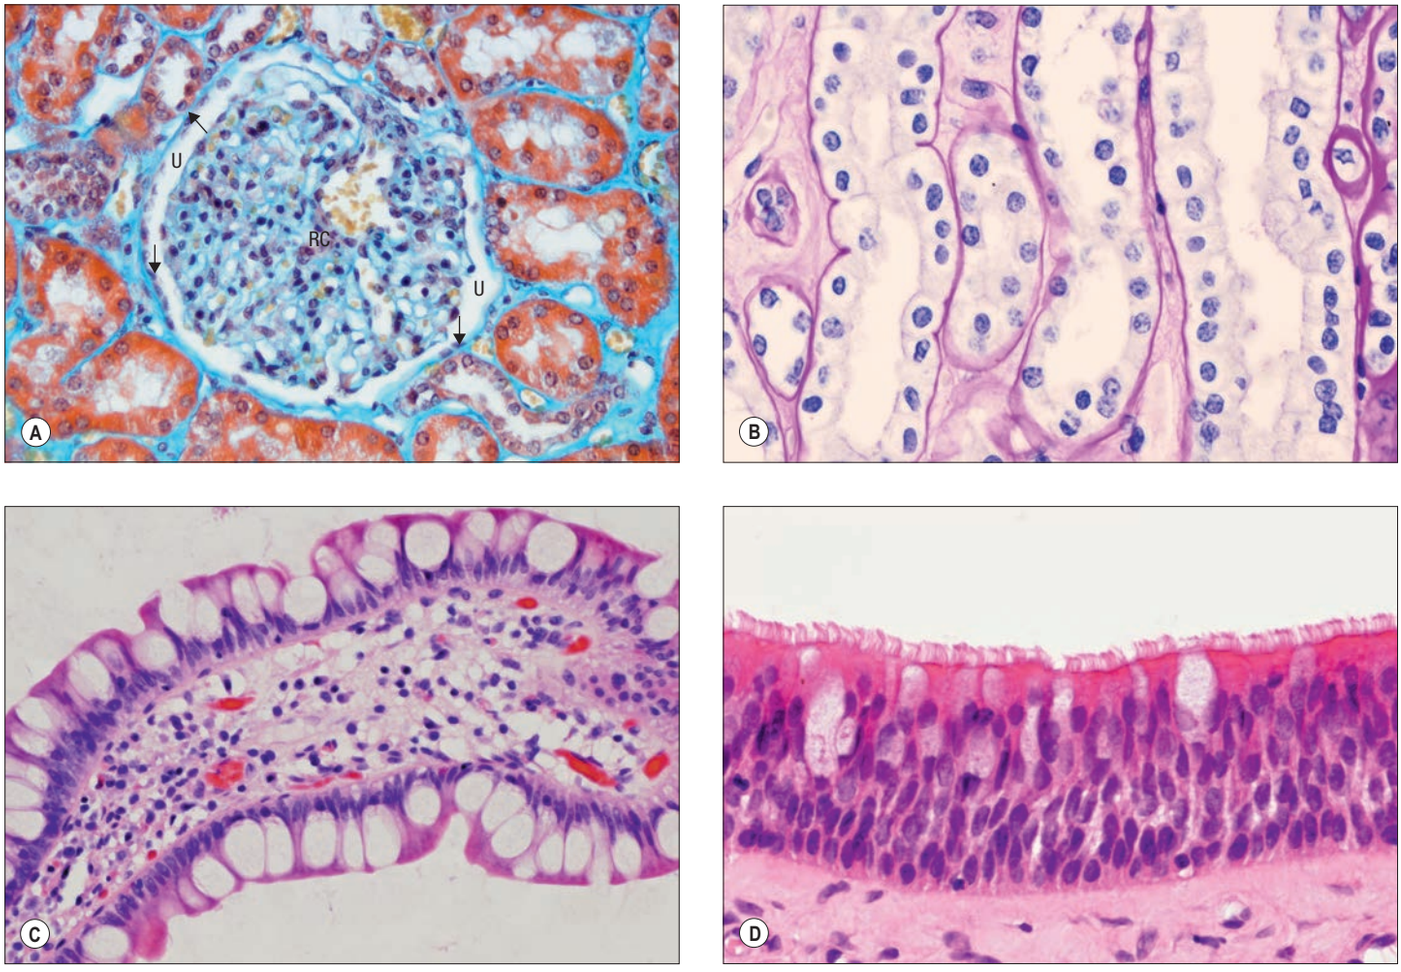

Fig. 2.2 A, Simple squamous epithelium lining the outer parietal layer (arrows) of a Bowman's capsule in the renal corpuscle (RC), stained with the trichrome, Martius Scarlet Blue (MSB). Oval epithelial nuclei project into the urinary space (U), within a highly attenuated cytoplasm. **B**, Simple cuboidal epithelium lining a group of collecting ducts sectioned longitudinally in the renal medulla. The basement membranes are stained magenta with periodic–acid Schiff (PAS) reagent. **C**, Simple columnar epithelium covering the tip (off field, right) of a villus in the ileum. Tall, columnar absorptive cells with oval, vertically orientated nuclei bear a striated border of microvilli, just visible as a deeper-stained apical fringe. Numerous interspersed goblet cells are present, with pale apical cytoplasm filled with mucinogen secretory granules and dark, flattened, basally situated nuclei. **D**, Ciliated columnar pseudostratified epithelium in the respiratory tract, and interspersed goblet cells, with pale, mucinogen granule-filled apical cytoplasm. squamous epithelia may be broadly subdivided into keratinized and non-keratinized types.

Keratinized epithelium

Keratinized epithelium (Fig. 2.5A) is found at surfaces that are subject to drying or mechanical stresses, or are exposed to high levels of abrasion. These include the entire epidermis and the mucocutaneous junctions of the lips, nostrils, distal anal canal, outer surface of the tympanic membrane and parts of the oral lining (gingivae, hard palate and filiform papillae on the anterior part of the dorsal surface of the tongue). Their cells, keratinocytes, are described in more detail on p. 146. A distinguishing feature of keratinized epithelia is that cells of the superficial layer, the stratum corneum, are anucleate, dead, flattened squames that eventually flake off from the surface. In addition, the tough keratin intermediate filaments become firmly embedded in a matrix protein. This unusual combination of strongly coherent layers of living cells and more superficial strata made of plates of inert, mechanically robust protein complexes, interleaved with water-resistant lipid, makes this type of epithelium an efficient barrier against different types of injury, microbial invasion and water loss.

Non-keratinized epithelium

Non-keratinized epithelium is present at surfaces that are subject to abrasion but protected from drying (Fig. 2.5B). These include: the buccal cavity (except for the areas noted above); oropharynx and laryngopharynx; oesophagus; part of the anal canal; vagina; distal uterine cervix; distal urethra; cornea; inner surfaces of the eyelids; and the vestibule of the nasal cavities. Cells go through the same transitions in general shape as are seen in the keratinized type, but they do not fill completely with keratin or secrete glycolipid, and they retain their nuclei until they desquamate at the surface. In sites where considerable abrasion occurs, e.g. parts of the buccal cavity, the epithelium is thicker and its most superficial cells may partly keratinize, so that it is referred to as parakeratinized, in contrast to the orthokeratinized state of fully keratinized epithelium. Diets deficient in vitamin A may induce keratinization of such epithelia, and excessive doses may lead to its transformation into mucus-secreting epithelium.

Stratified cuboidal and columnar epithelia

Two or more layers of cuboidal or low columnar cells (Fig. 2.5C) are typical of the walls of the larger ducts of some exocrine glands, e.g. the pancreas, salivary glands and the ducts of sweat glands, and they presumably provide more strength than a single layer. Parts of the male urethra are also lined by stratified columnar epithelium. The layers are not continually replaced by basal mitoses and there is no progression of form from base to surface, but they can repair themselves if damaged.

Urothelium (urinary or transitional epithelium)

Urothelium (Fig. 2.5D) is a specialized epithelium that lines much of the urinary tract and prevents its rather toxic contents from damaging surrounding structures. It extends from the ends of the collecting ducts of the kidneys, through the ureters and bladder, to the proximal portion of the urethra. In males it lines the urethra as far as the ejaculatory ducts, then becomes intermittent and is finally replaced by stratified columnar epithelium in the membranous urethra. In females it extends as far as the urogenital membrane.

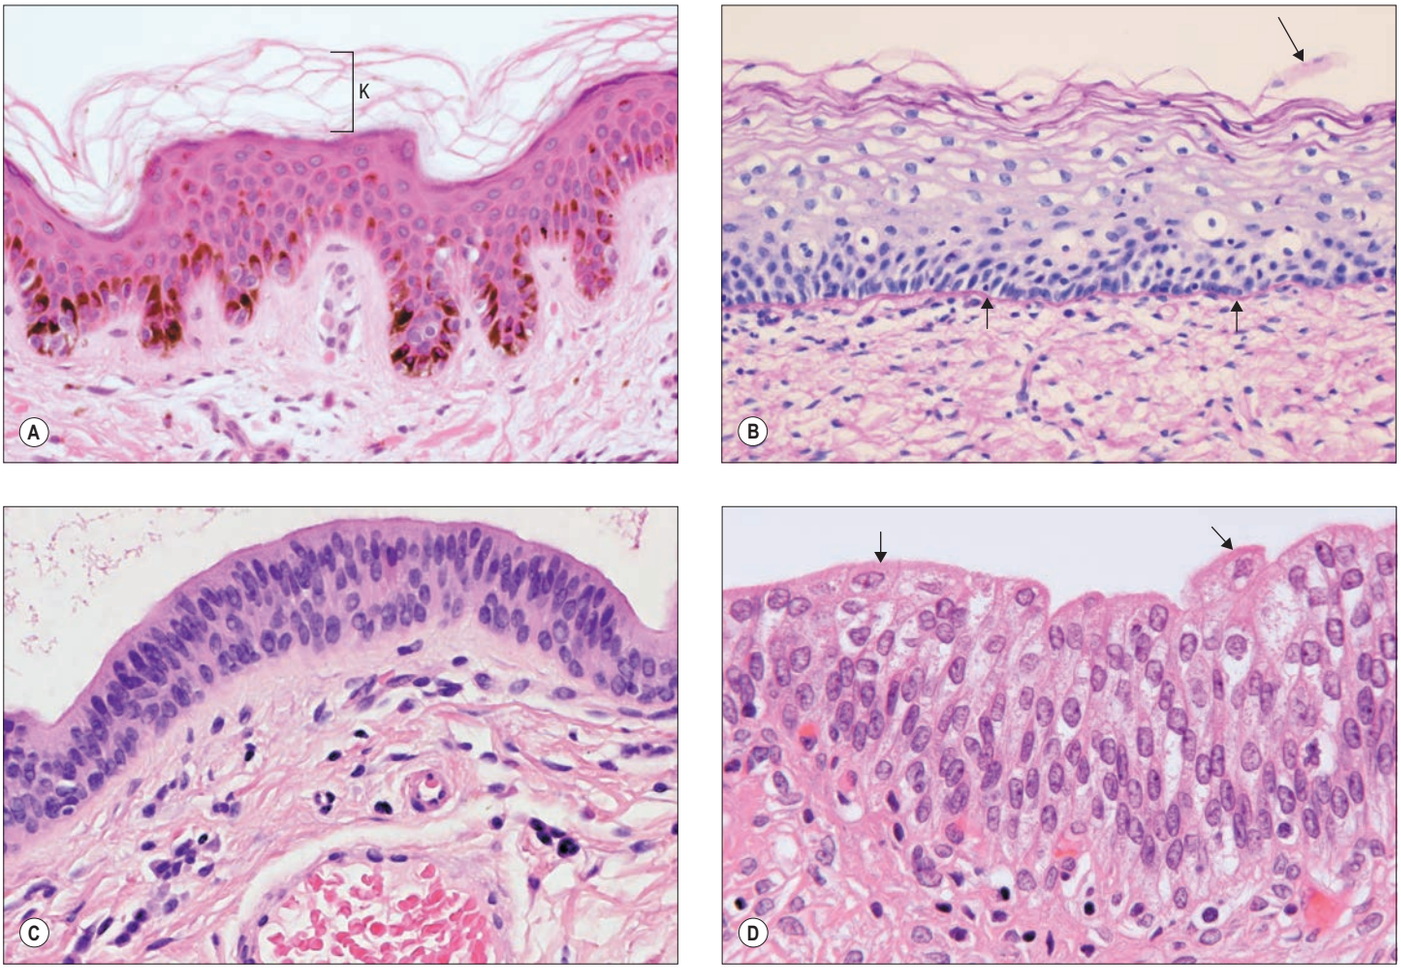

Fig. 2.5 A, Keratinized stratified squamous epithelium in thin skin. Pigmented melanocytes are seen in the basal layer and a few keratinocytes of the prickle cell layer also contain melanin granules. The dead, keratinized layer (K) lacks nuclei. **B**, Non-keratinized stratified squamous epithelium of the uterine ectocervix, stained with periodic–acid Schiff (PAS) reagent. The basement membrane (short arrows) and superficial squames, which retain their nuclei, are PAS-positive; squames sloughing off the surface are indicated (long arrow). **C**, Stratified low columnar epithelium of an interlobular excretory duct of the sublingual salivary gland. **D**, Urothelium (transitional epithelium) lining the relaxed urinary bladder. The most superficial cells have a thickened plasma membrane as a result of the presence of intramembranous plaques, which give an eosinophilic appearance to the luminal surface (arrows). All human tissues. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

The epithelium appears to be 4–6 cells thick and lines organs that undergo considerable distension and contraction. It can therefore stretch greatly without losing its integrity. In stretching, the cells become flattened without altering their positions relative to each other, because they are firmly connected by numerous desmosomes. However, the urothelium appears to be reduced to only 2–3 cells thick. The epithelium is called transitional because of the apparent transition from a stratified cuboidal epithelium to a stratified squamous epithelium, which occurs as it is stretched to accommodate urine, particularly in the bladder. The basal cells are basophilic and contain many ribosomes; they are uninucleate (diploid), and cuboidal when relaxed. More apically, they form large binucleate or, more often, polyploid uninucleate cells. The surface cells are the largest and may even be octoploid; in the relaxed state they typically bulge into the lumen as dome-shaped cells with a thickened, eosinophilic glycocalyx or cell coat. Their luminal surfaces are covered by a specialized plasma membrane in which plaques of intramembranous glycoprotein particles are embedded to stiffen the membrane. When the epithelium is relaxed, the surface area of the cells is reduced and the plaques are partially internalized by the hinge-like action of the more flexible interplaque membrane regions. The plaques re-emerge on to the surface when it is stretched.

Normally, cell turnover is very slow; cell division is infrequent and is restricted to the basal layer. However, when damaged, the epithelium regenerates quite rapidly (Balsara and Li 2017).

Seminiferous epithelium

Seminiferous epithelium is a highly specialized, complex stratified epithelium. It consists of a heterogeneous population of cells that form the lineage of the spermatozoa (spermatogonia, spermatocytes, spermatids), together with supporting cells (Sertoli cells). It is described in detail on page 1295.

GLANDS

One of the features of many epithelia is their ability to alter the environment facing their free surfaces by the directed transport of ions, water or macromolecules. This is particularly well demonstrated in glandular tissue, in which the metabolism and structural organization of the cells are specialized for the synthesis and secretion of macromolecules, usually from the apical surface. Such cells may exist in isolation amongst other non-secretory cells of an epithelium, e.g. goblet cells in the absorptive lining of the small intestine, or may form highly coherent sheets of epithelium with a common secretory function, e.g. the mucous lining of the stomach and, in a highly invaginated structure, the complex salivary glands.

Glands are conventionally subdivided into exocrine glands and endocrine glands. Exocrine glands secrete, usually via a duct, onto surfaces that are continuous with the exterior of the body, including the gastrointestinal and respiratory tracts, urinary and genital ducts and their derivatives, and the skin. Endocrine glands are ductless and secrete hormones directly into interstitial fluid and thence the circulatory system, to be conveyed throughout the body to affect the activities of other cells. The suprarenal (adrenal) medulla and the neurohypophysis are neurosecretory.

Paracrine glandular cells are similar to endocrine cells but their secretions diffuse locally to cellular targets in the immediate vicinity: many are classed as neuroendocrine cells because they secrete molecules active elsewhere in the nervous system as neurotransmitters or neuromodulators. Modes of signalling by secretory cells are illustrated in Fig. 1.9.

Exocrine glands

Types of secretory process

Secretory mechanisms vary. Secretions that are initially packaged into membrane-bound vesicles are conveyed to the cell surface, where they are discharged by exocytosis. This is merocrine secretion, which is by far the most common secretory mechanism, where vesicle membranes fuse with the plasma membrane to release their contents to the exterior (**Fig. 2.6**). Specialized transmembrane molecules in the secretory vesicle wall recognize marker proteins on the cytoplasmic side of the plasma membrane and bind to them. This initiates interactions with other proteins that cause the fusion of the two membranes and the consequent release of the vesicle contents. The stimulus for secretion varies with the type of cell but often appears to involve a rise in intracellular calcium. Glands such as the simple sweat glands of the skin, where ions and water are actively transported from plasma as an exudate, were once classified as eccrine glands. They are now known to synthesize and secrete small amounts of protein by a merocrine mechanism, and have been reclassified as merocrine glands.

In apocrine glands, some of the apical cytoplasm is pinched off with the contained secretions, which are stored in the cell as membrane-free droplets (see Fig. 2.6). The best understood example is the secretion of milk fat by mammary gland cells, where a small amount of cytoplasm is incorporated into the plasma membrane-bound lipid globule as it is released from the cell. Larger amounts of cytoplasm are included in secretions by specialized apocrine sweat glands in the axilla (Stoeckelhuber et al 2011) and anogenital regions of the body. A combination of different types of secretion occurs in some tissues, e.g. mammary gland cells secrete milk fat by apocrine secretion and milk protein, casein, by merocrine secretion.

In holocrine glands, the cells first fill with secretory products after which the entire cell disintegrates to liberate the accumulated mass of secretion into the adjacent duct or, more usually, hair follicle, e.g. sebaceous glands in the skin (see Fig. 2.6).

Structural and functional classification

Exocrine glands may be unicellular or multicellular. The latter may be in the form of simple sheets of secretory cells, e.g. the lining of the stomach, or may be structurally more complex and invaginated to a variable degree. Such glands may be simple units or their connection to the surface may be branched (see Fig. 2.6). Simple unbranched tubular glands exist in the walls of many of the hollow viscera, e.g. the small intestine and uterus, whereas some simple glands have expanded, flask-like ends (acini or alveoli). Such glands may consist entirely of secretory cells, or may have a blind-ending secretory portion that leads through a non-secretory duct to the surface, in which case the ducts may modify the secretions as they pass along them.

Glands with ducts may be branched (compound) and sometimes form elaborate ductal trees. Such glands generally have acinar or alveolar secretory lobules, as in the exocrine pancreas, but the secretory units may alternatively be tubular or mixed tubulo-acinar. More than one type of secretory cell may occur within a particular secretory unit, or individual units may be specialized to just one type of secretion (e.g. serous acini of salivary glands).

Exocrine glands are also classified by their secretory products. Secretory cells in mucus-secreting or mucous glands have frothy cytoplasm and basal, flattened nuclei. They stain deeply with metachromatic stains and periodic acid–Schiff (PAS) methods that detect carbohydrate residues. However, in general (i.e. non-specific) histological preparations, they are weakly stained because much of their content of water-rich mucin has been extracted by the processing procedures. Secretory cells in serous glands have centrally placed nuclei and eosinophilic secretory storage granules in their cytoplasm. They secrete mainly glycoproteins (including lysozyme) and digestive enzymes.

Some glands are almost entirely mucous (e.g. the sublingual salivary gland), whereas others are mainly serous (e.g. the parotid salivary gland). The submandibular gland is mixed, in that some lobules are predominantly mucous and others serous. Mucous acini may share a lumen with clusters of serous cells (seen in routine preparations as serous demilunes). Although this simple approach to classification is useful for general descriptive purposes, the diversity of molecules synthesized and secreted by glands is such that complex mixtures often exist within the same cell.

Endocrine glands

Endocrine glands secrete directly into connective tissue interstitial fluid and thence the circulation. Their cells are grouped around beds of capillaries or sinusoids, typically lined by fenestrated endothelia to allow the rapid passage of macromolecules through their walls. Endocrine cells may be arranged in clusters within vascular networks, in cords between parallel vascular channels or as hollow structures (follicles) surrounding their stored secretions. In addition to the cells of specialized ductless endocrine glands (e.g. pituitary, pineal, thyroid and parathyroid), hormone-producing cells also form components of other organ systems. These include the cells of the pancreatic islets; thymic epithelial cells; renin-secreting cells of the kidney juxtaglomerular apparatus; erythropoietin-secreting cells of the kidney; cells of the circumventricular organs; interstitial testicular (Leydig) cells; interstitial follicular and luteal ovarian cells; and placental cells (in pregnancy). Some cardiac myocytes, particularly in the walls of the atria, also have endocrine functions. These cells are all described in detail within the appropriate regional sections.

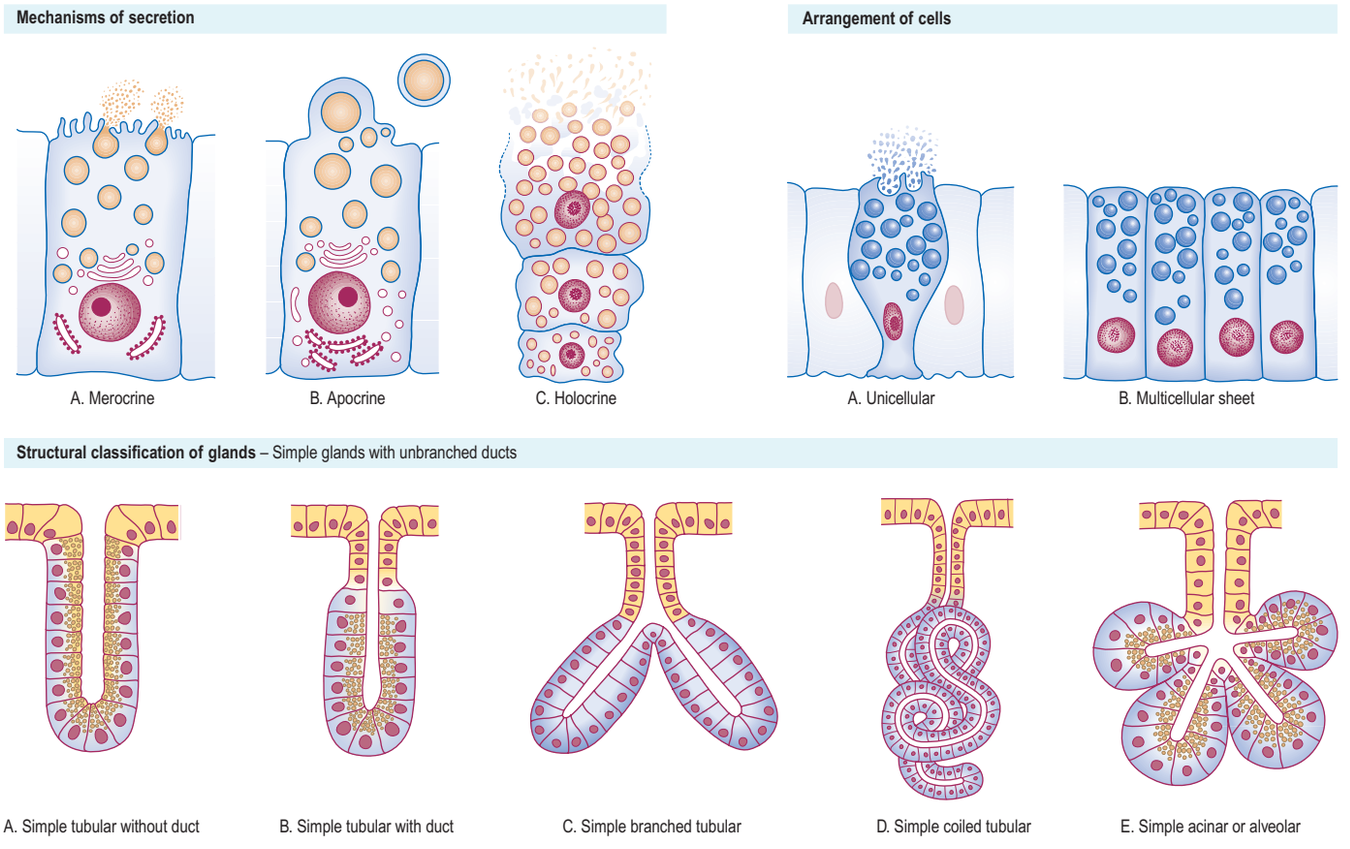

Fig. 2.6 Classification of the different types of epithelial gland.

Isolated endocrine cells scattered amongst other tissues form part of the dispersed neuroendocrine system, e.g. throughout the alimentary and respiratory tracts. They produce peptide hormones, many of which may function as neurotransmitters: they can express neurone-specific enolase, synaptophysin, secretogranins and chromogranins as well as enzymes involved in peptide hormone synthesis and processing (Asa and Mete 2018). Neuroendocrine cells are generally situated within a mucosal epithelium and their bases often rest on the basal lamina. In response to an external stimulus, they secrete their product basally into interstitial fluid. They typically have a well-developed rough endoplasmic reticulum for peptide synthesis, large Golgi complexes for packaging their hormones, and numerous secretory granules that store and also transport the hormones to the cell surface for release by exocytosis (Fig. 2.7). The secretory granules vary in shape, size and ultrastructure according to cell type. Neuroendocrine cells often take the name of the secretion they produce, e.g. gastrin-secreting G cells of the small intestine.

Control of glandular secretion

The activities of cells in the various tissue and organ systems of the body are tightly regulated by the coordinated activity of the endocrine and autonomic nervous systems. Endocrine (and paracrine) signals reach target cells in interstitial fluid, often via blood plasma, and together with autonomic nervous signals they ensure that the body responds to normal physiological stimuli and adjusts to changes in the external environment. Hormone secretion is itself controlled in a number of ways, e.g. by neural control, regulatory feedback loops or according to various cyclical, rhythmical or pulsatile patterns of release. Endocrine glands have a rich vascular supply and their blood flow is controlled by autonomic vasomotor nerves, which can thus modify glandular activity.

Glandular activity may also be controlled directly by autonomic secretomotor fibres, which may either form synapses on the bases of gland cells (e.g. in the suprarenal medulla) or release neuromediators in the vicinity of the glands and reach them by diffusion. Alternatively, the autonomic nervous system may act indirectly on gland cells, e.g. on neuroendocrine G cells via histamine, released neurogenically from another neuroendocrine cell in the gastric lining. Such paracrine activities of neuroendocrine cells are also important in the respiratory system.

Circulating hormones from the adenohypophysis stimulate synthesis and secretion by target cells in many endocrine glands. Such signals, mostly detected by receptors at the cell surface and mediated by second messenger systems, may increase the synthetic activity of gland cells, and may cause them to discharge their secretions by exocytosis. Secretions from certain exocrine glandular cells are expressed rapidly from those glands by the contraction of associated myoepithelial cells (see Figs 2.3–2.4) that enclose the secretory units and smaller ducts. Myoepithelial cells may be under direct neural control, as in the salivary glands, or they may respond to circulating hormones, as in the mammary gland, where they respond to the concentration of circulating oxytocin.

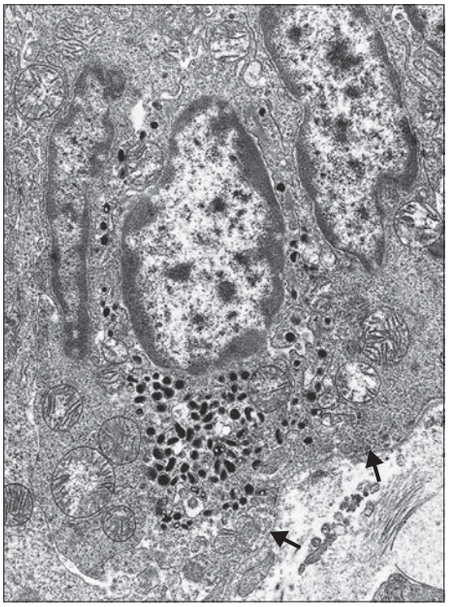

Fig. 2.7 An electron micrograph of a neuroendocrine cell between two absorptive cells in the colon (rat tissue). Dense neurosecretory granules are seen in the basal cytoplasm, apposed to the basal lamina (arrows). (Courtesy of Michael Crowder MD.)

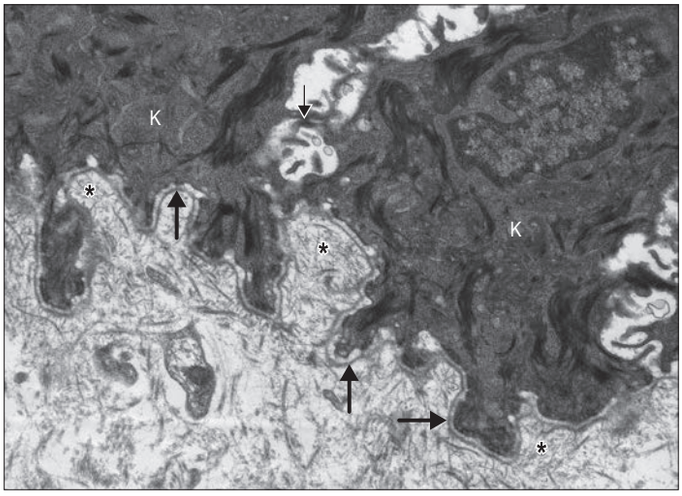

Fig. 2.8 The basal lamina as seen in an electron micrograph, underlying the basal epithelial layer of human skin (see Fig. 7.3). The finely fibrillar dense layer (thick arrows) corresponds to the lamina densa, and fine collagen fibrils (*) lie in the subjacent connective tissue. These contribute to the appearance of the basement membrane in light microscope preparations stained for carbohydrate-rich structures. The two cells seen in the upper field are basal keratinocytes (K), joined by desmosomes (thin arrow), with dense keratin filaments in their cytoplasm. (Courtesy of J McMillan MD, St John's Institute of Dermatology, St Thomas' Hospital, London.)

Feedback loops and endocrine axes

The pituitary gland, in particular the adenohypophysis, is often termed the master gland because of its central role in endocrine physiological processes (Ch. 30). It provides the means by which the central nervous system regulates and integrates, by non-neural mechanisms, the widespread functions of the body, including the activities of other endocrine glands and, often indirectly, exocrine glands such as the breast. Regulatory hormones from the adenohypophysis stimulate synthesis and secretion in target cells of many endocrine glands; these glands therefore respond to, as well as generate, hormonal signals.

The hypothalamus and the adenohypophysis in the brain are central to most regulatory feedback loops within the endocrine system. Loops can be either positive or negative, e.g. the hypothalamus stimulates release of follicle-stimulating hormone (FSH) by the adenohypophysis, which in turn stimulates ovarian follicular maturation and secretion of oestradiol, which acts on breast and endometrial target tissues. Oestradiol, in this case, also acts back on the adenohypophysis and hypothalamus to reinforce their function positively in a feedback loop. In contrast, hypothalamic and adenohypophysial stimulation of testicular production of testosterone, which acts on targets such as skeletal muscle, is negatively regulated in a feedback loop generated by circulating testosterone. Such negative feedback regulation is a widely utilized physiological mechanism.

BASEMENT MEMBRANE AND BASAL LAMINA

In early histological texts a narrow planar assembly of extracellular matrix proteins forming a two-dimensional layer that stained strongly for carbohydrates, and occurred at the interface between connective and other tissues, e.g. between epithelia and their supporting connective tissues, was termed the basement membrane. As almost all of its components are synthesized by the epithelium or other tissues, rather than the adjacent connective tissue, it will be discussed here.

As seen by electron microscopy, the basement membrane is composed of two distinct components: a thin, finely fibrillar layer, the basal lamina, associated closely with the basal cell surface (**Fig. 2.8**), and a reticular lamina of larger fibrils and glycosaminoglycans of the extracellular matrix that underlies the basal lamina and is continuous with the connective tissue proper. This reticular layer may be much reduced or largely absent in some tissues, e.g. surrounding muscle fibres, Schwann cells and capillary endothelia. In other tissues, the basal lamina separates two layers of cells and there are no intervening typical connective tissue elements, e.g. in the thick basal lamina of the renal glomerular filter and the basal lamina of the thin portions of the lung interalveolar septa across which gases exchange between blood and air.

The basal lamina is usually about 80 nm thick, varying between 40 and 120 nm, and consists of a sheet-like fibrillar layer, the lamina densa (20–50 nm wide), separated from the plasma membrane of the cell it supports by a narrow electron-lucent zone, the lamina lucida. The lamina lucida is absent from tissues prepared by rapid freezing and so may be an artefact. In many tissues this zone is crossed by integral plasma membrane proteins, e.g. keratinocyte hemidesmosomes are anchored into the lamina densa in the basal lamina of the epidermis. The basal lamina is a delicate felt-like network composed largely of two glycoprotein polymers, laminin and type IV collagen. The adhesive glycoprotein laminin is essential for the initial self-assembly of basal laminae into two-dimensional sheets interwoven with each other. Early embryonic basal lamina is formed only of the laminin polymer. Two other molecules cross-link and stabilize the network: nidogen (entactin), which crosslinks laminin to collagen IV and perlecan (a large heparan sulphate proteoglycan).

Although all basal laminae have a similar form, their thickness and precise molecular composition vary between tissues and even within a tissue, e.g. between the crypts and villi of the small intestine. The isoforms of laminin and collagen type IV differ in various tissues; thus Schwann cells and muscle cells express laminin-2 (merosin) rather than the prototypical laminin-1. Laminin-5, although not itself a basal lamina component, is found in the hemidesmosomes of the basal epidermis and links the basal lamina with epidermal transmembrane proteins, $\alpha_6\beta_4$ integrin and collagen type XVII (BPAG2, bullous pemphigoid antigen 2, one of the targets of the autoimmune blistering skin disease, bullous pemphigoid; Ch. 7). The particular isoform of collagen type IV in the basal lamina of different tissues is reflected in tissue-specific disease patterns. Mutations in certain collagen genes expressed in kidney glomeruli (and a few other tissues) cause Alport's syndrome, a heritable form of renal failure that can be either X-linked or autosomally transmitted (Savige et al 2016). Renal failure also occurs in Goodpasture's syndrome, in which renal basal lamina collagen is targeted by autoantibodies to a collagen domain that is normally unexposed but which may be revealed to the immune system by damaging events (Foster 2016).

In Descemet's membrane (posterior limiting lamina) in the cornea, collagen type VIII replaces collagen type IV in the much thickened (increasing with age up to 10 μm,) endothelial basal lamina. The basal lamina of the neuromuscular junction contains agrin, a heparan sulphate proteoglycan, which plays a part in the clustering of muscle acetylcholine receptors in the plasma membrane at these junctions (Rogers and Nishimune 2017).

Reticular lamina

The reticular lamina consists of a dense extracellular matrix that contains collagen. In skin, it contains fibrils of type VII collagen (anchoring fibrils), that bind the lamina densa to the adjacent connective tissue. The high concentration of proteoglycans in the reticular lamina is responsible

for the positive reaction of the entire basement membrane to stains for carbohydrates, as seen in sections prepared for light microscopy (see Fig. 2.2B).

Functions of basal lamina

Basal laminae perform a number of important roles. They form selectively permeable barriers (anionic filters) between adjacent tissues, e.g. in the glomerular filter of the kidney; anchor epithelial and connective tissues, and so stabilize and orientate the tissue layers; may exert instructive effects on adjacent tissues, and so determine their polarity, rate of cell division, cell survival, etc.; and regulate angiogenesis. In addition, they may act as pathways for the migration and pathfinding activities of growing cell processes, both in development and in tissue repair, e.g. in guiding the outgrowth of axons and the re-establishment of neuromuscular junctions during regeneration after injury in the peripheral nervous system. Changes in basal lamina thickness are often associated with pathological conditions, e.g. the thickening of the glomerular basal lamina in glomerulonephritis and diabetes.

CONNECTIVE AND SUPPORTING TISSUES

The connective tissues are defined as those composed predominantly of intercellular material, the extracellular matrix, which is secreted mainly by the connective tissue cells. Extracellular matrix is composed of fibrous proteins and a relatively amorphous ground substance (**Fig. 2.9**): the cells may be widely dispersed within the matrix. Many of the special properties of connective tissues are determined by the composition of the matrix and their classification is also largely based on its characteristics. In some types of connective tissue the cellular component eventually dominates the tissue, even though the original matrix cell ratio is high, e.g. adipose tissue.

Connective tissues play several essential roles in the body. These include structural roles, which largely reflect the special mechanical properties of the extracellular matrix components; defensive roles, where the cellular component has the dominant role; and trophic and morphogenetic roles in organizing and influencing the growth and differentiation of surrounding tissues, e.g. in the development of glands from an epithelial surface.

Structural connective tissues are divided into ordinary (or general) types, which are widely distributed and special skeletal types (cartilage and bone) (Ch. 5). Haemolymphoid tissues (peripheral blood cells, lymphoid tissues and their precursors), are often grouped with other types of connective tissue because of their similar mesenchymal origins and because the various defensive cells of the blood also form part of a typical connective tissue cell population that reaches connective tissues via the blood circulation, migrating into them through the endothelial walls of vessels (Ch. 4).

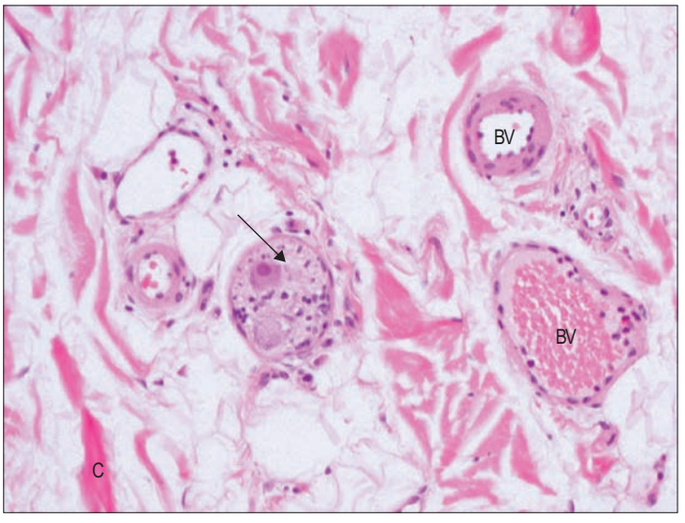

Fig. 2.9 General loose connective tissue (human), with bundles of collagen fibres (C) within an amorphous ground substance, penetrated by a neurovascular bundle of blood vessels (BV), lymphatics and nerves. A small autonomic ganglion is arrowed. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Cells of general connective tissues

Cells of general connective tissues can be separated into the resident cell population (fibroblasts, adipocytes, mesenchymal progenitor cells, etc.) and a population of migrant cells with various defensive functions (macrophages, lymphocytes, mast cells, neutrophils and eosinophils), which may change in number and moderate their activities according to demand. Embryologically, fibroblasts and adipocytes arise from mesenchymal progenitor cells, some of which may remain in the tissues to provide a source of replacement cells postnatally. As noted above, the cells of haemopoietic origin (Ch. 4) migrate into the tissue from bone marrow and lymphoid tissue.

Resident cells

Fibroblasts

Fibroblasts are usually the most numerous resident cells. They are flattened and irregular in outline, with extended processes, and in profile they appear fusiform or spindle-shaped (**Fig. 2.10**; see Fig. 2.13). Fibroblasts synthesize most of the extracellular matrix of connective tissue (see Fig. 2.10); accordingly, they have all the features typical of cells active in the synthesis and secretion of proteins. Their nuclei are relatively large and euchromatic, and possess prominent nucleoli. In young, highly active cells, the cytoplasm is abundant and basophilic (reflecting the high concentration of rough endoplasmic reticulum), mitochondria are abundant and several sets of Golgi apparatus are present. In old and relatively inactive fibroblasts (often termed fibrocytes), the cytoplasmic volume is reduced, the endoplasmic reticulum is sparse and the nucleus is flattened and heterochromatic.

Fibroblasts are usually adherent to the fibres of the matrix (collagen and elastin), which they lay down. In some highly cellular structures, e.g. liver, kidney and spleen, and in most lymphoid tissue, fibroblasts and delicate collagenous fibres (type III collagen; reticular fibres) form fibrocellular networks, which are often called reticular tissue. The fibroblasts may then be termed reticular cells or reticulocytes.

Fibroblasts are particularly active during wound repair following traumatic injury or inflammation, when tissue mass is lost through cell death. They proliferate and lay down a fibrous matrix that becomes invaded by numerous blood vessels (granulation tissue). Contraction of wounds is, at least in part, caused by the shortening of myofibroblasts, specialized contractile fibroblast-like cells with properties (α-smooth muscle actin isoform expression) in common with vascular smooth muscle cells. It was thought that myofibroblasts differentiated from fibroblasts or their mesenchymal progenitor cells (see below) in granulation tissue. However, recent evidence suggests that in wound healing and in many fibrotic disease processes the myofibroblast develops as a phenotypic variant of a wider number of cell types, including fibroblasts, cardiac smooth muscle cells, vascular pericytes, hepatic perisinusoidal stellate (Ito) cells, mesenchymal progenitor cells or cells derived from epithelial or endothelial/mesenchymal transitions (reviewed in Bochaton-Piallat et al (2016)).

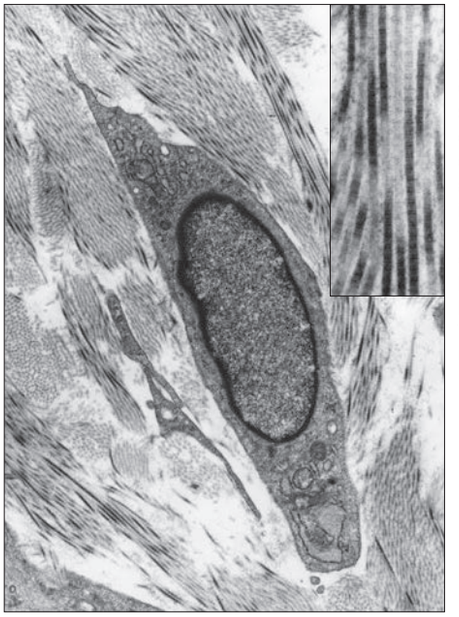

Fig. 2.10 An electron micrograph of a fibroblast in human connective tissue, surrounded by bundles of finely banded collagen fibrils (shown at high magnification in the insert), which they secrete. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

In fibrotic disease (including keloid scar formation, hepatic cirrhosis, pulmonary interstitial fibrosis), normal repair processes become dysregulated and excessive. Inflammatory macrophages communicate with myofibroblasts using soluble biochemical and cell contact-mediated signals, and physical and chemical signals transmitted through the extracellular matrix. In fibrosis, this signalling is temporally and spatially aberrant, such that the extracellular matrix of scar tissue fails to co-ordinate the normal healing process. Prolonged persistence of inflammatory cells and myofibroblasts, due at least in part to their failure to die through apoptosis, underlies the development of organ fibrosis. For further reading see Kendall and Feghali-Bostwick (2014), Pakshir and Hinz (2018).

In cases where the specialized cells of the damaged region cannot divide and regenerate functional tissue, e.g. cardiac muscle cells after infarction, connective tissue fibroblasts and their extracellular matrix fill the void to form a scar. An exception is the central nervous system, where glial scars are formed after injury. Fibroblast activity is influenced by various factors such as steroid hormone concentration, dietary content and prevalent mechanical stresses. Collagen formation is impaired in vitamin C deficiency.

Adipocytes (lipocytes, fat cells)

Adipocytes occur singly or in groups in many, but not all, connective tissues: as their name suggests, they are numerous in adipose tissue (**Fig. 2.11**). Individually, the cells are oval or spherical in shape, but when packed together they are polygonal. They vary in diameter, averaging 50 μm. Each cell consists of a peripheral rim of cytoplasm, in which the nucleus is embedded, surrounding a single large central globule of fat, which consists of glycerol esters of oleic, palmitic and stearic acids. There is a small accumulation of cytoplasm around the oval nucleus, which is typically compressed against the cell membrane by the lipid droplet, as is the Golgi complex. Many cytoskeletal filaments, some endoplasmic reticulum and a few mitochondria lie around the lipid droplet, which is in direct contact with the surrounding cytoplasm and not enclosed within a membrane. In sections of tissue not specially treated to preserve lipids, the lipid droplet is usually dissolved out by the solvents used in routine preparations, so that only the nucleus and the peripheral rim of cytoplasm surrounding a central empty space remain.

Another form of adipose tissue, brown fat, occurs in the interscapular region of neonates, a location it shares with the classic brown fat of rodents. Brown fat is characterized by the presence of large cells, each of which contains several separate droplets of fat (multilocular adipose tissue) rather than a single globule (typical of unilocular adipose tissue; see above), and by mitochondria in which the cristae are unusually large and numerous. White fat cells are specialized to store chemical energy, whereas the physiological role of brown adipose tissue (BAT) cells is to metabolize fatty acids and generate heat; BAT cells uncouple cellular respiration via the mitochondrial uncoupling protein UCP1. Although BAT cells are abundant in infancy but regress in adulthood, bioactive brown/beige adipocytes have been detected by positron emission tomography (PET) scanning in adults, mainly in the supraclavicular region, in the neck and along the spine. Beige fat cells, a distinctive subtype of thermogenic BAT, develop postnatally and are highly inducible; their recruitment is mediated by mechanisms that include *de novo* beige adipogenesis and white-to-brown adipocyte transdifferentiation (Wu et al 2012, Wang and Seale 2016, Rui 2017). They may represent an evolutionarily conserved cellular mechanism to provide flexibility in adaptive thermogenesis.

It has long been recognized that adipose tissue is central to the control of energy balance and lipid homeostasis. There is a growing view that it may play a similarly important role as an endocrine organ, secreting a class of peptides, including leptin, called adipokines which may enter the blood via capillaries or lymph. Different types of adipose tissue display functional and regional heterogeneity and differ in their involvement with disease processes (reviewed in Fasshauer and Blüher (2015)). The mobilization of fat is under nervous or hormonal control; noradrenaline (norepinephrine) released at sympathetic nerve endings in adipose tissue is particularly important in this respect. No new adipose tissue is thought to form after the immediate postnatal period, and accumulation of body fat, as in obesity, is due to excessive accumulation of lipid in existing adipocytes, which become very large. Conversely, weight loss results from the mobilization and metabolism of lipid from adipocyte stores, with the consequent shrinkage of the cells.

Mesenchymal progenitor cells

Mesenchymal progenitor cells are normally inconspicuous cells in connective tissues. They are derived from embryonic mesenchyme and are able to differentiate into the mature cells of connective tissue during normal growth and development, in the turnover of cells throughout life and, most conspicuously, in the repair of damaged tissues in wound healing. There is emerging evidence that, even in mature tissues, mesenchymal progenitor cells remain pluripotent and able to give rise to all the resident cells of connective tissues in response to local signals and cues. The potential therapeutic use of postnatal mesenchymal progenitor cell-based therapy for a wide range of autoimmune disorders and degenerative diseases is reflected in a burgeoning literature in the field of translational medicine. Much remains to be determined concerning the identity and regenerative potential of mesenchymal progenitor cells from different connective tissue sources (e.g., bone marrow and adipose tissue) before their clinical usefulness can be rigorously assessed (Ankrum and Karp 2010, Robey 2017).

Migrant cells

Macrophages

Macrophages are numerous in connective tissues, where they are either attached to matrix fibres or are motile and migratory (**Fig. 2.12**). They are relatively large cells, 15–20 μm in diameter, with indented and relatively heterochromatic nuclei and a prominent nucleolus. Their cytoplasm is

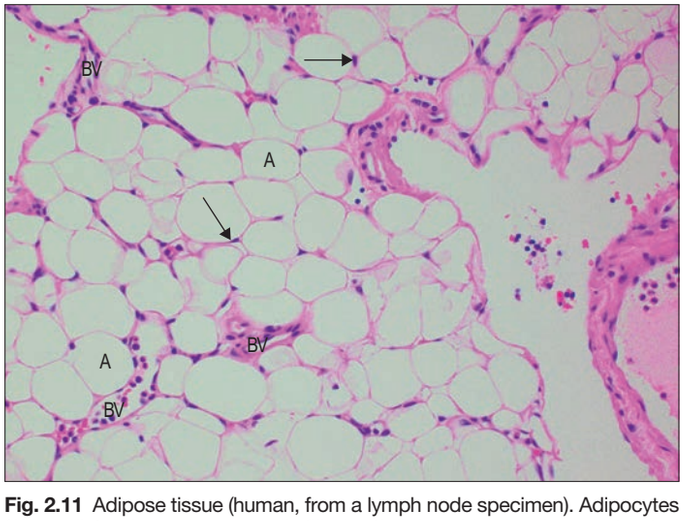

Fig. 2.11 Adipose tissue (human, from a lymph node specimen). Adipocytes (A) are distended polygonal cells filled with lipid, which has been extracted by the tissue processing. This leaves only the plasma membranes with scant cytoplasm and nuclei (arrows), occasionally visible compressed against the cell periphery. Small blood vessels (BV) penetrate the adipose tissue; a larger vessel is seen on the right. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

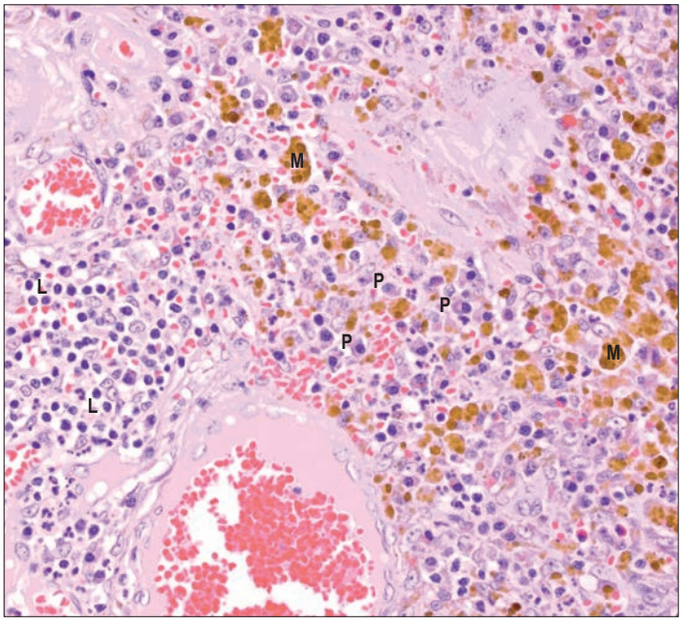

Fig. 2.12 Macrophages (M) in chronically inflamed human connective tissue, showing prominent pigmented, haemosiderin-containing cytoplasmic granules derived from ingested erythrocytes. Many are multinucleate. Also seen are plasma cells (P), small lymphocytes (L) and other haemopoietic cells. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

slightly basophilic, contains many lysosomes and typically has a foamy appearance under the light microscope. Macrophages are important phagocytes and form part of the mononuclear phagocyte system. They can engulf and digest particulate organic materials, such as bacteria, and are able to clear dead or damaged cells from a tissue too. They are also the source of a number of secreted cytokines that have profound effects on many other cell types. Macrophages are able to proliferate in connective tissues to a limited extent, but are derived and replaced primarily from haemopoietic stem cells in the bone marrow, which circulate in the blood as monocytes before migrating through vessel walls into connective tissues, where they differentiate.

Many properties of macrophages in general connective tissue are similar to those of related cells in other sites. These include: circulating monocytes, from which they are derived; alveolar macrophages in the lungs, which take up inhaled particles not cleared by the mucociliary rejection current; phagocytic cells in the lymph nodes, spleen and bone marrow; Kupffer cells of the liver sinusoids; and microglial cells (Ch. 3) of the central nervous system.

Lymphocytes

Lymphocytes are normally present in small numbers; they are numerous in general connective tissue only in pathological states, when they migrate in from adjacent lymphoid tissue or from the circulation. The majority are small cells (6–8 μm) with highly heterochromatic nuclei but they enlarge when stimulated. Two major functional classes exist, termed B and T lymphocytes. B lymphocytes originate in the bone marrow, then migrate to various lymphoid tissues, where they proliferate. When antigenically stimulated, they undergo further mitotic divisions, then enlarge as they mature, commonly in general connective tissues, to form plasma cells that synthesize and secrete antibodies (immunoglobulins). Mature plasma cells are rounded or ovoid, up to 15 μm across, and have an extensive rough endoplasmic reticulum. Their nuclei are spherical, often eccentrically situated, and have a characteristic 'clock-face' configuration of heterochromatin (see Fig. 4.12) that is regularly distributed in peripheral clumps. The prominent Golgi complex is visible with a light microscope as a pale region to one side of the nucleus and the remaining cytoplasm is deeply basophilic because of the abundant rough endoplasmic reticulum. Mature plasma cells do not divide.

T lymphocytes originate from precursors in bone marrow haemopoietic tissue but later migrate to the thymus, where they develop T-cell identity, before passing into the peripheral lymphoid system, where they continue to multiply. When antigenically stimulated, T cells enlarge and their cytoplasm becomes filled with free polysome clusters. The functions of T lymphocytes are numerous: different subsets recognize and destroy virus-infected cells, tissue and organ grafts, or interact with B lymphocytes and several other defensive cell types.

Mast cells

Mast cells are important defensive cells. They occur particularly in loose connective tissues and in the fibrous capsules of certain organs such as the liver, and are numerous around blood vessels. Mast cells are round or oval, approximately 20 μm in diameter, with many filopodia extending from the cell surface. The nucleus is centrally placed and relatively small. The cytoplasm contains large numbers of prominent vesicles and a well-developed Golgi apparatus, but scant endoplasmic reticulum. The vesicles have a high content of glycosaminoglycans and show a strongly positive reaction with the PAS stain for carbohydrates. They are membrane-bound, vary in size and shape (mean diameter 0.5 μm) and also have a rather heterogeneous content of dense, lipid-containing material, which may be finely granular, lamellar or in the form of membranous whorls.

The major granule components, many of them associated with inflammation, are the proteoglycan heparin, histamine, tryptase, superoxide dismutase, aryl sulphatase, β-hexosaminidase and various other enzymes, including chymase in connective tissue but not mucosal mast cells, together with chemotactic factors for neutrophil and eosinophil granulocytes. There are functional differences between mast cells found in different tissues.

Mast cells may be stimulated to release some or all of their contents, either by direct mechanical or chemical trauma, or after contact with particular antigens to which the body has previously been exposed. The consequences of granule release include alteration of capillary permeability, smooth muscle contraction, and activation and attraction to the locality of various other defensive cells. Responses to mast cell degranulation may be localized, e.g. urticaria, or there may occasionally be a generalized response to the release of large amounts of histamine into the circulation (anaphylactic shock). Mast cells closely resemble basophil granulocytes of the general circulation but are thought to develop as distinct descendants of an earlier myeloid lineage precursor. It is believed that they are generated in the bone marrow and circulate to the tissues as immature basophil-like cells, migrating through the capillary and venule walls to their final destination. For further reading, see Yamanishi and Karasuyama (2016).

Granulocytes (polymorphonuclear leukocytes)

Neutrophil and eosinophil granulocytes are immigrant cells from the circulation. Relatively infrequent in normal connective tissues, their numbers may increase dramatically in infected tissues, where they are important components of cellular defence. Neutrophils are highly phagocytic, especially towards bacteria. The functions of eosinophils are less well understood. These cells are described further in Chapter 4.

Cells of specialized connective tissues

Skeletal tissues, cartilage and bone are generally classified with the connective tissues, but their structure and functions are highly specialized and they are described in Chapter 5. As with the general connective tissues, these specialized types are characterized by their extracellular matrix, which forms the major component of the tissues and is responsible for their properties. The resident cells are different from those in general connective tissues. Cartilage is populated by chondroblasts, which synthesize the matrix, and by mature chondrocytes. Bone matrix is elaborated by osteoblasts. Their mature progeny, osteocytes, are embedded within the matrix, which they help to mineralize, turn over and maintain. A third cell type, the osteoclast, has a different lineage origin and is derived from haemopoietic tissue; osteoclasts are responsible for bone degradation and remodelling in collaboration with osteoblasts.

Extracellular matrix

The term extracellular matrix is applied collectively to the extracellular components of connective and supporting tissues. Essentially, it consists of a system of insoluble protein fibres, adhesive glycoproteins and soluble complexes composed of carbohydrate polymers linked to protein molecules (proteoglycans and glycosaminoglycans) that bind water. The extracellular matrix distributes the mechanical stresses on tissues and also provides the structural environment of the cells embedded in it, forming a framework to which they adhere and on which they can move (reviewed in Even-Ram and Yamada (2005),Wolf and Friedl (2011), Mouw et al (2014)). With the exception of bone matrix, it provides a highly hydrated medium, through which metabolites, gases and nutrients can diffuse freely between cells and the blood vessels traversing it or, in the case of cartilage, passing nearby.

There are many complex interactions between connective tissue cells and the extracellular matrix. The cells continually synthesize, secrete, modify and degrade extracellular matrix components, and respond to contact with the matrix in the regulation of cell metabolism, proliferation and motility. Degradation of the matrix is an important feature of embryonic development, morphogenesis, angiogenesis, tissue repair and remodelling (Mott and Werb 2004). Various types of proteinase are involved, principally metalloproteinases such as matrix metalloproteinases (MMPs), and those with a disintegrin and metalloproteinase domain (ADAMs) that include ADAMs with a thrombospondin domain (ADAMTS). Tissue remodelling depends on the controlled degradation of the extracellular matrix by secreted MMPs, regulated by their specific inhibitors (tissue inhibitors of metalloproteinases, TIMPs), as occurs, for instance, during involution of the postpartum uterus or during menstrual lysis and shedding of the endometrium (Gaide Chevronnay et al 2012). In the process of matrix degradation, bioactive peptides are liberated that act as growth factors, cytokines and other signalling molecules to change the behaviour of cells in the vicinity. While precisely regulated under physiological conditions, pathologically dysregulated extracellular matrix degradation is a cause of many diseases, such as atherosclerosis, emphysema, both rheumatoid and osteoarthritis, and diabetic vascular complications.

The insoluble fibres are mainly of two types of structural protein: members of the collagen family, and elastin (**Fig. 2.13**). The interfibrillar matrix (ground substance) includes a number of adhesive glycoproteins that perform a variety of functions in connective tissues, including cell–matrix adhesion and matrix–cell signalling. These glycoproteins include fibronectin, laminin, tenascin and vitronectin, in addition to a number of other less well characterized proteins. The glycosaminoglycans of the interfibrillar matrix are, with one notable exception, post-translationally modified proteoglycan molecules in which long polysaccharide side chains are added to short core proteins during transit through the secretory pathway between the rough endoplasmic reticulum and the *trans*-Golgi network. The exception, the polymeric disaccharide hyaluronan, has no protein core and is synthesized entirely by cell surface enzymes. For further reading on extracellular matrix molecules, see Pollard et al

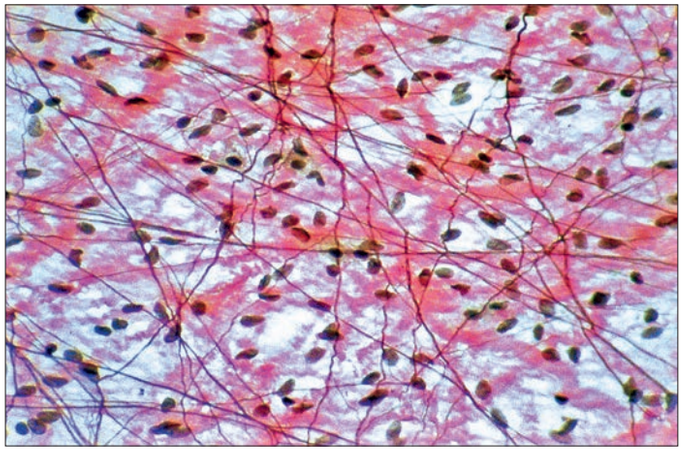

Fig. 2.13 Elastic fibres, seen as fine, dark, relatively straight fibres in a whole-mount preparation of mesentery, stained for elastin. The wavy pink bands are collagen bundles and oval grey nuclei are mainly of fibroblasts.

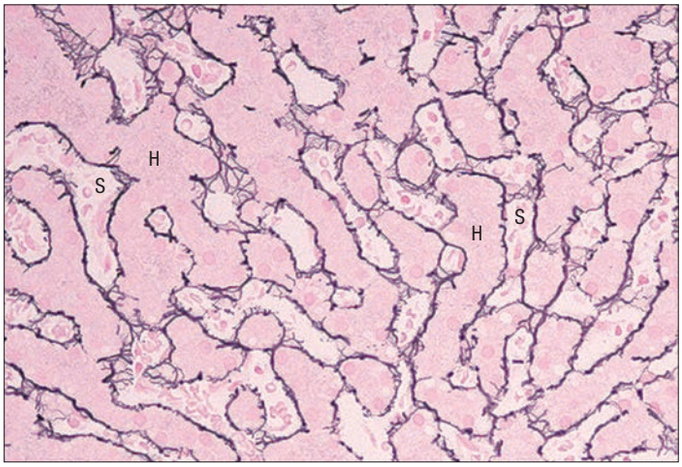

Fig. 2.14 Reticular fibres (type III collagen/reticulin demonstrated by silver staining) in human liver, forming a delicate meshwork within the space of Disse between hepatocyte (H) plasma membranes and the sinusoidal endothelia (S). (2017). Functional attributes of connective tissues vary and depend on the abundance of its different components. Collagen fibres resist tension, whereas elastin provides a measure of resilience to deformation by stretching. The highly hydrated, soluble polymers of the interfibrillar material (proteoglycans and glycosaminoglycans, mainly hyaluronan) generally form a stiff gel resisting compressive forces. Thus tissues that are specialized to resist tensile forces (e.g. tendons) are rich in collagen fibrils; tissues that accommodate changes in shape and volume (e.g. mesenteries) are rich in elastic fibres; and those that absorb compressive forces (e.g. cartilages) are rich in glycosaminoglycans and proteoglycans. In bone, mineral crystals take the place of most of the soluble polymers and endow the tissue with incompressible rigidity.

Fibrillar matrix

Collagens

Collagens make up a very large proportion (approximately 30%) of all the proteins of the body. They consist of a wide range of related molecules that have various roles in the organization and properties of connective (and some other) tissues. The first collagen to be characterized was type I, the most abundant of all the collagens and a constituent of the dermis, fasciae, bone, tendon, ligaments, blood vessels and the sclera of the eyeball. The characteristic collagen of cartilage and the vitreous body of the eye, with a slightly different chemical composition, is type II, whereas type III is present in several tissues, including the dermis and blood vessels, and type IV is in basal lamina. The other types are widely distributed in various tissues. Five of the collagens, types I, II, III, V and XI, form fibrils; types IV, VIII and X form sheets or meshworks; types VI, VII, IX, XII, XIV and XVIII have an anchoring or linking role; and types XIII and XVII are transmembrane proteins. Ehlers-Danlos syndrome is a diverse group of disorders resulting from defective structure or synthesis of different collagens. Typical features include hyperelasticity of skin and hypermobility of joints. The loss of tensile strength imparted by collagen leads to vulnerability to damage in joints, blood vessels and internal organs. For further reading see Kierszenbaum and Tres (2019).

Biochemically, all collagens have a number of features in common. Unlike most other proteins, they contain high levels of hydroxyproline and all are composed of three polypeptides that form triple helices and are substantially modified post-translationally. After secretion, individual molecules are further cross-linked to form stable polymers. Functionally, collagens are structural proteins with considerable mechanical strength. Just a few of their distinguishing structural features are described below. For further reading on the molecular structure and functions of the collagens, see Pollard et al (2017).

Type I collagen

Type I collagen is very widely distributed. It forms inextensible fibrils in which collagen molecules (triple helices) are aligned side by side in a staggered fashion, with three-quarters of the length of each molecule in contact with neighbouring molecules. The fibril has well-marked bands of charged and uncharged amino acids arranged across it; these stain with heavy metals in a banding pattern that repeats every 65 nm in longitudinal sections viewed in the electron microscope (see Fig. 2.10 insert).

Fibril diameters vary between tissues and with age. Developing tissues often have thinner fibrils than mature tissues. Corneal stroma fibrils are of uniform and thin diameter, whereas tendon fibrils may be up to 20 times thicker and quite variable. Tissues in which the fibrils are subject to high tensile loading tend to have thicker fibrils. Thick fibrils are composites of uniform thin fibrils with a diameter of 8–12 nm. The fibrils themselves are relatively flexible, but when mineralized (as in bone) or surrounded by high concentrations of proteoglycan (as in cartilage), the resulting fibre-reinforced composite materials are rigid.

Fresh type I collagen fibres are tightly packed assemblies of parallel fibrils and are white and glistening. They form variably wavy (crimped) bundles of various sizes that are generally visible at the light microscope level. The component fibres may leave one bundle and interweave with others. In some situations, collagen fibrils are laid down in precise geometrical patterns, in which successive layers alternate in direction, e.g. corneal stroma, where the high degree of order is essential for transparency. Tendons, aponeuroses and ligaments are also highly ordered tissues (Ch. 5).

Types II, III, V and XI collagens

Types II, III, V and XI collagens can also aggregate to form linear fibrils. Type II collagen occurs in extremely thin (10 nm), short fibrils in the vitreous humour of the eye and in very thick fibrils in ageing human cartilage. The amino-acid sequence and banding pattern are very similar to those of type I collagen, as are the post-translational modifications of the triple helical protein molecule. The fine fibrils in the vitreous may fuse into thicker aggregates in older tissue.

Type III collagen is very widely distributed, particularly in young and repairing tissues. It usually co-localizes with type I collagen, and covalent links between type I and type III collagen have been demonstrated. In skin, many fibrils are probably composites of type I and type III collagens.

Reticular fibres

Fine branching and anastomosing reticular fibres form the supporting mesh framework of many glands, including the liver (**Fig. 2.14**), the kidney and lymphoreticular tissue (lymph nodes, spleen, etc.). Classically, these fibres stained intensely with silver salts, although they are poorly stained using conventional histological techniques. They associate with basal laminae and are often found in the neighbourhood of collagen fibre bundles. Reticular fibres are formed principally of type III collagen.

Elastin

Elastin is a 70 kDa protein, rich in the hydrophobic amino acids valine and alanine. Elastic fibrils, which also contain fibrillin, are highly cross-linked via two elastin-specific amino acids, desmosine and iso-desmosine, which are formed extracellularly from lysine residues. They are less widely distributed than collagen, yellowish in colour, typically cross-linked and usually thinner (10–20 nm) than collagen fibrils. They can be thick, e.g. in the ligamenta flava and ligamentum nuchae. Unlike collagen type I, they show no banding pattern in the electron microscope. They stain poorly with routine histological stains but are visible when stained with orcein-containing preparations (see Fig. 2.13). They sometimes appear as

sheets, as in the fenestrated elastic lamellae of the aortic wall. Elastin-rich structures stretch easily with almost perfect recoil, although they tend to calcify with age and lose elasticity. Elastin is highly resistant to attack by acid and alkali, even at high temperatures. Autosomal dominant mutations in the fibrillin I gene lead to the defects in elastic tissue seen in Marfan syndrome, affecting mainly the ocular, skeletal and cardiovascular systems.

Interfibrillar matrix

Glycosaminoglycans

The structural soluble polymers characteristic of the extracellular matrix are the acidic glycosaminoglycans, which are unbranched chains of repeating disaccharide units, each unit carrying one or more negatively charged groups (carboxylate or sulphate esters, or both). The anionic charge is balanced by cations (Na^+, K^+, etc.) in the interstitial fluid. Their polyanionic character endows the glycosaminoglycans with high osmotic activity, which helps to keep the fibrils apart, confers stiffness on the porous gel that they collectively create, and gives the tissue a varying degree of basophilia. Glycosaminoglycans are named according to the tissues in which they were first found, e.g. hyaluronan (vitreous body), chondroitins (cartilage), dermatan (skin), keratan (cornea), heparan (liver). This terminology is no longer relevant, as most glycosaminoglycans are very widely distributed, whereas, conversely, some corneas contain little or no keratan sulphate. Of the glycosaminoglycans, all except hyaluronan have short protein cores and are highly variable in their carbohydrate side-chain structure.

Hyaluronan

Hyaluronan was formerly called hyaluronic acid (or hyaluronate, as only the salt exists at physiological pH). It is a very large, highly hydrated molecule (25,000 kDa). Hyaluronan is found in all extracellular matrices and in most tissues, and is a prominent component of embryonic and developing tissues.

Hyaluronan is important in the aggregation of proteoglycans and link proteins that possess specific hyaluronan-binding sites (e.g. laminin). Indeed, the very large aggregates that are formed may be the essential compression-resisting units in cartilage. Hyaluronan also forms very viscous solutions, which are probably the major lubricants in synovial joints. Because of its ability to bind water, it is often present in semi-rigid structures (e.g. vitreous humour in the eye), where it cooperates with sparse but regular meshworks of thin collagen fibrils.

Proteoglycans

Proteoglycan nomenclature is based on cellular and subcellular location, gene and protein homologies and the presence of specific core proteins (Iozzo and Schaefer 2015): the same core protein can bear different glycosaminoglycan side chains in different tissues. The functions of many proteoglycans are poorly understood. Some of the better-known proteoglycans are: aggrecan in cartilage, perlecan in basal laminae, decorin associated with fibroblasts in collagen fibril assembly, and syndecan in embryonic tissues.

Adhesive glycoproteins

These proteins include molecules that mediate adhesion between cells and the extracellular matrix, often in association with collagens, proteoglycans or other matrix components. All of them are glycosylated and they are, therefore, glycoproteins. General connective tissue contains the well-known families of fibronectins (and osteonectin in bone), laminins and tenascins; there is a rapidly growing list of other glycoproteins associated with extracellular adhesion (Pollard et al 2017). They possess binding sites for other extracellular matrix molecules and for cell adhesion molecules, especially the integrins; in this way they enable cells selectively to adhere to and migrate through, appropriate matrix structures (reviewed in Jacquemet et al (2013)). They also function as signalling molecules, which are detected by cell surface receptors and initiate changes within the cytoplasm (e.g. to promote the formation of hemidesmosomes or other areas of strong adhesion; reorganize the cytoskeleton; and promote or inhibit locomotion and cell division).

Fibronectin

Fibronectin is a large glycoprotein consisting of a dimer joined by disulphide links. Each subunit is composed of a string of large repetitive domains linked by flexible regions. Fibronectin subunits have binding sites for collagen, heparin, heparan sulphate, and cell surface receptors, especially integrins, and so can promote adhesion between all these elements. In connective tissues, the molecules are able to bind to cell surfaces in an orderly fashion, to form short fibronectin filaments. The liver secretes a related protein, plasma fibronectin, into the circulation. The selective adhesion of different cell types to the matrix during development and in postnatal life is mediated by numerous isoforms of fibronectin generated by alternative splicing. Isoforms found in embryonic tissues are also expressed during wound repair, when they facilitate cellular proliferation and cell movements; the adult form is re-expressed once repair is complete.

Laminin

Laminins are a family of large, mosaic glycoproteins composed of globular, laminin-type epidermal growth factor (EGF)-like repeats and α-helical domains that are found mainly in the basal laminae. Laminin is a large (850 kDa) flexible molecule composed of three polypeptide chains (designated α, β and γ). There are many isoforms of the different chains, and at least 18 types of laminin. The prototypical molecule has a cruciform shape, in which the terminal two-thirds are wound round each other to form the stem of a cross, and the shorter free ends form the upright and transverse members. Interactions between modular domains within the laminin molecule and other proteins enable laminins to mediate intercellular interactions via cell surface receptors (e.g. integrins and dystroglycan) and other components of the ECM (e.g. nidogens [also known as entactins], heparan sulphate, type IV collagen and perlecans). Laminin molecules can assemble themselves into flat regular meshworks, e.g. in the basal lamina.

Tenascin

Tenascin is large glycoprotein composed of six subunits that are joined at one end to form a structure that resembles the spokes of a wheel. There is a family of tenascin molecules, generated by alternative splicing of the tenascin gene transcript. Tenascin is abundant in embryonic tissues but its distribution is restricted in the adult. It appears to be important in guiding cell migration and axonal growth in early development: it may either promote or inhibit these activities, depending on the cell type and tenascin isoform. For further reading on extracellular matrix molecules, their regulation and clinical conditions involving disorders of connective tissues, see Pollard et al (2017: Ch. 29).

Classification of connective tissues

Connective and supporting tissues differ considerably in appearance, consistency and composition in different regions. These differences reflect local functional requirements and are related to the predominance of the cell types; the concentration, arrangement and types of fibre; and the characteristics of the interfibrillar matrix. On these bases, general connective tissues can be classified into irregular and regular types, according to the degree of orientation of their fibrous components.

Irregular connective tissues

Irregular connective tissues can be further subdivided into loose, dense and adipose connective tissue.

Loose (areolar) connective tissue

Loose connective tissue is the most generalized form and is extensively distributed. Its chief function is to bind structures together, while still allowing a considerable amount of movement to take place. It constitutes the submucosa in the digestive tract and other viscera lined by mucosae, and the subcutaneous tissue in regions where this is devoid of fat (e.g. eyelids, penis, scrotum and labia), and it connects muscles, vessels and nerves with surrounding structures. It is present in the interior of organs, where it binds together the lobes and lobules of glands, forms the supporting layer (lamina propria) of mucosal epithelia and vascular endothelia, and lies within and between fascicles of muscle and nerve fibres.

Loose connective tissue consists of a meshwork of thin collagen and elastin fibres interlacing in all directions (see Fig. 2.13) to give a measure of both elasticity and tensile strength. The large meshes contain the soft, semi-fluid interfibrillar matrix or ground substance, and different connective tissue cells scattered along the fibres or in the meshes. It also contains adipocytes, usually in small groups, and particularly around blood vessels.

A variant of loose connective tissue occurs in the choroid and the sclera of the eye, where large numbers of pigment cells (melanocytes) are also present (Ch. 45).

Dense irregular connective tissue

Dense irregular connective tissue is found in regions that are under considerable mechanical stress and where protection is given to ensheathed organs. The matrix is relatively acellular and contains a high proportion of collagen fibres organized into thick bundles interweaving in three

dimensions and imparting considerable strength. There are few active fibroblasts, which are usually flattened with heterochromatic nuclei. Dense irregular connective tissue occurs in: the reticular layer of the dermis; the superficial connective tissue sheaths of muscle and nerves, and the adventitia of large blood vessels; and the capsules of various glands and organs (e.g. testis, sclera of the eye, periostea and perichondria).

Adipose tissue

A few adipocytes occur in loose connective tissue in most parts of the body. However, they constitute the principal component of adipose tissue (see Fig. 2.11), where they are embedded in a vascular loose connective tissue, usually divided into lobules by stronger fibrous septa carrying the larger blood vessels. Adipose tissue only occurs in certain regions. In particular it is found: in subcutaneous tissue; in the mesenteries and omenta; in the female breast; in bone marrow; as retro-orbital fat behind the eyeball; around the kidneys; deep to the plantar skin of the foot; and as localized pads in the synovial membrane of many joints. Its distribution in subcutaneous tissue shows characteristic age and sex differences. Fat deposits serve as energy stores, sources of metabolic lipids, thermal insulation (subcutaneous fat) and mechanical shock-absorbers (e.g. soles of the feet, palms of the hands, gluteal region and synovial membranes).

Regular connective tissues

Regular connective tissues include highly fibrous tissues in which fibres are regularly orientated, either to form sheets such as fasciae and aponeuroses, or as thicker bundles such as ligaments or tendons (**Fig. 2.15**). The direction of the fibres within these structures is related to the stresses to which they are subjected: fibrous bundles display considerable interweaving, even within tendons, which increases their structural stability and resilience.

The fibroblasts that secrete the fibres may eventually become trapped within the fibrous structure as tenocytes (tendon cells), compressed, relatively inactive cells with stellate profiles and small heterochromatic nuclei. Fibroblasts on the external surface may be active in continued fibre formation and they constitute a pool of cells available for repair of injured tissue.

Although regular connective tissue is predominantly collagenous, some ligaments contain significant amounts of elastin, e.g. the ligamenta flava of the vertebral laminae and the vocal folds. The collagen fibres may form precise geometrical patterns, as in the cornea.

Mucoid tissue

Mucoid tissue is found chiefly as a stage in the development of connective tissue from mesenchyme. It exists in Wharton's jelly, which forms the bulk of the umbilical cord, and consists substantially of extracellular matrix, largely made up of hydrated mucoid material and a fine meshwork of collagen fibres, in which nucleated, fibroblast-like cells with branching processes are found. Fibres are usually rare in typical mucoid tissue, although the full-term umbilical cord contains perivascular collagen fibres. Postnatally, mucoid tissue is seen in the pulp of a developing tooth, the vitreous body of the eye (a persistent form of mucoid tissue that contains few fibres or cells) and the nucleus pulposus of the intervertebral disc.

TRANSDIFFERENTIATION AND METAPLASIA

Transitions occur between populations of cells forming an epithelium (sheets of polarized cells) and mesenchymal types (where the cells lack polarity) during normal development. In postnatal life, most well-described transitions between morphologically different cell types do not cross an epithelial–mesenchymal boundary but are transitions between types of epithelial cell or, less frequently, between mesenchymal (connective tissue) cell types. Most instances of such transdifferentiation (metaplasia, see Commentary 1.3) are adaptive, to changing environmental conditions or trauma, and almost all are pathological; the altered cells are termed metaplastic. A very common and physiologically normal example is the squamous metaplasia of columnar secretory epithelium of the distal endocervical canal, when exposed to the hormonally stimulated vaginal environment. Gastric metaplasia of the lower oesophagus may occur when chronic reflux of gastric juices exposes its stratified squamous epithelial lining to acid, and the original epithelium is replaced by a mucus-secreting columnar epithelium typical of the stomach (Barrett's oesophagus); this is pathological and susceptible to malignant change. Similarly, the respiratory epithelium (see Fig. 2.2D) of the upper airway often develops foci of stratified squamous metaplasia in response to irritants in cigarette smoke. Mesenchymal (osseous) metaplasia can occur, for example, in the fibrous connective tissue of muscles subjected to repeated damage, where trabeculi of bone develop. It is thought that stem cells (rather than the differentiated cells) in the affected tissue respond to changes in their environment by altering their differentiation pathway, a process that may be reversible if the stimulus is removed. There is evidence suggesting that cellular plasticity, known for many years to occur experimentally in the laboratory, may be more widespread in life than has been appreciated, playing a role in normal tissue homeostasis and repair after injury as well as in the development of malignancy. For a review, see Merrell and Stanger (2016).

MUCOSA (MUCOUS MEMBRANE)

A mucosa or mucous membrane (**Fig. 2.16**) lines many internal hollow organs in which the inner surfaces are moistened by mucus, such as the intestines, conducting portions of the airway, and the genital and urinary tracts. A mucosa proper consists of an epithelial lining, which may have the ducts of mucosal, submucosal or extrinsic glands opening

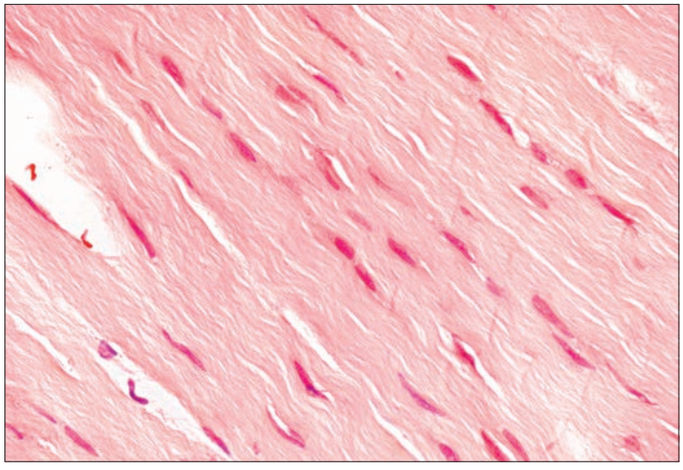

Fig. 2.15 Dense regular connective tissue in a tendon. Thick parallel bundles of type I collagen (here stained pink) present as wavy fibres in tissue sections; they give tendon its white colour in life. The elongated nuclei of inactive fibroblasts (tendon cells) are visible between collagen bundles. (Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

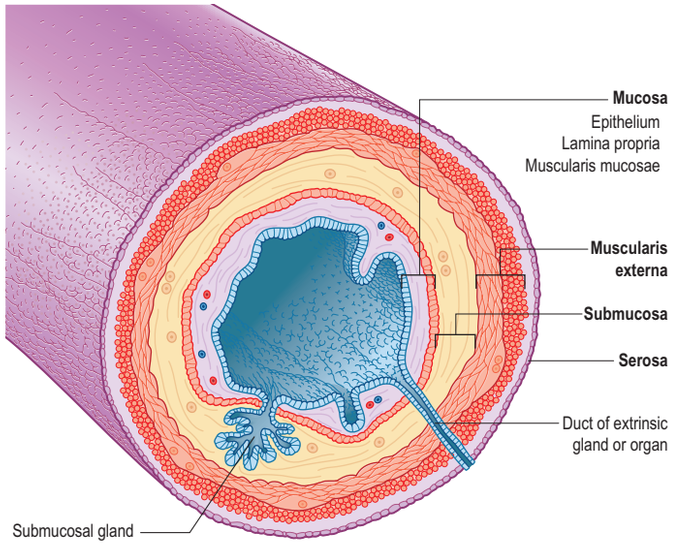

Fig. 2.16 A generalized mucosa and supporting tissues. For details and variations, see text.

onto its surface; an underlying loose connective tissue, the lamina propria; and a thin layer of smooth muscle, the muscularis mucosae. This last layer may be absent from some mucosae, or may be replaced by a layer of elastic fibres. The term mucous membrane reflects the fact that these tissues can all be peeled away as a sheet or membrane from underlying structures; the plane of separation occurs along the muscularis mucosae.

Submucosa is a layer of supporting connective tissue that usually lies below the muscularis mucosae. It may contain mucous or seromucous submucosal glands. Inflammation of the viscera involves, primarily, the connective tissues of the submucosa and lamina propria, and is characterized by dilated vessels, oedema, and accumulations of extravasated immune defence cells. Most mucosae are also supported by one or more layers of smooth muscle, the muscularis externa. Contraction of this muscle may constrict the mucosal lumen (e.g. in the airway) or, where there are two or more muscle layers orientated in opposing directions (e.g. in the intestines), cause peristaltic movement of the viscus and the contents of its lumen. The outer surface of the muscle may be covered by a serosa or, where the structure is retroperitoneal or passes through the pelvic floor, by a connective tissue adventitia.

MUCUS

Mucus is a viscous suspension of complex glycoproteins (mucins) of various kinds, and is secreted by scattered individual epithelial (goblet) cells, a secretory surface epithelium (e.g. the stomach lining) or mucous and seromucous glands. Its elasticity and viscosity play major roles in regulating the transport of food, drugs, particles (including nanoparticles and larger micron-scale particles), and infectious organisms, across mucosal linings (Bansil and Turner 2018).

The precise composition of the mucus varies with the tissue and secretory cells that produce it: all mucins consist of filamentous core proteins with attached carbohydrate chains that are usually branched; salivary mucins contain nearly 600 chains. Carbohydrate residues include glucose, fucose, galactose and *N*-acetylglucosamine (sialic acid). The terminals of some carbohydrate chains are identical to the blood group antigens of the ABO group in the majority of the population (secretors, bearing the secretor gene S^e), and can be detected in salivary mucus by means of appropriate clinical tests. The long polymeric carbohydrate chains bind water and protect surfaces against drying; they also provide good lubricating properties. In concentrated form, mucins form viscous layers that protect the underlying tissues against damage. Mucins may also exist as transmembrane glycoproteins and bind to selectins on complementary cell surfaces.

Synthesis of mucus starts in the rough endoplasmic reticulum, and progresses to the Golgi complex, where it is conjugated with sulphated carbohydrates to form the glycoprotein, mucinogen. This is exported in small, dense, membrane-bound vesicles that swell as they approach the cell surface, with which they fuse before releasing their contents. Secreted mucus is hydrated through the action of epithelial ion channels that transport chloride extracellularly and take up sodium; water follows the movement of chloride by osmosis and dilutes mucus. In this way, mucus gains more fluid and exhibits less viscous properties. In individuals with cystic fibrosis, the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene is defective, impairing the transport of chloride and hydration of mucus, which therefore remains thick and sticky, traps bacteria and leads to infection as well as causing obstruction of passages such as airways and ducts.

SEROSA (SEROUS MEMBRANE)

Serosa consists of a single layer of squamous mesothelial cells, expressing keratin intermediate filaments, supported by an underlying layer of loose connective tissue that contains numerous blood and lymphatic vessels. Serosa lines the pleural, pericardial and peritoneal cavities, and covers the external surfaces of organs lying within those cavities and, in the abdomen, the mesenteries that envelop them. A potential space, filled with a small amount of protein-containing serous fluid, largely an exudate of interstitial fluid, exists between the outer parietal and the inner visceral layers of the serosa.

FASCIA

Fascia is a generic term applied to sheaths, sheets or other dissectible masses of connective tissue that are large enough to be visible to the unaided eye. Deeper-lying condensations of connective tissue have been defined according to their location, e.g. investing muscles (fascia musculorum) or viscera (fascia visceralis). (See Commentary 1.6). Loosely packed connective tissue surrounds peripheral nerves, blood and lymph vessels as they pass between other structures, often linking them together as neurovascular bundles. Some large vessels, e.g. the common carotid and femoral arteries, are invested by a dense connective tissue sheath that may be functionally significant, aiding venous return by approximating large veins to pulsating arteries.

CHAPTER 3

Nervous system

The nervous system has two major divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain, spinal cord, optic nerve and retina, and contains the majority of neuronal cell bodies. The PNS includes all nervous tissue outside the CNS and consists of the cranial and spinal nerves, the peripheral autonomic nervous system (ANS) and the special senses (taste, olfaction, vision, hearing and balance). It is composed mainly of the axons of sensory and motor neurones that pass between the CNS and the body. The ANS is subdivided into sympathetic and parasympathetic components. It consists of neurones that innervate secretory glands and cardiac and smooth muscle, and is concerned primarily with control of the internal environment. Neurones in the wall of the gastrointestinal tract form the enteric nervous system (ENS) and are capable of sustaining local reflex activity that is independent of the CNS. The ENS contains as many intrinsic neurones in its ganglia as the entire spinal cord and is often considered as a third division of the nervous system (Gershon 1998).

In the CNS, the cell bodies of neurones are often grouped together in discrete areas termed nuclei, or they may form more extensive layers or masses of cells; collectively they constitute the grey matter. Neuronal dendrites and synaptic contacts are mostly confined to areas of grey matter and form part of its meshwork of neuronal and glial processes, termed the neuropil. Their axons join bundles of nerve fibres that tend to be grouped separately to form tracts. In the spinal cord, cerebellum, cerebral cortices and some other areas, concentrations of tracts constitute the white matter, so called because the axons are often ensheathed in lipid-rich sheaths of myelin, which is white when fresh (**Fig. 3.1**).

The PNS is composed of the efferent axons (fibres) of motor neurones situated inside the CNS, and the cell bodies of sensory neurones (grouped together as ganglia) and their afferent processes. Sensory cells in dorsal root ganglia give off both centrally and peripherally directed processes; there are no synapses on their cell bodies. Also included are ganglionic neurones of the ANS, which receive synaptic contacts from the peripheral fibres of preganglionic autonomic neurones whose cell bodies lie within the CNS.

When the neural tube is formed during prenatal development (Sanes et al 2011), its walls thicken greatly but do not completely obliterate the cavity within. The latter remains in the spinal cord as the narrow central canal and becomes greatly expanded in the brain to form a series of interconnected cavities called the ventricular system. In the fore- and hindbrains, parts of the neural tube roof do not generate neurones but become thin, folded sheets of secretory tissue, which are invaded by blood vessels and are called the choroid plexuses. The latter secrete cerebrospinal fluid (CSF), which fills the ventricles and subarachnoid spaces, and penetrates the intercellular spaces of the brain and spinal cord to create their interstitial fluid. The CNS has a rich blood supply, which is essential to sustain its high metabolic rate. The blood–brain barrier places considerable restrictions on the substances that are able to diffuse from the blood stream into the neuropil.

Neurones encode information, conduct it over considerable distances, and then transmit it to other neurones or to various non-neural targets such as muscle cells. The propagation of this information within the nervous system depends on rapid electrical signals, the action potentials. Transmission to other cells is mediated by secretion of neurotransmitters at special junctions, either with other neurones (synapses), or with cells outside the nervous system, e.g. muscle cells at neuromuscular junctions, gland cells or adipose tissue, and causes changes in the behaviour of the target cells.

The nervous system contains large populations of non-neuronal cells, termed neuroglia or glia. These cells do not generate action potentials, but convey information encoded as transient changes in intracellular calcium concentration, termed calcium signalling. Glia interact with neurones in many different ways; their two-way communication is essential for normal brain activity.

It was thought for many years that glia outnumbered neurones by 10 times in the CNS, but studies using the isotropic fractionator method challenged that popular view, suggesting instead that the two cell populations are rather similar in size (Azevedo et al 2009). That said, the glia : neurone ratio has been reported to be as high as 17 : 1 in the thalamus (Pakkenberg and Gundersen 1988).

The glial population in the CNS consists of microglia and macroglia; the latter are subdivided into oligodendrocytes and astrocytes. The principal glial cell in the PNS is the Schwann cell. Satellite cells surround each neuronal soma in ganglia.

NEURONES

Most of the neurones in the CNS are either clustered into nuclei, columns or layers, or dispersed within grey matter. Neurones in the PNS are confined to ganglia. Irrespective of location, neurones share many general features, which are discussed here in the context of central neurones. Special characteristics of ganglionic neurones and their adjacent tissues are discussed on p. 60.

Neurones exhibit great variability in their size (cell bodies range from 5 to 100 µm diameter) and shape (Spruston 2008). Their surface areas are extensive because most neurones display numerous branched cell processes. They usually have a rounded or polygonal cell body (perikaryon or soma). This is a central mass of cytoplasm that encloses a nucleus and gives off long, branched extensions with which most intercellular contacts are made. Typically, one of these processes, the axon, is much longer than the others, the dendrites (**Fig. 3.2**). Generally, dendrites conduct electrical signals towards a soma and axons conduct impulses away from it.

Neurones can be classified according to the number and arrangement of their processes (Bota and Swanson 2007). Multipolar neurones (**Fig. 3.3**) are common; they have an extensive dendritic tree that arises either from a single primary dendrite or directly from the soma, and a single axon. Bipolar neurones, which typify neurones of the special sensory systems, have only a single dendrite that emerges from the soma

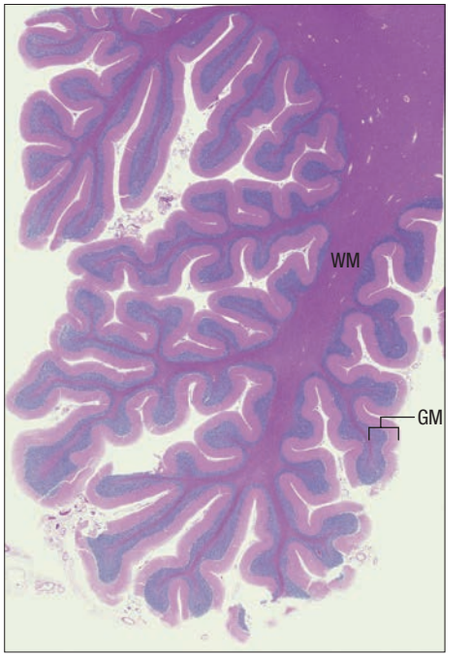

Fig. 3.1 A section through the human cerebellum stained to show the arrangement of the central white matter (WM, deep pink) and the highly folded outer grey matter (GM). In the cerebellum, GM consists of an inner granular layer of tightly packed small neurones (blue) and an outermost molecular layer (pale pink) where neuronal processes make synaptic contacts. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

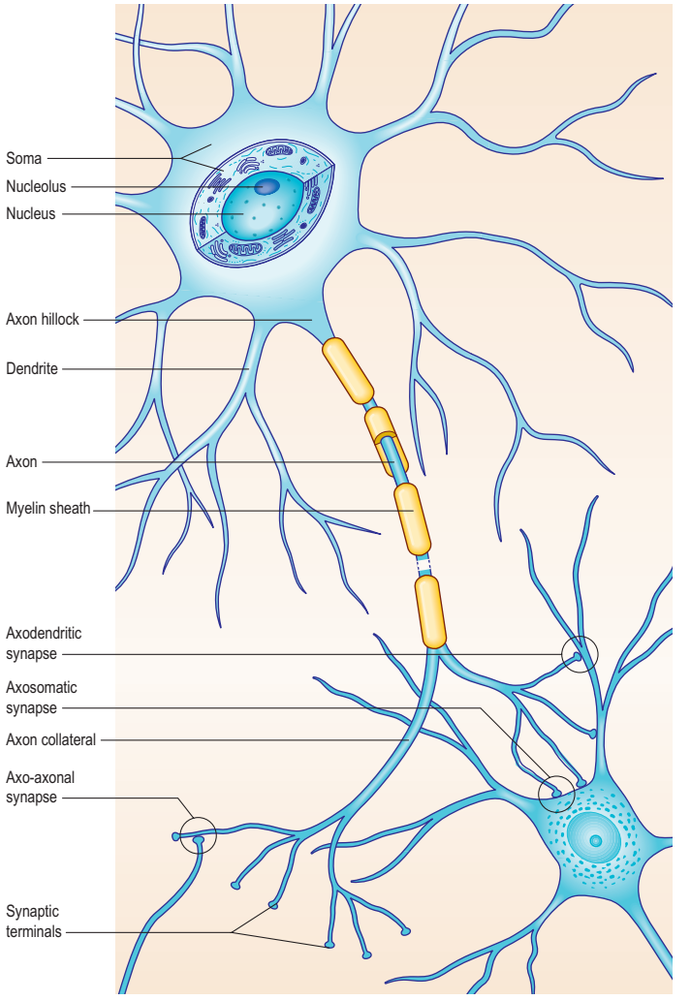

Fig. 3.2 A schematic view of typical neurones featuring one with the soma cut away to show the nucleus and cytoplasmic organelles, dendritic trees with synaptic contacts, other types of synapse, the axon hillock and a myelinated axon.

opposite the axonal pole. Unipolar neurones, which transmit general sensation, e.g. dorsal root ganglion neurones, have a single short process that bifurcates into a peripheral and a central process. This arrangement arises by the fusion of the proximal axonal and dendritic processes of a bipolar neurone during development, and so such neurones can also be termed pseudounipolar. Neurones may also be classified according to whether their axons terminate locally on other neurones (interneurones), or transmit impulses over long distances, often to distinct territories via defined tracts (projection neurones).

Neurones are postmitotic cells and, with few exceptions, they are not replaced when lost.

Soma

The plasma membrane of the soma is generally unmyelinated and is contacted by both inhibitory and excitatory axosomatic synapses; very occasionally, somasomatic and dendrosomatic contacts may be made. The non-synaptic surface may contain gap junctions and is partly covered by either astrocytic or satellite oligodendrocyte processes.

The cytoplasm of a typical soma (see Fig. 3.2) is rich in rough and smooth endoplasmic reticulum and free polyribosomes, indicating a high level of protein synthetic activity. Free polyribosomes often congregate in large groups associated with the rough endoplasmic reticulum. These aggregates of RNA-rich structures are visible by light microscopy as basophilic Nissl bodies or granules. They are distributed throughout the cell body and large dendrites; the axon hillock is conspicuously ribosome-free. Nissl bodies are more obvious in large, highly active cells, such as spinal motor neurones (**Fig. 3.4**), which contain large stacks of rough endoplasmic reticulum and polyribosome aggregates. Maintenance and turnover of cytoplasmic and membranous components are necessary activities in all cells; the huge total volume of cytoplasm within the soma and processes of many neurones requires a considerable commitment of protein synthetic machinery. Neurones also synthesize other proteins (enzyme systems, G-protein coupled receptors, scaffold proteins) involved in the production of neurotransmitters and in the reception and transduction of incoming stimuli. Various transmembrane channel proteins and enzymes are located at the surfaces of neurones, where they are associated with movements of ions.

The nucleus is characteristically large and euchromatic, and contains at least one prominent nucleolus; these are features typical of all cells engaged in substantial levels of protein synthesis. The cytoplasm contains many mitochondria and moderate numbers of lysosomes. Golgi complexes are usually close to the nucleus, near the bases of the main dendrites and opposite the axon hillock.

The neuronal cytoskeleton is a prominent feature of its cytoplasm and gives shape, strength and support to the dendrites and axons. A number of neurodegenerative diseases are characterized by abnormal aggregates of cytoskeletal proteins (reviewed in Cairns et al (2004)). Neurofilaments (the intermediate filaments of neurones) and microtubules are abundant in the soma and along dendrites and axons; the proportions vary with the type of neurone and cell process. Bundles of neurofilaments constitute neurofibrils, which can be seen by light microscopy in silver-stained or immunolabelled sections. Neurofilaments are heteropolymers of proteins assembled from three polypeptide subunits, NF-L (68 kDa), NF-M (160 kDa) and NF-H (200 kDa). NF-M and NF-H have long C-terminal domains that project as side arms from the assembled neurofilament and bind to neighbouring filaments. They can be heavily phosphorylated, particularly in the highly stable neurofilaments of mature axons, and are thought to give axons their tensile strength. Some axons are almost filled by neurofilaments.

Microtubules are important in axonal transport, although dendrites usually have more microtubules than axons. Centrioles persist in mature postmitotic neurones, where they are concerned with the generation of microtubules rather than cell division. Centrioles are associated with cilia on the surfaces of developing neuroblasts. Their significance, other than at some sensory endings (e.g. the olfactory mucosa), is unclear but recent experimental evidence suggests a complex signalling function (Guemez-Gamboa et al 2014).

Pigment granules (**Fig. 3.5**) appear in certain regions, e.g. neurones of the substantia nigra contain neuromelanin, which is probably a waste product of catecholamine synthesis. A similar pigment gives a bluish colour to the neurones in the locus coeruleus. Some neurones are unusually rich in metals, which may form components of enzyme systems, e.g. zinc in the hippocampus and iron in the red nucleus. Ageing neurones, especially in spinal ganglia, accumulate granules of lipofuscin (senility pigment) in residual bodies, which are lysosomes packed with partially degraded lipoprotein material.

Dendrites

Dendrites are highly branched, usually short processes that project from the soma (Shah et al 2010). The branching patterns of many dendritic arrays are probably established by random adhesive interactions between dendritic growth cones and afferent axons that occur during development. There is an overproduction of dendrites in early development, and this is pruned in response to functional demand as the nervous system matures and information is processed through the dendritic tree. There is evidence that dendritic trees may be plastic structures throughout adult life, expanding and contracting as the traffic of synaptic activity varies through afferent axodendritic contacts (see Wong and Ghosh (2002)). Groups of neurones with similar functions have a similar stereotypic tree structure (**Fig. 3.6**), suggesting that the branching patterns of dendrites are important determinants of the integration of the afferent inputs that converge on the tree (see Kulkarni and Firestein (2012)).

Dendrites differ from axons in many respects. They represent the afferent rather than the efferent system of the neurone, and receive both excitatory and inhibitory axodendritic contacts. They may also make dendrodendritic and dendrosomatic connections (see Fig. 3.9), some of which are reciprocal. Synapses occur either on small projections called dendritic spines or on the smooth dendritic surface. Dendrites contain ribosomes, smooth endoplasmic reticulum, microtubules, neurofilaments, actin filaments and Golgi complexes. Their neurofilament proteins are poorly phosphorylated and their microtubules are interconnected by the microtubule-associated protein (MAP)-2 almost exclusively in comparison with axons.

The shapes of dendritic spines range from simple protrusions to structures with a slender stalk and expanded distal end. Most spines are not more than 2 μm long, and have one or more terminal expansions; they can also be short and stubby, branched or bulbous. Large mushroom spines are assumed to have differentiated in response to afferent activity

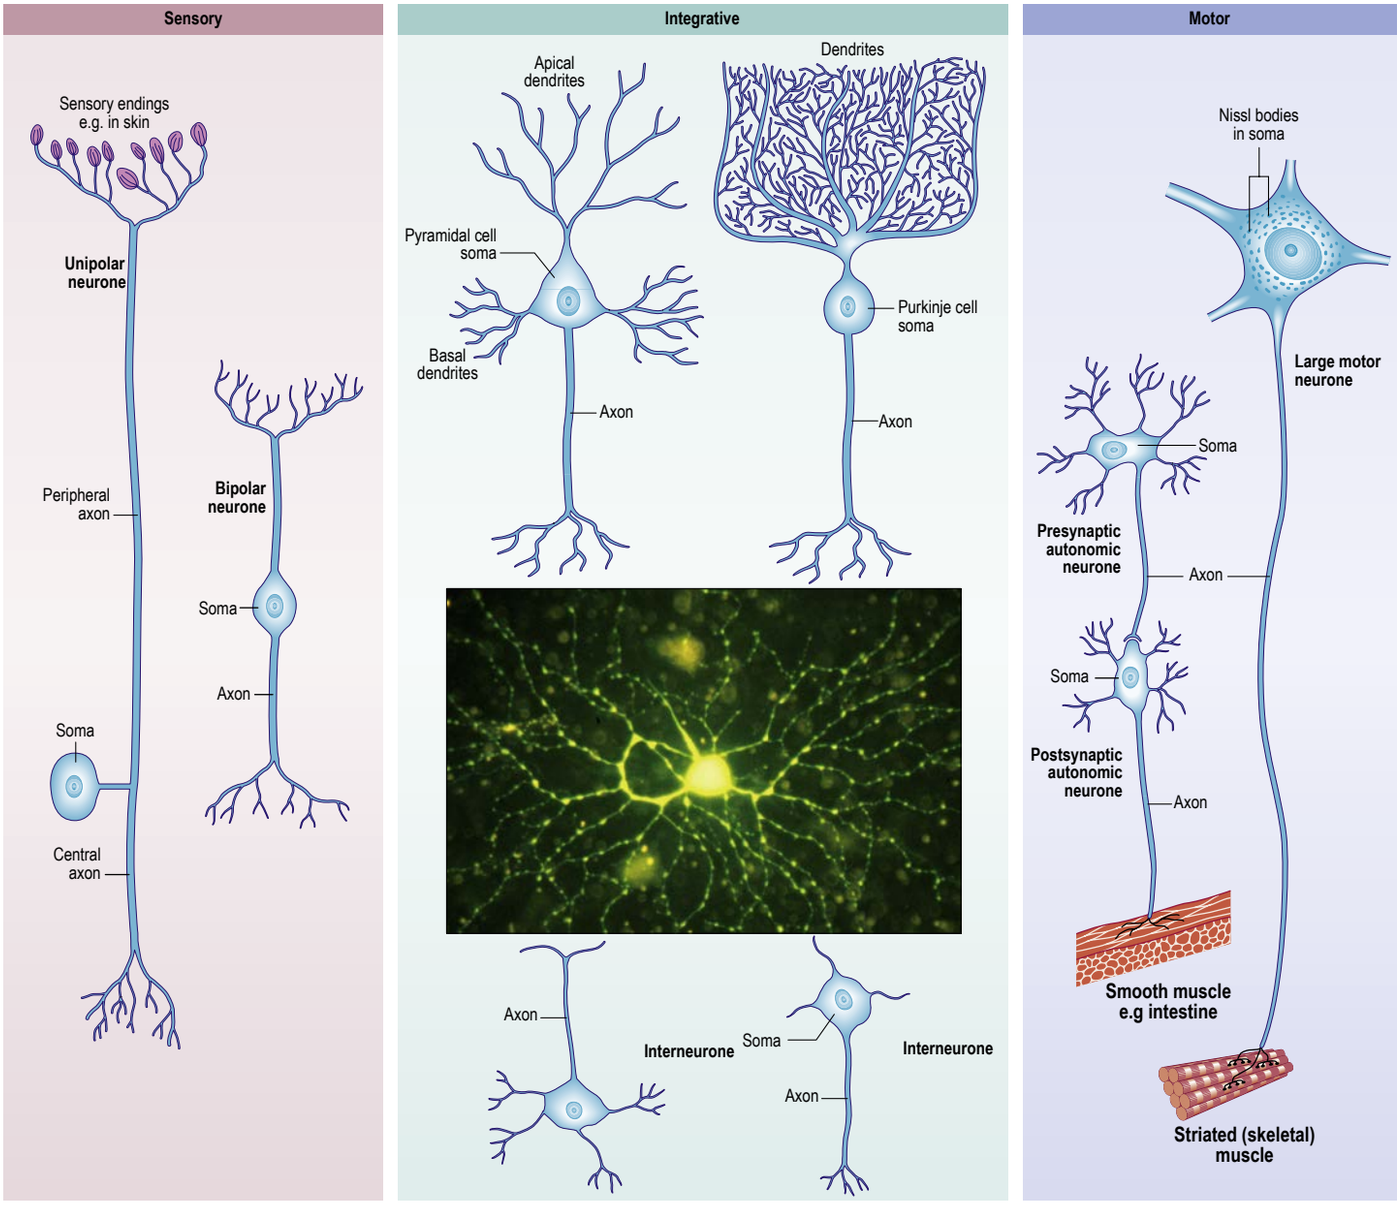

Fig. 3.3 The variety of shapes of neurones and their processes. The inset shows a human multipolar retinal ganglion cell, filled with fluorescent dye by microinjection. (Inset, Courtesy of Drs Richard Wingate, James Morgan and Ian Thompson, King's College, London.)

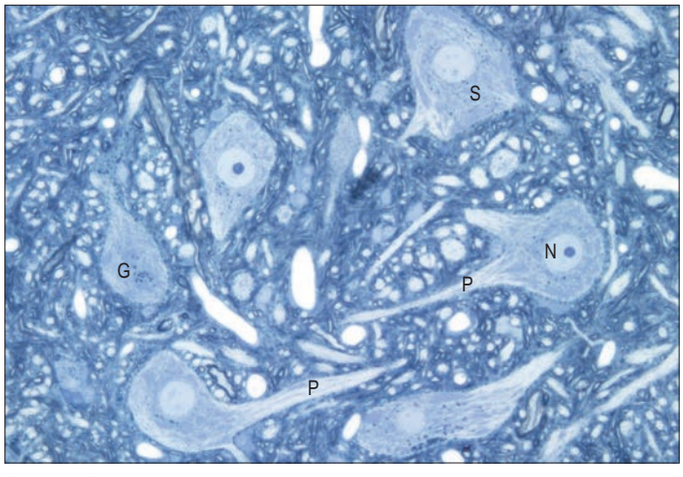

Fig. 3.4 Spinal motor neurones (toluidine blue stained resin section, rat tissue) showing a group of cell bodies (somata, S), some with the proximal parts of axonal and dendritic processes (P) visible. Their nuclei (N) typically have prominent, deeply staining nucleoli, indicative of metabolically highly active cells; two are visible in the plane of section. Nissl granules (G) are seen in the cytoplasm. Surrounding the neuronal somata is the neuropil, consisting of the interwoven processes of these and other neurones and of glial cells.

('memory spines'; Matsuzaki et al 2004). These large spines often contain a spine apparatus, an organelle consisting of small sacs of endoplasmic reticulum interleaved by electron-dense bars (Gray 1959, Segal et al 2010). Mouse mutants deficient in these organelles show memory deficits (Deller et al 2003). Free ribosomes and polyribosomes are concentrated at the base of the spine. Ribosomal accumulations near synaptic sites provide a mechanism for activity-dependent synaptic plasticity through the local regulation of protein synthesis (see Petralia et al 2016).

Axons

The axon originates either from the soma or from the proximal segment of a dendrite at a specialized region free of Nissl granules, the axon hillock. Action potentials are initiated here, at the junction with the proximal axon (axon initial segment) (Lörincz and Nusser 2010). The axonal plasma membrane (axolemma) is undercoated at the hillock by a concentration of cytoskeletal molecules, including spectrin and actin fibrils, which are important in anchoring numerous voltage-sensitive channels to the membrane (see Bender and Trussell (2012)). The axon hillock is unmyelinated and often participates in inhibitory axo-axonal synapses. It is unique because it contains ribosomal aggregates immediately below the postsynaptic membrane (Kole and Stuart 2012).

In the CNS, small, unmyelinated axons lie free in the neuropil, whereas in the PNS they are embedded in Schwann cell cytoplasm. Myelin, which is formed around almost all axons of >2 μm diameter by oligodendrocytes in the CNS and by Schwann cells in the PNS, begins at the distal end of the axon hillock. Nodes of Ranvier are specialized regions of myelin-free axon where action potentials are generated and where an axon may branch. In both CNS and PNS, the territory of a myelinated axon between adjacent nodes is called an internode; the region close to a node, where the myelin sheath terminates, is called the paranode; and the region just beyond that is the juxtaparanode. Myelin thickness and internodal lengths are, in general, positively correlated with axon diameter. The density of sodium channels in the axolemma is highest at nodes of Ranvier, and very low along internodal membranes; sodium channels are spread more evenly within the axolemma of unmelinated axons. Fast potassium chanels are present in the paranodal regions of myelinated axons. Fine processes of glial cytoplasm (astrocytic in the CNS, Schwann cell in the PNS) surround the nodal axolemma.

The terminals of an axon are unmyelinated. Most expand into presynaptic boutons, which may form connections with axons, dendrites, neuronal somata or, in the periphery, muscle fibres, glands and lymphoid tissue. Exceptions include the free afferent sensory endings in, for example, the epidermis, which are unspecialized structurally, and the peripheral terminals of afferent sensory fibres with encapsulated endings (see Fig. 3.29). Axon terminals contain abundant small clear synaptic vesicles and large dense-core vesicles. The former contain a neurotransmitter (e.g. glutamate, γ-aminobutyric acid (GABA), acetylcholine) that is released into the synaptic cleft on the arrival of an action potential at the terminal and which then binds to cognate receptors on the postsynaptic membrane. Depending on the nature of the transmitter and its receptors, the postsynaptic neurone will become excited or inhibited. The dense-core vesicles contain neuropeptides, including brain-derived neurotrophic factor (BDNF; Dieni et al 2012). Axon terminals may themselves be contacted by other axons, forming axo-axonal presynaptic inhibitory circuits (Veres et al 2014, Burke et al 2017).

Axons contain microtubules, neurofilaments, mitochondria, membrane vesicles, cisternae and lysosomes. They do not usually contain ribosomes or Golgi complexes, other than at the axon hillock; exceptionally, the neurosecretory fibres of hypothalamo-hypophysial neurones contain the mRNA of neuropeptides. Organelles are differentially distributed along axons, e.g. there is a greater density of mitochondria and membrane vesicles in the axon hillock, at nodes and in presynaptic endings. Axonal microtubules are interconnected by cross-linking MAPs, of which tau is the most abundant. Microtubules have an intrinsic polarity, and in axons all microtubules are uniformly orientated with their rapidly growing ends directed away from the soma towards the axon terminal. The microtubule binding protein tau plays an important role in Alzheimer's disease (Cairns et al 2004; Iqbal et al 2010): formation of tau oligomers and the subsequent pathological filament arrays are critical steps in the aetiopathogenesis of this condition. Neurofilament proteins ranging from high to low molecular weights are highly phosphorylated in mature axons, whereas growing and regenerating axons express a calmodulin-binding membrane-associated phosphoprotein, growth-associated protein-43 (GAP-43), as well as poorly phosphorylated neurofilaments. In dendrites, microtubules are the major cytoskeletal element, forming microtubule fascicles associated with filamentous MAPs such as MAP2 and MAP1B (Hirokawa 1994).

Neurones respond differently to injury, depending on whether the damage occurs in the CNS or the PNS. The glial microenvironment of a damaged central axon does not facilitate axonal regrowth; consequently, reconnection with original synaptic targets does not normally occur. In marked contrast, the glial microenvironment in the PNS is capable of facilitating axonal regrowth. However, functional outcome of clinical repair of a large mixed peripheral nerve, especially if the injury occurs some distance from the target organ, or produces a long defect in the damaged nerve, is frequently unsatisfactory (Birch 2011; see Commentary 1.5).

Axoplasmic flow

Neuronal organelles and cytoplasm are in continual motion. Bidirectional streaming of vesicles along axons results in a net transport of materials from the soma to the terminals, with more limited movement in the opposite direction. Two major types of transport occur, slow and relatively fast. Slow axonal transport is a bulk flow of axoplasm only in the anterograde direction, carrying cytoskeletal proteins and soluble, non-membrane-bound proteins from the soma to the terminals at a rate of approximately 0.1–3 mm a day. In contrast, fast axonal transport carries membrane-bound vesicular material (endosomes and lysosomal autophagic vacuoles) and mitochondria at approximately 200 mm a day in the retrograde direction (towards the soma) and approximately 40 mm per day anterogradely (in particular, precursors of synaptic vesicles and plasma membranes).

Rapid flow depends on microtubules. Vesicles with side projections line up along microtubules and are transported along them by molecular motors. Two microtubule-based motor proteins with adenosine 5′-triphosphatase (ATPase) activity are involved in fast transport: kinesin family proteins (KIFs) are responsible for the fast component of anterograde transport, and cytoplasmic dynein is responsible for retrograde transport (**Fig. 3.7**). Anterograde transport conveys synaptic vesicle precursors, vesicles containing neurotrophic factor receptors and mitochondria. Retrograde transport mediates the movement of neurotropic viruses. Specific pools of endocytic organelles, signalling endosomes, mediate the long-distance axonal transport of growth factors, such as neurotrophins and their signalling receptors. In dendrites, vesicles including transmitter receptors such as *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, mRNAs and mitochondria are transported along microtubules. Defects in axonal and dendritic transport have been linked to various neurodegenerative processes. (See Hirokawa et al (2010), Hinckelmann et al (2013) and Schmieg et al (2014) for reviews of axonal transport in health and disease.)

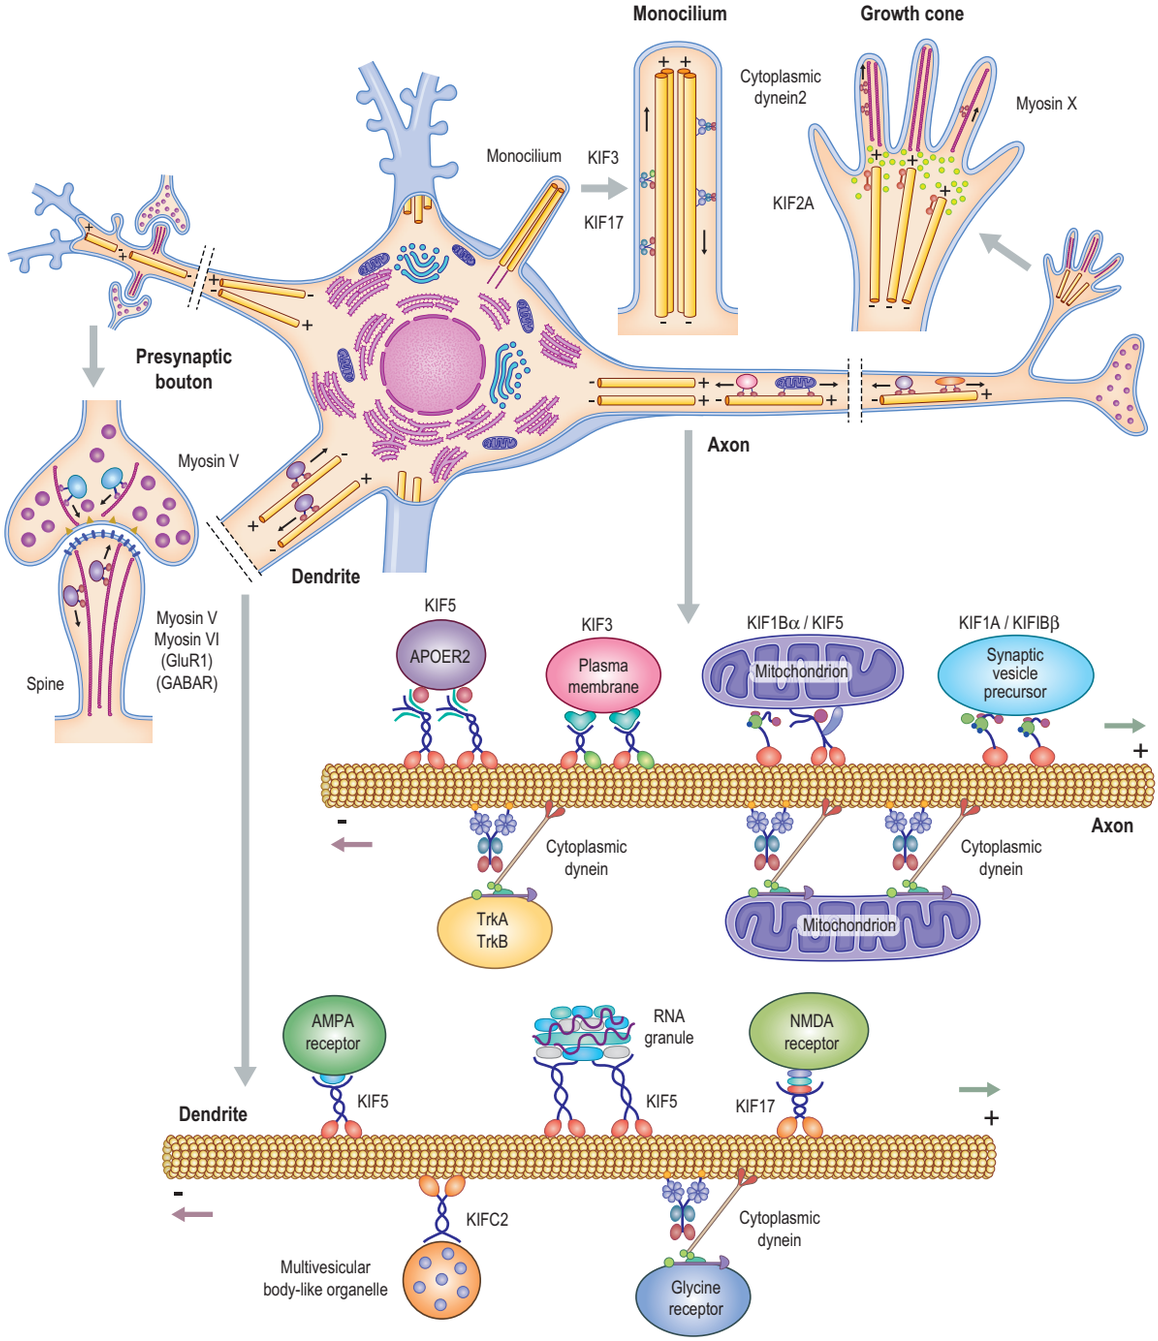

Fig. 3.7 Intracellular transport in neurones. Various kinesin family proteins (KIFs) transport membranous organelles anterogradely in axons and dendrites, whereas cytoplasmic dynein 1 and KIFC2 transport retrograde cargoes. In neuronal cilia, anterograde transport is performed by KIF3 and KIF17, while retrograde transport is performed by cytoplasmic dynein 2. In short-range transport, such as transport in pre- and post-synapses and growth cone filopodia, the myosin family proteins function as the molecular motors. APOER2, apolipoprotein E receptor2; GluR1, glutamate receptor1; GABAR, GABA receptor. For further details, see text and source reference. (Adapted with permission from Hirokawa N, Noda Y, Tanaka Y et al 2009 Kinesin superfamily motor proteins and intracellular transport. Nature Rev Mol Cell Biol 10:682–96.)

Intraflagellar transport (IFT)

Almost all vertebrate cell types, including neurones, have primary cilia that emanate from the cell surface. They lack motility and have critical functions in sensing the extracellular environment and in coordinating signalling pathways in brain development. Primary ciliary axonemes contain nine doublet microtubules (9+0 configuration). Protein complexes and membrane organelles are bidirectionally conveyed on axonemes by intraflagellar transport (IFT). Molecular motor proteins KIF3 and KIF17 and cytoplasmic dynein have functions in IFT (see Fig. 3.7).

Synapses

Transmission of impulses across specialized junctions (synapses) between two neurones is largely chemical and depends on the release of neurotransmitters from the presynaptic terminal. These neurotransmitters bind to cognate receptors in the postsynaptic neuronal membrane, resulting in a change of membrane conductance and leading to either a depolarization or a hyperpolarization (Ryan and Grant 2009).

The patterns of axonal termination vary considerably. A single axon may synapse with one neurone (e.g. climbing fibres ending on cerebellar Purkinje neurones), or more often with many neurones (e.g. cerebellar parallel fibres, which provide an extreme example of this phenomenon). In synaptic glomeruli (e.g. in the olfactory bulb), groups of synapses between two or many neurones form interactive units encapsulated by neuroglia (**Fig. 3.8**; Perea et al 2009).

Electrical synapses (direct communication via gap junctions) are rare in the human CNS and are confined largely to groups of neurones with tightly coupled activity, e.g. the inspiratory centre in the medulla. They will not be discussed further here.

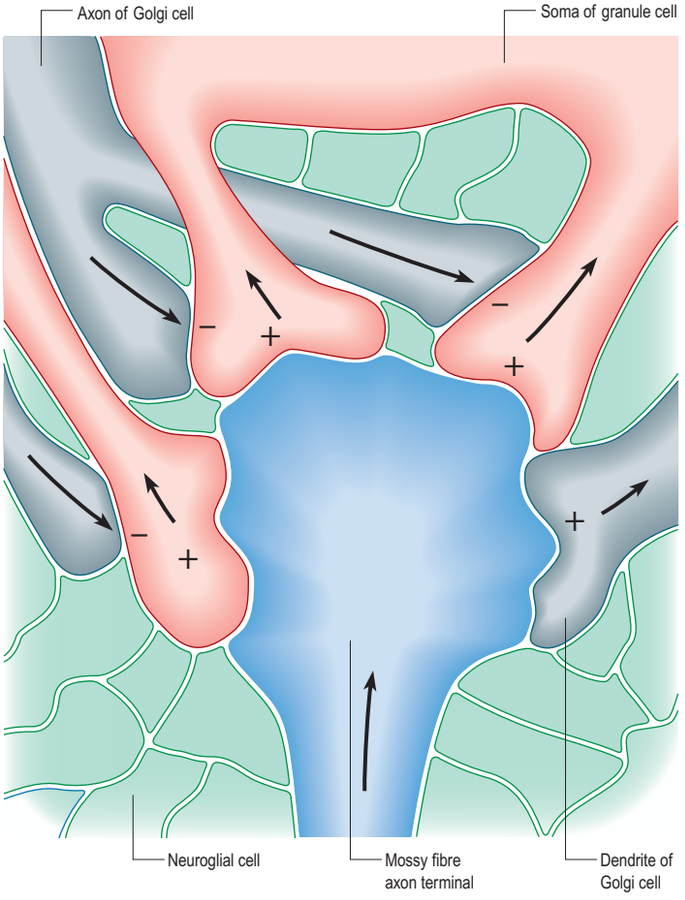

Fig. 3.8 The arrangement of a complex synaptic unit. A cerebellar synaptic glomerulus with excitatory ('+') and inhibitory ('–') synapses grouped around a central axonal bouton. The directions of transmission are shown by the arrows.

Classification of chemical synapses

Chemical synapses have an asymmetric structural organization in keeping with the unidirectional nature of their transmission (**Figs 3.9–3.10**) (Pereda 2014). Typical chemical synapses share a number of important features. They all display an area containing a presynaptic density apposed to a corresponding postsynaptic density; the two are separated by a narrow (20–30 nm) gap, the synaptic cleft. Synaptic vesicles containing the appropriate neurotransmitter are found on the presynaptic side, clustered near the presynaptic density at the presynaptic membrane. Together these define the active zone, the area of the synapse where neurotransmission takes place (Gray 1959, Eggermann et al 2012).

Chemical synapses can be classified according to a number of different parameters, including the neuronal regions forming the synapse, their ultrastructural characteristics, the chemical nature of their neurotransmitter(s) and their effects on the electrical state of the postsynaptic neurone. The following classification is limited to associations between neurones. Neuromuscular junctions share many (though not all) of these parameters, and are often referred to as peripheral synapses. They are described separately on p. 66.

Synapses can occur between almost any surface regions of the participating neurones. The most common type occurs between an axon and either a dendrite or a soma, when the axon is expanded as a small bulb or bouton (see Figs 3.9–3.10). This may be a terminal of an axonal branch (terminal bouton) or one of a row of bead-like endings, when the axon makes contact at several points, often with more than one neurone (bouton de passage). Boutons may synapse with dendrites, including thorny protrusions named dendritic spines (**Fig. 3.11**) or the flat surface of a dendritic shaft; a soma (usually on its flat surface, but occasionally on spines); the axon hillock; and the terminal boutons of other axons.

The connection is classified according to the direction of transmission, and the incoming terminal region is named first. Most common are axodendritic synapses, although axosomatic connections are frequent. All other possible combinations are found but are less common, i.e. axo-axonal, dendro-axonal, dendrodendritic, somatodendritic or somatosomatic. Axodendritic and axosomatic synapses occur in all regions of the CNS and in autonomic ganglia, including those of the ENS. The other types appear restricted to regions of complex interaction between larger sensory neurones and microneurones, e.g. in the thalamus.

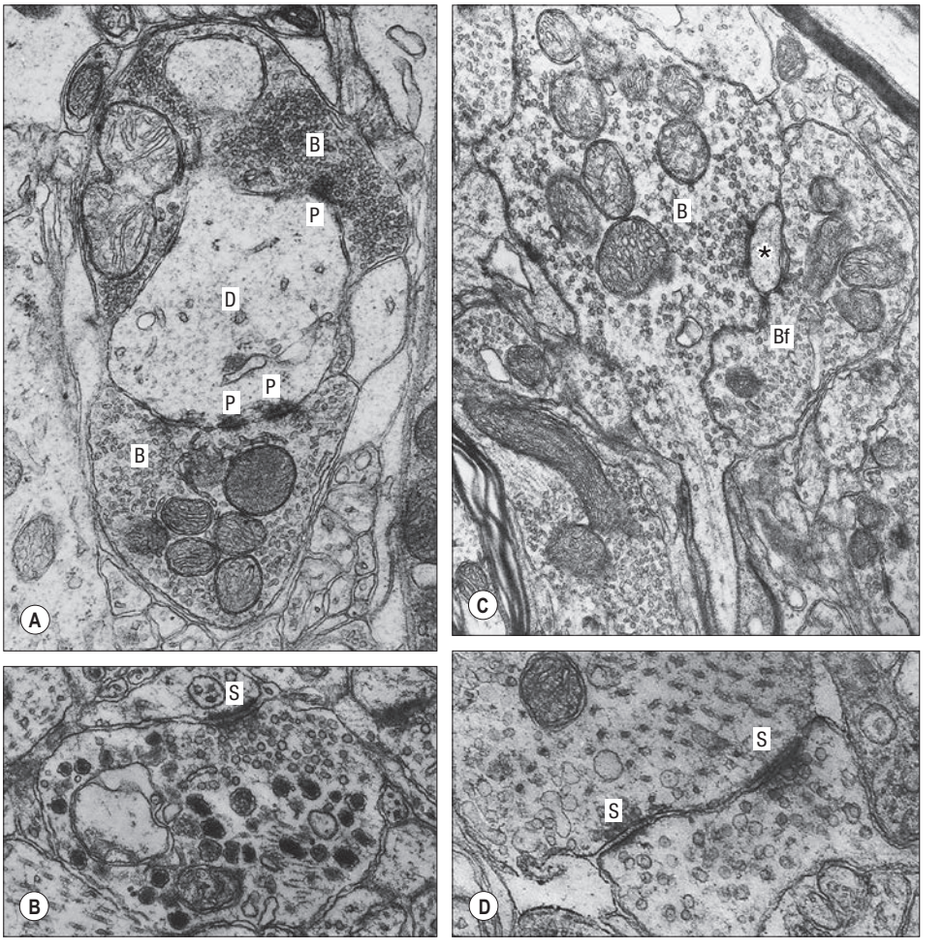

Fig. 3.9 Electron micrographs demonstrating various types of synapse. **A**, A cross-section of a dendrite (D) on which two synaptic boutons (B) end. The upper bouton contains round vesicles, and the lower bouton contains flattened vesicles of the small type. A number of pre- and postsynaptic (P) thickenings mark the specialized zones of contact. **B**, A type I synapse (S, postsynaptic site) containing both small, round, clear vesicles and also large, dense-cored vesicles of the neurosecretory type. **C**, A large terminal bouton (B) of an optic nerve afferent fibre, which is making contact with a number of postsynaptic processes, in the dorsal lateral geniculate nucleus of the rat. One of the postsynaptic processes (*) also receives a synaptic contact from a bouton (Bf) containing flattened vesicles. **D**, Reciprocal synapses (S) between two neuronal processes in the olfactory bulb. The presynaptic bouton is in contact with an astrocytic process (P). **B**, Reconstructed image of a dendritic spine (cyan) and the postsynaptic density (red) within the spine head. (Adapted with permission from Hirokawa N, Noda Y, Tanaka Y et al 2009 Kinesin superfamily motor proteins and intracellular transport. Nature Rev Mol Cell Biol 10:682–96.)

Ultrastructurally, synaptic vesicles may be internally clear or dense, and of different size (loosely categorized as small or large) and shape (round, flat or pleomorphic, i.e. irregularly shaped). The submembranous densities may be thicker on the postsynaptic than on the presynaptic side (asymmetric synapses), or equivalent in thickness (symmetric synapses), and can be perforated or non-perforated. Synaptic ribbons are found at sites of neurotransmission in the retina and inner ear. They have a distinctive morphology, in that the synaptic vesicles are grouped around a ribbon- or rod-like density orientated perpendicular to the cell membrane (see Fig. 3.10).

Synaptic boutons make obvious close contacts with postsynaptic structures but many other terminals lack specialized contact zones. Areas of transmitter release occur in the varicosities of unmyelinated axons, where effects are sometimes diffuse, e.g. the aminergic pathways of the basal ganglia, and in autonomic fibres in the periphery. In some instances, such axons may ramify widely throughout extensive areas of the brain and affect the behaviour of very large populations of neurones, e.g. the diffuse cholinergic innervation of the cerebral cortices. Pathological degeneration of these pathways can therefore cause widespread disturbances in neural function.

Neurones express a variety of neurotransmitters, either as one class of neurotransmitter per cell or more often as several. Good correlations exist between some types of transmitter and specialized structural features of synapses. In general, asymmetric synapses with relatively small spherical vesicles are associated with acetylcholine (ACh), glutamate, serotonin (5-hydroxytryptamine, 5-HT) and some amines; those with dense-core vesicles include many peptidergic synapses and other amines (e.g. noradrenaline (norepinephrine), adrenaline (epinephrine), dopamine). Symmetric synapses with flattened or pleomorphic vesicles have been shown to contain either GABA or glycine. Flattening of synaptic vesicles was claimed to be an artefact of aldehyde fixation (Walberg 1968), but this has not been supported in the subsequent literature. It appears that the shape and orientation of synaptic vesicles may be influenced by their movement toward the active zone of a synapse: a study using adult mouse brain tissue analysed by focused ion beam scanning electron microscopy (FIB-SEM) found that synaptic vesicles were not spherical but oblate or cigar-shaped ellipsoids (Khanmohammadi et al 2015).

Neurosecretory endings found in various parts of the brain and in neuroendocrine glands and cells of the dispersed neuroendocrine system share many features with presynaptic boutons. They all contain peptides or glycoproteins within dense-core vesicles. The latter are of characteristic size and appearance: they are often ellipsoidal or irregular in shape, and relatively large, e.g. oxytocin and vasopressin vesicles in the neurohypophysis may be up to 200 nm in diameter.

Synapses may cause depolarization or hyperpolarization of the postsynaptic membrane, depending on the neurotransmitter released and the classes of receptor molecule in the postsynaptic membrane. Depolarization of the postsynaptic membrane results in excitation of the postsynaptic neurone, whereas hyperpolarization has the effect of transiently inhibiting electrical activity. Subtle variations in these responses may also occur at synapses where mixtures of neuromediators are present and their effects are integrated. For details of the synaptic organization of the brain, see Shepherd (2003).

Type I and II synapses

There are two broad categories of synapse, type I and type II. In active zones of type I synapses the cytoplasmic density is thicker on the postsynaptic side. In type II synapses the pre- and postsynaptic densities are thinner and more symmetric. Type I boutons contain a predominance of small spherical vesicles approximately 50 nm in diameter, and type II boutons contain oval or flattened vesicles. Throughout the CNS, type I synapses are generally excitatory and type II are inhibitory. In a few instances, types I and II synapses are found in close proximity, orientated in opposite directions across the synaptic cleft (a reciprocal synapse).

Mechanisms of synaptic activity

Synaptic activation begins with arrival of one or more action potentials at the presynaptic bouton, which causes the opening of voltage-sensitive calcium channels in the presynaptic membrane. The response time in typical fast-acting synapses is then very rapid; classic neurotransmitter (e.g. ACh, glutamate or GABA) is released in less than a millisecond. Release-ready synaptic vesicles are docked to the presynaptic membrane and primed through processes not yet fully understood. On calcium ion influx through voltage-sensitive channels, their membranes fuse to open a pore through which neurotransmitter diffuses into the synaptic cleft (Gray 1959, Eggermann et al 2012).

Once the vesicle has discharged its contents, its membrane is incorporated into the presynaptic plasma membrane and is then recycled back into the bouton by endocytosis near the edges of the active zone. The recycling time for a synaptic vesicle may be in the range of a few seconds to minutes; newly recycled vesicles may be used instantly for the next cycle of neurotransmitter release (cycling pool of vesicles). The fusion of vesicles with the presynaptic membrane is responsible for the observed quantal behaviour of neurotransmitter release, both during neural activation and spontaneously, in the slightly leaky resting condition (Neher and Sakaba 2008, Suedhof 2012).

Postsynaptic events vary greatly, depending on the receptor molecules and their related molecular complexes (Murakoshi and Yasuda 2012). Receptors are generally classed as either ionotropic (ligand-gated channels) or metabotropic (membrane receptors that act through a second messenger).

Ionotropic receptors can be activated by conformational changes induced when neurotransmitter molecules bind to the receptor complex, causing a voltage change within the postsynaptic cell. Examples are the nicotinic ACh receptor and the related $GABA_A$ receptor, which are formed from five subunits, the tetrameric ionotropic glutamate receptors, such as the NMDA receptor or the AMPA receptor.

In metabotropic receptors, the receptor and ion channel may be separate molecules, coupled by G-proteins, some via a complex cascade of chemical interactions (a second messenger system), e.g. the adenylate cyclase pathway. Postsynaptic effects are generally rapid and short-lived, because the transmitter is quickly inactivated either by an extracellular enzyme (e.g. acetylcholinesterase, AChE), or by uptake into neurones or glial cells. Examples of such metabotropic receptors are the muscarinic ACh receptor and the dopamine receptor.

Neurohormones

Neurohormones are included in the class of molecules with neurotransmitter-like activity. They are synthesized in neurones and released into the blood circulation by exocytosis at synaptic bouton-like structures. As with classic endocrine gland hormones, they may act at great distances from their site of secretion. Neurones secrete into the CSF or local interstitial fluid to affect other cells, either diffusely or at a distance. To encompass this wide range of phenomena the general term neuromediation has been used, and the chemicals involved are called neuromediators.

Neuromodulators

Some neuromediators do not appear to affect the postsynaptic membrane directly but they can affect its responses to other neuromediators, either enhancing their activity (by increasing or prolonging the immediate response), or perhaps limiting or inhibiting their action. These substances are called neuromodulators. A single synaptic terminal may contain one or more neuromodulators in addition to a neurotransmitter, usually (though not always) in separate vesicles. Neuropeptides (see below) are nearly all neuromodulators, at least in some of their actions. They are stored within dense granular synaptic vesicles of various sizes and appearances.

Development and plasticity of synapses

The density of synapses in the human cerebral cortex increases dramatically in the first years of life, reaches its peak in adolescence and starts to decline gradually thereafter. Immature synapses are either maintained and reinforced to become stable mature synapses or eliminated from the neural circuit (Okabe 2017). This process, synapse pruning, is thought to be important in eliminating unnecessary connections between neurones for proper and effective information processing in mature neuronal networks in the adult brain (Kano et al 2018), although even in the adult brain, a fraction of synapses in the cerebral cortex and the hippocampus can be newly formed or eliminated. Although less drastic in the magnitude of alteration, synapses in neural circuits related to memory formation can change their functional strength according to the previous history of synaptic activity and firing frequency of presynaptic and postsynaptic neurones (Squire and Kandel 2008). This process, synaptic plasticity, includes both increased or decreased synaptic strength for some hours or longer (long-term potentiation, LTP, or long-term depression, LTD, respectively). Impaired memory is a hallmark of dementia such as Alzheimer's disease, where a reduction in the number of dendritic spines, together with pathological changes such as neurofibrillary tangles and deposits of amyloid-β protein, suggests that reduced synaptic connectivity impairs cognitive function in affected individuals (Tampellini 2015).

Neurotransmitter molecules

Until relatively recently, the molecules known to be involved in chemical synapses were limited to a fairly small group of classic neurotransmitters, e.g. ACh, noradrenaline (norepinephrine), adrenaline (epinephrine), dopamine and histamine, all of which had well-defined rapid effects on other neurones, muscle cells or glands. However, many synaptic interactions cannot be explained on the basis of classic neurotransmitters, and other substances, particularly some amino acids such as glutamate, glycine, aspartate, GABA and the monoamine serotonin, also function as transmitters. Substances first identified as hypophysial hormones or as part of the dispersed neuroendocrine system (see below) of the alimentary tract, can be detected widely throughout the CNS and PNS, often associated with functionally integrated systems. Many of these are peptides: more than one hundred (together with other candidates) function mainly as neuromodulators and influence the activities of classic transmitters.

Acetylcholine

Acetylcholine (ACh) is perhaps the most extensively studied neurotransmitter of the classic type. Its precursor, choline, is synthesized in the neuronal soma and transported to the axon terminals, where it is acetylated by the enzyme choline acetyl transferase (ChAT), and stored in clear spherical vesicles 40–50 nm in diameter. ACh is synthesized by motor neurones and released at all their motor terminals on skeletal muscle. It is released by preganglionic fibres at synapses in parasympathetic and sympathetic ganglia, and many parasympathetic, and some sympathetic, ganglionic neurones are cholinergic. ACh is also associated with the degradative extracellular enzyme AChE, which inactivates the transmitter by converting it to choline.

The effects of ACh on nicotinic receptors (i.e. those in which nicotine is an agonist) are rapid and excitatory. In the CNS, the nicotinic ACh receptor mediates the effect of tobacco (for review, see Albuquerque et al (2009)). In the peripheral autonomic nervous system, the slower, more sustained excitatory effects of cholinergic autonomic endings are mediated by muscarinic receptors via a second messenger system.

Monoamines

Monoamines include the catecholamines (noradrenaline (norepinephrine), adrenaline (epinephrine) and dopamine), the indoleamine serotonin (5-hydroxytryptamine, 5-HT) and histamine (Haas et al 2008). They are synthesized by neurones in sympathetic ganglia and by their homologues, the chromaffin cells of the suprarenal medulla and paraganglia. Within the CNS, the somata of monoaminergic neurones lie mainly in the brainstem, although their axons ramify widely into all parts of the nervous system. Monoaminergic cells are also present in the retina.

Noradrenaline is the chief transmitter present in sympathetic ganglionic neurones with endings in various tissues, notably smooth muscle and glands, and in other sites including adipose and haemopoietic tissues and the corneal epithelium. It is also found at widely distributed synaptic endings within the CNS; many of their neuronal somata are situated in the locus coeruleus in the medullary floor. The actions of noradrenaline depend on its site of action and vary with the type of postsynaptic receptor, e.g. it strongly inhibits neurones of the submucosal plexus of the intestine and of the locus coeruleus via α_2-adrenergic receptors, whereas it mediates depolarization, producing vasoconstriction, via β-receptors in vascular smooth muscle. Adrenaline is present in central and peripheral nervous pathways and occurs with noradrenaline in the suprarenal medulla. Both adrenaline and noradrenaline are found in dense-cored synaptic vesicles approximately 50 nm in diameter.

Dopamine is a neuromediator of considerable clinical importance, found mainly in neurones with cell bodies in the telencephalon, diencephalon and mesencephalon. A major dopaminergic neuronal population in the midbrain constitutes the substantia nigra, so called because its cells contain neuromelanin, a black granular by-product of dopamine synthesis (Ch. 31). Dopaminergic endings are particularly numerous in the corpus striatum, limbic system and cerebral cortex. Structurally, dopaminergic synapses contain numerous dense-cored vesicles that resemble those containing noradrenaline. Pathological reduction in dopaminergic activity has widespread effects on motor control, affective behaviour and other neural activities, as seen in Parkinson's syndrome.

Serotonin and histamine are found in neurones mainly within the CNS. Serotonin is typically synthesized in small midline neuronal clusters in the brainstem, mainly in the raphe nuclei; the axons from these neurones ramify extensively throughout the entire brain and spinal cord. Synaptic terminals contain rounded, clear vesicles approximately 50 nm in diameter and are of the asymmetric type. Histaminergic neurones appear to be relatively sparse and are restricted largely to the hypothalamus.

Amino acids

Three major amino acids: GABA, glutamate and glycine, bind to specific receptors (Barrera and Edwardson 2008). GABA is a major inhibitory transmitter released at the terminals of local circuit neurones within the brainstem and spinal cord (e.g. the recurrent inhibitory loop), cerebellum (where it is the main transmitter of Purkinje cells), basal ganglia, cerebral cortex, thalamus and subthalamus. It is stored in flattened or pleomorphic vesicles within symmetric synapses. GABA may be inhibitory to postsynaptic neurones, or may mediate either presynaptic inhibition or facilitation, depending on the synaptic arrangement (Gassmann and Bettler 2012).

Glutamate is the major excitatory transmitter present widely within the CNS, including the major projection pathways from the cortex to the thalamus, tectum, substantia nigra and pontine nuclei. It is found in the central terminals of the auditory and trigeminal nerves, and in the terminals of parallel fibres ending on Purkinje cells in the cerebellum. Structurally, glutamate is associated with asymmetric synapses containing small (approximately 30 nm), round, clear synaptic vesicles (Contractor et al 2011). For further reading, see Willard and Koochekpour (2013).

Glycine is a well-established inhibitory transmitter of the CNS, particularly the lower brainstem and spinal cord, where it is mainly found in local circuit neurones. Evidence suggests that glycine may also be released from glutamatergic axon terminals to participate in activation of NMDA receptors, and from astrocytes into the synaptic cleft via activation of non-NMDA-type glutamatergic ionotropic receptors in the glial cell membrane. For further reading see Harsing and Matyus (2013).

ATP and adenosine

ATP serves not only as a universal energy substrate, but also as an extracellular signalling molecule; an extensive literature has shown ATP acts as a co-transmitter with all the classical neurotransmitters in most, perhaps all, nerves in the peripheral and central nervous systems. There are two families of receptors for purines, P1 receptors for adenosine and P2 receptors for ATP and adenosine 5′-diphosphate (ADP). Multiple P1 (adenosine), P2X (ion channel) and P2Y (G protein-coupled) nucleotide receptor subtypes are now known to be expressed by astrocytes, oligodendrocytes and microglia (Burnstock et al 2011, Burnstock 2016).

Nitric oxide

Nitric oxide, NO, is a ubiquitous gasotransmitter (Shefa et al 2018), able to diffuse freely through cell membranes, and so not under such tight quantal control as vesicle-mediated neurotransmission. NO is thought to play a role in synaptic plasticity, for example acting presynaptically at both glutamatergic and GABAergic synapses to alter the synaptic machinery involved in transmitter release. NO has also been implicated in hippocampal long-term potentiation (LTP), when it may act as a retrograde messenger after postsynaptic NMDA receptor activation. Acting at autonomic and enteric synapses NO mediates smooth muscle relaxation. Its influence in the gastrointestinal tract is significant: NO plays an important regulatory role in gut homeostasis, affecting gut motility, vascular tone, blood supply, mucosal barrier function, secretions and immunity (Savidge 2014, Sharkey and Savidge 2014).

Neuropeptides

Many neuropeptides coexist with other neuromediators in the same synaptic terminals. As many as three peptides often share a particular ending with a well-established neurotransmitter, in some cases within the same synaptic vesicles. Some peptides occur in both the CNS and the PNS, particularly in the ganglion cells and peripheral terminals of the ANS, whilst others are entirely restricted to the CNS. Only a few examples are given here.

Most of the neuropeptides are classified according to the site where they were first discovered. For example, the gastrointestinal peptides were initially found in the gut wall, and a group that includes releasing hormones, adenohypophysial and neurohypophysial hormones was first associated with the pituitary gland. Some of these peptides are closely related to each other in their chemistry because they are derived from the same gene products (e.g. the pro-opiomelanocortin group), which are cleaved to produce smaller peptides.

Substance P (SP) was the first of the peptides to be characterized as a gastrointestinal neuromediator and is considered to be the prototypic neuropeptide. It is an 11-amino-acid polypeptide that belongs to the tachykinin neuropeptide family, and is a major neuromediator in the brain and spinal cord (Mashaghi et al 2016). Contained within large granular synaptic vesicles, SP is found in approximately 20% of dorsal root and trigeminal ganglion cells, in particular in small nociceptive neurones, and in some fibres of the facial, glossopharyngeal and vagal nerves. Within the CNS, SP is present in several apparently unrelated major pathways, and has been described in the limbic system, basal ganglia, amygdala and hypothalamus. Its known action is prolonged postsynaptic excitation, particularly from nociceptive afferent terminals, which sustains the effects of noxious stimuli. SP is one of the main neuropeptides that trigger an inflammatory response in the skin and has also been implicated in the vomiting reflex, changes in cardiovascular tone, stimulation of salivary secretion, smooth muscle contraction, and vasodilation.

Vasoactive intestinal polypeptide (VIP), another gastrointestinal peptide, is widely present in the CNS, where it is probably an excitatory neurotransmitter or neuromodulator. It is found in distinctive bipolar neurones of the cerebral cortex; small dorsal root ganglion cells, particularly of the sacral region; the median eminence of the hypothalamus, where it may be involved in endocrine regulation; intramural ganglion cells of the gut wall; and sympathetic ganglia.

Somatostatin (ST, somatotropin release inhibiting factor) has a broad distribution within the CNS, and may be a central neurotransmitter or neuromodulator. It also occurs in small dorsal root ganglion cells. Beta-endorphin, leu- and metenkephalins, and the dynorphins belong to a group of peptides called the naturally occurring opiates that possess analgesic properties. They bind to opiate receptors in the brain where, in general, their action seems to be inhibitory. Enkephalins have been localized in many areas of the brain. Their particular localization in the septal nuclei, amygdaloid complex, basal ganglia and hypothalamus suggests that they are important mediators in the limbic system and in the control of endocrine function. They have also been implicated strongly in the central control of pain pathways, because they are found in the periaqueductal grey matter of the midbrain, a number of reticular raphe nuclei, the spinal nucleus of the trigeminal nerve and the substantia gelatinosa of the spinal cord. The enkephalinergic pathways exert an important presynaptic inhibitory action on nociceptive afferents in the spinal cord and brainstem. Like many other neuromediators, enkephalins also occur widely in other parts of the brain in lower concentrations.

Adult neurogenesis

In mammalian brains, generation of neurones has been considered to occur only during embryonic and perinatal stages. That concept changed in the 1960s, when the presence of lifelong neurogenesis was identified by using infusions of the thymidine analogue bromodeoxyuridine (BrdU) in rodents and primates. After infusion, BrdU is incorporated into dividing precursor cells and can be immunocytochemically detected in neurones in postmortem tissues. The first report of adult neurogenesis in human brains appeared in 1998, using brains of cancer patients who had received BrdU while they were alive. Adult neurogenesis was reported to be regionally restricted to the subgranular zone of the hippocampal dentate gyrus (Eriksson et al 1998). In both human and rodent brains, the primary progenitor cells were identified as a subpopulation of astrocytes with stem-cell-like features (Gonzalez-Peres 2012). The persistence of adult neurogenesis in human brains remains controversial, with opposing claims that neurogenesis does not continue, or is extremely rare, in adult humans (Sorrells et al 2018) or that hippocampal neurogenesis not only occurs in adult humans but does not appear to decline with ageing (Boldrini et al 2018).

CENTRAL GLIA

Glial (neuroglial) cells vary considerably in type and number in different regions of the CNS (**Fig. 3.12**). There are two major groups, macroglia (astrocytes and oligodendrocytes) and microglia, classified according to origin. Macroglia arise within the neural plate, in parallel with neurones, and constitute the great majority of glial cells. Their functions are diverse

and are now known to extend beyond a passive supporting role (reviewed in Kettenmann and Ransom (2012)). Microglia have a small soma (see Fig. 3.21) and are derived from a distinct lineage of monocytic cells originating from the yolk sac.

Astrocytes

Astrocytes are the most abundant and diverse glial cell type but their identity is not well defined (Matyash and Kettenmann 2010). There is no common marker that labels all astrocytes, in the way that myelin basic protein is a marker for oligodendrocytes or the calcium-binding protein Iba1 is a marker for microglia. A commonly used marker is the expression of glial fibrillary acidic protein (GFAP), which forms intermediate filaments, but GFAP is not expressed in all astrocytes.

Classically, two forms of astrocytes were distinguished: protoplasmic and fibrous astrocytes. Protoplasmic astrocytes (star-shaped cells) are found in grey matter, possess several stem processes that branch further into a very complex network, and contact synapses, blood vessels, and the pial surface (as the glia limitans) . Fibrous astrocytes are predominantly found in white matter and their processes are often orientated in parallel with the axons. However, while all astrocytes share common properties, evidence from recent physiological and gene expression profiling studies has shown that they comprise a far more diverse cell population than was previously appreciated (Allen and Eroglu 2017).

Radial glial cells are found early in development and serve as stem cells for neurones and glial cells. They may be categorized as astrocytes because they transform later in development into typical astrocytes. There are a number of other types of astrocyte with specialized morphologies. Bergmann glial cells in the cerebellum have somata in the Purkinje cell layer, processes that intermingle with the dendritic trees of the Purkinje neurones and terminal end-feet at the pial surface. Müller cells in the retina have a radial morphology and span the entire retina. Other astrocytic cells are tanycytes, velate astrocytes (cerebellum) and pituicytes (infundibulum and neurohypophysis of the pituitary gland). Pituicyte processes end mostly on endothelial cells in the neurohypophysis and tuber cinereum.

Astrocyte complexity and morphological diversity has reached the highest evolutionary level in humans (**Fig. 3.13**). A single astrocyte may enwrap several neuronal somata and make contacts with tens of thousands of individual synapses; bipolar astrocytes located in layer 5 and 6 of the cortex may extend processes up to 1 mm long.

Astrocytes in grey matter form a syncytium in which cells are interconnected by gap junctions, permitting the exchange of ions (e.g. calcium, propagated in waves) and small molecules such as ATP or glucose. They are the only cells in the brain capable of converting glucose into glycogen, which serves as an energy store. Before re-releasing glucose, astrocytes convert it to lactate, which is taken up by neurones; failure in glucose flow through the astrocytic network results in impairment of neuronal function.

Astrocytes not only respond to neuronal activity but also modulate that activity. They enwrap all penetrating and intracerebral arterioles and capillaries, control the ionic and metabolic environment of the neuropil and mediate neurovascular coupling. They form specialized structures that contact blood vessels; their end-feet entirely enwrap blood vessels and are instrumental in the establishment of the blood–brain barrier.

Traumatic injury to the CNS induces astrogliosis, seen as a local increase in the number and size of GFAP-positive cells and a characteristic extensive meshwork of processes. The microenvironment of this glial scar, which may also include cells of oligodendrocyte lineage and myelin debris, plays an important role in inhibiting regrowth of damaged CNS axons (Seifert et al 2006; Robel et al 2011) and is a significant barrier to the long-term success of chronically implanted neural electrodes (Spencer et al 2017).

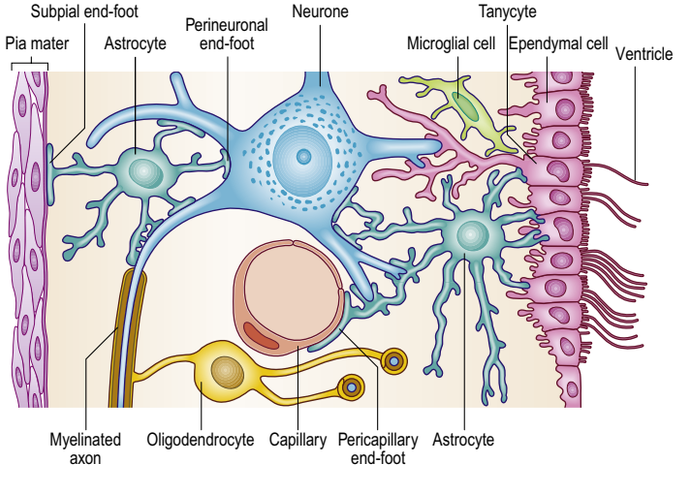

Fig. 3.12 The different types of non-neuronal cell in the CNS and their structural organization and interrelationships with each other and with neurones.

Blood–brain barrier

Proteins circulating in the blood enter most tissues of the body except those of the brain, spinal cord and peripheral nerves. This concept of a blood–brain or a blood–nerve barrier applies to many substances – some

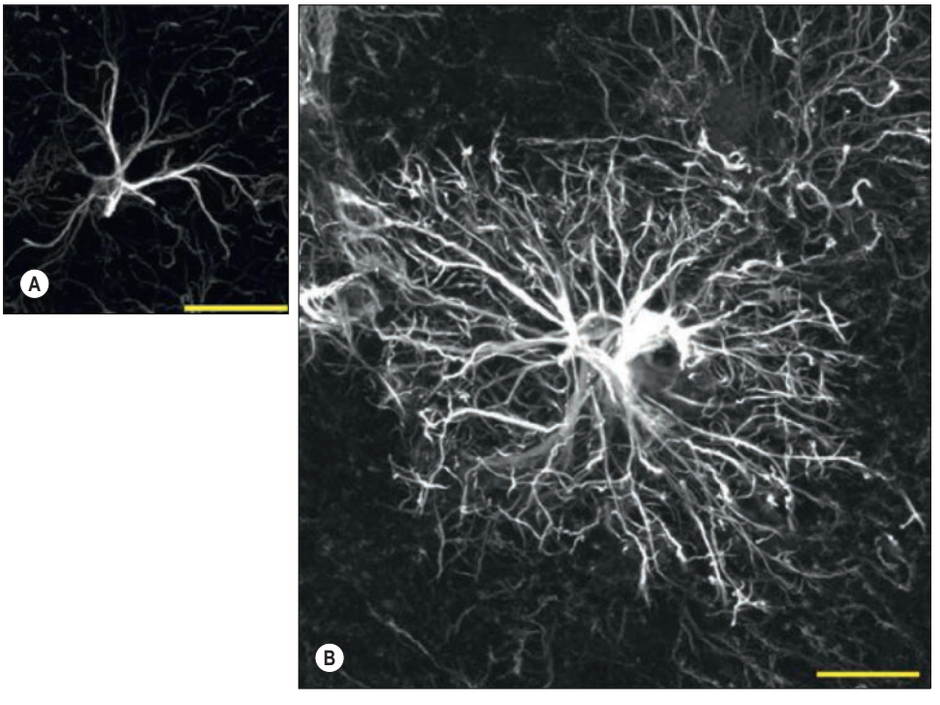

Fig. 3.13 Human protoplasmic astrocytes are larger and more complicated than their rodent counterparts. **A**, A typical mouse protoplasmic astrocyte. Glial fibrillary acidic protein (GFAP) immunostain; white. Scale bar = 20 µm. **B**, A typical human protoplasmic astrocyte to the same scale. Scale bar = 20 µm. (From Oberheim NA, Takano T, Han X et al 2009 Uniquely hominid features of adult human astrocytes. J Neurosci 29:3276–87.)

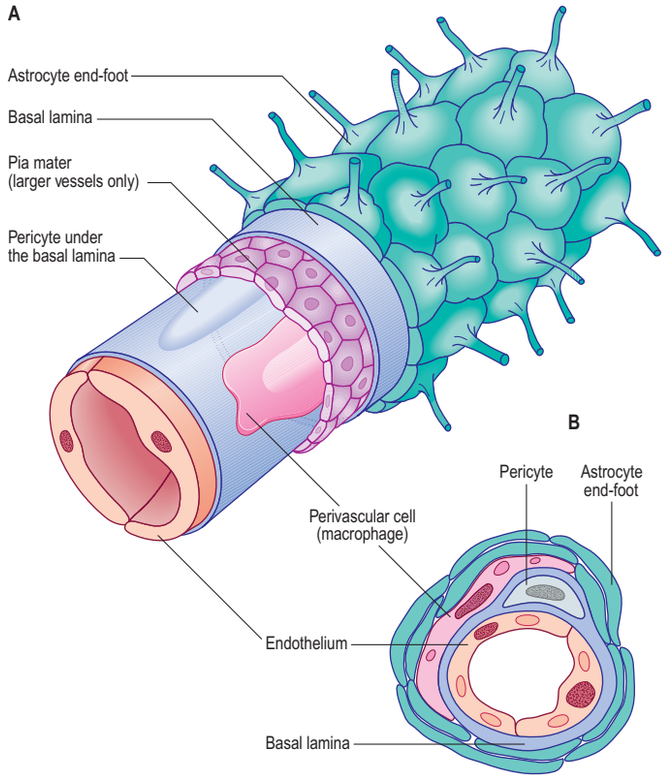

Fig. 3.14 The relationship between the glia limitans, perivascular cells and blood vessels within the brain, in longitudinal (**A**) and transverse (**B**) sections. A sheath of astrocytic end-feet wraps around the vessel and, in vessels larger than capillaries, its investment of pial meninges. Vascular endothelial cells are joined by tight junctions and supported by pericytes; perivascular macrophages lie outside the endothelial basal lamina (light blue).

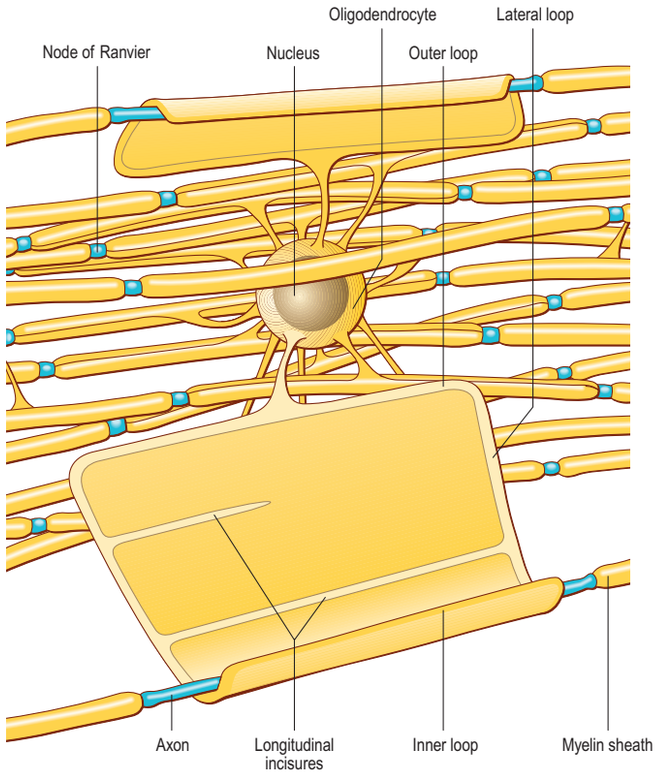

Fig. 3.15 The ensheathment of a number of axons by the processes of an oligodendrocyte. The oligodendrocyte soma is shown in the centre and its myelin sheaths are unfolded to varying degrees to show their extensive surface area. (Adapted with permission from Morell P, Norton WT 1980 Myelin. Scientific American 242(5):88–90, 92, 96; and Raine CS 1984 Morphology of myelin and myelination. In Morell P (ed) Myelin, 2nd ed. New York: Plenum Press.)

are actively transported across the blood–brain barrier, others are actively excluded. The blood–brain barrier is located at the capillary endothelium within the brain and is dependent on the presence of tight junctions (occluding junctions, zonulae occludentes) between endothelial cells coupled with a relative lack of transcytotic vesicular transport. The tightness of the barrier is substantially supported by the close apposition of astrocytes, which direct the formation of endothelial tight junctions, to blood capillaries (Abbott et al 2006, Cardoso et al 2010) (**Fig. 3.14**).

The blood–brain barrier develops during embryonic life but may not be fully completed by birth. There are certain areas of the adult brain where the endothelial cells are not linked by tight junctions, which means that a free exchange of molecules occurs between blood and adjacent brain. Most of these areas are situated close to the ventricles and are known as circumventricular organs; these areas make up less than 1% of the total area of the brain. Elsewhere, unrestricted diffusion through the blood–brain barrier is only possible for substances that can cross biological membranes because of their lipophilic character. Lipophilic molecules may be actively re-exported by the brain endothelium.

Breakdown of the blood–brain barrier occurs when the brain is damaged by ischaemia or infection, and is also associated with primary and metastatic cerebral tumours. Reduced blood flow to a region of the brain alters the permeability and regulatory transport functions of the barrier locally; the increased stress on compromised endothelial cells results in leakage of fluid, ions, serum proteins and intracellular substances into the extracellular space of the brain. The integrity of the barrier can be evaluated clinically using computed tomography and functional magnetic resonance imaging. Breakdown of the blood–brain barrier may be seen at postmortem in jaundiced patients who have had an infarction. Normally, the brain, spinal cord and peripheral nerves remain unstained by the bile post mortem, although the choroid plexus is often stained a deep yellow. However, areas of recent infarction (1–3 days) will also be stained by bile pigment because of the localized breakdown of the blood–brain barrier.

Oligodendrocytes

Oligodendrocytes myelinate CNS axons and are most commonly seen as intrafascicular cells in myelinated tracts (**Figs 3.15–3.16**). They usually have round nuclei and their cytoplasm contains numerous mitochondria, microtubules and glycogen. They display a spectrum of morphological variation, from cells with large euchromatic nuclei and pale cytoplasm, to cells with heterochromatic nuclei and dense cytoplasm. In contrast to Schwann cells, which myelinate only one axonal

segment, individual oligodendrocytes myelinate up to 50 axonal segments. Some oligodendrocytes are not associated with axons, and are either precursor cells or perineuronal (satellite) oligodendrocytes with processes that ramify around neuronal somata.

Within tracts, interfascicular oligodendrocytes are arranged in long rows interspersed at regular intervals with single astrocytes. Since oligodendrocyte processes are radially aligned to the axis of each row, myelinated tracts typically consist of cables of axons myelinated by a row of oligodendrocytes running down the axis of each cable.

Oligodendrocytes originate from the ventricular neurectoderm and the subependymal layer in the fetus, and continue to be generated from the subependymal plate postnatally. Stem cells migrate and seed into white and grey matter to form a pool of adult progenitor cells, which can later differentiate to replenish defunct oligodendrocytes, and possibly remyelinate axons in pathologically demyelinated regions. Several different names have been used to describe these cells since they were first recognized (NG2 glia; polydendrocyte (Nishiyama et al 2009); synantocyte (Butt et al 2005)). NG2 glia display a highly branching morphology and are widely distributed throughout the developing and mature mammalian CNS. In the postnatal CNS they either self-renew or diffeetate into myelinating and non-myelinating oligodendrocytes and are thus often designated oligodendrocyte precursor cells (OPCs). They express a complex set of voltage-gated channels and ionotropic receptors for glutamate and GABA and form direct synapses with axons, enabling transient activation of these receptors (Hill and Nishiyama 2014). They also express two OPC signature proteins, NG2 (Cspg4 gene product) and platelet-derived growth factor receptor α (Pdgfra), which are downregulated when they terminally differentiate into postmitotic oligodendrocytes (Zuo et al 2018). There is considerable support for the view that the NG2 cell is a distinct glial type.

Nodes of Ranvier and incisures of Schmidt–Lanterman

The territory ensheathed by an oligodendrocyte (or Schwann cell) process defines an internode, the interval between internodes is called a node of Ranvier (**Fig. 3.17**) and the territory immediately adjacent to the nodal gap is a paranode, where loops of oligodendrocyte cytoplasm abut the axolemma. The paranode acts as a diffusion barrier separating the voltage-gated sodium channels (Nav) channels in the node of Ranvier from the Kv1 channels in the juxtaparanodes. It also "glues" myelin to the axon, restricting membrane proteins to the node of Ranvier and reducing current flow under the myelin sheath and it is thought to direct protein traffic to the nodes via a neurofilamentous network. The strong interaction between myelin and the axolemma is achieved by a complex of axonal contactin-1 and contactin-associated protein 1 (Caspr1) and oligodendrocyte NF155. Nodal axolemma is often closely associated with astrocytic processes; their function is unknown.

Schmidt–Lanterman incisures are helical decompactions of internodal myelin where the major dense line of the myelin sheath splits to enclose a spiral of oligodendrocyte cytoplasm. Their structure suggests that they may play a role in the transport of molecules across the myelin sheath, but their function is not known.

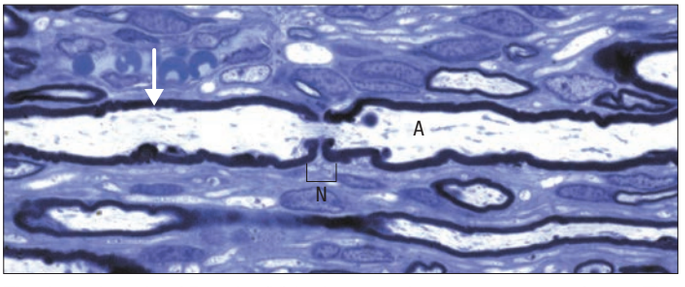

Fig. 3.17 A node of Ranvier (N) in the central nervous system of a rat. The pale-staining axon (A) is ensheathed by oligodendrocyte myelin (arrow), apart from a short, exposed region at the node. Toluidine blue stained resin section. (Courtesy of Dr Clare Farmer, King's College, London.)

Myelin and myelination

Myelin is formed by oligodendrocytes (CNS) and Schwann cells (PNS). A single oligodendrocyte may ensheathe up to 50 separate axon segments, depending on calibre, whereas myelinating Schwann cells ensheathe axons on a 1 : 1 basis.

In general, myelin is laid down around axons above 2 μm in diameter. However, the critical minimal axon diameter for myelination is smaller and more variable in the CNS than in the PNS (approximately 0.2 μm in the CNS compared with 1–2 μm in the PNS). There is considerable overlap between the size of the smallest myelinated and the largest unmyelinated axons, and so axonal calibre is unlikely to be the only factor in determining myelination. Moreover, the first axons to become ensheathed ultimately attain larger diameters than those that are ensheathed at a later date. There is a reasonable linear relationship between axon diameter and internodal length and myelin sheath thickness: as the sheath thickens from a few lamellae to up to 200, the axon may also grow from 1 to 15 μm in diameter. Internodal lengths increase about 10-fold during the same time (Nave 2010).

It is not known precisely how myelin is formed in either PNS or CNS. Akt/mTOR (mammalian (or mechanistic) target of rapamycin) signalling has emerged as one of the major pathways involved in myelination; it has been implicated in the regulation of several steps during the development of myelinating Schwann cells and oligodendrocytes (Norrmén and Suter 2013). In the CNS, myelination also depends in part on expression of a protein (Wiskott–Aldrich syndrome protein family verprolin homologous, WAVE), which influences the actin cytoskeleton, oligodendrocyte lamellipodia formation and myelination (Kim et al 2006). The ultrastructural appearance of myelin is usually explained in terms of the spiral wrapping of an extensive, flat glial process (lamellipodium) around an axon, and the subsequent extrusion of cytoplasm from the sheath at all points other than incisures and paranodes. In this way, the compacted external surfaces of the plasma membrane of the ensheathing glial cell are thought to produce the minor dense lines, and the compacted inner cytoplasmic surfaces, the major dense lines, of the mature myelin sheath (**Fig. 3.18**). These lines, first described in early electron microscope studies of the myelin sheath, correspond to the intraperiod and period lines respectively, defined in X-ray studies of myelin. The inner and outer zones of occlusion of the spiral process are continuous with the minor dense line and are called the inner and outer mesaxons. For further reading on aspects of myelination, see Bakhti et al (2014).

There are significant differences between central and peripheral myelin, reflecting the fact that oligodendrocytes and Schwann cells express different proteins during myelinogenesis. The basic dimensions of the myelin membrane are different. CNS myelin has a period repeat thickness of 15.7 nm whereas PNS myelin has a period to period line thickness of 18.5 nm, and the major dense line space is approximately

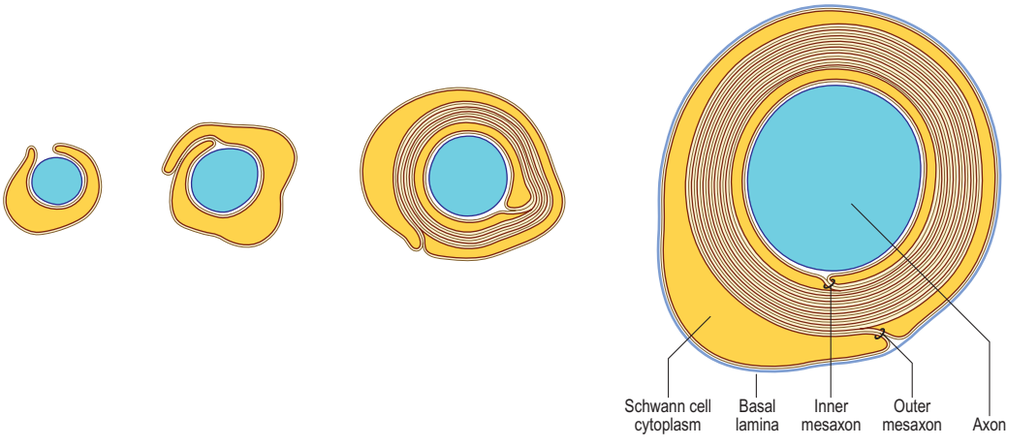

Fig. 3.18 Suggested stages in myelination of a peripheral axon by an ensheathing Schwann cell.

1.7 nm in CNS myelin, compared with 2.5 nm in PNS myelin. Myelin membrane contains protein, lipid and water, which forms at least 20% of the wet weight. It is a relatively lipid-rich membrane and contains 70–80% lipid. All classes of lipid have been found; perhaps not surprisingly, the precise lipid composition of PNS and CNS myelin is different. The major lipid species are cholesterol (the most common single molecule), phospholipids and glycosphingolipids. Minor lipid species include galactosylglycerides, phosphoinositides and gangliosides. The major glycolipids are galactocerebroside and its sulphate ester, sulphatide; these lipids are not unique to myelin but they are present in characteristically high concentrations. CNS and PNS myelin also contain low concentrations of acidic glycolipids, which constitute important antigens in some inflammatory demyelinating states. Gangliosides, which are glycosphingolipids characterized by the presence of sialic acid (*N*-acetylneuraminic acid), account for less than 1% of the lipid in myelin.

A relatively small number of protein species account for the majority of myelin protein. Some of these proteins are common to both PNS and CNS myelin, but others are different. Proteolipid protein (PLP) and its splice variant DM20 are found only in CNS myelin, whereas myelin basic protein (MBP) and myelin associated glycoprotein (MAG) occur in both. MAG is a member of the immunoglobulin supergene family, and is localized specifically at those regions of the myelin segment where compaction starts: namely, the mesaxons and inner periaxonal membranes, paranodal loops and incisures, in both CNS and PNS sheaths. It is thought to have a functional role in membrane adhesion.

In the developing CNS, axonal outgrowth precedes the migration of oligodendrocyte precursors, and oligodendrocytes associate with and myelinate axons after their phase of elongation; oligodendrocyte myelin gene expression is not dependent on axon association. In marked contrast, Schwann cells in the developing PNS are associated with axons during the entire phase of axonal growth. Myelination does not occur simultaneously in all parts of the body in late fetal and early postnatal development. White matter tracts and nerves in the periphery have their own specific temporal patterns that relate to their degree of functional maturity.

Mutations of the major myelin structural proteins have now been recognized in a number of inherited human neurological diseases. As would be expected, these mutations produce defects in myelination and in the stability of nodal and paranodal architecture that are consistent with the suggested functional roles of the relevant proteins in maintaining the integrity of the myelin sheath.

Ependyma

Ependymal cells line the ventricles (**Fig. 3.19**) and central canal of the spinal cord. They form a single-layered epithelium that varies from squamous to columnar in form. At the ventricular surface, cells are joined by gap junctions and occasional desmosomes. Their apical surfaces have numerous microvilli and/or cilia, the latter contributing to the flow of CSF. There is considerable regional variation in the ependymal lining of the ventricles but four major types have been described. These are: general ependymal, which overlies grey matter; general ependymal, which overlies white matter; specialized areas of ependyma in the third and fourth ventricles; and choroidal epithelium.

The ependymal cells overlying areas of grey matter are cuboidal. Each cell bears approximately 20 central apical cilia, surrounded by short microvilli. The cells are joined by gap junctions and desmosomes. Beneath them there may be a subependymal (or subventricular) zone, from two to three cells deep, consisting of cells that generally resemble ependymal cells. In rodents, the subventricular zone contains neural progenitor cells, which can give rise to new neurones, but the existence of these stem cells in the adult human brain is controversial (Kempermann 2011, Sanai et al 2011). The capillaries beneath the ependymal cells have no fenestrations and few transcytotic vesicles, which is typical of the CNS. Where the ependyma overlies myelinated tracts of white matter, the cells are much flatter and few are ciliated. There are gap junctions and desmosomes between these cells, but their lateral margins interdigitate, unlike their counterparts overlying grey matter. No subependymal zone is present.

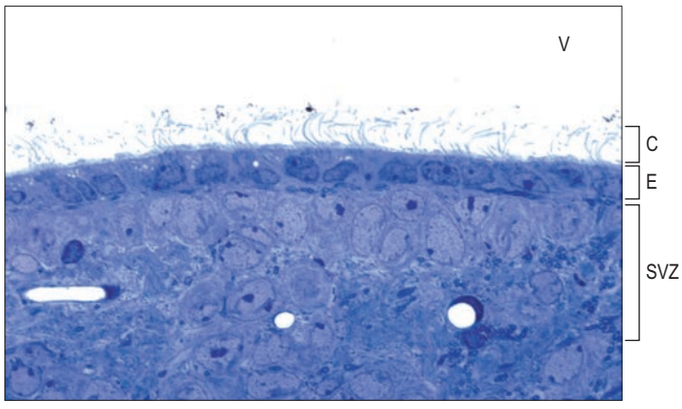

Fig. 3.19 Ciliated columnar epithelial lining of the lateral ventricle (V), overlying the subventricular zone (SVZ). C, cilia; E, ependymal cells. Mouse tissue, toluidine blue stained resin section.

Specialized areas of ependymal cells called the circumventricular organs are found in four areas around the margins of the third ventricle: namely, the lining of the median eminence of the hypothalamus; the subcommissural organ; the subfornical organ; and the vascular organ of the lamina terminalis. The area postrema, at the inferoposterior limit of the fourth ventricle, has a similar structure. In all of these sites the ependymal cells are only rarely ciliated and their ventricular surfaces bear many microvilli and apical blebs. They have numerous mitochondria, well-formed Golgi complexes and rather flattened basal nuclei. They are joined laterally by tight junctions, which form a barrier to the passage of materials across the ependyma, and by desmosomes. Many of the cells are tanycytes (ependymal astrocytes) and have basal processes that project into the perivascular space surrounding the underlying capillaries. Significantly, these capillaries are fenestrated and therefore do not form a blood–brain barrier. It is believed that neuropeptides can pass from nervous tissue into the CSF by active transport through the ependymal cells in these specialized areas, and so access a wide population of neurones via the permeable ependymal lining of the rest of the ventricle.

The ependyma is highly modified where it lies adjacent to the vascular layer of the choroid plexuses.

Motile cilia

Ependymal cells generate unidirectional flow in CSF by beating their motile cilia in a coordinated, whip-like manner. They have a highly ordered structure of nine peripheral microtubule doublets arranged around a pair of single microtubules, forming the axoneme. Various multiprotein complexes including radial spokes and dynein arms interconnect the microtubules: the dynein arms bind to the peripheral microtubules and are responsible for producing the force for the beating of the cilia.

Ependymal cells are arranged in a polarized manner within the plane of the epithelial sheets. Planar cell polarity (PCP) is the basis for generating the directed flow of CSF, by which various signalling molecules and trophic factors, such as insulin-like growth factors (IGFs), Sonic hedgehog (Shh), retinoic acid (RA), bone morphogenic proteins (BMPs), and others, are distributed throughout the ventricles. Disturbance of CSF flow through the ventricles and into the subarachnoid space results in hydrocephalus (Ch. 25).

Choroid plexus

The choroid plexus forms the CSF and actively regulates the concentration of molecules in the CSF (Ch. 25). It consists of highly vascularized masses of pia mater enclosed by pockets of ependymal cells. The ependymal cells resemble those of the circumventricular organs, except that they lack basal processes, and form a cuboidal epithelium that rests on a basal lamina adjacent to the enclosed fold of meningeal pia mater and its capillaries (**Fig. 3.20**). The cells possess numerous long microvilli with only a few cilia interspersed between them, many mitochondria, large Golgi complexes and basal nuclei, which are all features consistent with their secretory activity: they produce most components of the CSF. They are linked by tight junctions forming a transepithelial barrier (a component of the blood–CSF barrier), and by desmosomes. Their lateral margins are highly folded.

The choroid plexus has a villous structure where the stroma is composed of pial meningeal cells, and contains fine bundles of collagen and blood vessels. Choroidal capillaries are lined by a fenestrated endothelium. During fetal life, erythropoiesis occurs in the stroma, which is occupied by bone marrow-like cells. In adult life, the stroma contains phagocytic cells, which, together with the cells of the choroid plexus epithelium, phagocytose particles and proteins from the ventricular lumen.

Age-related changes occurring in the choroid plexus can be detected by neuroimaging. Calcification of the choroid plexus can be detected

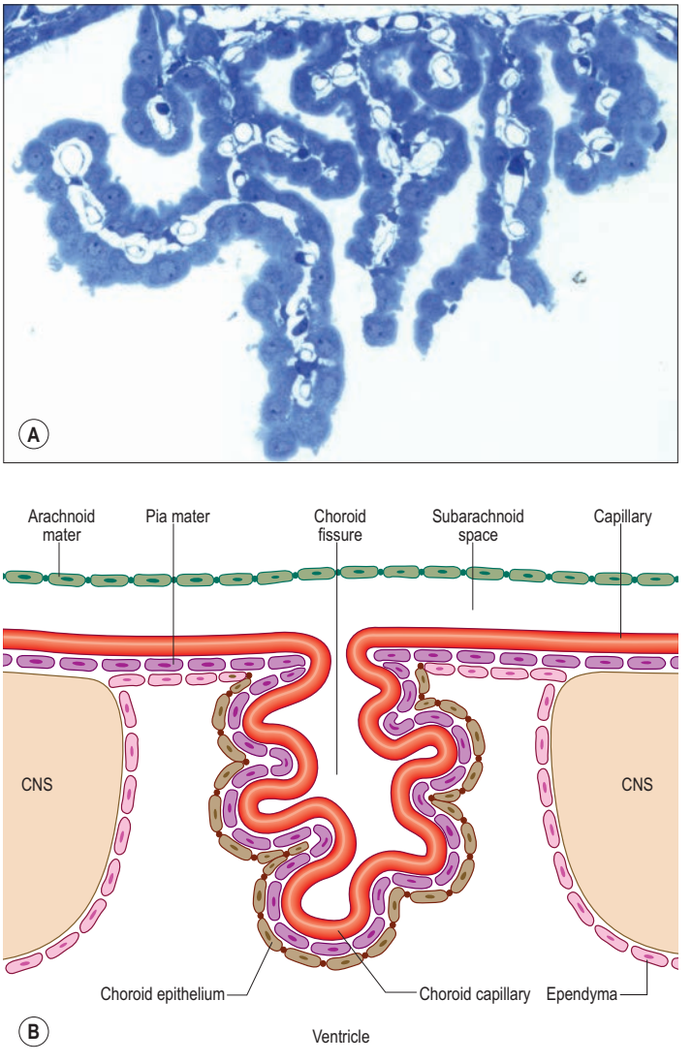

Fig. 3.20 **A**, A choroid plexus within the lateral ventricle. Frond-like projections of vascular stroma derived from the pial meninges are covered with a low columnar epithelium that secretes cerebrospinal fluid. Mouse tissue, toluidine blue stained resin section. **B**, The arrangement of tissues forming the choroid plexus.

by X-ray or CT scan very rarely in individuals in the first decade of life and in the majority in the eighth decade. The incidence of calcification rises sharply, from 35% of CT scans in the fifth decade to 75% in the sixth decade. Visible calcification is usually restricted to the glomus region of the choroid plexus, i.e. the vascular bulge in the choroid plexus as it curves to follow the anterior wall of the lateral ventricle into the temporal horn.

Microglia

Microglia are the primary innate immune cells of the brain (Kettenmann et al 2011, Eggen et al 2013, Butovsky and Weiner 2018). They originate from an embryonic monocyte precursor and invade the brain early during development. While the invading cells have an ameboid morphology, microglial cells in a mature brain are highly ramified cells. They have elongated nuclei, scant cytoplasm and several highly branched processes.

Microglia represent about 5–12% of total CNS cells in the healthy brain and the spinal cord. They occupy a defined territory in the brain parenchyma and are found in all areas of the CNS including optic nerve, retina and spinal cord. They comprise a heterogeneous community: different subpopulations in specific brain regions exhibit differing capacities and functions (Szepesi et al 2018).

Resting microglia, a term used to refer to microglia in the normal brain, should more accurately be described as surveying microglia. Microglial processes are fast-moving structures that rapidly scan their territory while the soma remains fixed in position (Shafer and Stevens 2015).

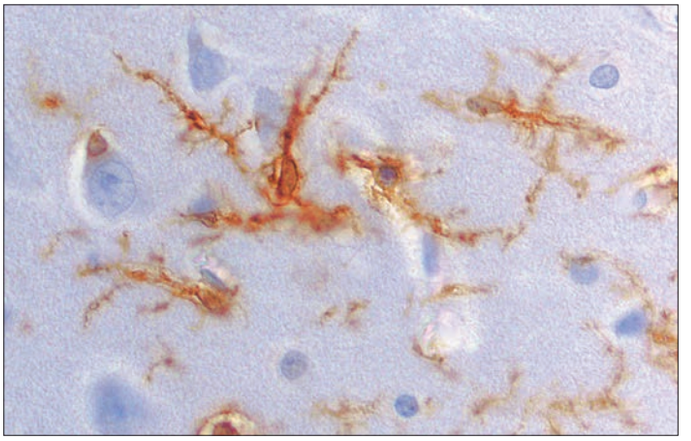

Fig. 3.21 Activated microglial cells in the human central nervous system, in a biopsy from a patient with Rasmussen's encephalitis, visualized using MHC class II antigen immunohistochemistry. (Courtesy of Dr Norman Gregson, Division of Neurology, GKT School of Medicine, London.)

All pathological changes in the brain result in the activation of microglial cells (Fig. 3.21), e.g. activated microglia are found in the brain tissue of multiple sclerosis, Alzheimer's disease and stroke patients. The most common indication of their activation is a change from a ramified to an ameboid morphology, which may occur within a few hours of the onset of injury or disease process.

In general, microglia respond to two types of signal: 'on' signals, which either appear *de novo* or are strongly upregulated, e.g. cell wall components of invading bacteria; and 'off' signals, which are normally present but disappear or decrease in pathological states, e.g. defined cytokines or neurotransmitters. Both types of event are interpreted as signals for activation. The functional repertoire of activated microglia includes proliferation; migration to the site of injury; expression of major histocompatibility complex (MHC) II molecules to interact with infiltrating lymphocytes; and the release of a variety of different substances including chemokines, cytokines and growth factors. These cells are therefore capable of significantly influencing ongoing pathological processes.

Microglial cells are the professional phagocytes of the nervous system and actively migrate through tissue. A number of factors such as ATP and complement factors act as chemoattractants. This behaviour is relevant not only in pathology but also during development where microglial cells remove apoptotic cells. After a pathological insult, microglial cells revert to their surveying phenotype, re-acquiring a ramified morphology.

Entry of inflammatory cells into the brain

Although the CNS has long been considered to be an immunologically privileged site, lymphocyte and macrophage surveillance of the brain may be a normal, but very low-grade, activity that is enhanced in disease. Lymphocytes can enter the brain in response to virus infections and as part of the autoimmune response in multiple sclerosis. Activated, but not resting, lymphocytes pass through the endothelium of small venules, a process that requires the expression of recognition and adhesion molecules (induced following cytokine activation), and subsequently migrate into the brain parenchyma. Within the CNS, microglia can be induced by T-cell cytokines to act as efficient antigen-presenting cells. After leaving the CNS, lymphocytes probably drain along lymphatic pathways to regional cervical lymph nodes.

Monocytes enter the CNS in the early stages of infarction and autoimmune disease and, in particular, in pyogenic infections, probably by passing through the endothelium of local vessels. Once in the brain, monocytes are difficult to distinguish from intrinsic microglia because both cell types express a similar marker profile. During the inflammatory phase of meningitis, polymorphonuclear leukocytes and lymphocytes pass into the CSF through the endothelium of large veins in the subarachnoid space.

Interaction between glial cells and synapses

Astrocytes in grey matter are classified as protoplasmic astrocytes and make contacts with a large number of synapses and regulate their functions. Neurotransmitters released from presynaptic boutons are effectively taken up by membrane transporters expressed in either neurones or astrocytes. Glutamate transporters in astrocytic processes in contact

with synapses efficiently maintain low levels of extracellular glutamate, which is excitotoxic. Internalized glutamate is converted into glutamine and transferred to local neurones and reconverted to glutamate via the glutamate–glutamine cycle. Astrocytes play a similar role in controlling extracellular GABA levels via expression of GABA transporters. Three synaptic components, i.e. pre- and postsynaptic neuronal elements and astrocytic processes, function as a unit for appropriate transmission of impulses, constituting a'tripartite synapse' (Haydon and Carmignoto 2006).

Astrocytes can also modulate synaptic transmission and neuronal activity by releasing neuroactive substances such as D-serine, ATP or glutamate and express neurotransmitter receptors and increase intracellular calcium in response to the activation of nearby neurones and synapses. These bidirectional interactions between neurones and astrocytes may be important in information processing by the brain.

Microglial cells express receptors for neurotransmitters and thus can sense neuronal activity. Resting microglia have highly branched and motile processes, which continuously survey synapses within their territories (Nimmerjahn et al 2005). Microglial cells are involved in synapse pruning, which is required for appropriate neuronal connections, including axonal projections of retinal ganglion cells to the visual thalamus (Hammond et al 2018). Active phagocytosis of synaptic structures by microglia is proposed to be the mechanism of synaptic pruning in the visual thalamus.

PERIPHERAL NERVES

Afferent nerve fibres connect peripheral receptors to the CNS; they are derived from neuronal somata located either in special sense organs (e.g. the olfactory epithelium) or in the sensory ganglia of the craniospinal nerves. Efferent nerve fibres connect the CNS to the effector cells and tissues and are the peripheral axons of neurones with somata in the central grey matter.

Peripheral nerve fibres are grouped in widely variable numbers into bundles (fasciculi). The size, number and pattern of fasciculi vary in different nerves and at different levels along their paths (**Fig. 3.22**). Their number increases and their size decreases some distance proximal to a point of branching. Where nerves are subjected to pressure, e.g. deep to a retinaculum, fasciculi are increased in number but reduced in size, and the amount of associated connective tissue and degree of vascularity also increase. At these points, nerves may occasionally show a pink, fusiform dilation, sometimes termed a pseudoganglion or gangliform enlargement.

Classification of peripheral nerve fibres

Classification of peripheral nerve fibres is based on various parameters such as conduction velocity, function and fibre diameter. Of two classifications in common use, the first divides fibres into three major classes, designated A, B and C, corresponding to peaks in the distribution of their conduction velocities. In humans, this classification is used mainly for afferent fibres from the skin. Group A fibres are subdivided into α, β, γ and δ subgroups; fibre diameter and conduction velocity are proportional in most fibres. Group Aα fibres are the largest and conduct most rapidly, and C fibres are the smallest and slowest.

The largest afferent axons (Aα fibres) innervate encapsulated cutaneous mechanoreceptors, Golgi tendon organs and muscle spindles, and some large alimentary enteroceptors. Aβ fibres form secondary endings on some muscle spindle (intrafusal) fibres and also innervate cutaneous and joint capsule mechanoreceptors. Aδ fibres innervate thermoreceptors, stretch-sensitive free endings, hair receptors and nociceptors, including those in dental pulp, skin and connective tissue. Aγ fibres are exclusively fusimotor to plate and trail endings on intrafusal muscle fibres. B fibres are myelinated autonomic preganglionic efferent fibres. C fibres are unmyelinated and have thermoreceptive, nociceptive and interoceptive functions, including the perception of slow, burning pain and visceral pain. This scheme can be applied to fibres of both spinal and cranial nerves except perhaps those of the olfactory nerve, where the fibres form a uniquely small and slow group. The largest somatic efferent fibres (Aα) innervate extrafusal muscle fibres (at motor endplates) exclusively and conduct at a maximum of 120 m/s. Fibres to fast twitch muscles are larger than those to slow twitch muscle. Smaller (Aγ) fibres of gamma motor neurones, and autonomic preganglionic (B) and postganglionic (C) efferent fibres conduct, in order, progressively more slowly (40 m/s to less than 10 m/s).

A different classification, used for afferent fibres from muscles, divides fibres into groups I–IV on the basis of their calibre; groups I–III are myelinated and group IV is unmyelinated. Group I fibres are large (12–22 μm), and include primary sensory fibres of muscle spindles (group Ia) and smaller fibres of Golgi tendon organs (group Ib). Group II fibres are the secondary sensory terminals of muscle spindles, with diameters of 6–12 μm. Group III fibres, 1–6 μm in diameter, have free sensory endings in the connective tissue sheaths around and within muscles and are nociceptive and, in skin, also thermosensitive. Group IV fibres are unmyelinated, with diameters below 1.5 μm; they include free endings in skin and muscle, and are primarily nociceptive.

Fig. 3.22 A transverse section of a biopsied human sural nerve, showing the arrangement of the connective tissue sheaths. Individual axons, myelinated and unmyelinated, are arranged in a small fascicle bounded by a perineurium. Abbreviations: P, perineurium; Ep, epineurium; E, endoneurium. (Courtesy of Professor Susan Standring, GKT School of Medicine, London.)

Connective tissue sheaths

Nerve trunks, whether uni- or multifascicular, are limited externally by an epineurium, which is connected to surrounding tissues by mesoneurium. Mesoneurium is a loose connective tissue sheath containing the extrinsic, segmental blood supply of the nerve, and so is of clinical importance in nerve injury. Individual fasciculi of the nerve trunk are enclosed by a multilayered perineurium, which in turn surrounds the endoneurium or intrafascicular connective tissue (see Fig. 3.22).

Epineurium

Epineurium is a condensation of loose (areolar) connective tissue derived from mesoderm. As a general rule, the more fasciculi present in a peripheral nerve, the thicker the epineurium. Epineurium contains fibroblasts, collagen (types I and III) and variable amounts of adipose tissue, and it cushions the nerve it surrounds. Loss of this protective layer may be associated with pressure palsies seen in wasted, bedridden patients. The epineurium also contains lymphatics (which probably pass to regional lymph nodes) and blood vessels, vasa nervorum, that pass across the perineurium to communicate with a network of fine vessels within the endoneurium, forming the intrinsic system of vascular plexuses.

Perineurium

Perineurium extends from the CNS–PNS transition zone to the periphery, where it is continuous with the capsules of muscle spindles and encapsulated sensory endings, but ends openly at unencapsulated endings and neuromuscular junctions. It consists of alternating layers of flattened polygonal cells, once thought to be related to fibroblasts, but now believed to include glial cells derived from the CNS (Kucenas 2015) (Ch. 14). The perineurium can often contain 15–20 layers, each layer enclosed by a basal lamina up to 0.5 μm thick and separated by varying amounts of collagen (Ushiki and Ide 1990).Within each layer the cells interdigitate along extensive tight junctions; their cytoplasm typically contains vesicles and bundles of microfilaments and their plasma membrane often shows evidence of pinocytosis. These features are consistent with the function of the perineurium as a metabolically active diffusion barrier; together with the blood–nerve barrier, the perineurium is thought to play an essential role in maintaining the osmotic

milieu and fluid pressure within the endoneurium (Liu et al 2018). There is experimental evidence that a subpopulation of perineurial glial cells may participate in the development and regeneration of peripheral nerves (Morris et al 2017).

Endoneurium

Strictly speaking, the term endoneurium is restricted to intrafascicular connective tissue and excludes the perineurial partitions within fascicles. Endoneurium consists of a fibrous matrix composed predominantly of type III collagen (reticulin) fibres, characteristically organized in fine bundles lying parallel to the long axis of the nerve, and condensed around individual Schwann cell–axon units and endoneurial vessels. The fibrous and cellular components of the endoneurium are bathed in endoneurial fluid at a slightly higher pressure than that outside in the surrounding epineurium. The major cellular constituents of the endoneurium are Schwann cells and endothelial cells; minor components are fibroblasts (constituting approximately 4% of the total endoneurial cell population), resident macrophages and mast cells. Schwann cell–axon units and blood vessels are enclosed within individual basal laminae and therefore isolated from the other cellular and extracellular components of the endoneurium.

Endoneurial arterioles have a poorly developed smooth muscle layer and do not autoregulate well. In sharp contrast, epineurial and perineurial vessels have a dense perivascular plexus of peptidergic, serotoninergic and adrenergic nerves. There are free nerve endings in all layers of neural connective tissue sheaths and there are some encapsulated (Pacinian) corpuscles in the endoneurium. These probably contribute to the acute sensitivity of nerves trapped in fibrosis after injury or surgery.

Schwann cells

Schwann cells are the major glial type in the PNS (Kidd et al 2013). *In vitro* they are fusiform in appearance. Both *in vitro* and *in vivo*, Schwann cells ensheathe peripheral axons, and myelinate those greater than 2 μm in diameter. In a mature peripheral nerve, they are distributed along the axons in longitudinal chains; the geometry of their association depends on whether the axon is myelinated or unmyelinated. In myelinated axons the territory of a Schwann cell defines an internode.

The molecular phenotype of mature myelin-forming Schwann cells is different from that of mature non-myelin-forming Schwann cells. Adult myelin-forming Schwann cells are characterized by the presence of several myelin proteins, some, but not all, of which are shared with oligodendrocytes and central myelin. In contrast, expression of the low-affinity neurotrophin receptor ($p75^{NTR}$) and GFAP intermediate filament protein (which differs from the CNS form in its post-translational modification) characterizes adult non-myelin-forming Schwann cells.

Schwann cells arise from Schwann cell precursors that, in turn, are generated from multipotent cells of the neural crest. Neuronal signals regulate many aspects of Schwann cell behaviour in developing and postnatal nerves. Axon-associated signals appear to control the proliferation of developing Schwann cells and their precursors; the developmentally programmed death of those precursors in order to match numbers of axons and glia within each peripheral nerve bundle; the production of basal laminae by Schwann cells; and the induction and maintenance of myelination. Axonal neuregulin 1 signalling via ErbB2/B3 receptors on Schwann cells is essential for Schwann cell myelination and also determines myelin thickness. An extensive literature supports the view that Schwann cells are key players in the acute injury response in the PNS (see Commentary 1.5), helping to provide a microenvironment that facilitates axonal regrowth (Birch 2011). Few Schwann cells persist in chronically denervated nerves.

Unmyelinated axons

Unmyelinated axons are commonly 1.0 μm in diameter, although some may be 1.5 μm or even 2 μm in diameter. Groups of up to 10 or more small axons (0.15–2.0 μm in diameter) are enclosed within a chain of overlapping Schwann cells that is surrounded by a basal lamina. Within each Schwann cell, individual axons are usually sequestered from their neighbours by delicate processes of cytoplasm. It seems likely, on the basis of quantitative studies in subhuman primates, that axons from adjacent cord segments may share Schwann cell columns; this phenomenon may play a role in the evolution of neuropathic pain after nerve injury. In the absence of a myelin sheath and nodes of Ranvier, action potential propagation along unmyelinated axons is not saltatory but continuous, and relatively slow (0.5–4.0 m/s).

Fig. 3.23 An electron micrograph of a transverse section of biopsied human sural nerve, showing a myelinated axon and several unmyelinated axons (A), ensheathed by Schwann cells (S). (Courtesy of Professor Susan Standring, GKT School of Medicine, London.)

Myelinated axons

Myelinated axons (**Fig. 3.23**) have a 1 : 1 relationship with their ensheathing Schwann cells. The territorial extent of individual Schwann cells varies directly with the diameter of the axon they surround, from 150 to 1500 μm. Specialized domains of axo-glial interaction define nodes of Ranvier and their neighbouring compartments, paranodes and juxtaparanodes (Pereira et al 2012; **Fig. 3.24**). These domains contain multiprotein complexes characterized by unique sets of transmembrane and cytoskeletal proteins and clusters of ion channels; the mechanisms regulating channel clustering and node formation remain a subject of intense scrutiny (Peles and Salzer 2000, Poliak and Peles 2003, Horresh et al 2008). The region under the compact myelin sheath that extends between two juxtaparanodes is the internode. The molecular domains of myelinated axons, including that of the axon initial segment are reviewed in Buttermore et al (2013).

Schwann cell cytoplasm forms a continuous layer only in the perinuclear (mid-internodal) and paranodal regions, where it forms a collar from which microvilli project into the nodal gap substance. Elsewhere it is dispersed as a lace-like network over the inner (adaxonal) and outer (abaxonal) surfaces of the myelin sheath.

Nodes of Ranvier

The nodal compartment consists of a short length of exposed axolemma, typically 0.8–1.1 μm long, surrounded by a nodal gap substance composed of various extracellular components, some of which may possess nerve growth-repulsive characteristics. Multiple processes (microvilli) protrude into the gap substance from the outer collar of Schwann cytoplasm and contact the nodal axolemma. Voltage-gated sodium channels, the cell adhesion molecules NrCAM and neurofascin-186, the cytoskeletal adaptor ankyrin G25,26 and the actin-binding protein spectrin βIV are clustered at nodes. The calibre of the nodal axon is usually significantly less than that of the internodal axon, particularly in large-calibre fibres. For further reading on the molecular organization of nodes of Ranvier, paranodes and juxtaparanodes, see D'Este et al (2016).

Paranodes

The axolemma on either side of a node is contacted by paranodal loops of Schwann cell cytoplasm via specialized septate junctions that spiral around the axon. The junctions are thought to form a partial diffusion barrier into the peri-axonal space; restrict the movement of potassium channels from under the compact myelin; and limit lateral diffusion of membrane components. Caspr, contactin and their putative ligand NF155 (an isoform of neurofascin) are concentrated in paranodes.

Juxtaparanodes

The region of the axon lying just beyond the innermost paranodal junction is now recognized as a distinct domain defined by the localization

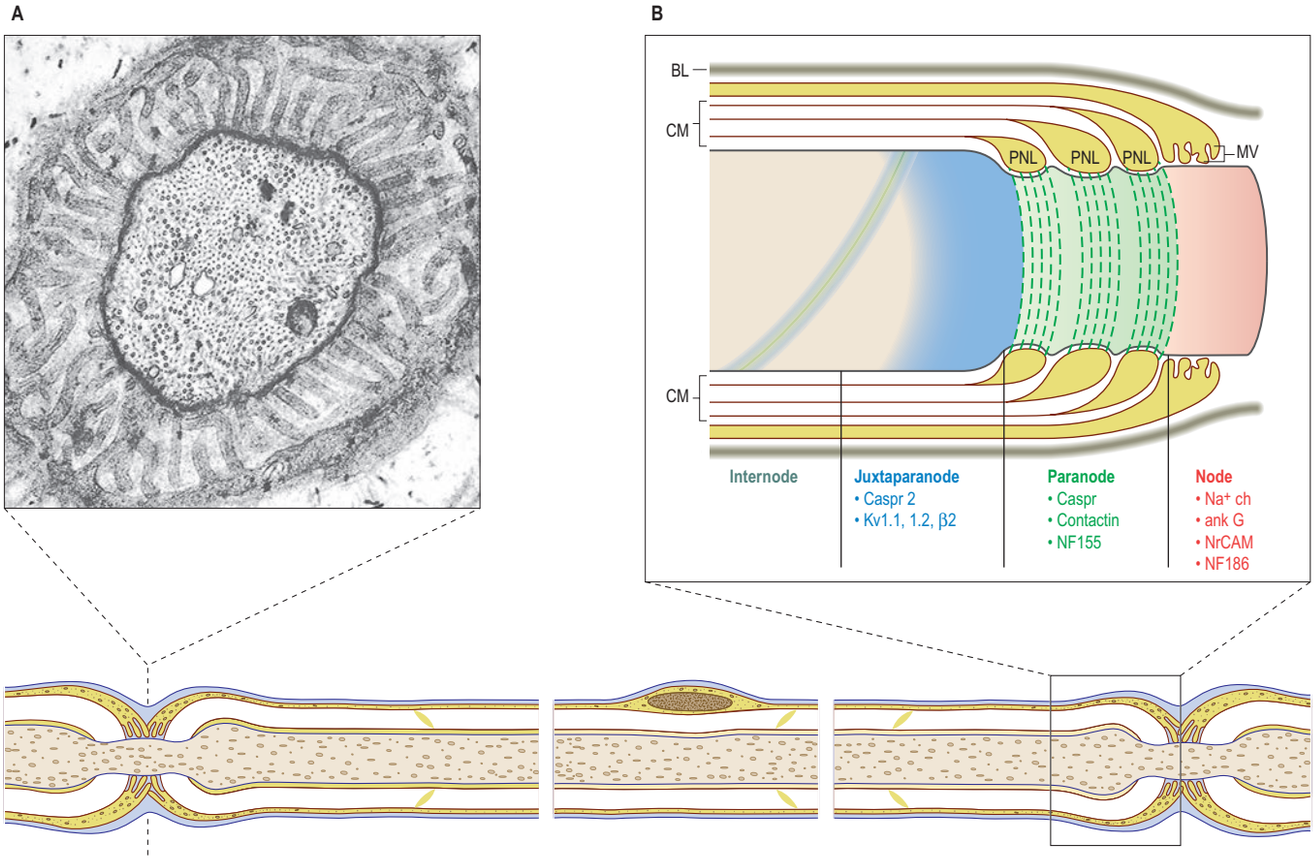

Fig. 3.24 The general plan of a peripheral myelinated nerve fibre in longitudinal section, including one complete internodal segment and two adjacent paranodal bulbs, used as a key for the more detailed microarchitecture of specific subregions. **A**, A transverse electron microscope section through the centre of a node of Ranvier, with numerous finger-like processes of adjacent Schwann cells converging towards the nodal axolemma. Many microtubules and neurofilaments are visible within the axoplasm. **B**, The arrangement of the axon, myelin sheath and Schwann cell cytoplasm at the node of Ranvier, in the paranodal bulbs and in the juxtaparanodal region. The axon is myelinated by a Schwann cell surrounded by a basal lamina (BL). Only a portion of the internode, which is located beneath the compact myelin (CM) sheath, is shown. A spiral of paranodal (green) and juxtaparanodal (blue) proteins extends into the internode; this spiral is apposed to the inner mesaxon of the myelin sheath (not shown). K^+ channels and Caspr2 are concentrated in the juxtaparanodal region. In the paranodal region, the compact myelin sheath opens up into a series of paranodal cytoplasmic loops (PNL) that invaginate and closely appose the axon, forming a series of septum-like junctions that spiral around the axon. Caspr, contactin and an isoform of neurofascin (NF155) are concentrated in this region. At the node, numerous microvilli (MV) project from the outer collar of the Schwann cell to contact the axolemma. The axon is enormously enriched in intramembranous particles at the node that correspond to Na^+ channels (Na^+ ch). Ankyrin G (ank G) isoforms and the cell adhesion molecules NrCAM and NF186 are also concentrated in this region. (A, Courtesy of Professor Susan Standring, GKT School of Medicine, London. B, Adapted with permission from Peles E, Salzer JL 2000 Molecular domains of myelinated axons. Curr Opin Neurobiol 10:558–65.)

of voltage-gated potassium channels (delayed-rectifier potassium channels Kv1.1, Kv1.2 and their Kvb2 subunit). Clustering of Kv1 channels at the juxtaparanodal region depends on their association with the Caspr2/TAG-1 adhesion complex.

Schmidt–Lanterman incisures

Schmidt–Lanterman incisures are helical decompactions of internodal myelin that appear as funnel-like profiles in teased fibre preparations labelled for markers of non-compacted myelin (e.g. MAG, Cx32). At an incisure the major dense line of the myelin sheath splits to enclose a continuous spiral band of cytoplasm passing between abaxonal and adaxonal layers of Schwann cell cytoplasm. The minor dense line of incisural myelin is also split, creating a channel connecting the peri-axonal space with the endoneurial extracellular fluid. The function of incisures is not known; their structure suggests that they may participate in transport of molecules across the myelin sheath.

Satellite cells

Many non-neuronal cells of the nervous system have been called satellite cells, including small, round extracapsular cells in peripheral ganglia, ganglionic capsular cells, Schwann cells, any cell that is closely associated with neuronal somata, and precursor cells associated with striated muscle fibres (Hanani 2010). Within the nervous system, the term is most commonly reserved for flat, epithelioid cells (ganglionic glial cells, capsular cells) that surround the neuronal somata of peripheral ganglia (see Fig. 3.25). Their cytoplasm resembles that of Schwann cells, and their deep surfaces interdigitate with reciprocal infoldings in the membranes of the enclosed neurones.

Enteric glia

Enteric nerves lack an endoneurium and so do not have the collagenous coats of other peripheral nerves. The enteric ganglionic neurones are supported by glia that closely resemble astrocytes; they contain more GFAP than non-myelinating Schwann cells and do not produce a basal lamina. Evidence for their roles in the local regulation of gastrointestinal motility and epithelial barrier function and in enteric neuroinflammation is emerging (Gulbransen and Sharkey 2012, Grubišić and Gulbransen 2017, Grundmann et al 2019).

Olfactory ensheathing glia

The olfactory system is unusual because it supports neurogenesis throughout life. Olfactory receptor neurones are continuously renewed from horizontal basal stem cells in the olfactory epithelium (Leung et al 2007, Forni and Wray 2012). They extend new axons through the lamina propria and cribriform plate into the CNS environment of the olfactory bulb, where they synapse with second-order

neurones. Olfactory ensheathing cells (OECs, also known as olfactory ensheathing glia) accompany olfactory axons from the lamina propria of the olfactory epithelium to their synaptic contacts in the glomeruli of the olfactory bulbs and are thought to play a role in directing them to their correct position in the olfactory bulb (Higginson and Barnett 2011). This unusual arrangement is unique; elsewhere in the nervous system the territories of peripheral and central glia are clearly demarcated at CNS–PNS transition zones. OECs and the end-feet of astrocytes lying between the bundles of olfactory axons both contribute to the glia limitans at the pial surface of the olfactory bulbs.

OECs share many properties with Schwann cells and express some similar antigenic and morphological properties (Oprych et al 2016). They ensheathe olfactory sensory axons in a manner comparable to the relationship that exists transitorily between Schwann cells and axons in very immature peripheral nerves, i.e. they surround, but do not segregate, bundles of up to 50 fine unmyelinated axons to form approximately 20 fila olfactoria. Both OECs and Schwann cells can myelinate axons, even though normally none of the axons in the olfactory nerve is myelinated. It was thought that OECs shared a common origin with olfactory receptor neurones in the olfactory placode, but fate-mapping experiments in chicken embryos and genetic linkage-tracing studies in mice have shown that OECs are derived from neural crest cells (Forni and Wray 2012).

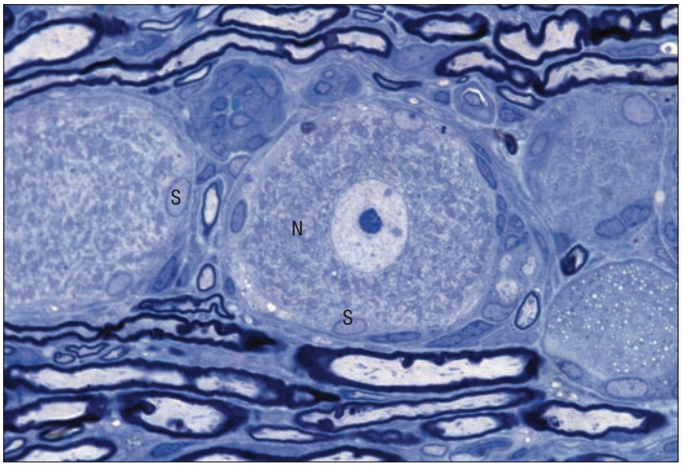

Fig. 3.25 Sensory neurones in a dorsal root ganglion (rat). Neurones (N) are typically variable in size but all are encapsulated by satellite cells (S). Myelinated axons are seen above and below the neuronal somata. Toluidine blue stained resin section. (Courtesy of Dr Clare Farmer, King's College, London.)

Blood supply of peripheral nerves

The blood vessels supplying a nerve end in a capillary plexus that pierces the perineurium. The branches of the plexus run parallel with the fibres, connected by short transverse vessels, forming narrow, rectangular meshes similar to those found in muscle. The blood supply of peripheral nerves is unusual because endoneurial capillaries have atypically large diameters and intercapillary distances that are greater than in many other tissues. Peripheral nerves have two separate, functionally independent vascular systems: an extrinsic system (regional nutritive vessels and epineurial vessels, the latter dominated by arteriovenous, AV, shunts) and an intrinsic system (longitudinally running microvessels in the endoneurium with fewer AV shunts). Anastomoses between the two systems produce considerable overlap between the territories of the segmental arteries. This unique pattern of vessels, together with a high basal nerve blood flow relative to metabolic requirements, means that peripheral nerves possess a high degree of resistance to ischaemia and probably explains why surgical mobilization of segments of a nerve does not inevitably produce ischaemic damage (Zochodne 2018).

Blood–nerve barrier

The endoneurial microenvironment is strictly regulated in two ways. Perineurial myofibroblasts provide a critical interface between the endoneurium and epineurial interstitial fluid. The blood–nerve barrier offers a restrictive microvascular barrier that operates at the level of the endoneurial capillary walls, where the endothelial cells are joined by tight junctions, are non-fenestrated and surrounded by continuous basal laminae (Palladino et al 2017, Liu et al 2018). The barrier is much less efficient in dorsal root ganglia and autonomic ganglia and in the distal parts of peripheral nerves.

Ganglia

Ganglia are aggregations of neuronal somata and are of varying form and size. They occur in the dorsal roots of spinal nerves; in the sensory roots of the trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal cranial nerves; and in the peripheral autonomic nervous system (ANS). Each ganglion is enclosed within a capsule of fibrous connective tissue and contains neuronal somata and neuronal processes. Enteric ganglia are an exception to this rule; they resemble the CNS in both structure and function, and are not covered by a connective tissue capsule. Some ganglia, particularly in the ANS, contain axons that originate from neuronal somata that lie elsewhere in the nervous system and which pass through the ganglia without synapsing.

Sensory ganglia

The sensory ganglia of dorsal spinal roots (Fig. 3.25) and the ganglia of the trigeminal, facial, glossopharyngeal and vagal cranial nerves are enclosed in a periganglionic connective tissue capsule that resembles the perineurium surrounding peripheral nerves. Ganglionic neurones are unipolar: they have spherical or oval somata of varying size, aggregated in groups between fasciculi of myelinated and unmyelinated nerve fibres. For each neurone, a single axodendritic process bifurcates into central and peripheral processes; in myelinated fibres the junction occurs at a node of Ranvier. The peripheral process terminates in a sensory ending and, because it conducts impulses towards the soma, it functions as an elongated dendrite, strictly speaking. However, it has the typical structural and functional properties of a peripheral axon, and is conventionally described as an axon.

Each neuronal soma is surrounded by a sheath of satellite glial cells (SGCs) (Pannese 2010). (A notable exception is the spiral, or cochlear, ganglion, where most neuronal somata are myelinated, presumably contributing to fast electrical transmission.) The axodendritic process and its peripheral and central divisions, ensheathed by Schwann cells, lie outside the SGC sheath. All the cells in the ganglion lie within a highly vascularized connective tissue that is continuous with the endoneurium of the nerve root. In dorsal root ganglia there is no clear regional mapping of the innervated body regions. There is evidence from animal experimental studies of some somatotopic organization within the trigeminal ganglion, but as yet, there is no evidence that this is the case in the human trigeminal ganglion (Wei et al 2017). Although sensory neurones receive no synapses, they are endowed with receptors for numerous neurotransmitters and hormones, and can thus communicate chemically amongst themselves and with SGCs.

SGCs are the main type of glial cell in sensory ganglia. They share several properties with astrocytes, including expression of glutamine synthetase and various neurotransmitter transporters. In addition, like astrocytes, the SGCs that surround a neurone are coupled by gap junctions and express receptors for ATP. Unlike astrocytes, SGCs completely surround individual sensory neurones (and more rarely two or three neurones) in a glial sheath. They undergo major changes as a result of injury to peripheral nerves, and appear to contribute to chronic pain in a number of animal pain models.

Herpes zoster

Primary infection with the varicella zoster virus causes chickenpox. Following recovery, the virus remains dormant within dorsal root ganglia or trigeminal ganglia, mostly in the neurones, and less commonly in the SGCs. Reactivation of the virus leads to herpes zoster (shingles), which involves the dermatome(s) supplied by the affected sensory nerve(s). Diagnostic signs are severe pain, erythema and blistering as occurs in chickenpox, often confined to one of the divisions of the trigeminal nerve or to a spinal nerve dermatome. Herpes zoster involving the geniculate ganglion compresses the facial nerve and results in a lower motor neurone facial paralysis, known as Ramsay Hunt syndrome. Occasionally, if the vestibulocochlear nerve becomes involved, there is vertigo, tinnitus and some deafness. The most important complication of herpes zoster is post-herpetic neuralgia, a severe and persistent pain that is highly refractory to treatment.

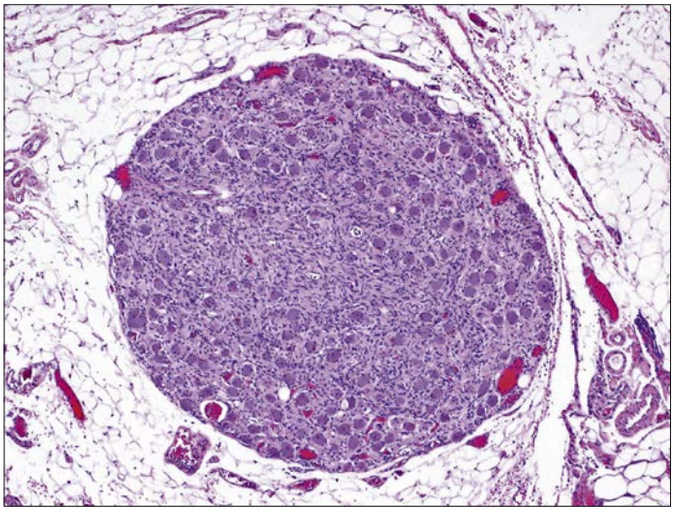

Fig. 3.26 A parasympathetic ganglion. Large neuronal somata, some with nuclei and prominent nucleoli in the plane of section, are encapsulated by satellite cells and surrounded by nerve fibres and non-neuronal cells. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

An enteric ganglionic neurone is arrowed. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Autonomic ganglia

The main types of cell in autonomic ganglia are the ganglionic neurones, small intensely fluorescent (SIF) cells and satellite glial cells (SGCs) (**Fig. 3.26**). Most of the neurones have somata ranging from 25 to 50 µm and complex dendritic fields; dendritic glomeruli have been observed in ganglia in experimental animals. Ganglionic neurones receive many axodendritic synapses from preganglionic axons; axosomatic synapses are less numerous. Postganglionic fibres commonly arise from the initial stem of a large dendrite and produce few or no collateral processes. Given their close relationship to the ganglionic neurones, autonomic SGCs may have the potential to influence synaptic transmission. SIF cells are characterized by being smaller than the neurones and by having numerous granules that contain noradrenaline (norepinephrine), dopamine and serotonin. They are almost completely invested by a sheath of SGCs and receive and make synapses; their physiological role is currently obscure, but they lend credence to the idea that autonomic ganglia are far more than simple relay stations.

Sympathetic neurones are multipolar and their dendritic trees, on which preganglionic motor axons synapse, are more elaborate than those of parasympathetic neurones. The neurones are surrounded by a mixed neuropil of afferent and efferent fibres, dendrites, synapses and non-neural cells. There is considerable variation in the ratio of pre- and postganglionic fibres in different types of ganglion. Preganglionic sympathetic axons may synapse with many postganglionic neurones for the wide dissemination and perhaps amplification of sympathetic activity, a feature not found to the same degree in parasympathetic ganglia. Dissemination may also be achieved by connections with ganglionic interneurones or by the diffusion within the ganglion of transmitter substances produced either locally (paracrine effect) or elsewhere (endocrine effect). Some axons within a ganglion may be efferent fibres en route to another ganglion, or afferents from viscera and glands. These fibres may synapse with neurones in the ganglion, e.g. substance P-containing axons of dorsal root neurones synapse on neurones in prevertebral ganglia, thereby enabling interactions between the sensory system and the ANS.

Enteric ganglia

The enteric nervous system (ENS) lies within the walls of the gastrointestinal tract (see Fig. 59.9) and includes the myenteric and submucosal plexuses and associated ganglia (Furness 2012, Neunlist et al 2013). The ganglionic neurones (**Fig. 3.27**) serve different functions, including the regulation of gut motility (in conjunction with interstitial cells of Cajal (Huizinga et al 2009)), mucosal transport and mucosal blood flow. Unlike the other two divisions of the ANS, the ENS is largely independent of the CNS, and the extrinsic autonomic fibres that supply the gut wall exert only modulatory effects on it. Submucosal neurones, together with sympathetic axons, regulate the local blood flow.

Hirschsprung's disease is a congenital disease in which dysfunctional neural crest migration means that the ganglia of both the myenteric and submucosal plexuses in the distal bowel fail to develop (Nagy et al 2017). The resulting lack of propulsive activity in the aganglionic bowel leads to functional obstruction and megacolon, which can be life-threatening. Around 1 in 5000 infants is born with the condition and is typically diagnosed in the neonatal period. Treatment usually consists of removing the diseased intestinal segment.

The enteric plexuses consist of sensory neurones, interneurones and a variety of motor neurones. These neurones are endowed with receptors for a large number of neurotransmitters and also release a variety of neurotransmitters. All classes of enteric neurone are equally distributed along the entire ganglionic network; consequently the ENS consists of numerous repeating modules.

The myenteric plexus contains the motor neurones that control the movements of gastrointestinal smooth muscle. The main excitatory neurotransmitter is acetylcholine, which may be co-localized with an excitatory peptide (usually a tachykinin, such as substance P). The main inhibitory neurotransmitter is nitric oxide (NO), released from neurones that may also release the inhibitory peptide vasoactive intestinal peptide (VIP).

An important function of myenteric neurones is to mediate the peristaltic reflex, which is induced by intestinal wall distension or by mechanical stimulation of the mucosa. These stimuli initiate contraction oral to the site of the stimulus, and relaxation anal to the site, creating a pressure gradient that propels the intestinal contents. Interstitial cells of Cajal (ICC) are pacemaker cells believed to integrate neuronal signals with rhythmic oscillations of muscle contraction; disturbance of ICC function may be a factor in a number of gastrointestinal disorders (Huizinga et al 2009).

Enteric glia are the main type of glial cell in the ENS. In some respects they resemble astrocytes, e.g. they form end-feet with blood vessels, respond to numerous chemical mediators, and are extensively coupled among themselves by gap junctions. They appear to play an important role in neuroprotection and in maintaining the integrity of the intestinal mucosal barrier.

DISPERSED NEUROENDOCRINE SYSTEM

Although the nervous, neuroendocrine and endocrine systems all operate by intercellular communication, they differ in the mode, speed and degree or localization of the effects produced (Day and Salzet 2002). The autonomic nervous system uses impulse conduction and neurotransmitter release to transmit information, and the responses induced are rapid and localized. The dispersed neuroendocrine system uses only secretion. It is slower and the induced responses are less localized, because the secretions, e.g. neuromediators, can act either on contiguous cells, or on groups of nearby cells reached by diffusion, or on distant cells via the blood stream. Many of its effector molecules operate in both the nervous system and the neuroendocrine system. The endocrine system proper, which consists of clusters of cells and discrete, ductless, hormone-producing glands, is even slower and less localized, although its effects are specific and often prolonged. These regulatory systems overlap in function, and can be considered as a single neuroendocrine regulator of the

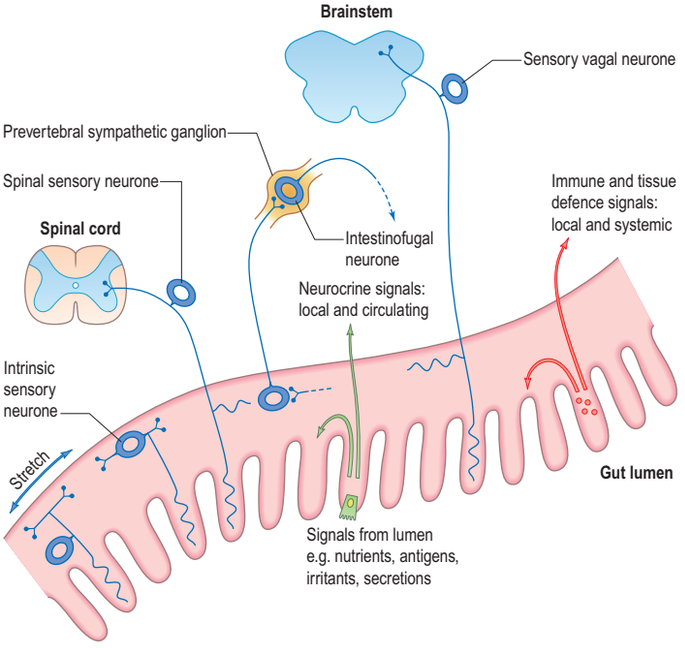

Fig. 3.28 The ways in which the nervous system, neuroendocrine system and immune system are integrated, demonstrated in the intestine. Neurocrine signals from enteric neuroendocrine cells and signals from immune defence cells (e.g. lymphocytes, macrophages and mast cells) act on other cells of those systems and on neurones with sensory endings in the intestinal wall, either locally or at a distance. Some neuronal soma lie within enteric ganglia in the gut wall; others have their bodies in peripheral ganglia. Neuronal signals may act locally, be transmitted to the CNS or enter a reflex pathway via sympathetic ganglia.

metabolic activities and internal environment of the organism, acting to provide conditions in which it can function successfully. Mediators of multi-directional crosstalk within a neuroimmune network of vessels, circulating hormones and nerve fibres that link the brain with all viscera, include the sympathetic innervation of immune tissue, cytokine activation of microglia and endocrine cells, the hormonal regulation of immunity and the activation and modulation of hypothalamic–pituitary units (Ashley and Demas 2016) (**Fig. 3.28**).

Some cells can take up and decarboxylate amine precursor compounds (amine precursor uptake and decarboxylation, or APUD, cells). They are characterized by dense-core cytoplasmic granules, similar to the neurotransmitter vesicles seen in some types of neuronal terminal. The group includes cells described as chromaffin cells (phaeochromocytes), derived from neuroectoderm and innervated by preganglionic sympathetic nerve fibres. Chromaffin cells synthesize and secrete catecholamines (dopamine, noradrenaline (norepinephrine) or adrenaline (epinephrine)). Their name refers to the finding that their cytoplasmic store of catecholamines is sufficiently concentrated to give an intense yellow–brown coloration, the positive chromaffin reaction, when they are treated with aqueous solutions of chromium salts, particularly potassium dichromate. Classic chromaffin cells include clusters of cells in the suprarenal medulla; the para-aortic bodies, which secrete noradrenaline; paraganglia; certain cells in the carotid bodies; and small groups of cells irregularly dispersed among the paravertebral sympathetic ganglia, splanchnic nerves and prevertebral autonomic plexuses.

The alimentary tract contains a large population of cells of a similar type (previously called neuroendocrine or enterochromaffin cells) in its wall. These cells act as sensory transducers, activating intrinsic and extrinsic primary afferent neurones via their release of 5-hydroxytryptamine (5-HT, serotonin). Communications between gut microbiota, the neuroendocrine system and the brain are mediated via humoral, immune and neural pathways that involve microbial metabolites, gut hormones, the enteric nervous system, the vagus nerve and spinal afferents (Farzi et al 2018). The neonatal respiratory tract contains a prominent system of neuroendocrine cells, both dispersed and aggregated (neuroepithelial bodies); the numbers of both types decline during childhood. Merkel cells in the basal epidermis of the skin store neuropeptides, which they release to associated nerve endings or other cells in a neuroendocrine role, in response to pressure and possibly other stimuli (Lucarz and Brand 2007). Experimental animal studies have revealed 5-HT-containing intraepithelial paraneurones in the urothelial lining of the urethra; these cells are thought to relay information from the luminal surface of the urethra to underlying sensory nerves.

A number of descriptions and terms have been applied to cells of this system in the older literature. They include: clear cells (so named because of their poor staining properties in routine preparations); argentaffin cells (reduce silver salts); argyrophil cells (absorb silver); small intensely fluorescent cells; peptide-producing cells (particularly of the hypothalamus, hypophysis, pineal and parathyroid glands, and placenta); Kulchitsky cells in the lungs; and paraneurones. Many cells of the dispersed (or diffuse) neuroendocrine system are derived embryologically from the neural crest. Some, particularly cells from the gastrointestinal system, are now known to be endodermal in origin.

SENSORY ENDINGS

General features of sensory receptors

There are three major forms of sensory receptor: neuroepithelial, epithelial and neuronal (**Fig. 3.29**).

A neuroepithelial receptor is a neurone with a soma lying near a sensory surface and an axon that conveys sensory signals into the CNS to synapse on second-order neurones. This is an evolutionarily primitive arrangement, and the only examples remaining in humans are the sensory neurones of the olfactory epithelium.

An epithelial receptor is a cell that is modified from a non-nervous sensory epithelium and innervated by a primary sensory neurone with a soma lying near the CNS, e.g. auditory receptors and taste buds. When activated, this type of receptor excites its neurone by neurotransmission across a synaptic gap.

A neuronal receptor is a primary sensory neurone that has a soma in a craniospinal ganglion and a peripheral axon ending in a sensory terminal. All cutaneous sensors and proprioceptors are of this type; their sensory terminals may be encapsulated or linked to special mesodermal or ectodermal structures to form a part of the sensory apparatus. The extraneural cells are not necessarily excitable, but create an appropriate environment for the excitation of the neuronal process.

The receptor stimulus is transduced into a graded change of electrical potential at the receptor surface (receptor potential), and this initiates an all-or-none action potential that is transmitted to the CNS. This may occur either in the receptor, when this is a neurone, or partly in the receptor and partly in the neurone that innervates it, in the case of epithelial receptors. Transduction varies with the modality of the stimulus, and usually causes depolarization of the receptor membrane (or hyperpolarization, in the retina). In mechanoreceptors, transduction may involve the deformation of membrane structure, which causes either strain or stretch-sensitive ion channels to open. In chemoreceptors, receptor action may resemble that for ACh at neuromuscular junctions. Visual receptors share similarities with chemoreceptors: light causes changes in receptor proteins, which activate G proteins, resulting in the release of second messengers and altered membrane permeability.

The quantitative responses of sensory endings to stimuli vary greatly and increase the flexibility of the functional design of sensory systems. Although increased excitation with increasing stimulus level is a common pattern ('on' response), some receptors respond to decreased stimulation ('off' response). Even unstimulated receptors show varying degrees of spontaneous background activity against which an increase or decrease in activity occurs with changing levels of stimulus. In all receptors studied, when stimulation is maintained at a steady level, there is an initial burst (the dynamic phase) followed by a gradual adaptation to steady level (the static phase). Though all receptors show these two phases, one or other may predominate, providing a distinction between rapidly adapting endings that accurately record the rate of stimulus onset, and slowly adapting endings that signal the constant amplitude of a stimulus, e.g. position sense. Dynamic and static phases are reflected in the amplitude and duration of the receptor potential and also in the frequency of action potentials in the sensory fibres. The stimulus strength necessary to elicit a response in a receptor, i.e. its threshold level, varies greatly between receptors, and provides an extra level of information about stimulus strength. For further reading, see Vanderah (2018).

Functional classification of receptors

Receptors have been classified in several ways. They may be classified by the modalities to which they are sensitive, such as mechanoreceptors (which are responsive to deformation, e.g. touch, pressure, sound waves, etc.), chemoreceptors, photoreceptors and thermoreceptors. Some receptors are polymodal, i.e. they respond selectively to more than one modality; they usually have high thresholds and respond to damaging stimuli associated with irritation or pain (nociceptors).

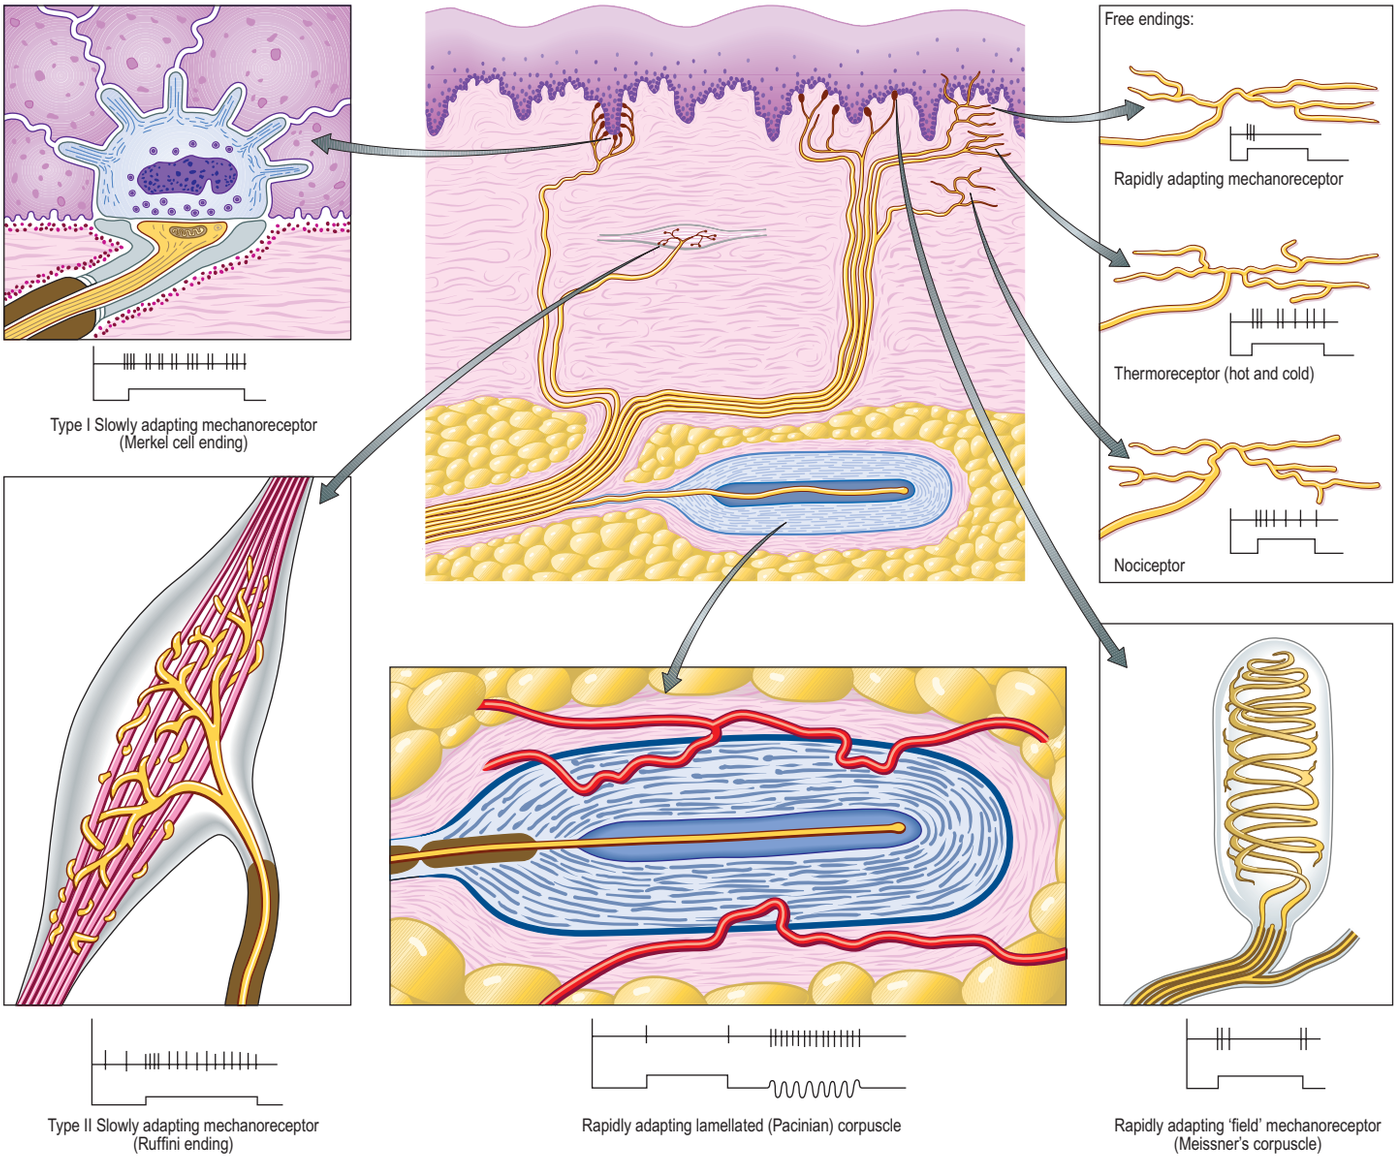

Fig. 3.29 Some major types of sensory ending of general afferent fibres (omitting neuromuscular, neurotendinous and hair-related types). The traces below each type of ending indicate (top) their response (firing rate (vertical lines) and adaption with time) to an appropriate stimulus (below) of the duration indicated. The response of the Pacinian corpuscle to vibration (rapid sequence of on–off stimuli) is also shown.

Another widely used classification divides receptors on the basis of their distribution in the body into exteroceptors, proprioceptors and interoceptors. Exteroceptors and proprioceptors are receptors of the somatic afferent components of the nervous system, while interoceptors are receptors of the visceral afferent pathways.

Exteroceptors respond to external stimuli and are found at, or close to, body surfaces. They can be subdivided into the general or cutaneous sense organs and special sensory organs. General sensory receptors include free and encapsulated terminals in skin and near hairs; none of these has absolute specificity for a particular sensory modality. Special sensory organs are the olfactory, visual, acoustic, vestibular and taste receptors.

Proprioceptors respond to stimuli to deeper tissues, especially of the locomotor system, and are concerned with detecting movement, mechanical stresses and position. They include Golgi tendon organs, muscle spindles, Pacinian corpuscles, other endings in joints, and vestibular receptors. Proprioceptors are stimulated by the contraction of muscles, movements of joints and changes in the position of the body. They are essential for the coordination of muscles, the grading of muscular contraction, and the maintenance of equilibrium.

Interoceptors are found in the walls of the viscera, glands and vessels, where their terminations include free nerve endings, encapsulated terminals and endings associated with specialized epithelial cells. Nerve terminals are found in the layers of visceral walls and the adventitia of blood vessels, but the detailed structure and function of many of these endings are not well established. Encapsulated (lamellated) endings occur in the heart, adventitia and mesenteries. Free terminal arborizations occur in the endocardium, the endomysium of all muscles, and connective tissue generally. Tension produced by excessive muscular contraction or by visceral distension often causes pain, particularly in pathological states, which is frequently poorly localized and of a deep-seated nature. Visceral pain is often referred to the corresponding dermatome (see Fig. 24.10). Polymodal nociceptors (irritant receptors) respond to a variety of stimuli such as noxious chemicals or damaging mechanical stimuli. They are mainly the free endings of fine, unmyelinated fibres that are widely distributed in the epithelia of the alimentary and respiratory tracts; they may initiate protective reflexes.

Interoceptors include vascular chemoreceptors, e.g. the carotid body, and baroceptors, which are concerned with the regulation of blood flow and pressure and the control of respiration.

Free nerve endings

Sensory endings that branch to form plexuses occur in many sites (see Fig. 3.29). They occur in all connective tissues, including those of the dermis, fasciae, capsules of organs, ligaments, tendons, adventitia of blood vessels, meninges, articular capsules, periosteum, perichondrium, Haversian systems in bone, parietal peritoneum, walls of viscera and the endomysium of all types of muscle. They also innervate the epithelium of the skin, cornea, buccal cavity, and the alimentary and

respiratory tracts and their associated glands. Within epithelia, free sensory endings lack Schwann cell ensheathment and are enveloped instead by epithelial cells. Afferent fibres from free terminals may be myelinated or unmyelinated but are always of small diameter and low conduction velocity. When afferent axons are myelinated, their terminal arborizations lack a myelin sheath. These terminals serve several sensory modalities. In the dermis, they may be responsive to moderate cold or heat (thermoreceptors); light mechanical touch (mechanoreceptors); damaging heat, cold or deformation (unimodal nociceptors); and damaging stimuli of several kinds (polymodal nociceptors). Similar fibres in deeper tissues may also signal extreme conditions, which are experienced, as with all nociceptors, as ache or pain. Free endings in the cornea, dentine and periosteum may be exclusively nociceptive.

Special types of free ending are associated with epidermal structures in the skin. They include terminals associated with hair follicles (peritrichial receptors), which branch from myelinated fibres in the deep dermal cutaneous plexus; the number, size and form of the endings are related to the size and type of hair follicle innervated. These endings respond mainly to movement when hair is deformed and belong to the rapidly adapting mechanoreceptor group.

Merkel tactile endings (see Commentary 1.4) lie either at the base of the epidermis or around the apical ends of some hair follicles, and most are innervated by large myelinated axons. Each axon expands into a disc that is applied closely to the base of a Merkel cell in the basal layer of the epidermis. The cells are believed to be derived from the epidermis, although a neural crest origin remains possible. They contain many large (50–100 nm) dense-core vesicles, presumably containing transmitters. Merkel endings are thought to be slow-adapting mechanoreceptors, responsive to sustained pressure and sensitive to the edges of applied objects. Their functions are controversial, however, and likely to be more varied.

Encapsulated endings

Encapsulated endings are a major group of special endings that includes lamellated corpuscles of various kinds (e.g. Meissner's, Pacinian), Golgi tendon organs, neuromuscular spindles and Ruffini endings (see Fig. 3.29). They exhibit considerable variety in their size, shape and distribution but share a common feature: namely, that each axon terminal is encapsulated by non-excitable cells (Proske and Gandevia 2012).

Meissner's corpuscles

Meissner's corpuscles (Wagner–Meissner corpuscles; tactile corpuscle-like bodies) are found in the dermal papillae of all parts of the hand and foot, the anterior aspect of the forearm, the lips, palpebral conjunctiva and mucous membrane of the apical part of the tongue. They are most concentrated in thick hairless skin, especially of the finger pads, where there may be up to 24 corpuscles per cm^2 in young adults. Mature corpuscles are cylindrical in shape, approximately 80 µm long and 30 µm across, with their long axes perpendicular to the skin surface. Each corpuscle has a connective tissue capsule and central core composed of a stack of flat modified Schwann cells (Fig. 3.30). Meissner's corpuscles are rapidly adapting mechanoreceptors, sensitive to shape and textural changes in exploratory and discriminatory touch; their acute sensitivity provides the neural basis for reading Braille text. Tactile corpuscle-like bodies have been reported in the oesophagus, stomach, gastroesophageal junction, and colorectum as incidental findings in samples taken during endoscopic procedures (Huber et al 2017).

Pacinian corpuscles

Pacinian corpuscles are situated subcutaneously in the palmar and plantar aspects of the hand and foot and their digits, the external genitalia, arm, neck, nipple, periosteal and interosseous membranes, and near joints and within the mesenteries (Fig. 3.31). They are oval, spherical or irregularly coiled and measure up to 2 mm in length and 100–500 µm or more across; the larger ones are visible to the naked eye. Each corpuscle has a capsule, an intermediate growth zone and a central core that contains an axon terminal. The capsule is formed by approximately 30 concentrically arranged lamellae of flat cells approximately 0.2 µm thick. Adjacent cells overlap and successive lamellae are separated by an amorphous proteoglycan matrix that contains circularly orientated collagen fibres, closely applied to the surfaces of the lamellar cells. The amount of collagen increases with age. The intermediate zone is cellular and its cells become incorporated into the capsule or core, so that it is not clearly defined in mature corpuscles. The core consists of approximately 60 bilateral, compacted lamellae lying on both sides of a central nerve terminal.

Each corpuscle is supplied by a myelinated axon, which initially loses its myelin sheath and subsequently loses its ensheathing Schwann cell at its junction with the core. The naked axon runs through the central axis of the core and ends in a slightly expanded bulb. It is in contact with the innermost core lamellae, is transversely oval and sends short projections of unknown function into clefts in the lamellae. The axon contains numerous large mitochondria, and minute vesicles, approximately 5 nm in diameter, which aggregate opposite the clefts. The cells of the capsule and core lamellae are thought to be specialized fibroblasts but some may be Schwann cells. Elastic fibrous tissue forms an overall external capsule to the corpuscle. Pacinian corpuscles are supplied by capillaries that accompany the axon as it enters the capsule.

Pacinian corpuscles act as very rapidly adapting mechanoreceptors. They respond only to sudden disturbances and are especially sensitive to very-high-frequency vibration. The rapidity may be partly due to the lamellated capsule acting as a high pass frequency filter, damping slow distortions by fluid movement between lamellar cells. Groups of corpuscles respond to pressure changes, e.g. on grasping or releasing an object.

Ruffini endings

Ruffini endings are slowly adapting mechanoreceptors. They are found in the dermis of thin, hairy skin, where they function as dermal stretch receptors and are responsive to maintained stresses in dermal collagen. They consist of the highly branched, unmyelinated endings of myelinated afferents. They ramify between bundles of collagen fibres within a spindle-shaped structure, which is enclosed partly by a fibrocellular

sheath derived from the perineurium of the nerve. Ruffini endings appear electrophysiologically similar to Golgi tendon organs, which they resemble, although they are less organized structurally; they are also found in joint capsules where they are thought to signal static joint position, changes in intra-articular pressure, and the direction, amplitude and velocity of joint movements (see below).

Golgi tendon organs

Golgi tendon organs are found mainly near musculotendinous junctions (**Fig. 3.32**), where more than 50 may occur at any one site. Each terminal is closely related to a group of muscle fibres (up to 20) as they insert into the tendon. Golgi tendon organs are approximately 500 μm long and 100 μm in diameter, and consist of small bundles of tendon fibres enclosed in a delicate capsule. The collagen bundles (intrafusal fasciculi) are less compact than elsewhere in the tendon, the collagen fibres are smaller and the fibroblasts larger and more numerous. A single, thickly myelinated 1b afferent nerve fibre enters the capsule and divides. Its branches, which may lose their ensheathing Schwann cells, terminate in leaf-like enlargements containing vesicles and mitochondria, which wrap around the tendon. A basal lamina or process of Schwann cell cytoplasm separates the nerve terminals from the collagen bundles that constitute the tendon. Golgi tendon organs are activated by passive stretch of the tendon but are much more sensitive to active contraction of the muscle. They are important in providing proprioceptive information that complements the information coming from neuromuscular spindles. Their responses are slowly adapting and they signal maintained tension.

Neuromuscular spindles

Neuromuscular spindles are mechanosensors essential for proprioception (Boyd 1985, Banks 2015). Each spindle contains a few small, specialized intrafusal muscle fibres, innervated by both sensory and motor nerve fibres (**Figs 3.33–3.34**). The whole is surrounded equatorially by a fusiform spindle capsule of connective tissue, consisting of an outer perineurium-like sheath of flattened fibroblasts and collagen, and an inner sheath that forms delicate tubes around individual intrafusal fibres (**Fig. 3.35**). A gelatinous fluid rich in glycosaminoglycans fills the space between the two sheaths.

There are usually 5–14 intrafusal fibres (the number varies between muscles) and two major types of fibre, nuclear bag and nuclear chain fibres, which are distinguished by the arrangement of nuclei in their sarcoplasm. In nuclear bag fibres, an equatorial cluster of nuclei makes the fibre bulge slightly, whereas the nuclei in nuclear chain fibres form a single axial row. Nuclear bag fibres are subdivided into bag1 and bag2 fibres, are greater in diameter than chain fibres and extend beyond the surrounding capsule to the endomysium of nearby extrafusal muscle fibres. Nuclear chain fibres are attached at their poles to the capsule or to the sheaths of nuclear bag fibres.

The intrafusal fibres resemble typical skeletal muscle fibres, except that the zone of myofibrils is thin around the nuclei. Dynamic bag1 fibres generally lack M lines, possess little sarcoplasmic reticulum, and have an abundance of mitochondria and oxidative enzymes, but little glycogen. Static bag2 fibres have distinct M lines and abundant glycogen. Nuclear chain fibres have marked M lines, sarcoplasmic reticulum and T-tubules, and abundant glycogen, but few mitochondria. Each

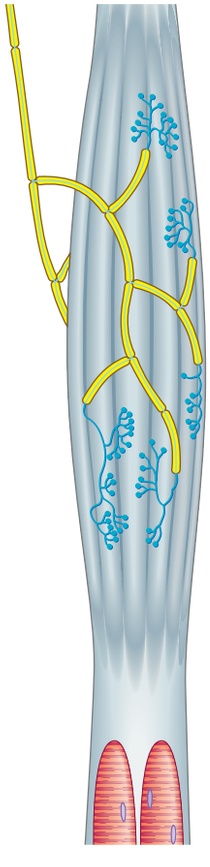

Fig. 3.32 The structure and innervation of a Golgi tendon organ. For clarity, the perineurium and endoneurium have been omitted to show the distribution of nerve fibres ramifying between the collagen fibre bundles of the tendon.

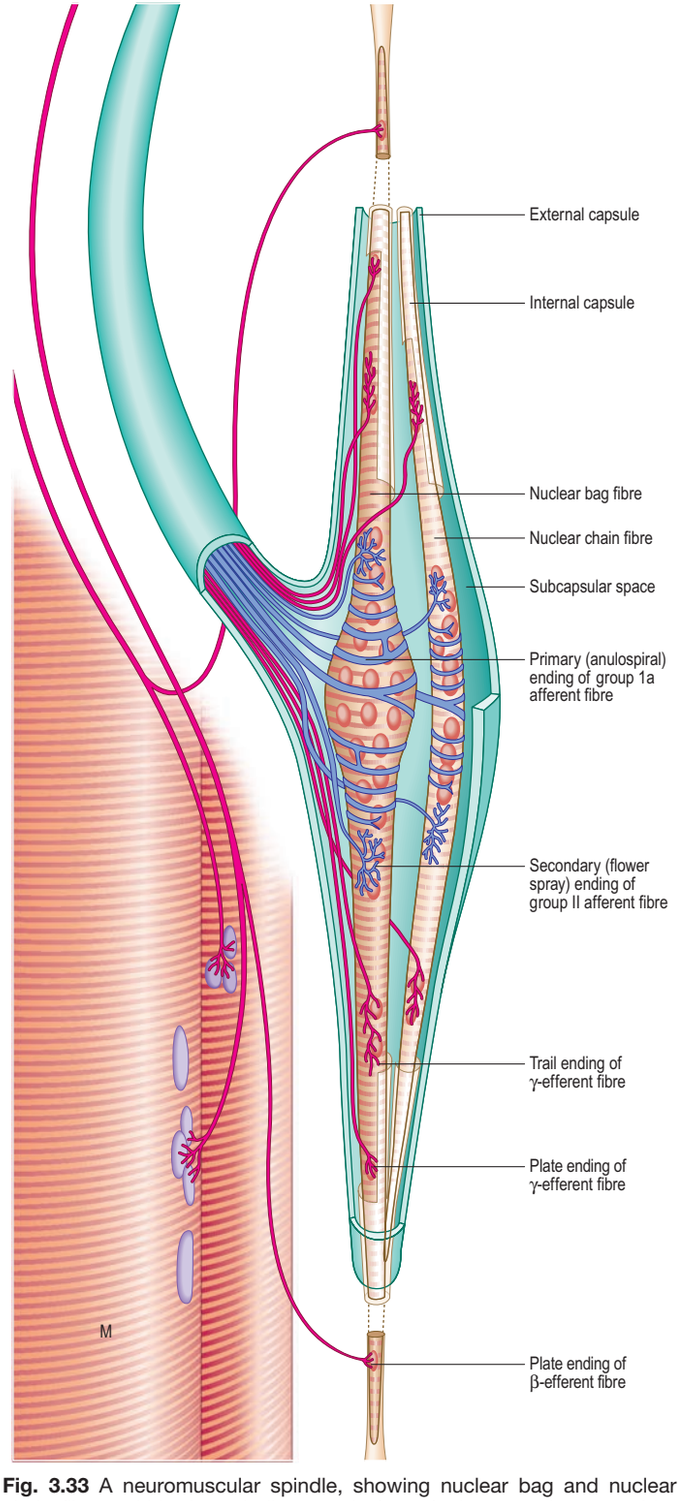

Fig. 3.33 A neuromuscular spindle, showing nuclear bag and nuclear chain fibres within the spindle capsule (green); these are innervated by the sensory anulospiral and 'flower spray' afferent fibre endings (blue) and by the γ and β fusimotor (efferent fibre) endings (red). The β efferent fibres are collaterals of fibres innervating extrafusal slow twitch muscle cells (M).

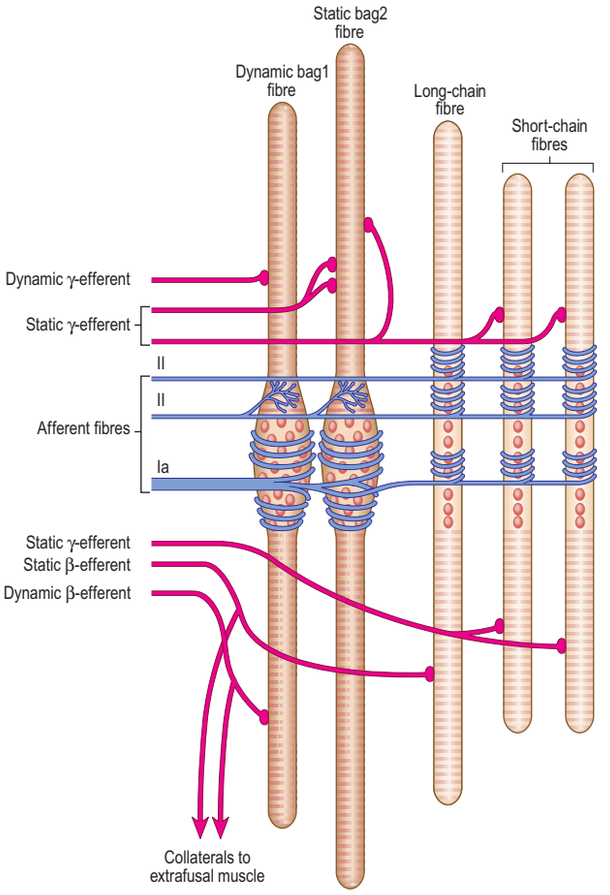

Fig. 3.34 Nuclear bag and nuclear chain fibres in a neuromuscular spindle. Dynamic β- and γ-efferents innervate dynamic bag1 intrafusal fibres, whereas static β- and γ-efferents innervate static bag2 and nuclear chain intrafusal fibres.

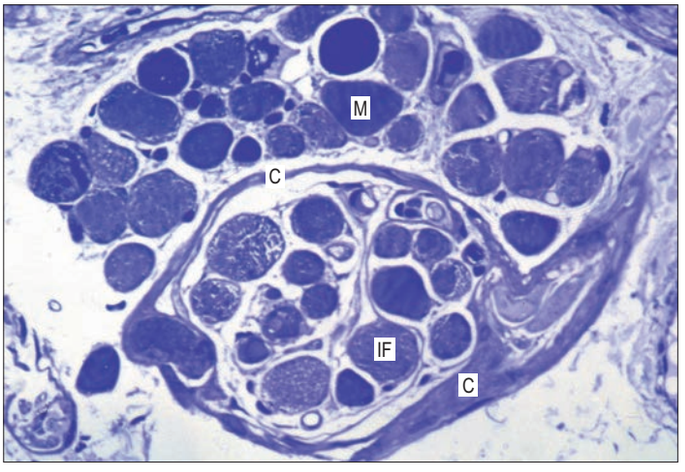

Fig. 3.35 A neuromuscular spindle in transverse section in a human extraocular muscle. The spindle capsule (C) encloses intrafusal fibres (IF) of varying diameters. Typical muscle fibres (M) in transverse section are shown above the spindle. Toluidine blue stained resin section.

fibre type carries distinct myosin heavy chain isoforms. These variations reflect the contractile properties of different intrafusal fibres.

Muscle spindles receive two types of sensory innervation via the unmyelinated terminations of large myelinated axons. Primary (anulospiral) endings are equatorially placed and form spirals around the nucleated parts of intrafusal fibres. They are the endings of large sensory fibres (group Ia afferents), each of which sends branches to a number of intrafusal muscle fibres. Each terminal lies in a deep sarcolemmal groove in the spindle plasma membrane beneath its basal lamina. Secondary (flower spray) endings, which may be spray-shaped or anular, are largely confined to bag2 and nuclear chain fibres, and are the branched terminals of somewhat thinner myelinated (group II) afferents. They are varicose and spread in a narrow band on both sides of the primary endings. They lie close to the sarcolemma, though not in grooves. In essence, primary endings are rapidly adapting, while secondary endings have a regular, slowly adapting response to static stretch.

There are three types of motor endings in muscle spindles. Two are from fine, myelinated, fusimotor (γ) efferents and one is from myelinated (β) efferent collaterals of axons that supply extrafusal slow twitch muscle fibres. The fusimotor efferents terminate nearer the equatorial region, where their terminals either resemble the motor end-plates of extrafusal fibres (plate endings) or are more diffuse (trail endings). Stimulation of the fusimotor and β-efferents causes contraction of the intrafusal fibres and, consequently, activation of their sensory endings.

Muscle spindles signal the length of extrafusal muscle both at rest and throughout contraction and relaxation, the velocity of their contraction and changes in velocity. These modalities may be related to the different behaviours of the three major types of intrafusal fibre and their sensory terminals. The sensory fusimotor endings of one type of nuclear bag fibre (dynamic bag1) are particularly concerned with signalling rapid changes in length that occur during movement, whilst those of the second bag fibre type (static bag2) and of chain fibres are less responsive to movement. These elements can therefore detect complex changes in the state of the extrafusal muscle surrounding spindles and can signal fluctuations in length, tension, velocity of length change and acceleration. Moreover, they are under complex central control; efferent (fusimotor) nerve fibres, by regulating the strength of contraction, can adjust the length of the intrafusal fibres and thereby the responsiveness of spindle sensory endings. In summary, the organization of spindles allows them to monitor muscle conditions actively in order to compare intended and actual movements, and to provide a detailed input to spinal, cerebellar, extrapyramidal and cortical centres about the state of the locomotor apparatus.

Joint receptors

The arrays of receptors situated in and near articular capsules provide information on the position, movements and stresses acting on joints. Structural and functional studies have demonstrated at least four types of joint receptor; their proportions and distribution vary with site. Three are encapsulated endings, the fourth a free terminal arborization.

Type I/Ruffini endings are encapsulated corpuscles of the slowly adapting mechanoreceptor type, equivalent to Ruffini endings in the dermis of skin. They lie in the superficial layers of the fibrous capsules of joints in small clusters and are innervated by myelinated afferent axons. Being slowly adapting, they provide awareness of joint position and movement, and respond to patterns of stress in articular capsules. They are particularly common in joints where static positional sense is necessary for the control of posture (e.g. hip, knee).

Type II endings are lamellated receptors and resemble small versions of the large Pacinian corpuscles found in general connective tissue. They occur in small groups throughout joint capsules, particularly in the deeper layers and other articular structures (e.g. the fat pad of the temporomandibular joint). They are rapidly adapting, low-threshold mechanoreceptors, sensitive to movement and pressure changes, and they respond to joint movement and transient stresses in the joint capsule. They are supplied by myelinated afferent axons but are probably not involved in the conscious awareness of joint sensation.

Type III endings are identical to Golgi tendon organs in structure and function; they occur in articular ligaments but not in joint capsules. They are high-threshold, slowly adapting receptors and may serve, at least in part, to prevent excessive stresses at joints by reflex inhibition of the adjacent muscles. They are innervated by large myelinated afferent axons.

Type IV endings are free terminals of myelinated and unmyelinated axons that ramify in articular capsules and the adjacent fat pads, and around the blood vessels of the synovial layer. They are high-threshold, slowly adapting receptors and are thought to respond to excessive movements, providing a basis for articular pain.

NEUROMUSCULAR JUNCTIONS

Skeletal muscle

The most intensively studied effector endings are those that innervate muscle, particularly skeletal muscle. All neuromuscular (myoneural) junctions are axon terminals of motor neurones. They are specialized for the release of neurotransmitter on to the sarcolemma of skeletal muscle fibres, causing a change in their electrical state that leads to

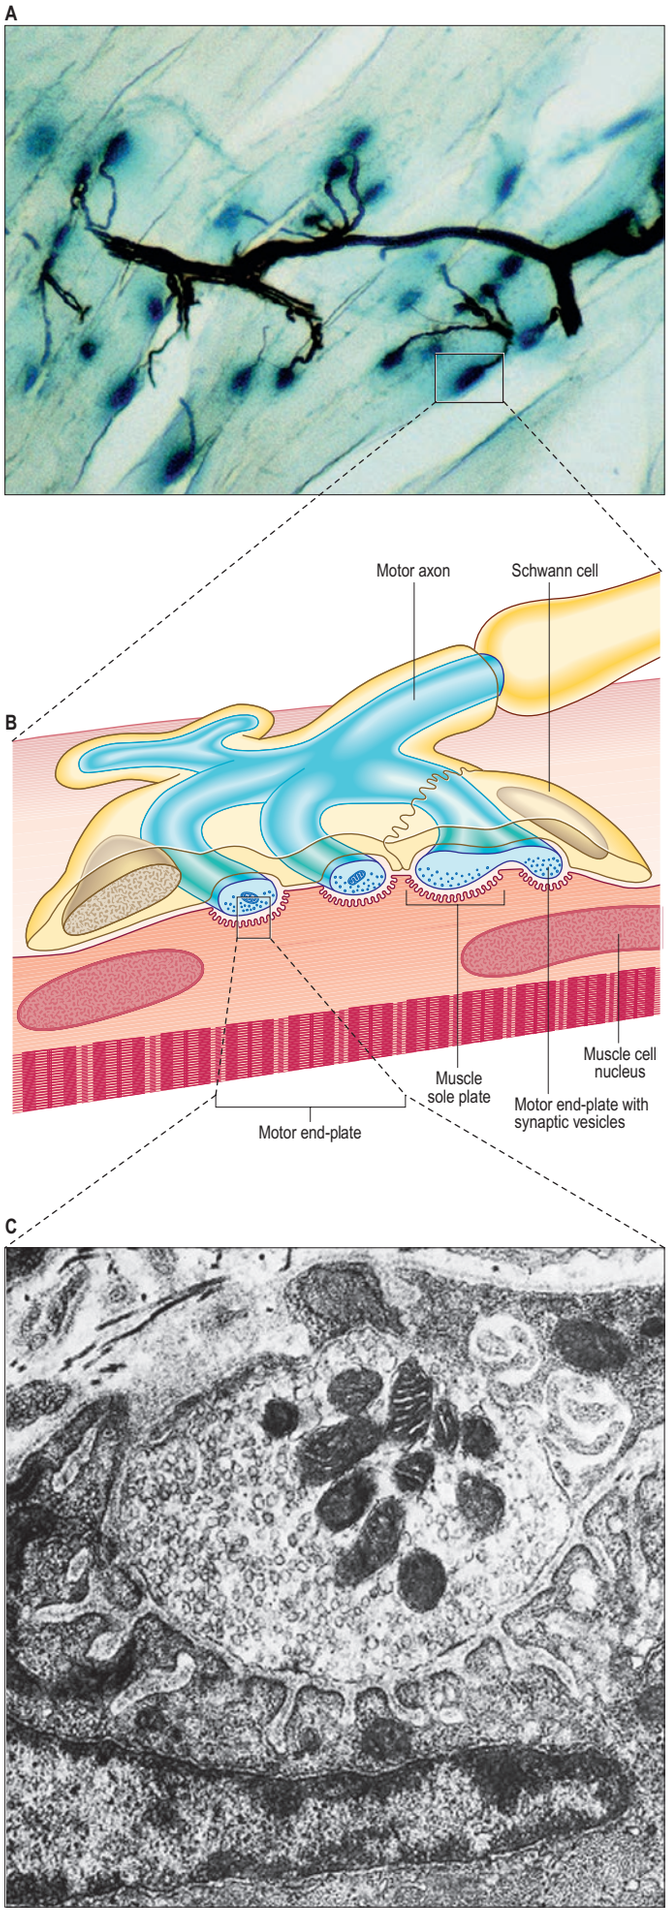

Fig. 3.36 The neuromuscular junction. **A**, Whole-mount preparation of teased skeletal muscle fibres (pale, faintly striated, diagonally orientated structures). The terminal part of the axon (silver-stained, brown) branches to form motor end-plates on adjacent muscle fibres. The sole plate recesses in the sarcolemma, into which the motor end-plates fit, are demonstrated by the presence of acetylcholinesterase (shown by enzyme histochemistry, blue). **B**, The axonal motor end-plate and the deeply infolded sarcolemma. **C**, Electron micrograph showing the expanded motor end-plate of an axon filled with vesicles containing synaptic transmitter (ACh) (above); the deep infoldings of the sarcolemmal sole plate (below) form subsynaptic gutters. (A, Courtesy of Dr Norman Gregson, Division of Neurology, GKT School of Medicine, London. C, Courtesy of Professor DN Landon, Institute of Neurology, University College London.)

contraction. Each axon branches near its terminal to innervate from several to hundreds of muscle fibres, the number depending on the precision of motor control required (Shi et al 2012).

The detailed structure of a motor terminal varies with the type of muscle innervated. Two major types of ending are recognized, innervating either extrafusal muscle fibres or the intrafusal fibres of neuromuscular spindles. In the former type, each axonal terminal usually ends midway along a muscle fibre in a discoidal motor end-plate (Fig. 3.36A), and usually initiates action potentials that are rapidly conducted to all parts of the muscle fibre. In the latter type, the axon gives off numerous branches that form a cluster of small expansions extending along the muscle fibre; in the absence of propagated muscle excitation, these excite the fibre at several points. Both types of ending are associated with a specialized receptive region of the muscle fibre, the sole plate, where a number of muscle cell nuclei are grouped within the granular sarcoplasm.

The sole plate contains numerous mitochondria, endoplasmic reticulum and Golgi complexes. The terminal branches of the axon are plugged into shallow grooves in the surface of the sole plate (primary clefts), from where numerous pleats extend for a short distance into the underlying sarcoplasm (secondary clefts) (Fig. 3.36B–C). The axon terminal contains mitochondria and many clear, 60 nm spherical vesicles similar to those in presynaptic boutons, which are clustered over the zone of membrane apposition. It is ensheathed by Schwann cells whose cytoplasmic projections extend into the synaptic cleft. The plasma membranes of the axon terminal and the muscle cell are separated by a 30–50 nm gap and an interposed basal lamina, which follows the surface folding of the sole-plate membrane into the secondary clefts. Endings of fast and slow twitch muscle fibres differ in detail: the sarcolemmal grooves are deeper, and the presynaptic vesicles more numerous, in the fast fibres.

Junctions with skeletal muscle are cholinergic: the release of ACh changes the ionic permeability of the muscle fibre (Sine 2012). Clustering of ACh receptors at the neuromuscular junction depends in part on the presence in the muscle basal lamina of agrin, which is secreted by the motor neurone, and is important in establishing the postjunctional molecular machinery. When the depolarization of the sarcolemma reaches a particular threshold, it initiates an action potential in the sarcolemma, which is then propagated rapidly over the whole cell surface and also deep within the fibre via the invaginations (T-tubules) of the sarcolemma, causing contraction. The amount of ACh released by the arrival of a single nerve impulse is sufficient to trigger an action potential. However, because ACh is very rapidly hydrolysed by the enzyme AChE, present at the sarcolemmal surface of the sole plate, a single nerve impulse only gives rise to one muscle action potential, i.e. there is a one-to-one relationship between neuronal and muscle action potentials. Thus the contraction of a muscle fibre is controlled by the firing frequency of its motor neurone.

Neuromuscular junctions are partially blocked by high concentrations of lactic acid, as in some types of muscle fatigue.

Autonomic motor terminations

Autonomic neuromuscular junctions differ in several important ways from the skeletal neuromuscular junction and from synapses in the CNS and PNS. There is no fixed junction with well-defined pre- and postjunctional specializations. Unmyelinated, highly branched, postganglionic autonomic axons become beaded or varicose as they reach the effector smooth muscle. These varicosities are not static but move along axons. They are packed with mitochondria and vesicles containing neurotransmitters, which are released from the varicosities during conduction of an impulse along the axon. The distance (cleft) between the varicosity and smooth muscle membrane varies considerably depending on the tissue, from 20 nm in densely innervated structures such as the vas deferens

to 1–2 μm in large elastic arteries. Unlike skeletal muscle, the effector tissue is a muscle bundle rather than a single cell. Gap junctions between individual smooth muscle cells are low-resistance pathways that allow electronic coupling and the spread of activity within the effector bundle; they vary in size from punctate junctions to junctional areas of more than 1 μm in diameter.

Adrenergic sympathetic postganglionic terminals contain dense-cored vesicles. Cholinergic terminals, which are typical of all parasympathetic and some sympathetic endings, contain clear spherical vesicles like those in the motor end-plates of skeletal muscle. A third category of autonomic neurones has non-adrenergic, non-cholinergic endings that contain a wide variety of chemicals with transmitter properties. ATP is a neurotransmitter at these terminals, which express purinergic receptors (Burnstock et al 2011). The axons typically contain large, 80–200 nm, dense opaque vesicles, congregated in varicosities at intervals along their length. These terminals are formed in many sites, including the lungs, blood vessel walls, the urogenital tract and the external muscle layers and sphincters of the gastrointestinal tract. In the intestinal wall, neuronal somata lie in the myenteric plexus, and their axons spread caudally for a few millimetres, mainly to innervate circular muscle. Purinergic neurones are under cholinergic control from preganglionic sympathetic neurones. Their endings mainly hyperpolarize smooth muscle cells, causing relaxation, e.g. preceding peristaltic waves, opening sphincters and, probably, causing reflex distension in gastric filling. Autonomic efferents innervate exocrine glands, myoepithelial cells, adipose tissue (noradrenaline (norepinephrine) released from postganglionic sympathetic axons binds to β_3-receptors on adipocytes to stimulate lipolysis) and the vasculature and parenchymal fields of lymphocytes and associated cells in several lymphoid organs, including the thymus, spleen and lymph nodes.

CNS–PNS TRANSITION ZONE

The transition between CNS and PNS usually occurs some distance from the point at which nerve roots emerge from the brain or the spinal cord. The segment of root that contains components of both CNS and PNS tissue is called the CNS–PNS transition zone (TZ; Redlich–Obersteiner's zone). All axons in the PNS, other than postganglionic autonomic neurones, cross such a TZ. Macroscopically, as a nerve root is traced towards the spinal cord or the brain, it splits into several thinner rootlets that may, in turn, subdivide into minirootlets. The TZ is located within either rootlet or minirootlet (**Fig. 3.37**). The arrangement of roots and rootlets varies according to whether the root trunk is ventral, dorsal or cranial. Thus, in dorsal roots, the main root trunk separates into a fan of rootlets and minirootlets that enter the spinal cord in sequence along the dorsolateral sulcus. In certain cranial nerves, the minirootlets come together central to the TZ and enter the brain as a stump of white matter.

Microscopically, the TZ is characterized by an axial CNS compartment surrounded by a PNS compartment. The zone lies more peripherally in sensory nerves than in motor nerves, but in both, the apex of the TZ is described as a glial dome, whose convex surface is usually directed distally. The centre of the dome consists of fibres with a typical CNS organization, surrounded by an outer mantle of astrocytes (corresponding to the glia limitans). From this mantle, numerous glial processes project into the endoneurial compartment of the peripheral nerve, where they interdigitate with its Schwann cells. The astrocytes form a loose reticulum through which axons pass. Peripheral myelinated axons usually cross the zone at a node of Ranvier, which is here termed a PNS–CNS compound node.

Boundary cap (BC) cells are neural crest derivatives that form transient, discrete clusters localized at the presumptive dorsal root entry zones and motor exit points of the embryonic spinal cord (Golding and Cohen 1997). They are thought to prevent cell mixing at these interfaces not only by helping dorsal root ganglion afferents navigate their path to targets in the spinal cord but also by preventing motoneurone cell bodies from exiting to the periphery (Maro et al 2004). In experimental studies in zebra fish, radial glial cells have been implicated as cellular gatekeepers controlling the unidirectional movement of glial cell types across the motor exit point transition zone (Smith et al 2016).

CONDUCTION OF THE NERVOUS IMPULSE

All cells generate a steady electrical potential across their plasma membrane (the membrane potential). This potential is generated by an uneven distribution of potassium ions across the membrane (higher in the intracellular compartment than in the extracellular compartment), and by a selective permeability of the membrane for potassium (**Fig. 3.38**). The distribution of sodium ions is opposite to that for potassium ions, but at rest the sodium conductance of the membrane is low. In neurones this membrane potential is known as the resting potential, and amounts to approximately –60 mV (potential inside the cell measured relative to the outside of the cell). Non-excitable cells have an even higher membrane potential. Neurones receive, conduct and transmit information by changes in membrane conductance for sodium, potassium, calcium or chloride ions. Increase in the sodium or calcium conductance causes an influx of these ions and results in a depolarization of the cell, while chloride influx or potassium efflux results in hyperpolarization. Plasma membrane permeability to these ions is altered by the opening or closing of ion-specific transmembrane channels, triggered by voltage changes or chemical signals such as transmitters (Catterall 2010).

Chemically triggered ionic fluxes may be either direct, where the chemical agent (neurotransmitter) binds to the channel itself to cause it to open, or indirect, where the neurotransmitter is bound by a transmembrane receptor molecule that activates a complex second messenger system within the cell to open separate transmembrane channels. Electrically induced changes in membrane potential depend on the presence of voltage-sensitive ion channels, which, when the transmembrane potential reaches a critical level, open to allow the influx or efflux of specific ions. In all cases, the channels remain open only transiently, and the numbers that open and close determine the total flux of ions across the membrane (Bezanilla 2008).

The types and concentrations of transmembrane channels and related proteins, and therefore the electrical activity of the membranes, vary in different parts of the cell. Dendrites and neuronal somata depend mainly on neurotransmitter action and show graded potentials, whereas axons have voltage-gated channels that give rise to action potentials.

In graded potentials, a flow of current occurs when a synapse is activated; the influence of an individual synapse on the membrane potential of neighbouring regions decreases with distance. Thus synapses on the distal tips of dendrites may, on their own, have relatively little effect on the membrane potential of the cell body. The electrical state of a neurone therefore depends on many factors, including the numbers and positions of thousands of excitatory and inhibitory synapses, their

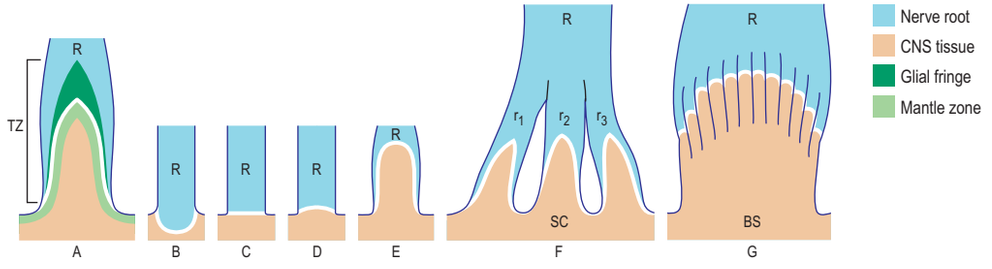

Fig. 3.37 The nerve root–spinal cord junction. **A–G**, Different CNS–PNS borderline arrangements. **A**, A pointed borderline. The extent of the transitional zone (TZ) is indicated. **B–G**, Glial fringe omitted. **B**, A concave borderline (white line) and inverted TZ. **C**, A flat borderline situated at the level of the root (R)–spinal cord junction. **D** and **E**, A convex, dome-shaped borderline; the CNS expansion into the rootlet is moderate in D and extensive in E. **F**, The root (R) splits into rootlets (r), each with its own TZ and attaching separately to the spinal cord (SC). **G**, The arrangement found in several cranial nerve roots (e.g. vestibulocochlear nerve). The PNS component of the root separates into a bundle of closely packed minirootlets, each equipped with a TZ. The minirootlets reunite centrally. BS, brainstem. (Adapted with permission from Dyck PJ, Thomas PK, Griffin JW et al (eds) Peripheral Neuropathy, 3rd ed. Philadelphia: Saunders, 1993.)

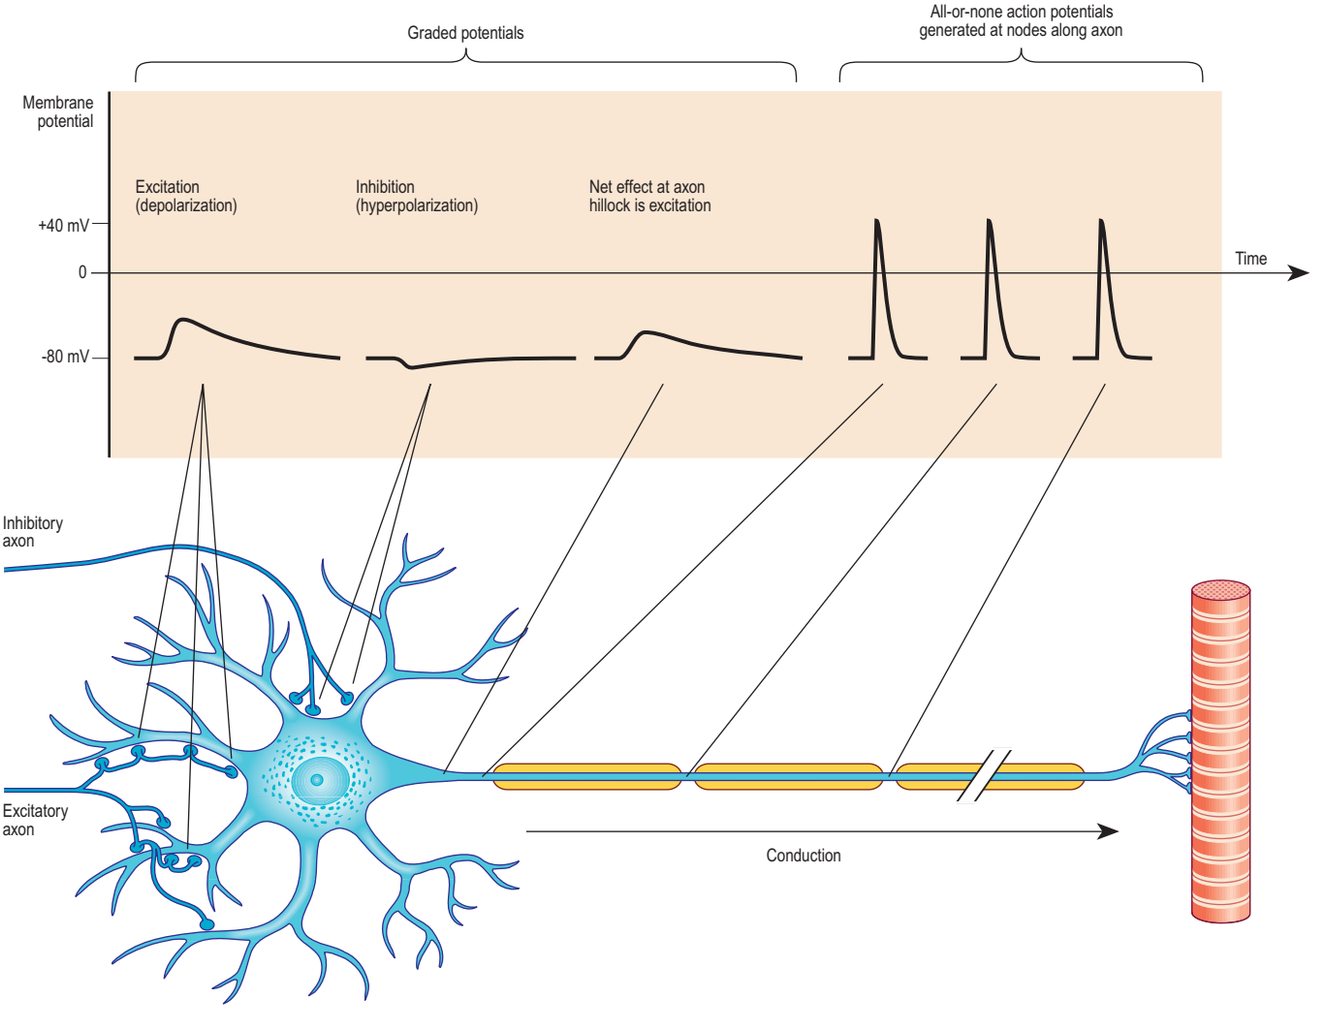

Fig. 3.38 The types of change in electrical potential that can be recorded across the cell membrane of a motor neurone at the points indicated. Excitatory and inhibitory synapses on the surfaces of the dendrites and soma cause local graded changes of potential that summate at the axon hillock and may initiate a series of all-or-none action potentials, which in turn are conducted along the axon to the effector terminals.

degree of activation, and the branching pattern of the dendritic tree and geometry of the cell body. The integrated activity directed towards the neuronal cell body is converted to an output directed away from the soma at the site where the axon leaves the cell body, at its junction with the axon hillock. Voltage-sensitive channels are concentrated at this trigger zone, the axon initial segment, and when this region is sufficiently depolarized, an action potential is generated and is subsequently conducted along the axon.

Action potential

The action potential is a brief, self-propagating reversal of membrane polarity. It depends on an initial influx of sodium ions, which causes a reversal of polarity to about +20 mV, followed by a rapid return towards the resting potential as potassium ions flow out. The rapid reversal process is completed in approximately 0.5 msec, followed by a slower recovery phase of up to 5 msec, when the resting potential is even hyperpolarized. Once the axon hillock reaches threshold, propagation of the action potential is independent of the initiating stimulus; thus the size and duration of action potentials are always the same (described as all-or-none) for a particular neurone, no matter how much a stimulus may exceed the threshold value.

Once initiated, an action potential spreads spontaneously and at a relatively constant velocity, within the range of 4–120 m/s. Conduction velocity depends on a number of factors related to the way in which the current spreads, e.g. axonal cross-sectional area, the numbers and positioning of ion channels, and membrane capacitance (influenced particularly by the presence of myelin). In axons lacking myelin, action potential conduction is analogous to a flame moving along a fuse. Just as each segment of fuse is ignited by its upstream neighbour, each segment of axon membrane is driven to threshold by the depolarization of neighbouring membrane. Sodium channels within the newly depolarized segment open and positively charged sodium ions enter, driving the local potential inside the axon towards positive values. This inward current in turn depolarizes the neighbouring, downstream, non-depolarized membrane, and the cyclic propagation of the action potential is completed. Several milliseconds after the action potential, the sodium channels are inactivated, a period known as the refractory period. The length of the refractory period determines the maximum frequency at which action potentials can be conducted along a nerve fibre; it varies in different neurones and affects the amount of information that can be carried by an individual fibre.

Myelinated fibres are electrically insulated by their myelin sheaths along most of their lengths, except at nodes of Ranvier. The distance between nodes, referred to as the internodal distance, is directly related to axon diameter and varies between 0.2 and 2.0 mm. Voltage-gated sodium channels are clustered at nodes, and the nodal membrane is the only place where high densities of inward sodium current can be generated across the axon membrane. Conduction in myelinated axons is self-propagating, but instead of physically adjacent regions of membrane acting to excite one another (as occurs along unmyelinated axons), it is the depolarization occurring in the neighbouring upstream node that excites a node to threshold. Reaching threshold causes the sodium channels at the node to open and generate inward sodium current, but instead of this acting on the adjacent membrane, the high resistance and low capacitance of the myelin sheath directs the current towards the next downstream node, exciting it to threshold and completing the cycle. The action potential thus jumps from node to node, a process known as saltatory conduction, which greatly increases the conduction velocity.

A number of disorders of the CNS and PNS include demyelination as a characteristic feature (Arancibia-Carcamo and Attwell 2014). Perhaps most common amongst these is multiple sclerosis, which is characterized

by primary demyelination at scattered sites within the CNS (it is now recognized that axonal loss also contributes to the progression of multiple sclerosis). Primary demyelination is the loss of the myelin sheath with axonal preservation, and is usually segmental, i.e. it rarely extends along the entire length of an affected axon. The phenomenon is associated with conduction block because the newly exposed, previously internodal, axolemma contains relatively few voltage-sensitive sodium channels. There is experimental and clinical evidence that remyelinated axons can conduct at near-normal speeds, because even though their sheaths are thinner than the original myelin sheaths, the safety factor (i.e. the factor by which the outward current at a quiescent node next to an excited node exceeds the minimum current required to evoke a response) is greater than 1. The myelin loss that occurs in the early stages of Wallerian degeneration in both CNS and PNS, usually distal to a site of trauma but also in response to a prolonged period of ischaemia or exposure to a neuronotoxic substance, is accompanied by axonal degeneration (the term secondary demyelination is sometimes used to describe this form of myelin loss) (see Commentary 1.5).

Axonal conduction is naturally unidirectional, from dendrites and soma to axon terminals. When an action potential reaches the axonal terminals, it causes depolarization of the presynaptic membrane, and as a result, quanta of neurotransmitter (which correspond to the content of individual vesicles) are released to change the degree of excitation of the next neurone, muscle fibre or glandular cell.

CHAPTER 4

Blood, lymphoid tissues and haemopoiesis

Blood is an opaque fluid with a viscosity greater than that of water (mean relative viscosity 4.75 at 18 °C), and a specific gravity of 1.06 at 15 °C. It is bright red when oxygenated, as in the systemic arteries, and dark red to purple when deoxygenated, in systemic veins. Blood is a mixture of a clear liquid, plasma, and cellular elements, and consequently the hydrodynamic flow of blood in vessels behaves in a complex manner that is not entirely predictable by simple Newtonian equations.

Plasma is a clear, yellowish fluid that contains many substances in solution or suspension: low-molecular-weight solutes give a mean freezing-point depression of 0.54 °C. Plasma contains high concentrations of sodium and chloride ions, as well as potassium, calcium, magnesium, phosphate, bicarbonate and traces of many other ions; also present are glucose, amino acids and vitamins. It also includes high molecular weight plasma proteins, e.g. clotting factors, particularly prothrombin; immunoglobulins and complement proteins involved in immunological defence; glycoproteins, lipoproteins, polypeptide and steroid hormones, and globulins for the transport of hormones and iron. The plasma is involved in the transport of most molecules that are released or secreted by cells in response to pathological or physiological stimuli and so the routine chemical analysis of plasma is of great diagnostic importance. There is increasing interest in using metabolomics approaches for the high-throughput analysis of small molecules or metabolites in the serum, as a potential aid to diagnosis and understanding of disease (Psychogios et al 2011, James and Parkinson 2015).

The precipitation of the protein fibrin from plasma to form a clot (**Fig. 4.1**) is initiated by the release of specific materials from damaged cells and blood platelets in the presence of calcium ions. If blood or plasma samples are allowed to stand, they will separate into a clot and a clear yellowish fluid, the serum. Clot formation is prevented by removal of calcium ions, e.g. by addition of citrate, oxalate or various calcium chelators (EDTA, EGTA) to the sample. Heparin is also widely used as an anticlotting agent because it interferes with fibrin clot formation.

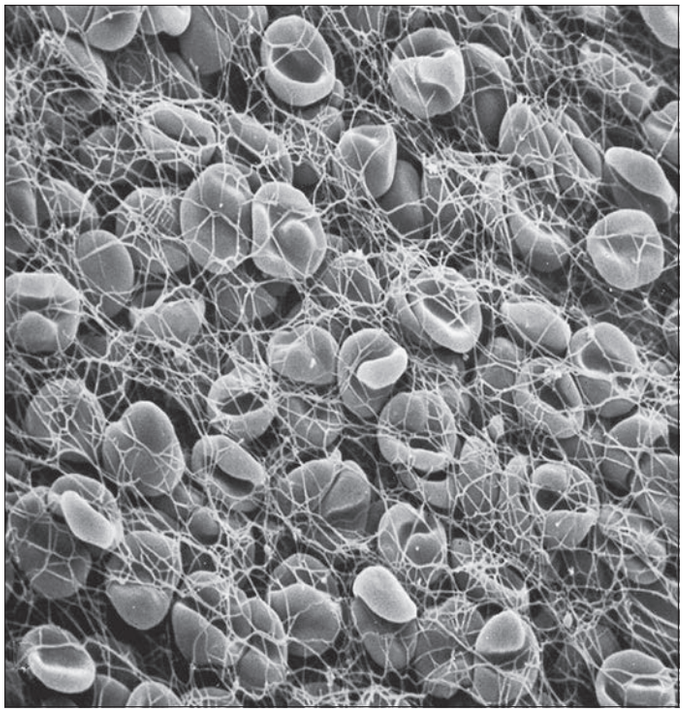

Fig. 4.1 Erythrocytes enmeshed in filaments of fibrin in a clot. (Courtesy of Michael Crowder MD.)

In postnatal life, blood cells are formed in the bone marrow. Haemopoiesis produces red cells (erythrocytes) and a wide variety of immune defense cells (white blood cells, or leukocytes). The latter include neutrophil, eosinophil and basophil granulocytes, B lymphocytes and monocytes. T lymphocytes develop in the thymus from bone marrow-derived progenitors. These cells all contribute to the immune system (for an overview of the immune system, see Murphy and Weaver (2016)). Platelets are produced in the bone marrow as cellular fragments of megakaryocytes. Only erythrocytes and platelets are generally confined to the blood vascular system, whereas all leukocytes can leave the circulation and enter extravascular tissues. The numbers of cells doing so increases greatly during inflammation caused by local infections or tissue damage.

The lymphoid tissues are the thymus, lymph nodes, spleen and the lymphoid follicles associated mainly with the alimentary and respiratory tracts. Lymphocytes populate lymphoid tissues and are concerned with immune defence. Lymphoid tissue also contains supportive stromal cells, which are non-haemopoietic in origin (e.g. thymic epithelium); non-haemopoietic follicular dendritic cells of lymph nodes and splenic follicles; haemopoietically derived dendritic cells; and macrophages of the mononuclear phagocyte system. Dendritic cells and blood monocyte-derived macrophages are found additionally in most tissues and organs, where they function as antigen-presenting cells (APCs).

CELLS OF PERIPHERAL BLOOD

Erythrocytes

Erythrocytes (red blood cells, RBCs) account for the largest proportion of blood cells (99% of the total number), with normal values of 4.1–6.0 × 10^6/μl in adult males and 3.9–5.5 × 10^6/μl in adult females. Polycythaemia (increased red cell mass) can occur in individuals living at high altitude, or pathologically in conditions resulting in arterial hypoxia. Reduction in red cell mass (anaemia) has many underlying causes but in rare instances can be due to structural defects in erythrocytes (see below).

Each erythrocyte is a biconcave disc (see Fig. 4.1; **Fig. 4.2**) with a mean diameter in dried smear preparations of 7.1 μm; in fresh preparations the mean diameter is 7.8 μm, decreasing slightly with age. Mature

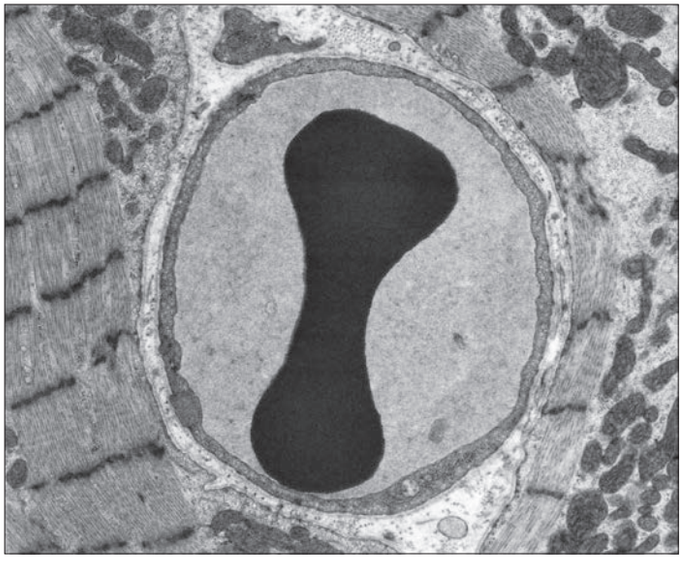

Fig. 4.2 A human heart muscle biopsy specimen, showing an erythrocyte within a capillary. The erythrocyte biconcave disc is typically electron-dense and almost fills the capillary lumen. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

In normal blood, five types of haemoglobin polypeptide chain can occur: namely, α, β and two β-like polypeptides, γ and δ. A third, β-like η chain is restricted to early fetal development. Each haemoglobin molecule contains two α-chains and two others, so that several combinations, and hence a number of different types of haemoglobin molecule, are possible. For example, haemoglobin A (HbA), which is the major adult class, contains 2 α- and 2 β-chains; a variant, HbA_2 with 2 α- and 2 δ-chains, accounts for only 2% of adult haemoglobin. Haemoglobin F (HbF), found in fetal and early postnatal life, consists of 2 α- and 2 γ-chains. Adult red cells normally contain less than 1% of HbF.

Mutations in the haemoglobin chains can result in a range of pathologies (Forget and Bunn 2013).

In the genetic condition thalassaemia, only one type of chain is expressed normally, the mutant chain being absent or present at much reduced levels. Thus, a molecule may contain 4 α-chains (β-thalassaemia) or 4 β-chains (α-thalassaemia). In haemoglobin S (HbS) of sickle-cell disease, a point mutation in the β-chain gene (valine substituted for glutamine) causes the haemoglobin to polymerize under conditions of low oxygen concentration, thus deforming the red blood cell.

erythrocytes lack nuclei. They are pale red by transmitted light, with paler centres because of their biconcave shape. The properties of their cell coat cause them to adhere to one another by their rims to form loose piles of cells (rouleaux). In normal blood, a few cells assume a shrunken, star-like, crenated form; this shape can be reproduced by placing normal biconcave erythrocytes in a hypertonic solution, which causes osmotic shrinkage. In hypotonic solutions erythrocytes take up water and become spherical; they may eventually lyse to release their haemoglobin (haemolysis), leaving red-cell ghosts.

Erythrocytes have a plasma membrane that encloses mainly a single protein, haemoglobin, as a 33% solution. The plasma membrane of erythrocytes is 60% lipid and glycolipid, and 40% protein.

More than 15 classes of protein are present, including two major types. Glycophorins A and B (each with a molecular mass of approximately 50 kDa) span the membrane, and their negatively charged carbohydrate chains project from the outer surface of the cell. Their sialic acid groups confer most of the fixed charge on the cell surface. A second transmembrane macromolecule, band 3 protein, forms an important anion channel, exchanging bicarbonate for chloride ions across the membrane and allowing the release of CO_2 in the lungs.

The filamentous protein, spectrin, is responsible for maintaining the shape of the erythrocyte. A dimer is formed of α1 and β1 spectrin monomers, and two dimers then come together to form a tetramer (Machnicka et al 2013). These are joined by junctional complexes that contain (among other proteins) ankyrin, short actin filaments, tropomyosin and protein 4.1, forming a hexagonal lattice that supports the plasma membrane (Mankelow et al 2012). The junctional complex also interacts with transmembrane proteins. This structure gives the membrane great flexibility; red cells are deformable but regain their biconcave shape and dimensions after passing through the smallest capillaries, which are 4 µm in diameter (Mohandas and Gallagher 2008). Erythrocyte membrane flexibility also contributes to the normally low viscosity of blood. Molecular defects in the cytoskeleton result in abnormalities of red cell shape, membrane fragility, premature destruction of erythrocytes in the spleen and haemolytic anaemia (Iolascon et al 1998).

Fetal erythrocytes up to the fourth month of gestation differ markedly from those of adults, in that they are larger, are nucleated and contain a different type of haemoglobin (HbF). After this time they are progressively replaced by the adult type of cell.

Haemoglobin

Haemoglobin (Hb) is a globular protein with a molecular mass of 67 kDa. It consists of globulin molecules bound to haem, an iron-containing porphyrin group. The oxygen-binding power of Hb is provided by the iron atoms of the haem groups, and these are maintained in the ferrous (Fe^{++}) state by the presence of glutathione within the erythrocyte. The Hb molecule is a tetramer, made up of four subunits, each a coiled polypeptide chain holding a single haem group.

Lifespan

Erythrocytes last between 100 and 120 days before being destroyed. As erythrocytes age, they become increasingly fragile, and their surface charge decreases as their content of negatively charged membrane glycoproteins diminishes. The lipid content of their membranes also reduces. Aged erythrocytes are taken up by the macrophages of the spleen (Mebius and Kraal 2005) and liver sinusoids, usually without prior lysis, and are hydrolysed in phagocytic vacuoles where the haemoglobin is split into its globulin and porphyrin moieties. Globulin is further degraded to amino acids, which pass into the general amino-acid pool. Iron is removed from the porphyrin ring and either transported in the circulation bound to transferrin and used in the synthesis of new haemoglobin in the bone marrow, or stored in the liver as ferritin or haemosiderin. The remainder of the haem group is converted in the liver to bilirubin and excreted in the bile. Haemoglobin that is released by destruction of erythrocytes in the body binds to haptoglobin, and is taken up via CD (antigenic Cluster of Differentiation marker of cell type)163 receptors expressed on the surface of macrophages (Kristiansen et al 2001).

The recognition of effete erythrocytes by macrophages takes place by a number of mechanisms. These include the exposure extracellularly of phospholipids (such as phosphatidyl serine) that are normally found on the inner leaflet of the membrane bilayer, alterations in the carbohydrates expressed by the cells (most notably the loss of sialic acid) and the binding of autoantibodies to antigens exposed on the aged erythrocyte. These lead to the cells being recognised and taken up by macrophages. Red cells are destroyed at the rate of 5×10^{11} cells a day (or nearly 6 million a second) and are normally replaced from the bone marrow (see Fig. 4.12) at the same rate.

Blood groups

Over 300 red cell antigens are recognizable with specific antisera. They can interact with naturally occurring or induced antibodies in the plasma of recipients of an unmatched transfusion, causing agglutination and lysis of the erythrocytes. Erythrocytes of a single individual carry several different types of antigen, each type belonging to an antigenic system in which a number of alternative antigens are possible in different persons. So far, 19 major groups have been identified. They vary in their distribution frequencies between different populations, and include the ABO, Rhesus, MNS, Lutheran, Kell, Lewis, Duffy, Kidd, Diego, Cartwright, Colton, Sid, Scianna, Yt, Auberger, Ii, Xg, Indian and Dombrock systems. Clinically, the ABO and Rhesus groups are of most importance.

Leukocytes also bear highly polymorphic antigens encoded by allelic gene variants. These belong to the group of major histocompatibility complex (MHC) antigens, also termed human leukocyte antigens (HLA) in humans. HLA class I antigens are expressed by all nucleated cells. Class II antigens are expressed on antigen-presenting cells (APCs) of the immune system, but can also be induced on many parenchymal cell types, e.g. after exposure to interferon. HLA class I and II antigens play important roles in cell–cell interactions in the immune system, particularly in the presentation of antigens to T lymphocytes by APCs.

Leukocytes

Leukocytes (white blood cells) belong to at least five different categories (see Fig. 4.12) and are distinguishable by their size, nuclear shape and cytoplasmic inclusions. In practice, leukocytes are often divided into two main groups: namely, those with prominent stainable cytoplasmic granules, the granulocytes, and those without.

Granulocytes

This group consists of eosinophil granulocytes, with granules that bind acidic dyes such as eosin; basophil granulocytes, with granules that bind basic dyes strongly; and neutrophil granulocytes, with granules that stain only weakly with either type of dye. Granulocytes (**Fig. 4.3**) all possess irregular or multilobed nuclei and belong to the myeloid series of blood cells (see Fig. 4.12).

Neutrophil granulocytes

Neutrophil granulocytes (neutrophils) are also referred to as polymorphonuclear leukocytes (polymorphs) because of their irregularly segmented (multilobed) nuclei. They form the largest proportion of the white blood cells (40–75% in adults, with a normal count of 2500–7500/µl) and have a diameter of 12–14 µm. The cells may be spherical in the circulation, but they can flatten and become actively motile within the extracellular matrix of connective tissues.

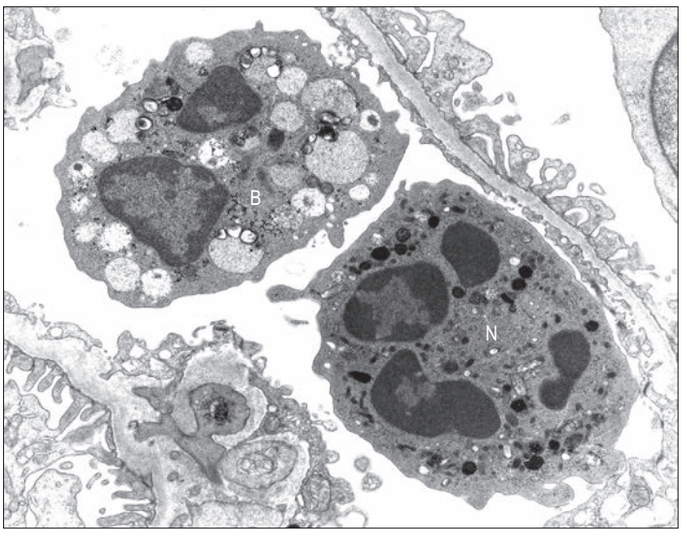

Fig. 4.3 Neutrophil (N) and basophil (B) granulocytes within a renal glomerular capillary in a human kidney biopsy. The neutrophil nucleus is more segmented (four lobes are visible) and the granules are smaller and more electron-dense than in the basophil. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

In the ABO system, two allelic genes are inherited in simple Mendelian fashion. Thus the genome may be homozygous and carry the AA complement, the blood group being A, or the BB complement, which gives blood group B, or it may carry neither (OO), producing blood group O. In the heterozygous condition the following combinations can occur: AB (blood group AB), AO (blood group A) and BO (blood group B). The ABO blood group antigens are all membrane glycolipids.

Individuals with group AB blood lack antibodies to both A and B antigens, and so can be transfused with blood of any group; they are termed universal recipients. Conversely, those with group O, universal donors, can give blood to any recipient, since anti-A and anti-B antibodies in the donated blood are diluted to insignificant levels. Normally, however, blood is only transfused between persons with corresponding groups because anomalous antibodies of the ABO system are occasionally found in blood and may cause agglutination or lysis. The anti-ABO agglutinins, unlike those of the Rhesus system, belong to the immunoglobulin M (IgM) class and do not cross the placenta during pregnancy.

The Rhesus antigen system is determined by three sets of alleles: namely, Cc, Dd and Ee. The most important clinically is Dd. Inheritance of the Rh factor also obeys simple Mendelian laws; it is therefore possible for a Rhesus-negative mother to bear a Rhesus-positive child. Under these circumstances, fetal Rh antigens can stimulate the production of anti-Rh antibodies by the mother; as these belong to the IgG class of antibody they are able to cross the placenta. For most of the pregnancy the stroma stops the blood group antibodies from crossing into the fetal circulation. However, immediately prior to birth, the antibodies can cross this barrier and cause destruction of fetal erythrocytes. In the first such pregnancy little damage usually occurs because anti-Rh antibodies have not been induced, but in subsequent Rh-positive pregnancies massive destruction of fetal red cells may result, causing fetal or neonatal death (haemolytic disease of the newborn). Sensitization of the maternal immune system can also result from abortion or miscarriage, or occasionally even from amniocentesis, which may introduce fetal antigens into the maternal circulation. Treatment is by exchange transfusion of the neonate or, prophylactically, by giving Rh-immune (anti-D) serum to the mother after the first Rh-positive pregnancy, which destroys the fetal Rh antigen in her circulation before sensitization can occur.

The numerous cytoplasmic granules are heterogeneous in size, shape and content, but all are membrane-bound and contain hydrolytic and other enzymes. Two major types can be distinguished according to their developmental origin and contents. Non-specific or primary (azurophilic) granules are formed early in neutrophil maturation. They are relatively large (0.5 μm) spheroidal lysosomes containing myeloperoxidase, acid phosphatase, elastase and several other enzymes. Specific or secondary granules are formed later, and occur in a wide range of shapes including spheres, ellipsoids and rods. These contain strong bacteriocidal components including alkaline phosphatase, lactoferrin and collagenase, none of which is found in primary granules. Conversely, secondary granules lack peroxidase and acid phosphatase. Some enzymes, e.g. lysozyme, are present in both types of granule.

In mature neutrophils the nucleus is characteristically multilobed with up to six (usually three or four) segments joined by narrow nuclear strands; this is known as the segmented stage. Less mature cells have fewer lobes. The earliest to be released under normal conditions are juveniles (band or stab cells), in which the nucleus is an unsegmented crescent or band. In certain clinical conditions, even earlier stages in neutrophil formation, when cells display indented or rounded nuclei (metamyelocytes or myelocytes) may be released from the bone marrow. In mature cells the edges of the nuclear lobes are often irregular. In females 3% of the nuclei of neutrophils show a conspicuous 'drumstick' formation, which represents the sex chromatin of the inactive X chromosome (Barr body). Neutrophil cytoplasm contains few mitochondria but abundant cytoskeletal elements, including actin filaments, microtubules and their associated proteins, all characteristic of highly motile cells.

Neutrophils are important in the defence of the body against microorganisms. They can phagocytose microbes and small particles in the circulation and, after extravasation, they carry out similar activities in other tissues. They function effectively in relatively anaerobic conditions, relying largely on glycolytic metabolism, and they fulfil an important role in the acute inflammatory phase of tissue injury, responding to chemotaxins released by damaged tissue. Phagocytosis of cellular debris or invading microorganisms is followed by fusion of the phagocytic vacuole with granules, which results in bacterial killing and digestion. Actively phagocytic neutrophils are able to reduce oxygen enzymatically to form reactive oxygen species including superoxide radicals and hydrogen peroxide, which enhance bacterial destruction probably by activation of some of the granule contents (Segal 2005, Nathan 2006). Neutrophils can also produce neutrophil extracellular traps (NETs), which are web-like structures composed of DNA and proteolytic enzymes that can trap bacteria and kill them (Kaplan and Radic 2012).

Phagocytosis is greatly facilitated by circulating antibodies to molecules such as bacterial antigens, which the body has previously encountered. Antibodies (acting as opsonins) coat the antigenic target and bind the plasma complement protein, C1, to their non-variable Fc regions. This activates the complement cascade via the classical pathway, which involves some 20 plasma proteins synthesized mainly in the liver, and completes the process of opsonization. The complement cascade involves the sequential cleavage of the complement proteins into a large fragment, which generally binds to the antigenic surface, and a small bioactive fragment, which is released. The final step is the recognition of complement by receptors on the surfaces of neutrophils and macrophages, which promotes phagocytosis of the microorganism.

Complement activation can be triggered via three pathways: classical, lectin and alternative. The classical pathway is activated by C1q binding to antigen-bound antibodies. The lectin pathway is triggered by mannan-binding lectin (MBL) interacting with carbohydrate patterns on the microbial surface. The alternative pathway relies on autoactivation of complement component C3 on the microbial surface. The products of complement activation have functions of opsonization, cytotoxicity and recruitment of infiltrating cells to the site of infection or injury.

Neutrophils are short-lived; they spend some 6–7 hours circulating in the blood and a few days in connective tissues. The number of circulating neutrophils varies, and often rises during episodes of acute bacterial infection. They die after carrying out their phagocytic role; dead neutrophils, bacteria, tissue debris (including tissue damaged by neutrophil enzymes and toxins) and interstitial fluid form the characteristic, greenish-yellow pus of infected tissue. The colour is derived from the natural colour of neutrophil myeloperoxidase.

Granules may also be released inappropriately from neutrophils. Their enzymes are implicated in various pathological conditions, e.g. rheumatoid arthritis, where tissue destruction and chronic inflammation occur.

Eosinophil granulocytes

Eosinophil granulocytes (eosinophils; for a review, see Rothenberg and Hogan (2006)) are similar in size (12–15 μm), shape and motile capacity to neutrophils, but are present only in small numbers in normal blood (100–400/μl). The nucleus has two prominent lobes connected by a thin strand of chromatin. Their cytoplasmic specific granules are uniformly large (0.5 μm) and give the living cell a slightly yellowish colour. The cytoplasm is packed with granules, which are spherical or ellipsoid and membrane-bound. The core of each granule is composed of a lattice of major basic protein, which is responsible for its strong eosinophilic staining properties. The surrounding matrix contains several lysosomal enzymes including acid phosphatase, ribonuclease, phospholipase and a myeloperoxidase unique to eosinophils.

Like other leukocytes, eosinophils are motile. When suitably stimulated, they are able to pass into the extravascular tissues from the circulation. They are typical minor constituents of the dermis, and of the connective tissue components of the bronchial tree, alimentary tract, uterus and vagina. The total lifespan of these cells is a few days, of which some 10 hours is spent in the circulation, and the remainder in the extravascular tissues.

Eosinophil numbers rise (eosinophilia) in worm infestations and also in certain allergic disorders, and it is thought that they evolved as a primary defence against parasitic attack. They have surface receptors for IgE that bind to IgE-antigen complexes, triggering phagocytosis and release of granule contents. However, they are only weakly phagocytic and their most important function is the destruction of parasites too large to phagocytose. This antiparasitic effect is mediated via toxic molecules released from their granules (e.g. eosinophil cationic protein and major basic protein). They also release histaminase, which limits the inflammatory consequences of mast cell degranulation. High local concentrations of eosinophils, e.g. in bronchial asthma and in cutaneous contact hyper sensitivity and allergic eczema, can cause tissue destruction as a consequence of the release of molecules such as collagenase from their granules.

Basophil granulocytes

Slightly smaller than other granulocytes, basophil granulocytes are 10–14 μm in diameter, and form only 0.5–1% of the total leukocyte population of normal blood, with a count of 25–200/μl. Their distinguishing feature is the presence of large, conspicuous basophilic granules. The nucleus is somewhat irregular or bilobed, and is usually obscured in stained blood smears by the similar colour of the basophilic granules. The granules are membrane-bound vesicles that display a variety of crystalline, lamellar and granular inclusions: they contain heparin, histamine and several other inflammatory agents, and closely resemble those of tissue mast cells. Both basophils and mast cells have high-affinity membrane receptors for IgE and are therefore coated with IgE antibody. If this binds to its antigen it triggers degranulation of the cells, causing vasodilation, increased vascular permeability, chemotactic stimuli for other granulocytes, and the symptoms of immediate hypersensitivity, e.g. in allergic rhinitis (hay fever). Despite these similarities, basophils and mast cells develop as separate lineages in the myeloid series, from haemopoietic stem cells in the bone marrow. Evidence from experimental animal models suggests that they are closely related (see Fig. 4.12) but studies on mast cell disorders in humans indicate that their lineages diverge from a more distant ancestral progenitor (Kocabas et al 2005). The role of mast cells in the regulation of responses to pain is of interest clinically as a therapeutic target (Chatterjea and Martinov 2015).

Mononuclear leukocytes

Monocytes

Monocytes are the largest of the leukocytes (15–20 μm in diameter) but they form only a small proportion of the total population (2–8% with a count of 100–700/μl of blood). The nucleus, which is euchromatic, is relatively large and irregular, often with a characteristic indentation on one side. The cytoplasm is pale-staining, particulate and typically vacuolated. Near the nuclear indentation it contains a prominent Golgi complex and vesicles. Monocytes are actively phagocytic cells and contain numerous lysosomes. Phagocytosis is triggered by recognition of opsonized material, as described for neutrophils. Monocytes are highly motile and possess a well-developed cytoskeleton.

Monocytes express class II MHC antigens and share other similarities to tissue macrophages and dendritic cells. Most monocytes are thought to be in transit via the blood stream from the bone marrow to the peripheral tissues, where they give rise to macrophages and dendritic cells; different monocyte subsets may target inflamed tissues. Like other leukocytes, they pass into extravascular sites through the walls of capillaries and venules.

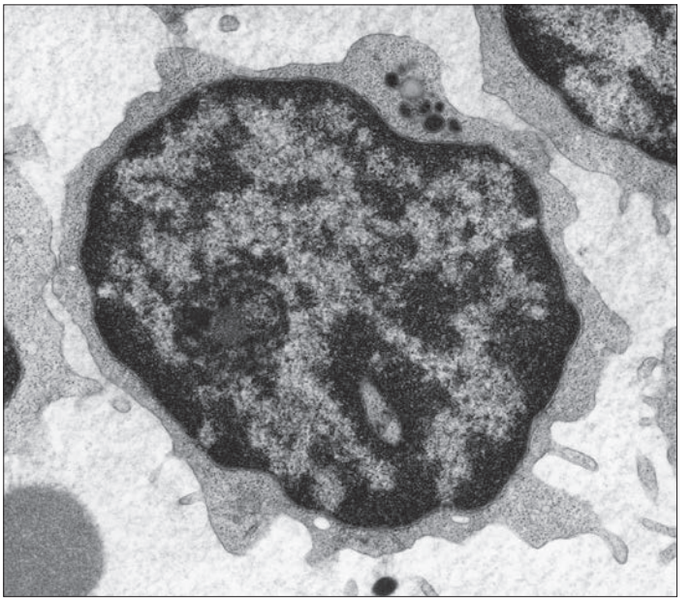

Fig. 4.4 A small, resting lymphocyte in human peripheral blood (electron micrograph). The nuclear:cytoplasmic ratio is high and the cytoplasm contains few organelles, indicative of its quiescent state. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

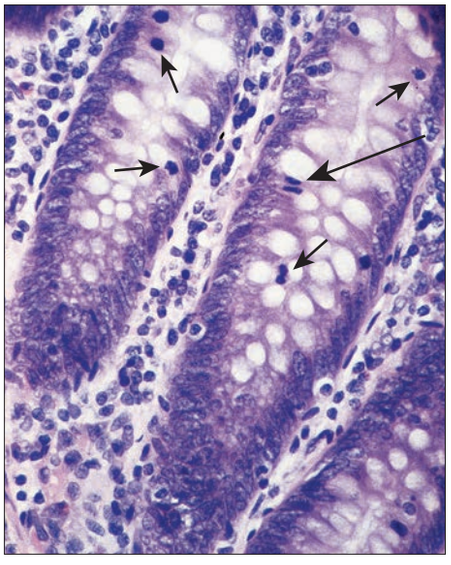

Fig. 4.5 Tubular glands in the appendix, showing intraepithelial lymphocytes (short arrows). A lymphocyte in anaphase is indicated (long arrow).

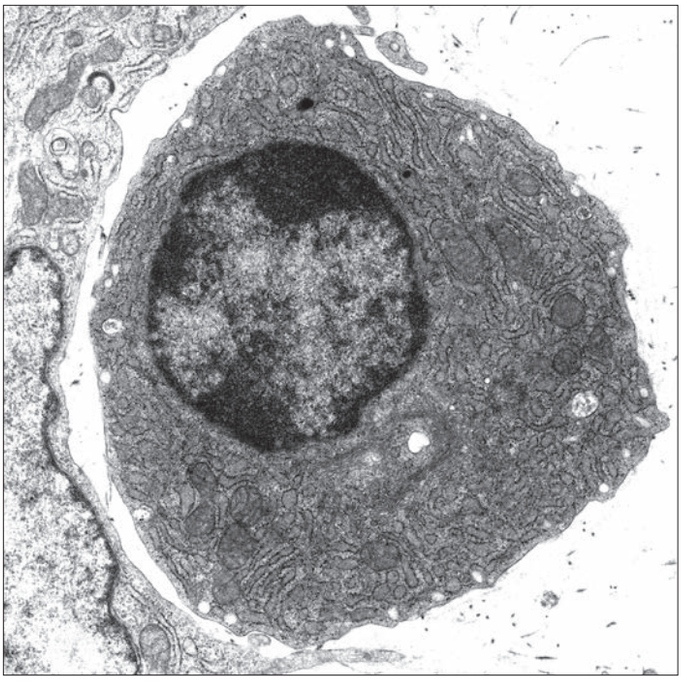

Fig. 4.6 A mature B cell (plasma cell) in human connective tissue. The abundant rough endoplasmic reticulum is typical of a cell actively synthesizing secretory protein, in this case immunoglobulin. The cell to the left is a fibroblast. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

Lymphocytes

Lymphocytes (**Fig. 4.4**; see Figs 4.6, 4.12) are the second most numerous type of leukocyte in adulthood, forming 20–30% of the total population (1500–2700/μl of blood). In young children they are the most numerous blood leukocyte. Most circulating lymphocytes are small, 6–8 μm in diameter; a few are medium-sized and have an increased cytoplasmic volume, often in response to antigenic stimulation. Occasionally, cells up to 16 μm are seen in peripheral blood. Lymphocytes, like other leukocytes, are found in extravascular tissues (including lymphoid tissue); however, they are the only white blood cells that return to the circulation. The lifespan of lymphocytes ranges from a few days (short-lived) to many years (long-lived). Long-lived lymphocytes are necessary for the maintenance of immunological memory.

Blood lymphocytes are a heterogeneous collection, mainly of B and T cells. About 85% of all circulating lymphocytes in normal blood are T cells. Primary immunodeficiency diseases can result from molecular defects in T and B lymphocytes that provide targets for gene therapy for these conditions (Cunningham-Rundles and Ponda 2005, Thrasher and Williams 2017).

Small lymphocytes (both B and T cells) contain a rounded, densely staining nucleus that is surrounded by a very narrow rim of cytoplasm, barely visible in the light microscope. By transmission electron microscopy (see Fig. 4.4), few cytoplasmic organelles can be seen apart from a small number of mitochondria, single ribosomes, sparse profiles of endoplasmic reticulum and occasional lysosomes; these features indicate a low metabolic rate and a quiescent phenotype. However, these cells become motile when they contact solid surfaces, and can pass between endothelial cells to exit from, or re-enter, the vascular system. They migrate extensively within various tissues, including epithelia (**Fig. 4.5**).

Larger lymphocytes include T and B cells that are functionally activated or proliferating after stimulation by antigen, and NK cells. They contain a nucleus, which is, at least in part, euchromatic; a basophilic cytoplasm, which may appear granular; and numerous polyribosome clusters, consistent with active protein synthesis. The ultrastructural appearance of these cells varies according to their class and is described below.

B cells

B cells and the plasma cells that develop from them synthesize and secrete antibodies that can specifically recognize and neutralize foreign (non-self) macromolecules (antigens), and can direct various non-lymphocytic cells (e.g. neutrophils, macrophages and dendritic cells) to phagocytose pathogens. B cells differentiate from haemopoietic stem cells in the bone marrow. After deletion of autoreactive cells, the selected B lymphocytes then leave the bone marrow and migrate to peripheral lymphoid sites (e.g. lymph nodes). Here, following stimulation by antigen, they undergo further proliferation and selection, forming germinal centres in the lymphoid tissues. Following this, some B cells differentiate into large basophilic (RNA-rich) plasma cells, either within or outside the lymphoid tissues. Plasma cells produce antibodies in their extensive rough endoplasmic reticulum (**Fig. 4.6**) and secrete them into the adjacent tissues. They have a prominent pale-staining Golgi complex adjacent to an eccentrically placed nucleus, typically with peripheral blocks of condensed heterochromatin resembling the numerals of a clock (clock-faced nucleus) (see Fig. 4.12). Other germinal centre B cells develop into long-lived memory cells capable of responding to their specific antigens not only with a more rapid and higher antibody output, but also with an increased antibody affinity compared with the primary response.

Antibodies are immunoglobulins, grouped into five classes according to their heavy polypeptide chain. Immunoglobulin G (IgG) forms the bulk of circulating antibodies. Immunoglobulin M (IgM) is normally synthesized early in immune responses. Immunoglobulin A (IgA) is present in breast milk, tears, saliva and other secretions of the alimentary tract, coupled to a secretory piece (a 70 kDa protein) that is synthesized by the epithelial cells. The secretory piece (or component) is a cleavage product of the epithelial plasma membrane Ig receptor, following internalization of the receptor–IgA complex and processing during

transcytosis. It protects the immunoglobulin from proteolytic degradation after secretion: secretory IgA (sIgA) contributes to mucosal immunity (Brandtzaeg 2013). IgA deficiency is relatively common, particularly in some ethnic groups (reviewed in Woof and Kerr (2006)). Immunoglobulin E (IgE) is an antibody that binds to receptors on the surfaces of mast cells, eosinophils and blood basophils, and is found only at low concentrations in the circulation. IgE is mostly associated with type I hypersensitivity (allergic) reactions. Immunoglobulin D (IgD) is found together with IgM as a major membrane-bound immunoglobulin on mature, immunocompetent but naïve (prior to antigen exposure) B cells, acting as the cellular receptor for antigen. IgG and IgM, when bound to self or microbial antigens, can activate the classical complement pathway, leading to a cascade of cytolytic and proinflammatory consequences.

When circulating antibodies bind to antigens they form immune complexes. If present in abnormal quantities, these may cause pathological damage to the vascular system and other tissues, either by interfering mechanically with the permeability of the basal lamina (e.g. some types of glomerulonephritis), or by causing local activation of the complement system that generates inflammatory mediators (e.g. C5a), attacks cell membranes and causes vascular disease. In pregnancy, maternal IgG crosses the placenta and confers passive immunity on the fetus. Maternal milk contains secretory immunoglobulins (IgA) that help to combat bacterial and viral organisms in the alimentary tract of the baby during the first few weeks of postnatal life.

T cells

There are a number of subsets of T (thymus-derived) lymphocytes, all progeny of haemopoietic stem cells in the bone marrow. They develop and mature in the thymus, and subsequently populate peripheral secondary lymphoid organs, which they constantly leave and re-enter via the circulation. As recirculating cells, their major function is immune surveillance. Their activation and subsequent proliferation and functional maturation are under the control of APCs. T cells undertake a wide variety of cell-mediated defensive functions that are not directly dependent on antibody activity, and which constitute the basis of cellular immunity. T-cell responses focus on the destruction of cellular targets such as virus-infected cells, certain bacterial infections, fungi, some protozoal infections, neoplastic cells and the cells of grafts from other individuals (allografts, when the tissue antigens of the donor and recipient are not sufficiently similar). Targets may be killed directly by cytotoxic T cells, or indirectly by accessory cells (e.g. macrophages) that have been recruited and activated by cytokine-secreting helper T cells. A third group, regulatory T cells, acts to regulate or limit immune responses.

Functional groups of T cells are classified according to the molecules they express on their surfaces. The majority of cytokine-secreting helper T cells express CD4, while cytotoxic T cells are characterized by CD8. Regulatory T cells co-express CD4 and CD25. The CD (cluster of differentiation) prefix provides a standard nomenclature for all cell-surface molecules. At present, more than 330 different CD antigens have been designated; each one represents a cell surface molecule that can be identified by specific antibodies. Further details of the classification are beyond the scope of this publication and are given in Male et al (2012).

Structurally, T lymphocytes present different appearances depending on their type and state of activity. When resting, they are typically small lymphocytes and are morphologically indistinguishable from B lymphocytes. When stimulated, they become large (up to 15 μm), moderately basophilic cells, with a partially euchromatic nucleus and numerous free ribosomes, rough and smooth endoplasmic reticulum, a Golgi complex and a few mitochondria, in their cytoplasm. Cytotoxic T cells contain dense lysosome-like vacuoles that function in cytotoxic killing.

Cytotoxic T cells

Cytotoxic T lymphocytes (CTLs) express CD8. They are responsible for the direct cytotoxic killing of target cells (e.g. virus-infected cells); the requirement for direct cell–cell contact ensures the specificity of the response. Recognition of antigen, presented as a peptide fragment on MHC class I molecules, triggers the calcium-dependent release of lytic granules by the CTLs. These lysosome-like granules contain perforin (cytolysin), which forms a pore in the target cell membrane, very similar to the membrane attack complex generated at the end of complement activation. They also contain several different serine protease enzymes (granzymes), which enter the target cell via the perforin pore and induce programmed cell death (apoptosis; p. 27) of the target. $CD8^+$ CTLs protect their own membranes from lysis by perforin and granzymes using cathepsin B, which is bound to the granules, and which can degrade their suicidal contents. CTLs and natural killer (NK) cells of the innate immune system have similar effector functions in IFN-γ production and cytotoxicity (see below).

Helper T cells

Helper T (Th) cells express CD4 and are characterized by the secretion of cytokines. Two major populations have been identified according to the range of cytokines produced. Th1 helper T cells (a part of cell-mediated adaptive immunity) typically secrete interleukin (IL)-2, tumour necrosis factor alpha (TNF-α) and interferon gamma (IFN-γ). Th2 helper T cells (a part of humoral adaptive immunity) produce cytokines such as IL-4, IL-5 and IL-13. These two CD4-expressing populations are termed Th cells because one aspect of their function is to help, i.e. stimulate, the proliferation and maturation of B lymphocytes and CTLs (mediated via cytokines such as IL-4, IL-2 and IFN-γ), thus enabling and enhancing the immune responses mediated by those cells. Th1 cells activate phagocytic cells via production of IFN-γ and TNF-α in order to eliminate pathogens. Macrophage activation by IFN-γ involves upregulation of MHC class II surface expression and enhancement of their antigen-capturing and presenting potency. IFN-γ also promotes the generation of specialized tumour necrosis factor/inducible nitric oxide synthase- (TNF/iNOS) producing dendritic cells, facilitating swift destruction of intracellular pathogens such as *Mycobacterium tuberculosis*.

Th cells are important in directing the destruction of pathogens by recruiting accessory cells (e.g. macrophages, neutrophils, eosinophils) to the site of infection and by activating their effector functions. This process is tightly coordinated. For example, Th1 helper T cells secrete cytokines that not only attract and activate macrophages but also provide help for B cells and guide their immunoglobulin production to the subclasses that fix complement. Thus, these antibodies opsonize the pathogen target, which can then be recognized, ingested and destroyed by the macrophage accessory cells that bear receptors for complement and the Fc region of IgG. These Th1 cells are sometimes referred to as delayed-type hypersensitivity T cells. In contrast, Th2 cells secrete cytokines that induce the development and activation of eosinophils, and also induce B cells to switch their immunoglobulins to non-complement-fixing classes (e.g. IgE). Pathogens such as parasitic worms can then be coated with IgE antibody and hence recognized and destroyed by the effector functions of the eosinophil accessory cells, which bear receptors for the Fc region of IgE.

If helper T-cell activities are non-functional, a state of immunodeficiency results. This means that potentially pathogenic organisms, normally kept in check by the immune system, may proliferate and cause overt pathology, e.g. in acquired immune deficiency syndrome (AIDS), where a virus (human immunodeficiency virus, HIV) specifically infects and kills (predominantly) helper T cells, though some APCs are also killed. Dysregulated Th1 immune responses can result in organ damage and autoimmune disease due to a sustained chronic inflammatory state. In general, most effector cells die within about two weeks following antigen stimulation.

Regulatory T cells

A third population of T cells, regulatory T or Treg cells, are important in controlling the immune response. These $CD4^+$, $CD25^+$ cells have an immunomodulatory function and can dampen the effector functions of both cytotoxic and helper T cells. Regulatory T cells (natural or central Tregs) are produced in the thymus and are an important additional mechanism for maintaining self-tolerance because their T cell receptors are directed in the thymus to recognize self-antigens (Safinia et al 2015). Treg function is antigen-specific and depends on direct cell–cell contact. Molecules secreted or induced by Treg cells, such as IL-10 or transforming growth factor beta (TGF-β), also play an important role in mediating Treg suppressive effects on the immune system. Similar regulatory T cells can be induced in the periphery by TGF-β (induced Tregs) and may be important in the induction of oral tolerance to ingested antigens, as well as tolerance to tissue-specific molecules that are not expressed in the thymus (Schmitt and Williams 2013). Induced Tregs are usually generated in response to microbial antigens, as opposed to central Tregs. Tregs are long-lived and constitute about 10% of circulating $CD4^+$ T cells.

Specialized lymphocytes

The adaptive immune response involving B and T lymphocytes becomes effective following clonal expansion and differentiation of plasma cells, Th2 or Th1 cells. Specialized lymphocytes that contain receptors of limited repertoire and recognize molecular patterns on non-self antigens or pathogen surfaces immediately play an important role in connecting innate and adaptive immune mechanisms. These cells include NK cells, NKT cells, γδ T cells, intestinal intraepithelial lymphocytes (IEL), mucosal-associated invariant T (MAIT) cells, B1 cells, and marginal zone B cells (see Fig. 4.15).

Other subsets of helper T cells have been described. They include Th17 cells which secrete the cytokine IL-17, implicated in autoimmune diseases such as rheumatoid arthritis and multiple sclerosis (Stockinger and Veldhoen 2007). Th17 cells are always present in small bowel tissues where they are likely to interact with commensal gut bacteria. Since Th17 cells bear IL-23 receptors, they can recruit neutrophils very quickly in response to IL-23 produced by activated macrophages. Further subsets (Th9, Th22) have been designated and many more subsets will likely be characterized in the future (Jiang and Dong 2013, Hirahara and Nakayama 2016).

NK cells have functional similarities to cytotoxic T cells. They secrete the proinflammatory cytokine IFN-γ, but lack other typical lymphocyte features and do not express antigen-specific receptors. NK cells are found in the circulation, and in organs such as liver, spleen, lungs and bone marrow, but not in lymph nodes. They normally form only a small percentage of all lymphocyte-like cells and usually have a large granular lymphocyte morphology. When mature, NK cells have a mildly basophilic cytoplasm. Ultrastructurally, their cytoplasm contains ribosomes, rough endoplasmic reticulum and dense, membrane-bound vesicles 200–500 nm in diameter with crystalline cores that contain the protein perforin, which is capable of inserting holes in the plasma membranes of target cells, and granzymes, which trigger subsequent target cell death by apoptosis. NK cells are activated to kill target cells by a number of factors, such as type I interferons (IFN-α/β) secreted by virus-infected cells. They can recognize and kill antibody-coated target cells via antibody-dependent cell-mediated cytotoxicity (ADCC) and express activating as well as inhibitory receptors on their surface. They also have receptors that inhibit NK cell destructive activity when they recognize MHC class I on normal cells (molecular signature of self). When NK cells detect the loss or downregulation of MHC class I antigens on certain virus-infected cells and some tumour cells (missing self), they activate apoptosis-inducing mechanisms that enable them to attack these abnormal cells, albeit relatively non-specifically. For further reading, see Vivier et al (2008) and Chan et al (2015).

There are a few additional types of specialized lymphocyte with limited recognition capacity that act to bridge the time gap between innate and adaptive immune responses. NKT cells are found in blood, bone marrow, spleen and liver. They express both NK and T cell receptors on their cell surface, recognize glycolipids in conjunction with CD1d, and are activated by Gram-negative bacteria. They retain cytolytic properties, can activate NK cells, and produce IL-4 and IFN-γ cytokines. γδ T cells are distinct from αβ T cell receptor-bearing $CD4^+$ and $CD8^+$ cells, can constitute up to 5% of the circulating lymphocyte population, and their activation can lead to IFN-γ production. They are capable of producing tissue growth factors that may be helpful in tissue repair following pathogen clearance and inflammation. Intraepithelial lymphocytes (IEL) containing αβ and γδ T cell receptors, are found in the lungs and bowel, where they behave similarly to $CD8^+$ CTLs. Mucosal associated invariant T cell (MAIT) cells are relatively rare and recognize non-canonical MHC I molecules presenting microbial components: they are considered to have a regulatory role in the lamina propria of mucosae. B1 cells are made in the fetus and produce natural antibodies without antigenic stimulation. They offer protection against pathogens during the early part of neonatal life and can produce IgM and IgA antibodies in response to conserved patterns on bacterial surfaces without requiring the participation of T cells. Marginal zone B cells can generate IgM and IgG3 antibody responses against blood-borne pathogens.

Platelets

Blood platelets, also known as thrombocytes, are relatively small (2–4 μm across) irregular or oval discs present in large numbers (200,000–400,000/μl) in blood. In freshly harvested blood samples they readily adhere to each other and to all available surfaces, unless the blood is treated with citrate or other substances that reduce the availability of calcium ions. Platelets are anucleate cell fragments, derived from megakaryocytes in the bone marrow. They are surrounded by a plasma membrane with a thick glycoprotein coat, which is responsible for their adhesive properties. A band of 10 microtubules lies around the perimeter of the platelet beneath the plasma membrane; the microtubules are associated with actin filaments, myosin and other proteins related to cell contraction. The cytoplasm also contains mitochondria, glycogen, scant smooth endoplasmic reticulum, tubular invaginations of the plasma membrane, and three major types of membrane-bound vesicle, designated α, δ and λ granules. Alpha granules are the largest (up to 500 nm diameter) and contain platelet-derived growth factor (PDGF), fibrinogen and other substances. Delta granules (up to 300 nm) contain 5-hydroxytryptamine (5-HT, serotonin) that has been endocytosed from the blood plasma. Lambda granules (up to 250 nm) contain lysosomal enzymes.

Platelets play an important role in haemostasis. When a blood vessel is damaged, platelets become activated, evert their membrane invaginations to form lamellipodia and filopodia, and aggregate at the site of injury, plugging the wound. They adhere to each other (agglutination) and to other tissues. Adhesion is a function of the thick platelet coat and is promoted by the release of adenosine diphosphate (ADP) and calcium ions from the platelets in response to vessel injury. The contents of released α granules, together with factors released from the damaged tissues, initiate a complex sequence of chemical reactions in the blood plasma, which leads to the precipitation of insoluble fibrin filaments in a three-dimensional meshwork, the fibrin clot (see Fig. 4.1). More platelets attach to the clot, inserting extensions of their surfaces, filopodia, deep into the spaces between the fibrin filaments, to which they adhere strongly. The platelets then contract (clot retraction) by actin–myosin interactions within their cytoplasm, thus concentrating the fibrin clot and pulling the walls of the blood vessel together, limiting any further leakage of blood. After repair of the vessel wall, which may be promoted by the mitogenic activity of PDGF, the clot is dissolved by enzymes such as plasmin, formed by plasminogen activators in the plasma, probably assisted by lysosomal enzymes derived from the γ granules of platelets. Platelets typically circulate for 10 days before they are removed, mainly by splenic macrophages.

LYMPHOID TISSUES

Lymphocytes are located in many sites in the body, most obviously at strategic sites that are liable to infection, e.g. the oropharynx. The main areas of lymphocyte concentration are classified as primary or secondary lymphoid organs, according to whether they are involved in *de novo* lymphocyte generation (primary lymphoid organs, e.g. bone marrow, thymus) or are the site of mature lymphocyte activation and initiation of an immune response (secondary lymphoid organs, e.g. lymph nodes, spleen).

All lymphocytes arise from pluripotent haemopoietic stem cells in the bone marrow. The B lymphocyte lineage develops through a series of differentiation stages within the bone marrow. The newly formed B cells then leave through the circulation and migrate to peripheral sites. In contrast, T-lymphocyte development requires the thymus; the bone marrow-derived stem cells must therefore migrate via the blood circulation to the thymus. After their differentiation and maturation into immunocompetent T cells that have survived thymic selection processes (1–3%), they re-enter the circulation and are transported to peripheral sites where they join the pool of naïve lymphocytes that recirculate through the secondary lymphoid organs via blood and lymphatic circulation systems.

The secondary or peripheral lymphoid organs are the specialized sites where B and T lymphocytes and APCs come together to initiate immune responses to foreign antigens (Malhotra et al 2013). They include lymph nodes, spleen, and lymphoid tissue associated with epithelial surfaces (mucosa-associated lymphoid tissue, MALT), e.g. the palatine and nasopharyngeal tonsils, Peyer's patches in the small intestine, lymphoid nodules in the respiratory and urogenital systems, the skin. The microstructure of lymph nodes and of MALT in general is described below. Details of all other lymphoid tissues and organs are included in the descriptions of the appropriate regional anatomy.

Most lymphocytes enter secondary lymphoid tissues from the blood, usually by migration through the walls of capillaries or high endothelial venules, HEVs (Ch. 6) and leave by the lymphatic system. In the spleen, lymphocyte entry and exit take place via the marginal zone and venous drainage respectively. APCs (dendritic cells) enter via the lymphatics, bringing with them antigen from peripheral infected sites. In all the secondary tissues there are specific areas where either B or T cells are concentrated. After activation, functionally competent lymphocytes migrate to other sites in the body, where they combat the original infection. Organized lymphoid structures, termed tertiary lymphoid organs, can also develop at sites of chronic inflammation (Stranford and Ruddle 2012).

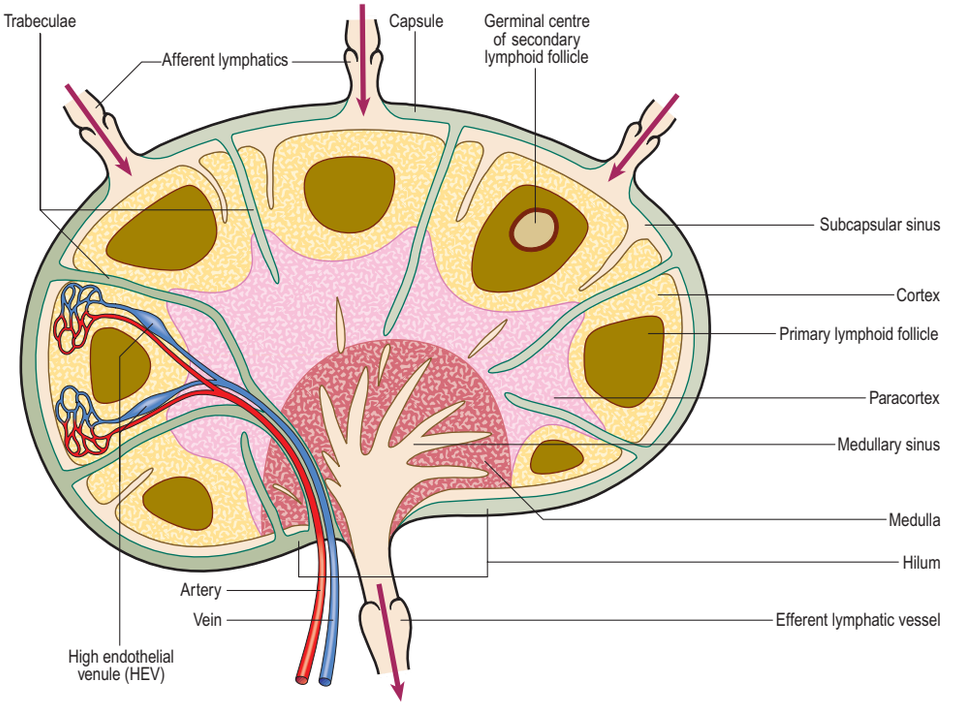

Fig. 4.7 The structure of a lymph node.

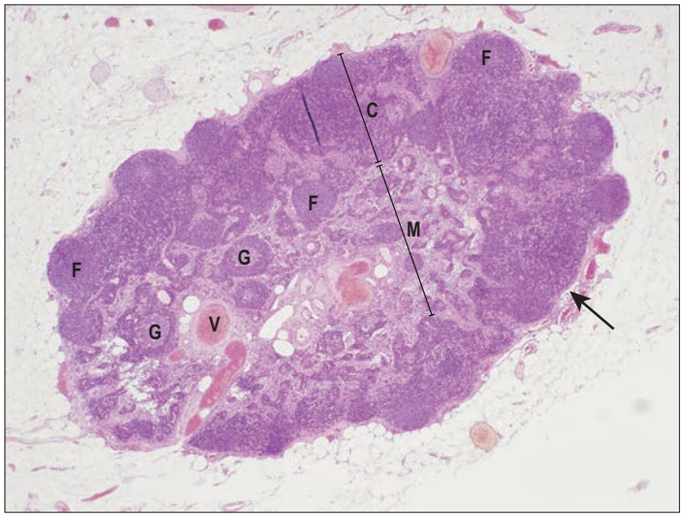

Fig. 4.8 A lymph node (human) showing cortex (C) and medulla (M), and lymphoid follicles (F), some with germinal centres (G). Also shown are the subcapsular sinus (arrow) and medullary blood vessels (V). The dark line (top, centre) is a small crease in the tissue section and is an artefact. Lymph nodes

Lymph nodes (Fig. 4.7) are small encapsulated, oval or kidney-shaped bodies, 0.1–2.5 cm long, lying along the course of the lymphatic vessels. A normal young adult body contains up to 450 lymph nodes, of which 60–70 are found in the head and neck, 100 in the thorax and as many as 250 in the abdomen and pelvis: they are particularly numerous in the neck, mediastinum, posterior abdominal wall, abdominal mesenteries, pelvis and proximal regions of the limbs (axillary and inguinal lymph nodes). By far the greatest number lie close to the viscera, especially in the mesenteries.

Microstructure

The capsule is composed mainly of collagen fibres, elastin fibres (especially in the deeper layers) and a few fibroblasts. Lymph nodes may be subdivided into cortex, paracortex and medulla (Girard et al 2012). Trabeculae of dense connective tissue extend radially into the interior of a node from the capsule and are continuous with a network of fine type III collagen (reticulin) fibrils that branch and interconnect to form a very dense network in the cortex. Reticulin and the associated proteoglycan matrix are produced by fibroblasts associated with the fibrous network. There are fewer fibres in the germinal centres of follicles (see below). The medulla contains a network of minute lymphatic channels (sinuses) through which lymph from the afferent lymphatics is filtered.

Lymphatic and vascular supply

Each lymph node usually has a slight indentation on one side, the hilum, where blood vessels enter or leave, and the efferent lymphatic vessel leaves (Fig. 4.8). Several afferent lymphatic vessels enter the capsule around the periphery. Afferent lymphatic vessels enter at many points on the periphery, branch to form a dense intracapsular plexus, and then open into the subcapsular sinus, a cavity that is peripheral to the whole cortex except at the hilum (see Fig. 4.7) (Roozendaal et al 2008). Numerous radial cortical sinuses lead from the subcapsular sinus to the medulla, where they coalesce as larger medullary sinuses. The latter become confluent at the hilum with the efferent vessel that drains the node. All of these spaces are lined by a continuous endothelium and traversed by fine reticular fibres.

Arteries and veins serving lymph nodes pass through the hilum, giving off straight branches that traverse the medulla and send out minor branches as they do so. In the cortex, arteries form dense arcades of arterioles and capillaries in numerous anastomosing loops, eventually returning to highly branched venules and veins. Capillaries are especially profuse around the follicles, which contain fewer vessels. Postcapillary HEVs are abundant in the paracortical zones. They form an important site of lymphocyte extravasation into lymphoid tissue, apparently by transcellular migration or paracellular transit through labile endothelial tight junctions (occluding junctions) and adherent junctions. The density of the capillary beds increases greatly when lymphocytes multiply in response to antigenic stimulation. Veins leave a node through its principal trabeculae and capsule, and drain them and the surrounding connective tissue.

Cells and cellular zones of lymph nodes

Although most of the cells in a lymph node are B and T lymphocytes, their distribution is not homogeneous. In the cortex, cells are densely packed and in the outer cortical area they form lymphoid follicles or nodules (see Fig. 4.8) populated mainly by B cells and specialized follicular dendritic cells (FDCs) (see Fig. 4.15). The number, degree of isolation and staining characteristics of follicles vary according to their state of antigenic stimulation. A primary follicle is uniformly populated by small, quiescent lymphocytes, whereas a secondary follicle has a germinal centre (Fig. 4.9), composed mainly of antigen-stimulated B cells, which are larger, less deeply staining and more rapidly dividing than those at its periphery.

The role of the germinal centre is to provide a microenvironment that allows the affinity maturation of the B-cell response, so that as the immune response progresses, the affinity or strength with which antibodies bind their antigen increases (Shlomchik and Weisel 2012, Victora and Nussenzweig 2012). B cells (centroblasts) undergo rapid proliferation in the 'dark zone', which is associated with hypermutation of the genes

encoding the variable regions of their antibody molecules. They then move into the 'light zone' (as centrocytes), where they can interact with the FDCs, which carry intact unprocessed antigen on their surface in the form of immune complexes (Rezk et al 2013). The centrocytes compete for binding to the antigen; only those expressing antibody with the highest affinity survive. T cells are also present, helping the survival of the B cells and inducing class switching. Macrophages in the germinal centre phagocytose apoptotic lymphocytes (the B cells that die as part of the process of affinity maturation), and their cytoplasm becomes filled with engulfed lipid and nuclear debris forming intracellular inclusions (hence the alternative name, tingible body macrophage).

The mantle zone (see Fig. 4.9) is produced as surrounding cells are marginalized by the rapidly growing germinal centre. It is populated by cells similar to those found in primary follicles: mainly quiescent B cells with condensed heterochromatic nuclei and little cytoplasm (hence the deeply basophilic staining of this region in routine preparations; **Fig. 4.10**), a few helper T cells, FDCs and macrophages. After numerous mitotic divisions the selected B cells give rise to small lymphocytes, some of which become memory B cells and leave the lymph node to join the recirculating pool, while others leave to mature as antibody-secreting plasma cells either in the lymph node medulla or in peripheral tissues.

The paracortex (deep cortex) lies between the cortical follicles and the medulla. It is populated mainly by T cells, both $CD4^+$ and $CD8^+$ T-cell subsets, which are not organized into follicles. It also contains interdigitating dendritic cells, including Langerhans cells from the skin and other squamous epithelia, which have migrated as veiled cells via the afferent lymphatics into the draining lymph nodes (see Fig. 4.14). Their role is to present processed antigen to T cells. The region expands greatly in T cell-dominated immune responses, when its cells are stimulated to proliferate and disperse to peripheral sites.

In the medulla, lymphocytes are much less densely packed and form irregular, branching medullary cords within the reticulin network. Other cells present include macrophages, which are more numerous than in the cortex, plasma cells and a few granulocytes.

Mucosa-associated lymphoid tissue (MALT)

Unencapsulated lymphoid tissue exists in the walls of the gastrointestinal, respiratory, reproductive and urinary tracts, and in the skin. Collectively, it is termed mucosa-associated lymphoid tissue (MALT): most is found in the gut as gut-associated lymphoid tissue (GALT) (Koboziev et al 2010).

Lymphoid cells are located in the lamina propria and in the submucosa as discrete follicles or nodules. More scattered cells, derived from these follicles, are found throughout the lamina propria and in the base of the epithelium (see Figs 4.5, 4.10). MALT includes macroscopically visible lymphoid masses, notably the peripharyngeal lymphoid ring of tonsillar tissue (palatine, nasopharyngeal, tubal and lingual), and the Peyer's patches of the small intestine, all of which are described elsewhere. Most MALT consists of unencapsulated microscopic aggregates of lymphoid tissue, where the lymphocyte populations are supported mechanically by a network of fine type III collagen (reticulin) fibres and associated fibroblasts, as they are in lymph nodes.

In common with lymph nodes, MALT provides centres for the activation and proliferation of B and T lymphocytes in its follicles and parafollicular zones, respectively. The function of cells in these zones, including APCs (follicular dendritic cells and interdigitating dendritic cells) and macrophages, as well as T and B cells, is similar to that found in lymph nodes. The close proximity of lymphocytes within MALT to an epithelial surface facilitates their access to pathogens. MALT lacks afferent lymphatic vessels. Lymphocytes migrate into MALT through its HEVs and leave mainly via its efferent lymphatics, which drain interstitial fluid as lymph. The lymphocyte population in MALT is not fixed. Migration from MALT follows a different route from the major peripheral route of recirculation. After antigen activation, lymphocytes travel via the regional lymph nodes to disperse widely along mucosal surfaces to provide protective T- and B-cell immunity.

Follicle-associated epithelium

The epithelium covering MALT varies in type according to its location. It is unusual in possessing cells that are involved in sampling antigens and transferring them to APCs in the underlying tissues; appropriate clones of T and B cells in local lymphoid tissues are then activated and amplified prior to their exit via the lymphatics. Specialized epithelial cells in the small and large intestine have characteristic short microvilli on their luminal surfaces and are known as microfold (M) cells (Kraehenbuhl and Neutra 2000); in the palatine tonsils they include modified stratified squamous reticulated epithelial cells (see p. 708). The main function of B lymphocytes in MALT is to produce IgA for secretion into the lumen of the tracts that they line (Cerutti et al 2011).

Many of the lymphocytes migrating between cells in the basal regions of epithelia (see Fig. 4.5) are effector cytotoxic and helper T cells that have already been selected in lymphoid nodules and are engaged in immune responses. Similar cells, and activated IgA-producing B cells and plasma cells, are also scattered throughout the entire mucosal lamina propria.

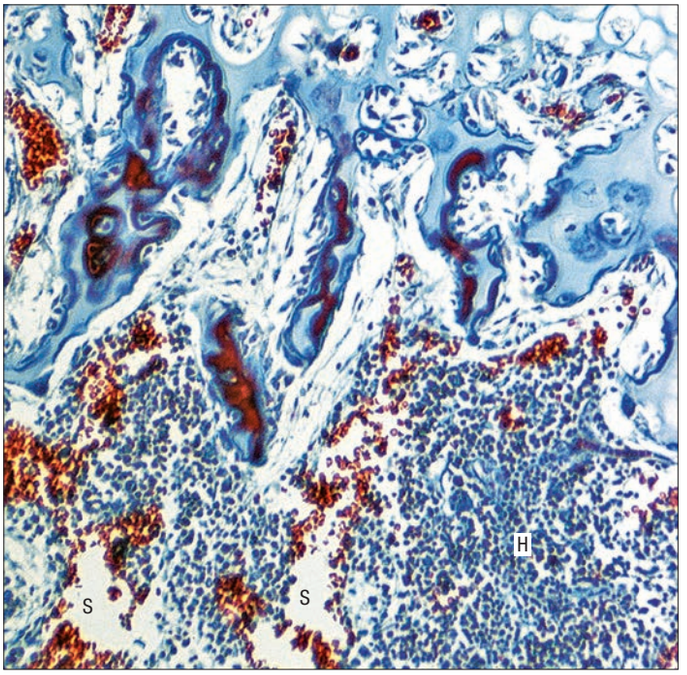

Fig. 4.11 Haemopoietic tissue (H) in the marrow cavity of a fetal long bone undergoing endochondral ossification (top). Islands of densely packed nucleated haemopoietic cells of different lineages are separated by large vascular sinusoids (S), which are filled with mature red blood cells in the general circulation.

HAEMOPOIESIS

Postnatally, blood cells are formed primarily in the bone marrow. Other tissues, particularly the spleen and liver, may develop haemopoietic activity once more, if production from the marrow is inadequate.

Bone marrow

Bone marrow is a soft pulpy tissue that is found in the marrow cavities of all bones (**Fig. 4.11**) and even in the larger Haversian canals of lamellar bone. It consists of vascular and extravascular compartments, both enclosed within a bony framework from which they are separated by a thin layer of endosteal cells. It differs in composition in different bones and at different ages, and occurs in two forms: yellow and red marrow.

Yellow marrow

Yellow marrow consists of a framework of connective tissue that supports numerous blood vessels and cells, most of which are adipocytes. A small population of typical red marrow cells persists and may be reactivated when the demand for blood cells becomes sufficiently great.

Red marrow

Red marrow is found throughout the skeleton in the fetus and during the first years of life. After about the fifth year, the red marrow, which represents actively haemopoietic tissue, is gradually replaced in the long bones by yellow marrow. The replacement starts earlier, and is generally more advanced, in the more distal bones. By 20–25 years of age, red marrow persists only in the vertebrae, sternum, ribs, clavicles, scapulae, pelvis and calvaria, and in the proximal ends of the femur and humerus.

Red bone marrow consists of a network of loose connective tissue, the stroma, supporting clusters of haemopoietic cells (haemopoietic cords or islands). The rich blood supply is derived from the nutrient

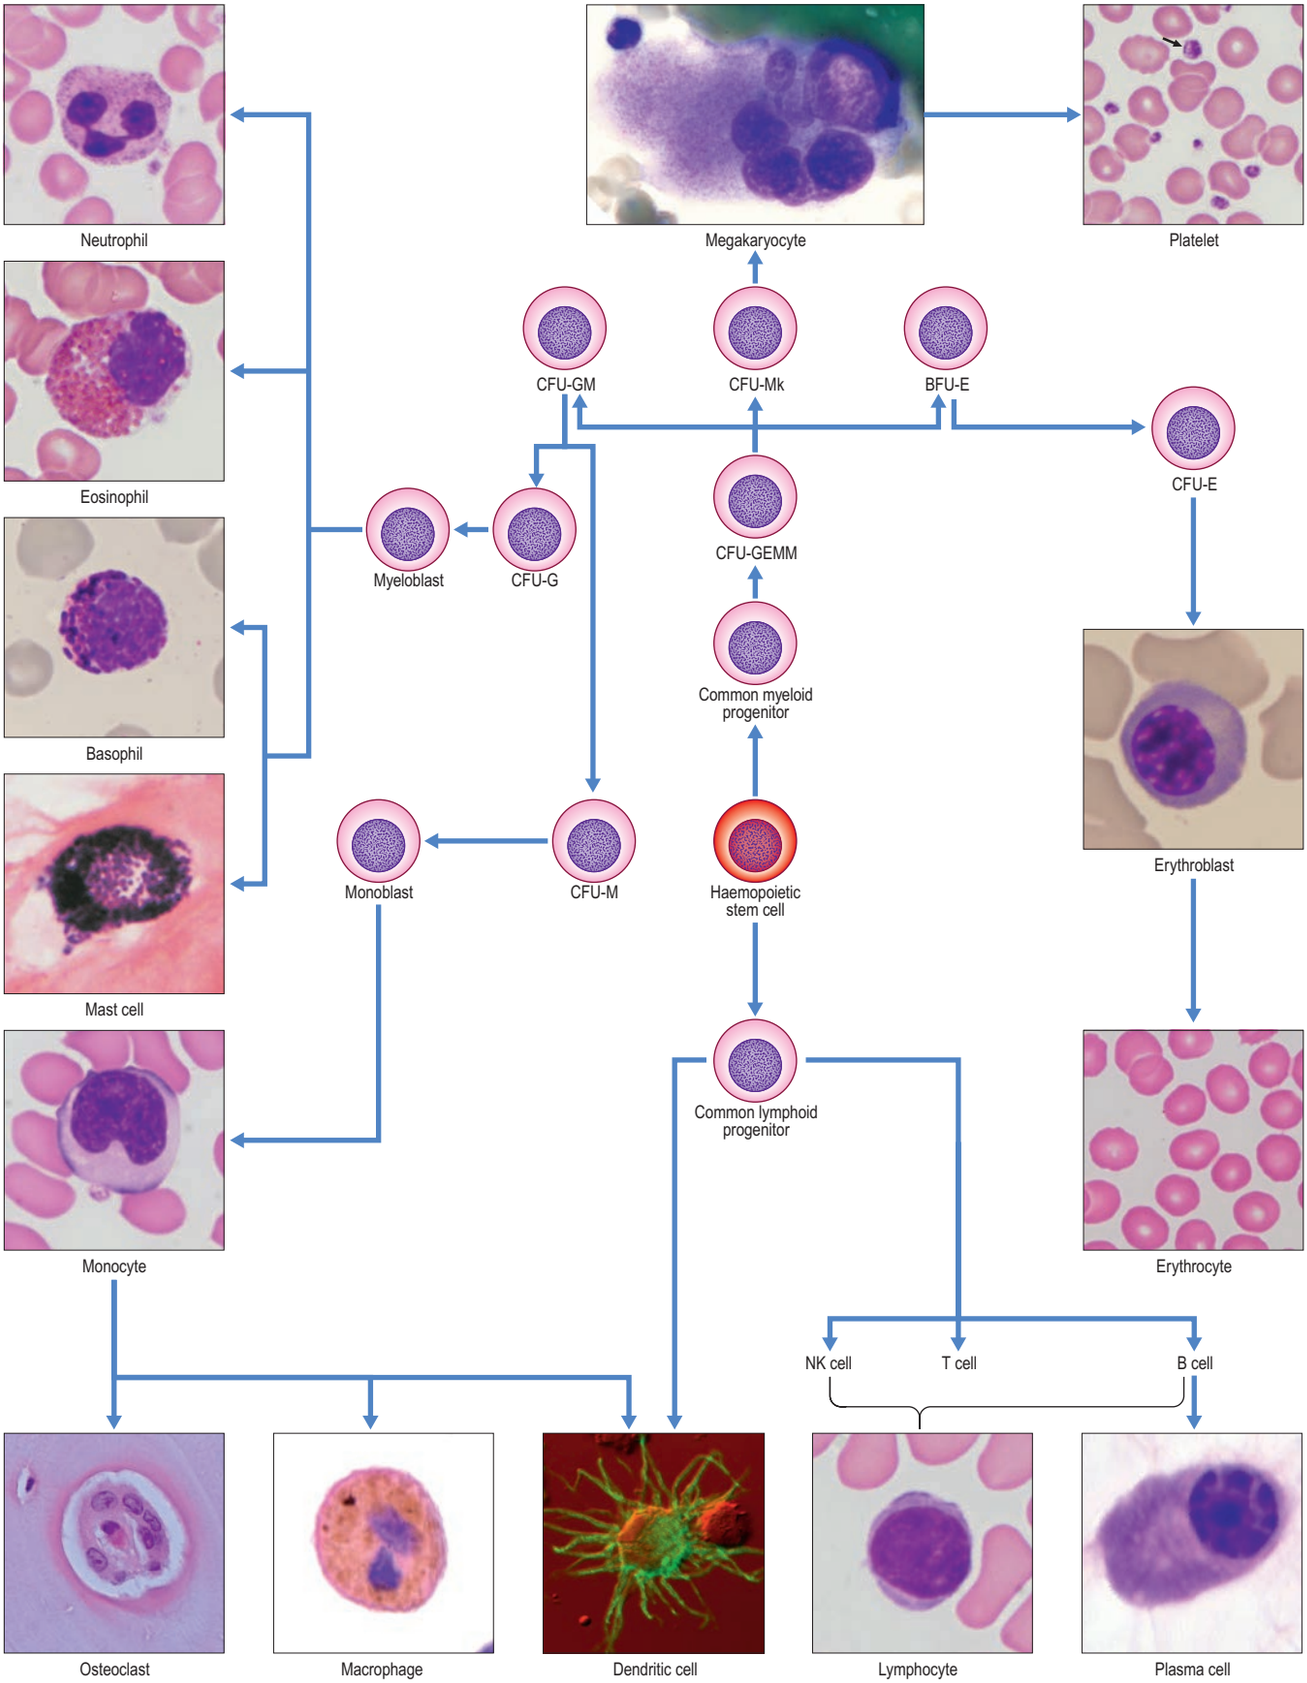

Fig. 4.12 The origins and lineage relationships of haemopoietically derived cells of the immune system. Mature cells and selected progenitors (all human) are illustrated (magnifications vary). The dendritic cell was cultured from peripheral blood, immunolabelled to show HLA-DR and photographed using Nomarski optics. The megakaryocyte and erythroblast are from a bone marrow smear, stained with May–Grünwald–Giemsa (MGG); the remaining cells illustrated are from peripheral blood smears (Wright's stain), sections of connective tissue (plasma cell, mast cell), bone (osteoclast, in Haversian canal) and lung alveolus (macrophage). Platelets (one is arrowed) are subcellular fragments of bone marrow megakaryocytes. Note that circulating small lymphocytes cannot be classified further with routine staining methods. For further explanation of cellular structure and staining properties, along with abbreviations, see the text. (Dendritic cell image courtesy of Dr Cécile Chalouni, Ludwig Institute for Cancer Research, Yale University School of Medicine, USA. All other images courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

artery to the bone. Vessels ramify in the bone marrow, becoming thin-walled arterioles from which sinusoids arise and drain into disproportionately large veins (see Fig. 4.11). The stroma contains a variable amount of fat, depending on site and the age and haematological status of the individual. Lymphatic vessels are absent from bone marrow but small patches of lymphoid tissue are present in the stroma.

Stroma

Stroma is composed of a delicate network of fine type III collagen (reticulin) fibres secreted by highly branched, specialized fibroblast-like cells (reticular cells) derived from embryonic mesenchyme. When haemopoiesis stops, as occurs in most limb bones in adult life, these cells (or closely related cells) become distended with lipid droplets and fill the marrow with yellow fatty tissue (yellow marrow). If there is a later demand for haemopoiesis, the stellate stromal cells reappear. The stroma also contains numerous macrophages attached to extracellular matrix fibres. These cells actively phagocytose cellular debris created by haemopoietic development, especially the extruded nuclei of erythroblasts, remnants of megakaryocytes and cells that have failed the B-lymphocyte selection process. Stromal cells play a major role in the control of haemopoietic cell differentiation, proliferation and maturation.

Marrow sinusoids are lined by a single layer of endothelial cells, supported by reticulin on their basal surfaces. Although the endothelial cells are interconnected by tight junctions, their cytoplasm is extremely thin in places, and the underlying basal lamina is discontinuous. The passage of newly formed blood cells from the haemopoietic compartment into the blood stream appears to occur through an interactive process with the endothelium, producing temporary apertures (large fenestrae) in their attenuated cytoplasm.

Haemopoietic tissue

Cords and islands of haematogenous cells consist of clusters of immature blood cells in various stages of development; several different cell lineages are typically represented in each focal group. One or more macrophages lie at the core of each such group of cells. These macrophages engage in phagocytic functions, are important in transferring iron to developing erythroblasts for haemoglobin synthesis, and may play a role, with other stromal cells, in regulating the rate of cell proliferation and maturation of the neighbouring haemopoietic cells.

Cell lineages

Haemopoietic stem cells

There is a very small number (0.05% of haemopoietic cells) of self-renewing, pluripotent stem cells within adult marrow capable of giving rise to all blood cell types, including lymphocytes (**Fig. 4.12**). Although they cannot be identified morphologically in the marrow, they can be recognized in aspirates by their expression of specific cell-surface marker proteins (e.g. CD34). It is thought that haemopoietic stem cells occupy specific environmental niches in the marrow associated with the endosteum of trabecular bone or with sinusoidal endothelium, and that their microenvironment is important in homeostasis, the balance between self-renewal and differentiation. Stem cells can also be found (at lower concentrations) in the peripheral blood, particularly after treatment with appropriate cytokines.

Progressively more lineage-restricted committed progenitor cells develop from these ancestors to produce the various cell types found in peripheral blood (Laiosa et al 2006). The committed progenitor cells are often termed colony-forming units (CFU) of the lineage(s), e.g. CFU-GM cells give rise, after proliferation, to neutrophil granulocytes, monocytes and certain dendritic cells, whereas CFU-E produce only erythrocytes. Each cell type undergoes a period of maturation in the marrow, often accompanied by several structural changes, before release into the general circulation. In some lineages, e.g. the erythroid series, the final stages of maturation take place in the circulation, whereas in the monocytic lineage, they occur after the cells have left the circulation and entered peripheral tissues where they differentiate into macrophages and some dendritic cells.

To generate a complete set of blood cells from a single pluripotent cell may take some months. The later progenitor cells form mature cells of their particular lineages more quickly. However, because they are not self-renewing, grafts of these later cells eventually fail because the cells they produce all ultimately die. This is of considerable importance in bone marrow replacement therapy. The presence of pluripotent stem cells in the donor marrow is essential for success; only 5% of the normal number are needed to repopulate the marrow. Following replacement therapy, T lymphocytes reconstitute more slowly than the other haemopoietic lineages, reflecting the progressive reduction in size of the thymus with age (chronic involution).

Within the bone marrow there is also a population of mesenchymal progenitor cells that can differentiate into a wide variety of non-haemopoietic cells. These pluripotent progenitor cells can also be found in the circulation, and are being investigated for their use in repairing damaged organs.

Lymphocytes

Lymphocytes are a heterogeneous group of cells that may share a common ancestral lymphoid progenitor cell, distinct from the myeloid progenitor cell (see Fig. 4.12). The first identifiable progenitor cell is the lymphoblast, which divides several times to form prolymphocytes; both cells are characterized by a high nuclear:cytoplasmic ratio. B cells undergo differentiation to their specific lineage subset entirely within the bone marrow and migrate to peripheral or secondary lymphoid tissues as naïve B cells, ready to respond to antigen. However, T cells require the specialized thymic microenvironment for their development. During fetal and early postnatal life, and subsequently at lower levels throughout life, progenitor cells migrate to the thymus where they undergo a process of differentiation and selection as T cells, before leaving to populate secondary lymphoid tissues.

B-cell development

B cells start their development in the subosteal region of the bone marrow and move centripetally as differentiation progresses. Their development entails the rearrangement of immunoglobulin genes to create a unique receptor for antigen on each B cell, and the progressive expression of cell-surface and intracellular molecules required for mature B-lymphocyte function. Autoreactive cells that meet their self-antigen within the bone marrow are eliminated. Overall, some 25% of B cells successfully complete these developmental and selection processes; those that fail die by apoptosis and are removed by macrophages. Bone marrow stromal cells (fibroblasts, fat cells and macrophages) express cell-surface molecules and secrete cytokines that control B-lymphocyte development. The mature naïve B lymphocytes leave via the central sinuses. They express antigen receptors (immunoglobulin) of IgM and IgD classes. Class switching to IgG, IgA and IgE occurs in the periphery following antigen activation in response to signals from T helper cells (see Fig. 4.15).

T-cell (thymocyte) development

T cells develop within the thymus from blood-borne, bone marrow-derived progenitors that enter the thymus via HEVs at the corticomedullary junction. They first migrate to the outer (subcapsular) region of the thymic cortex and then, as in the bone marrow, move progressively inwards towards the medulla as development continues. T-cell development involves gene rearrangements in the T-cell receptor (TcR) loci to create unique receptors for antigen on each cell, together with the progressive expression of molecules required for mature T-cell function. Selection of the receptor repertoire is more stringent for T cells than for B cells because of the way in which mature T cells recognize peptides derived from protein antigens presented in conjunction with specific molecules of the major histocompatibility complex (MHC) expressed on the surfaces of cells. Thus mature $CD8^+$ (cytotoxic) T cells recognize antigen in the form of short peptides complexed with the polymorphic MHC class I molecules, while $CD4^+$ (helper/regulatory) T cells recognize the peptides in the context of MHC class II molecules. As the TcR recognizes both the peptide and the MHC molecule, the T cell will only recognize peptides bound to their own (self) type of MHC; it will not 'see' peptides in combination with allelically different MHC molecules (i.e. those from other individuals). This is termed MHC restriction of T-cell recognition. Selection of T cells in the thymus must ensure the survival of those T cells that can respond only to foreign antigens, bound to their own (self) class of MHC molecule. Cells that are incapable of binding to self MHC molecules, or which bind to self-antigens, are eliminated by apoptotic cell death; it is estimated that up to 95% of T-cell progenitors undergo apoptosis in this way. Cells that express an appropriate TcR and have effective MHC-restricted binding properties survive to become mature, naïve T cells that leave the thymus and populate the periphery.

Thymic stromal cells play a crucial role in T-cell development and selection. Thymic epithelial cells in the cortex express both MHC class I and II molecules and are unique in their ability to select T cells that recognize self MHC with a moderate affinity (positive selection). Deletion of self-antigen reactive cells (negative selection) is mainly controlled by thymic dendritic cells located at the corticomedullary junction and in the medulla, although the epithelium can also perform this function. Apoptotic thymocytes are removed by thymic

macrophages. The role of the thymic epithelium in thymocyte differentiation is complex and involves cell–cell contact as well as the secretion of soluble mediators such as cytokines, chemokines, neuroactive peptides (e.g. somatostatin) and thymic hormones (e.g. thymulin). Thymic fibroblasts and the extracellular matrix also play a role.

Erythrocytes

Erythrocytes and granulocytes belong to the myeloid lineage. The earliest identifiable erythroid progenitor cells are capable of rapid bursts of cell division to form numerous daughter cells; they have thus been named burst-forming units of the erythroid line (BFU-E; see Fig. 4.12). They give rise to the CFU-E, which, with their immediate progeny, are sensitive to the hormone erythropoietin. This hormone, produced in the kidney, induces further differentiation along the erythroid line.

The first readily identifiable cell of the erythroid series is the proerythroblast, which is a large cell (about 20 μm) with a large euchromatic nucleus and a moderately basophilic cytoplasm. It responds to erythropoietin. The proerythroblast contains small amounts of ferritin and bears some of the protein spectrin on the cytoplasmic surface of its plasma membrane. Proerythroblasts proliferate to produce smaller (12–16 μm) basophilic erythroblasts, rich in ribosomes, in which haemoglobin RNA synthesis begins. The cytoplasm becomes partially, and then uniformly, eosinophilic (the polychromatic erythroblast and orthochromatic erythroblast, respectively). These cells are only 8–10 μm in diameter and contain very little cytoplasmic RNA. Their nuclei become pyknotic (dense, deep-staining, shrunken) and are finally extruded, leaving anucleate reticulocytes, which enter sinusoids. Their reticular staining pattern, visible using special stains, is a consequence of residual cytoplasmic RNA, which is usually lost within 24 hours of entering the peripheral blood circulation: reticulocyte numbers in peripheral blood are therefore a good indicator of the rate of red cell production. The whole process of erythropoiesis takes 5–9 days.

Granulocytes

Granulocyte formation involves major changes in nuclear morphology and cytoplasmic contents, which are best known for the neutrophil. Initially, myeloid progenitor cells transform into large myeloblasts (10–20 μm) that are similar in general size and appearance to proerythroblasts. These proliferative cells have large euchromatic nuclei and lack cytoplasmic granules. They differentiate into slightly larger promyelocytes, in which the first group of specialized proteins is synthesized in the rough endoplasmic reticulum and Golgi apparatus. The proteins are stored in large (0.3 μm) primary (non-specific) granules, which are large lysosomes containing acid phosphatase. Smaller secondary (specific) granules are formed in the smaller myelocyte, which is the final proliferative stage. Myelocyte nuclei are typically flattened or slightly indented on one side.

The next stage produces a metamyelocyte: the cell size decreases (10–15 μm), the nucleus becomes heterochromatic and horseshoe-shaped, and protein synthesis almost stops. As the neutrophil is released, the nucleus becomes first heavily indented (the juvenile stab or band form), and subsequently segmented into up to six lobes, characteristic of the mature neutrophil. The whole process usually takes 7 days to complete (3 days proliferating and 4 days maturing). Neutrophils may then be stored in the marrow for a further 4 days, depending on demand, before their final release into the circulation.

Eosinophils and basophils pass through a similar sequence but their nuclei do not become as irregular as that of the neutrophil. It is thought that these cells each arise from distinct colony-forming units, which are separate from the CFU-GM.

Monocytes

Monocytes are formed in the bone marrow. Monocytes and neutrophils appear to be closely related cells: together with some of the antigen-presenting dendritic cells, they arise from a shared progenitor, the colony-forming unit for granulocytes and macrophages (CFU-GM). Different colony-stimulating factors (CSF) act on the common progenitor to direct its subsequent differentiation pathway. Monocyte progenitors pass through a proliferative monoblast stage (14 μm) and then form differentiating promonocytes, which are slightly smaller cells in which production of small lysosomes begins. After further divisions, monocytes (up to 20 μm) are released into the general circulation. Most migrate into perivascular and extravascular sites that they populate as macrophages, while others may give rise to certain dendritic cells, including Langerhans cells.

Platelets

Platelets arise in a unique manner by the shedding of thousands of cytoplasmic fragments from the tips of processes of megakaryocytes in the bone marrow. The first detectable cell of this line is the highly basophilic megakaryoblast (15–50 μm), followed by a promegakaryocyte stage (20–80 μm), in which synthesis of granules begins. Finally, the fully differentiated megakaryocyte, a giant cell (35–160 μm) with a large, dense, polyploid, multilobed nucleus, appears. Once differentiation is initiated from the CFU-Meg, DNA replicates without cytoplasmic division (endoreduplication), and the chromosomes are retained within a single polyploid nucleus that may contain up to 256n chromosomes (where n is the haploid complement present in gametes).

The cytoplasm contains fine basophilic granules. It becomes partitioned into proplatelets by invaginations of the plasma membrane, that appear ultrastructurally as a network of tubular profiles which coalesce to form cytoplasmic islands 3–4 μm in diameter. Individual platelets are shed into the circulation from a long, narrow process of megakaryocyte cytoplasm that is protruded through an aperture in the sinusoidal endothelium.

PHAGOCYTES AND ANTIGEN-PRESENTING CELLS

Macrophages and neutrophils are specialized phagocytes. Certain dendritic cells (see Fig. 4.12), e.g. Langerhans cells of the skin and other stratified squamous epithelia, are 'professional' antigen-presenting cells (APCs); they take up foreign material by endocytosis and macropinocytosis, and are uniquely capable of efficiently activating naïve as well as mature T lymphocytes. Macrophages are able to process and present antigen to lymphocytes, but are less effective than dendritic cells. They also play an important role in the effector arm of the immune response, clearing the infectious agent by phagocytosis. The third major cell type involved in antigen presentation and T-cell activation is the B lymphocyte, which is particularly efficient at taking up antigen that binds to its surface immunoglobulin. Follicular dendritic cells (FDCs) of lymph nodes, MALT and the spleen are capable of presenting non-processed antigen to B lymphocytes, but are not classic APCs because they cannot present antigen to helper T cells.

APCs endocytose antigen, digest it intracellularly, mostly to peptide fragments, and present the fragments on their surfaces, generally in conjunction with MHC class II molecules. (Class II molecules are normally found only on APCs, although many other cells can express class II molecules in inflammatory situations.) Recognition of foreign antigen is controlled by a variety of APC cell-surface receptors: Fc and complement receptors mediate uptake of opsonized material, while pattern recognition receptors of the innate immune system, e.g. Toll-like receptors and scavenger receptors, directly recognize pathogen-derived molecules.

Macrophages

The mononuclear phagocyte system consists of the blood monocytes, from which the other types are derived, and various tissue macrophages, some of which have tissue-specific names. Certain dendritic cells are

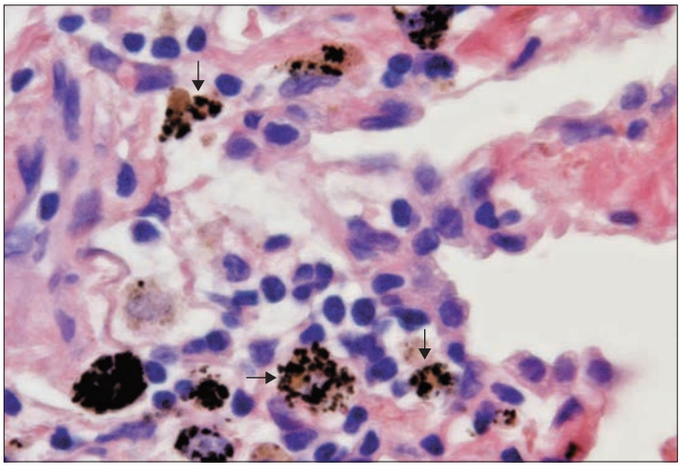

Fig. 4.13 Alveolar macrophages (dust cells, arrows) containing ingested carbon particles, in alveoli and interalveolar septa of the human lung. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

sometimes included in the mononuclear phagocyte system;: they share a common lineage ancestor but appear to form a discrete branch of the family tree. Most monocytes and macrophages express class II MHC molecules.

Macrophages are very variable in size (generally 15–25 μm) and are found in many tissues of the body, where they constitute a heterogeneous family of cells (Gordon and Taylor 2005). They are migrant cells in all general connective tissues, in bone marrow and all lymphoid tissues, and include alveolar macrophages in the lung and Kupffer cells in liver sinusoids. They often aggregate in subserous connective tissue of the pleura and peritoneum, where they are visible as milky spots near small lymphatic trunks, and cluster around the terminations of small (penicillar) arterioles in the spleen, where they are also distributed, more diffusely, throughout the splenic cords.

Osteoclasts in bone are closely related to macrophages; they are syncytial cells derived from the fusion of up to 30 progenitor monocytes in bone tissue, where they differentiate further. Microglia of the central nervous system originate from an embryonic monocyte precursor and migrate into the central nervous system during its development. They differ from macrophages in that normally they are quiescent cells in which MHC class II expression is downregulated, and they display little phagocytic activity.

Macrophages vary in structure depending on their location in the body. All have a moderately basophilic cytoplasm containing some rough and smooth endoplasmic reticulum, an active Golgi complex and a large, euchromatic and somewhat irregular nucleus. These features are consistent with an active metabolism: synthesis of lysosomal enzymes continues in mature cells. All macrophages have irregular surfaces with protruding filopodia and they contain varying numbers of endocytic vesicles, larger vacuoles and lysosomes. Some macrophages are highly motile, whereas others tend to remain attached and sedentary, e.g. in hepatic and lymphoid sinuses. Within connective tissues, macrophages may fuse to form large syncytia (giant cells) around particles that are too large to be phagocytosed, or when stimulated by the presence of infectious organisms, e.g. *Mycobacterium tuberculosis,* leading to granuloma formation.

When blood-borne monocytes enter the tissues through the endothelial walls of capillaries and venules, they can undergo a limited number of rounds of mitosis as tissue macrophages before they die and are replaced from the bone marrow, typically after several weeks. There is some evidence that alveolar macrophages of the lung are able to undergo many more mitoses than other macrophages.

Phagocytosis

The uptake of particulate material and microorganisms is carried out by macrophages in many tissues and organs. When present in general connective tissues, they ingest and kill invading microorganisms and remove debris that has been produced as a consequence of tissue damage. They recognize, engulf and rapidly ingest apoptotic cells in all situations. The mechanism of apoptotic cell uptake does not activate the phagocyte for antigen presentation, and so the process is immunologically silent. In the lung, alveolar macrophages constantly patrol the respiratory surfaces, to which they migrate from pulmonary connective tissue (Fig. 4.13). They engulf inhaled particles, including bacteria, surfactant and debris, and many enter the sputum (hence their alternative names, dust cells or, in patients with left heart failure or chronic pulmonary oedema, heart failure cells, which are full of extravasated erythrocytes). They perform similar scavenger functions in the pleural and peritoneal cavities. In lymph nodes, macrophages line the walls of sinuses and remove particulate matter from lymph as it percolates through them. In the spleen and liver, macrophages are involved in particle removal and in the detection and destruction of aged or damaged erythrocytes. They begin the degradation of haemoglobin for recycling iron and amino acids.

Phagocytes recognize molecular patterns on the pathogen surface (pathogen-associated molecular patterns, PAMPs) via their PAMP-recognising receptors (PRRs). Some PRRs are phagocytic receptors (mannose and scavenger receptors) while others can act as sensors (Toll-like receptors), causing macrophages to secrete proinflammatory cytokines, such as TNF-α.

Macrophages bear surface receptors for the Fc portions of antibodies and for the fragments of the C3 component of complement. Phagocytic activity is greatly increased when the target has been coated in antibody (opsonized) or complement, or both. Once phagocytosis has occurred, the vacuole bearing the ingested particle fuses with endosomal vesicles, which contain a wide range of lysosomal enzymes, including many hydrolases, and oxidative systems capable of rapid bacteriocidal action. These activities are much enhanced when macrophages are stimulated (activated macrophages) by cytokines, e.g. IFN-γ, which are secreted by other cells of the immune system, especially T lymphocytes.

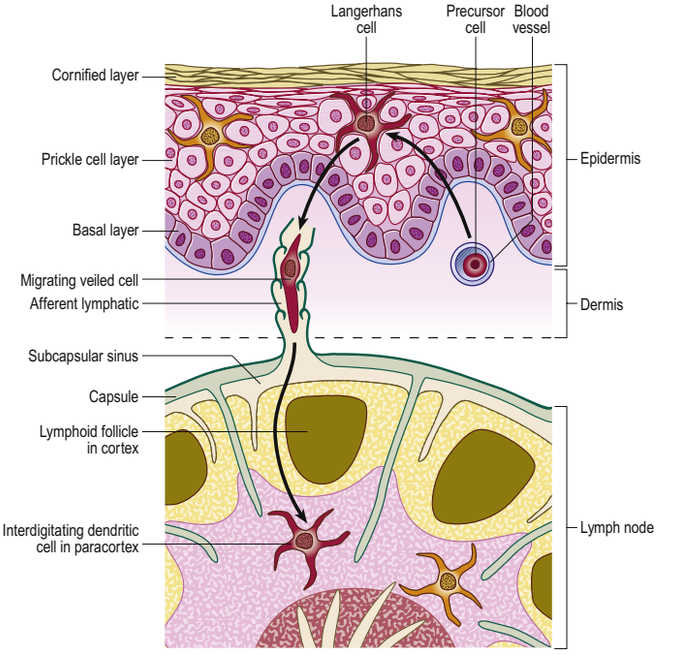

Fig. 4.14 Dendritic cells in the skin and lymphoid tissues. Their migratory routes are shown: from blood-borne, marrow-derived precursors to immature dendritic cells (Langerhans cells) in skin, and then to migrating veiled cells in afferent lymphatic vessels and interdigitating dendritic cells in lymph nodes. An example of each cell in the sequence (arrowed) is shown in red.

Close antibody-mediated binding may initiate the release of lysosomal enzymes onto the surfaces of the cellular targets to which the macrophages bind. This process of cytotoxicity is also used by other cells, including neutrophils and eosinophils, particularly if the targets are too large to be phagocytosed (e.g. nematode worm parasites).

Secretory activities

Activated macrophages can synthesize and secrete various bioactive substances, e.g. IL-1, which stimulate the proliferation and maturation of other lymphocytes, greatly amplifying the reaction of the immune system to foreign antigens. They also synthesize TNF-α, which is able to kill small numbers of neoplastic cells. TNF-α depresses the anabolic activities of many cells in the body, and may be a major factor mediating cachexia (wasting), which typically accompanies more advanced cancers. Other macrophage products include plasminogen activator, which promotes clot removal; various lysosomal enzymes; several complement and clotting factors; and lysozyme (an antibacterial protein). In pathogenesis, these substances may be released inappropriately and damage healthy tissues, e.g. in rheumatoid arthritis and various other inflammatory conditions.

Dendritic cells

There are two distinct groups of dendritic cells: myeloid dendritic cells (also known as classic dendritic cells) and plasmacytoid dendritic cells (Liu 2001, Merad et al 2013, Gerlach et al 2013). These cells can arise from common lymphoid progenitors and common myeloid progenitors. Both groups of cells are involved in antigen presentation, although they have somewhat different functional roles in controlling both the adaptive and innate immune systems. Myeloid dendritic cells are able to process and present antigen to T lymphocytes, including naïve T cells. They are present as immature dendritic cells in the epidermis of the skin (Fig. 4.14) and other stratified squamous epithelia, e.g. the oral mucosa (Langerhans cells), and in the dermis and most other tissues (tissue resident or interstitial dendritic cells), where they are concerned with immune surveillance. Immature dendritic cells have an antigen-capturing function. They can remain in the tissues for days to weeks before undergoing maturation.

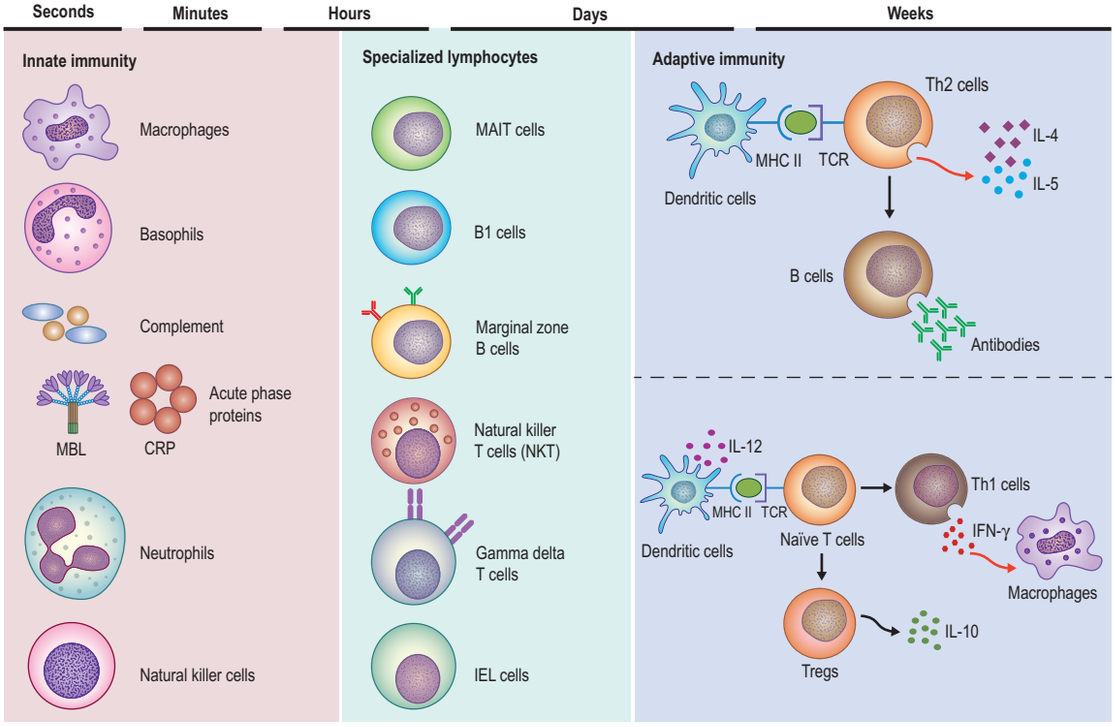

Fig. 4.15 The immune system has two well-developed arms: innate and adaptive**.** The innate immune response against invading pathogens is induced very swiftly, involving opsonization, phagocytosis, complement activation and pro-inflammatory cytokine production. Adaptive immunity develops within a few weeks, involving MHC class II loaded peptide presentation by dendritic cells to $CD4^+$ T cells. Subsequently, a Th2 response involving IL-4 and IL-5 instructs B cells to produce antibodies targeting extracellular pathogens, whereas a Th1 response, involving IFN-γ production, activates macrophages to eliminate intracellular pathogens. Specialized lymphocytes with limited recognition and effector properties act during the time between triggering of innate and adaptive immune responses, thus acting as a bridge between the two arms of the immune system. Abbreviations: CRP, C-reactive protein; IEL, intraepithelial lymphocyte; MAIT, mucosal-associated invariant T cell; MBL, mannan-binding lectin. (Adapted with permission from an illustration by Dr Iesha Singh, Imperial College London.)

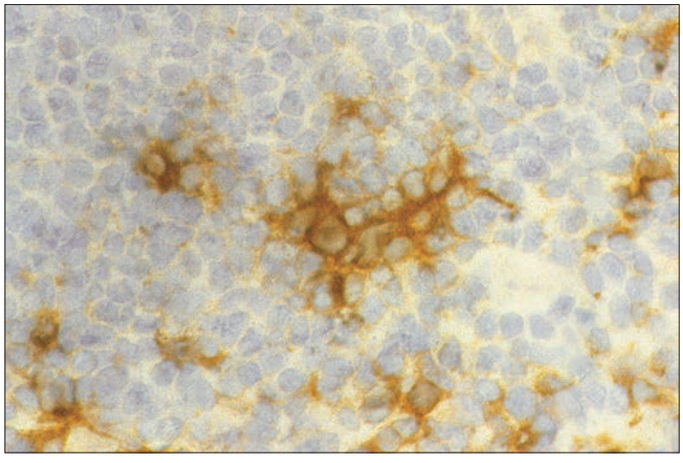

Fig. 4.16 Follicular dendritic cells (brown) in a germinal centre of the human palatine tonsil (immunoperoxidase-labelled). (Courtesy of Marta Perry MD, UMDS, London.)

Dendritic cells respond to chemotactic signals, e.g. defensins released by epithelial cells in the small intestine, and they express pattern recognition receptors (e.g. Toll-like receptors) on their surface. Binding of PAMPs derived from bacteria (e.g. carbohydrate, lipopolysaccharide or DNA) to these receptors stimulates the dendritic cells to become activated and migrate via the lymphatics to nearby secondary lymphoid tissues, where they can present antigen to T cells. They can also be activated by recognition of damage-associated molecular patterns (DAMPs), such as ATP, DNA, heat-shock proteins and high-mobility group box 1 (HMGB1) released from injured or necrotic cells.

Mature dendritic cells are known as veiled cells when in the afferent lymphatics and the subcapsular sinuses of lymph nodes, and as interdigitating dendritic cells once they are within the lymphoid tissue proper. Their function within the secondary lymphoid tissue is to present their processed antigen to T lymphocytes, and thus to initiate and stimulate the immune response. With maturation, innate immune receptors (PRRs) and phagocytic capabilities are lowered, while they start to express receptors that facilitate their migration to the T cell zones of the lymph nodes.

Dendritic cells are the most potent antigen-capturing and antigen-presenting immune cells. They are stimulated via PAMP-recognizing Toll-like receptors leading to upregulation of MHC class II molecules and expression of specialized co-stimulatory molecules required for naïve T cell proliferation. Thus, dendritic cells can act as a link between innate and adaptive immunity (**Fig. 4.15**).

Langerhans cells

Langerhans cells (see Fig. 4.14) are one of the best studied types of immature dendritic cell (Berger et al 2006, Chopin and Nutt 2015). They are present throughout the epidermis of skin, where they were first described, but are most clearly identifiable in the stratum spinosum. They have an irregular nucleus and a clear cytoplasm, and contain characteristic elongated membranous vesicles (Birbeck granules). Langerhans cells endocytose and process antigens, undergoing a process of maturation from antigen-capturing to antigen-presenting cells that express high levels of MHC class I and II molecules, co-stimulatory molecules and adhesion molecules. They migrate to lymph nodes to activate T lymphocytes.

Interdigitating dendritic cells

Immature dendritic cells are found all over the body, including peripheral blood, and function in antigen-processing and immune surveillance.

Mature dendritic cells are present in T-cell-rich areas of secondary lymphoid tissue (paracortical areas of lymph nodes, interfollicular areas of MALT, peri-arteriolar sheaths of splenic white pulp), where they are frequently referred to as interdigitating dendritic cells. Within the secondary lymphoid tissues, they are involved in the presentation to T lymphocytes of antigens associated with either MHC class I ($CD8^+$ T cells) or MHC class II ($CD4^+$ T cells) molecules. Naïve T cells can only respond to antigen presented by dendritic cells. T cells are stimulated by recognition of the antigen–MHC complex by the TcR, by interaction with co-stimulatory molecules expressed by the dendritic cells, and by cytokines secreted by the cells. These cytokines not only help activate the T cell but can also direct the nature of the T-cell response (e.g. Th1 or Th2). Appropriate T cells are thus activated to proliferate and are primed for carrying out their immunological functions. Once primed, T cells can then be stimulated by any APC, including macrophages and B cells.

Follicular dendritic cells

Follicular dendritic cells (FDCs; **Fig. 4.16**) are a non-migratory population of cells found in the follicles of secondary lymphoid tissues, where they attract and interact with B cells. Unlike other dendritic cells, FDCs are not haemopoietic in origin but are probably derived from the stromal cells of lymphoid tissues. They are unable to endocytose and process antigen, and they lack MHC class II molecules. However, Fc receptors and complement receptors CD21 and CD35 on FDCs allow the cells to bind immune complexes to their surface for subsequent presentation, as unprocessed antigen, to germinal centre B cells. Interactions between B cells, $CD4^+$ helper T cells and FDCs in the germinal centres are important in the selection of high-affinity B cells and their maturation to either plasma cells or memory B lymphocytes (Liu 2001).

CHAPTER 5

Functional anatomy of the musculoskeletal system

The musculoskeletal system comprises the specialized connective tissues of the articulated bony skeleton (including bone, cartilage and tendon) and the skeletal muscles that act across the articulations. Connective tissues are characterized by a sparse population of cells within an abundant and physically durable extracellular matrix. All of the specialized cells of the musculoskeletal system are related members of the connective tissue family and are derived from embryonic mesenchymal stem cells.

CARTILAGE

Cartilage is the fetal precursor tissue in the development of many bones. In the adult skeleton it persists at almost all joints between bones and in structures that must be deformable as well as strong, e.g. in the respiratory tract.

Microstructure of cartilage

Cartilage is a pliant, load-bearing connective tissue, covered by a fibrous perichondrium except at its junctions with bones and over the articular surfaces of synovial joints. It has a capacity for rapid interstitial and appositional growth in young and growing tissues. Three types of cartilage (hyaline cartilage, white fibrocartilage and yellow elastic cartilage) can be distinguished on the basis of the composition and structure of their extracellular matrices, but many features of the cells and matrix are common to all three types, and these features will be considered first.

Extracellular matrix

The matrix is mostly comprised of collagen (and, in some cases, elastic) fibres, embedded in a highly hydrated proteoglycan gel (**Fig. 5.1**). Large proteoglycan molecules have numerous side chains of glycosaminoglycans (GAGs), carbohydrates with remarkable water-binding properties. A preponderance of fixed negative charges on the surface of GAGs strongly attract polarized water molecules, causing wet cartilage to swell until restricted by tension in the collagen network, or by external loading. In this way, cartilage develops a compressive turgor that enables it to distribute loading evenly on to subchondral bone, rather like a water bed. Effectively, water is held in place by proteoglycans, which are themselves held in place by the collagen network. Cartilage proteoglycans are similar to those found in general, i.e. non-specialized, connective tissue. The most common GAG side chains in cartilage are chondroitin sulphate and keratan sulphate. The most common proteoglycan molecule, aggrecan, forms huge molecular aggregates with other proteoglycans and with hyaluronan (see Fig. 5.1). Other constituents of cartilage include dissolved salts, non-collagenous proteins and glycoproteins.

Collagens are described on p. 39. The collagen network varies in different types of cartilage and with age. Collagen type I forms large fibres with a wavy 'crimped' structure: it is common in most fibrous tissues, but in cartilage it occurs only in the outer layers of the perichondrium, and in white fibrocartilage. More typical of cartilage is collagen type II, which forms very thin fibrils dispersed between the proteoglycan molecules so that they do not clump together to form larger fibres. Collagen type II fibrils are often less than 50 nm in diameter and are too small to be seen by light microscopy. Transmission electron microscopy reveals that they have a characteristic cross-banding (65 nm periodicity) and are interwoven to create a three-dimensional meshwork. The length of collagen fibres and fibrils in cartilage is unknown, but even relatively short fibrils can reinforce the matrix by interacting physically and chemically with each other, and with other matrix constituents including proteoglycans (Hukins and Aspden 1985), reflecting the fact that the word collagen means 'glue-maker'. Collagen type II is found in hyaline cartilage, the notochord, the nucleus pulposus of an intervertebral disc, the vitreous body of the eye, and the primary corneal stroma.

Cartilage cells

The cells of cartilage are chondroblasts and chondrocytes. Chondroblasts are actively dividing cells, often flattened and irregular in shape, and are abundant in growing tissue where they synthesize the extracellular matrix (**Fig. 5.2**). Small projections arising from the cell membrane (**Fig. 5.3**) can form gap junctions with adjacent cells (Bruehlmann et al 2002), but these junctions may be lost when interstitial growth causes greater cell separation. As chondroblasts mature and lose the ability to divide, they develop into the larger but metabolically less active chondrocytes. These oval-shaped cells form sparse populations that maintain the extensive matrix of adult cartilage. The name 'chondrocyte' is commonly employed, as it is here, to denote all of the cartilage cells embedded in an extensive matrix. Chondrocytes are normally in close contact with their dense matrix (see Fig. 5.3); however, artefacts of tissue processing can sometimes give the illusion of an empty space or 'lacuna' surrounding

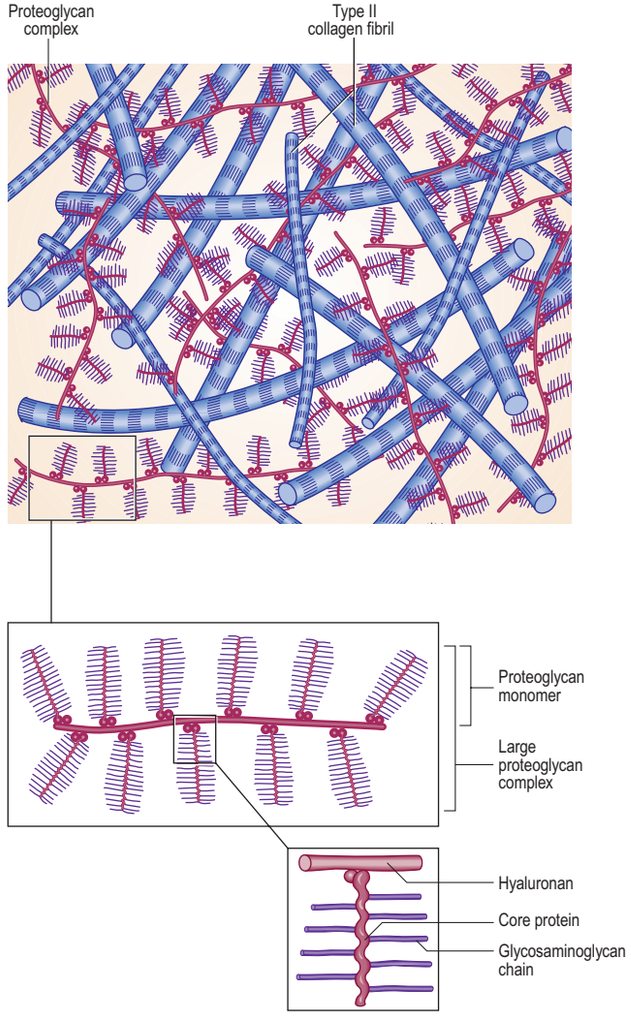

Fig. 5.1 The fine structural organization of hyaline cartilage matrix. Large proteoglycan complexes and type II collagen fibres (cross-banded and of different diameters) are depicted. Proteoglycan complexes bind to the surface of these fibres via their monomeric side chains and link them together. The arrangement of glycosaminoglycans and core protein of the proteoglycan monomer is illustrated in the expansion.

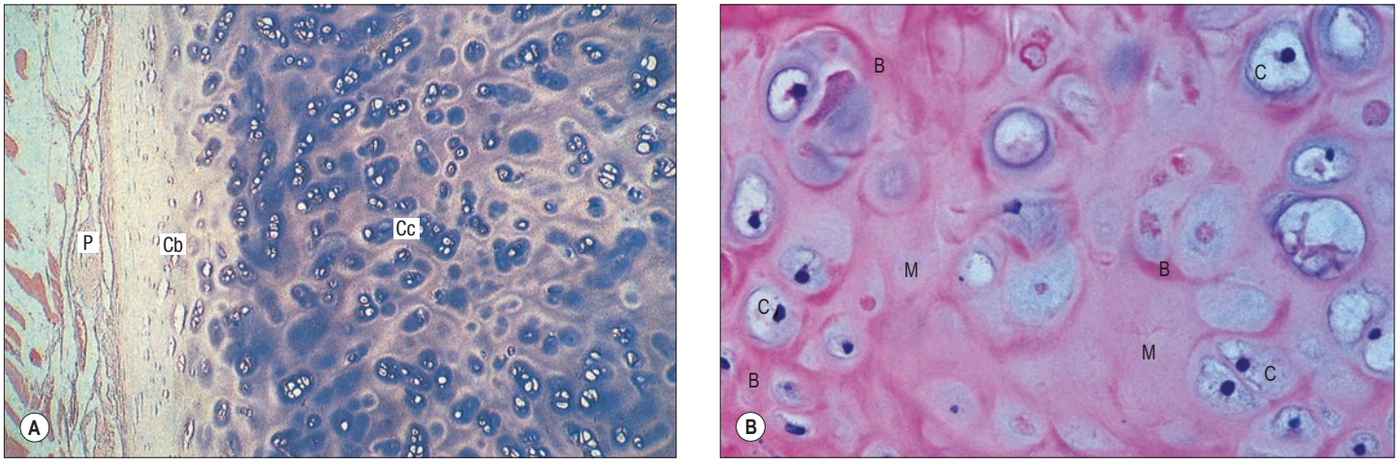

Fig. 5.2 Sections through hyaline cartilage. **A**, A low-power view of human rib, showing perichondrium (P), young chondroblasts (Cb) embedded in pale-staining interterritorial matrix, and mature chondrocytes (Cc) embedded in the basophilic interterritorial matrix (centre and right). **B**, Higher magnification of hyaline cartilage in human bronchial wall, showing isogenous groups of chondrocytes (C). Note the more deeply stained basophilic zones (B) (rich in acidic proteoglycans) around the cell clusters, with older, paler-staining matrix (M) between clusters. Fig. 5.3 An electron micrograph of chondroblasts in rabbit femoral condylar cartilage. The central cell has an active euchromatic nucleus with a prominent nucleolus, and its cytoplasm contains concentric cisternae of rough endoplasmic reticulum, scattered mitochondria, lysosomes and glycogen aggregates. The plasma membrane bears numerous short filopodia which project into the surrounding matrix. The latter shows a delicate feltwork of collagen fibrils within finely granular interfibrillary material. No pericellular lacuna is present; the matrix separates the central chondroblast from the cytoplasm of two adjacent chondroblasts (left, and crescentic profile). (Preparation courtesy of Susan Smith, Department of Anatomy, GKT School of Medicine, London.)

each cell or group of cells in histological sections. One or more chondrocytes can form a chondron, which consists of the cells and their pericellular matrix (**Fig. 5.2B**), surrounded by a protective basket of collagen (Roberts et al 1991, Youn et al 2006).

Cartilage cells synthesize and secrete all of the major components of their matrix, and their ultrastructure is typical of cells that are active in making and secreting proteins. The nucleus is round or oval, appears euchromatic and possesses one or more nucleoli. The cytoplasm is filled with rough endoplasmic reticulum, transport vesicles and Golgi complexes, and contains many mitochondria and frequent lysosomes, together with numerous glycogen granules, intermediate filaments (vimentin) and pigment granules. When these cells mature to the relatively inactive chondrocyte stage, the nucleus becomes heterochromatic, the nucleolus smaller and the protein synthetic machinery much reduced; the cells may also accumulate large lipid droplets.

Collagen is synthesized within the rough endoplasmic reticulum in the same way as it is in fibroblasts. Polypeptide chains are assembled into triple helices, and some carbohydrate is added. After transport to the Golgi apparatus, where further glycosylation occurs, the resulting procollagen molecules are secreted into the extracellular space. Terminal registration peptides are cleaved from their ends, forming tropocollagen molecules, and the final assembly into collagen fibrils takes place. Core proteins of the proteoglycan complexes are also synthesized in the rough endoplasmic reticulum and addition of GAG chains begins; the process is completed in the Golgi complex. Hyaluronan, which lacks a protein core, is synthesized by enzymes on the surface of the chondrocyte; it is not modified post-synthetically, and is extruded directly into the matrix without passing through the endoplasmic reticulum.

Matrix turnover is much slower in cartilage than in more metabolically active tissues. Collagen turnover is particularly slow, leaving it vulnerable to the slow process of non-enzymatic glycation, which makes the tissue yellow, stiff and vulnerable to injury (DeGroot et al 2004). Proteoglycans are turned over faster than collagen, with an estimated turnover time of 5 years for adult humans.

Cartilage is often described as avascular. Certainly, the ability of the matrix to deform under load makes it difficult for hollow blood vessels to persist in the tissue beyond early childhood, but a limited vascular supply is often found on the cartilage surface, from where it can revascularize the tissue following injury or degeneration (Lama et al 2018). Metabolite transport to cartilage cells is mostly by the process of diffusion down a concentration gradient from the cartilage surface, although fluid 'pumping' as a result of changing mechanical loading can contribute under certain circumstances. Metabolite transport severely limits cell density and metabolic rate in adult tissue, and this in turn restricts cartilage thickness to a few millimetres (Junger et al 2009). Cartilage cells situated further than this from a nutrient vessel do not survive, and their surrounding matrix typically becomes calcified. In the larger cartilages, and during the rapid growth of some fetal cartilages, vascular cartilage canals penetrate the tissue at intervals, providing an additional source of nutrients. In some cases these canals are temporary structures but others persist throughout life.

Hyaline cartilage

Hyaline (glassy) cartilage has a homogeneous, opalescent appearance, sometimes appearing bluish. It is firm and smooth to the touch and shows considerable deformability. The size, shape and arrangement of chondrocytes vary at different sites and with age. They are flat near the surface perichondrium, and rounded or angular deeper in the tissue (**Fig. 5.2A**). Groups of two or more cells frequently form a cell nest (isogenous cell group) surrounded by a basket of fine collagen fibrils (see Fig. 5.2B). Within such a 'chondron', daughter cells of a common chondroblast often meet at a straight line. The pericellular matrix closest to the cells is typically lacking in collagen fibrils, but rich in proteoglycans that can exhibit basophilic and metachromatic staining. More distant and older interterritorial matrix appears paler and is mostly collagen type II (75% of dry weight) and proteoglycans (22%).

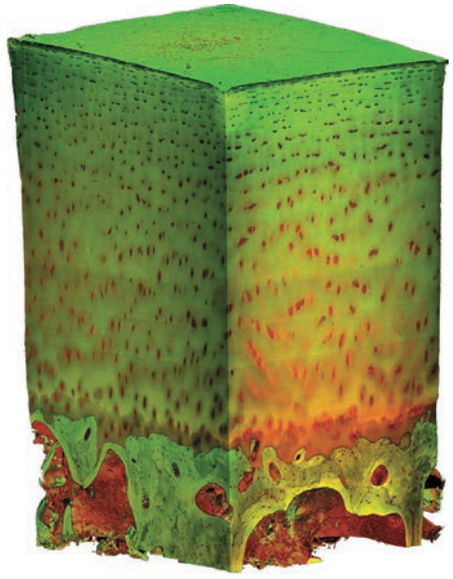

Fig. 5.4 Articular cartilage from the anterior region of the lateral femoral condyle of a young adult human female. Three-dimensional digital volumetric fluorescence imaging of serially sectioned, eosin-Y and acridine orange-stained tissue. Articular surface (top), articular cartilage and subchondral bone (below). Note the changes in size and spatial distribution of articular chondrocytes through the thickness of the cartilage. (Courtesy of Professor Robert L. Sah, Drs Won C. Bae, Kyle D. Jadin, Benjamin L. Wong, Kelvin W. Li and Mrs Barbara L. Schumacher, Department of Bioengineering and Whitaker Institute of Biomedical Engineering, University of California, San Diego.)

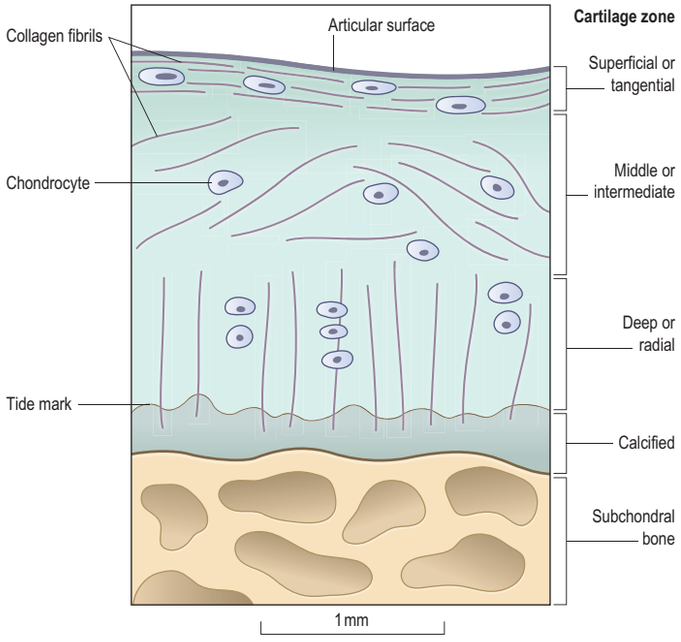

Fig. 5.5 Articular cartilage is not homogeneous: the various zones are different in terms of cell size and shape, and the orientation of the collagen fibril network.

After adolescence, hyaline cartilage may become calcified, either as part of the normal process of bone development, or as an age-related, degenerative change. In costal cartilage, the matrix tends to fibrous striation, especially in old age when cellularity diminishes. The xiphoid process and the cartilages of the nose, larynx and trachea (excepting the elastic cartilaginous epiglottis and corniculate cartilages) resemble costal cartilage in microstructure. Hyaline cartilage is the prototypical form, but it varies more with age and location than either elastic or fibrocartilage. Its regenerative capacity following injury is poor.

Articular cartilage, which covers the articular surfaces of synovial joints, is a specialized hyaline cartilage that lacks a perichondrium (**Fig. 5.4**). The synovial membrane overlaps and then merges into its structure circumferentially (see Fig. 5.32). The thickness of articular cartilage varies from 1 to 7 mm (typically 2 mm) in different joints, and decreases from middle to old age. Thickness does not increase in response to increased mechanical loading, at least in adults, although matrix composition and stiffness can adapt somewhat (Gahunia and Pritzker 2012). Central regions tend to be thickest on convex osseous surfaces, and thinnest on concave surfaces.

Articular cartilage provides an extremely smooth, firm yet deformable layer that increases the contact area between bones and thereby reduces contact stress (see Fig. 5.61). Microscopic undulations on the cartilage surface help to trap synovial fluid (see Fig. 5.60) and enable fluid-film lubrication to reduce friction and wear. Articular cartilage is generally too thin and stiff to be a good shock absorber, although shock absorption may be significant where there are multiple cartilage-covered surfaces, as in the carpus and tarsus.

Adult articular cartilage shows a structural zonation defined by its network of fine collagen type II fibrils (**Fig. 5.5**). Embedded in the deep calcified zone, fibrils rise vertically through the radial zone towards the cartilage surface, where they appear to reorientate to run parallel to the surface in the tangential zone. These collagen arcades can be visualized using phase-contrast microscopy (Thambyah and Broom 2007) but it is likely that each arcade represents numerous discrete fibrils rather than a single fibre. Their three-dimensional orientation can be appreciated by repeatedly piercing the cartilage surface with a needle; this creates a series of permanent elongated splits in the surface, which can be stained by Indian ink. The resulting split line pattern (Meachim el al 1974) reveals the predominant directions of collagen fibrils in the tangential zone, which may be related to internal lines of tension generated during joint movement.

Each zone of articular cartilage (see Fig. 5.5) has a distinct cell morphology and matrix composition. The tangential (or superficial) zone has relatively small, elongated cells orientated parallel to the surface. (Properties of the articular surface are described below under 'Synovial joints', p. 102). Deeper within the tangential zone, the collagen fibrils increase in diameter and density, and gradually merge with those of the transitional (or intermediate) zone. Here, the chondrocytes are large and rounded, and surrounded by collagen fibrils in a range of oblique orientations. Deeper still, in the radial zone, the cells are often disposed in vertical columns, interspersed with vertical collagen fibrils. The matrix in this zone contains collagen types IX and XI, as well as type II. An undulating band known as the tidemark indicates the start of the deepest zone, the zone of calcified cartilage, which has mechanical properties intermediate between cartilage and bone. This calcified zone is keyed into the subchondral bone by fine ridges and interdigitations, which serve to prevent shearing (gliding) movements between cartilage and bone. With age, articular cartilage thins by upward advancement of the tidemark, and gradual replacement of calcified cartilage by bone.

Cells of articular cartilage are capable of cell division, but mitosis is rarely observed in adult tissue and cartilage damage is not repaired. Superficial cells are lost progressively from normal young joint surfaces, to be replaced by cells from deeper layers. Age-related reductions in cell number and activity, and biochemical changes in the extracellular matrix, particularly affect the superficial zone of articular cartilage, increasing the risk of mechanical failure and of osteoarthritis (Lotz and Loeser 2012).

Articular cartilage derives nutrients by diffusion from vessels of the synovial membrane, synovial fluid and hypochondral vessels of an adjacent medullary cavity, some capillaries from which penetrate and occasionally traverse the calcified cartilage zone. The contributions from these sources are uncertain and may change with age. Small molecules freely traverse articular cartilage, with diffusion coefficients about half those in aqueous solution. Larger molecules have diffusion coefficients inversely related to their molecular size. The permeability of cartilage to large molecules is greatly affected by variations in its GAG (and hence water) content: a three-fold increase in GAGs increases the diffusion coefficient 100-fold.

Cartilaginous growth plates (see below under 'Bone', pp. 96–99) are also composed of hyaline cartilage, and there are similarities between active growth plates and growing articular cartilage on the epiphyses of long bones. In both cases, chondrocytes undergo a sequence of cell divisions and hypertrophy (with cells forming into columns) followed by cell death, and ossification by invading osteoblasts.

Fibrocartilage

Fibrocartilage is a dense, whitish tissue with a distinct fibrous texture. It forms the intervertebral discs of the spine and menisci of the knee,

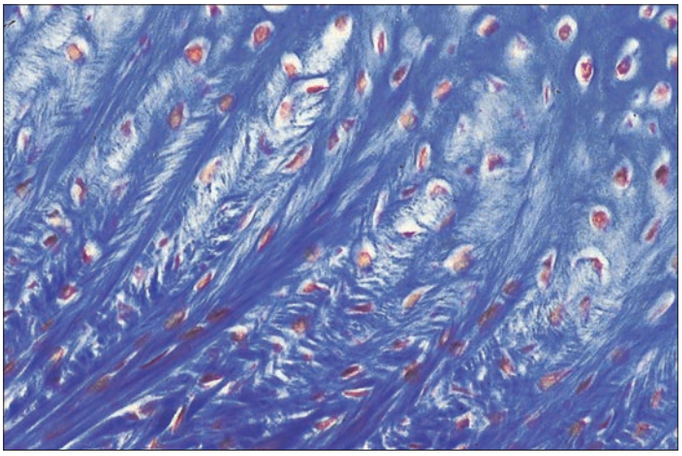

Fig. 5.6 White fibrocartilage in a late human fetal intervertebral disc. Chondroblasts lie between coarse collagen type I fibres (blue) derived from the anulus fibrosus. Mallory's triple stain.

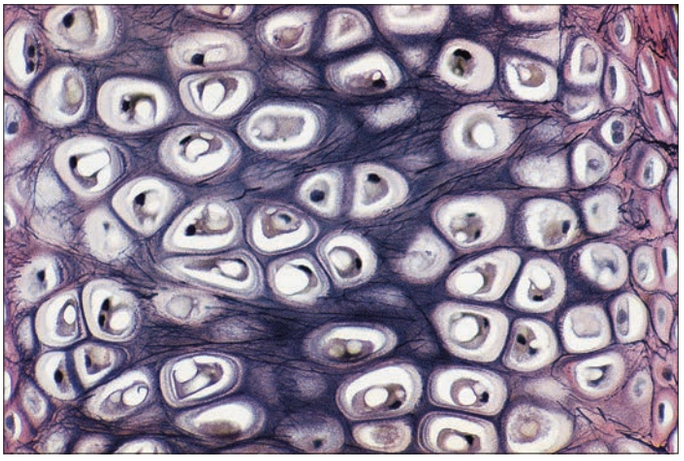

Fig. 5.7 Elastic cartilage, stained to demonstrate elastin fibres (blue–black). Chondroblasts and larger chondrocytes are embedded in the matrix, which also contains collagen type II fibres.

as well as smaller structures such as the glenoid and acetabular labra, and the lining of bony grooves for tendons. It is a versatile and tough material that combines considerable tensile strength with the ability to resist high compressive forces and to distribute them evenly on to underlying bone (Adams et al 2013). Histologically, fibrocartilage is intermediate between dense fibrous connective tissues such as tendon and ligaments, and hyaline cartilage. In some structures such as intervertebral discs, matrix composition and cell types vary from one location to another, reflecting varying mechanical properties.

Regions of fibrocartilage that are loaded predominantly in tension consist of large crimped fibres of collagen type I embedded in a hydrated proteoglycan gel. Cells are rounded in young tissue (Fig. 5.6), but become elongated and fibroblast-like with age. They may be linked by gap junctions (Bruehlmann et al 2002). Regions of fibrocartilage that are loaded predominantly in compression appear more homogeneous, contain a high proportion of fine collagen type II fibrils in an abundant proteoglycan gel, and contain rounded, chondrocyte-like cells. Fibrocartilage could therefore be regarded as a mingling of two types of tissue rather than a separate type of cartilage. However, no other tissue combines high proportions of proteoglycans with collagen type I, suggesting that fibrocartilage should be regarded as a distinct class of connective tissue.

The articular surfaces of bones that ossify in mesenchymal membranes (e.g. squamous temporal, mandible and clavicle) are covered by white fibrocartilage. The deep layers, adjacent to hypochondral bone, resemble calcified regions of the radial zone of hyaline articular cartilage. The superficial zone contains dense parallel bundles of thick collagen fibres, interspersed with typical dense connective tissue fibroblasts and little ground substance. Fibre bundles in adjacent layers alternate in direction, as they do in the cornea. A transitional zone of irregular bundles of coarse collagen and active fibroblasts separates the superficial and deep layers. The fibroblasts are probably involved in elaboration of proteoglycans and collagen, and may also constitute a germinal zone for deeper cartilage. Fibre diameters and types may differ at different sites according to the functional load.

Elastic cartilage

Elastic cartilage occurs in the external ear, corniculate cartilages, epiglottis and apices of the arytenoids. Like hyaline cartilage, it contains typical chondrocytes, either singly or in small groups, surrounded by a matrix rich in type II collagen fibrils. However, the more distant interterritorial matrix is pervaded by very fine yellow elastic fibres (Fig. 5.7) containing the protein elastin, which show no periodic banding structure under the electron microscope (as collagen fibrils do). A structure is termed 'elastic' if it returns to its original shape when loaded and then unloaded; elastic fibres (and cartilage) have the special property of being able to do this even after being subjected to deformations greater than 15%, which would damage collagen fibres. This characteristic is termed elastic recoil. Most sites in which elastic cartilage occurs have vibrational functions, such as laryngeal sound-wave production, or the collection and transmission of sound waves in the ear. Elastic cartilage is resistant to degeneration, and its capacity for limited regeneration following traumatic injury can be appreciated from the distorted repair of a cauliflower ear, as seen in participants of some contact sports.

Development and growth of cartilage

Cartilage is usually formed in embryonic mesenchyme. Mesenchymal cells proliferate and become tightly packed; the shape of their condensation foreshadows that of the future cartilage. They also become rounded, with prominent round or oval nuclei and a low cytoplasm : nucleus ratio. Each cell differentiates into a chondroblast as it secretes a basophilic halo of matrix, composed of a delicate network of fine type II collagen fibrils, type IX collagen and proteoglycan core protein. At some sites, continued secretion of matrix separates the cells, producing typical hyaline cartilage. Elsewhere, many cells become fibroblasts; collagen synthesis predominates and chondroblastic activity appears only in isolated groups or rows of cells that become surrounded by dense bundles of collagen fibres to form white fibrocartilage. In yet other sites, the matrix of early cellular cartilage is permeated first by anastomosing oxytalan fibres, and later by elastin fibres. In all cases, developing cartilage is surrounded by condensed mesenchyme, which differentiates into a bilaminar perichondrium. The cells of the outer layer become fibroblasts and secrete a dense collagenous matrix lined externally by vascular mesenchyme. The cells of the inner layer contain differentiated, but mainly resting, chondroblasts or prechondroblasts.

Cartilage grows by interstitial and appositional mechanisms. Interstitial growth is the result of continued mitosis of early chondroblasts throughout the tissue mass and is obvious only in young cartilage, where plasticity of the matrix permits continued expansion. When a chondroblast divides, its descendants temporarily occupy the same chondron. They are soon separated by a thin septum of secreted matrix, which thickens and further separates the daughter cells. Continuing division produces isogenous groups. Appositional growth is the result of continued proliferation of the cells that form the internal, chondrogenic layer of the perichondrium. Newly formed chondroblasts secrete matrix around themselves, creating superficial lacunae beneath the perichondrium. This continuing process adds additional surface, while the entrapped cells participate in interstitial growth. Apposition is thought to be most prevalent in mature cartilages, but interstitial growth must persist for long periods in growth-plate cartilage. Relatively little is known about the factors that determine the overall shape of cartilage structures.

BONE

Bone is a strong and rigid connective tissue that has evolved to enable fast terrestrial locomotion. Its strength provides support and protection for the body, while its rigidity enables it to create precisely shaped articular surfaces that do not distort under load, and ensures that forceful muscle contractions result in rapid limb movements rather than bending of bones. Unlike cartilage, bone is a highly vascular tissue with a high cell density; high cellularity enables it to adapt to changing mechanical demands, and to regenerate following injury.

Macroscopic anatomy of bone

Macroscopically, living bone is white. Its texture is either dense like ivory (compact bone) or honeycombed by large cavities (trabecular,

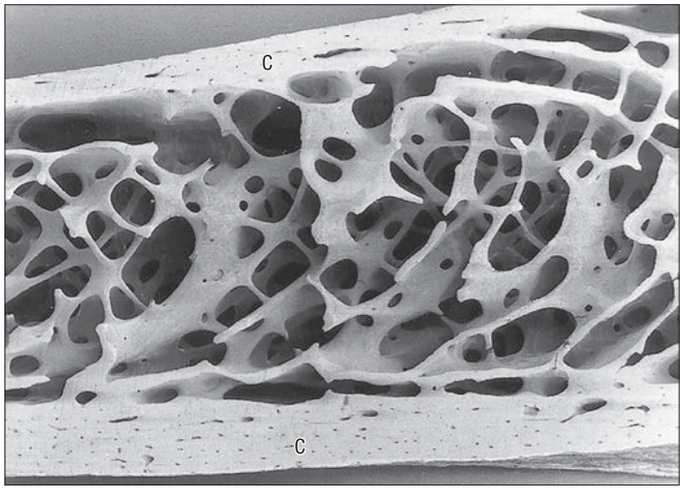

Fig. 5.8 A vertical section 2 cm below the anterosuperior border of the iliac crest (female, 42 years). The cancellous bone consists of intersecting curved plates and struts. Osteonal (Haversian) canals can just be seen in the two cortices (C) at this magnification.

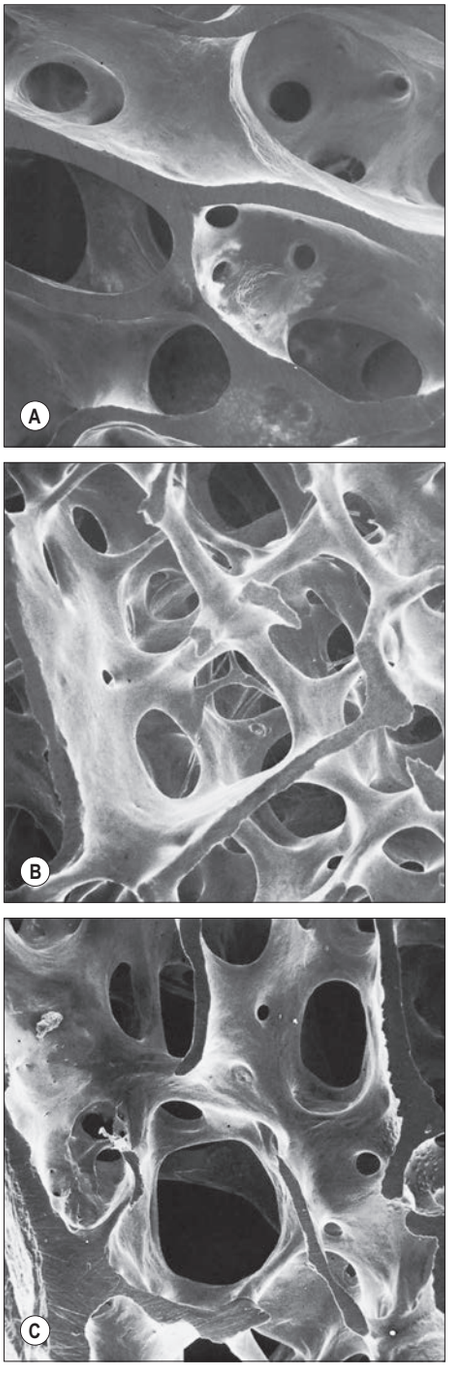

Fig. 5.9 Trabecular bone at different sites in the proximal part of the same human femur. All fields are shown at the same scale. **A**, Subcapital part of the neck. **B**, Greater trochanter. **C**, Rim of the articular surface of the head. Note the wide variation in thickness, orientation and spacing of the trabeculae. (From Whitehouse WJ, Dyson ED 1974 Scanning electron microscope studies of trabecular bone in the proximal end of the human femur. J Anat 118:417–44, by permission from Blackwell Publishing.)

cancellous or spongy bone), where the bony element is reduced to a latticework of bars and plates known collectively as trabeculae (Figs 5.8–5.9). Compact bone is usually limited to the outer shell or cortex of mature bones, where it is important in determining their strength and providing rigid articular surfaces. Cortical thickness and architecture vary between and within bones, and generally decrease with age in adults. Trabecular bone provides support to the cortex while minimizing weight. The presence of a large central medullary canal in long bones also helps to reduce their weight. Spaces within bones provide convenient and secure locations for the storage of haemopoietic tissues and fat. Bone forms a reservoir of metabolic calcium (99% of body calcium is in the bony skeleton) and of phosphate, which is under hormonal and cytokine control.

The proportions of compact to cancellous bone vary between and within bones. Generally, a thick cortex is required to provide strength in bending, e.g. in the mid-diaphysis of a long bone (see Fig. 5.20). Trabecular bone provides strength in compression and so is abundant in the epiphyses of long bones, and in the vertebral bodies of the spine. In flat bones such as the ribs, the interior is uniformly cancellous, and compact bone forms the surface. Internal cavities are usually filled with marrow, either red haemopoietic or yellow adipose, according to age and site. However, in some bones of the skull, notably the mastoid process of the temporal bone and the paranasal sinuses of the frontal, maxilla, sphenoid and ethmoid bones, many of the internal cavities are filled with air, i.e. they are variably pneumatized.

Bones vary not only in their primary shape but also in lesser surface details (secondary markings) that appear mainly in postnatal life. Most bones display features such as elevations and depressions, smooth areas and rough ridges. Broad elongated depressions are called fossae (e.g. the glenoid fossa); lengthy depressions are grooves or sulci (e.g. the humeral bicipital sulcus); a notch is an incisura; and an actual gap is a hiatus. A large projection is termed a process or, if elongated and slender or pointed, a spine. A curved process is a hamulus or cornu (e.g. the pterygoid hamuli of the sphenoid bone and the cornua of the hyoid). A rounded projection is a tuberosity or tubercle, and occasionally a trochanter. Long elevations are crests, or lines if they are less developed; crests are wider and present boundary edges or lips. An epicondyle is a projection close to a condyle and is usually a site where the common tendon of a superficial muscle group or a collateral ligament of the adjacent joint is attached. The terms protuberance, prominence, eminence and torus are occasionally applied to specific bony projections. The expanded proximal end of a long bone is often termed the 'head' or caput (e.g. humerus, radius, femur). A hole in a bone is a foramen and becomes a canal when lengthy. A large hole may be called an aperture or, if covered largely by connective tissue, a fenestra. Clefts in or between bones are fissures. A lamina is a thin plate; larger laminae may be called squamae (e.g. the temporal squama). Large areas on many bones are featureless and as smooth as articular surfaces, from which they differ by being pierced by visible vascular foramina.

Tendons are usually attached at roughened bone surfaces. Wherever any aggregation of collagen in a muscle reaches bone, surface irregularities correspond in form and extent to the pattern of tendinous fibres. Such markings are almost always elevated above the general surface, as if ossification advanced into the collagen bundles from periosteal bone. How such secondary markings are induced is uncertain but they may result from the continued incorporation of new collagen fibres into the bone, perhaps necessary for minor functional adjustment. There is evidence that their prominence may be related to the power of the muscles involved, and they increase with advancing years as if the pull of muscles and ligaments exercised a cumulative effect over a limited area. Surface markings delineate the shape of attached connective tissue structures, e.g. an obvious tendon, intramuscular tendon or septum, aponeurosis, or tendinous fibres mediating what is otherwise a direct muscular attachment. These markings may be facets, ridges, nodules, rough areas or complex mixtures; they afford accurate indications of the junctions of bone with muscles, tendons, ligaments or articular capsules.

Muscle fibres do not attach directly to periosteum or bone. Force transmission is through the connective tissue that encapsulates (epimysium) and pervades (perimysium and endomysium) all muscles. These two forms of attachment of muscles, which are at the extremes of a range of admixtures, differ in the density of collagen fibres between muscle and bone. Where collagen is visibly concentrated, markings appear on the bone surface. In contrast, the multitude of microscopic connective tissue ties of direct attachment that occur over a larger area do not visibly mark the bone, and so it appears smooth to unaided vision and touch.

Many bones articulate with their neighbours at synovial joints. Small articular surfaces are termed facets or foveae; larger, knuckle-shaped surfaces are condyles; a trochlea is grooved like a pulley. Articular surfaces are smooth and covered by articular cartilage, which means that they lack the vascular foramina typical of the surfaces of most other bones.

Microstructure of bone

Bone contains a mineralized collagenous extracellular matrix surrounding a range of specialized cells including osteoblasts, osteocytes and osteoclasts. Periosteum, endosteum and marrow are closely associated tissues. All of these components will be described first individually, and then their overall organization will be considered.

Bone organic matrix

Approximately 10–20% of bone mass is water. A significant proportion (30–40%) of the remaining dry weight is made up of the organic component of the extracellular matrix. Approximately 30% of this organic matrix is collagen; the remainder includes various non-collagenous proteins, glycoproteins and carbohydrates. The proportions of these components vary with age, location and metabolic status.

Most of the collagen in bone is an ordered branching network of type I fibres (**Fig. 5.10**). Although type I collagen fibres are found in most connective tissues, their molecular structure in bone is atypical: internal cross-linking between component fibrils is stronger and chemically more inert, and transverse spacings between collagen molecules within each fibril are larger, allowing more space for the deposition of minerals. A small amount of type V collagen is also present, probably to help regulate fibrillogenesis. Collagen fibres contribute greatly to the cohesive mechanical strength of bone, and also to its toughness (which is reflected in the energy required to break a bone).

Collagen is synthesized in bone by osteoblasts. Newly secreted molecules of tropocollagen lose part of their non-helical terminal regions, thus allowing them to polymerize in the extracellular matrix to form fibrils, which then associate to form fibres. These structures are stabilized by various cross-links, which increase in number and strength as the tissue matures. In primary bone, collagen fibres form a complex interwoven meshwork that incorporates other organic molecules; this 'osteoid' material is then mineralized to form woven (non-lamellar) bone. In time, primary bone is almost entirely replaced by regular laminar arrays of nearly parallel collagen fibres, which form the basis of lamellar bone (Currey 2002). Partially mineralized collagen networks can be seen within osteoid on the outer and internal surfaces of bone, and in the endosteal linings of vascular canals. Collagen fibres from the periosteum are incorporated in cortical bone (extrinsic fibres) and anchor this fibrocellular layer at its surface. Terminal collagen fibres of tendons and ligaments are incorporated deep into the matrix of cortical bone. They may be interrupted by new osteons during cortical drift (modelling) and turnover (remodelling), and remain as islands of interstitial lamellae or even trabeculae.

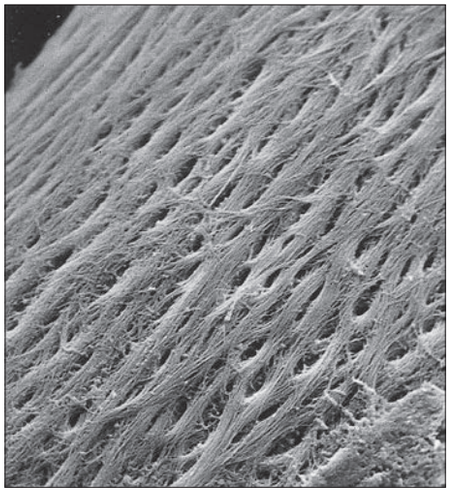

Fig. 5.10 A scanning electron micrograph of collagen fibres on the surface of human trabecular bone. Note the branching fibres (female, 2 months, sixth rib).

Bone organic matrix includes small amounts of various macromolecules attached to collagen fibres and surrounding bone crystals. They are secreted by osteoblasts and young osteocytes, and include osteonectin, osteocalcin, the bone proteoglycans biglycan and decorin, the bone sialoproteins osteopontin and thrombospondin, many growth factors including transforming growth factor beta (TGF-β), proteases and protease inhibitors, often in a latent form. The functions of some of these molecules are described with osteoblasts (see below).

Bone minerals

Approximately 60–70% of bone dry weight is made up of inorganic mineral salts in the form of microcrystalline hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$). The microcrystals confer hardness and much of the rigidity of bone, and are the main reason why bone is easily seen on radiographs. (Bone must be 50% mineralized to be visible on radiographs produced with a standard X-ray unit.) Bone mineral also has an important carbonate content, and a lower Ca:P ratio than pure hydroxyapatite, together with a small amount of calcium phosphate. Bone crystals are extremely small (which gives them a high surface : volume ratio). They take the form of thin plates or leaf-like structures. The largest are 150 nm long × 80 nm wide × 5 nm thick, although most are half that size. Up to two-thirds of the mineral content of bone is thought to be located within collagen fibrils, where the crystals are packed closely together, with their long axes nearly parallel to the fibrils; crystal formation is probably initiated in the gaps between individual collagen molecules. Narrow spaces between the crystals contain water and organic macromolecules. The mineral substances of bone are mostly acid-soluble. If they are removed, using calcium chelators such as citrates or ethylene diamine tetra-acetic acid (EDTA), the bone retains its shape but becomes highly flexible.

The major ions in bone mineral include calcium, phosphate, hydroxyl and carbonate. Less numerous ions are citrate, magnesium, sodium, potassium, fluoride, chloride, iron, zinc, copper, aluminium, lead, strontium, silicon and boron, many of which are present only in trace quantities. Fluoride ions can substitute for hydroxyl ions, and carbonate can substitute for either hydroxyl or phosphate groups. 'Group IIA cations', such as radium, strontium and lead, all readily substitute for calcium and are therefore known as bone-seeking cations. Since they can be either radioactive or chemically toxic, their presence in bone, where they may be close to haemopoietic bone marrow, may cause illness and characteristic appearances on X-rays.

Mineralization of newly synthesized osteoid is a gradual process that slows over time; it typically reaches 70–80% in 3 weeks (Fuchs et al 2008: data for rabbits). Immature woven bone mineralizes faster and so may be distinguished from adjacent lamellar bone by its higher degree of mineralization. In cortical bone, lamellae mostly take the form of cylindrical osteons (see Fig. 5.16). These structures mineralize from inside to out, so that the concentration of mineral is highest in the older, more peripheral, lamellae. Although new osteons are less mineralized than old ones, they may show one or more highly mineralized 'arrest lines' within their walls. Mineral distribution is most uniform in established, highly mineralized osteons. Overall, mineralization increases with age, even though bone mass decreases.

Osteoblasts

Osteoblasts are derived from osteoprogenitor (stem) cells of mesenchymal origin present in bone marrow and other connective tissues. They proliferate and differentiate into osteoblasts prior to bone formation, stimulated by bone morphogenetic proteins (BMPs). A layer of osteoblasts covers the forming surfaces of growing or remodelling bone (**Fig. 5.11**). In relatively quiescent adult bone, they appear to be present mostly on endosteal rather than periosteal surfaces, but they also occur deep within compact bone wherever osteons are being remodelled. Osteoblasts are responsible for the synthesis, deposition and mineralization of the bone matrix, which they secrete. Once embedded in the matrix, they become osteocytes.

Osteoblasts are basophilic, roughly cuboidal mononuclear cells 15–30 μm across. They contain prominent bundles of actin, myosin and other cytoskeletal proteins associated with the maintenance of cell shape, attachment and motility. Their plasma membranes display

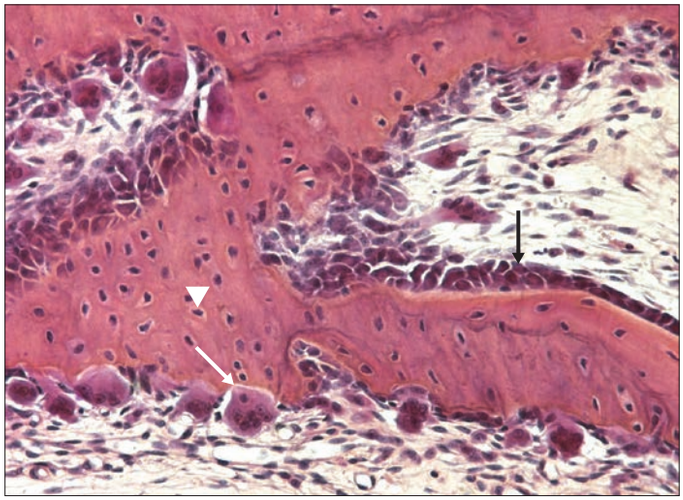

Fig. 5.11 Bone cells actively remodelling alveolar bone to accommodate a developing tooth. Large multicellular osteoclasts (white arrow) are actively resorbing bone on one surface, while a layer of osteoblasts (black arrow) is depositing osteoid on another. Osteoblasts that have become trapped in the matrix to form osteocytes are shown in the centre (white arrowhead). (Courtesy of Professor Tim Arnett, University College London.)

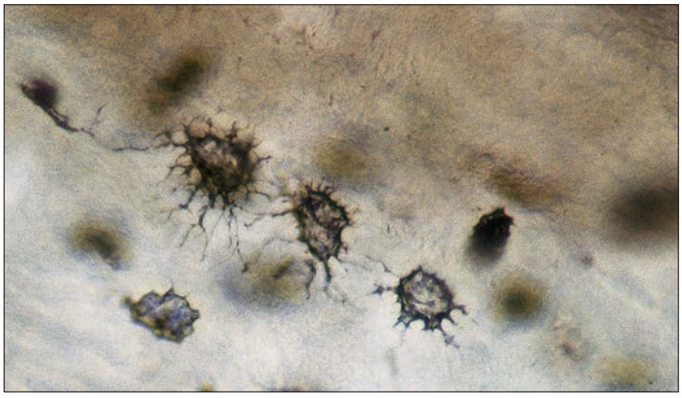

Fig. 5.12 Osteocyte lacunae shown at high magnification in a dry ground section of lamellar bone. The territories of three osteocytes are shown. Their branching dendrites contact those of neighbouring cells via the canaliculi seen here within the bone matrix. Several other osteocyte lacunae are present, out of the focal plane in this section, and tangential to the osteon axis.

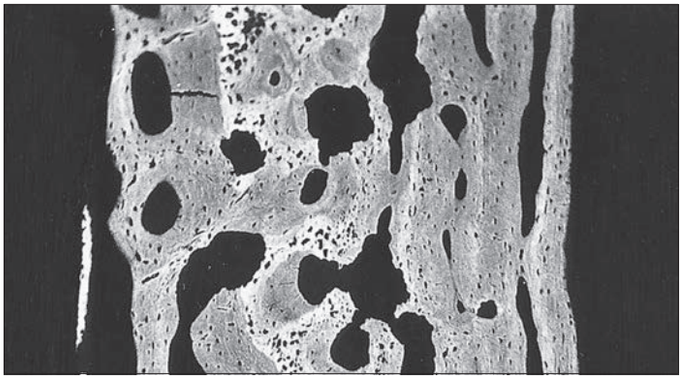

Fig. 5.13 Human parietal bone (male neonate) showing primary osteonal bone (grey) and woven bone (white) containing many connecting osteocyte lacunae (black). Internal resorption of the bone has produced large, irregular dark spaces (trabecularization).

many extensions, some of which contact neighbouring osteoblasts and embedded osteocytes at intercellular gap junctions. This arrangement facilitates coordination of the activities of groups of cells, e.g. in the formation of large domains of parallel collagen fibres.

Ultrastructurally, osteoblasts are typical protein-secreting cells. They synthesize and secrete collagens and a number of glycoproteins. Osteocalcin is required for bone mineralization, binds hydroxyapatite and calcium, and is used as a marker of new bone formation. Osteonectin is a phosphorylated glycoprotein that binds strongly to hydroxyapatite and collagen; it may play a role in initiating crystallization and may be a cell adhesion factor. RANKL is the cell surface ligand for RANK (receptor for activation of nuclear factor kappa B), an osteoclast progenitor receptor (see below). Osteoprotegerin is a soluble, high-affinity decoy ligand for RANKL, which restricts osteoclast differentiation. Biglycan and decorin are bone proteoglycans that attract water; decorin also binds the growth factor TGF-β. The bone sialoproteins, osteopontin and thrombospondin, mediate osteoclast adhesion to bone surfaces by binding to osteoclast integrins. In addition, osteoblasts secrete latent proteases and growth factors including BMPs and TGF-β (which is also secreted by osteoclasts and which may be a coupling factor for stimulating new bone formation at resorption sites).

Although extracellular fluid is generally supersaturated with respect to the basic calcium phosphates, mineralization does not occur in most tissues. In bone, osteoblasts secrete osteocalcin (which binds calcium at levels sufficient to concentrate the ion locally) and contain membrane-bound vesicles full of alkaline phosphatase (cleaves phosphate ions from various molecules to elevate concentrations locally) and pyrophosphatase (degrades inhibitory pyrophosphate in the extracellular fluid). The vesicles bud off from the osteoblast surface into newly formed osteoid, where they initiate hydroxyapatite crystal formation. Some alkaline phosphatase reaches the blood circulation, where it can be detected in conditions of rapid bone formation or turnover.

Osteoblasts also play a key role in the hormonal regulation of bone resorption. They express receptors for parathyroid hormone (PTH), 1,25-dihydroxy vitamin D_3 (calcitriol) and other promoters of bone resorption. When activated, osteoblasts promote osteoclast differentiation via PTH-activated expression of cell surface RANKL, which binds to RANK on immature osteoclasts, establishes cell–cell contact and triggers contact-dependent osteoclast differentiation. In the presence of PTH, osteoblasts also downregulate secretion of osteoprotegerin, a soluble decoy ligand with higher affinity for RANKL. In conditions favouring bone deposition, secreted osteoprotegerin blocks RANKL binding to RANK, restricting the number of mature osteoclasts.

Bone-lining cells are flattened epithelial-like cells that cover the free surfaces of adult bone not undergoing active deposition or resorption. Generally considered to be quiescent osteoblasts or osteoprogenitor cells, they line the periosteal surface and the vascular canals within osteons, and form the outer boundary of the marrow tissue on the endosteal surface of marrow cavities.

Osteocytes

Osteocytes are the major cell type of mature bone and are distributed throughout its matrix, interconnected by numerous dendritic processes to form a complex cellular network (**Fig. 5.12**). They are derived from osteoblasts that have become enclosed within their rigid matrix (see Fig. 5.11) and so have lost the ability to divide or to secrete new matrix. (The rigidity of mineralized bone matrix prevents interstitial growth, so that new bone must always be deposited on pre-existing surfaces.) Osteocytes retain contact with each other and with cells at the surfaces of bone (osteoblasts and bone-lining cells) throughout their lifespan.

Mature, relatively inactive osteocytes have an ellipsoid cell body with their longest axis (approximately 25 μm) parallel to the surrounding lamellae. The rather narrow rim of cytoplasm is faintly basophilic, contains relatively few organelles and surrounds an oval nucleus. Osteocytes in woven bone are larger and more irregular in shape (**Fig. 5.13**). Numerous fine branching processes containing bundles of microfilaments and some smooth endoplasmic reticulum emerge from each cell body. At their distal tips, these processes form gap junctions with the processes of adjacent cells (osteocytes, osteoblasts and bone-lining cells) so that they are in electrical and metabolic continuity.

Extracellular fluid fills the small, variable spaces between osteocyte cell bodies and their rigid lacunae, which may be lined by a variable (0.2–2 μm) layer of unmineralized organic matrix. The same fluid fills the narrow channels or canaliculi that surround the long processes of the osteocytes. Approximately 0.25–0.5 μm wide, the canaliculi provide a route for the diffusion of nutrients, gases and waste products between osteocytes and blood vessels. Canaliculi do not usually extend through and beyond the reversal line surrounding each osteon and so do not communicate with neighbouring systems.

In well-vascularized bone, osteocytes are long-lived cells that actively maintain the bone matrix. The average lifespan of an osteocyte varies

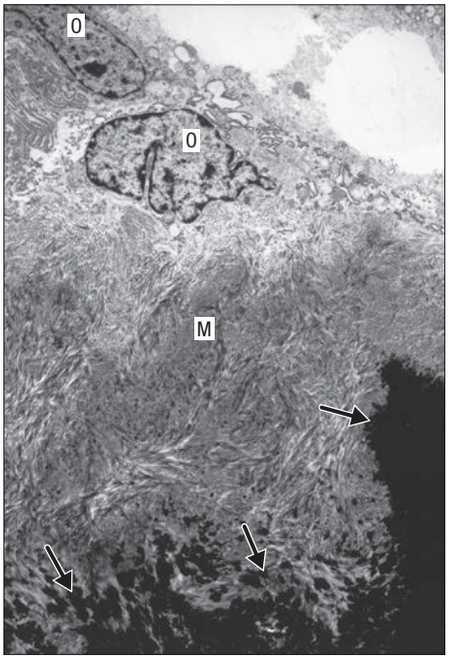

Fig. 5.15 An electron micrograph of woven bone from a failed fracture of human distal tibia. Two osteoblasts (O) lie on the free surface (top). Newly synthesized collagenous osteoid matrix (M) is seen in the centre field, with a mineralization front (electron-dense area) below (arrows). (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

with the metabolic activity of the bone and the likelihood that it will be remodelled, but is measured in years. Old osteocytes may retract their processes from the canaliculi; when they die, their lacunae and canaliculi may become plugged with cell debris and minerals, which hinders diffusion through the bone. Dead osteocytes occur commonly in interstitial bone (between osteons) and in central regions of trabecular bone that escape surface remodelling. They are particularly noticeable by the second and third decades. Bones that experience little turnover, e.g. the auditory ossicles, are most likely to contain aged osteocytes and have low osteocyte viability. Osteocyte death leads to matrix resorption by osteoclast activity. Osteocytes themselves are often mineralized.

Osteoclasts

Osteoclasts are large (diameters of 40 µm or more) polymorphic cells containing up to 20 oval, closely packed nuclei (see Fig. 5.11). They lie in close contact with the bone surface in resorption bays (Howship's lacunae). Their cytoplasm contains numerous mitochondria and membrane-bound organelles, many of which are acid phosphatase-positive lysosomes. Rough endoplasmic reticulum is relatively sparse but the Golgi complex is extensive. The cytoplasm also contains numerous coated transport vesicles and microtubule arrays involved in vesicle transport between the Golgi stacks and the cell's ruffled border (the highly infolded region of plasma membrane of an active osteoclast at a site of bone resorption). A well-defined zone of actin filaments and associated proteins occurs beneath the ruffled border around the circumference of a resorption bay, in a region termed the sealing zone.

Functionally, osteoclasts are responsible for the local removal of bone during bone growth and remodelling (**Fig. 5.14**). They dissolve bone minerals by proton release to create an acidic local environment, and they remove organic matrix by secreting lysosomal (cathepsin K) and non-lysosomal (e.g. collagenase) enzymes. Osteoclasts are stimulated to resorb bone by signals from local cells (including osteoblasts, macrophages and lymphocytes) and by blood-borne factors such as PTH and 1,25-dihydroxy vitamin D_3 (calcitriol). Calcitonin, produced by C cells of the thyroid follicle, reduces osteoclast activity.

Osteoclasts differentiate from myeloid stem cells via macrophage-colony-forming units. Differentiation is primarily regulated by two cytokines: macrophage-colony stimulating factor, secreted by osteoblasts, and RANKL, expressed by osteoblasts (see above). The mononuclear precursors fuse to form terminally differentiated multinuclear osteoclasts (Väänänen and Laitala-Leinonen 2008). Osteoclast differentiation inhibitors are potential therapeutic agents for bone loss-associated disorders, e.g. osteoporosis, rheumatoid arthritis, Paget's disease, periodontal disease and osteosarcoma.

Woven and lamellar bone

The mechanical properties of bone depend not only on matrix composition, as described above, but also on the manner in which the matrix constituents are organized. Woven bone and lamellar bone represent two quite distinct types of organization.

In woven (or bundle) bone, the collagen fibres and bone crystals are irregularly arranged. The diameters of the fibres vary, so that fine and coarse fibres intermingle, producing the appearance of the warp and weft of a woven fabric. Woven bone is typical of young fetal bones, but is also seen in adults during excessively rapid bone remodelling and during fracture repair (**Fig. 5.15**). It is formed by highly active osteoblasts during development, and is stimulated in the adult by fracture, growth factors or prostaglandin E_2.

Lamellar bone, which makes up almost all of an adult skeleton, is more organized and is produced more slowly. The precise arrangement of lamellae (bone layers) varies from site to site. In trabeculae and the outer (periosteal) and inner (endosteal) surfaces of cortical bone, a few lamellae form continuous circumferential layers that are more or less parallel to the bony surfaces. However, in more central regions of cortical bone, the lamellae are arranged in concentric cylinders around neurovascular channels called Haversian canals (**Fig. 5.16**). This interconnecting, three-dimensional, laminated construction increases the toughness of lamellar bone because the interfaces between lamellae are effective in stopping the growth of cracks; more energy is therefore required to propagate cracks that are sufficiently extensive to fracture the bone.

Each lamella consists of a sheet of mineralized matrix containing collagen fibres of similar orientation locally, running in branching bundles 2–3 µm thick and often extending the full width of a lamella. The orientation of collagen fibres and crystals differs between 0° and 90° in adjacent lamellae, as may be demonstrated by polarized light microscopy (see Fig. 5.19B). At the borders of lamellae, packing of collagen fibres into bundles is less perfect and intermediate and random orientations of collagen predominate.

Cortical bone

The cylindrical structural units that comprise most cortical bone are termed Haversian systems or osteons (**Fig. 5.17**). Osteons usually lie parallel with each other (**Fig. 5.18**); in long bones, they lie parallel with the long axis of the bone. Adjacent osteons may encroach on one another because they are usually formed at different times, during successive periods of bone remodelling. Irregular gaps between osteons are filled with interstitial lamellae (**Fig. 5.17A**), which are the fragmentary remains of older osteons and circumferential lamellae. Osteons may be spiral or they may branch, and some end blindly. They are round or ellipsoidal in cross-section. The main direction of collagen fibres within osteons varies: in the shaft of long bones, fibres are more longitudinal at sites that are subjected mainly to tension, and more oblique at sites subjected mostly to compression. Peripheral lamellae of osteons contain more transverse fibres.

It has been estimated that there are 21 million osteons in a typical adult skeleton. Their diameter varies from 100 to 400 µm, and they usually contain 5–20 lamellae. Each osteon is permeated by the canaliculi

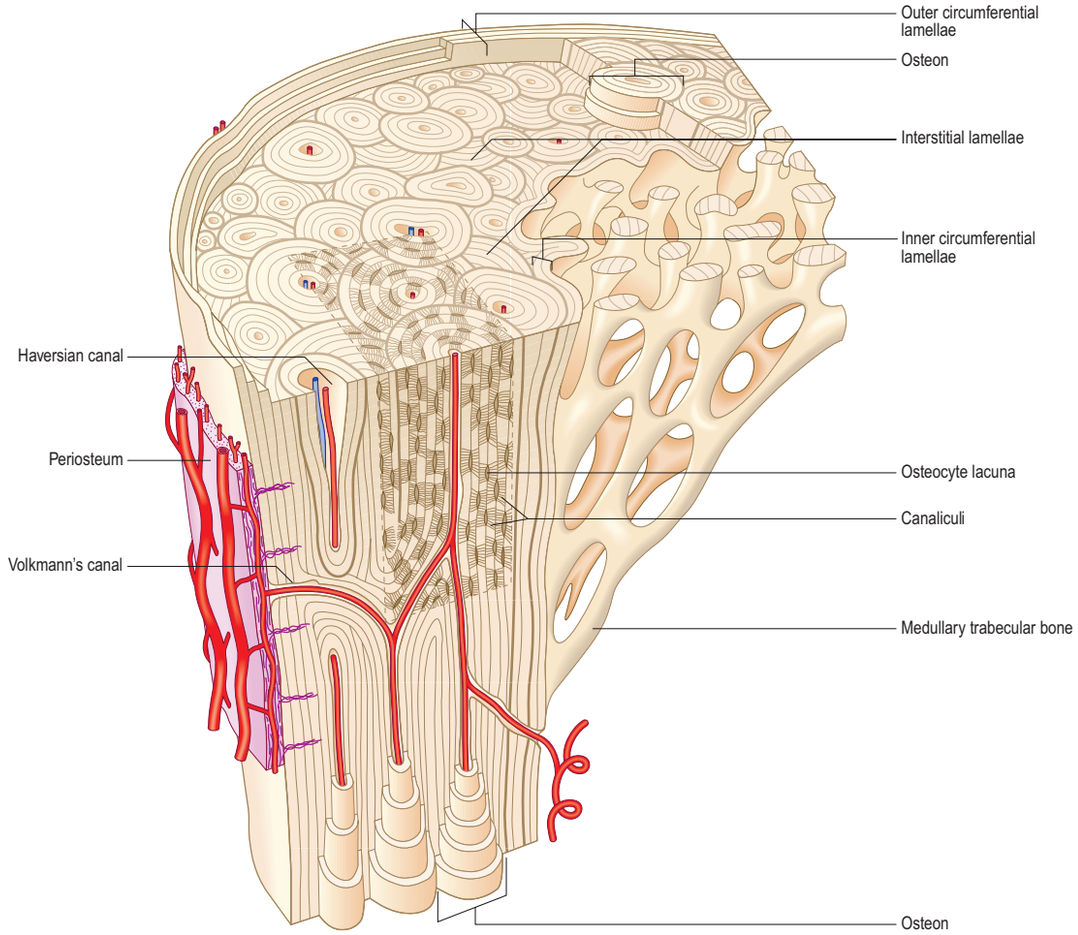

Fig. 5.16 The main features of the microstructure of mature lamellar bone. Areas of compact and trabecular (cancellous) bone are included. Note the general construction of the osteons; distribution of the osteocyte lacunae; Haversian canals and their contents; resorption spaces; and different views of the structural basis of bone lamellation.

of its resident osteocytes, which form pathways for the diffusion of metabolites between osteocytes and blood vessels. The maximum diameter of an osteon ensures that no osteocyte is more than 200 μm from a blood vessel, a distance that may be a limiting factor in their survival.

The central Haversian canals of osteons vary in size, with a mean diameter of 50 μm; those near the marrow cavity are somewhat larger. Each canal contains one or two capillaries lined by fenestrated endothelium and surrounded by a basal lamina, which also encloses typical pericytes. They usually contain a few unmyelinated and occasional myelinated axons. The bony surfaces of osteonic canals are perforated by the openings of osteocyte canaliculi and are lined by collagen fibres.

Haversian canals communicate with each other and directly or indirectly with the marrow cavity via vascular (nutrient) channels called Volkmann's canals, which run obliquely or at right-angles to the long axes of the osteons (see Fig. 5.18). The majority of these channels appear to branch and anastomose, but some join large vascular connections with vessels in the periosteum and the medullary cavity.

Osteons are distinguished from their neighbours by a cement line that contains little or no collagen, and is strongly basophilic because it has a high content of glycoproteins and proteoglycans. Cement lines are also known as reversal lines because they mark the limit of bone erosion prior to the formation of a new osteon. Canaliculi occasionally pass through cement lines, and so provide a route for exchange between interstitial bone lamellae and vascular channels within osteons. Basophilic resting lines can occur in the absence of erosion; they indicate where bony growth has been interrupted and then resumed.

Trabecular bone

The organization of trabecular bone (also known as cancellous or spongy bone) is basically lamellar, as shown most clearly under polarized light (**Fig. 5.19**). Trabeculae take the form of branching bars and curved plates of varying width, length and thickness (50–400 μm) (see Fig. 5.9). They are covered in endosteal tissue because they are adjacent to marrow cavities. Thick trabeculae and regions close to compact bone may contain small osteons, but blood vessels do not otherwise lie within trabeculae; osteocytes therefore rely on canalicular diffusion from adjacent medullary vessels. In young bone, calcified cartilage may occur in the cores of trabeculae, but this is generally replaced by bone during subsequent remodelling.

Periosteum, endosteum and bone marrow

The outer surface of bone is covered by a condensed collagenous layer, the periosteum. The inner surface is lined by a thinner, more cellular endosteum. Osteoprogenitor cells, osteoblasts, osteoclasts and other cells important in the turnover and homeostasis of bone tissue lie in these layers.

The periosteum is tethered to underlying bone by thick collagen fibres (Sharpey's fibres), which penetrate deep into the outer cortical bone tissue. It is absent from articular surfaces, and from the points of insertion of tendons and ligaments (entheses) (see Fig. 5.51). The periosteum is highly active during fetal development, when it generates osteoblasts for the appositional growth of bone. These cells form a layer, 2–3 cells deep, between the fibrous periosteum and new woven bone matrix. Osteoprogenitor cells within the mature periosteum are indistinguishable morphologically from fibroblasts. Periosteum is important in the repair of fractures; where it is absent (e.g. within the joint capsule of the femoral neck) fractures are slow to heal.

Quiescent osteoblasts and osteoprogenitor cells act as the principal reservoir of new bone-forming cells for remodelling or repair on the endosteal surfaces of resting adult bone. Bone endosteum is likely to be important in calcium homeostasis because it provides a total surface area of approximately 7.5 m^2. It is formed by flattened osteoblast precursor cells and reticular (type III collagen) fibres, and lines all the internal cavities of bone, including the Haversian canals. It overlies the endosteal circumferential lamellae and encloses the medullary cavity.

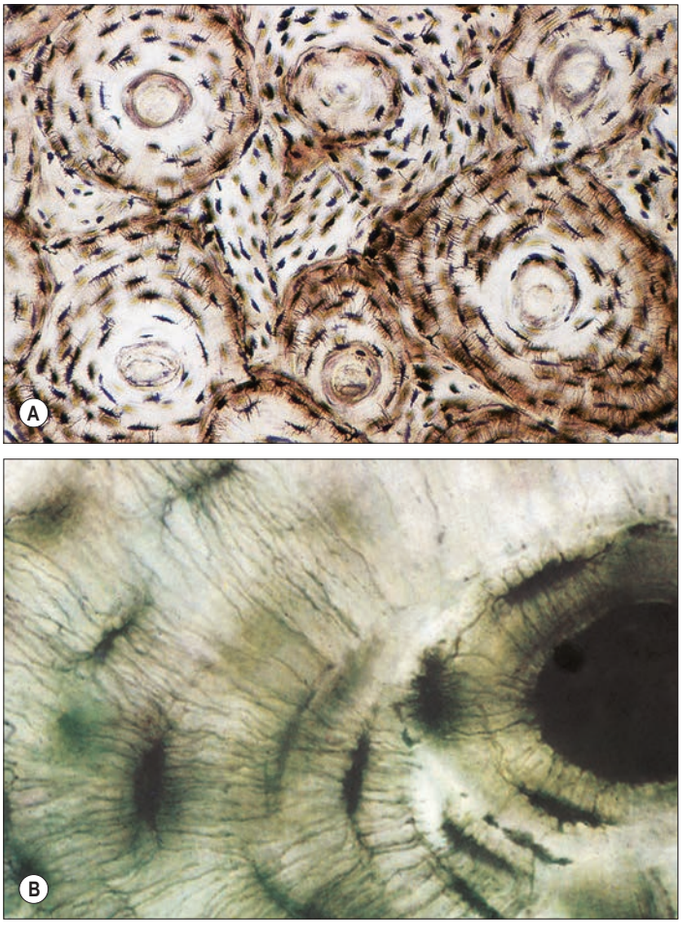

Fig. 5.17 **A**, Osteons in a dry ground transverse section of bone. Concentric lamellae surround the central Haversian canal of each complete osteon; they contain the dark lacunae of osteocytes and the canaliculi, which are occupied in life by their dendrites. These canaliculi interconnect with canaliculi of osteocytes in adjacent lamellae. Incomplete (interstitial) lamellae (e.g. centre field) are the remnants of osteons remodelled by osteoclast erosion. **B**, A high-power view of osteocytes within lamellae; a Haversian canal is seen on the right. Neurovascular supply of bone

Vascular supply

The osseous circulation supplies bone tissue, marrow, perichondrium, epiphysial cartilages in young bones, and, in part, articular cartilages. The vascular supply of a long bone depends on several points of inflow that feed complex and regionally variable sinusoidal networks within the bone. The sinusoids drain to venous channels that leave through all surfaces that are not covered by articular cartilage. The flow of blood through cortical bone in the shafts of long bones is mainly centrifugal (Fig. 5.20).

One or two main diaphysial nutrient arteries enter the shaft obliquely through nutrient foramina, which lead into nutrient canals. Their sites of entry and angulation are almost constant and characteristically directed away from the dominant growing epiphysis. Nutrient arteries do not branch in their canals but divide into ascending and descending branches in the medullary cavity; these approach the epiphyses, dividing repeatedly into smaller helical branches close to the endosteal surface. The endosteal vessels are vulnerable during surgical operations, such as intramedullary nailing, which involve passing metal implants into the medullary canal. Near the epiphyses, diaphysial vessels are joined by terminal branches of numerous metaphysial and epiphysial arteries (see Fig. 5.20). The former are direct branches of neighbouring systemic vessels; the latter come from peri-articular vascular arcades formed on non-articular bone surfaces. Numerous vascular foramina penetrate bones near their ends, often at fairly specific sites; some are occupied by arteries but most contain thin-walled veins. Within bone, the arteries are unusual in consisting of endothelium with only a thin layer of supportive connective tissue. The epiphysial and metaphysial arterial supply is richer than the diaphysial supply.

Medullary arteries in the shaft give off centripetal branches, which feed a hexagonal mesh of medullary sinusoids that drain into a wide, thin-walled central venous sinus. They also possess cortical branches, which pass through endosteal canals to feed fenestrated capillaries in Haversian systems. The central sinus drains into veins that retrace the paths of nutrient arteries, sometimes piercing the shaft elsewhere as independent emissary veins. Cortical capillaries follow the pattern of Haversian canals, and are mainly longitudinal with oblique connections

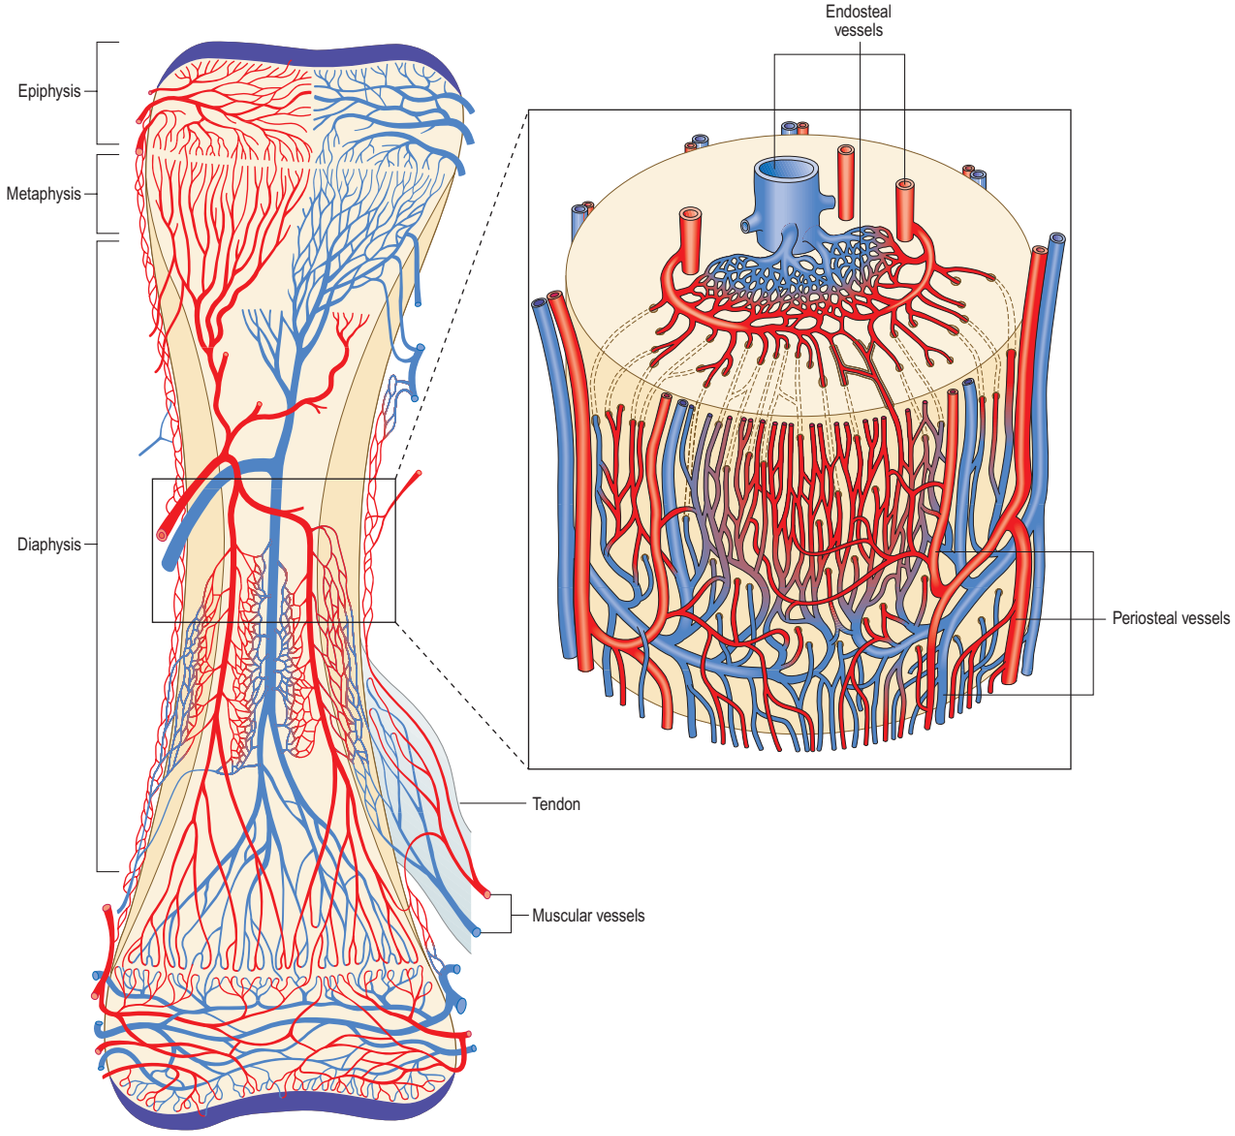

Fig. 5.20 The main features of the blood supply of a long bone. Note the contrasting supplies of the diaphysis, metaphysis and epiphysis, and their connections with periosteal, endosteal, muscular and peri-articular vessels. The expansion shows part of the diaphysis in more detail. The marrow cavity contains a large central venous sinus, a dense network of medullary sinusoids, and longitudinal medullary arteries and their circumferential rami. Longitudinally oblique transcortical capillaries emerge through minute 'cornet-shaped' foramina to become confluent with the periosteal capillaries and venules. The obliquity of the cortical capillaries is emphasized for clarity. Not to scale.

via Volkmann's canals (see Fig. 5.18). At bone surfaces, cortical capillaries make capillary and venous connections with periosteal plexuses (see Fig. 5.20) formed by arteries from neighbouring muscles that contribute vascular arcades with longitudinal links to the fibrous periosteum. A capillary network permeates the deeper, osteogenic periosteum from this external plexus. At muscular attachments, periosteal and muscular plexuses are confluent and the cortical capillaries then drain into interfascicular venules.

In addition to the centrifugal supply of cortical bone, there is an appreciable centripetal arterial flow to outer cortical zones from periosteal vessels. The large nutrient arteries of epiphyses form many intraosseous anastomoses, their branches passing towards the articular surfaces within the trabecular spaces of the bone. Near the articular cartilages, these form serial anastomotic arcades (e.g. there are three or four in the femoral head), which give off end-arterial loops. The latter often pierce the thin hypochondral compact bone to enter, and sometimes traverse, the calcified zone of articular cartilage, before returning to the epiphysial venous sinusoids.

In immature long bones, the supply is similar but the epiphysis is a discrete vascular zone. Epiphysial and metaphysial arteries enter on both sides of the growth cartilage and rarely, if ever, anastomose. Growth cartilages are probably supplied from both sources, and from an anastomotic collar in the adjoining periosteum. Occasionally, cartilage canals are incorporated into a growth plate. Metaphysial bone is nourished by terminal branches of metaphysial arteries and by primary nutrient arteries of the shaft, which form terminal blind-ended sprouts or sinusoidal loops in the zone of advancing ossification. Young periosteum is more vascular; its vessels communicate more freely with those of the shaft than their adult counterparts and give off more metaphysial branches.

Large, irregular bones such as the scapula and innominate not only receive a periosteal supply but are also often supplied by large nutrient arteries that penetrate directly into their cancellous bone, the two systems anastomosing freely. Short bones receive numerous fine vessels that supply their compact and cancellous bone and medullary cavities from the periosteum. Arteries enter vertebrae close to the base of their transverse processes (see Fig. 46.20). Each vertebral medullary cavity drains to two large basivertebral veins, which converge to a foramen on the posterior surface of the vertebral body (see Fig. 46.21). Flatter cranial bones are supplied by numerous periosteal or mucoperiosteal vessels. Large, thin-walled veins run tortuously in cancellous bone. Lymphatic vessels accompany periosteal plexuses but have not been convincingly demonstrated in bone. (For further reading on the role of the vasculature in bone development, function and regeneration, see Filipowska et al 2017).

Innervation

Nerves are most numerous in periosteum, the articular extremities of long bones, vertebrae and the larger flat bones. The nutrient blood vessels are richly innervated by postganglionic sympathetic axons. Periosteum is innervated by myelinated axons with encapsulated nerve

endings and by unmyelinated axons with free endings typical of nociceptors. Many of these afferents are mechanically sensitive and respond rapidly to mechanical distortion, some can be activated by multiple stimuli and may be polymodal, and some may be stretch receptors.

Fine myelinated (Aδ) and unmyelinated (C) axons with free fibre endings accompany nutrient vessels into bone and marrow, and lie in the perivascular spaces of Haversian canals. Animal studies have revealed that many of these sensory neurones have a nociceptive phenotype, e.g. they express substance P, alpha calcitonin gene-related peptide (αCGRP), tropomyosin receptor kinase A (TrkA), and transient receptor potential cation channel subfamily V member 1 (TRPV1) and respond to noxious chemical and mechanical stimuli such as raised intraosseous pressure (Ivanusic 2017). Osteoblasts and osteoclasts possess receptors for several of the neuropeptides found in these nerves; there is increasing experimental evidence that neuropeptide-mediated signalling plays a role in modulating bone cell metabolism (Niedermair et al 2018). Pathological changes that cause the release of inflammatory mediators in bone marrow and/or raised intraosseous pressure or mechanical compression or distortion of bone and periosteum can all trigger bone pain by activating nociceptors in bone.

Development and growth of bone

Some of the bones in the skull are laid down within a fibrocellular mesenchymal membrane, by a process known as intramembranous ossification. Most bones are formed by a process of endochondral ossification, in which preformed cartilage templates (models) define their initial shapes and positions, and the cartilage is replaced by bone in an ordered sequence.

Intramembranous ossification

Intramembranous ossification is the direct formation of bone (membrane bone) within highly vascular sheets or 'membranes' of condensed primitive mesenchyme. At centres of ossification, mesenchymal stem cells differentiate into osteoprogenitor cells, which proliferate around the branches of a capillary network, forming incomplete layers of osteoblasts in contact with the primitive bone matrix. The cells are polarized, and secrete osteoid only from the surface that faces away from the blood vessels. The earliest crystals appear in association with extracellular matrix vesicles produced by the osteoblasts. Crystal formation subsequently extends into collagen fibrils in the surrounding matrix, producing an early labyrinth of woven bone, the primary spongiosa. As layers of calcifying matrix are added to the early trabeculae, osteoblasts become enclosed within primitive lacunae. These new osteocytes retain intercellular contact by means of their fine cytoplasmic processes (dendrites) and, as these elongate, matrix condenses around them to form canaliculi.

As matrix secretion and calcification proceed, trabeculae thicken and vascular spaces become narrower. Where bone remains trabecular, the process slows and the spaces between trabeculae become occupied by haemopoietic tissue. Where compact bone is forming, trabeculae continue to thicken and vascular spaces continue to narrow. Meanwhile, the collagen fibres of the matrix, secreted on the walls of the narrowing spaces between trabeculae, become organized as parallel, longitudinal or spiral bundles, and the cells they enclose occupy concentric sequential rows. These irregular, interconnected masses of compact bone each have a central canal and are called primary osteons (primary Haversian systems). They are later eroded, together with the intervening woven bone, and replaced by generations of mature (secondary) osteons.

While these changes are occurring, mesenchyme condenses on the outer surface to form a fibrovascular periosteum. Bone is laid down increasingly by new osteoblasts, which differentiate from osteoprogenitor cells in the deeper layers of the periosteum. Modelling of the growing bone is achieved by varying rates of resorption and deposition at different sites.

Endochondral ossification

The hyaline cartilage model that forms during embryogenesis is a miniature template of the bone that will subsequently develop. It becomes surrounded by a condensed, vascular mesenchyme or perichondrium, which resembles the mesenchymal 'membrane' in which intramembranous ossification occurs. Its deeper layers contain osteoprogenitor cells.

The first appearance of a centre of primary ossification (Fig. 5.21) occurs when chondroblasts deep in the centre of the primitive shaft enlarge greatly, and their cytoplasm becomes vacuolated and accumulates glycogen. The intervening matrix is compressed into thin, often perforated, septa. The cells degenerate and may die, leaving enlarged and sometimes confluent lacunae (primary areolae) whose thin walls become calcified during the final stages (Fig. 5.22). Type X collagen is produced in the hypertrophic zone of cartilage. Matrix vesicles originating

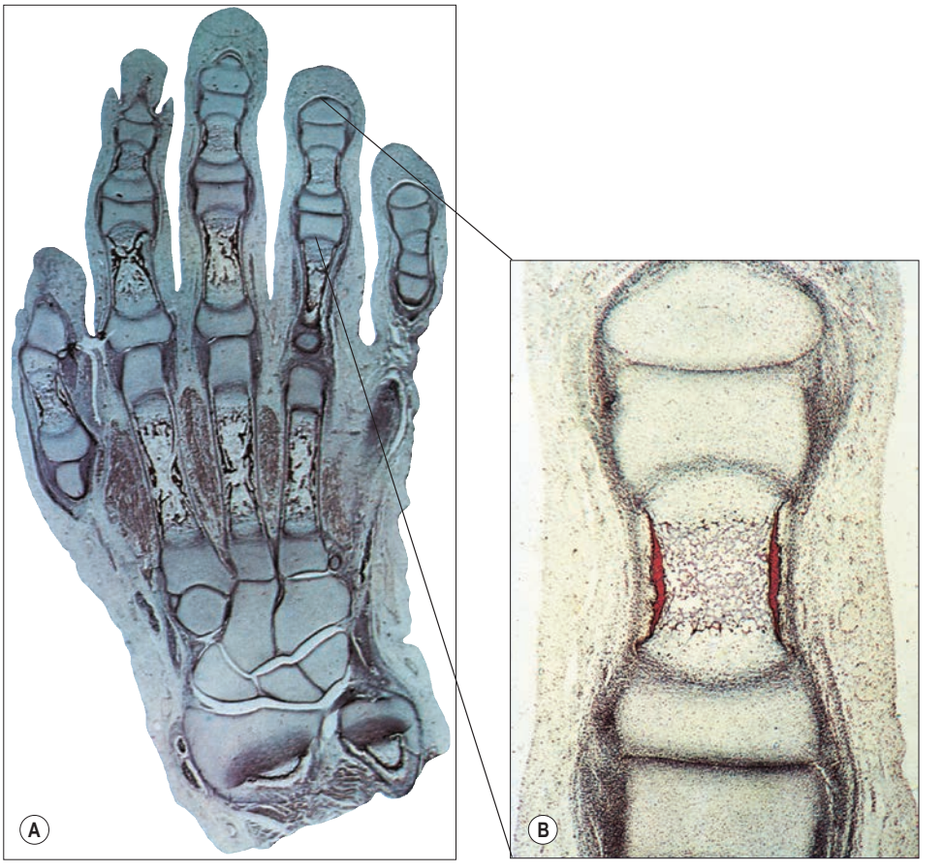

Fig. 5.21 A, A section of a human fetal hand showing cartilaginous models of the carpal bones and the primary ossification centres, which display varying stages of maturity, in the metacarpals and phalanges. Note that none of the carpal elements shows any evidence of ossification. **B,** A higher-power view of an early primary ossification centre. The cartilage cells in the shaft have hypertrophied and this region is surrounded by a delicate tube or collar of subperiosteal bone (red). Fig. 5.22 The sequence of cellular events in endochondral ossification. This low-magnification micrograph shows the primary ossification centre in a human fetal bone. See Fig. 5.24 for further details. Abbreviations: G, growth zone; H, hypertrophic zone; O, ossification zone; R, remodelling zone.

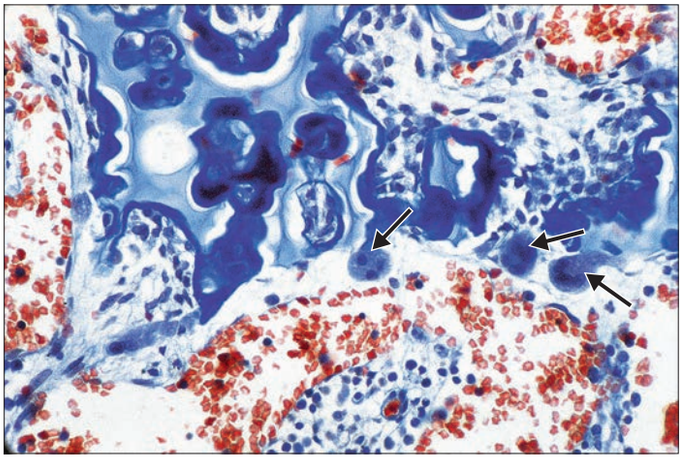

Fig. 5.24 Endochondral ossification in human fetal bone. Spicules of cartilaginous remnants (pale blue) serve as surfaces for the deposition of osteoid (dark blue), shown in the upper half of the field. Mineralized, woven bone is stained red. Three large multinucleate osteoclasts (arrows) are seen centre right, further eroding cartilage and remodelling the developing bone. Blood sinusoids and haemopoietic tissue (below) fill the spaces between areas of ossification. Heidenhain's azan trichrome preparation.

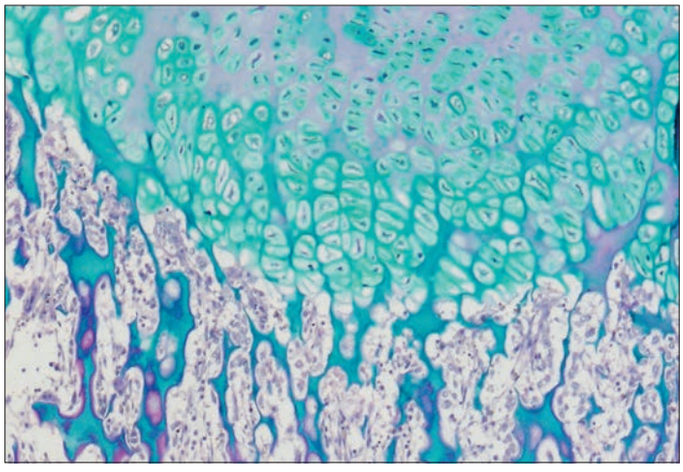

Fig. 5.23 An Alcian-blue periodic acid–Schiff (PAS)-stained section of human fetal femur showing the hypertrophy and palisading of cartilage cells as the ossifying (mineralizing) front of an early primary centre of ossification is approached (below). Lacunae are enlarged, and matrix partitions are reduced in width and exhibit increased staining density following cartilage calcification. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

from chondrocytes in the proliferation zone are most evident in the intercolumnar regions, where they appear to initiate crystal formation. At the same time, cells in the deep layer of perichondrium around the centre of the cartilage model differentiate into osteoblasts and form a peripheral layer of bone. Initially, this periosteal collar, formed by intramembranous ossification within the perichondrium, is a thin-walled tube that encloses and supports the central shaft (see Figs 5.21–5.22). As it increases in diameter, it also extends towards both ends of the shaft.

The periosteal collar, which overlies the calcified cartilaginous walls of degenerate chondrocyte lacunae, is invaded from the deep layers of the periosteum (formerly perichondrium) by osteogenic buds. These are blind-ended capillary sprouts that are accompanied by osteoprogenitor cells and osteoclasts. The latter excavate newly formed bone to reach adjacent calcified cartilage, where they continue to erode the walls of primary chondrocyte lacunae (**Figs 5.23–5.24**). This process leads to their fusion into larger, irregular communicating spaces, secondary areolae, which fill with embryonic medullary tissue (vascular mesenchyme, osteoblasts and osteoclasts, haemopoietic and marrow stromal cells, etc.). Osteoblasts attach themselves to the delicate residual walls of calcified cartilage and lay down osteoid, which rapidly becomes confluent, forming a continuous lining of bone. Further layers of bone are added, enclosing young osteocytes in lacunae and narrowing the perivascular spaces. Bone deposition on the more central calcified cartilage ceases as the formation of subperiosteal bone continues.

Osteoclastic erosion of the early bone spicules then creates a primitive medullary cavity in which only a few trabeculae, composed of bone with central cores of calcified cartilage (see Fig. 5.23), remain to support the developing marrow tissues. These trabeculae soon become remodelled and replaced by more mature bone or by marrow. Meanwhile, new, adjacent, cartilaginous regions undergo similar changes. Since these are most advanced centrally, and the epiphyses remain cartilaginous, the intermediate zones exhibit a temporospatial sequence of changes when viewed in longitudinal section (**Fig. 5.25**). This region of dynamic change from cartilage to bone persists until longitudinal growth of the bone ceases.

Expansion of the cartilaginous extremity (usually an epiphysis; see Fig. 5.20) keeps pace with the growth of the rest of the bone by both appositional and interstitial growth. The growth zone expands in all dimensions. Lateral growth of a developing long bone is caused by occasional transverse mitosis in its chondrocytes, and by appositional growth as a result of matrix deposition by cells from the perichondrial collar or ring at this level. The future growth plate therefore expands in concert with the shaft and adjacent future epiphysis. A zone of relatively quiescent chondrocytes (the resting zone) lies on the side of the plate closest to the epiphysis. An actively mitotic zone of cells faces towards the shaft of the bone; the more frequent divisions in the long axis of the bone soon create numerous longitudinal columns (palisades) of disc-shaped chondrocytes, each in a flattened lacuna (see Fig. 5.25). Proliferation and column formation occur in this zone of cartilage growth (the proliferative zone), and its continued longitudinal interstitial expansion provides the basic mode of elongation of a bone.

The columns of cells show increasing maturity towards the centre of the shaft, as their chondrocytes increase in size and accumulate glycogen. In the hypertrophic zone, energy metabolism is depressed at the level of the mineralizing front (see Fig. 5.23). The lacunae are now separated by transverse and longitudinal walls, and the latter are impregnated with apatite crystals in what has become the zone of calcified cartilage (or ossification zone; see Fig. 5.22). The calcified partitions enter the zone of bone formation and are invaded by vascular mesenchyme containing osteoblasts, osteoclasts, etc. The partitions, especially the transverse ones, are then partly eroded while osteoid deposition, bone formation and osteocyte enclosure occur on the surfaces of the longitudinal walls. Lysis of calcified partitions is mediated by osteoclast action, aided by cells associated with the terminal buds of vascular sinusoids that occupy, and come into close contact with, each incomplete columnar trabecular framework.

Continuing cell division in the growth zone adds to the epiphysial ends of cell columns, and the bone grows in length as this sequence of changes proceeds away from the diaphysial centre. The bone also grows in diameter as further subperiosteal bone deposition occurs near the epiphyses, and its medullary cavity enlarges transversely and longitudinally. Internal erosion and remodelling of the newly formed bone tissue continues.

Growth continues in this way for many months or years in different bones, but eventually one or more secondary centres of ossification

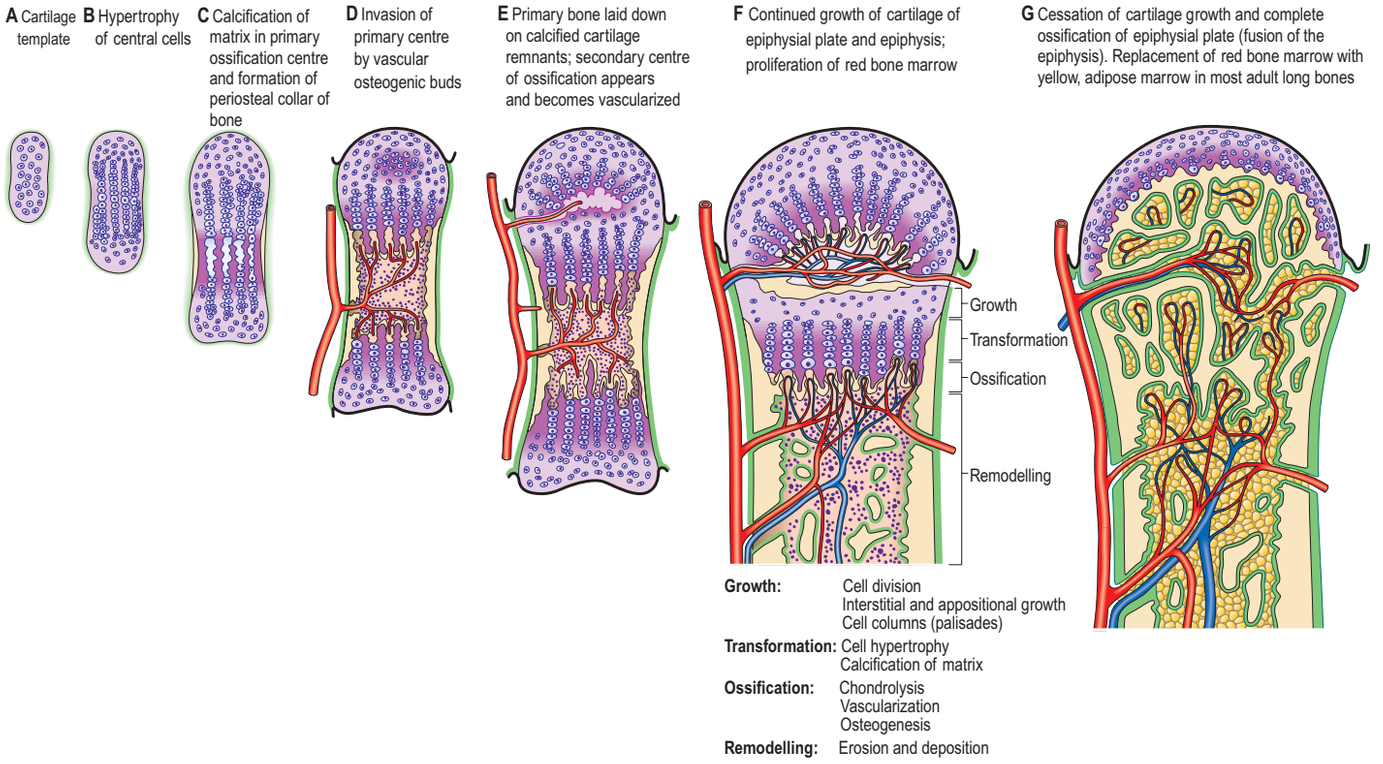

Fig. 5.25 The stages of endochondral ossification in a long bone.

usually appear in the cartilaginous extremities. Initially, these epiphysial centres (or the ends of bones that lack epiphyses) do not display cell columns. Instead, isogenous cell groups hypertrophy, with matrix calcification, and are then invaded by osteogenic vascular mesenchyme, sometimes from cartilage canals. Bone is formed on calcified cartilage, as described above. As an epiphysis enlarges, its cartilaginous periphery (perichondrium) also forms a zone of proliferation in which cell columns are organized radially; hypertrophy, calcification, erosion and ossification occur at increasing depths from the surface. The early osseous epiphysis is thus surrounded by a superficial growth cartilage, and the growth plate adjacent to the metaphysis soon becomes the most active region.

As a bone reaches maturity, epiphysial and metaphysial ossification processes gradually encroach upon the cartilaginous growth plate from either side; when they meet, bony fusion of the epiphysis occurs and longitudinal growth of the bone ceases. The events that take place during fusion are broadly as follows. As growth ceases, the cartilaginous plate becomes quiescent and gradually thins; proliferation, palisading and hypertrophy of chondrocytes stop, and the cells form short, irregular, conical masses. Patchy calcification is accompanied by resorption of calcified cartilage and some of the adjacent metaphysial bone, forming resorption channels that are invaded by vascular mesenchyme.

Some endothelial sprouts pierce the thin plate of cartilage, and the metaphysial and epiphysial vessels unite. Ossification around these vessels spreads into the intervening zones and results in fusion of epiphysis and metaphysis. This bone is visible in radiographs as a radiodense epiphysial line (a term that is also used to describe the level of the perichondrial collar or ring around the growth cartilage of immature bones, or the surface junction between epiphysis and metaphysis in a mature bone). In smaller epiphyses, which unite earlier, there is usually one initial eccentric area of fusion, and thinning of the residual cartilaginous plate. The original sites of fusion are subsequently resorbed and replaced by new bone. Medullary tissue extends into the whole cartilaginous plate until union is complete and no epiphysial 'scar' persists. In larger epiphyses, which unite later, similar processes also involve multiple perforations in growth plates, and islands of epiphysial bone often persist as epiphysial scars. Calcified cartilage coated by bone forms the epiphysial scar, and is also found below articular cartilage. It has been called metaplastic bone, a term also applied to sites of attachments of tendons, ligaments and other dense connective tissues to bone.

The cartilaginous surfaces of epiphyses that form synovial joints remain unossified, but the typical sequence of cartilaginous zones persists in them throughout life. A similar developmental sequence occurs at synchondroses, except that the proliferative rates of chondrocytes and the replacement of cartilage by bone are similar, although not identical, on either side of the synchondrosis.

Postnatal growth and maintenance of bone

Modelling, by which is meant changes in general shape, occurs in all growing bones. The process has been studied mainly in cranial and long bones with expanded extremities.

During calvarial growth, a bone such as the parietal thickens and expands, but also decreases in curvature. Accretion continues at its edges by proliferation of osteoprogenitor cells at sutures; periosteal bone is mainly added externally and eroded internally, but not at uniform rates or at all times. The rate of formation increases with radial distance from the centre of ossification (in this case, the future parietal eminence). Bone formation may also occur endocranially as well as ectocranially, so changing the curvature of the bone. The relative positions of the original centres of ossification change in three dimensions as the skull bones thicken and grow at the sutures and as the calvaria (vault) of the skull expands to accommodate the growth of the brain. Development of the outer and inner cortical plates is accompanied by internal development of trabeculae and marrow spaces.

Long bones increase in length mainly by endochondral ossification at the epiphysial growth plates. Simultaneous increase in width occurs by subperiosteal deposition and endosteal erosion. Growth at different locations can occur at different rates, or even be replaced by resorption, resulting in a change in the shape of a bone. This explains how, for example, the tibia changes its cross-sectional shape from tubular to triangular. Similarly, the waisted contours of metaphyses are preserved by differential rates of periosteal erosion and endosteal deposition, as metaphysial bone becomes diaphysial in position. The junction between a field of resorption and one of deposition on the surface of a growing bone is called a surface reversal line. The relative position of such a line may remain stable over long periods of growth and shape change.

Lamellar bone forms and is remodelled at variable rates throughout adult life (see below).

Normal development and maintenance of bone requires adequate intake and absorption of calcium, phosphorus and vitamins A, C and D, and a balance between growth hormone (GH, somatotropin), thyroid hormones, oestrogens and androgens. Other biological influences include prostaglandins and glucocorticoids. Vigorous mechanical loading is important for the maintenance of adequate bone mass. Prolonged deficiency in any of these factors can lead to loss of bone tissue (osteopaenia); if bone loss is severe (osteoporosis), it can lead to fracture and deformity.

Vitamin D influences intestinal transport of calcium and phosphate, and therefore affects circulatory calcium levels. In adults, prolonged deficiency (with or without low intake) produces bones that contain regions of deformable, uncalcified osteoid (osteomalacia). During growth,

vitamin D deficiency can lead to severe disturbance of growth cartilages and ossification, such as reductions of regular columnar organization in growth plates, and failure of cartilage calcification even though chondrocytes proliferate. Growth plates also become thicker and irregular, as exemplified in classic rickets or juvenile osteomalacia. In rickets, the uncalcified or poorly calcified cartilaginous trabeculae are only partially eroded; osteoblasts secrete layers of osteoid but these fail to ossify in the metaphysial region, and ultimately gravity deforms these softened bones.

Vitamin C is essential for the adequate synthesis of collagen and matrix proteoglycans in connective tissues. When vitamin C is deficient, growth plates become thin, ossification almost stops, and metaphysial trabeculae and cortical bone are reduced in thickness, causing fragility and delayed healing of fractures.

Vitamin A is necessary for normal growth and for a correct balance between deposition and removal of bone. Deficiency retards growth as a result of the failure of internal erosion and remodelling, particularly in the cranial base. Foramina are narrowed, sometimes causing pressure atrophy of the nerves that pass through them. The cranial cavity and spinal canal may fail to expand at the same rate as the developing central nervous system, impairing nervous function. Conversely, excess vitamin A stimulates vascular erosion of growth cartilages, which become thin or totally lost, and longitudinal growth ceases. Retinoic acid, a vitamin A derivative, is involved in pattern formation in limb buds and in the differentiation of osteoblasts.

Balanced endocrine functions are also essential to normal bone maturation, and disturbances in this balance may have profound effects. In addition to its role in calcium metabolism, excess parathyroid hormone (primary hyperparathyroidism) stimulates unchecked osteoclastic erosion of bone, particularly subperiosteally and later endosteally (osteitis fibrosa cystica). Growth hormone (GH) is required for normal interstitial proliferation in growth cartilages, ensuring normal increase in stature. Termination of normal growth is imperfectly understood, but may involve a fall in hormone production or in the sensitivity of chondroblasts to insulin-like growth factors regulated by GH. Reduction of GH production in the young leads to quiescence and thinning of growth plates and hence pituitary dwarfism. Conversely, continued hypersecretion in the immature leads to gigantism, and in the adult results in thickening of bones by subperiosteal deposition; the mandible, hands and feet are the most affected, a condition known as acromegaly.

While continued longitudinal growth of bones depends on adequate levels of GH, effective remodelling to achieve a mature shape also requires the action of thyroid hormones. Moreover, growth and skeletal maturity are closely related to endocrine activities of the ovaries, testes and suprarenal cortices. High oestrogen levels increase deposition of endosteal and trabecular bone; conversely, osteoporosis in postmenopausal women reflects reduced ovarian function. In men, fluctuations in the rate of growth, and the timing of skeletal maturation, depend on circulating levels of suprarenal and testicular androgens. In hypogonadism, growth-plate fusion is delayed and the limbs therefore elongate excessively; conversely, in hypergonadism, premature fusion of the epiphyses results in diminished stature.

Bone remodelling

Stiff materials (including bone) are vulnerable to the accumulation of microdamage during repeated loading. In metals this can result in crack propagation and 'fatigue failure'. Bone reduces the risk of such failure by periodically renewing itself, one small region of tissue at a time. This process is referred to as 'remodelling' because the volume and orientation of newly replaced matrix are not necessarily the same as the old; instead, bone takes this opportunity to adapt its mass and architecture to prevailing mechanical demands. Remodelling affects the local balance between resorption and deposition of bone. Its primary purpose is to renew bone rather than increase its mass, and the process continues throughout life, replacing approximately 10% of bone each year in adults (Brandi 2009).

Internal remodelling continuously supplies young osteons with labile calcium reserves, and provides a malleable bony architecture that is responsive to changing patterns of stress. A bone-remodelling unit consists of an advancing cutting cone and a closing cone. Activated osteoclasts form a cutting cone that excavates a cylindrical tunnel of bone (resorption canal) and advances ahead of a central growing blood vessel at a rate of 50 μm/day. A cutting cone is typically 2 mm long and takes 1–3 months to form; a similar period is required to create the new (secondary) osteon by completing the closing cone (**Fig. 5.26**). Osteoblasts follow the osteoclasts, filling in the space created with new osteoid, starting at the peripheral surface or walls of the tunnel. Successive layers of bone are deposited on the surface of the previous layer as cohorts of osteoblasts become embedded (as osteocytes) in the matrix they secrete, until the most central lamella is close to the blood vessel at the axis of the cylinder. The 'closing cone' (see Fig. 5.26) may contain 4000 osteoblasts per mm^2. In this way, the walls of resorption canals are lined with new lamellar matrix and the vascular channels are progressively narrowed. A hypermineralized basophilic cement (or growth-reversal) line marks the edge of a new osteon, indicating the border between the resorptive activity of the cutting cone and the bony matrix not remodelled by this activity. Remnants of the circumferential lamellae of old osteons form interstitial lamellae between newer osteons (see Fig. 5.17A).

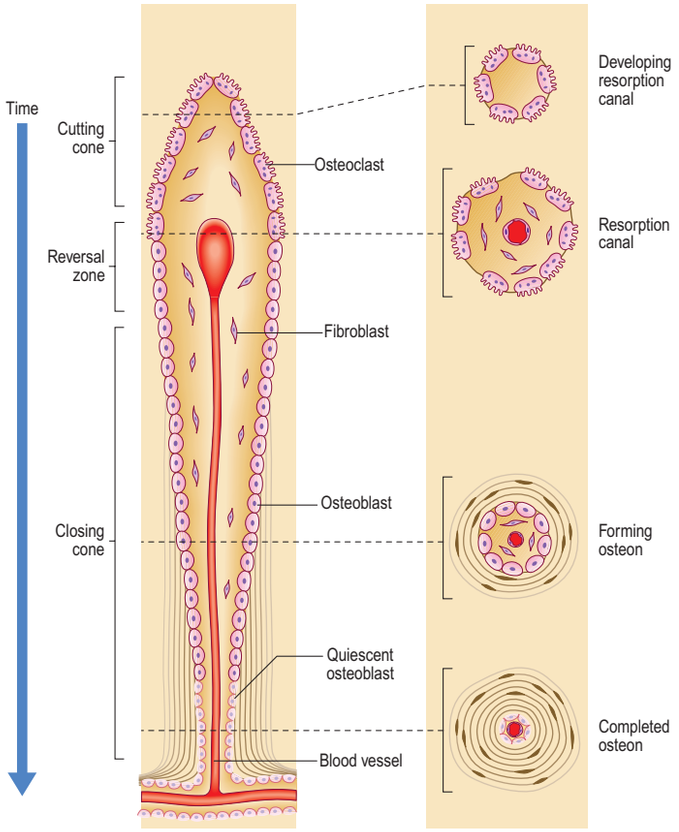

Fig. 5.26 Bone remodelling. Longitudinal and cross-sections of a time line illustrating the formation of an osteon. Osteoclasts cut a cylindrical channel through bone. Osteoblasts follow, laying down bone on the surface of the channel until matrix surrounds the central blood vessel of the newly formed osteon (closing cone of a new osteon).

The remodelling unit in cancellous bone, equivalent to the secondary osteon of compact bone, is the basic (or bony) structural unit; it has an average thickness of 40–70 μm and an average length of 100 μm, but may be more extensive and irregular in shape. Separate structural units can sometimes be visualized in microradiographs because of differences in their age and extent of mineralization (Farlay et al 2005).

Adult bone shape and mass are partly determined by genetic inheritance (Sigurdsson et al 2008). However, the pattern and extent of remodelling are largely dictated by the mechanical loading applied to the bone. Bone resorption occurs when muscle or gravitational forces are reduced, as occurs in bed rest, or in zero gravity conditions in space (Shackelford et al 2004). Reduced activity in old age is another major cause of bone loss. The rate of remodelling decreases with age, which means that numbers of osteons and osteon fragments can be used to estimate the age of skeletal material at death. Conversely, increased sporting or occupational loading of the skeleton can cause bone hypertrophy, as exemplified by the 35% increase in cortical thickness in the racket arm of elite tennis players (Jones et al 1977). Bones appear to respond to the maximum deformation they experience (see Fig. 5.68), rather than to cumulative load. Bone subjected to constant pressure can actually resorb, a response that underpins much orthodontic treatment, because teeth can be made to migrate slowly through alveolar bone by the application of steady lateral or medial pressure.

Growth of individual bones

Ossification centres appear over a long period during bone growth: many in embryonic life, some in prenatal life, and others well into the postnatal growing period. Ossification centres are initially microscopic

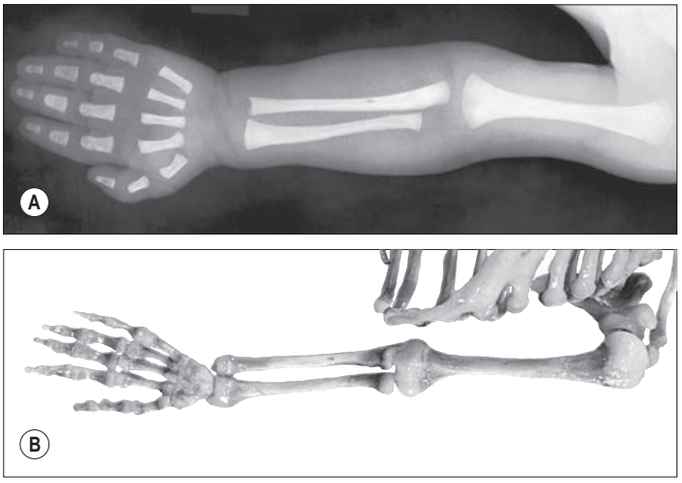

Fig. 5.27 A, A radiograph of a neonatal arm. Ossification from primary centres is well advanced in all of the limb bones except the carpals, which are still wholly cartilaginous. The gaps by which individual elements appear to be separated are filled by radiolucent hyaline cartilage, in which epiphysial or carpal ossification will subsequently occur. Note the flaring contours, narrow midshaft and relatively expanded metaphyses of the long bones, and the proportions of the limb segments – in particular, the relatively large hand – that are characteristic of this age. **B**, The bones and cartilages of a neonatal left arm. Compare the radiolucent areas in the radiograph (**A**) with the preserved cartilaginous epiphyses and carpal elements in this specimen. (B, Prepared by Michael C.E. Hutchinson; photographed by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)

but soon become macroscopic, which means that their growth can then be followed by radiological and other scanning techniques.

Some bones, including carpal, tarsal, lacrimal, nasal and zygomatic bones, inferior nasal conchae and auditory ossicles, ossify from a single centre, which may appear between the eighth intrauterine week and the tenth year: a wide interval for studying growth or estimating age. Most bones ossify from several centres, one of which appears in the centre of the future bone in late embryonic or early fetal life (seventh week to fourth month). Ossification progresses from the centres towards the ends, which are still cartilaginous at birth (Fig. 5.27). These terminal regions ossify from separate centres, which are sometimes multiple, and which appear between birth and the late teens; they are therefore secondary to the earlier primary centre from which much of the bone ossifies. This is the pattern in long bones, as well as in some shorter bones such as the metacarpals and metatarsals, and in the ribs and clavicles.

At birth, a bone such as the tibia is typically ossified throughout its diaphysis from a primary centre that appears in the seventh intrauterine week, whereas its cartilaginous epiphyses ossify from secondary centres. As the epiphyses enlarge, almost all the cartilage is replaced by bone, except for a specialized layer of articular (hyaline) cartilage that persists at the joint surface, and a thicker zone between the diaphysis and epiphysis. Persistence of this epiphysial growth plate, or growth cartilage, allows increase in bone length until the usual dimensions are reached, by which time the epiphysial plate has ossified. The bone has then reached maturity. Coalescence of the epiphysis and diaphysis is fusion, the amalgamation of separate osseous units into one.

Many long bones have epiphyses at both their proximal and their distal extremities, whereas metacarpals, metatarsals and phalanges have only one epiphysis. Typical ribs have epiphyses for the head and articular tubercle and another for the non-articular area. The costal cartilages represent the unossified hyaline cartilage of the developing rib and therefore do not display epiphyses. Epiphysial ossification is sometimes complex, e.g. the proximal end of the humerus is wholly cartilaginous at birth, subsequently developing three centres during childhood that coalesce into a single mass before they fuse with the diaphysis. Only one of these centres forms an articular surface, and the others form the greater and lesser tubercles, to which muscles are attached. Similar composite epiphyses occur at the distal end of the humerus and in the femur, ribs and vertebrae.

Many cranial bones ossify from multiple centres. The sphenoid, temporal and occipital bones are almost certainly composites of multiple elements in their evolutionary history;: some show evidence of fusion between membrane and cartilage bones that unite during growth.

If bone growth rate were uniform, ossification centres would appear in a strict descending order of bone size. However, disparate rates of ossification occur at different sites and do not appear to be related to bone size. The appearance of primary centres for bones of such different sizes as the phalanges and femora are separated by, at most, a week of embryonic life. Those for carpal and tarsal bones show some correlation between size and order of ossification, from largest (calcaneus in the fifth fetal month) to smallest (pisiform in the ninth to twelfth postnatal year). In individual bones, succession of centres is related to the volume of bone that each centre produces. The largest epiphyses, e.g. the adjacent ends of the femur and tibia, are the earliest to begin to ossify (immediately before or after birth) and are of forensic interest. At epiphysial plates, the rate of growth is initially equal at both ends of those bones that possess two epiphyses. However, experimental observations in other species have revealed that one epiphysis usually grows faster than the other after birth. Since the faster-growing end also usually fuses later with the diaphysis, its contribution to length is greater. Though faster rate has not been measured directly in human bones, later fusion has been documented radiologically. The more active end of a long limb bone is often termed the growing end but this is a misnomer.

The rate of increase in stature, which is rapid in infancy and again at puberty, demonstrates that rates of growth at epiphyses vary. The spurt at puberty, or slightly before, decreases as epiphyses fuse in post-adolescent years.

Growth cartilages do not grow uniformly at all points, which presumably accounts for changes such as the alteration in angle between the humeral shaft and its neck. The junctions between epiphysis and diaphysis at growth plates are not uniformly flat on either surface. Osseous surfaces usually become reciprocally curved by differential growth, and the epiphysis forms a shallow cup over the convex end of the shaft, with cartilage intervening – an arrangement that may resist shearing forces at this relatively weak region. Reciprocity of bone surfaces is augmented by small nodules and ridges, as can be seen when the surfaces are stripped of cartilage. These adaptations emphasize the formation of many immature bones from several elements held together by epiphysial cartilages. Most human bones exhibit these complex junctions, at which bone is bonded to bone through cartilage, throughout the active years of childhood and adolescence.

Forces at growth cartilages are largely compressive but with an element of shear. Interference with epiphysial growth may occur as a result of trauma but more frequently follows disease; the resulting changes in trabecular patterns of bone are visible radiographically as dense transverse lines of arrested growth (Harris's growth lines). Several such lines may appear in the limb bones of children afflicted by successive illnesses.

Variation in skeletal development occurs between individuals, sexes and possibly also races. The timing rather than the sequence of events varies, and females antedate males in all groups studied. Differences that are perhaps insignificant before birth may be as great as two years in adolescence.

JOINTS

Joints are the regions of the skeleton where two or more bones meet and articulate. These junctions are supported by a variety of soft tissue structures, and their prime functions are either to facilitate growth or to allow movement between bones. The simplest classifications of joints relate to either the range of movement possible or the nature of the intervening soft tissues; there is no satisfactory single classification. Free movement occurs at synovial joints, whereas restricted movement occurs at synarthroses, which can be subdivided into fibrous and cartilaginous joints. The general characteristics of each type of joint will be considered next. Features that are specific to individual joints are discussed in the relevant topographical chapters.

Fibrous joints

Bones in fibrous joints are joined by fibrous connective tissue that allows little movement. Three definable subtypes are sutures, gomphoses and syndesmoses (Fig. 5.28).

Suture

Sutures are restricted to the skull (see Chapter 34 for descriptions of individual sutures). In a suture, the two bones are separated by a layer of membrane-derived connective tissue. The sutural aspect of each bone is covered by a layer of osteogenic cells (cambial layer) overlaid by a capsular lamella of fibrous tissue that is continuous with the periosteum on both

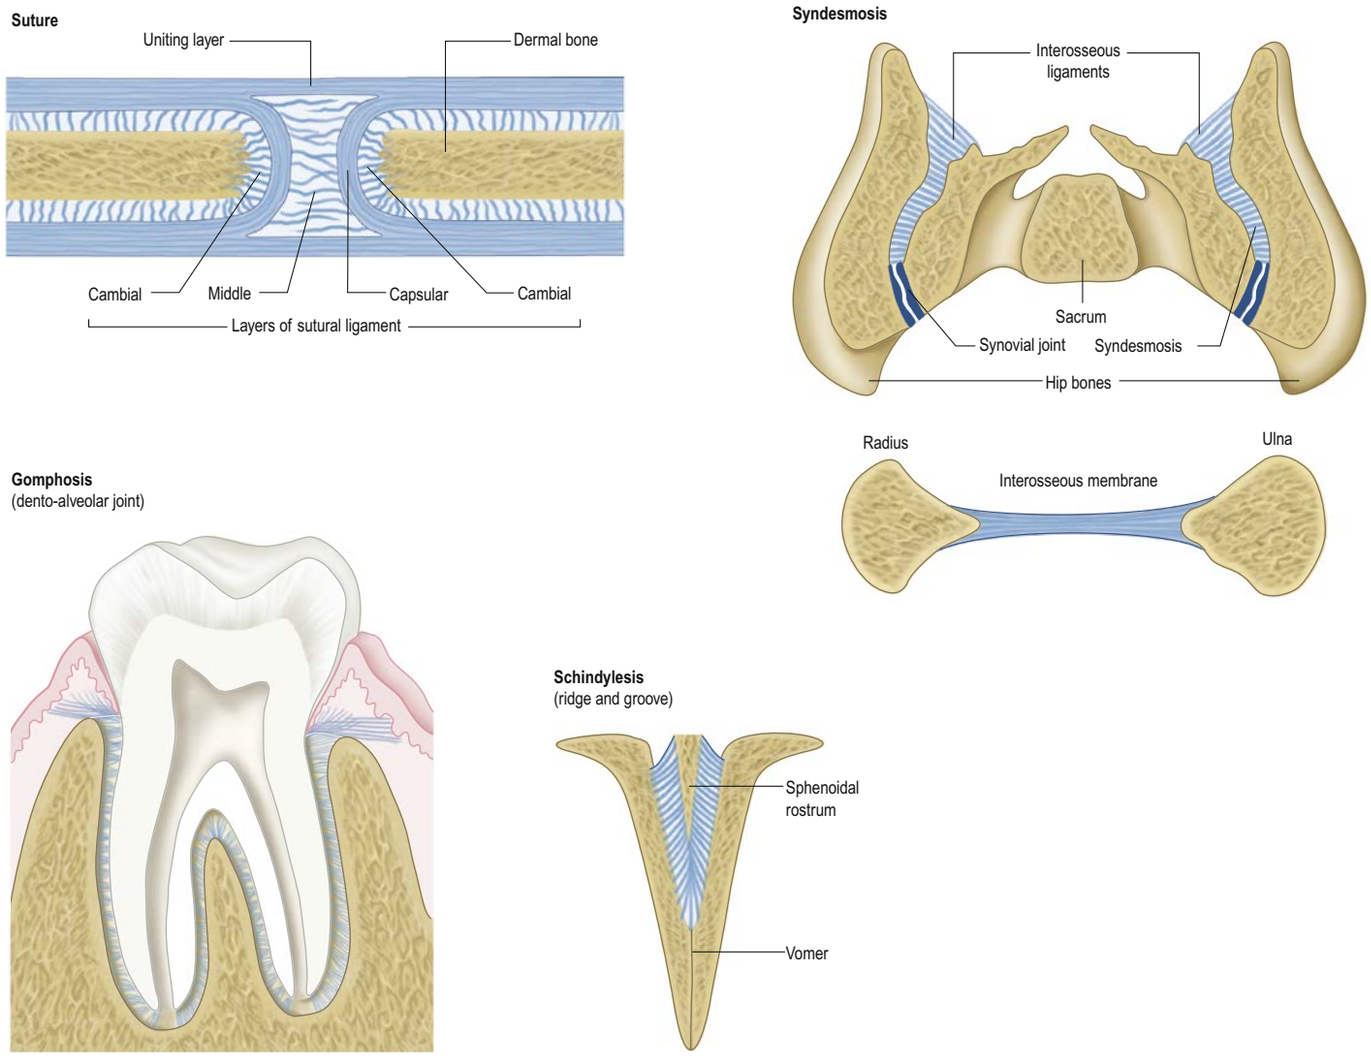

Fig. 5.28 Examples of the principal varieties of fibrous joints, each shown in section.

the endo- and ectocranial surfaces. The region between the capsular coverings contains loose fibrous connective tissue and decreases with age, so that the osteogenic surfaces become apposed. On completion of growth, many sutures synostose and are obliterated. Synostosis occurs normally as the skull ages; it can begin in the early twenties and continues into advanced age. A schindylesis is a specialized suture in which a ridged bone fits into a groove on a neighbouring element, e.g. where the cleft between the alae of the vomer receives the rostrum of the sphenoid (see Fig. 5.28).

Gomphosis

A gomphosis is a peg-and-socket junction between a tooth and its socket, where the two components are maintained in intimate contact by the collagen of the periodontium connecting the dental cement to the alveolar bone. Strictly speaking, a gomphosis is not an articulation between two skeletal structures.

Syndesmosis

A syndesmosis is a truly fibrous connection between bones. It may be represented by an interosseous ligament (e.g. the interosseous membrane between the radial and ulnar shafts), a slender fibrous cord, or a denser fibrous membrane (e.g. the posterior region of the sacroiliac joint: see Fig. 5.28).

Cartilaginous joints

Cartilaginous joints may be classified as primary (synchondrosis) or secondary (symphysis), depending on the nature of the intervening cartilage. While the distinction between fibrous and cartilaginous joints is usually clear, some degree of admixture can occur in which either a predominantly fibrous articulation contains occasional islands of cartilage, or a predominantly cartilaginous articulation contains aligned dense bundles of collagen. These joints tend to be less rigid than the fibrous articulations and some permit restricted movement (**Figs 5.29–5.30**).

Primary cartilaginous joints

Primary cartilaginous joints or synchondroses occur where advancing centres of ossification remain separated by an area of hyaline (but non-articular) cartilage (**Fig. 5.29A**). They are present in all postcranial bones that form from more than one centre of ossification. Since hyaline cartilage retains the capability to ossify with age, synchondroses tend to synostose when growth is complete. Primary cartilaginous joints are almost exclusively associated with growth plates (see above).

Secondary cartilaginous joints

Secondary cartilaginous joints, or symphyses, are largely defined by the presence of an intervening pad or disc of fibrocartilage interposed between the articular (hyaline) cartilage that covers the ends of two articulating bones (**Fig. 5.29B**). Intervertebral discs are prime examples. The pad or disc varies from a few millimetres to over a centimetre in thickness, and the whole region is generally bound by strong, tightly adherent, dense connective tissues. Collagenous ligaments extend from the periostea of the articulating bones across the symphysis. The ligaments blend with the hyaline and fibrocartilaginous perichondria but do not form a complete capsule. They contain plexuses of afferent nerve terminals, which also penetrate the periphery of the fibrocartilage. The combined strength of the ligaments and fibrocartilage can exceed that of the associated bones. A symphysis is designed to withstand a range of stresses (compression, tension, shear, bending and torsion) but the range of movement is generally limited, both by the physical nature of the articulation and by adjacent bones. Tears are

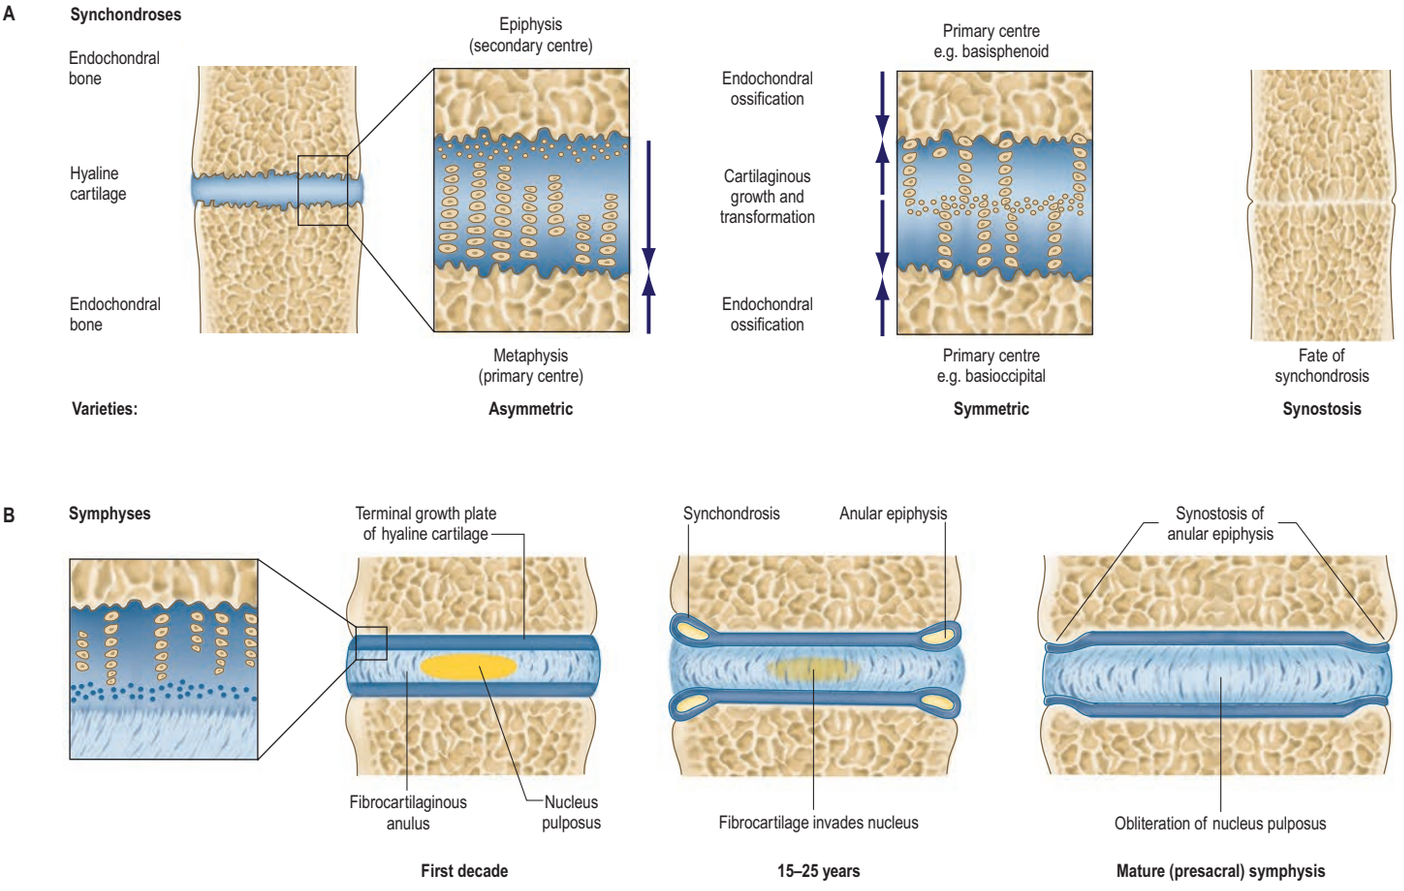

Fig. 5.29 Examples of varieties of cartilaginous joints (see also Fig. 5.30). **A**, A sectional view of the principal tissues involved, more detailed architecture and main growth patterns of symmetric and asymmetric synchondroses. Lesser degrees of asymmetry occur in some locations. Synostosis is the normal fate of almost all synchondroses when endochondral growth has ceased. **B**, Intervertebral symphyses (presacral), shown in section, displaying age-related changes. Partial or complete synostosis is the normal fate of sacral and coccygeal symphyses.

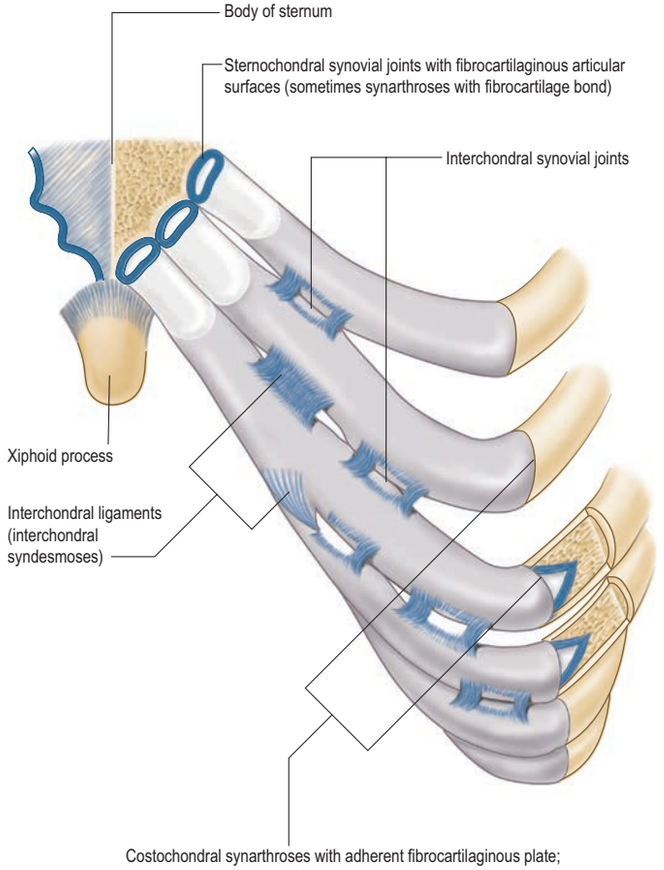

Fig. 5.30 Less common interchondral and osseochondral junctions: see text for other locations. General periosteum and perichondrium omitted.

usually the result of sudden stresses that occur when the body is in an inappropriate posture.

All symphyses occur in the midline (mandibular, manubriosternal, pubic and intervertebral) and all except the mandibular symphysis occur in the postcranial skeleton and resist synostosis. The mandibular symphysis (symphysis menti) is histologically different from the other symphyses; however, the widespread use of this descriptive term ensures that it remains, perhaps inappropriately, within this category.

The concept that synchondroses are temporary and concerned with growth, whereas symphyses are permanent and concerned with movement, is an oversimplification and only partly correct. Both types of joint must be strong, both are sites at which growth occurs, and both contribute either directly or indirectly to the total movement patterns of the parts involved. Movements that occur at a symphysis often depend on more than the mechanical properties of the fibrocartilaginous pad or disc, e.g. movements between vertebrae depend not only on the deformability of the intervertebral disc but also on the morphology of the apophysial joints and the properties of associated ligaments (Adams et al 2013).

The prominent role of synchondroses in skeletal growth is widely recognized, whereas growth of symphyses has received less attention. Symphysial growth may, for convenience, be considered from two interrelated aspects: namely, intrinsic growth of the fibrocartilaginous disc, and growth of the hyaline cartilaginous plates into which endochondral ossification progresses.

Synovial joints

These are freely moving joints in which the articulating bony surfaces are covered in smooth (hyaline) articular cartilage and separated by a film of viscous synovial fluid that serves as a lubricant (Fig. 5.31). Joint stability is provided by a fibrous capsule (which usually has intrinsic ligamentous thickenings), and often by internal or external accessory ligaments. Synovial fluid, which also aids metabolite transport to cells in the articular cartilages, is synthesized by the synovial membrane that lines the joint capsule.

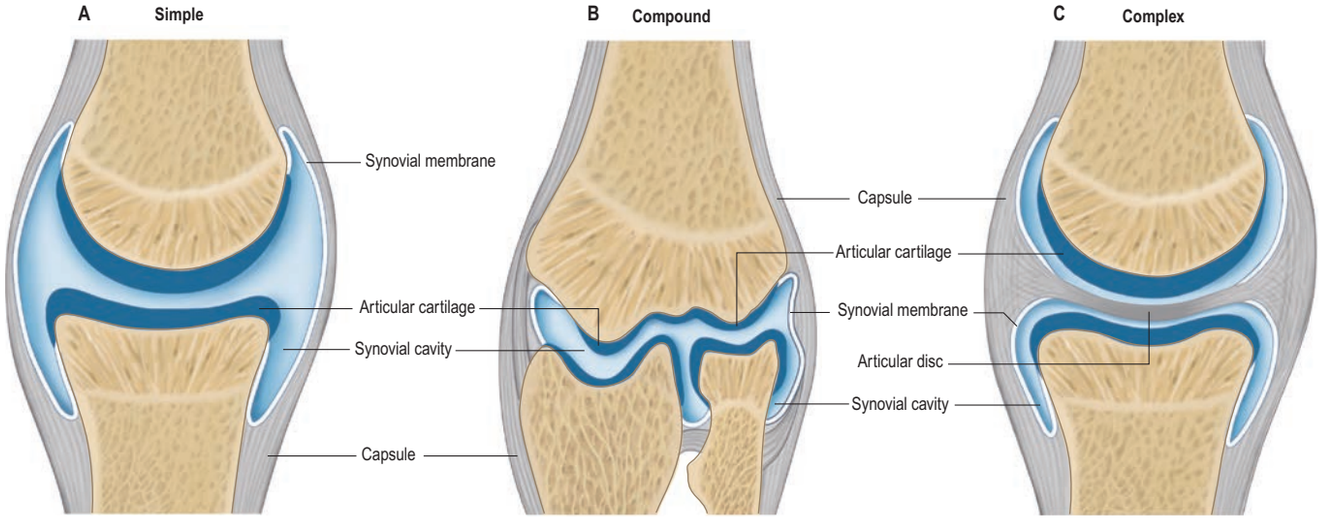

Fig. 5.31 Synovial joints, some main structural features and one elementary type of classification: **A**, simple; **B**, compound; **C**, complex joints. For clarity, the articular surfaces are artificially separated. **A** and **C** are purely diagrammatic and not related to particular joints; **B**, however, is a simplified representation of some features of an elbow joint: the complicated contours due to the olecranon, coronoid and radial fossae, and profiles of articular fat pads have been omitted for clarity.

Articular surfaces

Articular cartilage comprises a specialized type of hyaline cartilage, reflecting its origin as part of the cartilaginous 'model' of bone in embryonic life. Exceptions include the sternoclavicular, acromioclavicular and temporomandibular joints, where articulating surfaces are covered by dense fibrous tissue containing isolated groups of chondrocytes with little proteoglycan in their surrounding matrix, presumably reflecting their formation by intramembranous ossification.

The deformability of articular cartilage enables opposing cartilage surfaces to flatten slightly at their area of contact, increasing contact area and decreasing contact stress (see Fig. 5.57). This load-distributing property of articular cartilage depends on the congruence of opposing joint surfaces (see Fig. 5.61). Slight undulations in the surface trap synovial fluid so that fluid-film lubrication is possible under most circumstances; effectively, the bones 'aqua-plane' on each other (Fig. 5.60). This ensures very low friction and, consequently, low wear of the cartilage.

The most superficial layer of articular cartilage, directly adjacent to the synovial fluid, is acellular and approximately 3 μm thick. It contains fine collagen fibrils running parallel to the surface, and functions as an elastic and protective 'skin' for the underlying layers. It can appear to recoil under tension when damaged.

The acellular surface layer is coated with a large glycoprotein, lubricin, which projects from the surface so that a hydrophobic region of the molecule lies in the joint space, where it repels its counterpart on the opposing articular surface. In this way, lubricin acts in the manner of a lubricant such as grease to reduce friction and wear of the surfaces. This 'boundary lubrication' mechanism becomes important when the fluid film has been squeezed out, e.g. after sustained forceful loading of the joint, and loss of lubricin can lead to cartilage degeneration (Waller et al 2013). Transmission electron microscopy shows this lubricant layer as an interrupted electron-dense surface coat 0.03–0.1 μm thick. Synovial fluid and membranous debris, the product of chondrocytic necrosis, may contribute to this surface coat, which is transient in nature. A 'lamina splendens' is sometimes identified as a bright line at the free surface of articular cartilage when oblique sections are examined by negative phase contrast microscopy: it may be a microscopical artefact at the border between regions of different refractive index, rather than an anatomically distinct surface layer. Deeper zones of articular cartilage are described on p. 87.

With advancing age, undulations on the articular surfaces deepen and develop minute, ragged projections, perhaps as a consequence of wear and tear. These changes occur extremely slowly in healthy joints, but can be accelerated in pathologically 'dry' joints, or where synovial fluid viscosity is altered, or following injury.

Fibrous capsule

A fibrous capsule completely encloses each synovial joint except where it is interrupted by synovial protrusions (see descriptions of individual joints for details). It is composed of interlacing bundles of parallel fibres of collagen type I, and is attached continuously round the ends of the articulating bones. In small bones this attachment is usually near the periphery of the articular surfaces, but in long bones it varies considerably, and part or all of the attachment may be a significant distance from the articular surface. The joint capsule is perforated by vessels and nerves, and may contain apertures through which synovial membrane protrudes as bursae.

A fibrous capsule usually exhibits local thickenings of parallel bundles of collagen fibres, called capsular (intrinsic) ligaments, and named by their attachments. Some capsules are reinforced or replaced by tendons of nearby muscles, or expansions from them. Accessory ligaments are distinct structures that may be located inside or outside the joint capsule. All ligaments, although stiff in tension, are pliant in bending. They can rebound elastically from being stretched by up to 10–15%, and are protected from injury by reflex contraction of appropriate muscles. They do little to resist normal movements but become taut at the end of each normal range of movement.

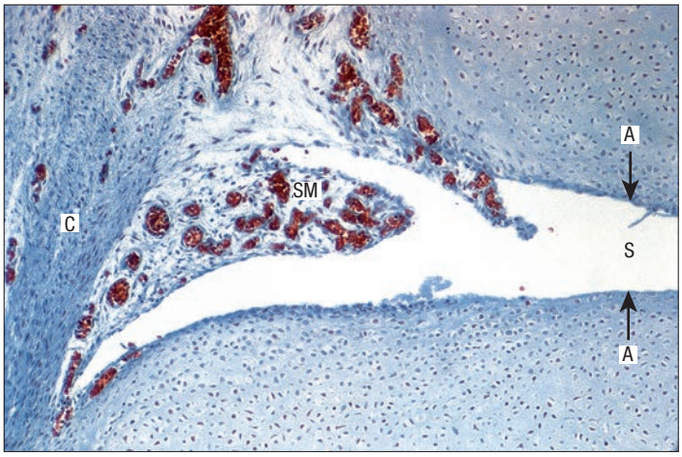

Fig. 5.32 A section of a synovial joint and its associated highly vascular synovial membrane in a human fetal hand. The two articular cartilage surfaces (A, arrows) are separated on the right by a layer of synovial fluid (S) secreted by the synovial membrane (SM), which extends a short distance into the joint space from the capsule (C).

Synovial membrane

Synovial membrane lines the fibrous joint capsule and exposed osseous surfaces, intracapsular ligaments, bursae and tendon sheaths (Fig. 5.32). It does not cover intra-articular discs or menisci, and stops at the margins of articular cartilages in a transitional zone that occupies the peripheral

few millimetres of cartilage. Where a tendon is attached to bone inside a synovial joint, an extension of the synovial membrane usually accompanies it beyond the capsule. Some extracapsular tendons are separated from the capsule by a synovial bursa that is continuous with the interior of the joint. All of these protrusions are potential routes for the spread of infection into joints.

Synovial membrane secretes and absorbs a fluid that lubricates the movement between the articulating surfaces.

Pink, smooth and shining, the internal synovial surface displays a few small synovial villi that increase in size and number with age. Folds and fringes of membrane may also project into a joint cavity; some are sufficiently constant to be named, e.g. the alar folds and ligamentum mucosum of the knee. Synovial villi are more numerous near articular margins and on the surfaces of folds and fringes, and become prominent in some pathological states.

Accumulations of adipose tissue (articular fat pads) occur within the synovial membrane in many joints. These pads, together with synovial folds and fringes, are deformable cushions that occupy potential spaces and irregularities in joints that are not wholly filled by synovial fluid. During movement they accommodate to the changing shape and volume of the irregularities, a function they share with intra-articular discs and menisci. They also increase the area of synovial membrane, and may help to spread synovial fluid over the articular surfaces.

Synovial membrane consists of a highly cellular intimal layer resting on a fibrous and vascular subintimal layer (subsynovial tissue). The subintima is often composed of loose, irregular connective tissue, but also contains organized collagen and elastin fibres lying parallel to the membrane surface, interspersed with occasional fibroblasts, macrophages, mast cells and fat cells. The elastic component may prevent formation of redundant folds during joint movement. Subintimal adipose cells form compact lobules surrounded by highly vascular fibroelastic interlobular septa that provide firmness and compressive turgor.

The intimal layer consists of pleomorphic synovial cells embedded in a granular, amorphous matrix. In normal human joints, synovial cells form an interlacing, discontinuous layer, 1–3 cells and 20–40 μm thick, between the subintima and the joint cavity. They are not separated from the subintima by a basal lamina, and are distinguished from subintimal cells only because they associate to form a superficial layer. In many locations, but particularly over loose subintimal tissue, areas are commonly found that are free from synovial cells. The synovial cells over fibrous subintimal tissue may be flattened and closely packed, forming endothelium-like sheets. Human synovial cells are generally elliptical, with numerous cytoplasmic processes. Neighbouring cells are often separated by gaps, but their processes may interdigitate where they lie close together. There is considerable regional variation in cell morphology and numbers.

There are at least two morphologically distinct populations of synovial cells or synoviocytes: type A macrophage-like synoviocytes (MLS) and type B fibroblast-like synoviocytes (FLS) (Iwanaga et al 2000). The phenotype of type A synoviocytes is similar to that of other tissue resident macrophage populations: morphologically they are characterized by surface ruffles or lamellipodia, plasma membrane invaginations and associated pinocytotic vesicles, a prominent Golgi apparatus but little rough endoplasmic reticulum. They probably synthesize and release lytic enzymes and phagocytose joint debris from synovial fluid. Type B synoviocytes, which predominate, resemble fibroblasts and have abundant rough endoplasmic reticulum but fewer vacuoles and vesicles, and a less ruffled plasma membrane than type A synoviocytes. They probably synthesize some of the hyaluronan of synovial fluid, the boundary lubricant lubricin, and inhibitors of the degradative enzymes synthesized by type A cells, limiting their potential to damage joint tissues. Synoviocytes do not divide actively in normal synovial membranes, but may do so in response to trauma and haemarthrosis. Under such conditions, type B synoviocytes divide *in situ*, while the population of type A cells increases by immigration of bone marrow-derived precursors. FLS and MLS play essential roles in the joint pathology of rheumatoid arthritis (Tu et al 2018).

Synovial fluid

Synovial fluid occupies synovial joints, bursae and tendon sheaths. In synovial joints it is clear or pale yellow, viscous and slightly alkaline at rest (the pH lowers during activity), and contains a small mixed population of cells and metachromatic amorphous particles. Fluid volume is low: usually less than 0.5 ml can be aspirated from a large joint such as the knee.

The composition of synovial fluid is consistent with it being mainly a transudate of blood plasma: it contains protein (approximately 0.9 mg/100 ml) derived from the blood. It also contains hyaluronan, which is thought to be a significant determinant of its viscoelastic and thixotropic (flow rate-dependent) properties. Approximately 2% of synovial fluid protein differs from plasma protein and is probably produced by type B synoviocytes. Approximately one-quarter of this appears to be a specialized lubricating glycoprotein, lubricin. Synovial fluid contains a few cells (approximately 60 per ml in resting human joints), including monocytes, lymphocytes, macrophages, synovial intimal cells and polymorphonuclear leukocytes; higher counts are found in young individuals. The amorphous metachromatic particles and fragments of cells and fibrous tissue found in synovial fluid are presumed to be the by-products of wear and tear.

Intra-articular menisci, discs and fat pads

An articular disc or meniscus can occur between articular surfaces where congruity (conformity of opposing articular surfaces) is low. The term meniscus should be reserved for incomplete discs, like those in the knee joint and, occasionally, in the acromioclavicular joint. Complete discs, such as those in the sternoclavicular and inferior radio-ulnar joints, extend across a synovial joint, and so divide it structurally into two synovial cavities; they often have small perforations. The disc in the temporomandibular joint may be complete or incomplete (Ch. 38).

The main part of a disc is relatively acellular, but the surface may be covered by an incomplete stratum of flat cells, continuous at the periphery with adjacent synovial membrane. Discs are usually connected to their fibrous capsule by vascularized connective tissue, so that they become invaded by blood vessels and afferent and vasomotor postganglionic sympathetic nerves. The union between disc and capsule can be close and strong, as occurs in the knee and temporomandibular joints. Discs and menisci are composed of fibrocartilage containing crimped type I collagen fibres, and are not covered by synovial membrane.

The functions of intra-articular fibrocartilages are uncertain. Evidence from structural or phylogenetic data, aided by mechanical analogies, suggests that their functions include the improvement of fit between articulating surfaces; deployment of weight over larger surface areas; shock absorption; facilitation of combined movements; limitation of translational (gliding) movements at joints such as the knee; protection of articular margins; facilitation of rolling movements; and spread of lubricant. The temporomandibular disc has attracted particular attention because of its exceptional, perhaps unique, design and biomechanical properties.

The functions of labra and fat pads, two other quite common types of intra-articular structure, are also uncertain. A labrum is a fibrocartilaginous anular lip, usually triangular in cross-section, attached to an articular margin such as the glenoid fossa or acetabulum. It deepens the socket and increases the area of contact between articulating surfaces, and may act as a lubricant spreader. Unlike menisci, labra are not compressed between articular surfaces. Small fibrous labra have been described along the ventral or dorsal margins of the zygapophysial joints at lumbar levels, as have meniscus-shaped fibroadipose meniscoids at the superior or inferior poles of the same joints. Fat pads are soft and change shape to fill joint recesses that vary in dimension according to joint position.

Vascular supply and lymphatic drainage

Numerous branches from peri-articular arterial plexuses pierce the fibrous capsules to form subsynovial vascular plexuses. Some synovial vessels end near articular margins in an anastomotic fringe, the circulus articularis vasculosus. A lymphatic plexus in the synovial subintima drains along blood vessels to the regional deep lymph nodes.

Articular cartilage, intra-articular menisci and cartilaginous discs are all avascular, presumably because high mechanical pressures in these deformable tissues would collapse any blood vessels inside them. Laboratory experiments show that proteoglycans inhibit vascular growth, so the high concentration of proteoglycans in the cartilaginous tissues of joints may help to exclude blood vessels. Injury and disease can alter both the mechanical and chemical environment within cartilage, and may allow revascularization in peripheral and disrupted regions. The blood supply to subchondral bone is described on p. 95.

Innervation

A movable joint is innervated by articular branches of the nerves that supply the muscles acting on the joint and that also supply the skin covering the joint (Hilton's law). Although there is overlap between the territories of different nerves, each nerve innervates a specific part of the capsule. The region made taut by muscular contraction is usually innervated by nerves that supply the antagonists. For example, during

abduction, stretching the portion of the capsule of the hip joint supplied by the obturator nerve elicits reflex contraction of the adductors that is usually sufficient to prevent damage.

Myelinated axons in articular nerves innervate Ruffini endings, lamellated articular corpuscles, and structures resembling Golgi tendon organs. Ruffini endings respond to stretch and adapt slowly, whereas lamellated corpuscles respond to rapid movement and vibration, and adapt rapidly; both types of receptor register the speed and direction of movement. Golgi tendon organs, innervated by the largest myelinated axons (10–15 μm diameter), are slow to adapt; they mediate position sense and also are concerned in stereognosis, i.e. recognition of shape of held objects. Simple endings are numerous at the attachments of capsules and ligaments, and are thought to be the terminals of unmyelinated and thinly myelinated nociceptive axons (see p. 62 for an account of sensory receptors).

Many unmyelinated postganglionic sympathetic axons terminate near vascular smooth muscle, and are presumably either vasomotor or vasosensory. The nerve endings in synovial membrane are believed to supply blood vessels exclusively, from which it is assumed that synovial membrane is normally relatively insensitive to pain.

Cartilaginous structures within joints normally have no nerve supply, partly because they are avascular and partly because axonal growth is inhibited by a high concentration of proteoglycans. However, when fibrocartilage is injured or diseased, nerves can accompany the consequent ingrowth of blood vessels (Lama et al 2018) and may give rise to pain. Subchondral bone is normally innervated and is a likely source of pain in the spine (Wang et al 2012).

Classification

Synovial joints can be classified according to their shape (Fig. 5.33). While this has some practical value, it should be remembered that they are merely variations, sometimes extreme, of basic forms. Articular surfaces are never truly flat, or complete spheres, cylinders, cones or ellipsoids.

Plane joints

Plane joints, such as intermetatarsal and some intercarpal joints, have almost flat surfaces. Slight curvature is often disregarded, although it is usual, and movements are considered to be pure translations (sliding) between bones.

Hinge joints

Movement takes place about a single stationary axis, and so is largely restricted to one plane. Examples are the interphalangeal and humeroulnar joints. However, the surfaces of biological hinges are not truly cylindrical, and actual motion can occur in more than one plane. Hinge joints possess strong collateral ligaments.

Bicondylar joints are predominantly uniaxial hinge joints, but the presence of two condyles side by side allows limited rotation about a second axis orthogonal to the first. These joints are formed from two convex condyles that articulate with concave or flat surfaces. The condyles may lie within a common fibrous capsule (as in the knee), or in separate capsules that necessarily cooperate in all movements as a condylar pair (as in the temporomandibular joints).

Pivot joints

These are uniaxial joints in which an osseous pivot inside an osteoligamentous ring allows rotation (twisting) only around the axis of the pivot. Pivots may rotate in rings (e.g. the head of the radius rotates within the anular ligament and ulnar radial notch), or rings may rotate around pivots (e.g. the atlas rotates around the dens of the axis).

Ellipsoid joints

Ellipsoid joints are biaxial, and consist of an oval, convex surface that is apposed to an elliptical concavity. Examples are the radiocarpal and

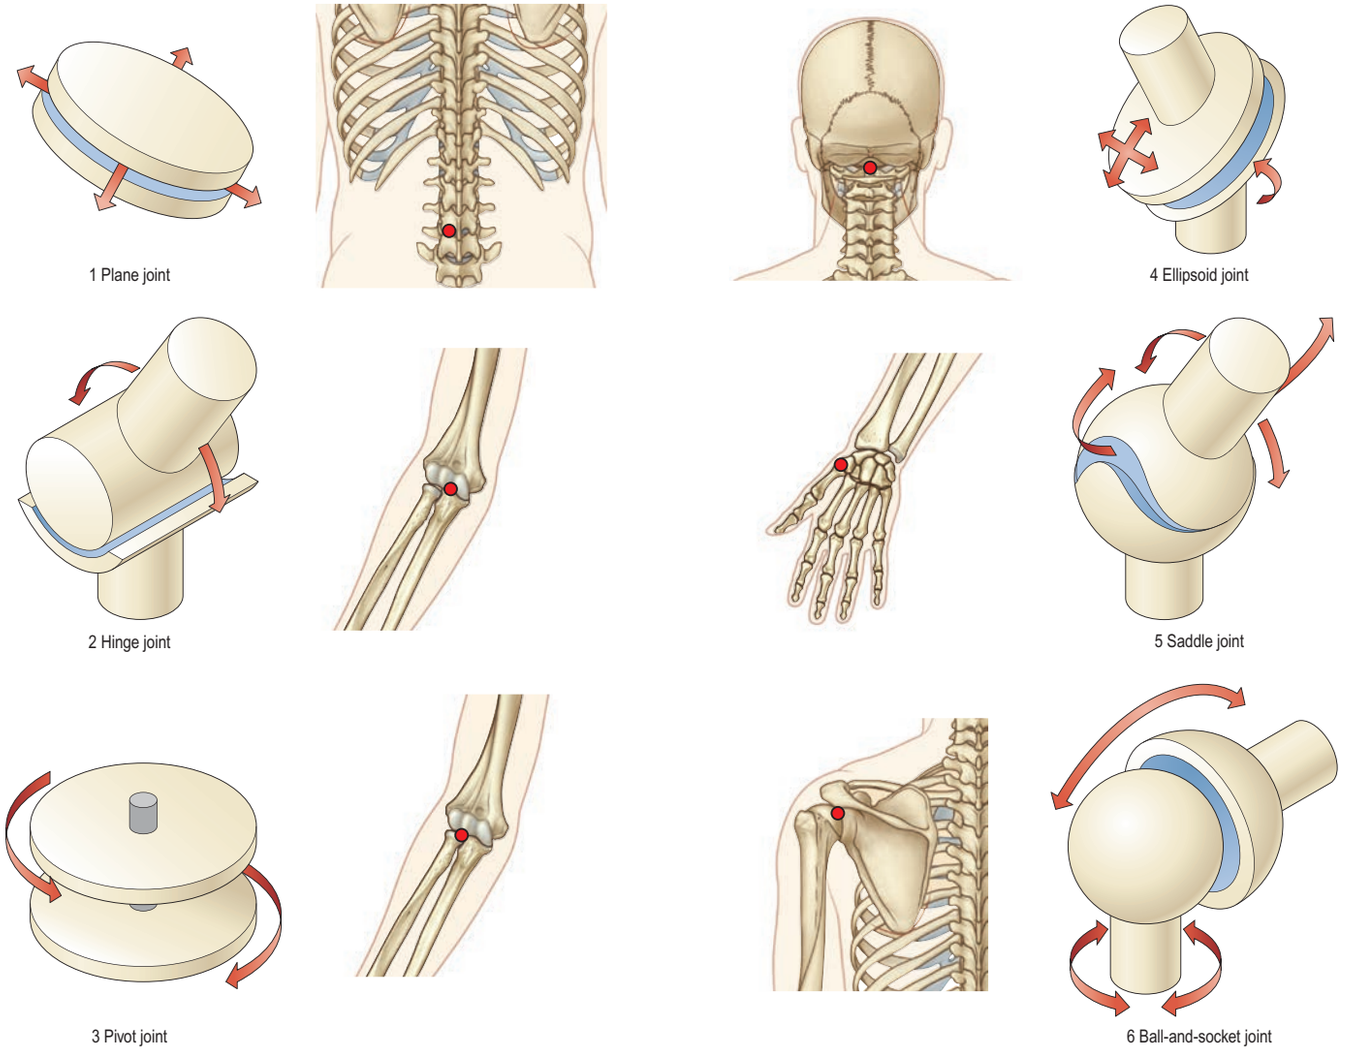

Fig. 5.33 Types of synovial joint, with selected examples.

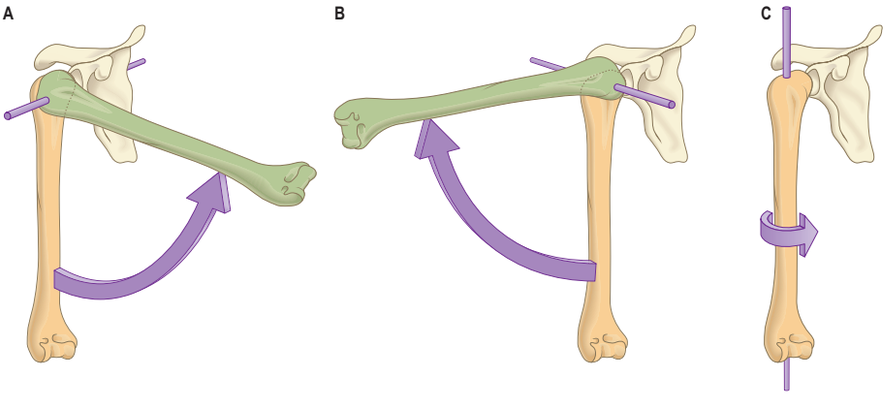

Fig. 5.34 The shoulder joint is multiaxial and possesses three degrees of freedom. The three mutually perpendicular axes are shown, around which the principal movements of flexion–extension (**A**), abduction–adduction (**B**) and medial and lateral rotation (**C**) occur. Note that these axes are referred to the plane of the scapula and not to the coronal and sagittal planes of the erect body. Although an infinite variety of additional movements may occur at such a joint, e.g. movements involving intermediate planes or combinations, they can always be resolved mathematically into components related to the three axes illustrated.

metacarpophalangeal joints. Primary movements such as flexion–extension and abduction–adduction occur around two orthogonal axes and may be combined as circumduction. Rotation around the third axis is largely prevented by general articular shape.

Saddle joints

Saddle joints are biaxial joints in which the articular surfaces have both concave and convex regions. Each surface is maximally convex in one direction and maximally concave in another, at right-angles to the first. The convexity of the larger surface is apposed to the concavity of the smaller surface and vice versa. Primary movements occur in two orthogonal planes but articular shape also causes axial rotation of the moving bone. Such 'coupled' rotation is never independent, and can be functionally significant in habitual positioning and limitation of movement. The most familiar saddle joint is the carpometacarpal joint of the thumb; other examples include the ankle and calcaneocuboid joints.

Ball-and-socket joints

These multiaxial joints are formed by a globoid 'head' articulating with an opposing cup. Prime examples are the hip and shoulder joints. Although their surfaces resemble parts of spheres, they are not strictly spherical but slightly ovoid, and consequently congruence is not perfect in most positions: it occurs in only one position, at the end of the most common movement.

Factors influencing movement

Movements at synovial joints depend on a number of factors, including the complexity and number of articulating surfaces, and the number and position of the principal axes of movement.

Complexity of form

Most synovial joints are simple articulations between two articular surfaces. A joint with more than two articular surfaces is called a compound joint, e.g. the knee and the elbow (see Fig. 5.31). In all compound joints, articulating territories remain distinct. A synovial joint that contains an intra-articular disc or meniscus is called a complex joint, e.g. the tibiofemoral joint of the knee, and the temporomandibular joint.

Degrees of freedom

Joint motion can be described by rotation and translation about three orthogonal axes. There are three possible rotations (axial, abduction–adduction, flexion–extension) and three possible translations (proximodistal, mediolateral, anteroposterior). Each is a degree of freedom. For most joints, translations are small and can be neglected (Fig. 5.34). A few joints have minor but pure translatory movements, but most joint motion is by rotation.

When movement is practically limited to rotation about one axis (e.g. the elbow), a joint is termed uniaxial and has one degree of freedom. If independent movements can occur around two axes (e.g. flexion–extension and axial rotation in the knee), the joint is biaxial and has two degrees of freedom. Since there are three axes for independent rotation, joints may have up to three degrees of freedom. Even though a true 'ball-and-socket' joint can rotate about many chosen axes, for each position there is a maximum of three orthogonal planes, which means that it can have, as a maximum, three degrees of freedom.

For a uniaxial hinge joint with a single degree of freedom, a single unchanging axis of rotation would be predicted. However, the complex shapes of joint surfaces can lead to a variable radius of curvature (Fig. 5.35), and consequently a variable axis of rotation, as joint movement progresses. If the variation is minor, as in the elbow, it is often appropriate to describe a mean position for the axis. Motion in one direction is often linked to motion in another. Coupled (or conjunct) movements occur as an integral and inevitable accompaniment of the main movement. Adjunct movements can occur independently and may or may not accompany the principal movement.

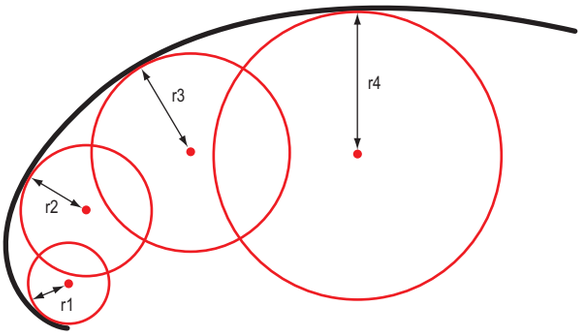

Fig. 5.35 A profile of a section through an ovoid surface showing that it may be considered as a series of segments of circles of changing radius. The radius of curvature of joint surfaces often changes from one location to another.

Types of joint movement

Joint surfaces usually move by a combination of translation (gliding) and angulation (rotation). Where movements are slight, the reciprocal surfaces are of similar size, but where they are substantial, the bone that is habitually more mobile has the larger articular surface.

Translation

Translation is the simplest motion and involves gliding or sliding without appreciable angulation. Although frequently combined with other movements, it is often considered the only motion permitted in some carpal and tarsal articulations. However, cineradiography reveals that considerable angulation occurs during movements of the small carpal and tarsal bones.

Flexion

Flexion is an example of angulation, where there is a change in angle between the topographical axes of the articulating bones. Although a widely used term, flexion is difficult to define. It often means approximation of two ventral surfaces around a transverse axis. However, the thumb is almost at right angles to the fingers: its 'dorsal' surface faces laterally so that flexion and extension at its joints occur around anteroposterior axes. At the shoulder, flexion is referred to an oblique axis through the centre of the humeral head in the plane of the scapular body, the arm moving anteromedially forwards and hence nearer to the ventral aspect of the trunk. At the hip, which has a transverse axis, flexion brings the morphologically dorsal (but topographically ventral) surface of the thigh to the ventral aspect of the trunk. Description of flexion at the ankle joint is complicated by the fact that the foot is set at a right-angle to the leg. Elevation of the foot diminishes this angle and is usually termed flexion, but because it involves the approximation of two dorsal surfaces it might equally be called extension. Since the terms 'dorsal' and 'plantar' are used to denote the superior and inferior surfaces, respectively, of the

foot, dorsiflexion and plantar flexion are the terms used to describe ankle movements.

Abduction and adduction

Abduction and adduction occur around anteroposterior axes except at the first carpometacarpal and shoulder joints. The terms generally imply lateral or medial angulation, except in digits, where arbitrary planes are chosen (midlines of the middle digit of the hand and second digit of the foot), because these are least mobile in this respect. Abduction of the thumb occurs around a transverse axis and away from the palm. Similarly, abduction of the humerus on the scapula occurs in the scapular plane around an oblique axis at right-angles to it.

Axial rotation

Axial rotation is a widely, but often imprecisely, used term. Its restricted sense denotes movement around some notional 'longitudinal' axis, which may even be in a separate bone, e.g. the dens of the second cervical vertebra, on which the atlas rotates. An axis may approximate to the centre of the shaft of a long bone, as in medial and lateral humeral rotation (see Fig. 5.34). Alternatively, the axis may be at an angle to the topographical axis of a bone, as in movement of the radius on the ulna in pronation and supination, where the axis joins the centre of the radial head to the base of the ulnar styloid process. In these examples, rotations can be independent adjunct motions, constituting a degree of freedom, or obligatory (coupled) rotations, which always accompany some other main movement as a consequence of articular geometry.

Circumduction

Circumduction combines successive flexion, abduction, extension and adduction, and occurs when the distal end of a long bone circumscribes the base of a cone that has its apex at the joint in question. Examples are circular movements of the hand and foot about the shoulder and hip joints, respectively.

Development of joints

The development of joints is described in the context of limb development on page 305.

MUSCLE

Most cells possess cytoskeletal elements that are capable of lengthening or shortening and so enable the cell to change its shape. This capacity is important in a variety of cellular functions, including locomotion, phagocytosis and mitosis. Slow movements can be effected by polymerization–depolymerization mechanisms involving actin and tubulin, but much faster and more forceful movements can be created by the so-called 'motor proteins', which use energy from the hydrolysis of adenosine 5′-triphosphate (ATP). Of these ATP-dependent systems, one of the most widespread is based on the interaction of the motor protein myosin with actin.

In muscle cells the filaments of actin, myosin and other associated proteins are so abundant that they almost fill the interior of the cell. Moreover, they align predominantly in one direction, so that interactions at the molecular level are translated into forceful linear contraction of the whole cell. The ability of these specialized cells to change shape has thus become their most important property. Assemblies of contractile muscle cells, the muscles, are machines for converting chemical energy into mechanical work. Muscle forces move limbs and drive many of the functions of the human body, and muscle tissue constitutes 40–50% of body mass.

Classification of muscle

Muscle cells ('fibres') are also known as myocytes (the prefixes myo- and sarco- are frequently used in naming structures associated with muscle). They differentiate along one of three main pathways to form skeletal, cardiac or smooth muscle. Both skeletal and cardiac muscle (Ch. 6) may be called striated muscle, because their myosin and actin filaments are organized into regular, repeating structures (sarcomeres), which give the cells a finely cross-striated appearance when viewed microscopically. Cardiac muscle fibres are relatively short, with branched ends, and are joined to adjacent fibres at intercellular junctional complexes called intercalated discs, which skeletal muscle lacks. Smooth muscle cells (Ch. 6) lack striations because their actin and myosin are not organized into sarcomeres.

Other contractile cells, including myofibroblasts and myoepithelial cells, are different in character and developmental origin. They contain smooth muscle-like contractile proteins and are found singly or in small groups.

Skeletal muscle

Skeletal muscle ('striated, voluntary') is the most common muscle tissue. It consists of long, parallel multinucleate cells bundled together by collagenous sheaths. Its regular organization enables skeletal muscle to generate powerful contractions, with a power output of approximately 100 watts per kilogram of tissue. However, the price paid for this organization is a limited contractile range: skeletal muscle can shorten by only 30%. If a larger range of movement is required, it must be achieved through the amplification provided by lever systems, as described in Fig. 5.63. Skeletal muscle is innervated by somatic motor nerves and is sometimes referred to as voluntary muscle, because its contractions are often initiated under conscious control. However, this is a misleading term because skeletal muscle is involved in many movements, such as breathing, blinking and swallowing, which are often initiated at an unconscious level.

Microstructure of skeletal muscle

Skeletal muscle fibres are enormous multinucleate cells (**Figs 5.36–5.37**) which develop by fusion of individual myoblasts (see below). Individual fibres are long, cylindrical structures that tend to be consistent in size within a given muscle, but in different muscles may range from 10 to 100 μm in diameter, and from a few millimetres to many centimetres in length. The cytoplasm of each fibre, the sarcoplasm, is surrounded by a plasma membrane often called the sarcolemma. The bulk of the sarcoplasm comprises the contractile machinery, organized into myofibrils (see Fig. 5.37) 1–2 μm in diameter, which extend the length of the fibre. Numerous moderately euchromatic, oval nuclei usually occupy a thin transparent rim of sarcoplasm between the myofibrils and the sarcolemma, and are especially numerous in the region of the neuromuscular junction (see Fig. 3.36). In transverse section, a muscle fibre may reveal only one or two nuclei, but it may contain several hundred along its entire length. Myogenic satellite cells lie between the sarcolemma and the surrounding basal lamina (see below).

Sarcomeres

Although myofibrils are too tightly packed to be visible by routine light microscopy, their presence can be inferred from transverse striations across the tissue. Cross-striations may be demonstrated more effectively using special stains (see Fig. 5.36) or under polarized light, which can differentiate dark, anisotropic A-bands (which are birefringent and rotate the plane of polarized light strongly) from lighter, isotropic I-bands (rotate the plane of polarized light to a negligible degree). In transverse

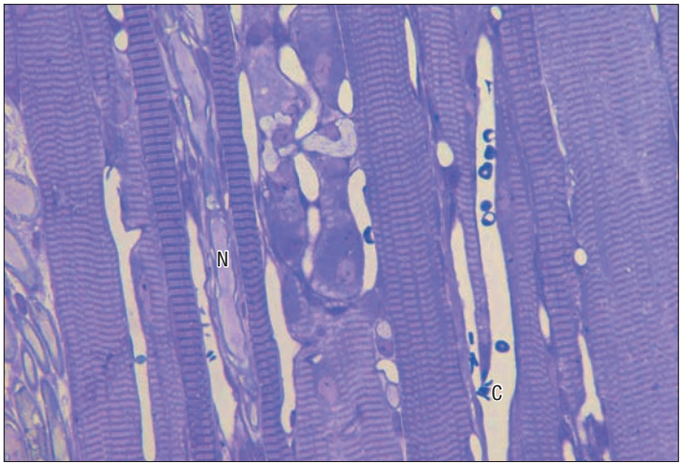

Fig. 5.36 Skeletal muscle fibres from human lateral rectus in longitudinal section, showing transverse striations representing the sarcomeric organization of actin and myosin filaments. The variation in fibre diameter is typical of extraocular muscles. Capillaries (C) and nerves (N) lie between the fibres, orientated mainly in parallel and so are also sectioned longitudinally. Toluidine blue stained resin section. (Courtesy of the Department of Optometry and Visual Science, City University, London.)

section, skeletal muscle fibres are usually polygonal (Fig. 5.38) and their sarcoplasm often has a stippled appearance, because transversely sectioned myofibrils are resolved as dots. The packing density of muscle fibres varies, from low (in the extrinsic muscles of the larynx) to high (in the group of muscles that elevate the mandible).

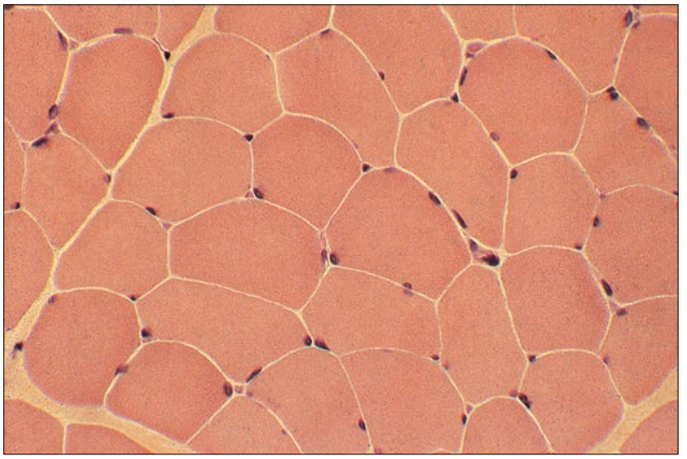

Fig. 5.38 A transverse cryostat section of adult human skeletal muscle. Note the tight packing of the fibres and the peripheral location of the dark-stained nuclei. Most detail is revealed by transmission electron microscopy (Fig. 5.39). Myofibrils, approximately 1 µm in diameter, are the dominant ultrastructural feature. In longitudinal sections they appear as ribbons that are interrupted at regular intervals by thin dark transverse lines, which correspond to discs in the parent cylindrical structure. These are the Z-lines or, more properly, Z-discs (Zwischenscheiben) that divide each myofibril into a linear series of repeating contractile units, the sarcomeres. A sarcomere is typically 2.2 µm long in resting muscle. At higher power, it can be seen to consist of two types of filament, thick and thin, organized into regular arrays (see Figs 5.37 and 5.39). Thick filaments, which are approximately 15 nm in diameter, are composed mainly of myosin. Thin filaments, which are 8 nm in diameter, are composed mainly of actin. The arrays of thick and thin filaments form a partially overlapping structure in which electron density (as seen in the electron microscope) varies according to the amount of protein present. The A-band consists of the thick filaments, together with lengths of thin filaments that interdigitate with, and thus overlap, the thick filaments at either end (see Fig. 5.39; **Fig. 5.40**). The central, paler region of the A-band, which is not penetrated by the thin filaments, is called the H-zone (Helle = light). At their centres, the thick filaments are linked together transversely by material that constitutes the M-line (Mittelscheibe = middle [of] disc), which is visible in most muscles. The I-band consists of the adjacent portions of two neighbouring sarcomeres in which the thin filaments are not overlapped by thick filaments. The thin filaments of adjacent sarcomeres are anchored in the Z-disc, which bisects the I-band.

The high degree of organization of thick and thin filaments is equally evident in transverse sections (see Fig. 5.40; **Fig. 5.41**). The thick myosin filaments form a hexagonal lattice. In the regions where they overlap the thin filaments, each myosin filament is surrounded by six actin filaments at the trigonal points of the lattice. In the I-band, the thin filament pattern changes from hexagonal to square as the filaments approach the Z-disc, where they are incorporated into a square lattice structure.

The banded appearance of individual myofibrils is a function of the regular alternation of the thick and thin filament arrays. The size of myofibrils places them at the limit of resolution of light microscopy; cross-striations are only visible at that level because of the alignment in register of the A- and I-bands in adjacent myofibrils across the width of the whole muscle fibre. In suitably stained relaxed material, the A-, I- and H-bands are quite distinct, whereas the Z-discs, which are such a prominent feature of electron micrographs, are thin and much less conspicuous in the light microscope, and M-lines cannot be resolved.

Muscle proteins

Myosin, the protein of the thick filament is the most abundant contractile protein (60% of the total myofibrillar protein). The thick filaments of skeletal and cardiac muscle are 1.5 µm long. Their composition from myosin heavy and light chain assemblies is described on page p. 13. The other components of myosin, the regulatory proteins tropomyosin and troponin, play a major part in the control of contraction.

Actin constitutes 20% of the total myofibrillar protein mass: its filamentous form, F-actin, is the principal protein of the thin filaments.

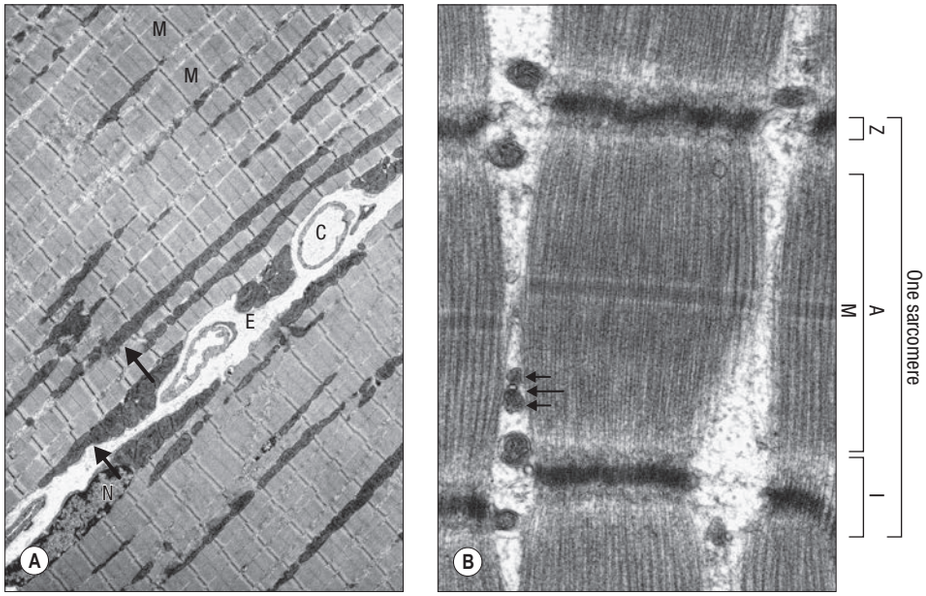

Fig. 5.39 The electron microscopic appearance of skeletal muscle in longitudinal section. **A**, A low-power view of parts of two adjacent muscle fibres, separated by endomysium (E) containing capillaries (C) and a peripherally placed nucleus (N) in the fibre. Mitochondria (arrows) are situated peripherally and between myofibrils (M). Myofibrils pack the cytoplasm, with their sarcomeres (contractile units) in register, as seen by the alignment of Z-discs (dark transverse lines) across each muscle fibre. **B**, A sarcomere within a myofibril, and parts of two others. (A sarcomere is the distance between adjacent Z-discs.) Also seen are the A-band, bisected by the M-line, and I-band, which here is almost obliterated in the contracted state (see Fig. 5.40). A triad is visible between myofibrils, comprised of a T-tubule (long arrow) and two terminal cisternae of sarcoplasmic reticulum (short arrows). (A, Courtesy of Professor Hans Hoppeler, Institute of Anatomy, University of Bern, Switzerland.)

A number of congenital myopathies result from gene mutations in components of the thin filament assembly (Clarkson et al 2004).

A third type of long sarcomeric filament (see Fig. 5.40) connects the thick filaments to the Z-disc, and is formed by the giant protein, titin, which has a molecular weight in the millions (Gregorio et al 1999). Single titin molecules span the half-sarcomere between the M-lines and the Z-discs, into which they are inserted. They have a tethered portion in the A-band, where they are attached to thick filaments as far as the M-line, and an elastic portion in the I-band. The elastic properties of titin endow the relaxed muscle fibre with passive resistance to stretching, and with elastic recoil.

A number of proteins that are neither contractile nor regulatory are responsible for the structural integrity of the myofibrils, particularly their regular internal arrangement. A component of the Z-disc, α-actinin, is a rod-shaped molecule that anchors the plus-ends of actin filaments from adjacent sarcomeres to the Z-disc. Nebulin inserts into the Z-disc, associated with the thin filaments, and regulates the lengths of actin filaments. Desmin, an intermediate filament protein characteristic of muscle, encircles the myofibrils at the Z-disc and, with the linking molecule plectrin, forms a meshwork that connects myofibrils together within the muscle fibre and to the sarcolemma. Myomesin holds myosin filaments in their regular lattice arrangement in the region of the M-line. Dystrophin is confined to the periphery of the muscle fibre, close to the cytoplasmic face of the sarcolemma. It binds to actin intracellularly and is also associated with a large oligomeric complex of glycoproteins, the dystroglycan/sarcoglycan complex that spans the membrane and links specifically with merosin, the α_2-laminin isoform of the muscle basal lamina. This stabilizes the muscle fibre and transmits forces generated internally on contraction to the extracellular matrix.

Dystrophin is the product of the gene affected in Duchenne muscular dystrophy, a fatal disorder that develops when mutation of the gene leads to the absence of the protein (Batchelor and Winder 2006). A milder form of the disease, Becker muscular dystrophy, is associated with a reduced size and/or abundance of dystrophin. Female carriers (heterozygous for the mutant gene) of Duchenne muscular dystrophy may also have mild symptoms of muscle weakness. At about 2500 kb, the gene is one of the largest yet discovered, which may account for the high mutation rate of Duchenne muscular dystrophy (approximately 35% of cases are new mutations). Other muscular dystrophies may involve deficiencies in proteins functionally associated with dystrophin, such as the dystroglycan/sarcoglycan complex or α_2-laminin; they may also be the result of mutations in proteins of the inner nuclear membrane (Azibani et al 2014, Koch and Holaska 2014).

Other sarcoplasmic structures

Although myofibrils are the dominant ultrastructural feature, skeletal muscle fibres contain other organelles essential for cellular function. Ribosomes, Golgi apparatus and mitochondria are located around the nuclei, between the myofibrils and the sarcolemma, and, to a lesser extent, between the myofibrils. Mitochondria, lipid droplets and glycogen provide the metabolic support needed by active muscle. The mitochondria are elongated and their cristae are closely packed. The number of mitochondria in an adult muscle fibre is not fixed, but can increase or decrease quite readily in response to sustained changes in activity. Spherical lipid droplets, approximately 0.25 μm in diameter, are distributed uniformly throughout the sarcoplasm between myofibrils. They represent a rich source of energy that can be tapped only by oxidative metabolic pathways; they are therefore more common in fibres that have a high mitochondrial content and good capillary blood supply. Small clusters of glycogen granules are dispersed between myofibrils and among the thin filaments. During brief bursts of activity, they provide an important source of anaerobic energy that is not dependent on blood flow to the muscle fibre.

Tubular invaginations of the sarcolemma penetrate between the myofibrils in a transverse plane at the limit of each A-band (see Fig. 5.39; **Fig. 5.42**). The lumina of these transverse (T-) tubules are thus in continuity with the extracellular space. At the ends of the muscle fibre, where force is transmitted to adjacent connective tissue structures, the sarcolemma is folded into numerous finger-like projections that strengthen the junctional region by increasing the area of attachment.

The sarcoplasmic reticulum (SR) is a specialized form of smooth endoplasmic reticulum and forms a plexus of anastomosing membrane cisternae that fills much of the space between myofibrils (see Fig. 5.42). The cisternae expand into larger sacs, junctional sarcoplasmic reticulum or terminal cisternae, where they come into close contact with T-tubules, forming structures called triads (see Figs 5.39, 5.42). The membranes of the SR contain calcium–ATPase pumps that transport calcium ions into the terminal cisternae, where the ions are bound to calsequestrin, a protein with a high affinity for calcium, in dense storage granules. In this way, calcium can be accumulated and retained in the terminal cisternae at a much higher concentration than elsewhere in the sarcoplasm. Calcium-release channels (ryanodine receptors) are concentrated mainly in the terminal cisternae and form one-half of the junctional 'feet' or 'pillars' that bridge the SR and T-tubules at the triads. The other half of the junctional feet is the T-tubule receptor that constitutes the voltage sensor.

Connective tissues of muscle

The endomysium is a delicate network of connective tissue that surrounds muscle fibres and forms their immediate external environment. It is the site of metabolic exchange between muscle and blood, and contains capillaries and bundles of small nerve fibres. Ion fluxes associated with the electrical excitation of muscle fibres take place across its proteoglycan matrix. The perimysium is a more substantial connective tissue structure that is continuous with the endomysium: it ensheathes groups of muscle fibres to form parallel bundles, or fasciculi. It carries larger blood vessels and nerves, and accommodates neuromuscular spindles. Perimysial septa are the inward extensions of a collagenous sheath, the epimysium, which forms part of the fascia that invests whole muscle groups.

Epimysium consists mainly of type I collagen; perimysium contains type I and type III collagen; endomysium contains collagen types III and IV. Collagen type IV is associated particularly with the basal lamina that invests each muscle fibre. The epimysial, perimysial and endomysial sheaths coalesce where the muscles connect to adjacent structures at tendons, aponeuroses and fasciae (see below).

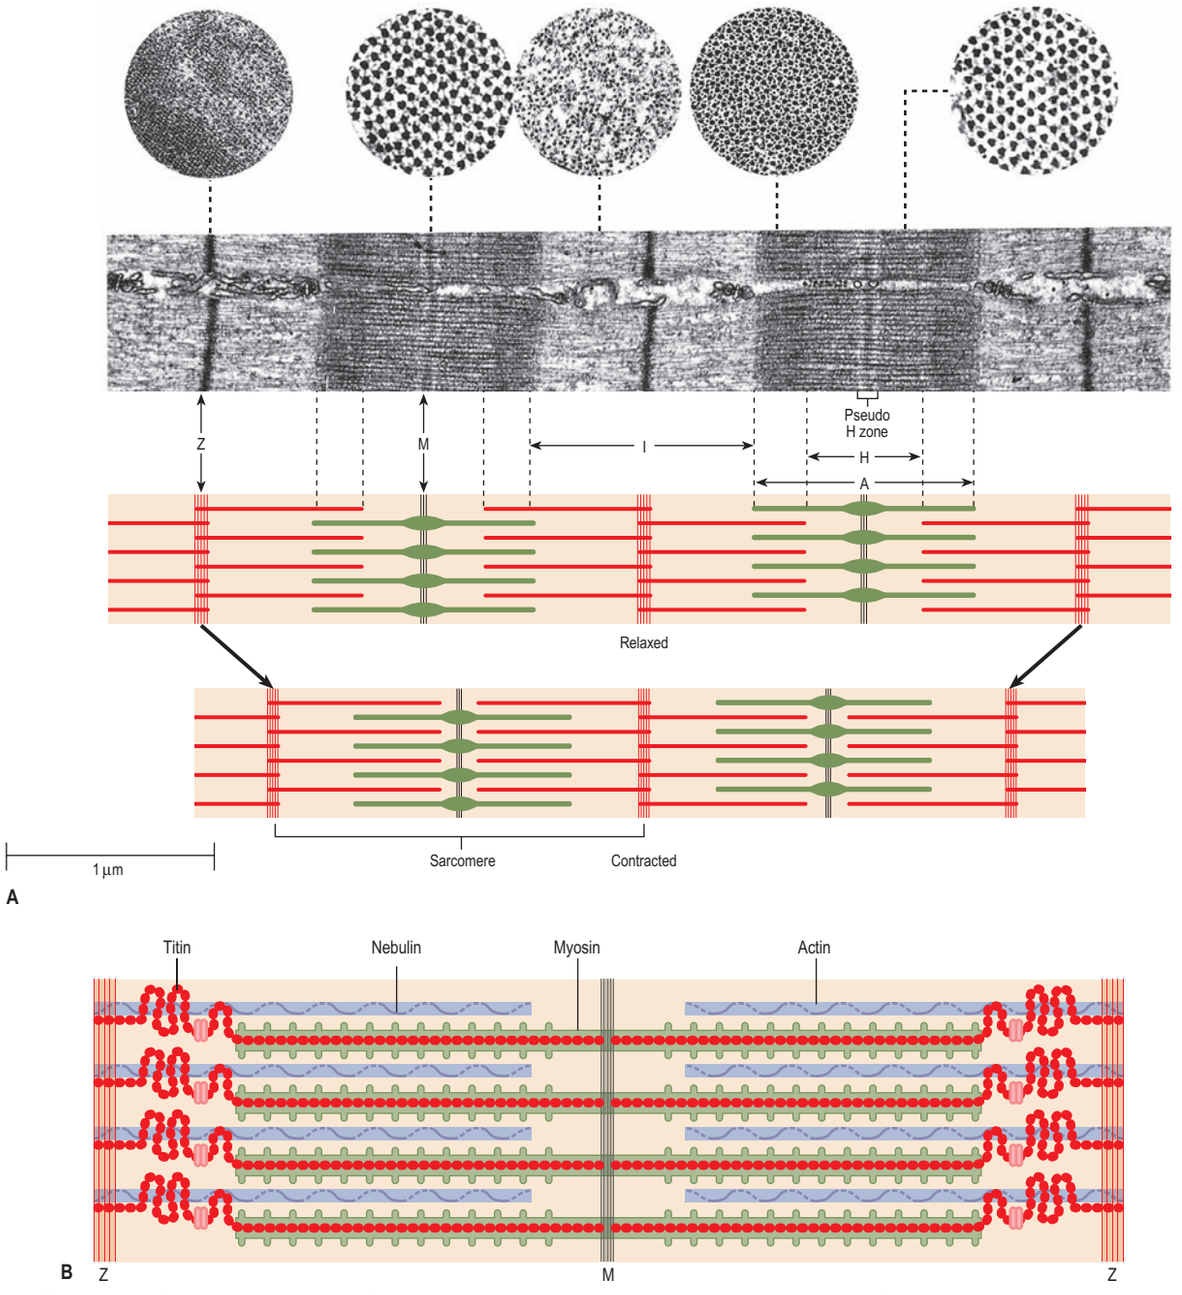

Fig. 5.40 **A**, Sarcomeric structures. The drawings below the electron micrograph (of two myofibrils sectioned longitudinally and with their long axes orientated transversely) indicate the corresponding arrangements of thick and thin filaments. Relaxed and contracted states are shown to illustrate the changes that occur during shortening. Insets at the top depict the electron micrographic appearance of transverse sections through the myofibril at the levels shown. Note that the packing geometry of the thin filaments changes from a square array at the Z-disc to a hexagonal array where they interdigitate with thick filaments in the A-band. **B**, The arrangement of titin and nebulin in a skeletal muscle sarcomere. A single titin molecule spans from the Z-disc to the M-band and contains a spring-like 'elastic' region that develops force when the sarcomere is stretched. Nebulin extends from the Z-disc for the full length of each actin filament. (A, Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago. Neurovascular supply of muscle

Vascular supply and lymphatic drainage

In most muscles, the major source artery enters on the deep surface, frequently in close association with the principal vein and nerve, at the neurovascular hilum. The vessels subsequently course and branch within the connective tissue framework of the muscle. Smaller arteries and arterioles ramify in the perimysial septa and give off capillaries that run in the endomysium. The smaller vessels lie mainly parallel to the muscle fibres, but also branch and anastomose around the fibres, forming an elongated mesh.

The gross vascular anatomy of muscles has been classified into five types according to the number and relative dominance of vascular pedicles that enter the muscle (Mathes and Nahai 1981) (**Fig. 5.43**). This classification has important surgical relevance in determining which muscles will survive and therefore be useful for pedicled or free tissue transfer procedures in plastic and reconstructive surgery. Type I muscles possess a single vascular pedicle supplying a muscle belly, e.g. tensor fasciae latae (supplied by the ascending branch of the lateral circumflex femoral artery) and gastrocnemius (supplied by the sural artery). Type II muscles are served by a single dominant vascular pedicle and several minor pedicles, and can be supported on a minor pedicle as well as the dominant pedicle, e.g. gracilis (supplied by the medial circumflex femoral artery in the dominant pedicle). Type III muscles are supplied by two separate dominant pedicles, each from different source arteries, e.g. rectus abdominis (supplied by the superior and inferior epigastric arteries)

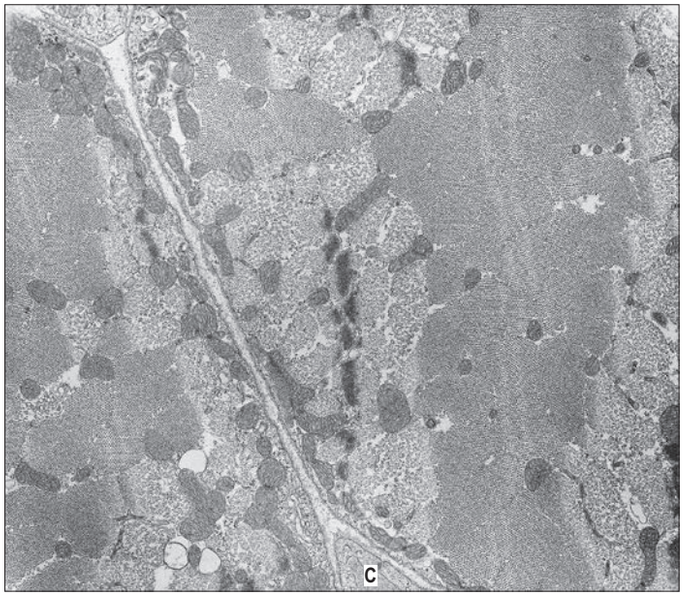

Fig. 5.41 An electron micrograph of skeletal muscle in transverse section, showing parts of two muscle fibres. Part of a capillary (C) is seen in transverse section in the endomysial space. The variation in the appearance of myofibrils in cross-section is explained in Fig. 5.40. (Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

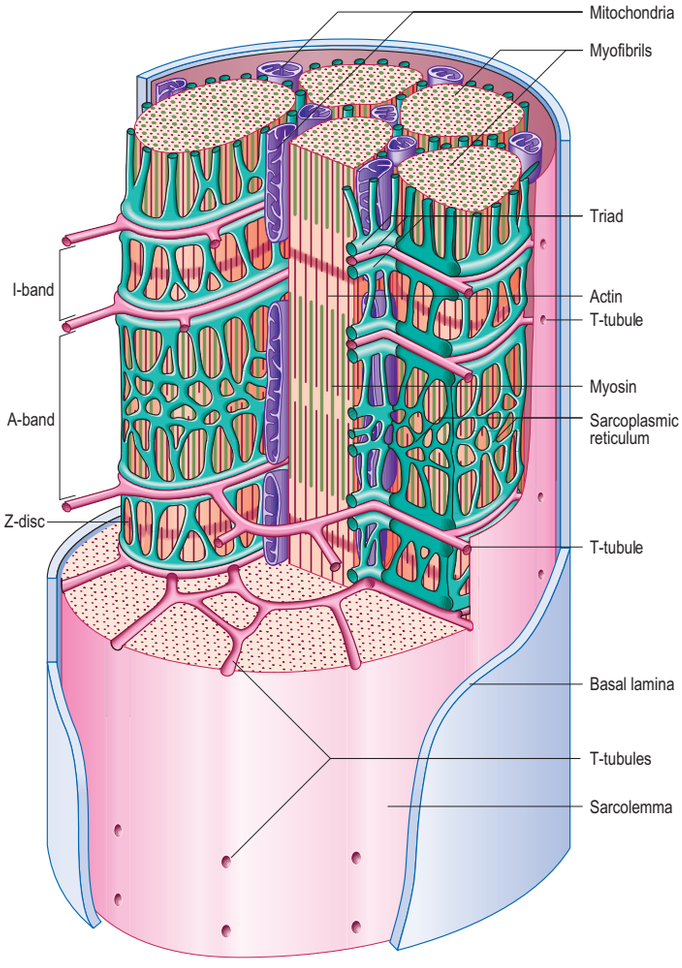

Fig. 5.42 A three-dimensional reconstruction of a mammalian skeletal muscle fibre, showing in particular the organization of the transverse (T) tubules and sarcoplasmic reticulum. Mitochondria lie between the myofibrils. Note that transverse tubules are found at the level of the A/I junctions, where they form triads with the terminal cisternae of the sarcoplasmic reticulum.

and gluteus maximus (supplied by the superior and inferior gluteal arteries). Type IV muscles have multiple small pedicles that, in isolation, are not capable of supporting the whole muscle, e.g. sartorius and tibialis anterior; about 30% survive reduction on to a single vascular pedicle. Type V muscles have one dominant vascular pedicle and multiple secondary segmental pedicles, e.g. latissimus dorsi (supplied by the thoracodorsal artery as the primary pedicle, thoracolumbar perforators from the lower six intercostal arteries and the lumbar arteries as the segmental supply) and pectoralis major (supplied by the pectoral branch of the thoraco-acromial axis as the dominant pedicle, and anterior perforators from the internal thoracic vessels as the segmental supply).

In cross-sections of muscle, the number of capillary profiles found adjacent to fibres usually varies from 0 to 3. Muscle fibres involved in sustained activities, such as maintenance of posture, are served by a denser capillary network than fibres that are recruited only infrequently. It is common for muscles to receive their arterial supply via more than one route. The accessory arteries penetrate the muscle at places other than the hilum, and ramify in the same way as the principal artery, forming vascular territories. The boundaries of adjacent territories are spanned by anastomotic vessels, sometimes at constant calibre, but more commonly through reduced-calibre arteries or arterioles that are referred to as 'choke vessels'. These arterial arcades link the territories into a continuous network.

Veins branch in a similar way, forming venous territories that correspond closely to the arterial territories. In the zones where the arterial territories are linked by choke vessels, the venous territories are linked by anastomosing veins – in this case, without change of calibre. On either side of these venous bridges, the valves in the adjacent territories direct flow in opposite directions towards their respective pedicles, but the connecting veins themselves lack valves and therefore permit flow in either direction.

Because of the potential for relative movement within muscle groups, vessels tend not to cross between muscles, but radiate to them from more stable sites or cross at points of fusion. Where a muscle underlies the skin, blood vessels bridge between the two. These may be primarily cutaneous vessels, which supply the skin directly but contribute small branches to the muscle as they pass through it, or they may be the terminal branches of intramuscular vessels, which leave the muscle to supplement the cutaneous blood supply. The latter are less frequent

where the muscle is mobile under the deep fascia. Correspondence between the vascular territories in the skin and underlying tissues gave rise to the concept of angiosomes, which are composite blocks of tissue supplied by named distributing arteries and drained by their companion veins (see Taylor and Pan (1998), Taylor (2013) for further analyses of muscle angiosomes).

Pressure exerted on valved intramuscular veins during muscle contraction functions as a 'muscle pump' that promotes venous return to the heart. In some cases this role appears to be amplified by veins that pass through the muscle after originating elsewhere in superficial or deep tissues. The extent to which the muscle capillary bed is perfused can be varied in accordance with functional demand. Arteriovenous anastomoses, through which blood can be returned directly to the venous system without traversing the capillaries, provide an alternative, regulated pathway.

The lymphatic drainage of muscles begins as lymphatic capillaries in epimysial and perimysial, but not endomysial, sheaths. These converge to form larger lymphatic vessels that accompany the veins and drain to the regional lymph nodes.

Innervation

Every skeletal muscle is supplied by one or more nerves. Muscles in the limbs, face and neck are usually innervated by a single nerve, even though the axons it contains may be derived from neurones located in several spinal cord segments and their associated sensory and sympathetic ganglia. Muscles such as those of the abdominal wall, which originate from several embryonic segments, are supplied by more than one nerve. In most cases, the nerve travels with the principal blood vessels within a neurovascular bundle (see Fig. 2.9), approaches the muscle near to its least mobile attachment, and enters the deep surface at a position that is more or less constant for each muscle.

Nerves supplying muscle are frequently referred to as 'motor nerves' but they contain both motor and sensory components. The motor component is mainly composed of large myelinated α-efferent axons that supply the muscle fibres; small, thinly myelinated γ-efferents, or fusimotor fibres, that innervate the intrafusal muscle fibres of neuromuscular spindles (see p. 65); and fine, unmyelinated postganglionic sympathetic fibres that innervate vascular smooth muscle. The sensory component consists of large, myelinated IA and smaller group II afferents from the neuromuscular spindles, large myelinated IB afferents from the Golgi tendon organs (see p. 65), and fine myelinated and unmyelinated axons that convey pain and other sensations from free terminals in the connective tissue sheaths of the muscle.

Within muscles, nerves travel through the epimysial and perimysial septa before entering the fine endomysial tissue around muscle fibres. Alpha motor axons branch repeatedly before they lose their myelinated sheaths to terminate in a narrow zone towards the centre of the muscle belly, known as the motor point. Clinically, this is the place on a muscle from which it is easiest to elicit a contraction with stimulating electrodes. Long muscles generally have two or more terminal (end-plate) bands because many muscle fibres do not run the full length of an anatomical muscle. The terminal branch of an α motor axon contacts a muscle fibre at a specialized synapse, the neuromuscular junction (see Fig. 3.36). It gives off several short, tortuous branches that each end in an elliptical area, the motor end-plate. The underlying discoidal patch of sarcolemma, the sole plate or subneural apparatus, is thrown into deep synaptic folds. This discrete type of neuromuscular junction (*en plaque* ending) is found on muscle fibres that are capable of propagating action potentials. A different type of ending is found on slow tonic muscle fibres that do not have this capability, e.g. in the extrinsic ocular muscles, where slow tonic fibres form a minor component of the anatomical muscle. In this case, the propagation of excitation is taken over by the nerve terminals, which branch over an extended distance to form a number of small neuromuscular junctions (*en grappe* endings). Some muscle fibres of this type receive the terminal branches of more than one motor neurone. The terminals of the γ-efferents that innervate the intrafusal muscle fibres of the neuromuscular spindle also take a variety of different forms.

The terminal branches of α motor axons are normally in a 'one-to-one' relationship with their muscle fibres: a muscle fibre receives only one branch, and any one branch innervates only one muscle fibre. When a motor neurone is excited, an action potential is propagated along the axon and all of its branches to all of the muscle fibres that it supplies. The motor neurone and the muscle fibres that it innervates can therefore be regarded as a functional unit: the 'motor unit'. This arrangement accounts for the more or less simultaneous contraction of a number of fibres within the muscle. The size of a motor unit varies considerably. In muscles used for precision tasks, such as the extraocular and intrinsic laryngeal muscles, each motor neurone innervates perhaps ten muscle fibres, whereas in a large limb muscle, a motor neurone may innervate several hundred muscle fibres. Within a muscle, fibres belonging to one motor unit are distributed over a wide territory without regard to fascicular boundaries, and they intermingle with the fibres of other motor units. Motor units become larger in cases of nerve damage because denervation induces collateral or terminal sprouting of the remaining axons. Each new branch can potentially reinnervate a fibre, thus increasing the territory of its parent motor neurone (see Commentary 1.5).

Muscle contraction

The arrival of an action potential at the motor end-plate of a neuromuscular junction causes acetylcholine (ACh) to be released from storage vesicles into the highly infolded 30–50 nm synaptic cleft that separates the nerve ending from the sarcolemma (see Fig. 3.36). ACh is rapidly bound by receptor molecules located in the junctional folds, triggering an almost instantaneous increase in the permeability, and hence conductance, of the postsynaptic membrane. This generates a local depolarization (the end-plate potential), which initiates an action potential in the surrounding sarcolemma. The activity of the neurotransmitter is rapidly terminated by the enzyme acetylcholinesterase (AChE), which is bound to the basal lamina in the sarcolemmal junctional folds. The sarcolemma is an excitable membrane, and action potentials generated at the neuromuscular junction propagate rapidly over the entire surface of the muscle fibre.

Action potentials are conducted radially into the interior of the fibre via extensions of the sarcolemma, the T-tubules, ensuring that all parts of the muscle fibre are activated rapidly and almost synchronously. Excitation–contraction coupling is the process whereby an action potential triggers the release of calcium from the terminal cisternae of the sarcoplasmic reticulum into the cytosol. This activates a calcium-sensitive switch in the thin filaments and so initiates contraction. At the end of excitation, the T-tubular membrane repolarizes, calcium release ceases, calcium ions are actively transported back to the calsequestrin stores in the sarcoplasmic reticulum by the calcium–ATPase pumps, and the muscle relaxes.

The lengths of the thick and thin filaments do not change during muscle contraction. The sarcomere shortens by the sliding of thick and thin filaments past one another, drawing the Z-discs towards the middle of each sarcomere (see Fig. 5.40). As the overlap increases, the I- and H-bands narrow to near-extinction, while the width of the A-bands remains constant. Filament sliding depends on the making and breaking of bonds (cross-bridge cycling) between myosin head regions and actin filaments. Myosin heads 'walk' or 'row' along actin filaments using a series of short power strokes, each resulting in a relative movement of 5–10 nm. Actin filament binding sites for myosin are revealed only by the presence of calcium, which is released into the sarcoplasm from the sarcoplasmic reticulum, causing a repositioning of the troponin–tropomyosin complex on actin: this is the calcium-sensitive switch. Myosin head binding and release are both energy-dependent and require ATP. In the absence of ATP (as occurs post mortem) the bound state is maintained, and is responsible for the muscle stiffness known as rigor mortis.

The summation of myosin power strokes leads to an average sarcomere shortening of up to 1 μm; an anatomical muscle shortens by a centimetre or more, depending on the muscle, because each muscle has thousands of sarcomeres in series along its length.

Slow-twitch versus fast-twitch fibres

The passage of a single action potential through a motor unit elicits a twitch contraction where peak force is reached within 25–100 ms, depending on the motor unit type involved. However, the motor neurone can deliver a second nervous impulse in less time than it takes for the muscle fibres to relax. When this happens, the muscle fibres contract again, building the tension to a higher level. Because of this mechanical summation, a sequence of impulses can evoke a larger force than a single impulse and, within certain limits, the higher the impulse *frequency*, the more force is produced ('rate recruitment'). An alternative strategy is to recruit more motor units. In practice, the two mechanisms appear to operate in parallel, but their relative importance may depend on the size and/or function of the muscle; in large muscles with many motor units, motor unit recruitment is probably the more important mechanism.

With the exception of rare tonic fibres, skeletal muscles are composed entirely of fibres of the twitch type. These fibres can all conduct action potentials but they differ in other respects. Some fibres obtain their energy very efficiently by aerobic oxidation of substrates, particularly of fats and fatty acids. They have large numbers of mitochondria; contain myoglobin, an oxygen-transport pigment related to haemoglobin, and

are supported by a well-developed network of capillaries that maintains a steady nutrient supply of oxygen and substrates. Such fibres are well suited to functions such as postural maintenance, in which moderate forces need to be sustained for prolonged periods. At the other end of the spectrum, some fibres have few mitochondria, little myoglobin and a sparse capillary network, and store energy as cytoplasmic glycogen granules. Their immediate energy requirements are met largely through anaerobic glycolysis, a route that provides prompt access to energy but that is less sustainable than oxidative metabolism. They are capable of brief bursts of intense activity that must be separated by extended quiescent periods during which intracellular pH and phosphate concentrations are restored to normal values, and glycogen and other reserves are replenished.

In some animals, different types of muscle fibre tend to be segregated into different muscles. This causes some muscles to have a conspicuously red appearance, reflecting their rich blood supply and high myoglobin content associated with a predominantly aerobic metabolism, whereas other muscles have a much paler appearance, reflecting a more anaerobic character. These variations in colour led to the early classification of muscle into red and white types; this classification has now been largely superseded by myosin-based typing and the presence of specific disease-related enzymes.

In humans, all muscles are mixed, with fibres specialized for aerobic working conditions intermingling with fibres of a more anaerobic or intermediate metabolic character. Different types of fibre are not readily distinguished in routine histological preparations but are clear when specialized enzyme histochemical techniques are used. On the basis of metabolic differences, individual fibres can be classified as oxidative slow-twitch (red) fibres, or glycolytic fast-twitch (white) fibres. Muscles composed mainly of oxidative slow-twitch fibres correspond to the red muscles of classical descriptions. Muscles that are predominantly oxidative in their metabolism contract and relax more slowly than muscles relying on glycolytic metabolism. This difference in contractile speed is due in part to the activation mechanism (volume density of the sarcotubular system and proteins of the calcium 'switch' mechanism), and in part to molecular differences between the myosin heavy chains of these types of muscle. These differences affect the ATPase activity of the myosin head, which in turn alters the kinetics of its interaction with actin, and hence the rate of cross-bridge cycling. Differences between myosin isoforms can be detected histochemically, and ATPase histochemistry continues to play a significant role in diagnostic typing (Table 5.1). Two main categories have been described: type I fibres, which are slow-contracting, and type II, which are fast-contracting. Molecular analyses have revealed that type II fibres can be further subdivided according to their content of myosin heavy-chain isoforms into types IIA and IIX. Muscle fibres may contain only one (i.e. a pure fibre) or a combination (i.e. a hybrid fibre) of these isoforms; the five most prevalent muscle fibre types in humans are I, I/IIA, IIA, IIA/IIX, IIX. (For further reading, see Galpin et al (2012), Holland and Ohlendieck (2013).) There is a correlation between categories and fatigue resistance, such that type I fibres are generally oxidative (slow oxidative) and resistant to fatigue; type IIA are moderately oxidative, glycolytic (fast oxidative glycolytic) and fatigue-resistant; and type IIX largely rely on glycolytic metabolism (fast glycolytic) and so are easily fatigued.

TABLE 5.1 Physiological, structural and biochemical characteristics of the major histochemical fibre types

Characteristic	Fibre types		
	Type I	Type IIA	Type IIX
Physiological			
Function	Sustained forces, as in posture	Powerful, fast movements	
Motor neurone firing threshold	Low	Intermediate	High
Motor unit size	Small	Large	Large
Firing pattern	Tonic, low-frequency	Phasic, high-frequency	
Maximum shortening velocity	Slow	Fast	Fast
Rate of relaxation	Slow	Fast	Fast
Resistance to fatigue	Fatigue-resistant	Fatigue-resistant	Fatigue-susceptible
Power output	Low	Intermediate	High
Structural			
Capillary density	High		Low
Mitochondrial volume	High	Intermediate	Low
Z-disc	Broad	Narrow	Narrow
T-tubule and sarcoplasmic reticulum systems	Sparse		Extensive
Biochemical			
Myosin ATPase activity	Low		High
Oxidative metabolism	High	Intermediate	Low
Anaerobic glycolysis	Low	Intermediate	High
Calcium transport ATPase	Low		High

Fibre type transformation

Fibre type proportions in a named muscle may vary between individuals of different age or athletic ability. Fibre type grouping, where fibres with similar metabolic and contractile properties aggregate, increases after nerve damage and with age. Grouping occurs as a result of reinnervation episodes, where denervated fibres are 'taken over' by a sprouting motor neurone and adopt its type properties. If the nerves to fast white and slow red muscles are cut and cross-anastomosed in experimental animals, so that each muscle is reinnervated by the other's nerve, the fast muscle becomes slower-contracting, and the slow muscle faster-contracting. There is evidence that such fibre type transformation may be a response to the patterns of impulse traffic in the nerves innervating the muscles (Minetto et al 2013). If fast muscles are stimulated continuously for several weeks at 10 Hz, a pattern similar to that normally experienced by slow muscles, they develop slow contractile characteristics and acquire a red appearance and a resistance to fatigue even greater than that of slow muscles.

The initial phase of slowing can be explained by less rapid cycling of calcium, resulting from reduced sarcoplasmic reticulum and changes in the amount and molecular type of proteins involved in calcium transport and binding. Chronic stimulation also triggers the synthesis of myosin heavy and light chain isoforms of the slow muscle type; the associated changes in cross-bridge kinetics result in a lower intrinsic speed of shortening. The muscle becomes more resistant to fatigue through changes in the metabolic pathways responsible for the generation of ATP and a reduced dependence on anaerobic glycolysis. There is a switch to oxidative pathways, particularly those involved in the breakdown of fat and fatty acids, and an associated increase in capillary density and in the fraction of the intracellular volume occupied by mitochondria. If stimulation is discontinued, the sequence of events is reversed and the muscle regains, over a period of weeks, all of its original characteristics. The reversibility of transformation is one of several lines of evidence that the changes take place within existing fibres, and not by a process of degeneration and regeneration.

Many of the changes in the protein profile of a muscle that are induced by stimulation are now known to be the result of transcriptional regulation. For example, analysis of the messenger RNA species encoding myosin heavy chain isoforms shows that expression of the fast myosin heavy chain mRNA is downregulated within a few days of the onset of chronic stimulation, while the slow myosin heavy chain mRNA is upregulated. Although myosin isoform expression is responsive to the increase in use induced by chronic stimulation, it tends to be stable under physiological conditions unless these involve a sustained departure from normal postural or locomotor behaviour.

Development and growth of skeletal muscle

Most information about the early development of the skeletal musculature in humans has been derived from other vertebrate species. However, where direct comparisons with the developing human embryo have been made, the patterns and mechanisms of muscle formation have been found to be the same.

The majority of the skeletal muscle in the body develops from paraxial mesenchyme and its segmental derivatives, the somites. A small portion forming the extraocular muscles is derived from prechordal mesenchyme, which joins with the most rostral paraxial mesenchyme and which has been demonstrated to have a myogenic fate. Skeletal muscle precursor myoblasts delaminate from dermomyotomes, the lateral portion of the somites (see Fig. 18.2). Those destined for the limbs migrate into the appropriate limb bud, proliferate, express myogenic determination factors and ultimately differentiate into skeletal muscle (Ch. 19). Myogenic regulatory factors are a family of transcription factors consisting of Myogenic factor 5 (Myf5), myogenin (MyoG), Myogenic Differentiation 1 (MyoD) and Myogenic Regulatory Factor 4 (MRF4, also known as Myf-6 (herculin) in man): they activate transcription of a wide variety of

muscle-specific genes and play a crucial role in myogenesis and in the specification of muscle satellite cell lineage (Buckingham et al 2003, Zammit 2017).

Formation of muscle fibres

In both myotomes and limb buds, myogenesis proceeds in the following way. Myoblasts become spindle-shaped and begin to express muscle-specific proteins. The mononucleate myoblasts aggregate and fuse to form multinucleate cylindrical syncytia, or myotubes, in which the nuclei are aligned in a central chain (**Fig. 5.44**). These primary myotubes attach at each end to the tendons and developing skeleton. The initiation of fusion does not depend on the presence of nerve fibres, since these do not penetrate muscle primordia until after the formation of primary myotubes.

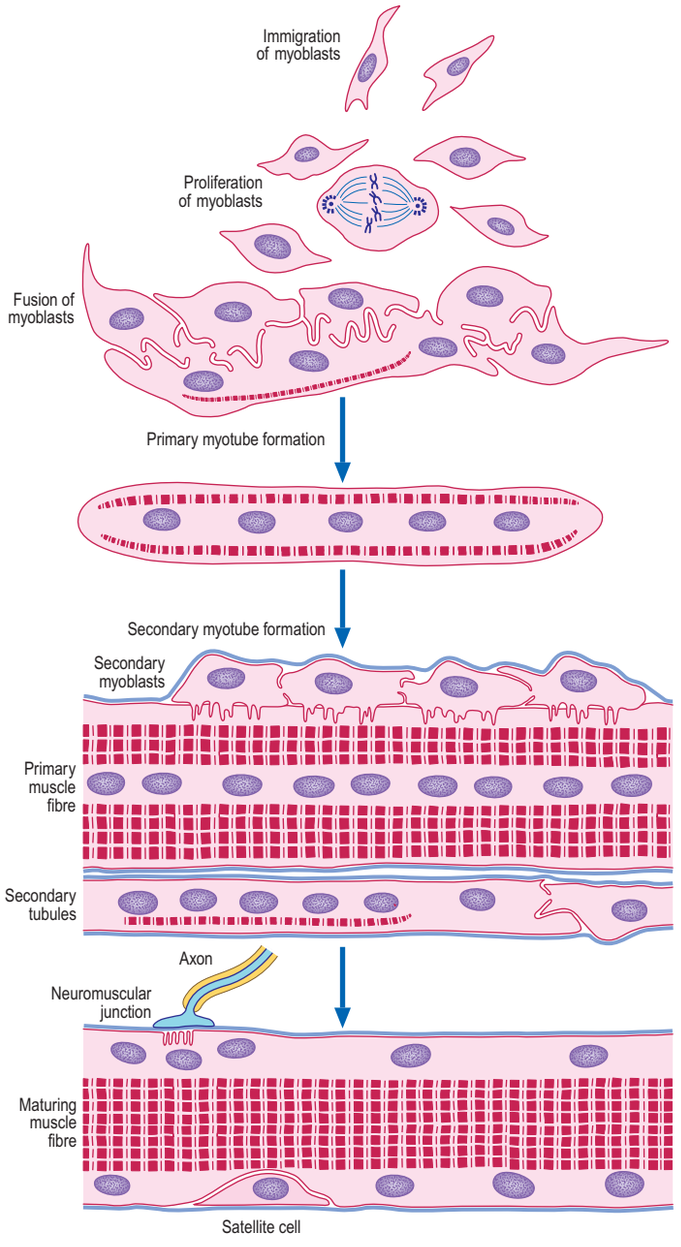

Fig. 5.44 Stages in formation of skeletal muscle. Mononucleate myoblasts fuse to form multinucleate primary myotubes, characterized initially by central nuclei. Subsequently, other myoblasts align along the primary myotubes and begin to fuse with one another, forming secondary myotubes. In large animals, such as humans, further generations of new muscle fibres are similarly formed. As the contractile apparatus is assembled, the nuclei move to the periphery, cross-striations become visible and primitive features of the neuromuscular junction emerge. Later, small adult-type myoblasts – satellite cells – can be seen lying between the basal lamina and the sarcolemma of the mature muscle fibre. These too appear to be derived from cells that originated in the somites during early development. (Adapted with permission from Terry Partridge, Department of Genetic Medicine, Children's National Medical Center, Washington DC.)

Although synthesis of the contractile machinery is not dependent on fusion of myoblasts, it proceeds much more rapidly after fusion. Sarcomere formation begins at the Z-disc, which binds actin filaments constituting the I-band to form I–Z–I complexes. The myosin filaments assemble on the I–Z–I complexes to form A-bands. Nebulin and titin are among the first myofibrillar proteins to be incorporated into the sarcomere, and may well determine the length and position of the contractile filaments. Desmin intermediate filaments connect the Z-discs to the sarcolemma at an early stage, and these connections are retained.

Myogenic cells continue to migrate and to divide, and from postfertilization weeks 7–9 there is extensive *de novo* myotube formation. Myoblasts aggregate near the midpoint of the primary myotubes and fuse with each other to form secondary myotubes, a process that may be related to early neural contact. Several of these smaller-diameter myotubes may be aligned in parallel with each of the primary myotubes. Each develops a separate basal lamina and makes independent contact with the tendon. Initially, the primary myotube provides a scaffold for the longitudinal growth of the secondary myotubes but eventually they separate. At the time of their formation, the secondary myotubes express an 'embryonic' isoform of the myosin heavy chains, whereas the primary myotubes express a 'slow' muscle isoform apparently identical to that found in adult slow muscle fibres. In both primary and secondary myotubes, sarcomere assembly begins at the periphery of the myotube and progresses inwards towards its centre. Myofibrils are added constantly and lengthen by adding sarcomeres to their ends. T-tubules are formed and grow initially in a longitudinal direction; since they contain specific proteins not found in plasma membranes, they are probably assembled via a different pathway from that which supports the growth of the sarcolemma. The sarcoplasmic reticulum wraps around the myofibrils at the level of the I-bands.

By the end of the embryonic period, the primordia of most muscle groups are well defined, contractile proteins have been synthesized and the primitive beginnings of neuromuscular junctions can be observed, confined initially to the primary myotubes. Although some secondary fibre formation can take place in the absence of a nerve, most is initiated at sites of innervation of the primary myotubes. The pioneering axons branch and establish contact with the secondary myotubes. By postmenstrual week 11 these nerve–muscle contacts have become functional neuromuscular junctions and the muscle fibres contract in response to impulse activity in the motor nerves. Under this new influence, the secondary fibres express fetal (sometimes referred to as neonatal) isoforms of the myosin heavy chains. At this stage, several crucial events take place, which may be dependent on, or facilitated by, contractile activity. As the myofibrils encroach on the centre of the myotube, the nuclei move to the periphery and the characteristic morphology of the adult skeletal muscle myofibre is established. The myofibrils become aligned laterally, and A- and I-bands in register across the myotube produce cross-striations that are visible at the light microscopic level. T-tubules change from a longitudinal to a transverse orientation and adopt their adult positions; they may be guided in this process by the sarcoplasmic reticulum, which is more strongly bound to the myofibrils.

The myotubes and myofibres are grouped into fascicles by growing connective tissue sheaths, and fascicles are assembled to build up entire muscles. As development proceeds, the increase in intramuscular volume is accommodated by remodelling of the connective tissue matrix.

At about postmenstrual week 15, primary myotubes are still in the majority, but by postmenstrual week 20 the secondary myotubes predominate. During postmenstrual weeks 16–17, tertiary myotubes appear; they are small and adhere to the secondary myotubes, with which they share a basal lamina. They become independent by postmenstrual weeks 18–23, their central nuclei move to the periphery, and they contribute a further generation of myofibres. The secondary and tertiary myofibres are always smaller and more numerous than the primary myofibres. In some large muscles, higher-order generations of myotubes may be formed.

Late in fetal life, a final population of myoblasts appears, and will become the satellite cells of adult muscle. These normally quiescent cells lie outside the sarcolemma beneath the basal lamina (see Fig. 5.44; **Fig. 5.45**). M-cadherin, a cell adhesion protein of possible regulatory significance, occurs at the site of contact between a satellite cell and its muscle fibre. In a young individual, there is one satellite cell for every 5–10 muscle fibre nuclei. The latter are incapable of DNA synthesis and mitosis, and satellite cells are therefore important as the sole source of additional muscle fibre nuclei during postnatal growth of muscle (to maintain the ratio of cytoplasmic volume per nucleus as fibres increase in mass). After satellite cells divide, one of the daughter cells fuses with the growing fibre, the other remaining as a satellite cell capable of further rounds of division. In adult skeletal muscle, satellite cells provide a reservoir of cells that enable exercise-induced hypertrophy, and regeneration of muscle after damage (see below).

Development of fibre types

Developing myotubes express an embryonic isoform of myosin that is subsequently replaced by fetal and adult myosin isoforms. The major isoform of sarcomeric actin in fetal skeletal muscle is cardiac α-actin; only later is this replaced by skeletal α-actin. The significance of these developmental sequences is not known.

The pattern of expression is fibre-specific and changes over time. In primary myotubes, embryonic myosin is replaced by adult slow myosin from stage 23 onwards (postfertilization days 53-58). In secondary and higher-order myotubes, the embryonic myosin isoform is superseded first by fetal and then by adult fast myosin, and a proportion go on to express adult slow myosin. Other fibre-specific, tissue-specific and species-specific patterns of myosin expression have been described in mammalian limb muscles and jaw muscles.

The origin of this diversity in the temporal patterns of expression of different fibres, even within the same muscle, is far from clear. It has been suggested that intrinsically different lineages of myoblast emerge at different stages of myogenesis or in response to different extracellular cues. If this is the case, their internal programmes may be retained or overridden when they fuse with other myoblasts or with fibres that have already formed. The fibres that emerge from this process go on to acquire a phenotype that will depend on the further influence of hormones and neural activity.

In humans, unlike many smaller mammals, muscles are histologically mature at birth, but fibre type differentiation is far from complete. In postural muscles, the expression of type I ('slow') myosin increases significantly over the first few years of life. During this same period, the proportions of fibre types in other muscles become more divergent. The presence in adult muscles of a small proportion of fibres with an apparently transitional combination of protein isoforms reinforces the view that changes in fibre type continue to some extent in all muscles and throughout adult life. Fibre type transitions also occur in relation to damage or neuromuscular disease; under these conditions, the developmental sequence of myosins may be recapitulated in regenerating fibres.

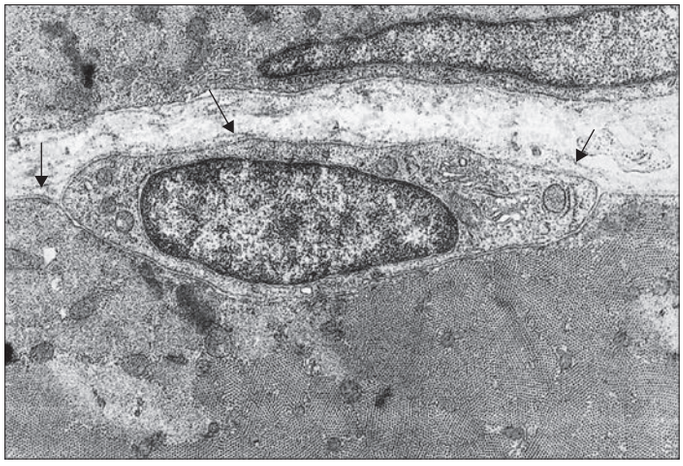

Fig. 5.45 An electron micrograph of a satellite cell. Note the two plasma membranes that separate the cytoplasm of the satellite cell from that of the muscle fibre, and the basal lamina (arrows) of the transversely sectioned muscle fibre, which continues over the satellite cell (see also Fig. 5.39A). Compare this appearance with the normal muscle nucleus, which is seen in the adjacent fibre at the top of the micrograph. (Courtesy of Dr Michael Cullen, School of Neurosciences, University of Newcastle upon Tyne.)

Growth and regulation of fibre length

Muscle fibres grow in length by addition of sarcomeres to the ends of myofibrils. In order for the mean sarcomere length, and hence filament overlap, to be optimized for maximum force, the number of sarcomeres must be regulated throughout life. This is achieved by the addition or removal of sarcomeres in response to any prolonged change of length. For example, if a limb is immobilized in a plaster cast, the fibres of muscles that have been fixed in a shortened position lose sarcomeres, while those that have been fixed in a lengthened position add sarcomeres; the reverse process occurs after the cast has been removed.

Satellite cells and muscle repair

Until the mid-twentieth century, the mechanisms responsible for maintenance and repair of skeletal muscle were unclear. These issues were largely resolved by the discoveries that multinucleated muscle fibres were formed by the fusion of mononucleated precursors, myoblasts, and that a population of satellite cells, so called because of their position on the edge of the fibre, exist between the basal lamina of the mature muscle fibre and its sarcolemma, where they constitute 2–5% of the nuclei enclosed by the basal lamina.

Studies in mouse models, where genetic analysis is possible, have shown that the functional properties of postnatal satellite cells depend on the expression of the *Pax7* gene, whereas the prenatal development of muscle is not similarly dependent. This implies that satellite cells are not simply the relics of prenatal myogenic cells, even though they appear to be derived from the same embryonic source in the somites. Moreover, satellite cells are not a homogeneous population: no two differentiation markers concur completely. This is also the situation in human tissue (**Fig. 5.46**). It has yet to be determined whether this variation reflects a difference in position in the lineage, functional status or adjacent environment.

The satellite cell has been established rigorously in experimental animal models as being both necessary and sufficient for effective regeneration of damaged skeletal muscle (Relaix and Zammit 2012, Järvinen et al 2014, Laumonier and Menetrey 2016, Segalés et al 2016). These cells proliferate to replace their resident region of muscle in 3–4 days and to replenish the quiescent satellite cell population. In humans, there is histological evidence of the rapid accumulation of myoblasts, presumably derived from local satellite cells, at sites of muscle damage. The presumed central role of satellite cells in muscle growth and adaptation has, however, been questioned by some recent research. Satellite cells are undoubtedly important during early postnatal development and growth, and in muscle regeneration following acute injury or eccentric damage. In other situations, however, regulation of protein synthesis and degradation may be more important determinants of muscle mass (Schiaffino et al 2013).

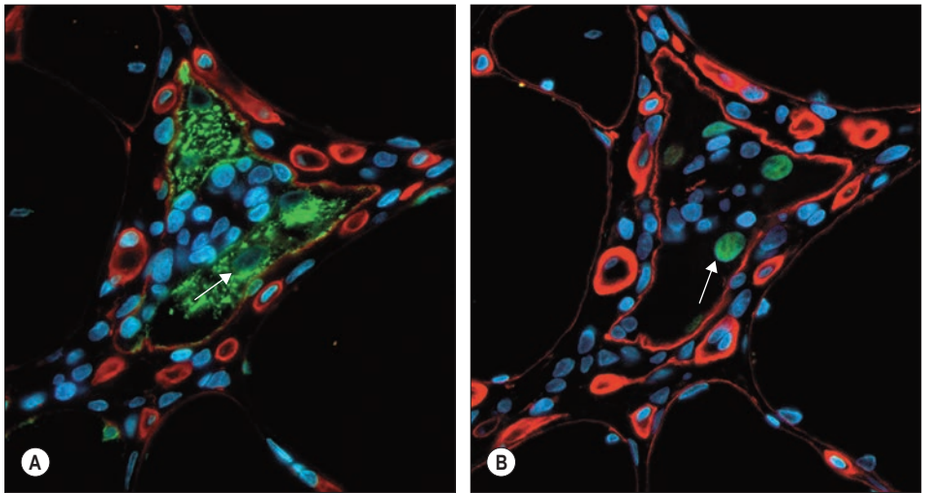

Fig. 5.46 Two adjacent sections, fluorescence-immunolabelled, of a regenerating muscle fibre in a power lifter's trapezius. **A**, Anti-laminin antibody (red) shows basal lamina. Anti-CD56 (green) is a marker of myogenic cells and of newly formed myotubes. **B**, Basal lamina (red) and myogenin-positive nuclei (green). Basal laminae outline transversely sectioned muscle fibres, including the original outline of the regenerating fibre (centre field). Numerous small blood vessels, also outlined by basal laminae, are present and probably reflect local inflammation. Within the CD56-positive zone, several nuclei (one arrowed) are positive for myogenin, indicating their terminally differentiated status. Numerous other nuclei (Hoechst dye, blue) within the basal lamina surrounding the area of regeneration probably include proliferating myogenic cells and inflammatory cells. (Courtesy of Ms Mona Lindström and Professor Lars-Eric Thornell, Department of Anatomy, Umeå University, Sweden.)

A detail of wide pathological interest is the demonstration that the failing regenerative potency of satellite cells in ageing muscle seems in large part to be attributable to age-related changes in the systemic environment rather than a decline in the intrinsic capabilities of the satellite cells themselves (Conboy et al 2005).

Regulation of muscle mass

Muscles respond to resistance exercise in training, or rehabilitation following illness or injury, by increasing in mass. This process is termed hypertrophy, particularly when applied to the increased muscle bulk that occurs in response to intense physical activity. Individual muscle fibres increase in size by the synthesis of new myofibril proteins, increased protein turnover rates and the recruitment of satellite cells to provide new nuclei for existing fibres or to form new myotubes. In inactivity, as seen in those confined to bed or wheelchair, in immobilized limbs, and in patients with disorders of voluntary movement, muscles decrease in mass. This is termed atrophy, or disuse atrophy, in contrast to the pathological wasting of skeletal muscle associated with some disease states, including cancer cachexia, heart failure, diabetes and obesity. It is also recognized that loss of skeletal muscle mass and function may be a consequence of reduced physical activity in normal healthy ageing, when it is termed sarcopenia. There is experimental evidence that this process may be associated with apoptosis of satellite cells and capillary endothelial cells (Wang et al 2014).

Form and function of skeletal muscle

The names given to individual muscles are usually descriptive and are based on their shape, size, number of heads or bellies, position, depth, attachments or actions. The meanings of some of the terms used are summarized in **Table 5.2**. The functional roles implied by the names should be interpreted with caution because they are often oversimplified, and terms denoting action may emphasize only one of a number of usual actions. A given muscle may play different roles in different movements and these roles may change if the movements are assisted or opposed by gravity.

TABLE 5.2 Terms used in naming muscles

Shape
Deltoid (triangular) Quadratus (square) Rhomboid (diamond-shaped) Teres (round) Gracilis (slender) Rectus (straight) Lumbrical (worm-like)
Size
Major, minor, longus (long) Brevis (short) Latissimus (broadest) Longissimus (longest)
Number of heads or bellies
Biceps (two heads) Triceps (three heads) Quadriceps (four heads) Digastric (two bellies)
Depth
Superficialis (superficial) Profundus (deep) Externus/externi (external) Internus/interni (internal)
Attachment
Sternocleidomastoid (from sternum and clavicle to mastoid process) Coracobrachialis (from the coracoid process to the arm)
Position
Anterior, posterior, medial, lateral, superior, inferior, supra-, infra- Interosseus (between bones) Dorsi (of the back) Abdominis (of the abdomen) Pectoralis (of the chest) Brachii (of the arm) Femoris (of the thigh) Oris (of the mouth) Oculi (of the eye)
Action
Extensor, flexor Abductor, adductor Levator, depressor Supinator, pronator Constrictor, dilator

Fibre architecture

Muscles can be classified according to their general shape and the predominant orientation of their fibres relative to the direction of pull (**Fig. 5.47**). Muscles with fibres (cells) that are largely parallel to the line of pull vary in form from flat, short and quadrilateral (e.g. thyrohyoid) to long and strap-like (e.g. sternohyoid, sartorius). In such muscles, individual fibres may run for the entire length of the muscle, or over shorter segments when there are transverse, tendinous intersections at intervals (e.g. rectus abdominis). In a fusiform muscle, the fibres may be close to parallel in the 'belly', but converge to a tendon at one or both ends. Where fibres are oblique to the line of pull, muscles may be triangular (e.g. temporalis, adductor longus) or pennate (feather-like) in construction. The latter vary in complexity from unipennate (e.g. flexor pollicis longus) and bipennate (e.g. rectus femoris, dorsal interossei) to multipennate (e.g. deltoid). Fibres may pass obliquely between deep and superficial aponeuroses, in a type of 'unipennate' form (e.g. soleus), or they may start from the walls of osteofascial compartments and converge obliquely on a central tendon in circumpennate fashion (e.g. tibialis anterior). Muscles may exhibit a spiral or twisted arrangement (e.g. sternocostal fibres of pectoralis major or latissimus dorsi, which undergo a 180°-twist between their medial and lateral attachments). Muscles may spiral around a bone (e.g. supinator, which winds obliquely around the proximal radial shaft), or contain two or more planes of fibres arranged in differing directions, a type of spiral sometimes referred to as cruciate (sternocleidomastoid, masseter and adductor magnus are all partially spiral and cruciate). Many muscles display more than one of these major types of arrangement, and show regional variations that correspond to contrasting, and in some cases independent, actions.

Direction of force

Although muscles differ in their internal architecture, the resultant force must be directed along the line of the tendon, so forces transverse to this direction must be in balance (see Fig. 5.47; **Fig. 5.48**). In strap-like muscles, the transverse component is negligible. In fusiform, bipennate and multipennate muscles, symmetry in the arrangement of the fibres produces a balanced opposition between transverse components, whereas in asymmetric muscles (e.g. unipennate muscles), the fibres generate an unopposed lateral component of force that is balanced by intramuscular pressure.

Muscles that incorporate a twist in their geometry unwind it as they contract, so that they tend not only to approximate their attachments but also to bring them into the same plane. Muscles that spiral around a bone tend to reduce the spiral on contraction, causing rotation.

Force versus range of contraction

Muscle fibre architecture varies because some muscles are required to develop a large force on their tendinous insertion, whereas other muscles are required to move their insertion through a considerable distance. These demands are largely incompatible and require different muscle architecture.

The force developed by an active muscle depends on the tension developed in each muscle fibre. If all of the muscle fibres are parallel (as in the strap-like muscle in Fig. 5.47), then the muscle force is equal to the sum of the tension in each fibre, and so will be proportional to the total cross-sectional area of those fibres. The range of contraction generated by an active muscle depends on the relative motion that can take place between the overlapping proteins in the sarcomere, and this sets a natural limit (approximately 30%) to the amount of fibre shortening that can take place. Hence, the movement of the tendinous insertion is proportional to the length of the muscle fibres.

If these principles are applied to a long, strap-like muscle in which the fibres are predominantly parallel to the line of pull (see Fig. 5.47), it will be evident that the whole muscle will be able to contract by 30% of its length (the same as each muscle fibre). However, such a strap-like muscle contains relatively few muscle fibres, so the maximum tension it can develop will not be great. Compare this to the bipennate muscle in **Fig. 5.49**, which contains perhaps three times as many muscle fibres, all set at an angle (typically 30°) to the axis of the tendon. Each short fibre will not be able to contract very far, and the contraction of the tendon will be even less, because the muscle fibres are pulling on it

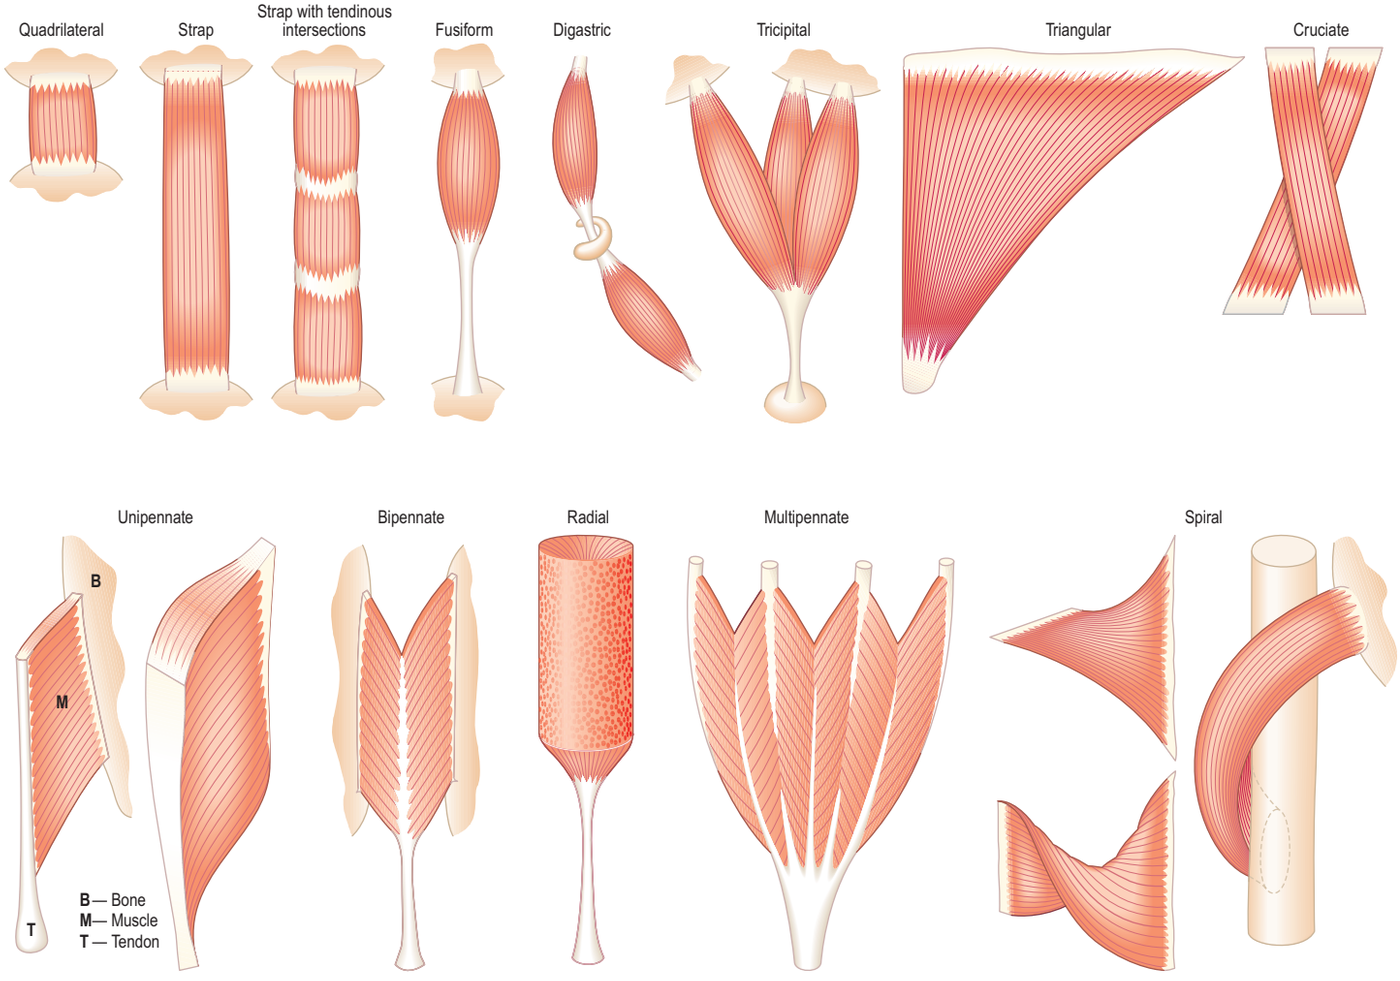

Fig. 5.47 Morphological 'types' of muscle based on their general form and fascicular architecture.

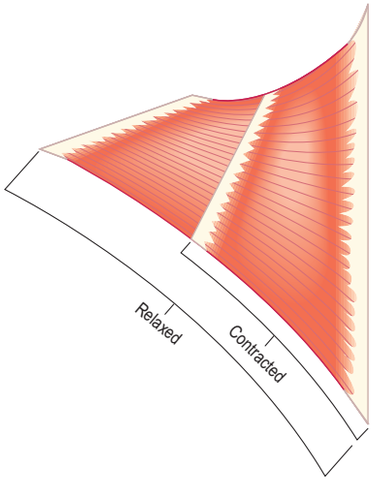

Fig. 5.48 The 'detorsion' or untwisting that results from the contraction of a spirally arranged muscle.

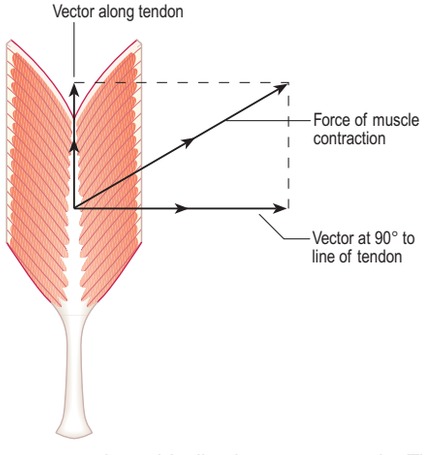

Fig. 5.49 Force vectors in an idealized pennate muscle. The increase in effective cross-sectional area made possible by this architecture outweighs the small reduction in the component of force acting in the direction of the tendon.

obliquely. So, the bipennate muscle has a poor contraction distance. However, the total force its fibres can generate will be approximately three times as great as the tension in the strap-like muscle. Even after this force is reduced to allow for its obliquity (in this case by cos 30°, which equals 0.87), the overall tension in the direction of the tendon will exceed that in the strap-like muscle by a factor of 2.6 (3×0.87). So, the bipennate muscle sacrifices contraction distance for greater maximum force. This effect would be much greater in the multipennate muscle shown in Fig. 5.47.

Force, strength and power

In descriptions of muscle performance, 'force', 'strength' and 'power' are often used interchangeably but these terms are not synonymous. When considering human performance, it is possible for strength to increase without a concomitant increase in the true force-generating capacities of the muscles involved. Strength is usually measured under circumstances that require the participation of several muscles, and so depends on skilful coordination of these muscles as well as the forces they generate. This disparity can be marked during the early stages of physical training.

Power is the rate at which a muscle can perform external work, and is equal to force multiplied by contraction velocity. Since force depends on the total cross-sectional area of muscle fibres, and velocity (the rate of muscle shortening) depends on muscle fibre length, powerful muscles tend to be long as well as fat. A prime example is the quadriceps, which is the prime mover when someone stands up from a

seated position. A lack of power in this and other muscles is the critical factor that limits the ability of many elderly people to live independently (Reid and Fielding 2012).

Actions of muscles

Historically, the actions of specific muscles were estimated from simple observation. Muscle attachments were identified by dissection, and their probable action deduced from the line of pull. With the use of localized electrical stimulation it became possible to study the actions of selected muscles systematically in the living subject. This approach was pioneered by Duchenne de Boulogne in the mid-nineteenth century. However, the study of isolated muscles cannot reveal the manner in which they interact during voluntary movements. Duchenne appreciated this, and supplemented electrical stimulation with observations of patients with partial paralysis to make more accurate deductions about the way in which muscles cooperate. Manual palpation can be used to detect muscle contraction, but only in superficial muscles under quasi-static conditions. Modern knowledge of muscle action has been acquired almost entirely by recording the electrical activity that accompanies mechanical contraction, a technique known as electromyography (EMG). This technique can be used to study activation of deep as well as superficial muscles, under static and dynamic conditions. Multiple channels of EMG can reveal coordination between different muscles that participate in a movement. These data can be further supplemented by monitoring joint angle and ground reaction force, and by recording the movement on camera or with a three-dimensional motion analysis system.

Conventionally, the action of a muscle is defined as the movement that takes place when it contracts. However, this is an operational definition: equating 'contraction' with shortening, and 'relaxation' with lengthening is too simple in the context of whole muscles and real movements. Whether a muscle approximates its attachments on contraction depends on the degree to which it is activated, and the forces against which it has to act.

Movements that involve shortening of an active muscle are termed concentric, e.g. contraction of biceps/brachialis while raising a weight and flexing the elbow. Movements in which the active muscle undergoes lengthening are termed eccentric, e.g. in lowering the weight previously mentioned, biceps/brachialis 'pays out' length as the elbow extends. Eccentric contractions stretch the collagenous tissue sheaths within muscle (see below), which increases the risk of tears in muscles such as the hamstrings, and of a more general delayed-onset muscle soreness (Proske and Morgan 2001). Muscle contraction that does not involve change in muscle length is isometric.

Natural movements are accomplished by groups of muscles. Each muscle may be classified, according to its role in the movement, as a prime mover, antagonist, fixator or synergist. It is usually possible to identify one or more muscles that are consistently active in initiating and maintaining a movement: these are its prime movers. Muscles that wholly oppose the movement, or initiate and maintain the opposite movement, are antagonists. For example, brachialis is the prime mover in elbow flexion, and triceps is the antagonist. To initiate a movement, a prime mover must overcome passive and active resistance and impart an angular acceleration to a limb segment until the required angular velocity is reached; it must then maintain a level of activity sufficient to complete the movement.

When prime movers and antagonists contract together they behave as fixators, stabilizing the corresponding joint by increased transarticular compression, and creating an immobile base on which other prime movers may act. For example, flexors and extensors of the wrist co-contract to stabilize the wrist when an object is grasped tightly in the fingers.

Acting across a uniaxial joint, a prime mover produces a simple movement. Acting at multiaxial joints, or across more than one joint, prime movers may produce more complex movements that contain elements that have to be eliminated by contraction of other muscles. The latter assist in accomplishing the movement and are considered to be synergists, although they may act as fixators, or even as partial antagonists of the prime mover. For example, flexion of the fingers at the interphalangeal and metacarpophalangeal joints is brought about primarily by the long flexors, superficial and deep. However, these also cross intercarpal and radiocarpal joints, and if movement at these joints were unrestrained, finger flexion would be less efficient. Synergistic contraction of the carpal extensors eliminates this movement, and even produces some carpal extension, which increases the efficiency of the desired movement at the fingers.

In the context of different movements, a given muscle may act as a prime mover, antagonist, fixator or synergist. Even the same movement may involve a muscle in different ways if it is assisted or opposed by gravity. For example, in thrusting out the hand, triceps is the prime mover responsible for extending the forearm at the elbow, and the flexor antagonists are largely inactive. However, when the hand lowers a heavy object, the extensor action of the triceps is replaced by gravity, and the movement is controlled by active lengthening (eccentric 'contraction') of the flexors. It is important to remember that all movements take place against the background of gravity and its influence must not be overlooked.

TENDONS AND LIGAMENTS

Forces developed by skeletal muscles are transferred to bone by tendons, aponeuroses and fasciae, whereas ligaments prevent excessive separation of adjacent bones. All of these force-transmitting structures comprise dense fibrous connective tissues containing a high proportion of type I collagen (see Commentary 1.6).

Tendons

Gross structure and function

Tendons take the form of whitish-looking cords or straps, usually with a round or oval cross-section. They are composed of dense, regular connective tissue, with 60% of their dry weight comprising large crimped fibres of collagen type I (**Fig. 5.50**; see Fig. 2.15). Other components of their matrix include collagen types II and V, elastin, glycoproteins and proteoglycans (Wang 2006). Fascicles (bundles) of collagen fibres are orientated mainly parallel to the long axis of the tendon but are to some extent interwoven; they may be conspicuous enough to give tendons a longitudinally striated appearance to the unaided eye. Tendons generally have smooth surfaces, although large tendons may be ridged longitudinally by coarse fasciculi (as in the osseous aspect of the angulated tendon of obturator internus). Loose connective tissue between fascicles provides a conduit for small vessels and nerves; it condenses on the surface as a sheath or epitendineum, which may contain elastin and irregularly arranged collagen fibres. The loose attachments between this sheath and the surrounding tissue present little resistance to movements of the tendon. In situations where greater freedom of movement is required, a tendon is separated from adjacent structures by a synovial sheath.

Tendons can be stretched by 6–15% of their length without damage (Wang 2006). Some of this extensibility is attributable to the reorientation of collagen type I fibres, some to the straightening of the crimped (wave-like) structure of these fibres, and some to sliding between adjacent collagen fibrils and fibres (Screen et al 2004). Sliding is possible because discrete collagen fibres appear to reinforce connective tissue in the manner of a 'chopped fibre-composite' material such as fibre glass (Hukins and Aspden 1985), rather than by forming a fixed scaffold (which would make growth difficult). It takes a great deal of energy to stretch a long and strong tendon, and most of this 'strain energy' can be recovered when the tension is released. During locomotion, the rhythmic storing and releasing of strain energy in stretched tendons helps to smooth the movement, so that tendons (rather than cartilage) act as the body's

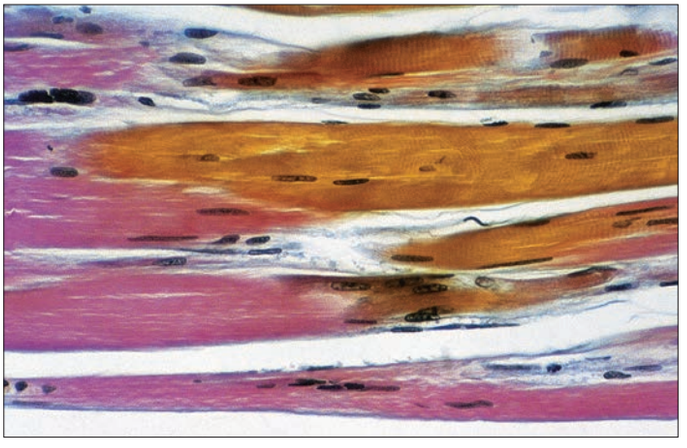

Fig. 5.50 The attachment of a tendon (pink) to skeletal muscle (orange). The regular dense connective tissue of the tendon consists of parallel bundles of type I collagen fibres, which are orientated in the long axes of the tendon and the muscle to which it is attached. A few elongated fibroblast nuclei are visible in the tendon. Trichrome stain.

natural shock absorbers. This energy storage and release also reduces the metabolic cost of locomotion. Tendons are sufficiently flexible that they can be diverted around osseous surfaces or deflected under retinacula to redirect the angle of pull.

The vascular supply of tendon is sparse but not negligible. Small arterioles from adjacent muscle tissue pass longitudinally between the fascicles, branching and anastomosing freely, and are accompanied by venae comitantes and lymphatic vessels. This longitudinal plexus is augmented by small vessels from adjacent loose connective tissue or synovial sheaths. Blood vessels rarely pass between bone and tendon at osseous attachments, and the junctional surfaces are usually devoid of foramina. A notable exception is the calcaneal (Achilles) tendon, which does receive a blood supply across its osseotendinous junction. During postnatal development, tendons enlarge by interstitial growth, particularly at myotendinous junctions, where there are high concentrations of fibroblasts. Growth decreases along a tendon from the muscle to the osseous attachments. The thickness finally attained by a tendon depends on the size and strength of the associated muscle, but also appears to be influenced by additional factors such as the degree of pennation of the muscle. The cellularity, and hence the metabolic rate, of large adult tendons is very low, but increases during infection or injury. Repair involves an initial proliferation of fibroblasts followed by interstitial deposition of new collagen fibres (Wang 2006). Complete turnover (replacement) of the tissue, as seen in bone, does not occur in adult tendons, so healed tendons do not quite recover their original strength. Tendons can adapt their stiffness and strength to match prevailing mechanical demands, but the process is slow and may be incomplete (Rumian et al 2009).

The nerve supply to tendons is largely sensory and there is no evidence of any capacity for vasomotor control. Golgi tendon organs, specialized endings that are sensitive to force, are found near myotendinous junctions; their large myelinated afferent axons run within branches of muscular nerves or in small rami of adjacent peripheral nerves. They play an important role in 'tendon reflexes', which serve to protect the musculoskeletal system from injury.

Tendon attachments

Muscles connect to bones by means of tendons, aponeuroses and fasciae. The epimysial, perimysial and endomysial sheaths within muscle coalesce at these attachments, and interdigitate with adjacent collagenous structures to form strong connections in which force transmission is aided by shear stress transfer.

At the myotendinous junction, muscle fibres separate into finger-like processes separated by insertions of tendinous collagen fibres. Although there are no desmosomal attachments at these junctions, other specializations assist in the transmission of force from the interior of the fibre to the extracellular matrix. Actin filaments from the adjacent sarcomeres, which would normally insert into a Z-disc at this point, instead penetrate a dense, subsarcolemmal filamentous matrix that provides attachment to the plasma membrane. This matrix is similar in character to the cytoplasmic face of an adherens junction. The structure as a whole is homologous to the intercalated discs of cardiac muscle. Integrins at the extracellular surface of the junctional sarcolemma provide contact with the basal lamina, which adheres closely to collagen and reticular fibres (type III collagen) of the adjacent tendon or other connective tissue structure.

Tendinous attachments to bone (also known as entheses or osteotendinous junctions) have been broadly categorized as either fibrocartilaginous or fibrous (Benjamin et al 2006). In fibrocartilaginous entheses, four zones of tissue can be distinguished: pure dense fibrous connective tissue (continuous with and indistinguishable from the tendon), uncalcified fibrocartilage, calcified fibrocartilage, and bone (continuous with and indistinguishable from the rest of the bone). There are no sharp boundaries between zones, and the proportions of each component vary between entheses. A largely fibrocartilaginous enthesis is usually found where a tendon approaches the bone at a high angle, e.g. triceps brachii (**Fig. 5.51A–B,D**). At fibrous entheses, which are characteristic of the shafts of long bones, the tendon approaches the bone at an acute angle and merges with the periosteum before attaching to bone by dense fibrous connective tissue, e.g. pronator teres (**Fig. 5.51C**). Fibrous entheses generally attach to a greater area of bone compared to fibrocartilaginous entheses, enabling them to reduce stress.

For further reading on tendons see Magnusson and Kjaer (2019).

Ligaments

The microstructure and biology of ligaments is broadly similar to that of tendons (Rumian et al 2007). Ligaments consist mostly of large crimped fibres of collagen type I, and their cells are predominantly elongated fibroblasts. However, there are two major differences between tendons

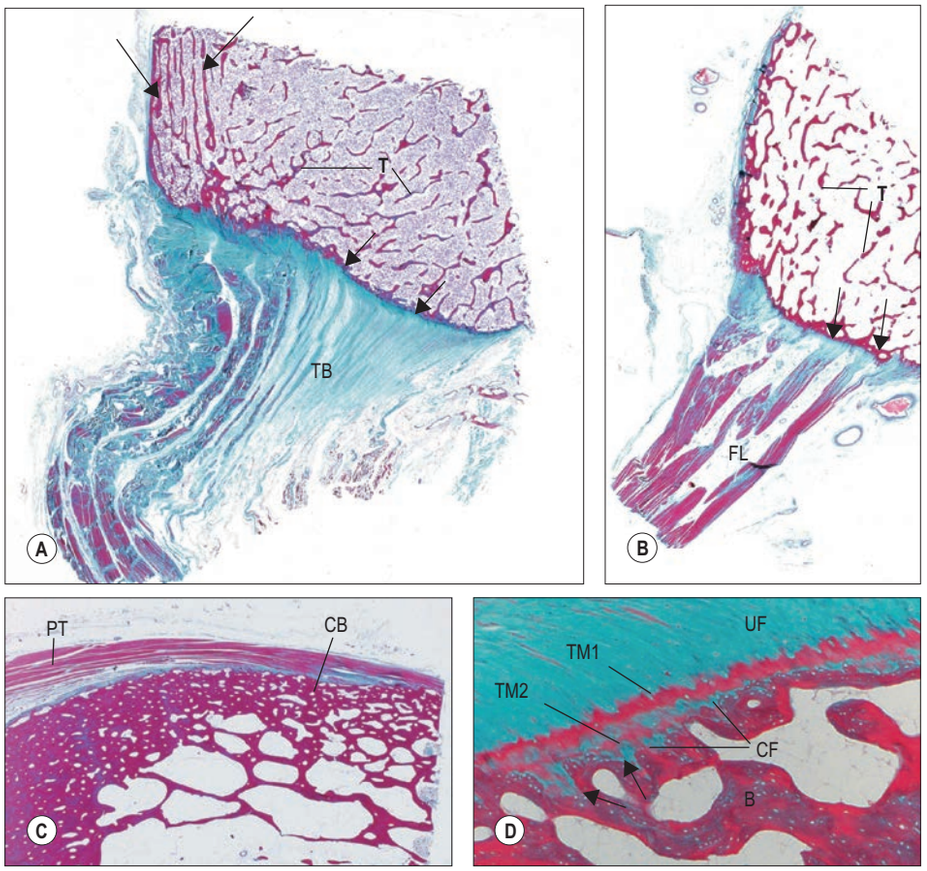

Fig. 5.51 The microstructure of bone at entheses. **A**, **B**, The cortical shell of bone (short arrows) is very thin at fibrocartilaginous attachment sites. In these examples showing the attachment of the tendons of triceps brachii (TB) and of fibularis longus (FL), the cortical shell is approximately the same thickness as the underlying trabeculae (T). Note that in **A**, the superficial trabeculae (long arrows) are aligned along the direction of pull of the tendon of triceps. **C**, In marked contrast, the layer of cortical bone (CB) at the fibrous attachment site of pronator teres (PT) to the mid-shaft of the radius, is much thicker. **D**, Higher-power view of the cortical calcified shell of tissue at a fibrocartilaginous attachment site (the calcaneal or Achilles tendon), which consists of bone (B) and calcified fibrocartilage (CF). In this specimen, there are two tidemarks, TM1 and TM2, associated with the cortical shell of calcified tissue. TM1 is adjacent to the zone of uncalcified fibrocartilage (UF), and marks the mechanical boundary between hard and soft tissues. TM2 lies nearer the bone and indicates an earlier phase of calcification. Note the relative straightness of the tidemarks but the highly irregular interface between calcified fibrocartilage and bone (arrows), which is important in anchoring the tendon to the bone. Sections of human cadaveric bone stained with Masson's trichrome. (Courtesy of Professor Michael Benjamin, Cardiff University, from sections cut and stained by S. Redman.)

and ligaments, relating to gross structure and to composition. Structurally, ligaments tend to have fibres orientated in a range of directions because they must resist the separation of bones in more than one direction, whereas collagen fibres in a tendon must simply align with tension in the adjacent muscle. More diverse mechanical roles of ligaments are also reflected in their composition. For example, the ligamentum flavum, which joins adjacent vertebrae in the spine, has a very high elastin content that enables it to be stretched more than 80% when the spine is flexed, and yet remain under tension in all postures. Maintaining tension is important because this ligament lies adjacent to the spinal cord, and could impinge on it if it became slack (and buckled) when the spine was moved into extension.

BIOMECHANICS

The purpose of this section is to explain, in a non-mathematical way, how mechanical principles shape the human musculoskeletal system. Mechanical considerations explain why bones are stiff and tendons are tough, why the surfaces of some synovial joints are imperfectly matched, and why some tendons insert closer to joints than others. The emerging subject of 'mechanobiology' considers how cells adapt their matrix to prevailing mechanical demands and explains why some tissues are better at doing this than others.

Mechanical concepts

Forces, moments and torques

A force is an action that deforms an object, or that causes it to move, and can be termed compressive, tensile or shear, according to the manner in which it deforms that object (Fig. 5.52). A force F acting at the end of a lever of length L will generate a bending moment (F × L) acting about the pivot point of the lever. A torsional moment or torque (Fig. 5.52F) can be quantified in similar terms. The combined influence of several forces can be calculated as shown in Fig. 5.53. If the forces all act in the same direction, they may be added. However, if they act in different directions, each force must be resolved into two imaginary components that act in two anatomically convenient directions at 90° to each other, using simple trigonometry. All components acting in the same direction are added to form two forces (S and C in Fig. 5.53), that can be used to calculate the magnitude and direction of the single 'resultant' force which has a similar effect to all of the individual forces combined. Forces acting on a stationary object are analysed according to the principle that all forces acting in any given direction must balance each other (i.e. add to zero), and all moments or torques acting about a given pivot point must also balance each other.

Mechanical properties of structures

Most anatomical structures deform readily when a sufficient force is applied to them, but their resistance to deformation increases steadily as the magnitude of the force increases. The resulting graph of force against deformation usually resembles the one shown in Fig. 5.54. Stiffness is the ratio of force to deformation (typical units N/mm) and so is represented by the gradient of the graph. The initial region of low stiffness, or 'toe region', is followed by a stiffer region in which the graph is almost linear. In many biological structures, the 'toe region' can be explained by the straightening out of the zig-zag 'crimped' structure of collagen type I fibres, whereas the linear region represents direct stretching of the straightened collagen fibres (and some slipping between them). If the deformed structure springs back immediately to its original dimensions when the deforming force is removed, the deformation is termed 'elastic'; a deformation that shows no sign of recovering is plastic;

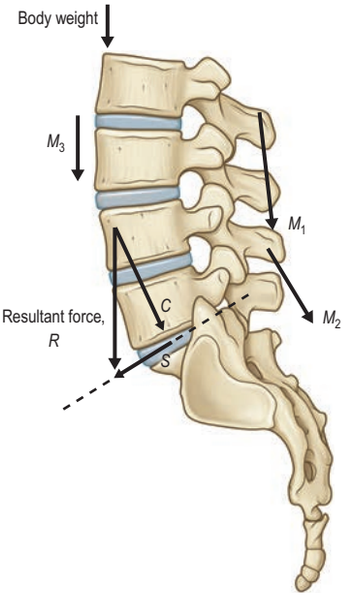

Fig. 5.53 The combined effect of several muscle forces (M_1–M_3) and body weight can be calculated by resolving each force into two components acting in two anatomically meaningful directions (in this case parallel and perpendicular to the mid plane of the lumbosacral intervertebral disc). The components acting in these two directions are then summed to give the total compressive (C) and shear (S) forces acting on the disc. The magnitude and direction of the resultant force (R), which represents the combined effect of all four forces, can be calculated using trigonometry.

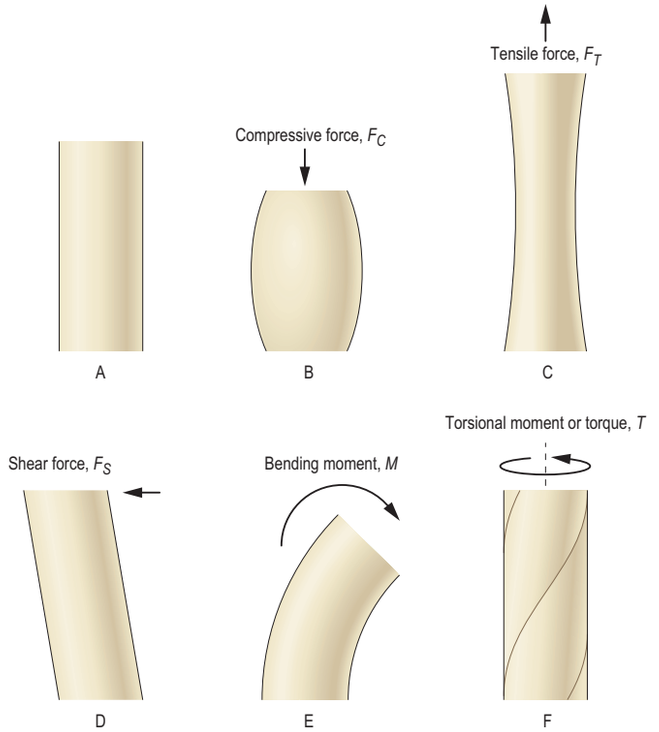

Fig. 5.52 The effects of different types of loading on a solid object (**A**) are illustrated in **B–F**.

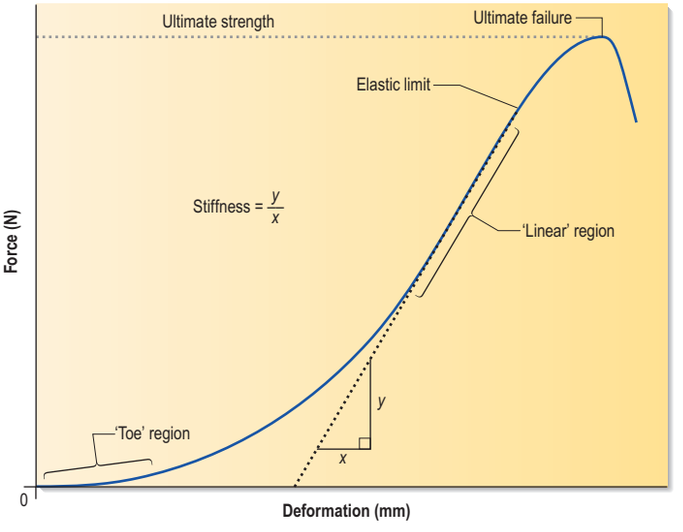

Fig. 5.54 A typical force–deformation graph for a skeletal structure subjected to mechanical loading. In the initial 'toe region', deformation increases rapidly with force, but this is followed by a linear region in which the deformation increases more slowly, and in proportion to the applied force. The gradient of the graph indicates the stiffness of the structure at any given load. Strength is the force at which an object becomes damaged, and this is usually interpreted either as the force at which the gradient first reduces (the elastic limit) or as the force when the gradient falls to zero (the ultimate strength).

a deformation that recovers eventually, but gradually, is viscoelastic (see below). 'Strength' is the force at which an object becomes damaged, and is usually interpreted either as the force at which the gradient of the graph first reduces (the elastic limit) or as the force when the gradient falls to zero (the ultimate strength).

Properties of materials

The properties of materials must be expressed in such a way that they are independent of the size and shape of the structure they constitute. A force divided by the area over which that force is applied gives a stress value (force per unit area) and the resulting deformation divided by the original length of the object gives a strain value (fractional or percentage deformation). Stress divided by strain is the size-independent material equivalent of the stiffness of an object, and is an important physical property termed the 'modulus' (sometimes 'Young's modulus'). There are different types of moduli but essentially they are measures of the stiffness, or resistance to deformation, of a material or tissue.

Energy and shock absorption

Deforming an object may require a considerable expenditure of energy. Technically, the work done (i.e. energy expended) is proportional to the average force exerted, multiplied by the distance moved. This is mathematically equivalent to the area under the graph in **Fig. 5.55**, and is referred to as the strain energy, i.e. the energy expended in deforming the object. If the object has elastic properties, it will spring back to its original shape when the deforming force is removed, and all the strain energy is then released. (This release of strain energy explains why a stretched rope can recoil violently if it snaps.) Structures such as coiled springs, which can resist high forces and also deform extensively, are capable of storing large amounts of energy, and so can act as shock absorbers when they are continually compressed and stretched. Tendons act in a similar manner during locomotion: they store strain energy when they are stretched by muscle contraction, and release most of this energy when the muscles relax later in the gait cycle. Internal friction between matrix components means that a small fraction of the stored strain energy, the hysteresis energy, is dissipated as heat (see Fig. 5.55). This heat can cause the temperature to rise by several degrees centigrade in large tendons that are involved in vigorous repetitive activity. Any material or structure that is capable of absorbing large amounts of strain energy before failure is termed tough; otherwise it is brittle. From Fig. 5.55 it is apparent that tough materials must be both strong and extensible. In contrast, brittle materials such as glass and tooth enamel undergo minimal deformation and so absorb little strain energy, even though they are strong. The shock-absorbing characteristics of tendons are important during locomotion, making movements smoother and reducing metabolic cost (Alexander 1988).

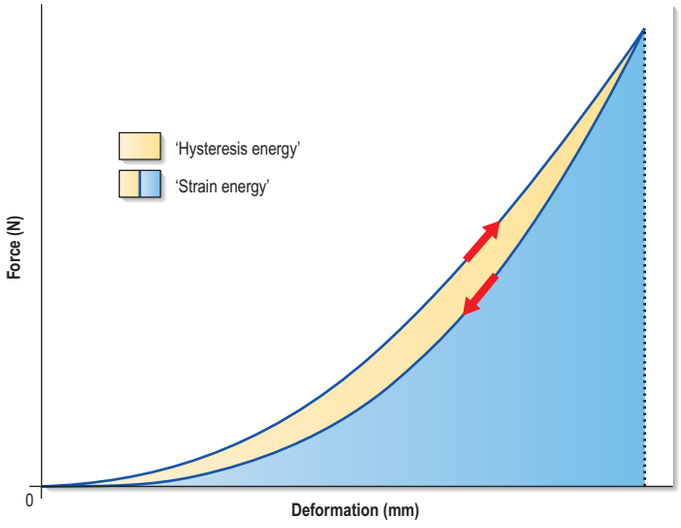

Fig. 5.55 This force–deformation graph shows how an object deforms when a force is applied to it (upward arrow) and how it recovers its shape when the force is gradually released (downward arrow). The area under the loading curve represents the strain energy that has been expended in deforming the object. The area under the unloading curve represents the energy that is given up when the object is allowed to spring back to its original shape. The small area in between represents energy that cannot be recovered but is dissipated as heat. This is the hysteresis energy.

Liquids

A liquid has negligible rigidity and so deforms readily to take the shape of its container. When compressed, it maintains practically the same volume, but it flows to equalize the intensity of loading within it. As a result, a static liquid under load exhibits a single internal stress (force per unit area) that does not vary with location or direction: this is 'pressure'. Even delicate objects are not deformed when immersed in a high-pressure liquid if they themselves are filled with liquid, because the internal and external pressures on them are exactly equal; this explains why cells can survive high pressures in liquids without damage to their delicate plasma membrane. Of the musculoskeletal tissues, only the nucleus pulposus of intervertebral discs exhibits a true fluid pressure (Adams et al 2013). Some other tissues, including bone and cartilage, contain liquid that is able to move through pores in the solid matrix.

Viscoelasticity

Materials are said to be viscoelastic if they behave partly like a thick (viscous) fluid and partly like an elastic solid. Viscoelastic deformations change with time, even when the deforming stress is constant, and complete recovery from such deformations also takes some time after the stress is removed (**Fig. 5.56**). In most biological materials, viscous behaviour occurs because applied loading causes fluid to flow from the most heavily loaded regions to the least loaded, by percolating through very small (nanometre-scale) pores in the matrix, a process that can take hours; for this reason, the term poroelastic is often preferred to viscoelastic when referring to tissues such as cartilage.

Creep and stress relaxation are two important manifestations of viscoelasticity. Creep may be described as continuing deformation under constant load (see Fig. 5.56), whereas stress relaxation is a gradual decrease in force resisted by a viscoelastic material when it is initially deformed by a certain amount, and then held with the same constant deformation. Creep can reduce the thickness of loaded articular cartilage and intervertebral discs, typically by 20% in 5 minutes and 3 hours, respectively. Creep deformation is reversed over a comparable timescale when the compressive loading is reduced and water is reabsorbed. Bone creeps at a much slower rate, but in old osteoporotic vertebrae, creep probably contributes significantly to vertebral deformity (Luo et al 2012).

Material properties of skeletal tissues

The material properties of several skeletal tissues are compared in **Table 5.3**.

Bone

Bone consists mainly of collagen type I and microcrystals of the mineral hydroxyapatite. Collagen gives bone considerable tensile strength, and

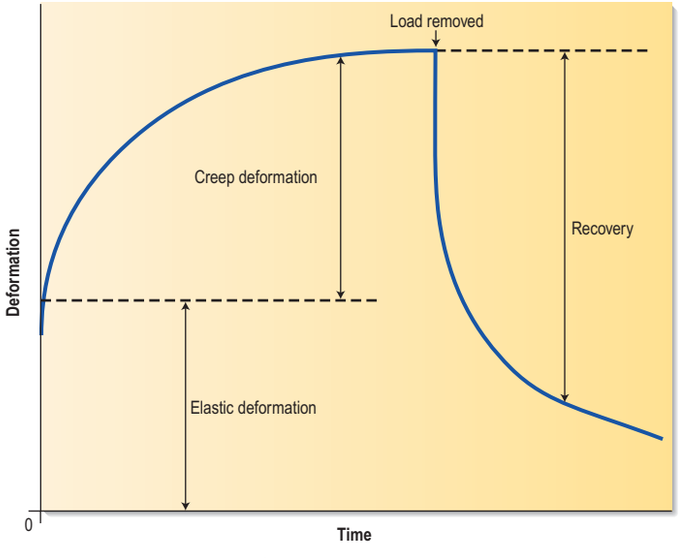

Fig. 5.56 The deformation of viscoelastic materials varies with time. In this example, a load is applied at zero time, which causes an immediate elastic deformation, followed by a slowly increasing time-dependent deformation (creep). When the load is removed, some deformation is recovered immediately, but full recovery is achieved only slowly.

TABLE 5.3 Tensile material properties of skeletal tissues*

	Cortical bone	Tendon (ligament)	Articular cartilage
Strength (MPa)	130	50–110	5–20?
Modulus (MPa)	17,000	500–1800 (150–800)	4–10
Failure strain (%)	1–2.5	10–20	30–100

*For comparison, alloy steel has a strength of 600 MPa and a modulus of 20,000 MPa.

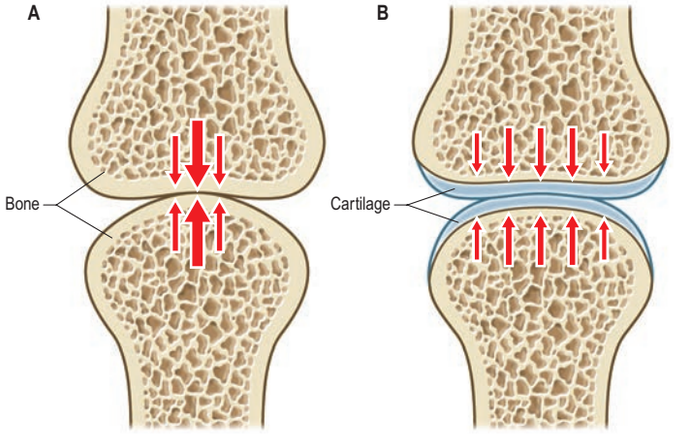

Fig. 5.57 Articular cartilage in a synovial joint is not as stiff as the underlying bone, so the presence of cartilage in a loaded joint increases the area of contact (**B**) compared to a joint without cartilage (**A**).

renders it very tough when fractured, whereas the mineral component gives bone a very high compressive modulus and high compressive strength. Rigidity (high stiffness or modulus) is the defining characteristic of bone; it enables the tissue to provide precisely shaped surfaces in synovial joints that will deform very little under load, and it also enables fast locomotion when muscles pull on bones. If bones were strong and tough but not rigid, rapid muscle contractions would cause them to bend alarmingly and would slow the angular movement of limbs.

Tendon, ligament and fascia

Tendons, ligaments and fascia consist primarily of densely packed collagen type I fibres, giving these tissues high tensile strength. The crimped nature of the collagen fibres allows them to be stretched by 10–15% before failure, and this combination of strength and extensibility enables tendons, ligaments and fascia to absorb more strain energy per unit weight than any other biological material. An important difference between tendons and ligaments is that ligaments often contain bundles of collagen fibres orientated in a range of directions, presumably because bones can be moved apart in a range of directions, whereas the fibres in a tendon are all aligned with the direction of muscle tension. Fascia usually contains collagen fibres aligned in adjacent sheets to resist forces in at least two different directions.

Hyaline cartilage

Hyaline cartilage consists mainly of very fine collagen type II fibrils and large proteoglycan molecules, which have the property of attracting water and swelling. Collagen gives cartilage its tensile stiffness and strength, and the proteoglycans give the tissue a high water content that confers compressive 'turgor'. During growth and healing, proteoglycans enable cartilage to swell and occupy space that later will be strengthened by other components of the matrix. Articular cartilage is a particular type of hyaline cartilage that covers the ends of articulating bones; its high water content enables it to distribute loading evenly on the underlying bone. Because cartilage is softer than bone, it deforms more when loaded, increasing the area of contact between articular surfaces and reducing contact stress (Fig. 5.57). Cartilage creep (see above) causes the area of contact to increase, and further reduces contact stress. Creep in articular cartilage also causes water to be exuded into the joint cavity, assisting in fluid-film lubrication (see below). Articular cartilage 'wear' (loss of material) during high and repetitive loading is minimized because the collagen type II fibrils in the superficial zone are aligned parallel to the surface, an arrangement that provides maximal resistance to surface splitting and the subsequent loss of tissue.

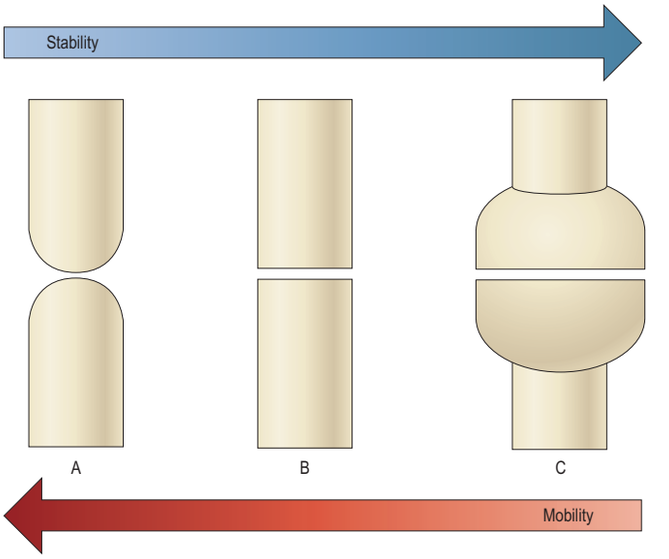

Fig. 5.58 In synovial joints, the shapes of the opposing bone ends largely determine how much movement is possible, and the stability of the joint. Curved bone ends (**A**) lead to high mobility but low stability (in the plane of the page). Conversely, very wide bone ends (**C**) lead to low mobility and high stability. Some joints resemble (**A**) in one plane but (**B**) or (**C**) in others.

Fibrocartilage and elastic cartilage

Fibrocartilage and elastic cartilage combine the high proteoglycan and water content that characterizes cartilage with a high proportion of either collagen type I (fibrocartilage) or elastin (elastic cartilage). Collagen type I confers extra tensile strength and toughness, whereas elastin fibres provide elastic recoil, i.e. the ability to spring back into shape after large deformations.

Mechanical properties of skeletal structures

Long bones

Long bones are characterized by enlarged ends covered in cartilage, a long hollow shaft and various bony protuberances. The enlarged ends serve to reduce contact stress where long bones meet in synovial joints, and to increase the stability of such joints (Fig. 5.58). A different relationship between stability and mobility can exist in different anatomical planes, even for the same joint, e.g. the knee joint favours stability in the frontal plane and mobility in the sagittal plane. The hollow shaft of a long bone minimizes bone mass and so increases the speed of movement. However, it also maximizes the bone's strength in bending for a given mass of material, because bending strength is increased by having as much bone as possible far from the axis of bending (Fig. 5.59). The precise cross-sectional shape of a long bone therefore gives a clear indication of the planes in which the shaft is most likely to be subjected to severe bending. Bony prominences or processes on long bones serve to increase the lever arm of the muscles attached to them: if a large prominence is close to the centre of rotation of a joint, then it can increase the lever arm by over 100%, and the maximum torque developed by the muscle about that centre of rotation would increase by the same amount.

Synovial joints

Typically, synovial joints are designed for full and free movements, but they must also provide some stability in specific planes (see Fig. 5.58). In a joint with a small range of movement, the intrinsic stability provided by its articular surfaces and ligaments may be more important than the extrinsic stability provided by surrounding muscles. Low-friction movement is facilitated by the smooth surfaces of articular cartilage being made slippery by the presence of the boundary lubricant lubricin, which is bound to the cartilaginous surfaces. This boundary lubrication reduces friction during slow movements, especially when forces are high. During rapid movements, microscopic undulations in the cartilage surface trap small quantities of synovial fluid between the articular surfaces, so that fluid-film lubrication (akin to aquaplaning) can also occur (Fig. 5.60), and friction and wear are greatly reduced. The sticky, viscous nature of

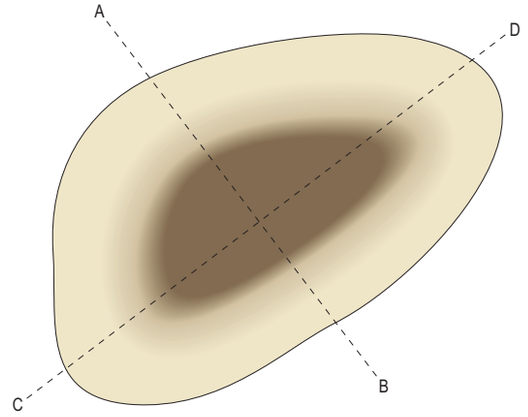

Fig. 5.59 A cross-section through the shaft of a long bone, showing how the irregular shape gives information about the bone's strength in bending about different axes. Strength will be greatest about the axis A–B because a high proportion of bone mass is located a long distance from this axis, and so will resist bending very strongly. Strength will be minimal about the axis C–D for a similar reason.

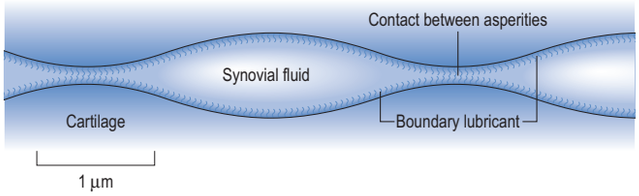

Fig. 5.60 The articular cartilage surfaces of synovial joints contain microscopic undulations that trap small quantities of synovial fluid between the surfaces, enabling fluid-film lubrication to occur. Boundary lubrication at the points of contact between cartilage asperities (roughness) is facilitated by lubricants adhering to the cartilage surface.

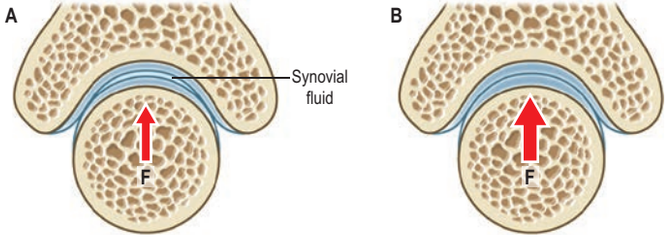

Fig. 5.61 Some synovial joints are incongruent in the sense that the opposing articular surfaces have slightly different curvatures. This ensures that there is a fluid-filled gap between them when the joint is subjected to low loading (**A**). Under high loading (**B**) this gap disappears, but peak loading at the apex of the joint remains lower than it would be if the surfaces had the same curvature, and this is a major advantage for an incongruent joint. The shape of the concave articular surface is sometimes referred to as a Gothic arch. Abbreviation: F, loading force.

synovial fluid enables it to persist between the cartilage surfaces for longer than water, which would be squeezed out much too quickly. Fluid-film lubrication is assisted by joint incongruity, in which the opposing articular surfaces have slightly different curvatures (Fig. 5.61), producing a potential fluid-filled gap that moves as the joint moves, washing synovial fluid across the cartilage surfaces. Incongruity can also help to reduce peak loading on the apex of the joint.

Intervertebral discs

Intervertebral discs are composed of three tissues: the anulus fibrosus (fibrocartilage), the nucleus pulposus (a hydrated collagen–proteoglycan gel) and the cartilage end-plates (hyaline cartilage) (Ch. 46). The water content of the nucleus pulposus can reach 90% in children and young adults, enabling the tissue to behave like a fluid. When compressive loading is applied to the vertebral column, the fluid pressure in the nucleus presses evenly on the adjacent vertebral bodies, even when they are orientated at small angles to each other. The anulus resists radial expansion of the nucleus and can deform vertically to facilitate spinal

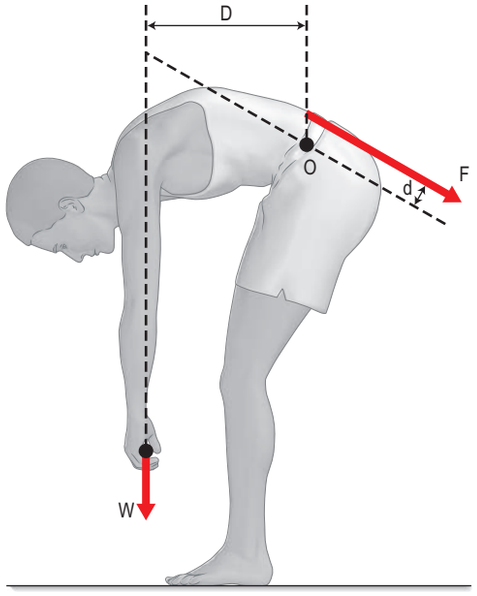

Fig. 5.62 During manual labour, muscle tension often rises to high levels in order to generate sufficient bending moment to move external objects. In this example, the back muscles act only a short distance (d) from the pivot point in the intervertebral discs (O), whereas the weight being lifted acts on a much bigger lever arm (D). In order for the moments to balance, the back muscle tension (F) must exceed the weight being lifted (W) by the ratio of D/d. In practice, this can lead to the lumbar spine being compressed by approximately 500 kg during moderate manual handling. (For simplicity, the above analysis disregards the weight of the upper body.)

bending in various planes. The relatively dense hyaline cartilage end-plate helps to maintain a fluid pressure in the nucleus by slowing down water loss into the vertebral body through perforations in the vertebral end-plate. Nevertheless, discs lose approximately 20% of their water gradually, in the course of each day. This net loss of water is regained at night when, in recumbency, the load on the spine is relieved. Diurnal variations in disc water content cause adults to be approximately 2 cm taller in the early morning, and more flexible in the evening (Adams et al 2013).

Muscles and lever systems

Collagenous architecture of muscle

Muscles are supported by a hierarchy of collagenous sheaths (endomysium, perimysium and epimysium) that surround individual muscle fibres, fascicles and whole muscles, respectively. Muscles are also bound together into functional groups by collagenous fasciae. Together, these sheaths create a strong honeycomb structure that contributes to the muscle's resistance to tension. When muscle is stretched during eccentric (lengthening) contractions, high tensile forces in the collagenous structures add to the tension generated by muscle fibre contraction, leading to high and potentially damaging forces at the musculotendinous junction.

Internal muscle forces

Generally speaking, muscle forces exert greater mechanical loading on the skeleton than does body weight. For example, during relaxed standing, 50% of the compressive force acting on the lumbar spine arises from the antagonistic activity of the muscles of the back and abdomen, and 50% comes from superincumbent body weight (Adams et al 2013). However, when bending the trunk to lift weights from the ground, more than 90% of the high compressive force acting on the spine can be attributed to muscle tension (Fig. 5.62). Similarly, muscle forces acting on the knee can exceed body weight by a factor of 200–400% during stair climbing and during deep squatting movements. Muscle forces can exceed the strength of adjacent bones if they contract in alarm, so that normal inhibitory reflexes are suppressed; it is not uncommon for vertebrae to be crushed by muscle tension during major epileptic fits. According to Newton's Second Law of motion (force = mass × acceleration), muscle forces rise to high levels when attempting to accelerate body parts, e.g. during jumping or throwing: it follows that any attempt to achieve maximum acceleration will naturally require maximal muscle

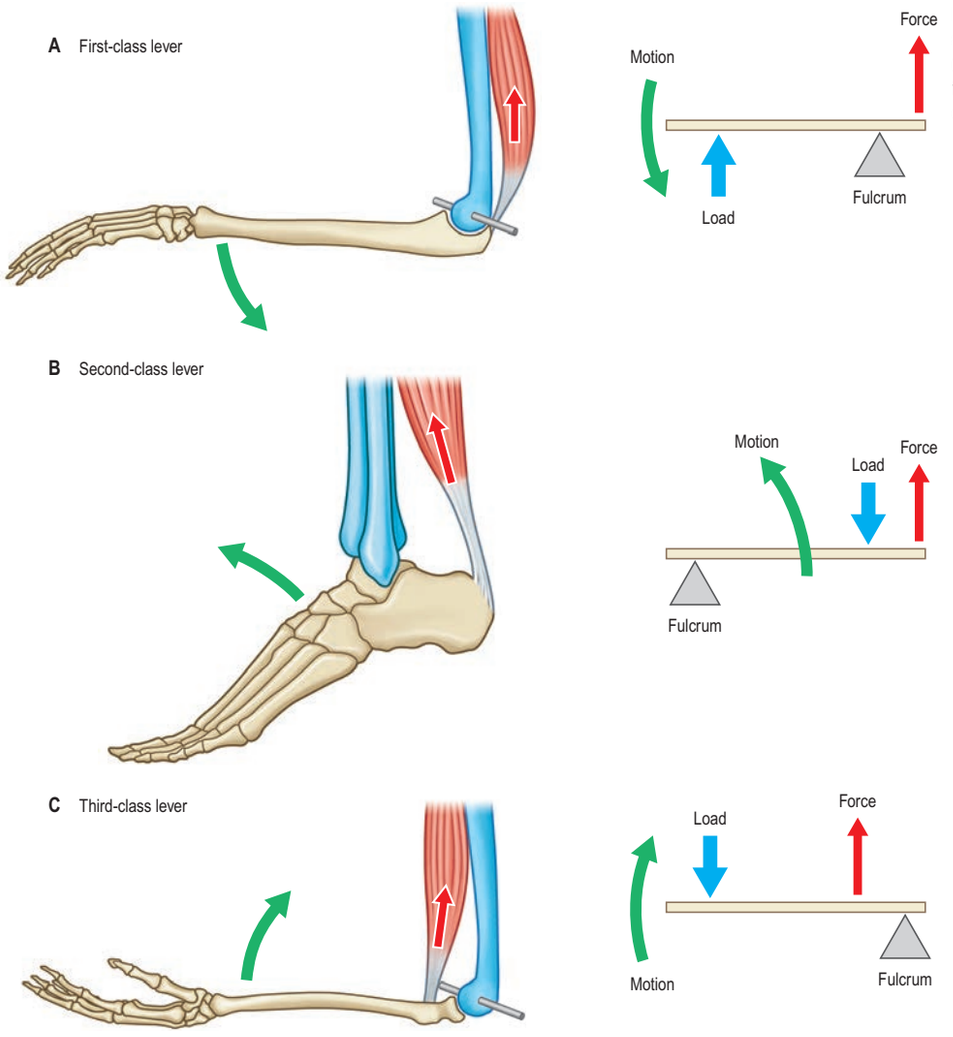

Fig. 5.63 Muscle lever systems can be classified as first-class (**A**), second-class (**B**) or third-class (**C**), according to the relative positions of the fulcrum (or pivot), the muscle insertion and the externally applied load.

tension. The size and potential dangers of internal muscle forces are often overlooked, leading some authors to draw spurious distinctions between weight-bearing and non-weight-bearing joints, and to suggest erroneously that only the former are subjected to high loading. It is likely that a watchmaker's finger joints are subjected to stresses as high, and as often, as those applied to his ankles.

Muscle lever systems

Muscle tension generates bending moments and torques about joints. Moments and torques depend on lever arms as well as muscle forces. It is conventional (although not particularly illuminating) to distinguish between three types of muscle lever system (Fig. 5.63). Generally, the length of the lever arm (the perpendicular distance between the line of action of the muscle and the centre of rotation of the joint) is more important than lever type (Fig. 5.64). If the lever arm is short, then a given muscle contraction will move the joint through a large angle, so the lever system is suited to large and/or rapid movements of that joint. Conversely, a long lever arm leads to small and/or slow movements but greater moment generation. Elite weightlifters may have muscle attachments with particularly large lever arms about particular joints.

Movements

Movements of bones

Movement of a bone is referred to as translation if it does not involve any change in orientation relative to a fixed frame of reference (or to another bone). A pure rotation involves no translation, merely a pivoting of the bone about some fixed point or centre of rotation. Spin (twisting) is the rotation of a bone about its mechanical axis, which for a long bone would coincide with its long axis. Spin can occur in conjunction with other joint rotations (Fig. 5.65). Most body movements combine rotation, translation and spin, although the translational component is often small.

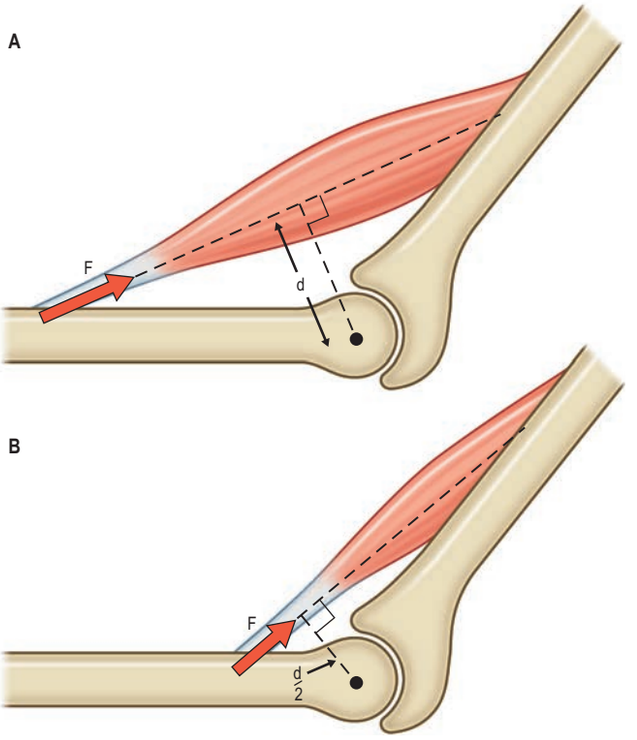

Fig. 5.64 The precise location of a muscle insertion relative to a joint greatly influences the function of that joint. **A**, If the perpendicular distance (d) between the muscle's line of action and the centre of rotation of the joint (•) is large, then the joint is suited to slow but forceful movements. **B**, If d is small, then the joint is suited to rapid but less forceful movements. Abbreviation: F, force, showing line of muscle action.

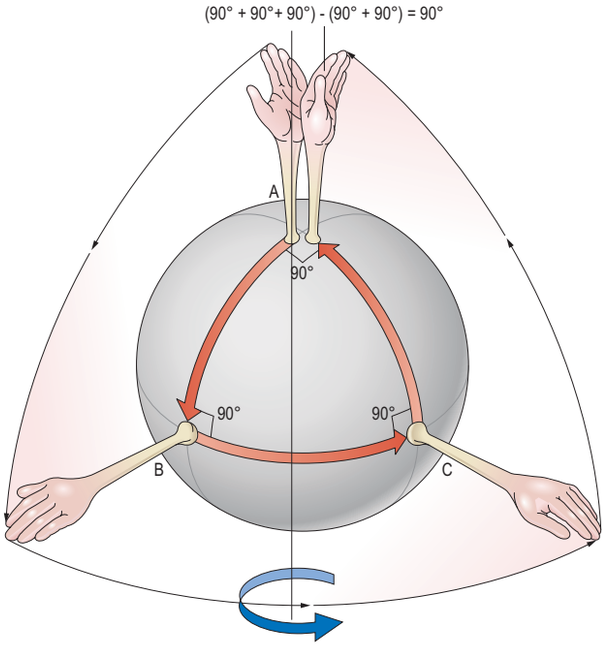

Fig. 5.65 Complex movements of the body's joints are sometimes required to produce apparently simple movements of the limbs. In this example, moving the hand as shown from A to B to C requires a hidden 'spin' movement of the arm of 90° about its mechanical (long) axis.

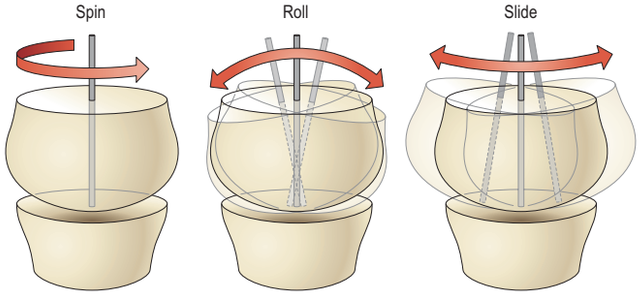

Fig. 5.66 The surfaces of incongruent joints move relative to each other by various combinations of spin, roll and slide.

Movements at articular surfaces

Opposing joint surfaces are never perfectly congruent, but substantial regions of these surfaces may fit together closely in a certain position known as the close-packed position, in which the joint is most stable. For example, the close-packed position of the knee joint corresponds to full extension. In other (loose-packed) positions, the surfaces of incongruent joints are less closely matched, and are able to move relative to each other by a combination of spin, roll and slide (Fig. 5.66). In final close-packing, when surfaces are most congruent and in maximal contact, the fibrous capsule and joint ligaments are maximally 'spiralized' and tensed, so no further movement is possible. The joint is said to be 'screwed home'. Close-packed surfaces cannot be separated by normal external force (as they may be in other positions), and bones can be regarded as temporarily locked, as if no joint existed. Any force that tends to further movement can only be resisted by contraction of appropriate muscles, and if these fail, the joint is vulnerable to injury. Therefore, movement just short of close-packing is physiologically desirable.

In symmetric standing, the knee and hip joints approach close-packed positions sufficiently to maintain an erect posture with minimal energy. Close- and loose-packed positions of several major joints are shown in Table 5.4 (see MacConaill and Basmajian (1977)). Opinions may vary in connection with some of these positions e.g. a close-packed position may possibly occur in some joints at both extremes of the range of movement. It is difficult to assess the situation in small tarsal and carpal joints and the first carpometacarpal joints.

TABLE 5.4 The close- and loose-packed positions of joints

Joint	Close-packed position	Loose-packed position
Shoulder	Abduction + lateral rotation	Semi-abduction
Ulnohumeral	Extension	Semi-flexion
Radiohumeral	Semi-flexion + semi-pronation	Extension + supination
Wrist	Dorsiflexion	Semi-flexion
2nd–5th metacarpophalangeal	Full flexion	Semi-flexion + ulnar deviation
Interphalangeal (fingers)	Extension	Semi-flexion
1st carpometacarpal	Full opposition	Neutral position of thumb
Hip	Extension + medial rotation	Semi-flexion
Knee	Full extension	Semi-flexion
Ankle	Dorsiflexion	Neutral position
Tarsal joints	Full supination	Semi-pronation
Metatarsophalangeal	Dorsiflexion	Neutral position
Interphalangeal (toes)	Dorsiflexion	Semi-flexion
Intervertebral	Extension	Neutral position

Data from MacConaill MA, Basmajian JV 1977 Muscles and Movements, 2nd ed. New York: Kriger.

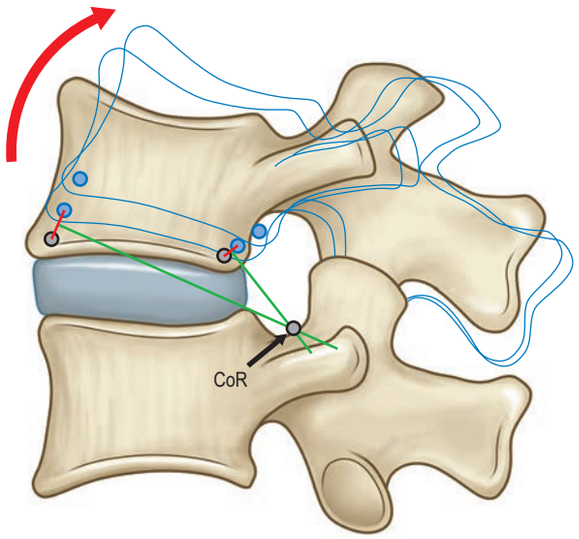

Fig. 5.67 When a bone is rotated, the centre of rotation (CoR) can be located by drawing lines between the initial and final positions of anatomical landmarks on the bone, and then determining where the perpendicular bisectors of these lines meet. The CoR may not correspond to a precise anatomical landmark.

Centre of rotation

The centre of rotation is a theoretical concept and may not correspond closely to any anatomical landmark or natural pivot. For a finite movement of one bone relative to a fixed reference (perhaps an anatomical plane), the centre of rotation can be located by drawing theoretical lines between the initial and final positions of two anatomical landmarks on the bone, and determining where the perpendicular bisectors of these two lines meet (Fig. 5.67). Real movements of real joints often involve varying combinations of rotation and translation as the movement progresses. It can be instructive to break the whole movement down into a series of small movements, calculate the centre of rotation for each one, and then join up the centres to create the locus of the instantaneous centre of rotation for the whole movement. Joint disease sometimes leads to an abnormally long and tortuous locus of the centre of rotation, because degenerative changes can reduce the restraint to motion offered by one or more tissues.

Coupled movements

An attempt to move a joint in one plane sometimes causes articular surfaces to meet at an oblique angle, creating small rotations in other planes. These secondary rotations, which are usually smaller than the

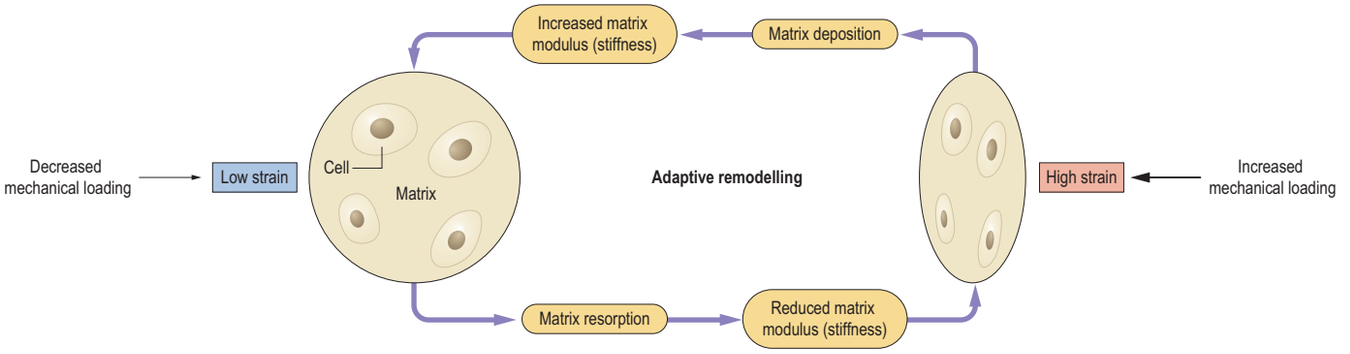

Fig. 5.68 Adaptive remodelling is the process by which musculoskeletal tissues adapt to prevailing mechanical demands. If a tissue is subjected to increased mechanical loading (right), it deforms more. Cells respond to this increased strain by depositing more matrix and increasing its modulus (stiffness) until strain levels return to normal. Similarly, reduced loading leads to reduced tissue strain (left), reduced matrix deposition and reduced modulus until strain levels rise to normal.

primary rotations, are referred to as coupled movements, e.g. lateral bending of the lumbar spine normally produces coupled axial rotations. Joint pathology can lead to abnormal coupled movements.

Mechanobiology

Adaptive remodelling

Skeletal tissues are generally able to adapt their mechanical properties to match the forces applied to them. This process is understood by bone biologists who refer to the general principle as Wolff's law. As illustrated in **Fig. 5.68**, the deformation of a tissue (i.e. the strain) depends on mechanical loading. Cells detect any change in maximum strain and respond by producing more (or less) extracellular matrix, which increases (or decreases) the modulus (stiffness) of the tissue until peak strain returns to normal levels. This negative feedback ensures that bone adapts (remodels) to suit its immediate mechanical environment (Currey 2002). Bone responds to maximal rather than time-averaged loading, and bone hypertrophy increases linearly with increasing maximum strain (Sugiyama et al 2012).Only 36 relatively severe loading cycles per day are sufficient to produce a maximal hypertrophic response, whereas four loading cycles per day are enough to prevent bone resorption (Rubin and Lanyon 1984). Articular cartilage adapts similarly to its mechanical environment (Hall et al 1991): anabolic changes are more evident in children whereas catabolic changes predominate increasingly with age (Gahunia and Pritzsker 2012). Therefore the mechanical properties of adjacent tissues remain suitably matched. However, different tissues cannot adapt at the same rate: highly vascularized tissues such as muscle and bone can adapt rapidly, whereas poorly vascularized tissues such as tendon do not. Avascular tissues such as articular cartilage and intervertebral discs adapt so slowly that turnover times for some matrix macromolecules can exceed 100 years. Consequently large differences in adaptive potential between adjacent musculoskeletal tissues could lead to problems in the less well-vascularized tissue when levels of mechanical loading increase abruptly (Adams and Dolan 1997).

Mechanotransduction

Various mechanisms have been proposed to explain how cells in musculoskeletal tissues detect mechanical loading. Cells in bone respond to tissue strain, possibly by detecting fluid flow within the microscopic canaliculi of the matrix. Cells in cartilage and ligaments also detect tissue strain, possibly because it deforms the cells in shear (**Fig. 5.52D**). Cells in articular cartilage and in the nucleus pulposus of intervertebral discs appear to detect hydrostatic pressure in their surrounding matrices, although only nucleus pulposus cells would normally experience a fluid pressure in life. (The pore pressure in a 'biphasic' solid such as articular cartilage can vary from place to place and is not equivalent to a single fluid pressure.) Muscle cells respond to strain and microinjury, which may disturb intracellular proteins such as titin. In general, mechanotransduction appears to be mediated by matrix molecules such as fibronectin pulling on transmembrane proteins such as integrins, which in turn disturb the cell cytoskeleton.

Injury and degeneration

Injured tissue is, by definition, less able to resist external forces. It deforms more readily under load, so that a higher proportion of any applied load must be resisted by surrounding intact tissue. This explains why focal tissue damage (and also cracking in engineering materials) naturally spreads outwards from the region of initial damage. Experiments on cadaveric intervertebral discs confirmed that measured compressive stresses decrease markedly in the immediate vicinity of damage and increase greatly in adjacent intact tissue (Adams et al 2013). The biological significance of this finding is that cartilage cells are most active and synthesize most matrix when they are subjected to moderate compressive stresses; matrix synthesis falls in response to low *and* to high stress (Hall et al 1991). Very high stress causes cartilage cells to secrete more matrix-degrading enzymes. Cartilage injury therefore creates a focal region of weakened tissue that spreads outwards and degrades progressively over time.

CHAPTER 6

Smooth muscle and the cardiovascular and lymphatic systems

The cardiovascular system carries blood from the heart to all parts of the body through a series of tubes, all but the smallest of which are muscular. The muscle in these tubes is of two types: smooth muscle is characteristic of the walls of blood vessels, whereas cardiac muscle provides the walls of the heart chambers with their powerful contractile pumping action. The general characteristics and classification of muscle tissues are given on p. 107. Smooth muscle also forms an important contractile element in the walls of many other organ systems, e.g. the gastrointestinal tract and airways.

SMOOTH MUSCLE

In smooth muscle tissue, the contractile proteins actin and myosin are not organized into regular sarcomeres, visible as transverse striations, and so the cytoplasm has a smooth (unstriated) appearance. Smooth muscle is also referred to as involuntary muscle because its activity is neither initiated nor monitored consciously. It is much more variable, in both form and function, than either striated or cardiac muscle, a reflection of its varied roles in different systems of the body.

Smooth muscle is typically found in the walls of tubular structures and hollow viscera. It regulates diameter (e.g. in blood vessels, and branches of the bronchial tree); propels liquids or solids (e.g. in the ureter, hepatic duct and intestines); or expels contents (e.g. in the urinary bladder and uterus). The actual arrangement of the cells varies with the tissue. The account that follows will therefore be concerned with the generic properties of smooth muscle. The more specialized morphologies of smooth muscle are described in the appropriate regional chapters.

Microstructure of smooth muscle

Smooth muscle cells (fibres) are smaller than those of striated muscle. Their length can range from 15 μm in small blood vessels to 200 μm, and even to 500 μm or more in the uterus during pregnancy. The cells are spindle-shaped, tapering towards the ends from a central diameter of 3–8 μm (Fig. 6.1). The nucleus is single, located at the midpoint, and often twisted into a corkscrew shape by the contraction of the cell.

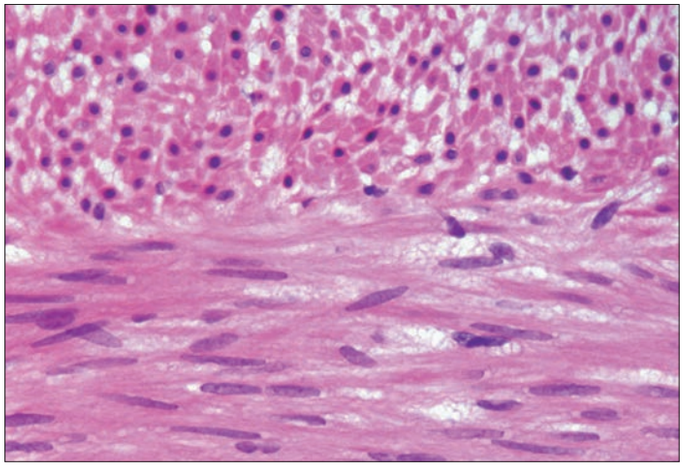

Fig. 6.1 Smooth muscle cells (fibres) in longitudinal (bottom) and transverse (top) section at the boundary of circular and longitudinal muscle layers in the human intestinal wall. Individual cells are spindle-shaped with a single central nucleus, aligned in parallel with neighbouring cells in a fasciculus. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Smooth muscle cells align with their long axes parallel and staggered longitudinally, so that the wide central portion of one cell lies next to the tapered end of another. Such an arrangement achieves both close packing and a more efficient transfer of force from cell to cell. In transverse section, smooth muscle is seen as an array of circular or slightly polygonal profiles of very varied size, and nuclei are present only in the centres of the largest profiles (Fig. 6.2). This appearance contrasts markedly with that of skeletal muscle cells, which show a consistent diameter in cross-section and peripherally placed nuclei throughout their length.

Smooth muscle has no attachment structures equivalent to the fasciae, tendons and aponeuroses associated with skeletal muscle. There is a special arrangement for transmitting force from cell to cell and, where necessary, to other soft tissue structures. Cells are separated by a gap of 40–80 nm. Each cell is covered almost entirely by a prominent basal lamina, which merges with a reticular layer consisting of a network of fine elastin, reticular fibres (collagen type III) and type I collagen fibres (Fig. 6.3). These elements bridge the gaps between adjacent cells and provide mechanical continuity throughout the fascicle. The cell attaches to components of this extracellular matrix at dense plaques (Fig. 6.3A, Fig. 6.4), where the basal lamina is thickened; cell–cell attachment occurs at intermediate junctions or small desmosome-like junctions, formed of two adjacent dense plaques. At the boundaries of fascicles, the connective tissue fibres become interwoven with those of interfascicular septa, so that the contraction of different fascicles is communicated throughout the tissue and to neighbouring structures. The components of the reticular network, the ground substance and collagen and elastic fibres, are synthesized by the smooth muscle cells themselves, not by fibroblasts or other connective tissue cells, which are rarely found within fasciculi.

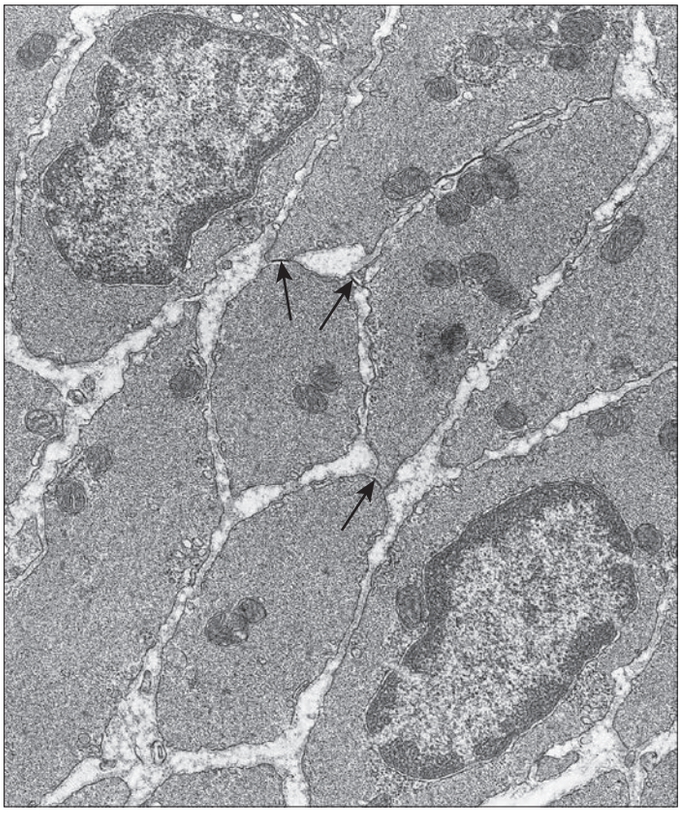

Fig. 6.2 A transmission electron micrograph showing smooth muscle fibres in transverse section, two at the level of their single central nucleus. In several places, the plasma membranes of adjacent cells are closely approximated at gap junctions (arrows).

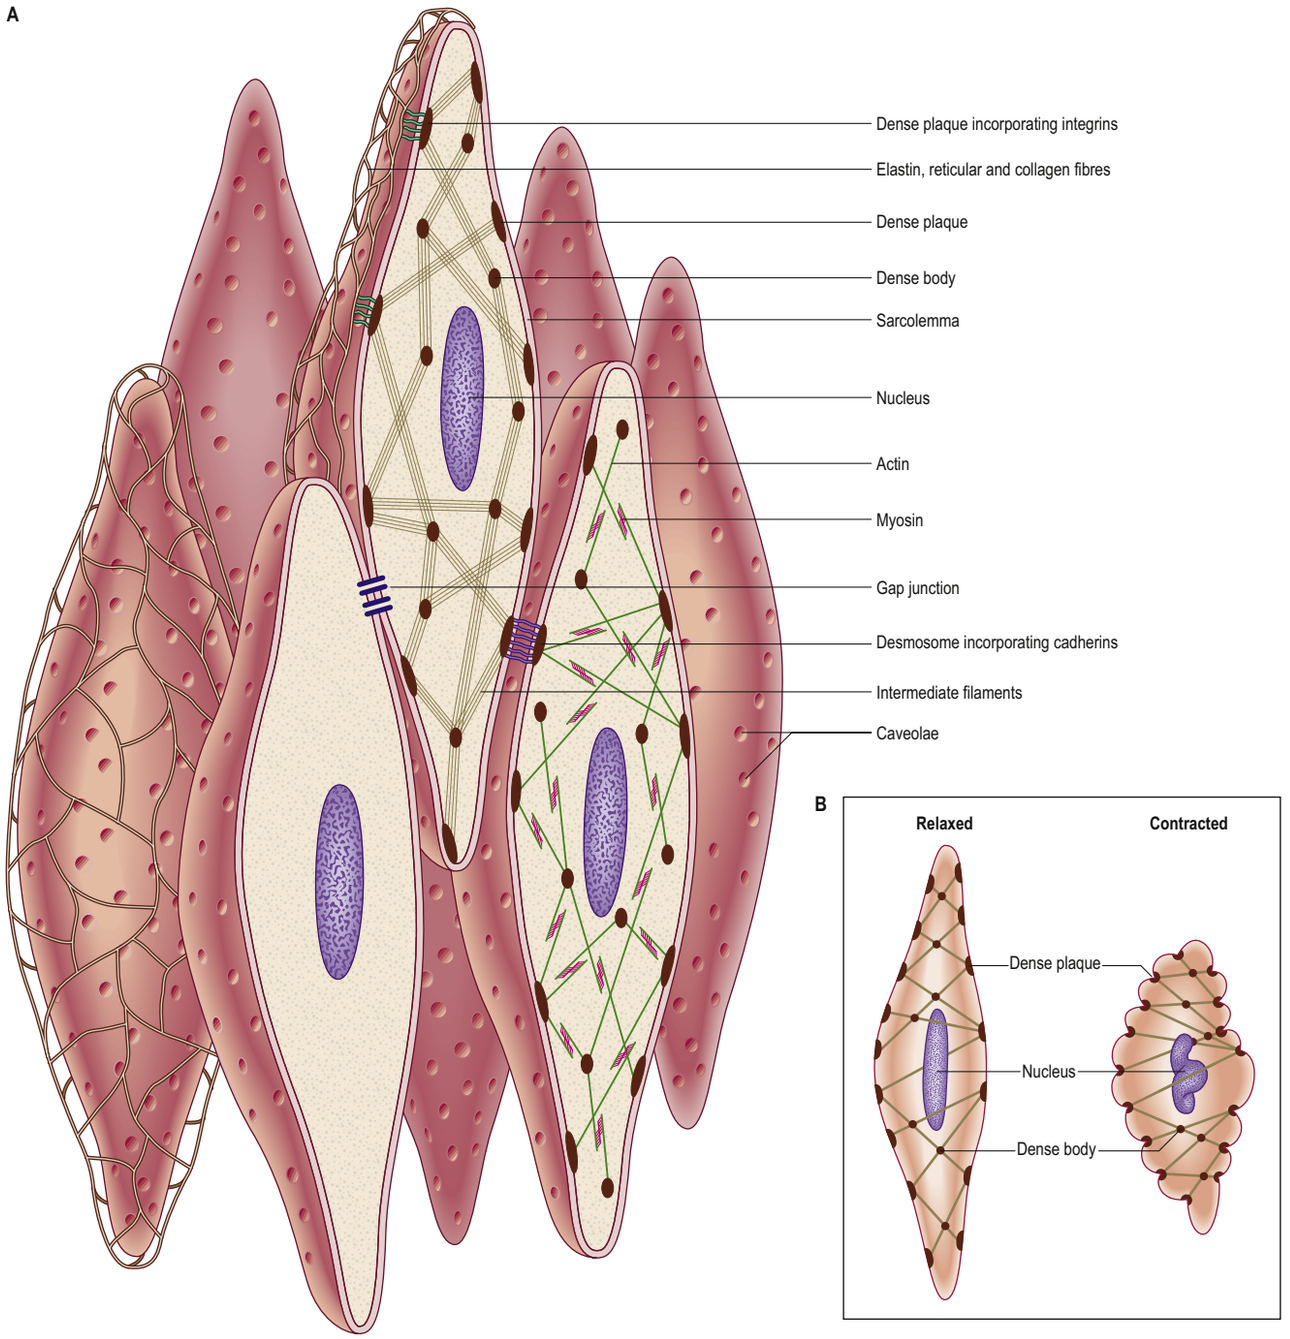

Fig. 6.3 **A**, A three-dimensional representation of smooth muscle cells. For clarity, some structural features have been separated for illustration in different cells. The spindle-shaped cells interdigitate with their long axes parallel; mechanical continuity between the cells is provided by a reticular layer of elastin and collagen fibres. The cytoskeletal framework consists of intermediate filament arrays (mainly longitudinal) and bundles of actin and myosin filaments (shown in separate cells) inserted into cytoplasmic dense bodies and submembraneous dense plaques to form a three-dimensional network. The sarcolemma contains anchoring desmosome-like (adheren) junctions, gap junctions and caveolae. **B**, The concertina-like change in shape of smooth muscle cells as they contract.

The membrane of smooth muscle cells contains molecules such as proteoglycans, glycoproteins and glycolipids on its exterior surface that form a thin, negatively charged network, the glycocalyx. Whilst less studied than that of endothelial cells, the smooth muscle cell glycocalyx has been shown to be important for mechanotransduction in small blood vessels. There are also a number of cell membrane-spanning proteins that extend through the glycocalyx and interact with the extracellular matrix, including cadherins and integrins. These provide structural and signalling links with the extracellular matrix and other cells, e.g. at desmosomes. The cytosolic ends of these proteins interact with components of the cytoskeleton via a complex of other proteins and kinases, and provide an important signalling pathway linking cell function to the exterior, which can modulate, for example, gene transcription and phenotype (Stegemann 2005).

Discontinuities occur in the basal lamina between adjacent cells, and here the cell membranes approach to 2–4 nm of one another to form a gap junction (see Fig. 6.2). These junctions are structurally similar to their counterparts in cardiac muscle, and are formed by binding of adjacent connexon complexes on the surface of the two cells. They provide a low-resistance channel through which electrical excitation and small molecules can pass, e.g. enabling a coordinated wave of contraction. The incidence of gap junctions varies with the anatomical site of the tissue: they appear more abundant in the type of smooth muscle that generates rhythmic (phasic) activity. In addition, they link the endothelium functionally with the underlying smooth muscle (via myoendothelial gap junctions) in small resistance arteries and arterioles.

Caveolae, cup-like invaginations of the plasma membrane with a resemblance to endocytotic vesicles, are a characteristic feature of smooth muscle cells, and may form up to 30% of the membrane (see Fig. 6.4). They are associated with many receptors, ion channels, kinases and the peripheral sarcoplasmic reticulum, and may thus act as highly localized

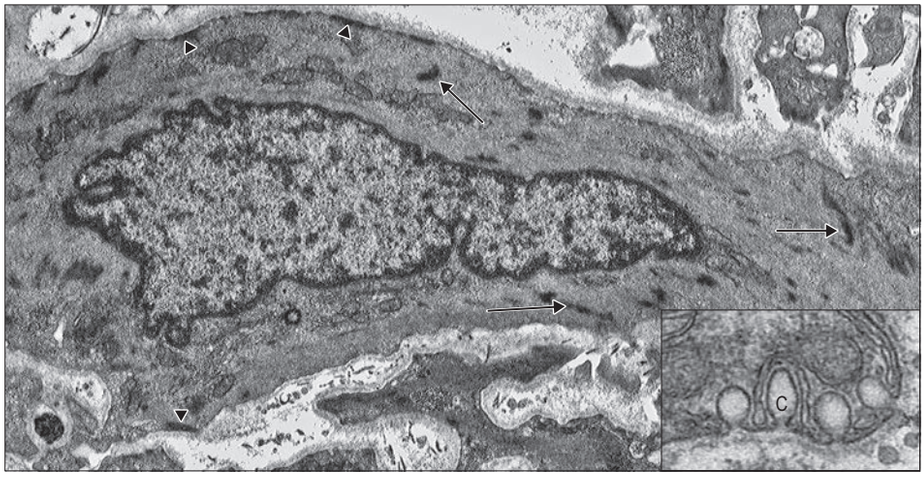

Fig. 6.4 Transmission electron micrographs showing the characteristic features of smooth muscle cells. Vascular smooth muscle in human kidney tissue, showing a cytoplasm packed densely with microfilaments (actin and myosin), cytoplasmic dense bodies (arrows) and submembraneous dense plaques (arrowheads). A basal lamina encloses the cell. The inset shows four caveolae (C) (vesicular invaginations of the cell surface at high magnification). These are associated with receptors, enzymes and ion channels important in smooth muscle function. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK. Inset courtesy of Professor Chun Y Seow, University of British Columbia.)

signalling microdomains. They may also act as specialized pinocytotic structures involved in fluid and electrolyte transport into the cell. Other organelles (mitochondria, ribosomes, etc.) are largely confined to the filament-free perinuclear cytoplasm, although in some smooth muscle types, including vascular smooth muscle, peripheral mitochondria, sarcoplasmic reticulum and sarcolemma form important signalling microdomains.

Neurovascular supply of smooth muscle

Vascular supply

The blood supply of smooth muscle is less extensive than that of striated muscle. Where the tissue is not too densely packed, afferent and efferent vessels gain access via connective tissue septa, and capillaries run in the connective tissue between small fascicles. However, unlike striated muscle, capillaries are not found in relation to individual cells.

Innervation

Smooth muscle may contract in response to nervous or hormonal stimulation, mechanical deformation, or electrical depolarization transferred from neighbouring cells. Some muscles receive a dense innervation to all cells and are often referred to as multi-unit smooth muscles: most blood vessels are of this type. Such innervation can precisely define contractile activity, e.g. in the iris, specific nervous control can produce either pupillary constriction or dilation. Other muscles are more sparsely innervated and have been referred to as unitary smooth muscles. They tend to display myogenic activity, initiated spontaneously or in response to stretch, which may be markedly influenced by hormones. In these muscles, which include those in the walls of the gastrointestinal tract, urinary bladder, ureter, uterus and uterine tube, innervation tends to exert a more global influence on the rate and force of intrinsically generated contractions. The terms multi-unit and unitary smooth muscles are widely used, but in practice such distinctions are better regarded as the extremes of a continuous spectrum.

Smooth muscles are innervated by unmyelinated axons with cell bodies located in autonomic ganglia, either in the sympathetic chain or, in the case of parasympathetic fibres, closer to the point of innervation (Fig. 6.5). They ramify extensively, spreading over a large area of the muscle and sending branches into the muscle fasciculi. The terminal portion of each axonal branch is beaded and consists of expanded portions, varicosities, packed with vesicles and mitochondria, separated by thin, intervaricose portions. Each varicosity is regarded as a transmitter release site and may be considered as a nerve ending in the functional sense. In this way the axonal arborization of a single autonomic neurone bears a very large number of nerve endings (up to tens of thousands), as opposed to a maximum of a few hundred in somatic motor neurones. The neuromuscular terminals of autonomic efferents are considered in more detail on p. 67.

The neuromuscular junctions in smooth muscles do not show the consistent appearance seen in skeletal muscles. The neurotransmitter diffuses across a gap that can vary from 10 to 100 nm; even separations of up to 1 μm may still allow neuromuscular transmission to take place, although more slowly. The nerve ending is packed with vesicles but the adjacent area of the muscle cell is not structurally differentiated from that of non-junctional regions, i.e. there is no distinct synapse.

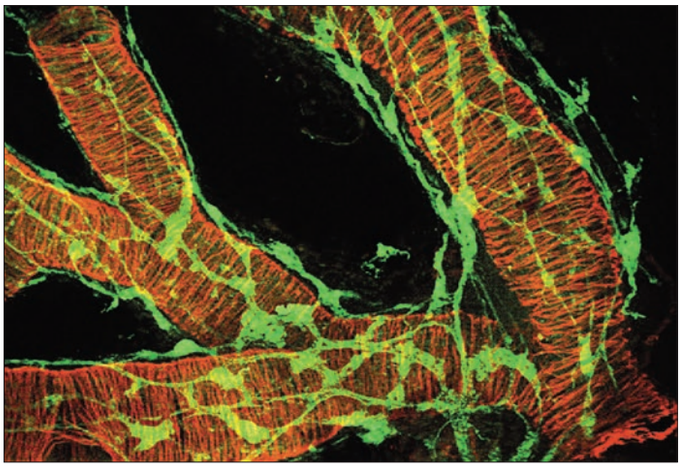

Fig. 6.5 A confocal fluorescence micrograph illustrating the innervation of airway smooth muscle in the developing human lung. Smooth muscle cells are arranged circumferentially and are labelled for actin (red); nerves and ganglia form a loose network around the smooth muscle, separated from it by up to 40 μm. Nervous tissue is labelled for PGP 9.5 (green). (With permission from Sparrow MP, Weichselbaum M, McCray PB Jr 1999 Development of the innervation and airway smooth muscle in human fetal lung. Am J Respir Cell Mol Biol 20:550–60.)

Intramuscular afferent nerves are the peripheral processes of small sensory neurones in the dorsal root ganglia. Since they are unmyelinated, contain axonal vesicles and have a beaded appearance, they are difficult to distinguish from efferent fibres, except by differential staining for neurotransmitters.

Structural basis of contraction

High-resolution immunocytochemistry of the internal architecture of the smooth muscle cell suggests a structural model for contractile function, which is illustrated in Fig. 6.3. This depends on the interaction of two systems of filaments, one forming the cytoskeleton and the other the contractile apparatus.

Excluding the perinuclear region, the cytoplasm of a smooth muscle cell effectively consists of two structural domains. The cytoskeleton forms a structural framework that maintains the spindle-like form of the cell and provides an internal scaffold with which other elements can interact. Its major structural component is the intermediate filament desmin, with the addition of vimentin (which may also be present alone) in vascular smooth muscle. The intermediate filaments are arranged mainly in longitudinal bundles, but some filaments interconnect the bundles with each other and with the sarcolemma to form a three-dimensional network. The bundles of intermediate filaments insert into focal, electron-dense bodies, approximately 0.1 μm in diameter, which are distributed uniformly throughout the cytoplasm and also attach to dense plaques underlying the plasma membrane (see Fig. 6.3A). The cytoplasmic dense bodies and submembraneous dense plaques are equivalent to the Z-discs of striated muscle cells. They contain the actin-binding protein α-actinin

In some blood vessels, notably those of the pulmonary circulation, and in the airways and probably in other smooth muscle types, there is evidence for heterogeneity of cell phenotype. The smooth muscle cells of small blood vessels and bronchioles exhibit different functional properties from those in larger vessels and airways, and may differ in morphology, expression of signalling proteins such as ion channels, and excitation–contraction coupling mechanisms. Even within individual tissues there is evidence of heterogeneity. Some myofibroblast-like cells have a function that is more secretory than contractile. The secretory phenotype is often increased in disease (e.g. chronic severe asthma, pulmonary hypertension) and is associated with increased proliferation and remodelling, and with secretion of cytokines and other mediators. Many smooth muscles seem to exhibit considerable phenotypic plasticity between these contractile and secretory phenotypes (Halayko and Solway 2001).

and thus also anchor the actin filaments of the contractile apparatus. These form a lattice of obliquely arranged bundles throughout the cytoplasm, which transmit force to the plasma membrane and thus the basal lamina and extracellular matrix via dense plaques. These are associated with a highly structured arrangement of ancillary proteins, including vinculin and talin, which in turn attach to integrins that cross the membrane and provide attachment to components of the extracellular matrix (Gunst and Zhang 2008).

An analogous arrangement underlies cell–cell attachment at desmosomes, but here the attachment between dense plaques is provided by transmembrane cadherin glycoproteins and intracellular catenins instead of integrins and talin. Mechanical deformation of the cell may be linked to cell signalling mechanisms via focal adhesion kinase (FAK) and its substrate paxillin; phosphorylation of talin and paxillin may modulate the deformability of the smooth muscle cell. Other regulatory proteins also associate specifically with actin, such as caldesmon and calponin. The cytoskeleton is not a passive structure. It adapts dynamically to load and is modulated by cell surface receptors including integrins and agonist binding to G-protein coupled receptors, and so contributes to contraction (Gunst and Zhang 2008). This presumably contributes to the low energy requirements of smooth muscle contraction because dynamic reorganization of the cytoskeleton following active contraction allows cell shortening to be maintained without further energy expenditure.

The ratio of actin to myosin is about eight times greater in smooth compared to striated muscle, reflecting the greater length of actin filaments in smooth muscle. Smooth muscle myosin filaments are 1.5–2 μm long, somewhat longer than those of striated muscle, and are formed of a slower isoform of myosin. Although smooth muscle cells contain less myosin, the longer filaments are capable of generating considerable force. The myosin filaments of smooth muscle are also assembled differently, such that their head regions lie symmetrically on either side of a ribbon-like filament, rather than imposing a bipolar organization on the filament. Actin filaments, to which they bind, can thus slide along the whole length of the myosin filament during contraction. In addition, dynamic polymerization of both myosin and actin monomers during activation can alter the length of the contractile filaments. These differences underpin the ability of smooth muscle to undergo much greater changes in length than striated muscle. Actin–myosin filament sliding generates tension, which transmits to focal regions of the plasma membrane, changing the cell to a shorter, more rounded shape (**Fig. 6.3B**) and often deforming the nucleus to a corkscrew-like profile.

Although some smooth muscles can generate as much force per unit cross-sectional area as skeletal muscle, the force develops much more slowly. Smooth muscle can contract by more than 80%, much greater than the 30% or so to which striated muscle is limited. The significance of this is illustrated by the urinary bladder, which is capable of emptying completely from an internal volume of 300 ml or more. Smooth muscles can maintain tension for long periods with very little expenditure of energy. Many smooth muscle structures are able to generate spontaneous contractions, examples are found in the walls of the intestines, ureter and uterine tube.

Excitation–contraction coupling in smooth muscle

Excitation–contraction coupling in smooth muscle is more complex than in skeletal or cardiac muscle, and may be electromechanical or pharmacomechanical. Electromechanical coupling involves depolarization of the cell membrane by an action potential, and may be generated when a membrane receptor, usually linked with an ion channel, is occupied by a neurotransmitter, hormone or other blood-borne substance. It is most commonly seen in unitary and phasic smooth muscles such as those of the viscera, with transmission of electrical excitation from cell to cell via gap junctions. In some types of smooth muscle depolarization may be the consequence of other stimuli, such as cooling, stretch and even light.

Pharmacomechanical coupling is a receptor-mediated and G-protein coupled process, and is the major mechanism in tonic smooth muscles such as in the vasculature and airways. It may involve several pathways, including formation of inositol trisphosphate, which triggers intracellular calcium release from the sarcoplasmic reticulum, activation of voltage-independent calcium channels in the sarcolemma, and depolarization causing activation of voltage-dependent calcium channels (reviewed in Berridge (2008)). Many receptors also couple to kinases that modulate contraction in a calcium-independent fashion, either via myosin phosphatase (see below) or via the actin cytoskeleton (see above). The extent to which any of these pathways contributes to activation varies between different types of smooth muscle.

Whilst the regulation of contraction of smooth muscle is largely calcium-dependent, the effects of an elevation of intracellular calcium are mediated via myosin, not actin/tropomyosin as in cardiac and skeletal muscle. Most smooth muscles contain little or no troponin, and instead calcium binds to calmodulin. The calcium–calmodulin complex regulates the activity of myosin light chain kinase, which phosphorylates myosin regulatory light chains and initiates the myosin–actin adenosine 5′-triphosphatase (ATPase) cycle. The enzymatic activation process is therefore inherently slow. Myosin phosphatase dephosphorylates myosin and thus promotes relaxation. The degree of myosin phosphorylation and therefore contraction depends on the relative activities of myosin light chain kinase and myosin phosphatase. Thus inhibition of the phosphatase, e.g. by Rho kinase, increases phosphorylation for any level of calcium (i.e. increases calcium sensitivity). The latter is a central component of the response to many constrictor agonists.

Regulation of smooth muscle intracellular calcium

Intracellular calcium is a key determinant of smooth muscle function, including contraction and also proliferation, migration and secretion of mediators. Its regulation in smooth muscle is particularly complex, and involves calcium entry via both voltage-dependent and independent ion channels, release from and reuptake into intracellular stores such as the sarcoplasmic reticulum, and modulation by mitochondria.

Origin of smooth muscle

Smooth muscle cells develop from a range of mesenchymal sources: the muscularis layer of visceral tubular systems, e.g. gut, airways etc. derive from local splanchnopleuric mesenchyme, whereas the smooth muscle of the sphincter and dilator pupillae is derived from neurectoderm. The origin of the tunica media of blood and larger lymphatic vessels varies throughout the body; sources include local splanchnopleuric mesenchyme condensing around endothelial networks and, within and around the vertebrae and muscles of the back and the descending aorta, from local somites (Wiegreffe et al 2007).

Following a period of proliferation, clusters of myoblasts become elongated in the same orientation. Dense bodies, associated with actin and cytoskeletal filaments, appear in the cytoplasm, and the surface membrane starts to acquire its specialized features, i.e. caveolae, adherens junctions and gap junctions. Cytoskeletal filaments extend to insert into the submembraneous dense plaques and cytoplasmic dense bodies. Thick filaments are seen a few days after the first appearance of thin filaments and intermediate filaments, and from this time the cells are able to contract. During development, dense bodies increase in number and further elements of the cytoskeleton are added. In addition to synthesizing the cytoskeleton and contractile apparatus, the differentiating cells express and secrete components of the extracellular matrix.

In a developing smooth muscle, all the cells express characteristics of the same stage of differentiation and there are no successive waves of differentiation. From its earliest appearance to maturity, a smooth muscle increases several hundred-fold in mass, partly by a 2–4-fold increase in the size of individual cells, but mainly by a very large increase in cell number. Growth occurs by division of cells in every part of the muscle, not just at its surface or ends. Mitosis occurs in cells in which differentiation is already well advanced, as evidenced by the presence of myofilaments and membrane specializations. Mitotic smooth muscle cells may be found at any stage of life but their numbers peak before birth, at a time that differs for different muscles; they are rare in the adult unless the tissue is stimulated to hypertrophy (as in the pregnant uterus) or to repair. The ability of mature cells to undergo mitosis therefore differs between the three major types of muscle: skeletal muscle cells cannot divide at all after differentiation; cardiac muscle cells can divide but only before birth; and smooth muscle cells appear to remain capable of division throughout life.

During the early stages of development, smooth muscle expresses embryonic and non-muscle isoforms of myosin. The proportions of these isoforms decrease progressively. Initially, SM-1 is the dominant or exclusive smooth muscle heavy chain isoform and the SM-2 isoform becomes more established later. For a review of the development of vascular smooth muscle, see Wang et al (2015).

Smooth muscle remodelling in disease

The ability of smooth muscle cells to divide and change phenotype throughout life means that smooth muscle has significant plasticity and can adapt to changing needs and stimuli, e.g. in the walls of the uterus

The arrangement of peripheral signalling microdomains (see above) is vital to this process. Sequential release from inositol trisphosphate receptors and calcium-sensitive ryanodine receptors (calcium release channels) in the sarcoplasmic reticulum, together with reuptake via the sarco-endoplasmic reticulum calcium ATPase (SERCA), give rise to slow calcium oscillations; it is now thought that the rate of oscillations, rather than the average level of calcium, is the prime driver for smooth muscle function, including contraction and activation of gene transcription (Berridge 2008).

during pregnancy. This can, however, have detrimental consequences in disease.

CARDIOVASCULAR AND LYMPHATIC SYSTEMS

General organization

Cells of peripheral blood, suspended in plasma, circulate through the body in the blood vascular system. Fluid and solutes exchange between the plasma and interstitium across capillaries and small venules. Excess interstitial fluid from peripheral tissues returns to the blood vascular system via the lymphatic system, which also provides a channel for the migration of leukocytes and the absorption of certain nutrients from the gut.

The cardiovascular system carries nutrients, oxygen, hormones, etc. throughout the body and the blood redistributes and disperses heat. As a consequence of the hydrostatic pressure, the system also has mechanical effects, such as maintaining tissue turgidity. Blood circulates within a system made up of the heart, the central pump and main motor of the system; arteries, which lead away from the heart and carry the blood to the periphery; and veins, which return the blood to the heart. The heart is essentially a pair of muscular pumps, one feeding the pulmonary circulation, which is responsible for gas exchange in the lungs and has a low hydrostatic pressure, and the other feeding the systemic circulation, which has a high hydrostatic pressure and serves the rest of the body. With limited exceptions, both circulations form a closed system of tubes, so that blood *per se* does not usually leave the circulation.

From the centre to the periphery, the vascular tree shows three main modifications. The arteries increase in number by repeated bifurcation and by sending out side branches, in both the systemic and the pulmonary circulation. For example, the aorta, which carries blood from the heart to the systemic circulation, gives rise to about 4×10^6 arterioles and four times as many capillaries. The arteries also decrease in diameter, although not to the same extent as their increase in number, so that a hypothetical cross-section of all the vessels will show an increase in total area with increasing distance from the heart. At its emergence from the heart, the aorta of an adult man has an outer diameter of approximately 30 mm (cross-sectional area of nearly 7 cm^2). The diameter decreases along the arterial tree until it is as little as 10 μm in arterioles (each with a cross-sectional area of about 80 μm^2). However, given the enormous number of arterioles, the total cross-sectional area at this level is approximately 150 cm^2, more than 200 times that of the aorta. As a result, blood flow is faster near the heart than at the periphery.

The walls of arteries decrease in thickness towards the periphery, although this is not as substantial as the reduction in vessel diameter. Consequently, in the smallest arteries (arterioles), the thickness of the wall represents about half the outer radius of the vessel, whereas in a large vessel it represents between one-fifteenth and one-fifth, e.g. in the thoracic aorta the radius is approximately 17 mm and the wall thickness 1.1 mm.

Venules, which return blood from the capillaries, converge on each other, forming a progressively smaller number of veins of increasingly large size. As with arteries, the hypothetical total cross-sectional area of all veins at a given level reduces nearer to the heart. Eventually, only the two largest veins, the superior and inferior venae cavae, open into the heart from the systemic circulation. A similar pattern is found in the pulmonary circulation but here the vascular loop is shorter and has fewer branch points, and consequently, the number of vessels is smaller than in the systemic circulation. The total end-to-end length of the vascular network in a typical adult is twice the circumference of the earth.

Large arteries, such as the thoracic aorta and subclavian, axillary, femoral and popliteal arteries, lie close to a single vein that drains the same territory as that supplied by the artery. Other arteries are usually flanked by two veins, satellite veins (venae comitantes), which lie on either side of the artery and have numerous cross-connections; the whole is enclosed in a single connective tissue sheath. The artery and the two satellite veins are often associated with a nerve, and when they are surrounded by a common connective tissue sheath they form a neurovascular bundle.

The close association between the larger arteries and veins in the limbs allows counterflow exchange of heat. This mechanism promotes heat transfer from arterial to venous blood and thus helps to preserve body heat. Counterflow heat exchange systems are found in certain organs, e.g. in the testis, where the pampiniform plexus of veins surrounds the testicular artery (this arrangement not only conserves body heat, but also maintains the temperature of the testis below average body temperature). Counterflow exchange mechanisms are found in the microcirculation, as in the vasa recta in the renal medulla. Here, countercurrent exchange retains solutes at a high concentration in the medullary interstitium, with efferent venous blood transferring solutes to the afferent arterial supply; this mechanism is essential for concentration of the urine.

Arteries and veins are named primarily according to their anatomical position. In functional terms, four main classes of vessel are described: conducting and distributing vessels (large arteries), resistance vessels (small arteries but mainly arterioles), exchange vessels (capillaries, sinusoids and small venules) and capacitance vessels (veins). Structurally, arteries can also be divided into elastic and muscular types. Although muscle cells and elastic tissue are present in all arteries, the relative amount of elastic material is greatest in the largest vessels, whereas the relative amount of smooth muscle increases progressively towards the smallest arteries.

The large conducting arteries that arise from the heart, together with their main branches, are characterized by the predominantly elastic properties of their walls. Distributing vessels are smaller arteries supplying the individual organs, and their walls are characterized by a well-developed muscular component. Resistance vessels include the smallest arteries and arterioles, and are highly muscularized. They provide the major part of peripheral resistance to blood flow and so cause the largest drop in blood pressure before the blood flows into the tissue capillary beds.

Capillaries, sinusoids and small (postcapillary) venules are collectively termed exchange vessels. Their thin walls allow exchange between blood and the interstitial fluid that surrounds all cells: this is the essential function of a circulatory system. Arterioles, capillaries and venules constitute the microvasculature, the structural basis of the microcirculation.

Larger venules and veins form an extensive but variable, large-volume, low-pressure system of vessels conveying blood back to the heart. Their high capacitance is due to the significant distensibility (compliance) of their walls, so that the content of blood is high even at low pressures. Veins contain the greatest proportion of blood, reflecting their large relative volume.

Blood from the gastrointestinal tract (with the exception of the lower part of the anal canal) and from the spleen, pancreas and gallbladder drains to the liver via the portal vein. The portal vein ramifies within the substance of the liver like an artery and ends in the hepatic sinusoids. These drain into the hepatic veins, which in turn drain into the inferior vena cava. Blood supplying the abdominal organs thus passes through two sets of capillaries before it returns to the heart. The first provides the organs with oxygenated blood, and the second carries deoxygenated blood, rich in absorption products from the intestine, through the liver parenchyma. A venous portal circulation also connects the median eminence and infundibulum of the hypothalamus with the adenohypophysis. In essence, a venous portal system is a capillary network that lies between two veins, instead of between an artery and a vein, which is the more usual arrangement in the circulation. A capillary network may also be interposed between two arteries, e.g. in the renal glomeruli, where the glomerular capillary bed lies between afferent and efferent arterioles. This maintains a relatively high-pressure system, which is important for renal filtration.

A parallel circulatory system is provided by the lymphatic vessels and lymph nodes. Lymphatic vessels originate in peripheral tissues as blind-ended endothelial tubes that collect excess fluid from the interstitial spaces between cells and conduct it as lymph. Lymph is returned to the blood vascular system via lymphatic vessels, which converge on the large veins in the root of the neck.

Certain pathologies of the cardiovascular and lymphatic systems are described below; for information on vascular tumours, see Sepulveda and Buchanan (2014). The development of blood vessels is described in Chapter 13.

General features of vessel walls

All blood vessels, with the exception of capillaries and venules, have walls consisting of three concentric layers (tunicae) (see Fig. 6.8). The intima (tunica intima) is the innermost layer. Its main component, the endothelium, lines the entire vascular tree, including the heart and lymphatic vessels. The media (tunica media) contains muscle cells, elastic fibres and collagen. While it is by far the thickest layer in arteries, the media is absent in capillaries and is comparatively thin in veins. The adventitia (tunica adventitia) is the outer coat of the vessel and consists of connective tissue, nerves and vessel capillaries (vasa vasorum). It links the vessels to the surrounding tissues. Vessels differ in the relative thicknesses and detailed compositions of these layers.

Sustained stress (physical or oxidative), tissue damage, inflammatory mediators and other stimuli can promote enhanced growth, apoptosis (programmed cell death, p. 27) and switching to a more secretory phenotype (see above). Increased mediator release by the more secretory phenotype can potentiate such changes and attract inflammatory cells, resulting in a positive feedback loop. Chronic disease and inflammation can therefore lead to extensive smooth muscle remodelling, a major contributing factor to, for example, chronic asthma and pulmonary hypertension, which significantly worsens conditions (Stenmark et al 2006, Mahn et al 2010). Peripheral vascular remodelling may also occur in essential hypertension and diabetes.

Large elastic arteries

The aorta and its largest branches (brachiocephalic, common carotid, subclavian and common iliac arteries) are large elastic arteries that conduct blood to the medium-sized distributing arteries.

The intima is made of an endothelium, resting on a basal lamina, and a subendothelial connective tissue layer. The endothelial cells are flat, elongated and polygonal in outline, with their long axes parallel to the direction of blood flow (see Fig. 6.17). The subendothelial layer is well developed, contains elastic fibres and type I collagen fibrils, fibroblasts and small, smooth muscle-like myointimal cells. The latter accumulate lipid with age, and in an extreme form this contributes to atherosclerosis (see below). Thickening of the intima progresses with age and is more marked in the distal than in the proximal segment of the aorta.

A prominent internal elastic lamina, sometimes split, lies between intima and media. This lamina is smooth, measures about 1 μm in thickness, and, with the elastic lamellae of the media, is stretched under the effect of systolic pressure, recoiling elastically in diastole. Elastic arteries can thus sustain continuous blood flow despite the pulsatile cardiac output, and smooth out the cyclical pressure wave. The media has a markedly layered structure, in which fenestrated layers of elastin (elastic lamellae) alternate with interlamellar smooth muscle cells (**Fig. 6.6**), collagen and fine elastic fibres. The arrangement is very regular, such that each elastic lamella and adjacent interlamellar zone is regarded as a 'lamellar unit' of the media. In the human aorta there are approximately 52 lamellar units, measuring about 11 μm in thickness. Number and thickness of lamellar units increases during postnatal development, from 40 at birth.

The adventitia is well developed. In addition to collagen and elastic fibres, it contains flattened fibroblasts with extremely long, thin processes, macrophages and mast cells, nerve bundles and lymphatic vessels. The vasa vasorum is usually confined to the adventitia.

Muscular arteries

Muscular arteries are characterized by the predominance of smooth muscle in the media (**Fig. 6.7**). The intima consists of an endothelium, similar to that of elastic arteries, which rests on a basal lamina and subendothelial connective tissue. The internal elastic lamina (see Fig. 6.7; **Fig. 6.8**) is a distinct, thin layer, sometimes duplicated and occasionally absent. It is thrown into wavy folds as a result of contraction of smooth muscle in the media. Some 75% of the mass of the media consists of smooth muscle cells that run spirally or circumferentially around the vessel wall. The relative amount of extracellular matrix is therefore less than in large arteries, although fine elastic fibres that run mainly parallel to the muscle cells are present. An external elastic lamina, composed of sheets of elastic fibres, forms a less compact layer than the internal lamina, and separates the media from the adventitia in larger muscular arteries. The adventitia is made of fibroelastic connective tissue, and can be as thick as the media in the smaller arteries. The inner part of the adventitia contains more elastic than collagen fibres.

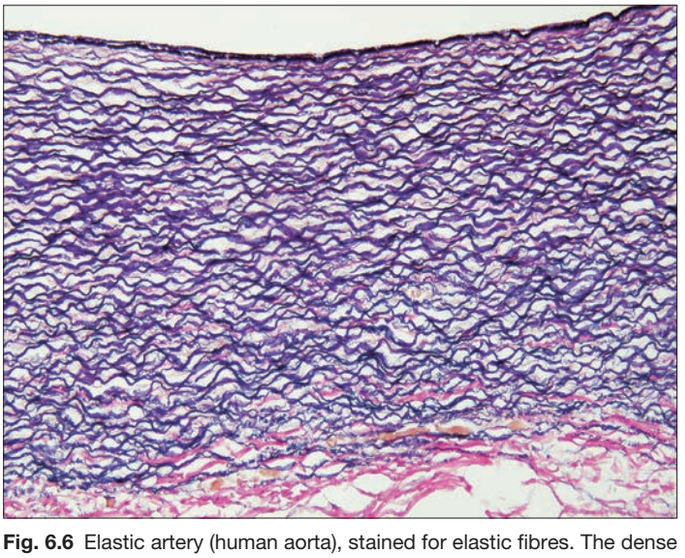

Fig. 6.6 Elastic artery (human aorta), stained for elastic fibres. The dense staining of the internal elastic lamina is seen close to the luminal surface (top); elastic lamellae fill the tunica media and merge with the external elastic lamina at its junction with the collagenous adventitia (red fibres, below). Compare with Fig. 6.20. van Gieson stain. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Arterioles

The endothelial cells in arterioles are smaller than in large arteries, but their nuclear region is thicker and often projects markedly into the lumen (**Figs 6.9–6.10**). The nuclei are elongated and orientated parallel to the vessel length, as is the long axis of the cell. The basal surface of the endothelium contacts a basal lamina, but an internal elastic lamina is either absent or highly fenestrated and traversed by cytoplasmic processes of muscle or endothelial cells. The muscle cells are larger in cytoplasmic volume than those in the walls of large arteries and form a layer one or two cells thick. They are arranged circumferentially and are tightly wound around the endothelium. In the smallest arterioles each cell makes several turns, producing extensive apposition between parts of the same cell. Contraction of the muscle constricts the lumen, and so controls blood flow into the capillary bed; arterioles thus act functionally as precapillary sphincters, even though the absence of an anatomically delineated sphincter means that the term is no longer commonly used. Contraction of arterioles is primarily regulated by local vasoactive and metabolic factors, but can also be controlled by central mechanisms.

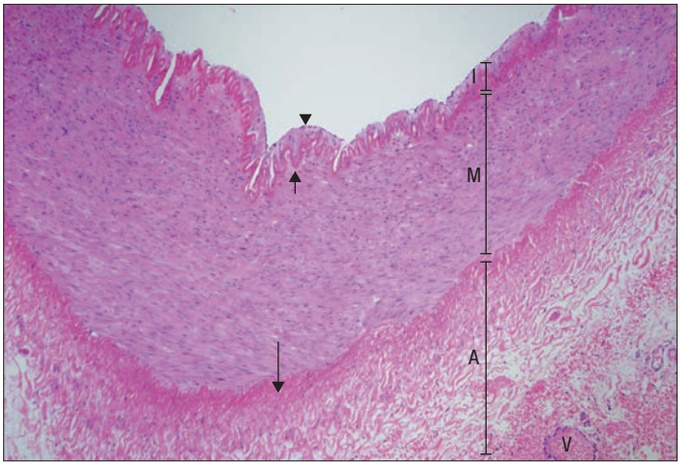

Fig. 6.7 The wall of a human muscular artery. The intima (I) forms the innermost layer, lined by an endothelium (arrowhead) and separated from the middle muscular layer, the media (M), by an internal elastic lamina (short arrow). A more diffuse external elastic lamina (long arrow) divides the media from the outermost collagenous adventitia (A), within which lie the vasa vasorum (V). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

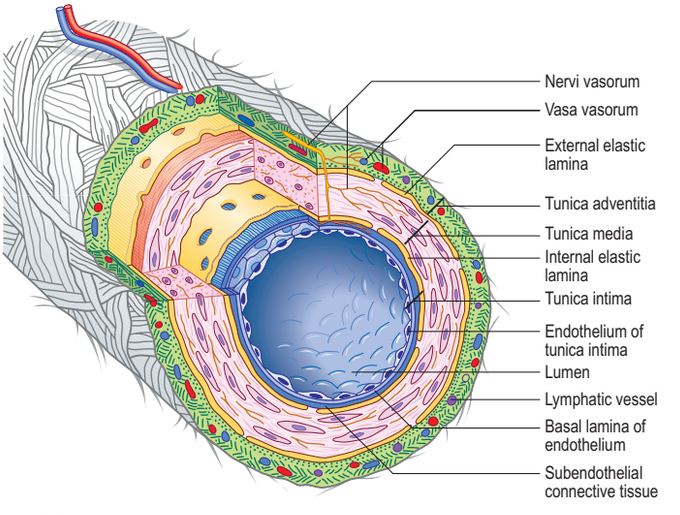

Fig. 6.8 The principal structural features of the larger blood vessels as seen in a muscular artery.

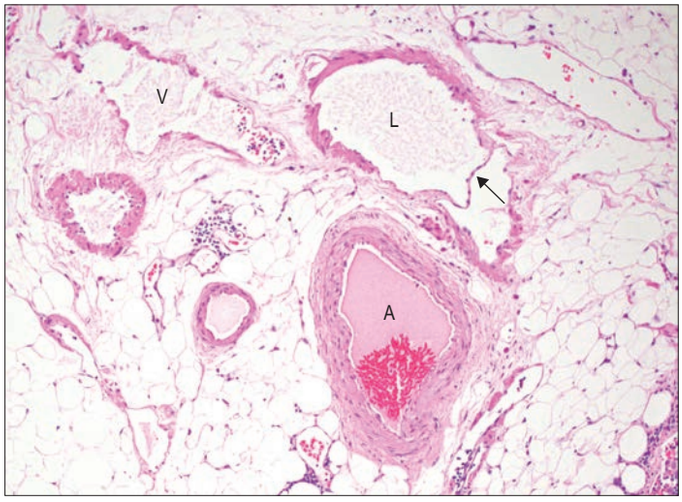

Fig. 6.9 An arteriole (A) and accompanying venule (V) and lymphatic vessel (L) (with a valve, arrow) in adipose tissue around a lymph node (human). Note the relative thicknesses of the vessel walls, in comparison with the diameters of their lumens. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

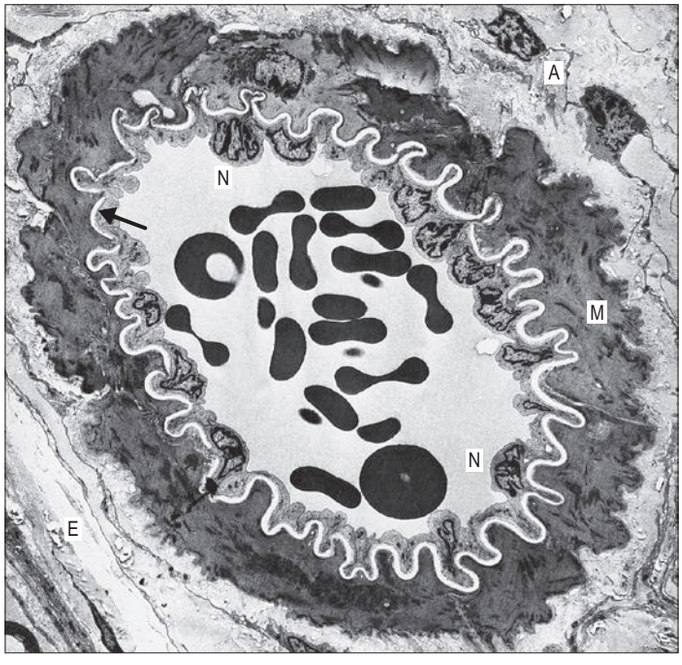

Fig. 6.10 A transmission electron micrograph of a small arteriole in the epineurium of a peripheral nerve. The vessel lumen contains erythrocytes and is lined by endothelial cells (with nuclei, N, projecting into the lumen); note the electron-lucent internal elastic lamina (pale, wavy line, arrow), the media containing densely filamentous smooth muscle cells (M) and the connective tissue of the adventitia (A) merging with that of the epineurium (E). (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

Arterioles are usually densely innervated by sympathetic fibres, via small bundles of varicose axons packed with transmitter vesicles, mostly of the adrenergic type. The distance between axolemma and muscle cell membrane can be as little as 50–100 nm and the gap is occupied only by a basal lamina. Autonomic neuromuscular junctions are very common in arterioles. Arteriolar adventitia is very thin.

Capillaries

The capillary wall (Fig. 6.11) is formed by an endothelium and its basal lamina, plus a few isolated pericytes. Capillaries are the vessels closest to the tissue they supply and their wall constitutes a minimal barrier between blood and the surrounding tissues. Capillary structure varies in different locations. Capillaries measure 4–8 µm in diameter (much more in the case of sinusoids) and are hundreds of microns long. Their lumen is just large enough to admit the passage of single blood cells, usually with considerable deformation. Typically a single endothelial cell forms the wall of a capillary, and there are junctional complexes between extensions of the same cell.

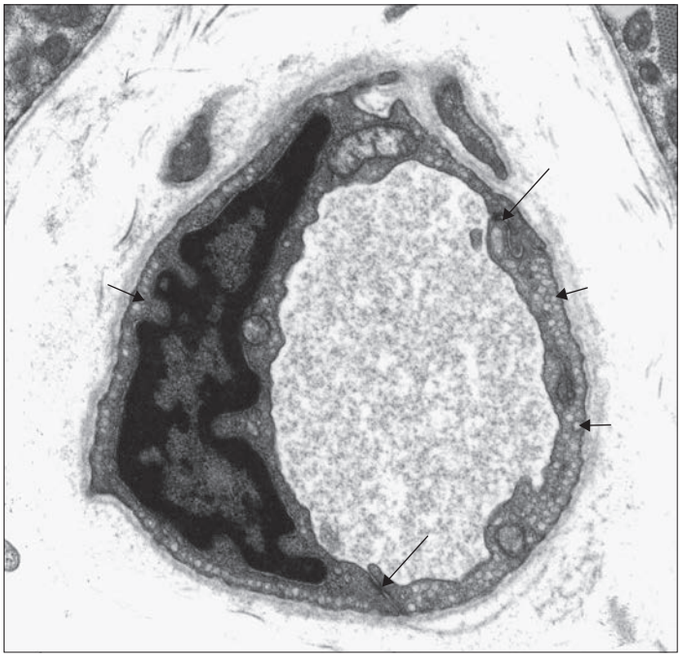

Fig. 6.11 Transmission electron micrograph of a capillary in a human muscle biopsy specimen. An endothelial cell with its nucleus in the plane of section forms adherens junctions (long arrows) with either a second cell or an extension of itself. The cytoplasm contains numerous transcytotic vesicles (short arrows). A basal lamina surrounds the capillary. (Courtesy of Dr Bart Wagner, Histopathology Department, Sheffield Teaching Hospitals, UK.)

Endothelial cells are joined by tight junctions (occluding junctions, zonulae occludentes), forming a diffusion barrier. Capillary permeability varies greatly among tissues and is correlated largely with the type of endothelium. The majority of tissues, including brain, muscle, lung and connective tissues, contain capillaries with a continuous, unbroken layer of endothelium (continuous endothelium). This is impermeable to proteins, although electrolytes can diffuse through the tight junctions, albeit relatively slowly. Their passage is further limited in brain, thymic cortex and testis by particularly tight junctions.

Endothelial cells of some capillaries have fenestrations (pores) through their cytoplasm that facilitate diffusion. Fenestrations are approximately circular and 50–100 nm in diameter, and at their edge the luminal and abluminal membranes of the endothelial cell come into contact. The fenestration itself is usually occupied by a thin, electron-dense diaphragm containing glycoprotein PV-1, which restricts passage of large molecules such as proteins. Fenestrated capillaries occur in intestinal mucosae, endocrine and exocrine glands, and renal glomeruli, where they may lack a diaphragm. Fenestrations are almost invariably present in capillaries that lie close to an epithelium, including the skin.

Sinusoids

Sinusoids are expanded capillaries (Fig. 6.12), and are large and irregular in shape. They have true discontinuities in their walls, allowing intimate contact between blood and the parenchyma. The discontinuities are formed by gaps between fenestrated endothelial cells, such that the sinusoidal lining, and sometimes also the basal lamina, is incomplete. Sinusoids occur in large numbers in the liver (where a basal lamina is completely absent), spleen, bone marrow, adenohypophysis (see Fig. 6.12) and suprarenal medulla.

Venules

When two or more capillaries converge, the resulting vessel is larger (10–30 µm) and is known as a venule (postcapillary venule). Venules (see Fig. 6.9) are essentially tubes of flat, oval or polygonal endothelial cells surrounded by basal lamina and, in the larger vessels, by a delicate adventitia of a few fibroblasts and collagen fibres mainly running longitudinally. Pericytes (see Fig. 6.21) support the walls of these venules.

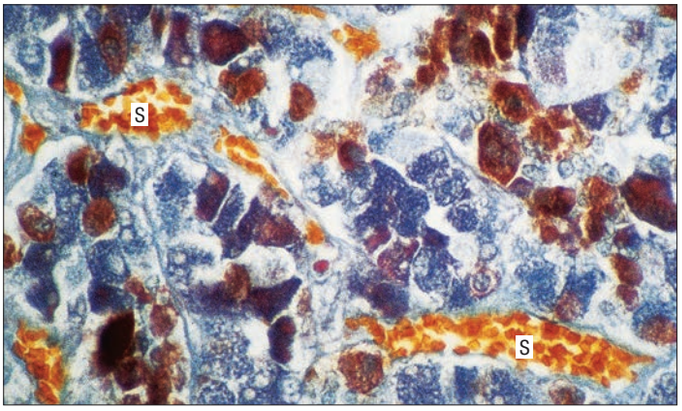

Fig. 6.12 Expanded sinusoids (S), typical of endocrine glands and certain other tissues, are seen here containing erythrocytes (orange) in the adenohypophysis. Endocrine cells stain either blue or reddish-brown, or are poorly stained in this trichrome preparation.

Postcapillary venules are sites of leukocyte migration. In venules of mucosa-associated lymphoid tissue (MALT), particularly of the gut and bronchi, and in the lymph nodes and thymus, endothelial cells are taller and have intercellular junctions through which lymphocytes and other blood components can readily pass. These are known as high endothelial venules (HEVs) (see Figs 6.18–6.19). Elsewhere, venules are believed to be a major site where migration of neutrophils, macrophages and other leukocytes into extravascular spaces occurs, and where neutrophils may temporarily attach, forming marginated pools.

In general, the endothelium of venules has few tight junctions and is relatively permeable. The intercellular junctions of venules are sensitive to inflammatory agents, which increase their permeability to fluids and defensive cells, and facilitate leukocyte extravasation by diapedesis.

Venules do not acquire musculature until they are about 50 μm in outer diameter, when they are known as muscular venules. This distinction is important because postcapillary venules, which lack muscle in their walls, are as permeable to solutes as capillaries and are thus part of the microcirculatory bed. The cross-sectional area of the vascular tree is at its maximum at the level of the postcapillary venule, and there is a dramatic fall in pressure (from 25 mmHg in the capillary to approximately 5 mmHg). Muscular venules converge to produce a series of veins of progressively larger diameter. Venules and veins are capacitance vessels because they have thin distensible walls that can hold a large volume of blood and accommodate luminal pressure changes.

Fluid exchange in the microvasculature

The microvasculature is important for the creation and maintenance of the interstitial fluid that bathes the cells. The thin walls of capillaries and small venules allow easy diffusion of fluid and most small molecules, but the endothelial barrier prevents movement of proteins; consequently, plasma and interstitial fluid have almost identical compositions, except that the latter contains very little protein. Fluid transfer across these exchange vessels is driven by the balance between the hydrostatic pressure (i.e. blood pressure within them) forcing fluid into the tissues, and the oncotic pressure (colloidal osmotic pressure, reflecting the difference in protein concentrations) drawing fluid back into the vessels. These 'Starling forces' are normally closely balanced, so differences in hydrostatic pressure mean that fluid tends to be filtered into the tissue at the arterial side of the exchange vessels and largely reabsorbed at the venous side. The balance forms lymph. Disruption of the balance (e.g. high venous pressure in the feet) can lead to accumulation of tissue fluid (oedema) and swelling.

Inflammation and endothelial permeability

Inflammatory mediators increase the permeability of capillaries and small venules by causing contraction of endothelial cells and so loosening tight junctions. This facilitates leukocyte extravasation by diapedesis but also disrupts normal barrier function, allowing extravasation of protein and fluids. The consequence is tissue oedema and the swelling that is commonly associated with inflammation. There is considerable cross-talk between endothelial cells and cells of the immune system.

Veins

Veins are characterized by relatively thin walls in comparison to arteries of similar size and by a large capacitance. Wall thickness is not correlated exactly with the size of the vein and varies in different regions, e.g. the wall is thicker in veins of the leg than it is in veins of a similar size in the arm.

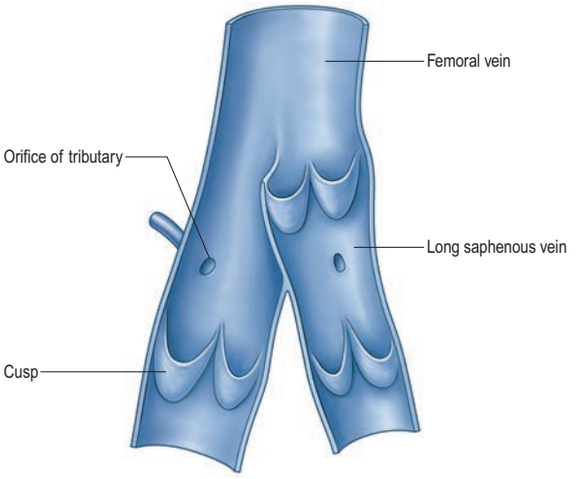

Fig. 6.13 The upper portions of the femoral and long saphenous veins laid open to show the valves, at about two-thirds of their natural size.

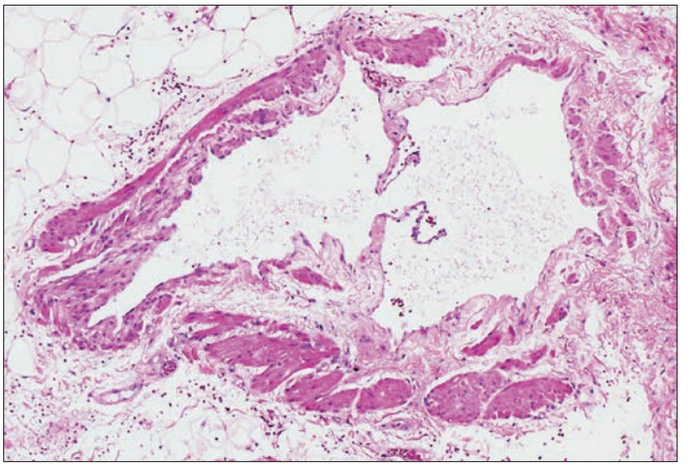

Fig. 6.14 A valve in a human small vein, formed from flap-like extensions of the intima that close when pressure increases on the proximal side, preventing backflow. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

The structural plan of the wall is similar to that of other vessels, except that the amount of muscle is considerably less than in arteries, while collagen and, in some veins, elastic fibres, predominate. In most veins, e.g. those of the limbs, the muscle is arranged approximately circularly. Longitudinal muscle is present in the iliac, brachiocephalic, portal and renal veins and in the superior and inferior venae cavae. Muscle is absent in the maternal placental veins, dural venous sinuses, pial and retinal veins, veins of trabecular bone and the venous spaces of erectile tissue: these veins consist of endothelium supported by variable amounts of connective tissue. Distinction between the media and adventitial layers is often difficult, and a discrete internal elastic lamina is absent.

Tethering of some veins to connective tissue fasciae and other surrounding tissues may prevent collapse of the vessel even under negative pressure (e.g. in the cranium). Pressure within the venous system does not normally exceed 5 mmHg, and it decreases as the veins grow larger and fewer in number, approaching zero close to the heart. As they contain only a small amount of muscle and commonly have a large calibre, veins have limited influence on blood flow. However, venoconstriction is an important component of the baroreceptor reflex because it reduces vein compliance and therefore capacity, effectively mobilizing blood to maintain or increase central venous pressure, and hence cardiac output. A sudden fall in blood volume, e.g. following a haemorrhage, also initiates the elastic recoil and reflex constriction of veins, in order to compensate for the blood loss and maintain central venous pressure and venous return to the heart. Vasoconstriction in cutaneous veins in response to cooling is important in thermoregulation.

Most veins have valves to prevent reflux of blood (Figs 6.13–6.14). A valve is formed by an inward projection of the intima, strengthened

by collagen and elastic fibres, and covered by endothelium that differs in orientation on its two surfaces. Surfaces facing the vessel wall have transversely arranged endothelial cells, whereas on the luminal surface of the valve, over which the main stream of blood flows, cells are arranged longitudinally in the direction of flow. Most commonly two, or occasionally three, valves lie opposite one another; sometimes only one is present. They are found in small veins or where tributaries join larger veins. The valves are semilunar (cusps) and attached by their convex edges to the venous wall. Their concave margins are directed with the flow and lie against the wall as long as flow is towards the heart. When blood flow reverses, the valves close and blood fills an expanded region of the wall, a sinus, on the cardiac side of the closed valve. This may give a 'knotted' (varicose) appearance to the distended veins, if these have many valves. In the limbs, especially the legs where venous return is against gravity, valves are of great importance in aiding venous flow. Blood is moved towards the heart by the intermittent pressure produced by contractions of the surrounding muscles (the muscle pump). Valves are absent in the veins of the thorax and abdomen.

Vascular shunts and anastomoses

Arteriovenous shunts and anastomoses

Communications between the arterial and venous systems are found in many regions of the body. In some parts of the microcirculation (e.g. in the mesenteries), the capillary circulation can be bypassed by wider thoroughfare channels formed by metarterioles (Fig. 6.15A). These have similarities to both capillaries and the smallest arterioles, and have a discontinuous layer of smooth muscle in their walls. Metarterioles can deliver blood directly to venules or to a capillary bed, according to local demand and conditions. When functional demand is low, blood flow is largely limited to the bypass channel. Periodic opening and closing of different arterioles irrigates different parts of the capillary network. The number of capillaries in individual microvascular units and the size of their mesh determine the degree of vascularity of a tissue; the smallest meshes occur in the lungs and the choroid of the eye.

Arteriovenous anastomoses (Fig. 6.15B) are direct connections between smaller arteries and veins. Connecting vessels may be straight or coiled, and often possess a thick muscular tunic. Under sympathetic control, the vessel is able to close completely, diverting blood into the capillary bed. When patent, the vessel carries blood from artery to vein, partially or completely excluding the capillary bed from the circulation. Simple arteriovenous anastomoses are widespread and occur notably in the skin of the nose, lips and ears, nasal and gastrointestinal mucosae, erectile tissue, tongue, thyroid gland and sympathetic ganglia. There are few arteriovenous anastomoses in the neonate, but they develop rapidly during the early years. In old age they atrophy, sclerose and diminish in number. These factors may contribute to the less efficient temperature regulation that occurs at the two extremes of age.

In the skin of the hands and feet, especially in digital pads and nail beds (see Fig. 7.27), anastomoses form a large number of small units termed glomera. Each glomus organ has one or more afferent arteries, stemming from branches of cutaneous arteries that approach the surface. The afferent artery gives off a number of fine periglomeral branches and then immediately enlarges, makes a sinuous curve, and narrows again into a short, funnel-shaped vein that opens at right-angles into a collecting vein (Fig. 6.16).

Arterial anastomoses

Arteries can be joined to each other by an anastomosis, so that one can supply the territory of the other. An end-to-end anastomosis occurs when two arteries communicate directly, e.g. the uterine and ovarian arteries, the right and left gastro-epiploic arteries, the ulnar artery and the superficial palmar branch of the radial artery. Anastomosis by convergence occurs when two arteries converge and merge, as happens when the vertebral arteries form the basilar artery at the base of the brain. A transverse anastomosis occurs when a short arterial vessel links two large arteries transversely, e.g. the anastomoses between the two anterior cerebral arteries; the posterior tibial artery and the fibular artery; and the radial and ulnar arteries at the wrist.

The angiosome concept and vascular territories

The blood supply to the skin and underlying tissues has been mapped using ink injection studies, corrosion casts, dissection, perforator

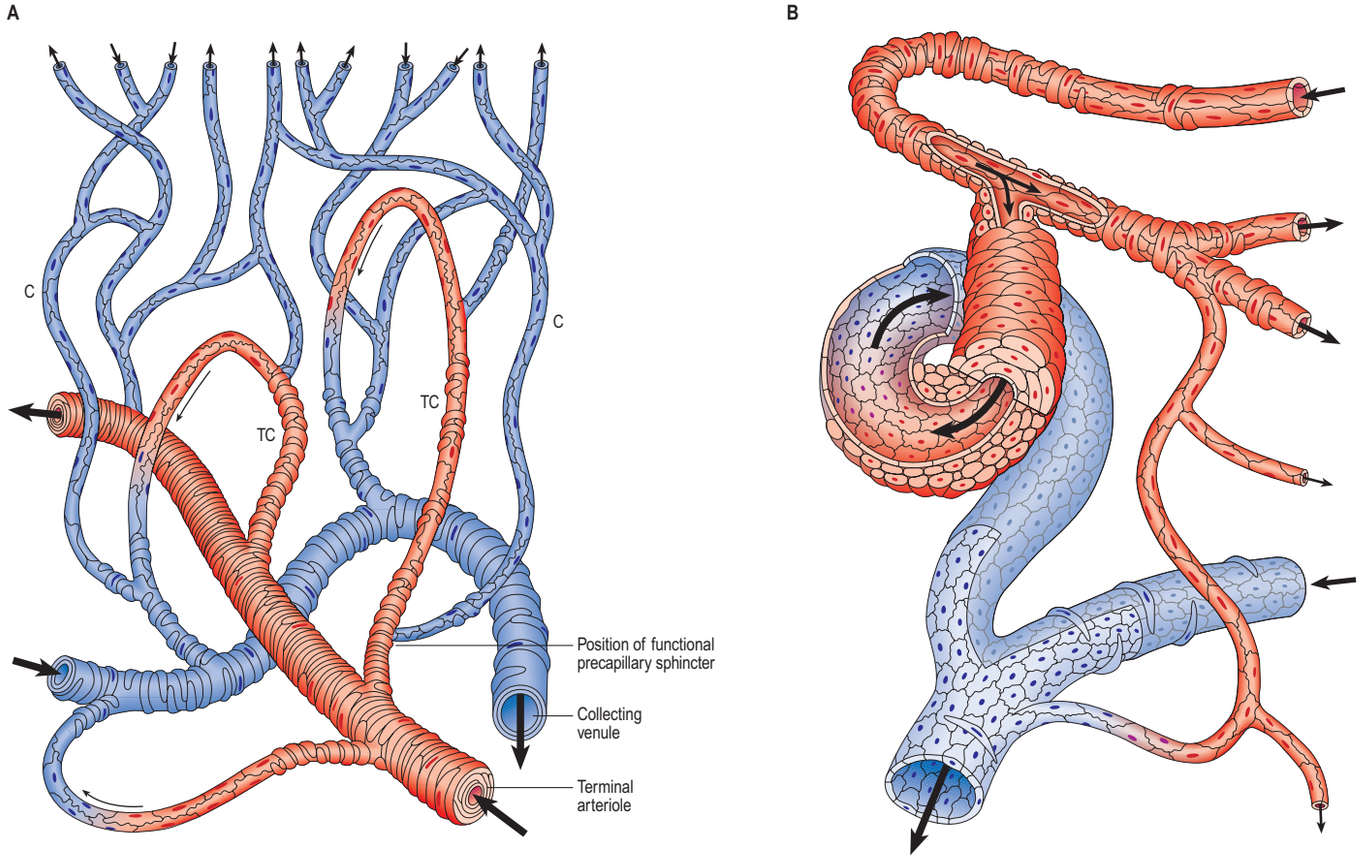

Fig. 6.15 A, A microcirculatory unit, showing a terminal arteriole, thoroughfare channels (TC) formed of metarterioles, capillaries (C) and collecting venule. The distribution of smooth muscle cells and one of the precapillary sites where perfusion of the capillary bed is regulated are also shown. **B**, An arteriovenous anastomosis. Note the thick wall of the anastomotic channel composed of layers of modified smooth muscle cells.

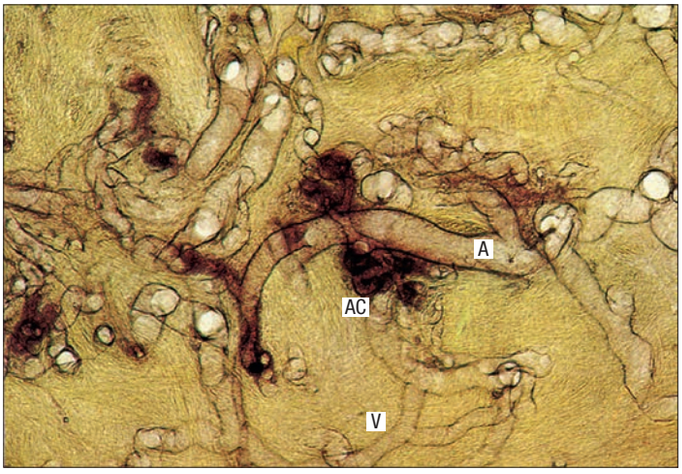

Fig. 6.16 A digital arteriovenous anastomosis, prepared by intravascular perfusion of stain in a full-thickness specimen of skin, followed by clearance. The heavily stained, thick-walled, tortuous anastomotic channels (AC) contrast with the central arterial stem (A) and the thin-walled venous (V) outflow channels. mapping and two- and three-dimensional radiographic analyses of fresh cadavers and isolated limbs injected with solutions containing lead oxide.

Findings from these different studies all support the clinically important concept of the angiosome, a three-dimensional block of tissue supplied by a source artery, its perforating branches and their accompanying veins (Taylor and Palmer 1987, Levy et al 2003, Taylor 2003, Pan and Taylor 2009). Angiosomes form a complex three-dimensional jigsaw puzzle; some pieces have a predominantly cutaneous component while others are predominantly muscular. Each consists of arteriosomes and venosomes linked to neighbouring angiosomes by either similar calibre (true) or reduced calibre (choke) anastomoses. Anastomoses between adjacent angiosomes may occur within the skin or within muscle. Some muscles are supplied by a single artery and its accompanying veins and therefore lie within one angiosome, while other muscles are supplied by more than one vessel and therefore cross more than one angiosome. A detailed knowledge of anatomical vascular territories and spatial angiosome architecture is essential in designing, evaluating and raising axial flaps based on vascular connections in plastic and reconstructive surgery.

Microstructure of blood vessels

Intima

The intimal lining of blood vessels consists of an endothelium, and a variable amount of subendothelial connective tissue, depending on the vessel.

Endothelium

Endothelium is a monolayer of flattened polygonal cells that extends continuously over the luminal surface of the entire vascular tree; its structure varies in different regions of the vascular bed (see Fig. 6.10; Fig. 6.17).

As a key component of the vessel wall, endothelium subserves several major physiological roles. Endothelial cells are in contact with the blood stream and thus influence blood flow. They regulate the diffusion of substances and migration of cells out of and into the circulating blood. In the brain, endothelial cells of small vessels actively transport substances, e.g. glucose, into the brain parenchyma. Endothelial cells play an important role in haemostasis because they produce von Willebrand factor, which promotes platelet adhesion (see below); secrete prostacyclin and thrombomodulin, which limits clot formation; and promote fibrinolysis by secreting tissue plasminogen activator. They have selective phagocytic activity and are able to extract substances from the blood. For example, the endothelium of pulmonary vessels removes and inactivates several polypeptides, biogenic amines, bradykinin, prostaglandins and lipids from the circulation, and converts the precursor of angiotensin II to its active form.

Endothelial cells secrete vasoconstrictor (thromboxane) and vasodilator (prostacyclin) prostaglandins, nitric oxide (NO) and endothelin (a vasoconstrictor). They respond to stretch (e.g. increased pressure) and the shear effect of blood flow via stretch-sensitive ion channels in the cell membrane. Endothelial cells synthesize components of the basal lamina. They proliferate to provide new cells during growth of blood vessels, to replace damaged endothelium, and to provide solid cords of cells that develop into new blood vessels (angiogenesis). Angiogenesis, which may be stimulated by local production of autocrine growth factors in response to tissue hypoxia, is important in wound healing and in the growth of tumours. Endothelial cells are also active participants in, and regulators of, inflammatory processes (Pober and Sessa 2007).

Although endothelial cells are thin, they extend over a relatively large surface area. They are thickest at the nucleus, where they can reach 2–3 μm, causing a slight bulge into the lumen (see Fig. 6.10). Elsewhere, they are thin and laminar, and are often as little as 0.2 μm thick in capillaries. They are generally elongated in the direction of blood flow, especially in arteries (see Fig. 6.17).

Except in sinusoids, endothelial cells usually adhere to each other at their edges, so there is no discontinuity in the lining of the lumen. They adhere to adjacent cells through the junctional complex, an area of apposition where adherent and tight junctions are found. They also communicate via gap junctions, which are most marked in continuous capillaries. Cell contacts and myoendothelial gap junctions between endothelial and smooth muscle cells are common in small resistance arteries and arterioles, where the separation between endothelium and media is reduced and the inner elastic lamina is either very thin or absent. Myoendothelial gap junctions play an important role in the integration and regulation of vascular function (Figueroa and Duling 2009).

Transcytotic (pinocytotic) vesicles (see Fig. 6.11) are present in all endothelial cells but are particularly numerous in exchange vessels; they include caveolae (see Fig. 6.4) typical of smooth muscle cells. They shuttle small amounts of interstitial fluid or plasma across the endothelial cytoplasm and thus facilitate bulk exchange of nutrients and metabolites between these compartments. They are normally the only means by which protein can cross the endothelium. Endothelial cells secrete many factors but they do not have the morphological characteristics of secretory cells.

The Wiebel–Palade body is characteristic of endothelial cells. It is an elongated cytoplasmic vesicle, 0.2 × 2–3 μm in length, which contains regularly spaced tubular structures parallel to its long axis. Wiebel–Palade bodies play a role in both inflammation and haemostasis because they store the adhesion molecule P-selectin (see below) and von Willebrand factor (vWF), which mediates platelet adhesion to the extracellular matrix after vascular injury.

Von Willebrand factor

Available with the *Gray's Anatomy* e-book.

Endothelial cell–leukocyte interactions

The luminal surface of endothelial cells does not normally support the adherence of leukocytes or platelets. However, many functions of human

Von Willebrand factor is a very large, multimeric glycoprotein consisting of at least 80 monomers of 250 kDa each, responsible for the characteristic appearance of Wiebel–Palade bodies. Its function is to bind to other proteins and provide a bridge between them.

On release from endothelial cells, vWF binds to collagen in the subendothelial matrix; when this is exposed following vascular damage, vWF facilitates platelet adhesion by binding to platelet glycoprotein receptors. This is particularly efficient in high-flow/shear-stress conditions, when it also causes platelet activation. Although the major source of vWF is probably endothelial cells, it is also produced by megakaryocytes and stored in platelet α-granules. vWF is present in plasma, where it binds and stabilizes factor VIII, a clotting protein secreted into the blood stream by hepatocytes. Hereditary deficiency or defective function of vWF causes defective haemostasis and a tendency to bleed (von Willebrand disease) (reviewed in Sadler (2005)).

vascular endothelial cells are dynamic rather than fixed. Activated endothelial cells and the characteristic endothelium of high endothelial venules (HEVs) of lymphoid tissues are sites of leukocyte attachment and diapedesis (see below).

HEVs (Fig. 6.18) are located within the T-cell domains, between and around lymphoid follicles in all secondary lymphoid organs and tissues except the spleen. They are specialized venules of 7–30 μm diameter, which possess a conspicuous cuboidal endothelial lining. The luminal aspect of HEVs shows a cobblestone appearance. The endothelial cells rest on a basal lamina and are supported by pericytes and a small amount of connective tissue (Fig. 6.19). They are linked by discontinuous adhesive junctions at their apical and basal aspects; the junctions are circumnavigated by migrating lymphocytes. Ultrastructurally, the endothelial cells have the characteristics of metabolically active secretory cells. Thus they contain large, rounded, euchromatic nuclei with one or two nucleoli, prominent Golgi complexes, many mitochondria, ribosomes and pinocytotic vesicles. Typically, they also possess Wiebel–Palade bodies (see above).

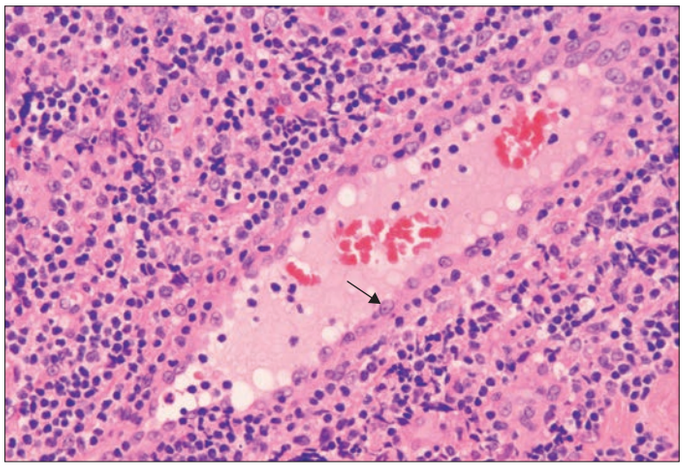

Fig. 6.18 A high endothelial venule in a human lymph node, sectioned longitudinally, lined by cuboidal endothelium (arrow). Erythrocytes and leukocytes (mainly lymphocytes and neutrophils) are seen in the lumen. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

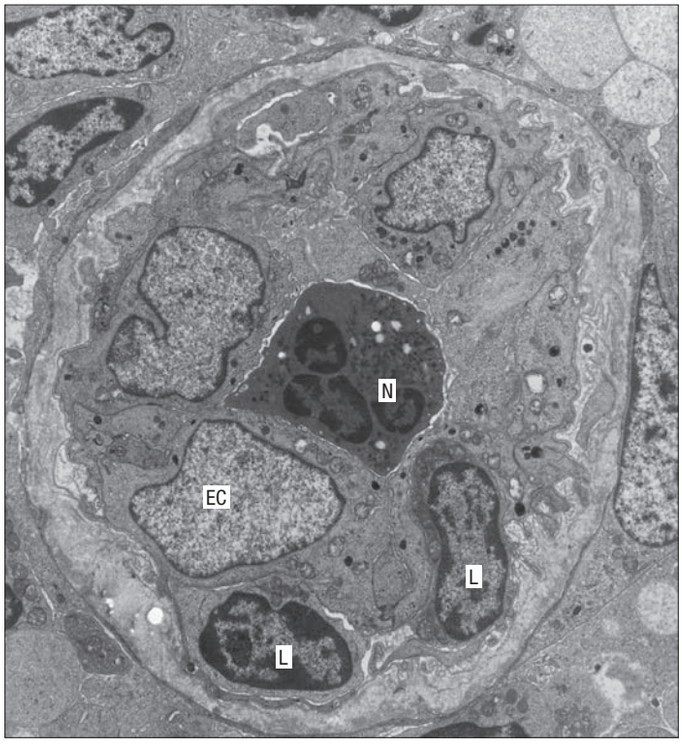

Fig. 6.19 A transmission electron micrograph of a high endothelial venule in transverse section in a human palatine tonsil. The lumen is completely filled by a neutrophil (N). Cuboidal endothelial cells (EC) line the vessel. Two lymphocytes (L) with heterochromatic nuclei are seen below, in transit within the wall of the vessel. (Courtesy of Dr Marta Perry, Department of Anatomy, St Thomas's Hospital Medical School, London.)

The adhesion molecules that mediate interactions between blood leukocytes and HEVs or cytokine-activated endothelium can be divided into three general families: selectins, integrins and the immunoglobulin supergene family. Selectins and integrins are expressed on leukocytes and mediate adhesion of circulating cells to the endothelium, which expresses selectins and members of the immunoglobulin supergene family. Regulated expression of these molecules by both cell types provides the means by which leukocytes recognize the vessel wall (leukocyte homing antigens and vascular addressins), adhere to it and subsequently leave the circulation.

The first step in this cascade is the loose binding or tethering of leukocytes, and this is initiated via L-, P- or E-selectin. This weak, reversible adhesion allows leukocytes to roll along the endothelial surface of a vessel lumen at low velocity, making and breaking contact, and sampling the endothelial cell surfaces. Recognition of chemokines (chemotactic signalling molecules) presented by the endothelium leads to 'inside-out' signalling and conversion of integrins at the leukocyte surface into actively adhesive configurations that bind strongly to their endothelial ligands, resulting in stable arrest. Finally, the leukocyte migrates through the vessel wall (diapedesis), passing either between (paracellular migration) or across (transcellular migration) endothelial cells. Transcellular migration is thought to be the preferred pathway; endothelial transcytotic vesicles (caveolae), intermediate filaments (vimentin) and F-actin are important in the creation of transient transcellular channels through which leukocytes pass. They then cross the basal lamina and migrate into the surrounding tissue by mechanisms that involve CD31 antigen and matrix metalloproteinases (reviewed in Vestweber (2007)).

Cell adhesion molecules

Available with the *Gray's Anatomy* e-book.

Subendothelial connective tissue

The subendothelial connective tissue, also termed the lamina propria, is a thin but variable layer. It is largely absent in the smallest vessels, where the endothelium is supported instead by pericytes (see Fig. 6.21). It contains a typical fibrocollagenous extracellular matrix, a few fibroblasts and occasional smooth muscle cells. Endothelial von Willebrand factor concentrates in this layer and participates in haemostasis and platelet adhesion when the overlying endothelium is damaged.

Media

The media consists chiefly of concentric layers of circumferentially or helically arranged smooth muscle cells with variable amounts of elastin and collagen.

Smooth muscle

Smooth muscle forms most of the media of arteries (see Fig. 6.7) and arterioles. A thinner layer of smooth muscle is also found in venules and veins; small segments of the pulmonary veins nearest to the heart contain striated cardiac muscle. Contraction of the smooth muscle in arteries and arterioles reduces the calibre of the vessel lumen, reducing blood flow through the vessel. This is particularly effective in small resistance vessels, where the wall is thick relative to the diameter of the vessel. Smooth muscle activation also increases the rigidity of the vessel wall, reducing its compliance. In arteries this affects propagation of the pulse, whereas in veins it effectively reduces their capacity.

The smooth muscle cells synthesize and secrete elastin, collagen and other extracellular components of the media, which bear directly on the mechanical properties of the vessels. The mechanics of the musculature of the media are complex. Distensibility, strength, self-support, elasticity, rigidity, concentric constriction, etc. are interrelated functions and are finely balanced in the different regions of the vascular bed.

In large arteries, where the blood pressure is high, the muscle cells are shorter (60–200 μm) and smaller in volume than in visceral muscle. In arterioles and veins, smooth muscle cells more closely resemble those from the viscera. The cells are packed with myofilaments and other elements of the cytoskeleton, including intermediate filaments. Vascular muscle cells contain intermediate filaments of either vimentin alone or both vimentin and desmin, whereas the intermediate filaments of visceral smooth muscle are exclusively of desmin. Intercellular junctions are mainly of the adhesive (adherens) type, coupling cells mechanically. Gap junctions couple cells electrically and allow passage of small signalling

There are three known members of the selectin family of adhesive proteins: L-selectin (also known as lymphocyte homing receptor), E-selectin and P-selectin. L-selectin is expressed on most leukocytes. Endothelial cells of HEVs in lymphoid organs express its oligosaccharide ligand, although other molecules such as mucins may be alternative ligands. L-selectin mediates homing of lymphocytes, especially to peripheral lymph nodes, but also promotes the accumulation of neutrophils and monocytes at sites of inflammation. E-selectin is an inducible adhesion molecule that mediates adhesion of leukocytes to inflammatory cytokine-activated endothelium, and is only transiently expressed on endothelium. P-selectin is rapidly mobilized from Wiebel–Palade bodies, where it is stored, to the endothelial surface after endothelial activation. It binds to ligands expressed on neutrophils, platelets and monocytes, and, like E-selectin, tethers leukocytes to endothelium at sites of inflammation. P-selectin is quickly endocytosed by the endothelial cells and so its expression is short-lived.

The integrins are a large family of molecules that mediate cell-to-cell adhesion as well as interactions of cells with extracellular matrix. Certain β_1 integrin heterodimers are expressed on lymphocytes 2–4 weeks after antigenic stimulation (very late antigens, VLAs) and bind to the extracellular matrix. Additionally, VLA-4, present on resting lymphocytes (expression increases after activation), monocytes and eosinophils, binds to the vascular cell adhesion molecule-1 (VCAM-1), the ligand on activated endothelium. In contrast to β_1 integrins, which many cells express, the expression of β_2 integrins is limited to white blood cells. Although the leukocyte integrins are not constitutively adhesive, they become highly adhesive after cell activation and therefore play a key role in the events required for cell migration. The endothelial ligands for one such β_2 integrin are the intercellular adhesion molecules-1 and 2 (ICAM-1 and ICAM-2), which belong to the immunoglobulin superfamily.

Three members of the large immunoglobulin superfamily of proteins are involved in leukocyte–endothelial adhesion, providing integrin counter-receptors on the endothelial cell membrane. ICAM-1 and ICAM-2 are constitutively expressed but upregulated by inflammatory cytokines. VCAM-1 is absent from resting endothelium but is induced by cytokines on activated endothelium and promotes extravasation of lymphocytes at sites of inflammation.

molecules. Junctions between muscle cells and the connective tissue matrix are particularly numerous, especially in arteries.

The muscle cells of the arterial media can be regarded as multifunctional mesenchymal cells. After damage to the endothelium, muscle cells migrate into the intima and proliferate, forming bundles of longitudinally orientated cells that reform the layer. In certain pathological conditions, muscle cells (and macrophages) undergo fatty degeneration and participate in the formation of atheromatous plaques.

Collagen and elastin

Components of the extracellular matrix (Ch. 2) are major constituents of vessel walls; in large arteries and veins they make up more than half of the mass of the wall, mainly in the form of collagen and elastin. Other fibrous components such as fibronectin, and amorphous proteoglycans and glycosaminoglycans, are present in the interstitial space.

Elastin is found in all arteries and veins and is especially abundant in elastic arteries (see Fig. 6.6). Individual elastic fibres (0.1–1.0 μm in diameter) anastomose with each other to form net-like structures, which extend predominantly in a circumferential direction. More extensive fusion produces lamellae of elastic material, which, though usually perforated and thus incomplete, separate the layers of muscle cells. The internal elastic lamina is a conspicuous elastic lamella in arteries, between intima and media, which allows the vessel to recoil after distension. When the intraluminal pressure falls below physiological limits (post mortem), it is compressed and coils up into a regular corrugated shape (**Fig. 6.20**; see Figs 6.7, 6.10), reducing but not obliterating the lumen; the profile of the artery remains circular. Fenestrations in the elastic lamina, which may also be split in thickness, allow materials to diffuse between intima and media. An outer elastic lamina, similar in appearance to, but markedly less well developed and less compact than, the internal elastic lamina, lies at the outer aspect of the media at its boundary with the adventitia (see Fig. 6.7). These laminae are less evident in elastic arteries, where elastic fibres occupy much of the media (see Fig. 6.6).

Collagen fibrils are found in all three layers of the vessel wall. Type III collagen (reticulin) occupies much of the interstitial space between the muscle cells of the media and is also found in the intima. Collagen is abundant in the adventitia, where type I collagen fibres form large bundles that increase in size from the junction with the media to the outer limit of the vessel wall. In veins, collagen is the main component of the vessel wall and accounts for more than half its mass.

In general, collagen and elastic fibres in the media run parallel to, or at a small angle to, the axes of the muscle cells, and they are therefore arranged mainly circumferentially. In contrast, the predominant arrangement of collagen fibres in the adventitia is longitudinal. This arrangement imposes constraints on length change in large vessels under pressure, e.g. in large arteries, in which the radial distension under the effect of the pulse far exceeds the longitudinal distension. The outer sheath of type I collagen in the adventitia therefore has a structurally supportive role. The more delicate type III collagen network of the media provides attachment to the muscle cells and its role is to transmit force around the circumference of the vessel. In a distended vessel, the elastic fibres store energy and, by recoiling, help to restore the resting length and calibre.

The extracellular material of the media, including collagen and elastin, is produced by the muscle cells. Its turnover is slow compared to that in other tissues. In the adventitia, collagen is synthesized and secreted by fibroblasts, as it is in other connective tissues. During postnatal development, while vessels are increasing in diameter and wall thickness, there is a concomitant increase in elastin and collagen content. Subsequent changes in vessel structure, seen during ageing, include an increase in the ratio of collagen to elastin, with a reduction in vessel elasticity.

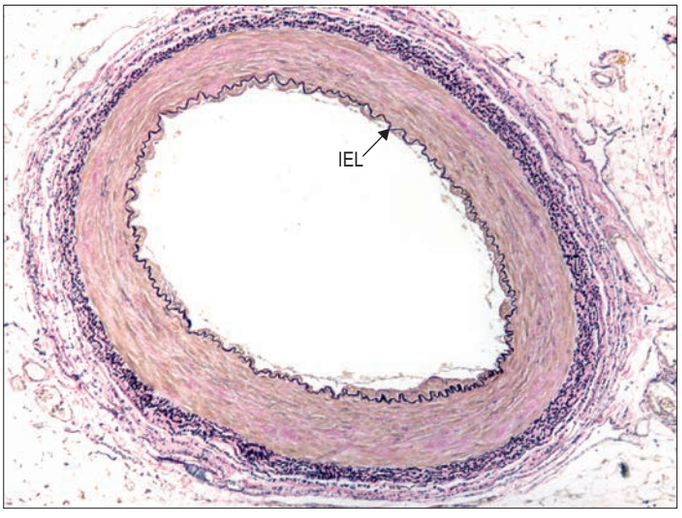

Fig. 6.20 The wall of a human muscular artery, stained for elastin (black), showing the internal elastic lamina (IEL). Fine, incomplete elastic lamellae are interspersed between smooth muscle cells of the tunica media. The endothelium is partly detached in this postmortem specimen. van Gieson stain.

Adventitia

The adventitia is formed of general connective tissue: the thickness and density of its collagen fibre bundles vary.

Vasa vasorum

In smaller vessels, the nourishment of the tissues of the vessel wall is provided by diffusion from the blood circulating in the vessel itself. The wall thickness at which simple diffusion from the lumen becomes insufficient is 1 mm; larger vessels have their own vascular supply within the adventitia, in the form of a network of small vessels, the vasa vasorum (see Fig. 6.8). These originate from, and drain into, peripheral branches of the vessel they supply. They ramify within the adventitia and, in the largest of arteries, penetrate the outermost part of the media. The vasa vasorum of the pulmonary arteries arise from adjacent systemic arteries. The larger veins are also supplied by vasa vasorum but these may penetrate the wall more deeply, perhaps because of the lower oxygen tension.

Nervi vasorum

Blood vessels are innervated by efferent autonomic fibres that regulate the state of contraction of the musculature (muscular tone) and thus the diameter of the vessels and the resistance of arteries and arterioles. Perivascular nerves branch and anastomose within the adventitia of an artery, forming a meshwork around it. Nerves are occasionally found within the outermost layers of the media in some of the large muscular arteries.

Nervi vasorum are small bundles of axons which are almost invariably unmyelinated and typically varicose. Most are postganglionic axons derived from neurones in sympathetic ganglia. The density of innervation varies in different vessels and in different areas of the body; it is usually sparser in veins and larger lymphatic vessels, whereas large veins with a pronounced muscle layer, such as the hepatic portal vein, are well innervated. Some vessels in the brain may be innervated by intrinsic cerebral neurones, although neural control of brain vessels is of minor importance compared with metabolic and autoregulation (local response to stretch stimuli).

The control of vascular smooth muscle is complex. Vasoconstrictor adrenergic fibres release noradrenaline (norepinephrine), which acts on α-adrenergic receptors in the muscle cell membrane. In addition, circulating hormones and factors such as nitric oxide, prostaglandins and endothelin, which are released from endothelial cells, exert a powerful effect on the muscle cells. Neurotransmitters reach the muscle from the adventitial surface of the media, whereas hormonal and endothelial factors diffuse from the intimal surface. In a few tissues, sympathetic cholinergic fibres inhibit smooth muscle contraction and induce vasodilation. Vascular smooth muscle exhibits endogenous (myogenic) activity in response to stretch and shear.

Most arteries are accompanied by nerves that travel in parallel with them to the peripheral organs that they supply: these paravascular nerves do not innervate the vessels they accompany.

Pericytes

Pericytes are present at the outer surface of capillaries and the smallest venules (postcapillary venules), where an adventitia is absent and there are no muscle cells. They are elongated cells, with long cytoplasmic processes that wrap around the endothelium. They are usually absent from fenestrated capillaries, scattered in a discontinuous layer around the outer circumference of capillaries and form a more continuous layer around postcapillary venules (**Fig. 6.21**). They are gradually replaced by smooth muscle cells as vessels converge and increase in diameter.

Pericytes are enclosed by their own basal lamina, which merges in places with that of the endothelium. Most display areas of close apposition with endothelial cells, and occasionally form adherens junctions where their basal laminae are absent. Pericyte cytoplasm contains actin, myosin, tropomyosin and desmin, which suggests that they are capable of contractile activity. They also have the potential to act as connective

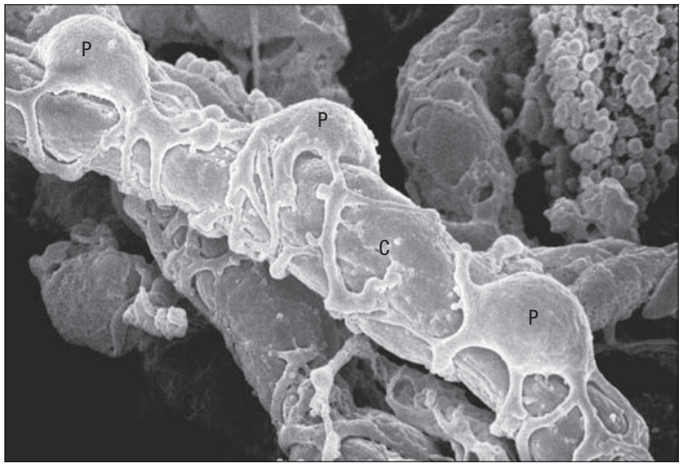

Fig. 6.21 A scanning electron micrograph of a capillary (C) and pericytes (P) supporting the vessel wall. (Courtesy of T. Fujiwara and Y. Uehara, Department of Anatomy, Ehime University School of Medicine, Japan.)

tissue progenitor cells, and participate in repair processes by proliferating and giving rise to new blood vessel and connective tissue cells.

Pericytes, or closely related cells, may be one source of myofibroblasts that contribute to fibrosis in disease processes (reviewed in Duffield (2012); see also Chapter 2). The role of pericytes is becoming recognized in other disease states with a component of vascular pathology, e.g. diabetes, where complications include retinopathy, nephropathy and neuropathy. Pericytes respond to aberrant local cues, including high glucose levels, such that their role in supporting the microvasculature is compromised: leaky vessels and the ensuing inflammation contribute to tissue damage and impaired function. There is evidence that pericytes may influence the tumour microenvironment in cancer, with detrimental consequences (reviewed in Ferland-McCollough et al (2017)).

Regional adaptations

Cerebral vasculature

Cerebral function is critically dependent on an adequate blood supply and tight regulation of the composition of cerebrospinal fluid. All cerebral vessels except capillaries have a thin outer coating of meningeal cells, usually one layer thick, with adjacent meningeal cells joined by desmosomes and gap junctions. Cerebral capillaries, the site of the blood–brain barrier, are lined by endothelial cells joined by particularly tight junctions. The endothelial cytoplasm contains a few pinocytotic vesicles. The cells are surrounded by a basal lamina (see Fig. 3.14); at points of contact with perivascular astrocytes, the intervening basal lamina is formed by fusion of the endothelial and glial basal laminae. Pericytes, completely surrounded by basal lamina, are present around capillaries (see Fig. 3.14); recent evidence suggests that relaxation of pericytes and thus dilation of capillaries is the major determinant of increased blood flow in response to increased neuronal activity (Hall et al 2014). Perivascular macrophages are attached to the outer walls of capillaries and to other vessels; they are phenotypically distinct from parenchymal microglia, which are also of monocytic origin. For further descriptions of the cerebral vasculature, see Chapter 26.

Pulmonary vasculature

The pulmonary circulation is a low pressure/high flow system. It receives the whole cardiac output, and thus must accommodate a wide range of blood flows (e.g. as occur in rest and exercise). Unlike arterioles in the systemic circulation, pulmonary arterioles smaller than 50–100 μm in diameter have little or no smooth muscle, and pulmonary vascular blood flow is largely independent of neural, local metabolic and myogenic mechanisms. Hypoxia produces hypoxic pulmonary vasoconstriction (HPV), when small pulmonary arteries constrict rather than dilate (as occurs in the systemic vasculature). This mechanism diverts blood away from poorly ventilated areas of the lung, and so optimizes ventilation/perfusion matching (Sylvester et al 2012). However, in hypoxic lung disease or at altitude, this can lead to pulmonary hypertension; if sustained, this can lead to extensive vascular remodelling, and eventually to right heart failure. Other causes of pulmonary hypertension include left heart failure, thromboembolism, and more rarely, dysfunction of the pulmonary vasculature itself. For further descriptions of the pulmonary vasculature, see Chapter 54.

Renal vasculature

Regulation of body water and solutes by the kidney depends on ultrafiltration of plasma in the glomeruli. The renal vasculature exhibits a high degree of autoregulation. Afferent arterioles leading to the glomerular capillaries in Bowman's capsule have a fenestrated endothelium (and thus a high permeability) and a specialized basement membrane, and are covered by podocytes (modified epithelial cells). The basement membrane and podocyte processes form the ultrafiltration membrane (see Figs 72.15, 72.18). The capillaries are surrounded by phagocytic mesangial cells. Glomerular capillary pressure is higher than elsewhere, and is regulated via differential constriction of the afferent and efferent arterioles. The efferent arterioles lead to peritubular capillaries which surround the cortical nephron, and to the vasa recta which descend deep into the medulla. The vasa recta help to maintain the medullary osmotic gradient essential for concentration of urine. Decreased pressure and/or stimulation by the sympathetic nerves innervating the afferent arterioles causes release of renin from granular cells in the endothelium: renin then activates the precursor of angiotensin 2, an important hormone for regulation of blood pressure and volume. Renal artery obstruction, e.g. in atherosclerosis, can cause hypertension; essential hypertension may also originate in renal dysfunction, and renal sympathetic nerve ablation has been promoted as a treatment for resistant hypertension (Papademetriou et al 2014). For further descriptions of the renal vasculature, see Chapter 72.

Cutaneous vasculature

Thermoregulation is a primary function of the skin. Heat transfer from blood to the surface is facilitated by vascular plexuses, and in the extremities (hands, feet, ears, lips, nose) arteriovenous anastomoses (see above and Chapter 7). Skin blood flow and thus heat loss are primarily controlled centrally by the hypothalamus (Ch. 30) and sympathetic nervous system, but are also affected by local mechanisms. In moderate conditions (the thermoneutral zone), changes in skin blood flow alone are sufficient to maintain body core temperature.

Raynaud's phenomenon

Raynaud's phenomenon (or syndrome) is an exaggerated and episodic vasoconstrictor response to cold or stress in the skin of the extremities, especially the fingers.

Diseases of the vasculature

Available with the *Gray's Anatomy* e-book.

Lymphatic vessels

Lymphatic capillaries form wide-meshed plexuses in the extracellular matrices of most tissues. They begin as dilated, blind-ended tubes with larger diameters and less regular cross-sectional appearances than those of blood capillaries. Their basal laminae are incomplete or absent and they lack associated pericytes. The smaller lymphatic vessels are lined by endothelial cells, which have numerous transcytotic vesicles within their cytoplasm and so resemble blood capillaries. However, unlike capillaries, their endothelium is generally quite permeable to much larger molecules: they are readily permeable to large colloidal proteins and particulate material such as cell debris and microorganisms, and also to cells. Permeability is facilitated by gaps between the endothelial cells, which lack tight junctions (discontinuous endothelium), and by pinocytosis. The lymphatic system provides an important transport pathway for leukocytes and defence against infection (reviewed in Saharinen et al (2004)).

Lymph is formed from interstitial fluid, which is derived from blood plasma via filtration in the microcirculation. Much of the filtered fluid is reabsorbed by the time the blood leaves the venules, but about 15% or 8 litres per day enters the lymphatics. Lymphatic vessels take up this residual fluid by passive diffusion and the transient negative pressures in their lumina, that are generated intrinsically by contractile activity of smooth muscle in the largest lymphatic vessel walls, and extrinsically by compression of the lymph vessels as a result of contraction of adjacent muscle or arterial pulsation. The unidirectional flow of lymph is maintained by the presence of valves in the larger vessels (Fig. 6.27). Lymphatic capillaries are prevented from collapsing by anchoring filaments, which tether their walls to surrounding connective tissue structures and exert radial traction.

In most tissues, lymph is clear and colourless; in the lymphatic capillaries it has an identical composition to interstitial fluid. In contrast, lymph from the small intestine is dense and milky, reflecting the presence

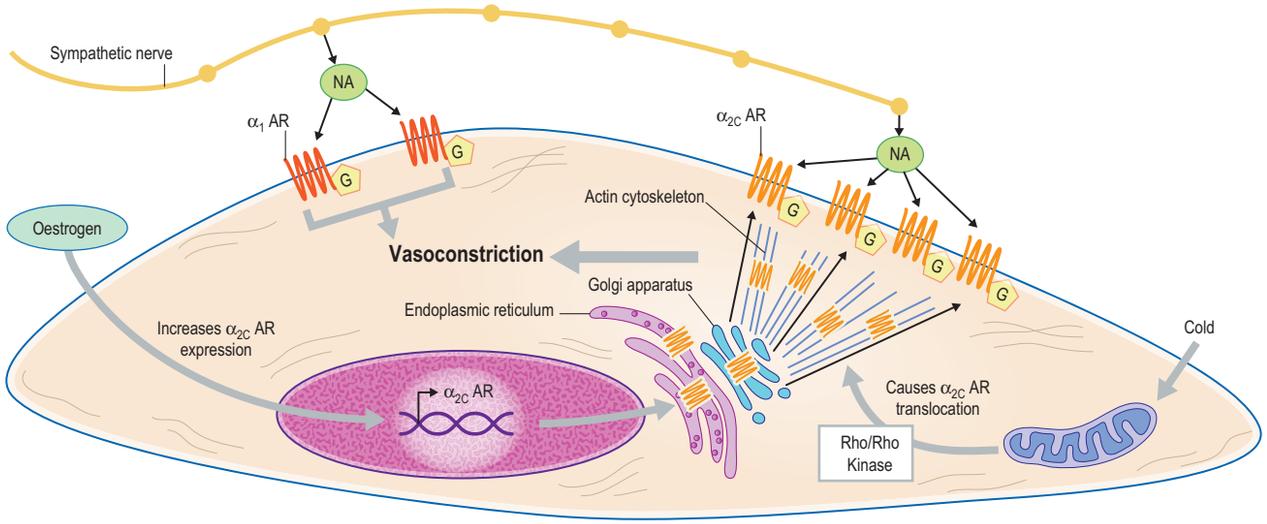

Fig. 6.22 Mechanisms underlying the response of cutaneous vascular smooth muscle to cold. Central control is mediated by release of noradrenaline (NA) from sympathetic nerves, which activates G-protein coupled α_1- and α_{2c}-adrenergic receptors (AR) to initiate vasoconstriction. Local cooling, sensed by mitochondria, causes translocation of α_{2c} AR from the Golgi and endoplasmic reticulum (ER) to the membrane via a Rho/Rho kinase and actin cytoskeleton-mediated mechanism, augmenting vasoconstriction. The female hormone oestrogen increases expression of α_{2c} AR, so enhancing the response. Raynaud's phenomenon may involve dysregulation of these processes (see Fardoun et al 2016).

Under such conditions adrenergic sympathetic activity maintains a level of tonic vasoconstriction via release of noradrenaline, which activates α_1- and α_2-adrenergic receptors on vascular smooth muscle cells. Arteriovenous anastomoses are particularly sensitive to noradrenaline and are normally strongly vasoconstricted. A fall in temperature increases sympathetic activity and thus cutaneous vasoconstriction. This is augmented locally by cold-induced and cytoskeleton-facilitated translocation of endoplasmic reticulum/Golgi associated α_{2C}-adrenergic receptors to the vascular smooth muscle cell membrane, effectively increasing sensitivity to noradrenaline (**Fig. 6.22**) (Fardoun et al 2016). The combined effects can reduce cutaneous blood flow by 90% in cold conditions. Conversely, an increase in temperature reduces sympathetic activity resulting in vasodilation and opening of arteriovenous anastomoses, greatly increasing blood flow and heat loss. Further increases occur at higher temperatures as sympathetic cholinergic neurones activate sweat glands (Ch. 7) which secrete bradykinin (a powerful vasodilator), and also release vasodilator co-transmitters (nitric oxide, substance P). Skin blood flow can increase 30-fold in very hot conditions.

Raynaud's phenomenon is characterized by a classic, often clearly demarcated, triphasic colour change of intense pallor (white, ischaemia), cyanosis (deoxygenation), and red (reperfusion), with associated pain and occasionally ulceration. Prevalence is 5–10% of the general population, but varies geographically: the condition is more common in premenopausal women than in men. Most cases are idiopathic (primary Raynaud's phenomenon), but about 15% are secondary to a clinical condition, especially connective tissue disorders such as scleroderma and systemic lupus erythematosus, or are induced by drugs (e.g. chemotherapy, β-adrenergic receptor antagonists), environmental/occupational exposure (e.g. smoking, vinyl chloride, arsenic), or sustained mechanical vibration of the fingers (Fardoun et al 2016, Khouri et al 2016).

The causes of Raynaud's phenomenon may be multiple, but are clearly associated with abnormalities of the cutaneous microcirculation (or possibly peripheral sympathetic nerves). There is some evidence for genetic predisposition in primary Raynaud's phenomenon. Recent studies have focused on mechanisms underlying the translocation of α_{2C}-adrenergic receptors to the vascular smooth muscle cell membrane. Interestingly, the female hormone oestrogen has been shown to potentiate expression, translocation and activity of α_{2C}-adrenergic receptors in vascular smooth muscle of the skin, suggesting a reason for the increased prevalence of Raynaud's phenomenon in premenopausal women (Fardoun et al 2016).

For a review of vascular disease and the role of extracellular matrix proteins in the vascular wall in a number of disease states, see Xu and Shi (2014).

Atherosclerosis and arteriosclerosis

Atherosclerosis is by far the most important arterial disease. It is the principal cause of death and disability in many Western countries, primarily due to ischaemic heart disease and stroke. Atherosclerosis arises and progresses as an inflammatory response of the vessel wall to chronic multifactorial injury due to hyperlipidaemia, hypertension, smoking or diabetes mellitus. It is a focal intimal disease of medium-to-large arteries, including the aorta, and carotid, coronary, iliofemoral, and cerebral arteries. Some medium-sized arteries, e.g. internal thoracic artery, are spared, as are pulmonary arteries and veins.

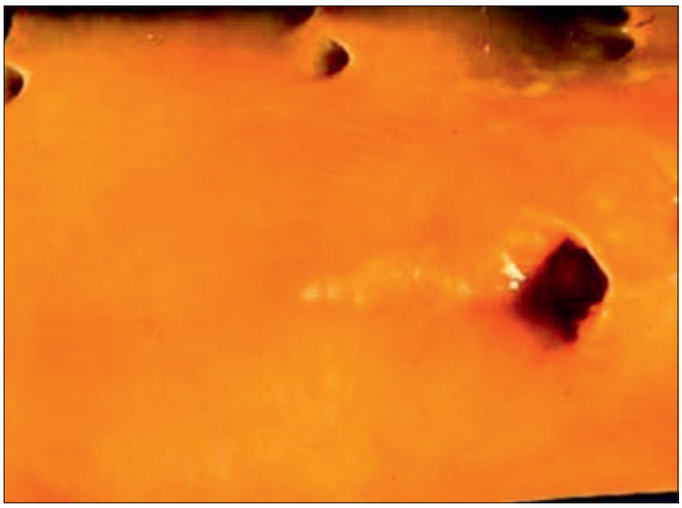

Fig. 6.23 A fatty streak (yellow) on the intimal surface of the aorta close to an arterial branch. (Courtesy of Professor Mary Sheppard, CRY Centre for Cardiac Pathology, St George's University of London, UK.)

Low-density lipoprotein (LDL) from the plasma moves freely in and out of the intima. Within the intima a small proportion of the LDL undergoes oxidative change. The oxidized LDL acts as an inflammatory stimulus, which invokes adhesion molecule expression by endothelial cells, monocyte migration, and cytokine production. Once oxidized, the LDL is taken up by macrophage scavenger receptors, and lipid uptake continues until the cytoplasm is packed with lipid to form macrophage-derived foam cells. This influx of lipid into macrophages results in infiltration of the vessel wall by T lymphocytes, with smooth muscle proliferation, and deposition of collagen and elastin in the intima, extending into the media. The earliest visible lesion is the fatty streak which consists of raised intimal areas full of lipid-filled foam cells (macrophages) and features of inflammation (**Fig. 6.23**). As these intimal lesions develop, they acquire combinations of extracellular lipid, intracellular lipid within foam cells, and collagen and other connective tissue matrix components produced by smooth muscle cells. The resulting larger intimal lesions are termed atherosclerotic plaques (**Fig. 6.24**), with a collagen cap, a core of variable lipid with calcium deposits, and

vascularization from the vasa vasorum. These plaques can increase in size and narrow the lumen of blood vessels leading to ischaemia. Progression of disease leads to further luminal narrowing and changes in the plaques, including surface ulceration, intraplaque haemorrhage, rupture and thrombosis.

Involvement of the coronary arteries results in major clinical complications, namely myocardial infarction, i.e. sudden cardiac death. Involvement of the cerebral circulation results in transient ischaemic attacks or cerebral infarcts (stroke). Atherosclerosis in the aorta results in aneurysm, rupture (particularly in the abdominal aorta), and narrowing of the iliofemoral vessels, which leads to gangrene of the lower extremities.

Arteriosclerosis means hardening of an artery. It differs from atherosclerosis as there is no intimal lipid deposition with resultant inflammation; it can affect both arteries and arterioles. Arteriosclerosis is due to gradual replacement of smooth muscle cells by collagen and deposition of plasma proteins in the smooth muscle to produce hyaline change. This process is accelerated by age, hypertension and diabetes mellitus. Arteriosclerosis lowers the compliance of the arterial tree and contributes to the age-related increase in systolic blood pressure. The lack of vascular compliance greatly increases susceptibility to hypotension which accounts for the increased mortality of shock in elderly and hypertensive patients. The term 'intimal hyperplasia' is used to describe the intimal thickening associated with arteriosclerosis, in which smooth muscle cells, collagen and elastic fibres infiltrate the intima (Fig. 6.25). This is also a feature of ageing and hypertension.

Fig. 6.24 A raised fibrofatty atheromatous plaque on the intimal surface of the aorta. (Courtesy of Professor Mary Sheppard, CRY Centre for Cardiac Pathology, St George's University of London, UK.)

Venous disease

Venous thrombosis is common and due to slow blood flow, especially in the veins of the legs. It is often due to obesity combined with immobility and is common after surgical operations or long haul flights. Leg or pelvic vein thrombosis is the principal cause of pulmonary thromboembolism. Thrombosis starts at the valves of the deep calf veins, causing deep vein thrombosis. It may propagate into the posterior tibial, popliteal, femoral, or iliac veins and into the inferior vena cava. The outcomes of venous thrombosis include: massive pulmonary embolism and sudden death; asymptomatic pulmonary embolism; pulmonary infarction; pulmonary hypertension. Sudden death is seen with total occlusion of the right side of the heart, and/or one or both left and right pulmonary arteries (Fig. 6.26). Occlusion of smaller vessels is survivable with or without pulmonary infarction. Occlusion of more than half the pulmonary arterial tree results in pulmonary hypertension and right ventricular failure. Occlusion of many vessels by showers of small emboli over months or years results in chronic pulmonary hypertension (see above).

Thrombophlebitis refers to thrombosis of veins with associated inflammation. Migrating thrombophlebitis is thrombosis and inflammation of superficial veins in association with cancer, particularly of the pancreas and gastrointestinal tract. Infected thrombi may cause pyaemia or embolism to form distant abscesses, e.g. an appendix abscess may give rise to liver abscess formation.

Varicosities (varicose veins) are caused by venous hypertension, which leads to dilated tortuous veins with failure of the venous valves, usually in the lower limbs. Standing, obesity, old age, cardiac failure and pregnancy predispose to varicose leg veins, which are very common. Although thrombosis occurs in varicose veins, the thrombi do not usually lead to embolization because they adhere to the vein wall. Varicose veins may lead to bleeding and infection, but the usual complication is poor wound healing with venous ulceration, a cause of widespread morbidity in elderly people. Oesophageal varices complicate portal hypertension in cirrhosis of the liver (usually alcohol-related): bleeding from ruptured oesophageal varices is often the terminal event in such patients. Haemorrhoids (piles) are caused by venous hypertension in the pelvic and abdominal veins as a result of constipation, obesity and pregnancy. A varicocele is a mass formed by varicosity of the pampiniform venous plexus in the testicle.

of lipid droplets (chylomicrons) derived from fat absorbed by the mucosal epithelium. The terminal lymphatic vessels in the mucosa of the small intestine are known as lacteals and the lymph as chyle. Lymphatic capillaries are not ubiquitous: they are not present in cornea, cartilage, thymus, the central or peripheral nervous systems or bone marrow, and there are very few in the endomysium of skeletal muscles.

Lymphatic capillaries join into larger vessels that pass to local lymph nodes. Typically, lymph percolates through a series of nodes before reaching a major collecting duct. There are exceptions to this arrangement: the lymph vessels of the thyroid gland and oesophagus, and of the coronary and triangular ligaments of the liver, all drain directly to the thoracic duct without passing through lymph nodes. In the larger vessels, a thin external connective tissue coat supports the endothelium. The largest lymphatic vessels (200 μm) have three layers, like small veins, although their lumen is considerably larger than that of veins with a similar wall thickness. The tunica media contains smooth muscle cells, mostly arranged circumferentially. Elastic fibres are sparse in the tunica intima, but form an external elastic lamina in the tunica adventitia.

The larger lymphatic vessels differ from small veins in having many more valves (see Fig. 6.27). The valves are semilunar, generally paired and composed of an extension of the intima. Their edges point in the direction of the current, and the vessel wall downstream is expanded into a sinus, which gives the vessels a beaded appearance when they are distended. Valves are important in preventing the backflow of lymph.

Deep lymphatic vessels usually accompany arteries or veins, and almost all reach either the thoracic duct or the right lymphatic duct, which usually joins the left or right brachiocephalic veins respectively at the root of the neck.

The thoracic duct is structurally similar to a medium-sized vein but the smooth muscle in its tunica media is more prominent. Most lymphatic vessels anastomose freely. Larger vessels have their own plexiform vasa vasorum and accompanying nerve fibres. If their walls are acutely infected (lymphangitis) this vascular plexus becomes congested, marking the paths of superficial vessels by red lines that are visible through the skin and tender to the touch.

Lymphatic vessels repair easily. New vessels form readily after damage, beginning as solid cellular sprouts from the endothelial cells of persisting vessels that subsequently become canalized.

Diseases of the lymphatics

Lymphoedema occurs when insufficient lymphatic drainage leads to accumulation of fluid in the tissues (oedema) and swelling, typically in the limbs. In the developed world, secondary lymphoedema is most commonly the consequence of treatment for cancer, particularly breast cancer, following either surgical removal of lymph nodes and vessels, or their damage by radiation therapy. Tumours can themselves cause lymphoedema if they compress and block lymph vessels. Lymphangiectasia refers to a pathological dilation of lymph vessels, often caused by lymphatic obstruction; both can be primary or acquired. Acute lymphangitis is usually caused by invasion by virulent bacteria, e.g. *Streptococcus pyogenes*, causing subcutaneous red streaks draining an infected area: it leads to lymphadenitis and may herald septicaemia.

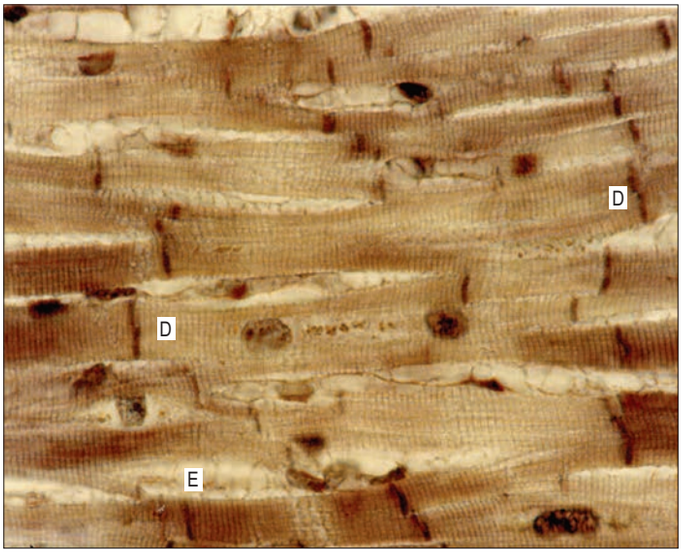

Fig. 6.28 Cardiac muscle fibres in human myocardium, sectioned longitudinally. Cell branching and fine cross-striations are clearly visible and indicate the intracellular organization of sarcomeres. The dark transverse lines are intercalated discs (D). Endomysium (E) contains nuclei of endothelial cells and fibroblasts.

CARDIAC MUSCLE

In cardiac muscle, as in skeletal muscle, the contractile proteins are organized structurally into sarcomeres that are aligned in register across the fibres, producing fine cross-striations that are visible in the light microscope. Both types of muscle contain the same contractile proteins (although commonly different isoforms), which are assembled in a similar way. The molecular basis for contraction, but not its regulation, is the same. Elevation of cytosolic calcium triggers contraction, corresponding to cardiac systole and the pumping phase of the heart cycle. Removal of cytosolic calcium induces relaxation, corresponding to diastole and cardiac filling. Despite the similarities, there are major functional, morphological and developmental differences between cardiac and skeletal muscle.

Microstructure of cardiac muscle

The myocardium, the muscular component of the heart, constitutes the bulk of its tissues. It consists predominantly of cardiac muscle cells, which are usually 120 μm long and 20–30 μm in diameter in a normal adult. Each cell has one or two large nuclei occupying the central part of the cell, whereas skeletal muscle has multiple, peripherally placed nuclei. The cells are branched at their ends, and the branches of adjacent cells are so tightly associated that their appearance under light microscopy is of a network of branching and anastomosing fibres (**Fig. 6.28**). Cells are bound together by elaborate junctional complexes, the intercalated discs (**Fig. 6.29**; see Fig. 6.31).

Fine fibrocollagenous connective tissue is found between cardiac muscle fibres. Although this is equivalent to the endomysium of skeletal muscle, it is less regularly organized because of the complex three-dimensional geometry imposed by the branching cardiac cells. Numerous capillaries and some nerve fibres are found within this layer. Coarser connective tissue, equivalent to the perimysium of skeletal muscle, separates the larger bundles of muscle fibres, and is particularly well developed near the condensations of dense fibrous connective tissue that form the 'skeleton' of the heart. The ventricles of the heart are composed of spiralling layers of fibres that run in different directions. Consequently, microscope sections of ventricular muscle inevitably contain the profiles of cells cut in a variety of orientations. A linear arrangement of cardiac muscle fibres is found only in the papillary muscles and trabeculae carneae.

Electron micrographs of cardiac muscle cells in longitudinal section show that the myofibrils separate before they pass around the nucleus, leaving a zone that is occupied by organelles, including sarcoplasmic reticulum, Golgi complex, mitochondria, lipid droplets and glycogen (**Fig. 6.30**). At the light microscopic level, these zones appear in longitudinal sections as unstained areas at the poles of each nucleus.

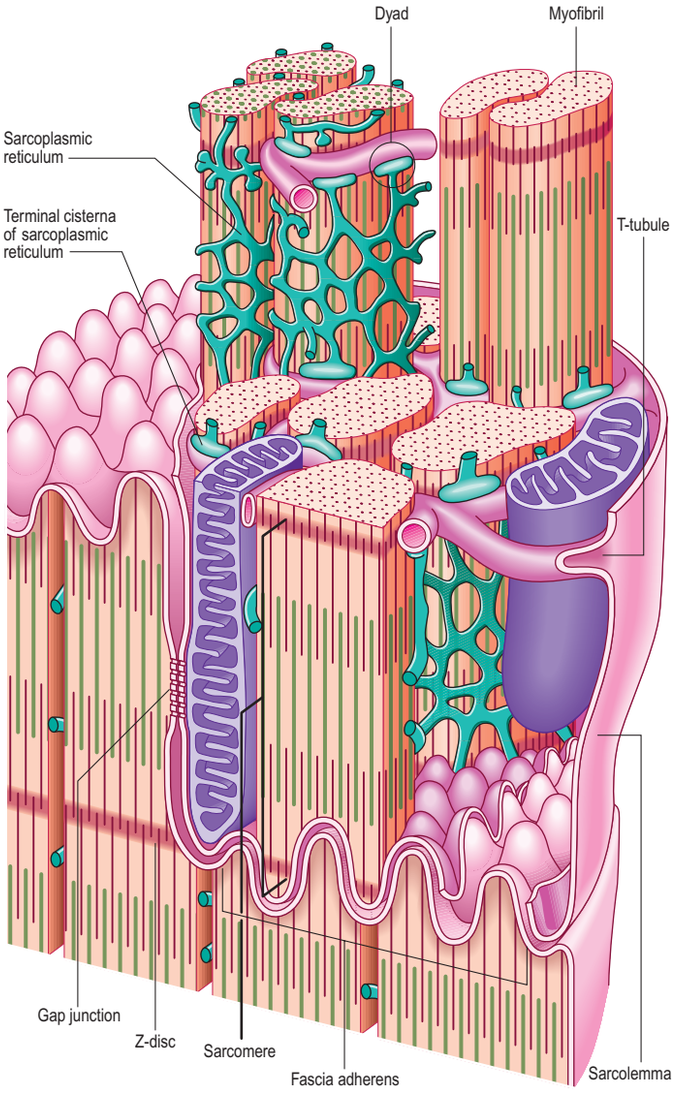

Fig. 6.29 A three-dimensional reconstruction of cardiac muscle cells in the region of an intercalated disc, a junctional complex between neighbouring cells. The interdigitating transverse parts of the intercalated disc form a fascia adherens, with numerous desmosomes; gap junctions are found in the longitudinal parts of the disc. The organization of the transverse tubules and sarcoplasmic reticulum is also shown.

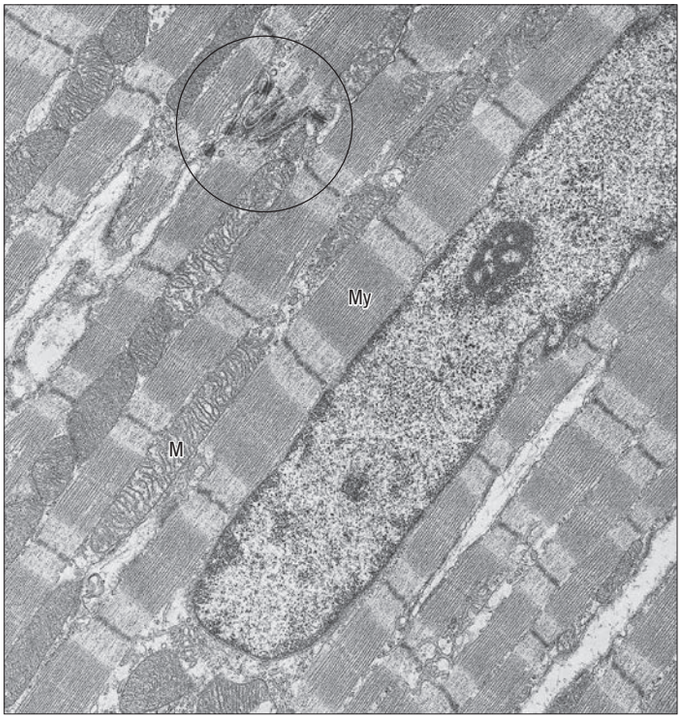

Fig. 6.30 A low-power transmission electron micrograph of cardiac muscle in longitudinal section, including the perinuclear zone of one of the fibres. Note the abundant large mitochondria (M) between myofibrils (My), and an intercalated disc (circled). (Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

They often contain lipofuscin granules, which accumulate there in individuals over the age of 10; the reddish-brown pigment may be visible even in unstained longitudinal sections.

The cross-striations of cardiac muscle are less conspicuous than those of skeletal muscle because the contractile apparatus of cardiac muscle lies within a mitochondria-rich sarcoplasm. The myofibrils are also less well delineated in cardiac muscle; in transverse sections they often fuse into a continuous array of myofilaments, irregularly bounded by mitochondria and longitudinal elements of sarcoplasmic reticulum. The large mitochondria, with their closely spaced cristae, reflect the highly developed oxidative metabolism of cardiac tissue. The proportion of the cell volume occupied by mitochondria (approximately 35%) is even greater in cardiac muscle than it is in slow twitch skeletal muscle fibres. The high demand for oxygen is also reflected in high levels of myoglobin and an exceptionally rich network of capillaries around the fibres.

The force of contraction is transferred through the ends of the cardiac muscle cells via the junctional strength provided by the intercalated discs. As in skeletal muscle, force is also transmitted laterally to the sarcolemma and extracellular matrix via vinculin-containing elements that bridge between the Z-discs of peripheral myofibrils and the plasma membrane. The actin-binding proteins spectrin and dystrophin, important components of the cardiac muscle cell cytoskeleton, associate independently with the sarcolemma to provide mechanical support. Both protein complexes form components of the costamere (Samarel 2005, Peter et al 2011), which, in addition to transmitting force from sarcomeres to the sarcolemma and extracellular matrix, is central to mechanically generated signalling mechanisms.

Atrial muscle cells are smaller than ventricular cells. The cytoplasm near the Golgi complexes at the poles of the nuclei exhibits dense membrane-bound granules that contain the precursor of atrial natriuretic peptide. This hormone promotes loss of sodium and water in the kidneys, reducing blood volume and thereby lowering blood pressure. It is released into the blood in response to stretch of the atrial wall. Atrial natriuretic peptide and aldosterone have antagonistic effects on renal sodium and water handling, via independent mechanisms.

The sarcolemma of ventricular cardiac muscle cells invaginates to form T-tubules with a wider lumen than those of skeletal muscle; atrial muscle cells have few or no T-tubules. Unlike skeletal muscle, most T-tubules penetrate the sarcoplasm at the level of the Z-discs (see Fig. 6.29). The T-tubules are interconnected at intervals by longitudinal branches to form a complex network. They serve a similar function in skeletal and cardiac muscle, i.e. to carry the wave of depolarization into the cores of the cells.

The sarcoplasmic reticulum is a membrane-bound tubular plexus that surrounds and defines, sometimes incompletely, the outlines of individual myofibrils. Its main role, as in skeletal muscle, is the storage, release and re-accumulation (sequestration) of calcium ions. The calcium-binding protein calsequestrin allows large amounts of calcium to be stored within the sarcoplasmic reticulum and modulates activity of the calcium release channels (ryanodine receptors) (Györke and Terentyev 2008). The sarcoplasmic reticulum is separated from the T-tubules by a 15 nm gap spanned by structures termed junctional processes, which are thought to be the cytoplasmic part of the calcium release channels; similar processes are found in skeletal muscle at the junctional surface of the terminal cisternae. Sarcoplasmic reticulum bearing junctional processes is termed junctional sarcoplasmic reticulum to distinguish it from free sarcoplasmic reticulum, which forms a longitudinal network. Junctional sarcoplasmic reticulum makes contact with both the T-tubules and the sarcolemma (of which the T-tubules are an extension). Sarcoplasmic reticulum forms small globular extensions (corbular sarcoplasmic reticulum) in the vicinity of the Z-discs, but not in immediate relation to T-tubules or the sarcolemma. Since the junctions between T-tubules and sarcoplasmic reticulum usually involve only one structure of each type, the corresponding profiles in electron micrographs are referred to as dyads, rather than triads as in skeletal muscle.

Intercalated discs

Intercalated discs are unique, complex junctions between cardiac myocytes. In the light microscope they are seen as transverse lines crossing the

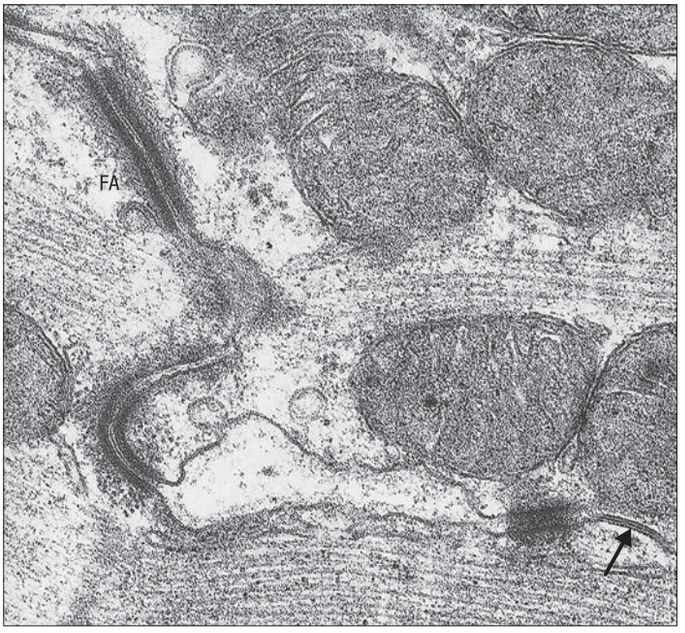

Fig. 6.31 An intercalated disc in cardiac muscle, with several zones of electron-dense fascia adherens (FA) and a gap junction (arrow). (Courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

tracts of cardiac cells (see Fig. 6.28). They may step irregularly within or between adjacent tracts, and may appear to jump to a new position as the plane of focus is altered. Ultrastructurally, they are seen to have transverse and lateral portions (see Fig. 6.29; **Fig. 6.31**). The transverse portions occur wherever myofibrils abut the end of the cell, and each takes the place of the last Z-disc. At this point, the actin filaments of the terminal sarcomere insert into a dense subsarcolemmal matrix that anchors them, together with other cytoplasmic elements such as intermediate filaments, to the plasma membrane. Prominent desmosomes, often with a dense line in the intercellular space, occur at intervals along each transverse portion. This junctional region is homologous with, and probably similar in composition to, the structure found on the cytoplasmic face of the myotendinous junction, and is a type of fascia adherens junction. It provides firm adhesion between cells, and a route for the transmission of contractile force from one cell to the next.

The lateral portions of an intercalated disc run parallel to the myofilaments and the long axis of the cell, for a distance that corresponds to one or two sarcomeres before turning again to form another transverse portion. They are therefore responsible for the stepwise progression of the intercalated disc, which is seen microscopically. The lateral portions contain gap junctions between adjacent cells (see Fig. 6.31), which provide electrical coupling and so enable the electrical impulse to propagate from one cell to the next, spreading excitation and contraction rapidly along the branching tracts of interconnected cells. The activity of the individual cells of the heart is thus coordinated so that they function as if they were a syncytium.

Contractile protein isoforms of cardiac muscle

As in skeletal muscle, the contractile proteins of cardiac muscle exist in a number of tissue- and stage-specific forms.

The cardiac isoform of α-actin is not identical to the skeletal muscle form and is encoded by a different gene, although the two are so similar as to be functionally interchangeable. Both skeletal and cardiac isoforms of sarcomeric actin are expressed in fetal ventricular muscle. Cardiac muscle α-actin increases postnatally and exceeds that of the skeletal isoform by 4:1 in the adult.

The myosin heavy chain of human cardiac muscle exists in two isoforms, α and β, both of which are present in the fetal heart. The α-form persists as the adult isoform in atrial muscle, whereas the β-form (which is associated with a slower rate of contraction) predominates in ventricular muscle. Interestingly, the β-form of myosin heavy chain in cardiac muscle is identical to the isoform in slow twitch skeletal muscle. This identity between cardiac and slow twitch skeletal protein isoforms is true of several proteins, including ventricular myosin light chains and cardiac troponin-C. Other proteins, such as troponin-I and T, exist in cardiac-specific forms in the adult, although skeletal isoforms are expressed in the fetus and neonate. The appearance of cardiac-specific isoforms of troponin-I and T in the blood, following their release from damaged cardiac cells, is now a standard diagnostic test for myocardial infarction.

Mutations in genes encoding cardiac contractile proteins, often exhibiting autosomal dominant inheritance, are associated with several cardiomyopathies.

Hypertrophic cardiomyopathy is relatively common (1 in 500) and normally asymptomatic. However, it is the foremost cause of sudden cardiac death in young athletes. Most cases show mutations in β myosin heavy chain and cardiac myosin binding protein C. Disordered myocardial growth leads to left ventricular hypertrophy, often asymmetric, and commonly valve obstruction and arrhythmias.

Dilated cardiomyopathy involves dilation of all cardiac chambers and impaired systolic function, and is the third most common cause of heart failure. About 30–40% of cases have been positively associated with mutations in genes for sarcomere and cytoskeletal proteins, e.g. β myosin heavy chain, troponin and dystrophin. However, dilated cardiomyopathy can also be acquired via infections (myocarditis), substance abuse (alcohol, cocaine), and around childbirth (peripartum cardiomyopathy).

Arrhythmogenic right ventricular cardiomyopathy is rare (1 in 5000), but can cause sudden cardiac death, especially in young adults. Right ventricular muscle exhibits an abnormal structure and electrical conduction, potentially causing fatal re-entrant ventricular tachycardias and arrhythmias. Mutations in genes for desmosome proteins have been implicated.

Endocardium

The whole inner surface of the heart is covered by a thin layer of cells forming the endocardium, which separates the myocardium from the blood. These cells are very similar to the endothelial cells that line blood vessels, with a similar biological activity and embryological origin. They are now recognized as playing an important signalling role in cardiac muscle function (reviewed in Brutsaert (2003)).

Neurovascular Supply of Cardiac Muscle

Vascular supply

The activity of the heart is equivalent to a constant power expenditure of 1.3 watts under basal conditions, and escalates to 3 watts or more during physical exertion. Cardiac muscle cells contain glycogen, which is a reserve during peaks of activity, but the majority of their energy requirement is continuous and supplied only through a highly developed oxidative metabolism, as is evident from the high proportion of the cell volume that is occupied by mitochondria. This metabolism has to be supported by a rich blood supply. Myocardium has a very high perfusion rate of 0.5 ml/min/g of tissue (5 times that of liver and 15 times that of resting skeletal muscle). No cardiac muscle cell is more than 8 μm from a capillary, and vascular channels occupy a high proportion of the total interstitial space. Cardiac muscle is supplied by the coronary vessels. Although there is some variation in the detailed distribution of the arterial branches, the left ventricle, which has the highest workload and largest mass, receives the highest arterial blood flow. Branches run in the myocardium along the coarser aggregations of connective tissue and ramify extensively in the endomysial layer, creating a rich plexus of anastomosing vessels. This plexus includes lymphatic as well as blood capillaries, which is not the case in skeletal muscle.

The high oxygen requirement of the myocardium makes it vulnerable to ischaemic damage arising from atheroma or embolism in the coronary arteries. This vulnerability is exacerbated in the left ventricle because embedded coronary arteries are compressed by contraction of the myocardium, limiting perfusion during systole. Arterial anastomoses, often more than 100 μm in diameter, are found throughout the heart and are an important factor in determining whether an adequate collateral circulation may develop after a coronary occlusion.

Innervation

Although the impulse-generating and conducting system of the heart establishes an endogenous rhythm, the rate and force of contraction are under neural influence. Both divisions of the autonomic nervous system supply unmyelinated postganglionic fibres to the heart. The innervation is derived bilaterally but it is functionally asymmetric. Activation of the left stellate ganglion (sympathetic) has little effect on heart rate but

increases ventricular contractility, whereas activation of the right stellate ganglion influences both rate and contractility. Activation of the right vagus nerve (parasympathetic) slows heart rate mainly through its influence on the pacemaker region, the sinuatrial (SA) node, whereas activation of the left vagus slows propagation of the impulse mainly through its effect on the atrioventricular (AV) node. Vagal activity has little direct effect on ventricular contractility.

Postganglionic sympathetic nerve fibres from the cervical sympathetic ganglia reach the heart via the recurrent cardiac nerves. Parasympathetic fibres in the heart are derived from ganglion cells in the cardiac plexuses and atrial walls that are innervated by preganglionic cardiac branches of the vagus. Adrenergic, cholinergic and peptidergic endings have been demonstrated in the myocardium. Fibres often end close to muscle cells and blood vessels, but junctional specializations are not seen, and a gap of at least 100 nm remains between myocyte and axon. It is probable that neurotransmitters diffuse across this gap to the adjacent cells. Some of the endings represent efferent nerve terminals, while others function as pain receptors, mechanoreceptors or chemoreceptors.

Excitation–contraction coupling in cardiac muscle

The molecular interaction between actin and myosin that underlies the generation of force is initiated by elevation of cytosolic calcium in both cardiac and skeletal muscle. However, there are significant differences in both the mechanisms by which this occurs and the physical arrangement and molecular composition of the contractile elements (reviewed in Bers (2002)).

One of the major functional differences between cardiac and skeletal muscle is the way in which contractile force is regulated. Smoothness and gradation of contraction in skeletal muscle depend on recruitment and asynchronous firing of different numbers of motor units. Individual motor units can also build up a contraction through a brief series of re-excitations. In the heart, the entire mass of muscle must be activated almost simultaneously, and mechanical summation by re-excitation is not possible, because the cells are electrically refractory until mechanical relaxation has taken place (see below).

As in skeletal muscle, cardiac muscle contraction is initiated when calcium binds to troponin-C, a component of the regulatory protein complex on the thin filaments. During basal activity of the heart, the amount of calcium bound to troponin-C during each systole induces less than half-maximal activation of the contractile apparatus. Contractile force can therefore be increased by increasing cytosolic calcium and thus the amount bound to troponin-C. This is achieved by controlling the amount of free calcium that is released into the cytosol during systole.

A special feature of the cardiac muscle cell is the long duration of its action potential. This is due to activation of voltage-dependent L-type calcium channels in the sarcolemma by the initial depolarization, through which calcium enters the cell, sustaining the depolarization and so causing a long-lasting electrical plateau of equivalent length to the contraction. However, calcium influx during the plateau only accounts for about 25% of the elevation of cytosolic calcium; the rest is released from the sarcoplasmic reticulum.

Action potentials are conducted into the T-tubules, where they activate L-type channels and calcium influx. This causes a localized increase in free calcium in the narrow space between the T-tubules and junctional sarcoplasmic reticulum, which activates calcium release channels on the latter, causing calcium to flood out into the cytosol. This 'calcium-induced calcium release' is a vital component of cardiac muscle activation and is the principal or only mechanism by which calcium can be released from the sarcoplasmic reticulum in the myocardium. This major difference between cardiac and skeletal muscle is reflected in tissue-specific isoforms of calcium release channels.

Systolic activation is terminated on repolarization of the action potential by reuptake (sequestration) of calcium from the cytosol back into the sarcoplasmic reticulum. This is mediated by a high-affinity sarco-endoplasmic reticulum calcium ATPase (SERCA), which rapidly reduces cytosolic free calcium to resting levels. The activity of this ATPase controls the rate of decay of the calcium transient and is therefore a determinant of the rate of relaxation of the heart. The sarcoplasmic reticulum contains a cardiac form of calsequestrin, a homologue of the proteins found in skeletal and smooth muscle. This calcium-binding protein buffers the free calcium concentration inside the sarcoplasmic reticulum, allowing it to store considerable amounts of total calcium without increasing the gradient against which SERCA must pump. It may also modulate the activity of the calcium release channels (Györke and Terentyev 2008).

Whilst SERCA therefore allows rapid relaxation of the myocardium, the calcium that entered the cell during the action potential must also be transported out again to prevent calcium overload. This is accomplished primarily by a sodium–calcium exchanger (NCX) in the sarcolemma, and to a much lesser extent by a sarcolemmal calcium ATPase. These act more slowly than SERCA, continuously removing calcium from the cell during the diastolic interval as calcium slowly leaks from the sarcoplasmic reticulum.

The extent of the elevation of cytosolic calcium and therefore force generation during systole is determined by both the size of the initial stimulus (amount of calcium entering through L-type channels) and the amount of calcium stored within the sarcoplasmic reticulum. The greater the amount stored, the more is available for release. This provides an intrinsic mechanism for matching any increase in heart rate with a progressive increase in contractile force. At higher heart rates, more calcium enters per unit time, but as the diastolic interval is reduced there is less time for calcium to be removed from the cell by the sarcolemmal sodium–calcium exchanger. The amount of calcium stored in the sarcoplasmic reticulum therefore increases, so more can be released during systole. Increased heart rate is therefore coupled with an increase in force, a phenomenon called the staircase response.

The most potent physiological means of enhancing cardiac contractility is through the action of β-adrenergic agents, specifically the sympathetic neurotransmitter noradrenaline (norepinephrine) and circulating adrenaline (epinephrine). Activation of β-adrenergic receptors produces cyclic adenosine monophosphate (cAMP), which enhances calcium influx via L-type calcium channels during depolarization, so stimulating greater release from the sarcoplasmic reticulum. In addition, cyclic AMP enhances the activity of SERCA via promoting phosphorylation of an associated protein, phospholamban. This enables a more rapid reduction of the cytosolic calcium pump and accelerated relaxation, which is important when the heart rate is increased. Phosphorylation of troponin-I on the thin filaments also increases the rate of cross-bridge cycling, further accelerating relaxation.

Dysfunction of cardiac muscle excitation–contraction coupling in disease

In coronary heart disease the myocardium may be inadequately perfused (myocardial ischaemia), leading to energy deficit, loss of contractility and eventually cell death. The process may culminate in irretrievable myocardial damage and progress to heart failure, which is the inability to provide adequate cardiac output for the tissues.

Channelopathies are conditions associated with mutations in genes encoding cardiac muscle ion channels (Webster and Berul 2013). They are mostly autosomal dominant, inherited conditions which increase the likelihood of arrhythmias, fainting and sudden cardiac death, especially in young otherwise healthy adults.

Origin of cardiac muscle

Cardiac myocytes differentiate from the splanchnopleuric coelomic epithelial cells of the pericardium initially subjacent to the endoderm (see Fig. 13.2). As the primitive heart tube is formed, the presumptive myocardial cells start to express genes that encode characteristic myocardial proteins, including myosin, actin, troponin and other components of the contractile apparatus. Myofibrils begin to appear in the developing myoblasts, and the first functional heart beats start soon afterwards.

Committed cardiac myoblasts do not fuse to form multinucleated myotubes, as occurs in skeletal muscle, but remain as single cells coupled physically and electrically through intercellular junctions. Differentiated cardiac myocytes continue to divide during fetal development and withdraw from the cell cycle only after birth. This is markedly different from skeletal muscle development, when differentiation, including the activation of muscle-specific genes, coincides with withdrawal from the cell cycle. During fetal maturation, successive changes in gene expression give rise to the characteristics of fetal, neonatal and adult myocardium, and are responsible for the divergence of the properties of atrial and ventricular muscle cells.

The regulatory mechanisms underlying differentiation of cardiac muscle appear to be distinct from those of skeletal muscle. It is anticipated that counterparts will be found for the transcriptional factors Myf-5, myogenin, MyoD and Myf-6, which are responsible for inducing differentiation of skeletal muscle. It is known that Tbx5 and Nkx2–5 are required for formation of atrial and ventricular myocardium (see Fig. 13.6).

The body responds to this challenge with a variety of neurohumoral mechanisms, including increased sympathetic stimulation to the heart, increasing heart rate and contractility via noradrenaline (norepinephrine; see above). Treatment includes administration of positive inotropic agents (drugs that increase contractility) such as β-adrenergic agonists and phosphodiesterase inhibitors that prevent the breakdown of cyclic AMP. The classic positive inotropic drug is digitalis (digoxin), which at therapeutic doses causes partial inhibition of the sodium pump (sodium–potassium ATPase) that maintains the ionic gradient across the sarcolemma. This leads to a reduced sodium concentration gradient, impairing operation of the sarcolemmal sodium–calcium exchanger. Less calcium is therefore extruded from the cell, so more is left in the sarcoplasmic reticulum for release during systole, increasing force. However, positive inotropes are now only used in the short term because, if used chronically, they can hasten progression of the disease. The following explains why this is the case.

An energy deficit has far-reaching consequences beyond the inhibition of actin and myosin interactions. ATP is vital for many cellular processes, in particular, the activities of the sodium pump and SERCA. Impaired operation of the sodium pump leads to reduced extrusion of calcium (see above). Inhibition of SERCA impairs calcium reuptake into the sarcoplasmic reticulum and relaxation at the end of systole. The net effect is calcium overload. Mitochondria can mitigate the effects by taking up calcium, but eventually this causes mitochondrial damage and so worsens the energy deficit. As ATP falls further, operation of the sodium pump declines, the ionic gradient is dispersed and the cell depolarizes, causing calcium entry through L-type channels, which worsens the calcium overload and leads to cell death. Positive inotropes, by increasing both cytosolic calcium and energy requirements, will clearly worsen the situation.

This sequence of events has led to development of agents that act via increasing the binding of troponin-C to calcium, rather than by increasing calcium. However, therapy for chronic heart failure is still currently focused on limiting disease progression, largely by interrupting neurohumoral compensation mechanisms. Paradoxically, this includes β-adrenergic receptor antagonists, and also antagonists to angiotensin II and aldosterone (reviewed in Francis (2001)), which may inhibit cardiac remodelling (see below).

Concurrent with the development of contractile proteins, cardiac myocytes develop numerous specific intracellular vesicles containing substances shown to induce natriuresis and diuresis, and a family of polypeptides generally known as atrial natriuretic peptides. These vesicles develop from the Golgi complex in both atria and ventricles during fetal life but become restricted to atrial muscle in the adult. Atrial natriuretic peptide is measurable when the heart is recognizably four-chambered; almost all cells within the atria are capable of its synthesis.

The impulse-generating (AV node) and conducting systems of the heart (AV node; bundle of His, Purkinje fibres) are formed from cardiac myocytes that differ in their morphology from the working myocardium of the heart chambers. Cells of the SA and AV nodes tend to be smaller with slow cell-to-cell electrical conduction, whilst those of the bundle of His and Purkinje fibres are larger in diameter with very rapid electrical conduction.

Cardiac plasticity and regeneration of cardiac muscle

The heart exhibits a significant degree of plasticity. Physiological and pathophysiological stimuli can initiate cardiac remodelling (reviewed in Hill and Olson (2008)). For example, increased loads as a result of exercise training or pregnancy induce physiological hypertrophy of the heart, where the ventricular walls thicken due to an increase in the size (but not number) of cardiac muscle cells. Conversely, hypertrophy resulting from cardiac damage, high blood pressure and/or extended activation of neurohumoral compensatory mechanisms (e.g. sympathetic stimulation, production of angiotensin II and aldosterone) can be maladaptive, increasing the risk and rate of progression of heart failure and sudden death due to arrhythmias.

Both increased mechanical stress and circulating or local mediators can initiate the gene transcription and protein synthesis associated with cardiac hypertrophy and remodelling. At least part of the response is mediated through calcium-dependent mechanisms involving calcineurin, and isoforms of protein kinase C and calcium–calmodulin-dependent kinase, but growth factors, inflammatory cytokines and other humoral mediators also activate complex signalling cascades that modify activity of transcription factors. Notably, physiological and pathological cardiac remodelling show significant differences in gene transcription and expression of certain proteins; pathological hypertrophy is associated with phenotypic switching towards fetal and less efficient isoforms of contractile proteins such as myosin heavy chain (Hill and Olson 2008).

Chronic heart failure is regarded as irreversible and progressive, and pathological cardiac remodelling plays a major role in its progression. Therapy is largely focused on agents that suppress pro-remodelling pathways (e.g. β-blockers, angiotensin-converting enzyme inhibitors, aldosterone antagonists) and therefore slow progression (Francis 2001). However, recent developments have raised hope for future treatments that might reverse cardiac damage.

In skeletal muscle, a population of precursor cells (satellite cells) is retained in adult life, constituting a pool of myoblasts capable of dividing, fusing with existing muscle fibres and initiating regeneration after damage. It was thought that cardiac muscle lacked an equivalent population of cells and was therefore incapable of regeneration. There is some evidence that the heart does contain endogenous progenitor cells capable of regenerating myocardial function (Oh et al 2004), although to a very limited extent compared to skeletal muscle and insufficient to restore heart function after ischaemic or other injury. It has been suggested that there is a slow but continuous renewal of cardiac muscle cells throughout life even in healthy individuals, with a turnover of between 0.4 and 1% per year (Bergmann et al 2009).

CHAPTER 7

Skin and its appendages

In this chapter, the types and functions of skin in different parts of the body are described first, followed by the microstructure of the epidermis and dermis, and the appendages of skin, including the pilosebaceous units, sweat glands and nails. The development of skin, natural skin lines and age-related changes, and clinical aspects of skin, e.g. grafts, surgical skin flaps and wound healing, are also described. The integumental system includes the skin and its derivatives, hairs, nails, sweat and sebaceous glands; subcutaneous fat and deep fascia; the mucocutaneous junctions around the openings of the body orifices; and the breasts. Mucocutaneous junctions and breast tissues are covered in the appropriate regional sections.

TYPES AND FUNCTIONS OF SKIN

The skin is the largest organ of the human body and constitutes approximately 15% of the total body weight. In an average 70 kg person, the skin weighs approximately 13 kg and has a surface area of about 2 m^2. It covers the entire external surface of the body, including the external acoustic meatus, the lateral aspect of the tympanic membrane and the vestibule of the nose. It is continuous with the mucosae of the alimentary, respiratory and urogenital tracts, and fuses with the conjunctiva at the margins of the eyelids, and with the lining of the lacrimal canaliculi at the lacrimal puncta. The thickness of the skin ranges from 1.5 to 5.0 mm and depends mainly on its location.

The skin forms a self-renewing interface between the body and its environment. It provides an effective barrier against microbial organisms, and protects against mechanical, chemical, osmotic, thermal and ultraviolet radiation damage. It is an important site of immune surveillance against the entry of pathogens and the initiation of primary immune responses. For instance, the skin produces various antimicrobial peptides such as human cathelicidin LL-37, a small cationic peptide that can prevent the immunostimulatory effects of bacterial wall molecules such as lipopolysaccharide and therefore protect against endotoxaemia. It can inhibit neutrophil apoptosis and stimulate angiogenesis, tissue regeneration and release of cytokines such as interleukin (IL)-8. Specific innate immune defenses in the skin are present throughout the epidermis, dermis, hair follicles and appendages, and in the absence of skin diseases or trauma, provide a resilient buffer against external microorganisms (Tikoo et al 2018).

Skin performs many biochemical synthetic processes, including the formation of vitamin D under the influence of ultraviolet B (UVB) radiation and synthesis of cytokines and growth factors. Skin is the target of a variety of hormones such as thyroxine, androgens and oestrogens. These activities can affect the appearance and function of individual skin components, such as the sebaceous glands, the hairs and the pigment-producing cells.

Control of body temperature is an important function of skin, and is effected mainly by regulation of heat loss from the cutaneous circulation through the rapid increase or reduction in the flow of blood to an extensive external surface area. This process is also assisted by sweating. In disorders such as erythroderma, in which more than 90% of the skin is inflamed and red, insensible fluid losses can exceed several litres per day and can result in shock if treatment is not initiated promptly. Skin is involved in socio-sexual communication and can signal emotional states by means of muscular and vascular responses. It is a major sensory organ, richly supplied by nerve terminals and specialized receptors for touch, temperature, pain and other stimuli.

Skin has good frictional properties, assisting locomotion and manipulation by its texture. It is elastic, and can be stretched and compressed within limits. The outer surface is covered by skin lines, some of which are large and conspicuous while others are microscopic, or are only revealed after manipulation or incision of the skin.

The colour of human skin is derived from, and varies with, the amount of blood (and its degree of oxygenation) in the cutaneous circulation, the thickness of the cornified layer and the ratio of eumelanin (brown/black) to pheomelanin (red/yellow). Melanin has a protective role against UV radiation and acts as a scavenger of harmful free radicals. Ethnic variations in colour are mainly due to differences in the amount, type and distribution of melanin and are genetically determined. These genetic variants may also determine the prevalence of benign skin lesions such as freckles, as well as susceptibility to common forms of non-melanoma skin cancers and skin ageing (Law et al 2017).

The appearance of skin is affected by many other factors, e.g. size, shape and distribution of hairs and of skin glands (sweat, sebaceous and apocrine), and changes associated with maturation, ageing, metabolism and pregnancy. The general state of health is reflected in the appearance and condition of the skin, and the earliest signs of many systemic disorders may be apparent in the skin.

Skin microbiome

Classification of skin

Although skin in different parts of the body is fundamentally of similar structure, there are many local variations in parameters such as thickness, mechanical strength, softness, flexibility, degree of keratinization (cornification), size and number of hairs, frequency and types of glands, pigmentation, vascularity and innervation (**Figs 7.1–7.4**). Human skin is divided into two main types: hairless (glabrous) skin and hair-bearing skin. Hairless skin is found on the palms and soles where it has a grooved surface, with alternating ridges and sulci giving rise to the dermatoglyphics (fingerprints). In palmar and plantar skin, there is a compact cornified layer which may be up to 10 times thicker than in other body sites: this skin is thus also termed thick skin. There are, however, sites such as the lips and nipples, where hairless skin has a relatively thin cornified layer.

Regional variations in skin

Available with the *Gray's Anatomy* e-book.

MICROSTRUCTURE OF SKIN AND SKIN APPENDAGES

Epidermis

The epidermis (see Figs 7.2–7.3) is a self-renewing stratified epithelial tissue consisting mainly of keratinocytes. Other cells within the epidermis include melanocytes (pigment-forming cells from the embryonic neural crest), Langerhans cells (immature antigen-presenting dendritic cells derived from bone marrow), lymphocytes and Merkel cells. Merkel cells may function as sensory mechanoreceptors or possibly as part of the dispersed neuroendocrine system and many are associated with nerve endings. Free sensory nerve endings are sparsely present within the epidermis.

The population of keratinocytes undergoes continuous renewal throughout life (Gonzales and Fuchs 2017). Turnover is mediated by epidermal stem cells in the basal layer of the epidermis which generate daughter cells that undergo a series of biochemical and physical changes as they migrate towards the surface of the skin to form the various layers of the epidermis. They transform from polygonal living cells to non-viable flattened squames full of intermediate filament proteins (keratins) embedded in a dense matrix of cytoplasmic proteins to form mature keratin.

The epidermis consists of several layers. The innermost layer, the basal layer (stratum basale) is succeeded by the spinous or prickle cell layer (stratum spinosum), granular layer (stratum granulosum), clear layer (stratum lucidum) and cornified layer (stratum corneum), which is the most superficial (see Fig. 7.4). The first three of these layers are metabolically active compartments through which cells pass and change their morphology as they undergo cellular differentiation. The more superficial layers of cells undergo terminal keratinization

Each square centimetre of skin contains approximately one million bacteria (comprising hundreds of distinct species) forming a complex community that also contains viruses and fungi. The exact composition of the community of these organisms varies across different body sites and depends on several factors, including sebaceous gland concentration, moisture content and temperature, host genetics and exogenous environmental factors. The multiple organisms are not just commensals but play a much bigger role in immune modulation and epithelial health (Chen et al 2018). Dissecting the nature of microbe–host interactions and discovering the factors that drive microbial colonization are likely to provide greater insight into the pathogenesis of skin diseases such as atopic dermatitis, and inform the development of potential new therapies.

Hairless skin has numerous encapsulated sensory endings within the dermis, but lacks hair follicles and associated sebaceous glands. Hair-bearing skin (most thin skin bears hairs) has both hair follicles and sebaceous glands associated with the follicles. Hair follicle size, structure and density can vary between different body sites. Notably, scalp has large hair follicles whereas the forehead has only small, vellus hair-producing follicles. Some hair-bearing sites, such as the axilla, contain apocrine glands as well as eccrine sweat glands. Sebaceous gland function varies with age, being active in neonates, and from puberty onwards: the relative activity influences the composition of the skin surface lipids and the skin microbiome. There are regional variations in the structure of the dermal–epidermal junction, with more hemidesmosomes and anchoring fibrils in the skin of the leg than in the skin of the arm. In the dermis, the arrangement and size of elastic fibres varies, e.g. they are very large in perianal skin, whereas there are almost none in the scrotum. Cutaneous blood supply varies markedly between areas such as the eyelid and more rigid areas such as the fingertips.

(cornification), which involves not only structural changes in keratinocytes, but also molecular and biochemical changes within the cells and their surroundings.

The epidermal appendages (pilosebaceous units, sweat glands and nails) are formed developmentally by the ingrowth of the epidermis.

Keratinocytes

Basal layer

The basal layer is the innermost layer of the epidermis, next to the dermis and is the site of epidermal cellular proliferation. It is in contact with a basal lamina, which is a thin layer of specialized extracellular matrix not usually visible by light microscopy (Fig. 7.5; see Fig. 2.8). By transmission electron microscopy, the basal lamina consists of a clear lamina lucida adjacent to the basal cell plasma membrane and a darker electron-dense lamina densa (Fig. 7.6). The basal plasma membranes of the basal keratinocytes, the extracellular basal laminae and the anchoring fibrils of type VII collagen within the subjacent dermal matrix (lamina fibroreticularis) which insert into the lamina densa, collectively form the basement membrane zone (BMZ) at the dermal–epidermal junction. This is a highly convoluted interface, particularly in thick, hairless skin, where dermal papillae (rete ridges) project into the epidermis, interlocking with adjacent downward projections of the epidermis (rete pegs) (see Fig. 7.4).

The majority of basal keratinocytes are columnar to cuboidal in shape, with large (relative to their cytoplasmic volume), mainly euchromatic nuclei and prominent nucleoli (see Fig. 7.3). The cytoplasm contains variable numbers of melanosomes and keratin filament bundles corresponding to the keratin tonofilaments of classical electron microscopy. In the basal keratinocytes, these keratins consist mostly of keratin 5 (K5) and keratin 14 (K14) proteins. The plasma membranes of interconnecting cells are coupled by desmosomes; those of the basal keratinocytes are linked to the basal lamina by hemidesmosomes (see Figs 7.5–7.6, 1.26). Melanocytes (see Fig. 7.13), Langerhans cells (see Figs 7.16–7.17) and Merkel cells (see Fig. 3.29) are interspersed among the basal keratinocytes. Merkel cells are connected to keratinocytes by desmosomes,

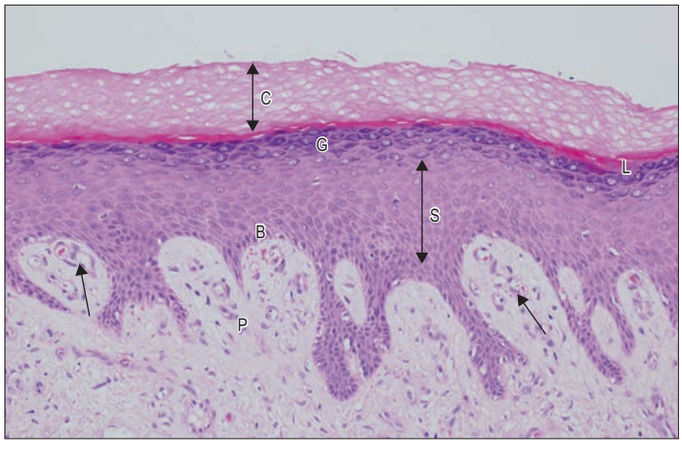

Fig. 7.4 The epidermis and papillary dermis (P) of human thick skin, showing the thick cornified layer (C, stratum corneum), the eosinophilic clear layer (L, stratum lucidum), the granular layer (G, stratum granulosum), the prickle cell layer (S, stratum spinosum) and the basal layer (B, stratum basale). Capillary loops (arrows) are seen entering the deep papillae (rete ridges) of the dermis, between downward-projecting epidermal rete pegs. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

but melanocytes and Langerhans cells lack these specialized contacts. Intraepithelial lymphocytes are present in small numbers.

Keratinocyte stem cells are found within the basal layer of the epidermis (Fuchs 2016): they are thought to reside mainly in the interfollicular epidermis in the troughs of rete pegs, and in the outer root sheath bulge of the hair follicle and in sebaceous glands. Their progeny, called transit (or transient) amplifying cells, also reside within the basal layer and pass through a few rounds of proliferation before terminally differentiating. The activity of epidermal stem cells and transit amplifying cells in the basal layer provides a continuous supply of differentiating cells that move suprabasally, eventually forming the cornified (corneocyte) layer of the epidermis.

Epidermal stem cells and their differentiated progeny are organized into columns, the epidermal proliferation units. Several layers of prickle and granular cells overlie a cluster of 6–8 basal cells, forming a columnar proliferative unit. Each group of basal cells consists of a central stem cell with an encircling ring of transit amplifying proliferative cells and postmitotic maturing cells. From the periphery of this unit, postmitotic cells transfer into the prickle cell layer. The normal total epidermal turnover time is between 52 and 75 days. In some skin disorders, the turnover rates and transit times are significantly shortened, e.g. in psoriasis, the total epidermal turnover time may be as little as 8 days. In homeostatic conditions, the multiple stem cell populations in skin generally contribute only to the differentiation programme of restricted local cells. However, following injury that inflicts systemic and local environmental change, the various stem cell populations, e.g. those in hair follicles, may display remarkable plasticity, responding to wound-induced stimuli by exiting their niche and participating in re-epithelializing damaged tissue. This

process may involve a transient or permanent switch of their tissue regeneration programme depending upon the particular type of wound. Understanding the molecular basis of the 'switch' is likely to have considerable relevance to improving wound healing and developing the field of regenerative medicine.

Prickle cell layer

The prickle cell layer (stratum spinosum) (see Fig. 7.3; **Fig. 7.7**), consists of several layers of closely packed keratinocytes that are connected to each other by desmosomes, the specialized cell–cell junctions that provide tensile strength and cohesion to the layer. When a section of skin is stained by haematoxylin and eosin and viewed by routine light microscopy, intercellular bridges corresponding to the locations of the desmosomes are seen between the dehydrated keratinocytes, giving these suprabasal cells their characteristic spiny appearance. However, ultrastructurally, the desmosome junctions have a tight laminated appearance (**Fig. 7.8**). The cytoplasm of these keratinocytes contains prominent bundles of cytokeratin filaments, mostly cytokeratins 1 (K1) and 10 (K10), arranged concentrically around a euchromatic nucleus and attached to the dense plaques of the desmosomes and melanosomes, either singly or aggregated within membrane-bound organelles (compound melanosomes). Langerhans cells (see Fig. 7.16) and occasional lymphocytes are present in the prickle cell layer.

Granular layer

Extensive changes in keratinocyte structure occur in the 3–4 layers of flattened cells in the granular layer, also known as the stratum granulosum (Yokouchi et al. 2016). The nuclei become pyknotic and begin to disintegrate. Organelles such as ribosomes and membrane-bound mitochondria and Golgi bodies degenerate. Cytokeratin filament bundles become more compact and associated with irregular, densely staining keratohyalin granules (see Fig. 7.7). Small round granules (100 ×300 nm) with a lamellar internal structure (lamellar granules, Odland bodies, keratinosomes) also appear in the cytoplasm. Keratohyalin granules contain a histidine-rich, sulphur-poor protein, profilaggrin, which becomes modified to filaggrin as the cell reaches the cornified layer. Defects in the filaggrin protein, as a result of loss-of-function mutations in the filaggrin (*FLG*) gene, have been shown to cause ichthyosis vulgaris, a common dry scaly skin condition, as well as being a major risk factor for atopic eczema (Irvine et al 2011). In addition, copy number variation in the *FLG* gene may influence the amount of filaggrin in the skin and also contribute to the pathogenesis of both dry skin and eczema (Weidinger et al. 2018). The degradation products of filaggrin, including urocanic acid, contribute to the formation of natural moisturizing factor, a key component of the epidermal barrier function.

The lamellar granules release their hydrophobic glycophospholipid contents into the intercellular space both within the granular layer and between the granular and the cornified layers. These glycophospholipids form an important component of the permeability barrier of the epidermis: permeability is also regulated by tight junctions within the middle and upper parts of the granular layer (**Fig. 7.9**).

Clear layer

The clear layer is only found in thick palmar or plantar skin. It stains more strongly than the cornified layer with acidic dyes (see Fig. 7.6), is more optically refractile and often contains nuclear debris. Ultrastructurally, the cells contain compacted keratin filaments and resemble the incompletely keratinized cells that are occasionally seen in the innermost part of the cornified layer of thin skin.

Cornified layer

The cornified layer (see Figs 7.3, 7.7) is the final product of epidermal differentiation (Akiyama 2017). It consists of closely packed layers of flattened polyhedral squames or corneocytes (**Fig. 7.10**), ranging in surface area from 800 to 1100 μm^2. These cells overlap at their lateral margins and interlock with cells of apposed layers by ridges, grooves and microvilli. In thin skin, this layer may be a few cells deep, but in thick skin it may be more than 50 cells deep. The plasma membrane of the corneocytes appears thicker than that of other keratinocytes, partly due to the cross-linking of a soluble precursor, involucrin, at the cytoplasmic face of the plasma membrane, in the complex insoluble cornified envelope. The outer surface is also covered by a monolayer of bound lipid. The intercellular region contains extensive lamellar sheets of glycolipid derived from the lamellar granules of the granular layer. The cells lack a nucleus and membranous organelles, and consist entirely of a dense array of keratin filaments embedded in a cytoplasmic matrix composed partly of filaggrin derived from keratohyalin granules. The cornified layer has physical and chemical properties that vary across the layer, providing different amounts of absorption, hydration and mechanical defence (**Fig. 7.11**).

Under normal conditions, the production of epidermal keratinocytes in the basal layer is matched by the loss of corneocytes from the cornified layer. Desquamation of these cells is normally imperceptible. When excessive, it may appear as dandruff on the scalp or the flaking or peeling skin that follows sunburn. The thickness of the cornified layer can be influenced by local environmental factors including chronic scratching, which can lead to a considerable thickening of the whole epidermis including the cornified layer.

Keratins

Keratins are the intermediate filament proteins found in all epithelial cells. There are two types: type I (acidic) and type II (neutral/basic). They form heteropolymers, are co-expressed in specific pairs and are assembled into 10 nm intermediate filaments. Fifty-four different functional keratin genes are recognized in humans (Coulombe 2017). They are expressed in highly specific patterns according to the stage of cellular differentiation. Antibodies to individual keratins are useful analytical tools (**Fig. 7.12**). Keratins K5 and K14 are expressed by basal keratinocytes. Keratins K1 and K10 are synthesized suprabasally. In the granular layer the filaments become associated with keratohyalin granules containing profilaggrin, a histidine-rich phosphorylated protein. As the cells pass into the cornified layer, profilaggrin is cleaved by phosphatases into filaggrin, which causes aggregation of the filaments and forms the matrix in which they are embedded. Other types of keratin expression

occur elsewhere, particularly in hair and nails, where highly specialized hard keratin is expressed. This becomes chemically modified and is much tougher than in the general epidermis.

Epidermal lipids

The epidermis serves as an important barrier to trans-epidermal loss of water and other substances through the body surface (apart from in sweating and sebaceous secretion). This is possible in part because of the presence of an epidermal lipid layer that consists of a variety of lipids that are synthesized in the epidermis. These include triglycerides, fatty acids, phospholipids, cholesterol, cholesterol esters, glycosphingolipids and ceramides. Furthermore, 7-dehydrocholesterol, an intermediate molecule in the cholesterol biosynthesis pathway and a precursor of vitamin D, is synthesized in the skin. The content and composition of epidermal lipids change with differentiation (Elias et al 2014). Phospholipids and glycolipids first accumulate within keratinocytes above the basal layer, but higher up they are broken down and are practically absent from the cornified layer. Cholesterol and its esters, fatty acids and ceramides accumulate towards the surface and are abundant in the cornified layer. The lamellar arrangement of the extracellular lipids is a major factor in their barrier function.

Melanocytes

Melanocytes are melanin pigment-producing cells derived from the neural crest (Figs 7.13–7.14). They are present in the epidermis and its appendages, oral epithelium, some mucous membranes, uveal tract (choroid coat) of the eyeball, parts of the middle and internal ear, and in the pial and arachnoid meninges, principally over the ventrolateral surfaces of the medulla oblongata. The cells of the retinal pigment epithelium, developed from the outer wall of the optic cup, also produce melanin, and neurones in different locations within the brainstem (e.g. the locus coeruleus and substantia nigra) synthesize a variety of melanin called neuromelanin. In humans there are two classes, the brown–black eumelanin and the red–yellow pheomelanin, both derived from the substrate tyrosine. Most natural melanins are mixtures of eumelanin and pheomelanin; pheomelanic pigments, trichochromes, occur in red hair.

Melanocytes are dendritic cells and lack desmosomal contacts with apposed keratinocytes, although hemidesmosomal contacts with the basal lamina are present. In routine tissue preparations, melanocytes appear as clear cells in the basal layer of the epidermis. The numbers per unit area of epidermis range from 2300 per mm^2 in cheek skin to 800 per mm^2 in abdominal skin. It is estimated that a single melanocyte may be in functional contact via its dendritic processes with up to 30 keratinocytes. The nucleus is large, round and euchromatic, and the cytoplasm contains intermediate filaments, a prominent Golgi complex and vesicles and associated rough endoplasmic reticulum, mitochondria and coated vesicles, together with a characteristic organelle, the melanosome.

The melanosome is a membrane-bound structure that undergoes a sequence of developmental stages during which melanin is synthesized and deposited within it by a tyrosine–tyrosinase reaction. Mature melanosomes move into the dendritic processes along the surfaces of microtubules and are transferred to keratinocytes through their phagocytic activity (Wu and Hammer 2014). Keratinocytes engulf and internalize the tip of the dendrite, so that the contained melanosomes are pinched off into the keratinocyte cytoplasm. Here, they may exist as individual granules in heavily pigmented skin, or be packaged within secondary lysosomes as melanosome complexes in lightly pigmented skin. In basal keratinocytes they can be seen to accumulate in a crescent-shaped cap over the distal part of the nucleus. As the keratinocytes progress towards the surface of the epidermis, melanosomes undergo degradation, and melanin remnants in the cornified layer form dust-like particles. Melanosomes are degraded more rapidly in light-skinned than in dark-skinned individuals, in whom melanosomes persist in cells of the more superficial layers. Melanosomes are acidic, which explains why the larger melanosomes present in dark skin types are associated with a more acidic skin surface (pH 4.3), compared to lighter skin types (pH 5.3). Melanosomes (and their melanin content) are mainly found in basal keratinocytes (Fig. 7.15).

Melanin protects the skin against the harmful effects of UV radiation on DNA and is also an efficient scavenger of damaging free radicals. However, a high concentration of melanin may adversely affect synthesis of vitamin D in darker-skinned individuals living in northern latitudes. Melanin pigmentation is both constitutive and facultative. Constitutive pigmentation is the intrinsic level of pigmentation and is genetically determined, whereas facultative pigmentation represents reversible changes

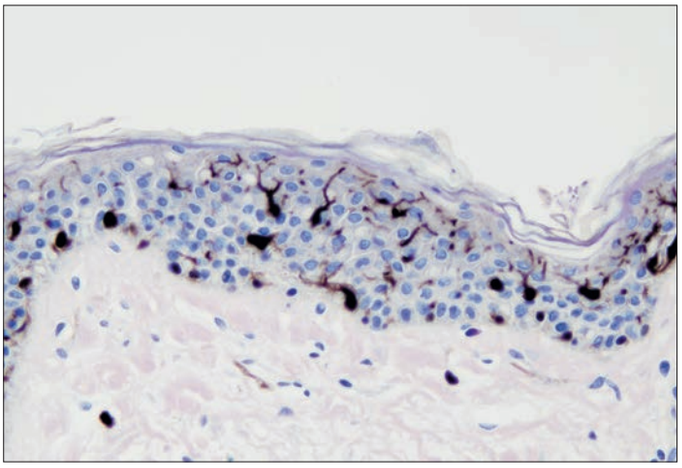

Fig. 7.16 Langerhans cells immunolabelled using a peroxidase method for the marker protein S100, extending dendrites between keratinocytes, mainly in the prickle cell layer of human thin skin. Basal layer melanocytes and scattered dermal cells (possibly of neural origin) are also positive for S100. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

induced by environmental agents, e.g. UV and X-radiation, chemicals and hormones. Racial variations in pigmentation are due to differences in melanocyte morphology and activity rather than to differences in number or distribution. In skin with naturally heavy pigmentation, the cells tend to be larger and more dendritic and to contain more large, late-stage melanosomes than the melanocytes of paler skins. The keratinocytes in turn contain more melanosomes, individually dispersed, whereas in light skins the majority are contained within secondary lysosomes to form melanosome complexes (D'Mello et al 2016).

The response to UV light includes immediate tanning with pigment darkening and can occur within minutes as a result of photo-oxidation of pre-existing melanin. Delayed tanning occurs after about 48 hours, and involves stimulation of melanogenesis within the melanocytes, and transfer of additional melanosomes to keratinocytes. There may also be some increase in size of active melanocytes, and in their apparent numbers, mainly through activation of dormant cells.

Langerhans cells

Langerhans cells are dendritic antigen-presenting cells that are distributed throughout the basal and prickle cell layers of the epidermis and its appendages, although their dendritic processes extend between tight junctions in the granular layer (Kubo et al 2014, Deckers et al 2018) (Figs 7.16–7.17). They are also present in other stratified squamous epithelia, including the buccal, tonsillar and oesophageal epithelia, as well as the cervical and vaginal mucosae, and the transitional epithelium of the bladder. In the eye, they are found in the conjunctiva but not in the cornea. In routine haematoxylin and eosin histological preparations, they appear as clear cells. They enter the epidermis from the bone marrow during development to establish the postnatal population (460–1000/mm^2, 2–3% of all epidermal cells, with regional variations), which is maintained by continual replacement from the marrow.

The nucleus is euchromatic and markedly indented, and the cytoplasm contains a well-developed Golgi complex, lysosomes (which often contain ingested melanosomes) and a characteristic organelle, the Birbeck granule, which is the ultrastructural hallmark of the Langerhans cell. The latter are discoid or cup-shaped, or have a distended vesicle resembling the head of a tennis racket; in section they often appear as a cross-striated rod 0.5 µm long and 30 nm wide. When stimulated by antigen, Langerhans cells migrate out of the epidermis to lymphoid tissues (see Fig. 4.14). Their numbers are increased in chronic skin inflammatory disorders, particularly of an immune aetiology, such as some forms of dermatitis.

Merkel cells

Merkel cells (see Commentary 1.4) are present as clear oval cells, singly or in groups, in the basal layer of the epidermis and in the outer root sheath of some large hair follicles. They are thought to be derived embryologically from the epidermis, although a neural crest origin has been considered. They can only be distinguished histologically from other clear cells (melanocytes and Langerhans cells) by immunohistochemical and ultrastructural criteria.

The plasma membrane of a Merkel cell has short, stiff processes that interdigitate with the adjacent basal keratinocytes to which it is attached by small desmosomes. The cytoplasm contains numerous closely packed intermediate filaments (mostly K8 and K18, but also K19 and K20) and characteristic 80–110 µm dense-core granules. The basal plasma membranes of many Merkel cells are closely opposed to the membrane of an axonal terminal that conveys the sensation of touch. They are slowly adapting mechanoreceptors that respond to directional deformations of the epidermis and the direction of hair movement by releasing a transmitter from their dense-core cytoplasmic granules. There is evidence that a subpopulation of Merkel cells lacks axonal contact and may serve a neuroendocrine function locally.

Merkel cells can undergo malignant transformation and give rise to a rare and aggressive tumour called a Merkel cell carcinoma (see Commentary 1.4) that typically presents with a painless, rapidly growing nodule on sun-exposed sites. The Merkel cell polyomavirus is clonally integrated in about 80% of Merkel cell carcinomas; the remaining 20% have a large number of ultraviolet-associated mutations.

Dermis

The dermis lies beneath the epidermis and is 15–40 times thicker than the epidermis, depending on the anatomical site (see Figs 7.1, 7.4). It is vital for the survival of the epidermis: important morphogenetic signals are exchanged at the interface between the two both during development and postnatally.

The dermis is an irregular, moderately dense connective tissue composed of an interwoven collagenous and elastic network in an amorphous ground substance of glycosaminoglycans, glycoproteins and bound water. It also contains nerves, blood vessels, lymphatics and epidermal appendages. Mechanically, the dermis provides considerable strength to the skin by virtue of the number and arrangement of its collagen fibres (which give it tensile strength) and its elastic fibres (which allow it to stretch and recoil). The density of its fibre meshwork, and therefore its physical properties, varies with different parts of the body, and with age and gender.

The dermis can be divided into two zones: a narrow, superficial papillary layer and a deeper reticular layer. The boundary between these two zones is indistinct. Fibroblasts, the main cell type of human dermis, are heterogeneous and at least four distinct sub-populations have been defined (Philippeos et al 2018). At a cellular level, different types of fibroblasts may have different properties with regard to Wnt (wingless gene family) signalling and responsiveness to interferon-γ. Their roles in the organisation of the extracellular matrix and tissue morphogenesis are only partially characterized: from a clinical perspective, future strategies involving *ex vivo* expansion or *in vivo* ablation of specific types of fibroblasts may have therapeutic applications in improving wound healing and reducing tissue fibrosis (Lynch and Watt 2018).

Adult dermal collagen is mainly of types I and III, in proportions of 80–85% and 15–20% respectively. Type I collagen fibres are coarse and found predominantly in the deeper reticular dermis, and the finer type III collagen is found in the papillary dermis and around blood vessels. Type IV collagen is found in the basal lamina between epidermis and dermis, and around Schwann cells of peripheral nerves and endothelial cells of vessels. Types V, VI and VII are minor collagenous components of the dermis. Elastic fibres form a fibrous network interwoven between the collagen bundles throughout the dermis and are more prominent in some regions, e.g. the axilla.

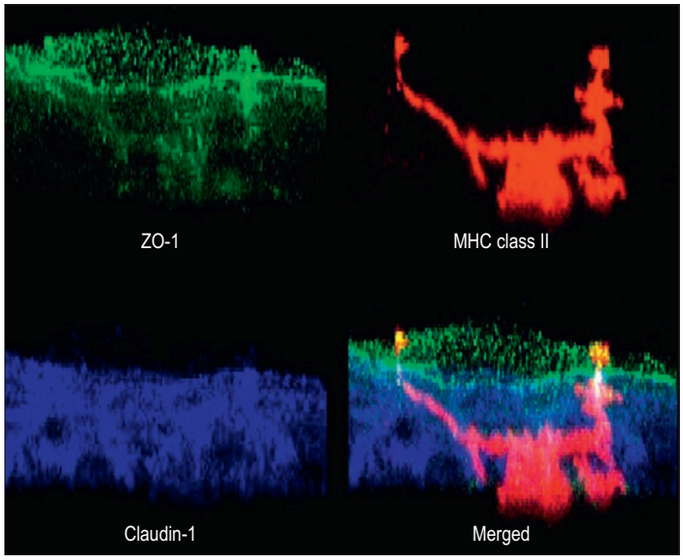

Fig. 7.17 Langerhans cell with dendritic processes extending through tight junctions (mouse skin). ZO-1 (zonula occludens-1; green) and claudin-1 (blue) are tight junction proteins; the Langerhans cell is positive for MHC class II antigen (red). The merged image reveals the close association of the Langerhans cell with tight junctions in antigen presentation. (Courtesy of Dr Akiharu Kubo, Keio University, Japan.)

Two major categories of cell are present in postnatal dermis, permanent and migrant, as is typical of all general connective tissues (Ch. 2). The permanent resident cells include cells of organized structures such as nerves, vessels, cells of the arrector pili muscles, and fibroblasts, which synthesize all components of the dermal extracellular matrix. The migrant cells originate in the bone marrow (see Fig. 4.12) and include macrophages, mast cells, eosinophils, neutrophils, T and B cells (including antibody-secreting plasma cells), and dermal interstitial dendritic cells, which are capable of immune surveillance and antigen presentation.

Layers of the dermis

Papillary layer

The papillary layer is a relatively thin zone immediately subjacent to the dermal–epidermal junction. It provides mechanical anchorage, metabolic support and trophic maintenance to the overlying epidermis, as well as supplying sensory nerve endings and blood vessels. The cytoskeleton of the basal epidermal keratinocytes is linked to the fibrous matrix of the papillary dermis through the attachment of keratin filament bundles to hemidesmosomes, then via anchoring filaments of the basal lamina, to the anchoring fibrils of type VII collagen, which extend into the papillary dermis. This arrangement provides a mechanically stable substratum for the epidermis.

The superficial surface of the dermis is shaped into numerous papillae or rete ridges, which interdigitate with rete pegs in the base of the epidermis and form the dermal–epidermal junction at their interface. The papillae have round or blunt apices, which may be divided into several cusps. In thin skin, especially in regions with little mechanical stress and minimal sensitivity, papillae are few and very small, while in the thick skin of the palm and sole of the foot they are much larger, closely aggregated, and arranged in curved parallel lines following the pattern of ridges and grooves on these surfaces (see Fig. 7.1). Lying under each epidermal surface ridge are two longitudinal rows of papillae, one on either side of the epidermal rete pegs, through which the sweat ducts pass on the way to the surface. Each papilla contains densely interwoven and fine bundles of types I and III collagen fibres. Elastic fibres are not fully formed in the papillary dermis. Also present is a capillary loop (see Fig. 7.4), and in some sites, especially in thick hairless skin, Meissner's corpuscle nerve endings. (see Figs 3.29, 3.30)

Reticular layer

The reticular layer is much thicker than the papillary dermis. Its bundles of collagen fibres are coarser and more compacted and form a strong but deformable three-dimensional lattice that contains a variable number of elastic fibres. The mostly parallel orientation of the collagen fibres may be related to local mechanical forces on the dermis and may be involved in the development of skin lines. In the reticular dermis, the elastic fibres are composed of amorphous elastin surrounding microfibrils within the centre of the elastic fibres. The elastic fibres lose their elastin component at the intersection of the reticular and papillary dermis, whereas the microfibrils continue into the papillary dermis as naked microfibrils that organize horizontally as elaunin fibres and vertically as oxytalan fibres.

Hypodermis

The hypodermis (subcutaneous tissue) is a layer of loose connective tissue of variable thickness that merges with the deep aspect of the dermis. It is often adipose, particularly between the dermis and musculature of the body wall (**Fig. 7.18**). It mediates the increased mobility of the skin, and its adipose component contributes to thermal insulation, acts as a shock absorber and constitutes a store of metabolic energy. Subcutaneous nerves, vessels and lymphatics travel in the hypodermis, their main trunks lying in its deepest layer, where adipose tissue is sparse. In the head and neck the hypodermis also contains striated muscles, e.g. platysma, which are remnants of more extensive sheets of skin-associated musculature found in other mammals (panniculus adiposus).

The amount and distribution of subcutaneous fat varies according to gender: it is generally more abundant and more widely distributed in females, whereas it diminishes from the trunk to the extremities in males. The total amount of subcutaneous fat tends to increase in both males and females in middle age. (At any age, the amount of adipose tissue reflects the quantity of lipid stored in adipocytes rather than a change in the number of cells.) There is an association with climate (rather than ancestry): superficial fat is more abundant in colder geographical regions. The hypodermis is most distinct on the lower anterior abdominal wall, where it is rich in elastic tissue and appears many-layered as it passes through the inguinal regions into the thighs. It is well differentiated in the limbs and the perineum, but is thin where it passes over the dorsal aspects of the hands and feet, the sides of the neck and face, around the anus, and over the penis and scrotum. It is almost absent from the external ears and atypical in the scalp and in the palms and soles.

The layers of the skin, including the subcutaneous tissues are tethered tightly together by connective tissue bands, the retinacula cutis (**Fig. 7.19**), forming densely packed ligament-like structures in some parts (Herlin et al 2014).

Pilosebaceous unit

The pilosebaceous unit consists of the hair and its follicle with an associated arrector pili muscle, sebaceous gland and sometimes an apocrine gland (see Fig. 7.1; **Fig. 7.20**). Not all elements of the unit occur together in all body regions.

Hairs

Hairs are filamentous cornified structures present over almost the entire body surface. They grow out of the skin at an angle (see Fig. 46.1), as is evident in the sloping of the hairs on the dorsum of forearm, hand and fingers towards the ulnar side. Hairs are absent from several areas of the body, including the thick skin of the palms, soles, the flexor surfaces of the digits, the thin skin of the lip, umbilicus, nipples, glans penis and clitoris, the labia minora and the inner aspects of the labia majora and prepuce. The presence, distribution and relative abundance of hair in certain regions such as the face (in males), pubis and axillae, are secondary sexual characteristics that play a role in socio-sexual communication. There are individual variations in density, form, distribution and pigmentation. Hairs assist in thermoregulation, e.g. on the scalp they provide some protection against injury and the harmful effects of solar radiation. They also have a sensory function.

Hair density varies from approximately 600 per cm^2 on the face to 60 per cm^2 on the rest of the body. In length, hairs range from less than a millimetre to more than a metre, and in width from 0.005 to 0.6 mm. They can be straight, coiled, helical or wavy, and differ in colour depending on the type and degree of pigmentation. Curly hairs tend to have a flattened cross-section, and are weaker than straight hairs. Over most of the body surface, hairs are short and narrow (vellus hairs) and in some areas these hairs do not project beyond their follicles, e.g. in eyelid skin. In other regions they are longer, thicker and often heavily pigmented (terminal hairs); these include the hairs of the scalp, the eyelashes and eyebrows, and the postpubertal skin of the axillae and pubis, and the moustache, beard and chest hairs of males. The presence in females of coarse terminal hairs in a male-like pattern is termed hirsutism and can be familial or a sign of an endocrine disorder involving excess androgen production.

Hair follicle

The hair follicle (see Figs 7.1, 7.20; **Fig. 7.21A**) is a downgrowth of the epidermis containing a hair. It may extend deep (3 mm) into the hypodermis, or may be superficial (1 mm) within the dermis. Typically, the long axis of the follicle is oblique to the skin surface; with curly hairs it is also curved. There are cycles of hair growth and loss, during which the follicle presents with different appearances. In the anagen phase, the hair is actively growing and the follicle is at its maximal extent of development. In the involuting or catagen phase, hair growth ceases and the follicle shrinks. During the resting or telogen phase, the inferior segment of the follicle is absent. This is succeeded by the next anagen phase. Further details of the hair growth cycle are given below.

Anagen follicle

The anagen follicle has several regions. The innermost part is the inferior segment, which includes the hair bulb region extending up to the level of attachment of the arrector pili muscle at the follicular bulge. Between this point and the site of entry of the sebaceous duct is the isthmus, above which is the infundibulum, or dermal pilary canal, which is continuous with the intraepidermal pilary canal. Below the sebaceous duct, the hair shaft and follicular wall are closely connected, and towards the upper end of the isthmus the hair becomes free in the pilary canal. Below the infundibulum, the follicle is surrounded by a thick perifollicular dermal coat containing type III collagen, elastin, sensory nerve fibres and blood vessels, and into which the arrector pili muscle fibres blend. A thick, specialized basal lamina, the glassy membrane, marks the interface between dermis and the epithelium of large hair follicles.

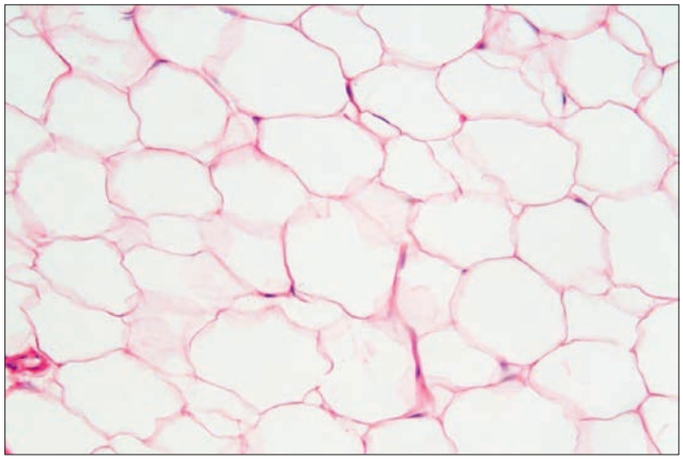

Fig. 7.18 Adipocytes (fat cells) in human skin.

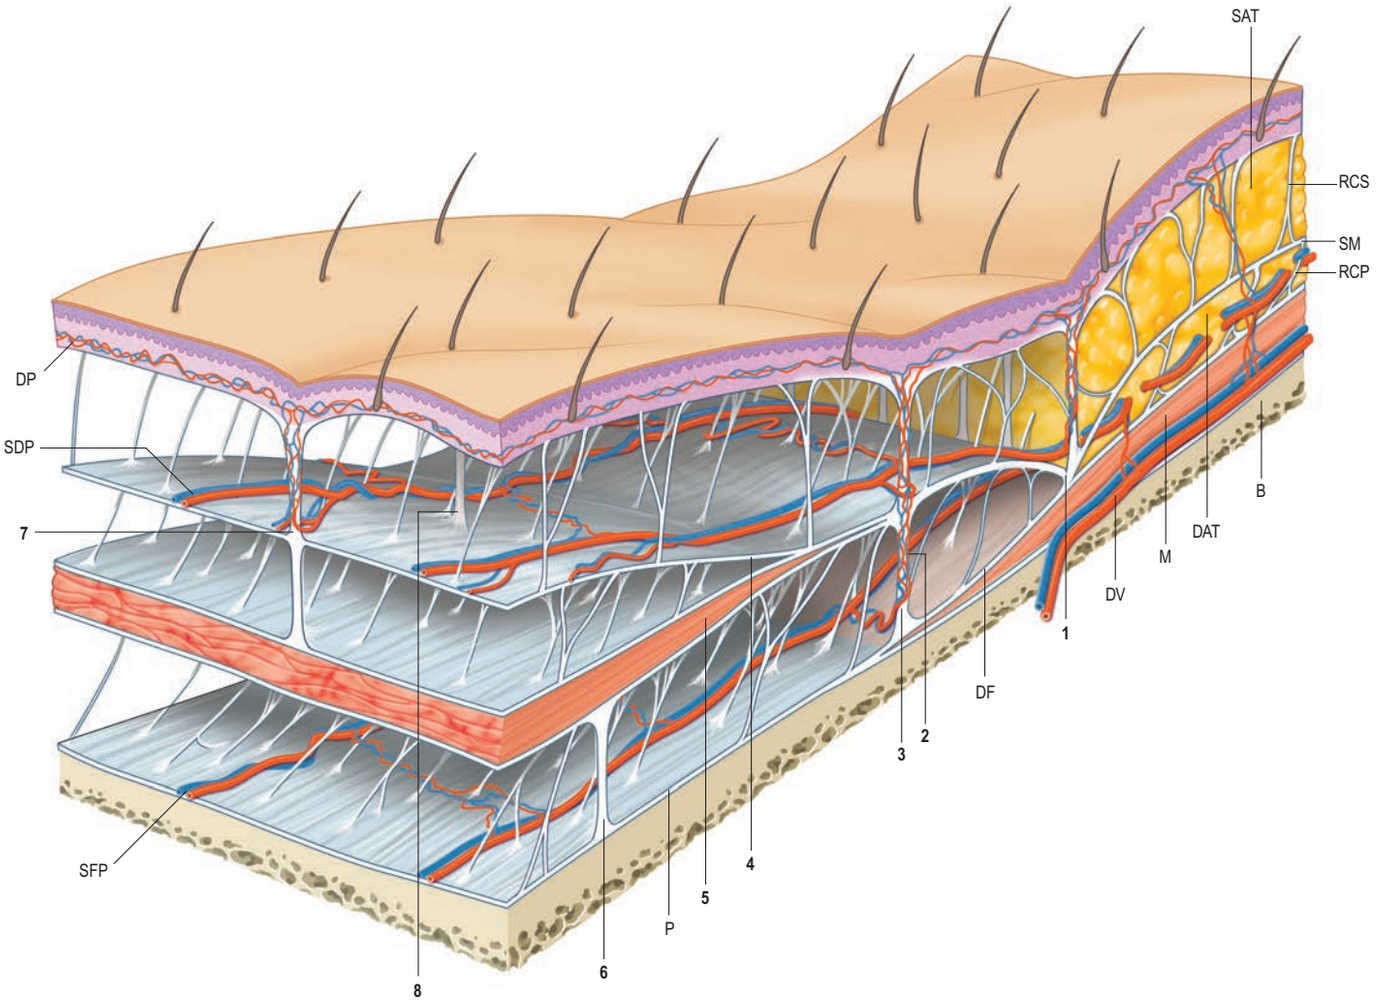

Fig. 7.19 Generic model of the skin/subcutaneous tissue complex. Note retinacula cutis. Interlobular septa are not shown. Abbreviations: B, bone; DAT, deep adipose tissue; DF, deep fascia; DP, dermal plexus; DV, deep vessels; M, muscle; P, periosteum; RCP, retinaculum cutis profondus; RCS, retinaculum cutis superficialis; SAT, superficial adipose tissue; SM, stratum membranosum (superficial fascia) SDP, sub-dermal plexus; SFP, suprafascial plexus. Key: 1, region of adhesion between the SM and the DP (opposite the sternum or the iliac crest); 2, perforating vessels running with RCP and RCS thickening; 3, skin 'ligaments' consisting of combined densification of the RCS and RCP (e.g. Furnas' ligament, McGregor's patch, Cooper's ligaments); 4, SM duplication that appears mostly in fatty areas (e.g. cheeks, lower back, breasts, thighs); 5, superficial fascia containing smooth muscle (e.g. superficial musculo-aponeurotic system (SMAS), dartos, areolar muscle, corrugator cutis ani, palmaris brevis); 6, thickening of the RCP connecting the SM and SMAS at a deep level; 7 and 8, thickening of the RCSs connecting the SM and SMAS to the skin. (Adapted from Herlin et al 2015 Three-dimensional study of the skin/subcutaneous complex using in vivo whole body 3T MRI: review of the literature and confirmation of a generic pattern of organization.)

Hair bulb

The hair bulb forms the lowermost portion of the follicular epithelium and encloses the dermal hair papilla of connective tissue cells (**Fig. 7.21B**). The dermal hair papilla is an important cluster of inductive mesenchymal cells, which is required for hair follicle growth in each cycle throughout adult life; it is a continuation of the layer of adventitious mesenchyme that follows the contours of the hair follicle. The hair bulb generates the hair and its inner root sheath. A hypothetical line drawn across the widest part of the hair bulb divides it into a lower germinal matrix and an upper bulb. The germinal matrix is formed of closely packed, mitotically active pluripotential keratinocytes, among which are interspersed melanocytes and some Langerhans cells. The upper bulb consists of cells arising from the matrix. These migrate apically and differentiate along several lines. Those arising centrally form the hair medulla. Radially, successive concentric rings of cells give rise to the cortex and cuticle of the hair and, outside this, to the three layers of the inner root sheath. The latter are, from innermost to outer, the cuticle of the inner root sheath, Huxley's layer and Henle's layer. Henle's layer is surrounded by the outer root sheath, which forms the cellular wall of the follicle (see Fig. 7.21). Differentiation of cells in the various layers of the hair and its inner root sheath begins at the level of the upper bulb and is asynchronous, beginning earliest in Henle's layer and Huxley's layer.

Structure of hair and its sheaths

A fully developed hair shaft consists of three concentric zones, which are, from outermost to inner, the cuticle, cortex and medulla. Each has different types of keratin filament proteins and different patterns of cornification. In finer hairs the medulla is usually absent. The cuticle forms the hair surface and consists of several layers of overlapping cornified squames directed apically and slightly outwards (**Fig. 7.22**). Immature cuticle cells have dense amorphous granules aligned predominantly along the outer plasma membrane with a few filaments. The cortex forms the greater part of the hair shaft and consists of numerous closely packed, elongated squames, which may contain nuclear remnants and melanosomes. Immature cortical cells contain bundles of closely packed filaments but no dense granules, and when fully cornified, they have a characteristic thumbprint appearance with filaments arranged in whorls. The medulla, when present, is composed of loosely aggregated and often discontinuous columns of partially disintegrated cells containing vacuoles, scattered filaments, granular material and melanosomes. Air cavities lie between the cells or even within them.

Henle's layer and Huxley's layer of the inner root sheath contain irregular dense keratohyalin granules and associated filaments in the precornified state. At the level of the upper bulb, Henle's layer begins to cornify, as does Huxley's layer at the middle of the inferior follicle. When fully differentiated, cells of both layers have a thickened cornified

envelope enclosing keratin filaments embedded in a matrix. The cells of the inner root sheath cuticle undergo terminal differentiation at a level closer to the hair bulb than that of Huxley's layer, but lack a clear-cut filament pattern such as is seen in the cortical cells of the hair shaft. As they cornify, the cuticle cells of the inner root sheath and hair become interlocked. At about the level of entry of the sebaceous duct, above the isthmus, the inner root sheath undergoes fragmentation, and the hair then lies free in the pilary canal.

The outer root sheath, beginning at the level of the upper bulb, is a single or double layer of undifferentiated cells containing glycogen. Higher up the follicle it becomes multilayered. At the isthmus all remaining cell layers of the follicle sheath become flattened, compressed and attenuated. On emerging from the isthmus, the outer root sheath assumes the stratified, differentiating characteristics of interfollicular epidermis, with which it becomes continuous. At the level of entry of the sebaceous duct, it forms the wall of the pilary canal.

Fig. 7.20 A pilosebaceous unit in thin, hairy skin seen at low magnification. The hair follicle, hair shaft and hair root extend almost vertically through the field, the follicle joining the interfollicular epidermis (E). The acini (A) of a sebaceous gland, which are also sectioned tangentially through their capsules (centre bottom, below the portion of the hair follicle in section), open into the follicle in centre field. Note the associated arrector pili smooth muscle (AP).

Hair cycle and growth of hair

Recurrent cyclic activity of hair follicles involves growth rest, and shedding of hair in phases (Purba et al 2016). In humans, these occur in irregular cycles of variable duration; there are regional and other variations in the length of the individual phases. In the growing or anagen phase, follicle and hair are as described above. Melanocytes are active only in mid-anagen, and are capable of producing both pheo- and eumelanosomes, which they pass to precortical and medullary keratinocytes. Changes in hair colour of an individual, usually in adolescence, are due to alterations in the dominant type of melanosome produced.

Anagen is followed by the involuting or catagen phase, during which mitotic activity of the germinal matrix ceases, the base of the hair condenses into a club that moves upwards to the level of the arrector pili muscle, and the whole inferior segment of the follicle degenerates. The dermal papilla also ascends and remains close to the base of the shortened follicle and its enclosed club hair, a situation that persists during the resting or telogen phase. During telogen, melanocytes become amelanotic and can be identified only ultrastructurally. At the beginning of the next anagen, the epithelial cells at the base of the follicle divide to form a secondary hair rudiment, which envelops the dermal papilla to form a new hair bulb. This grows downwards, reforming the inferior segment of the follicle, from which a new hair grows up alongside the club hair, which is eventually shed.

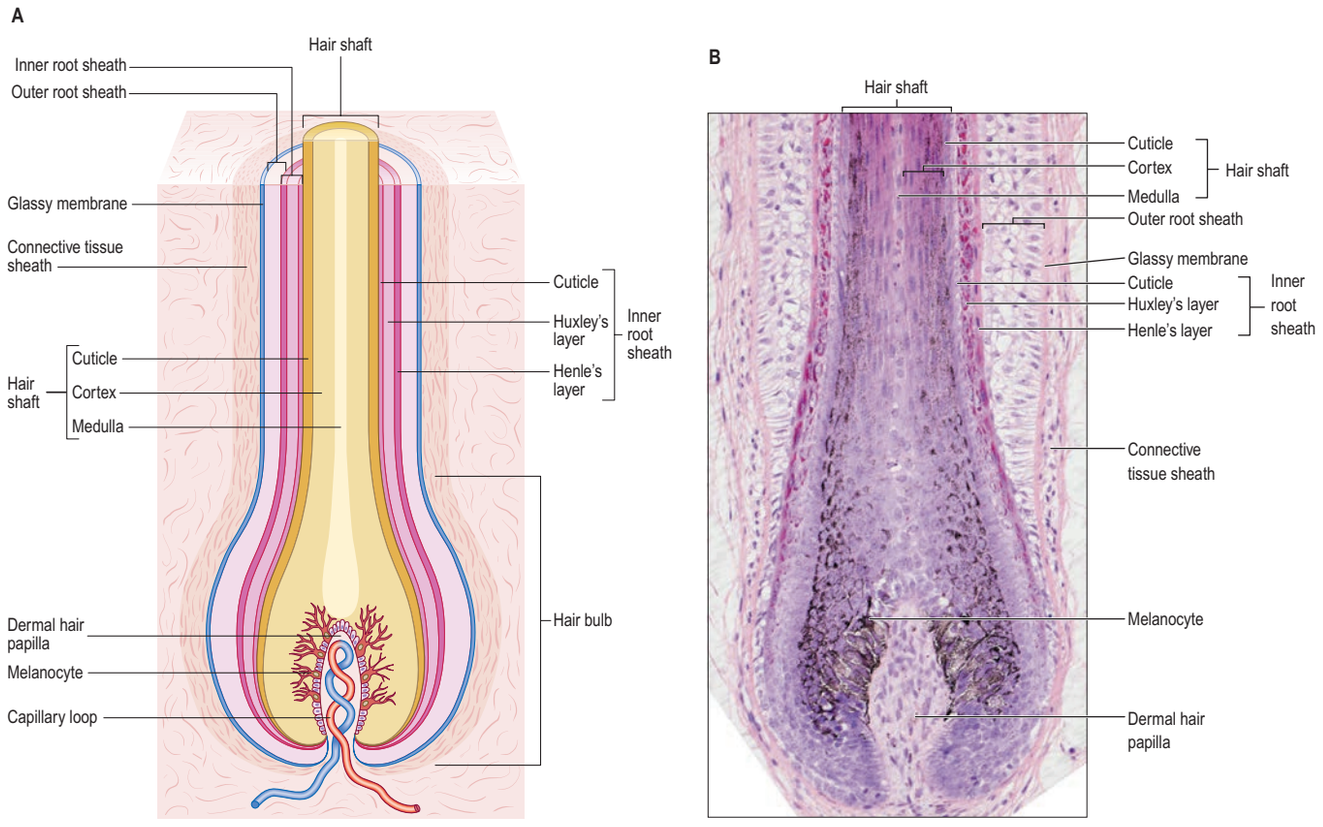

Fig. 7.21 **A**, The major structural features of the base of a hair follicle, showing the organization of the major layers of the hair and surrounding sheath, arising from the hair bulb. A dermal hair papilla invaginates the bulb, and along the basal layer of the epidermis, at its interface with the dermis, melanocytes insert their dendrites among the keratinocytes forming the hair. **B**, The hair bulb at the base of the human hair follicle. The dermal hair papilla invaginates the bulb from its fibrous outer sheath, carrying a loop of capillaries. Melanocytes in the germinal matrix (equivalent to the basal layer of interfollicular epidermis) extend dendrites into the adjacent layers of keratinocytes, to which they pass melanosomes. The layers of the hair shaft and root sheaths are also indicated. (B, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

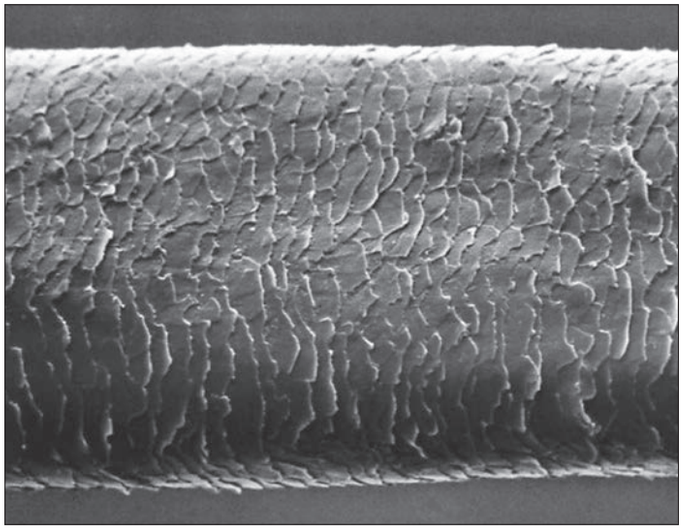

Fig. 7.22 A scanning electron micrograph of a scalp hair, showing details of its surface structure. Note that the cuticular cells overlap each other; their free ends point towards the apex of the hair. (Courtesy of Michael Crowder MD.)

Postnatally, hairs exhibit regional asynchrony of cycle duration and phase leading to an irregular pattern of growth and replacement. In some regions, such as the scalp, the cycle is measured in years; in others, such as general body hair, the cycle is much shorter and hairs are therefore limited in length. At puberty, hair growth and generation of much thicker hairs occurs on the pubes and axillae in both sexes, and on the face and trunk in males. The actions of hormones on hair growth are complex, and involve not only sex hormones, but also those of the thyroid, suprarenal cortex and pituitary glands. Androgens stimulate facial and general body hair formation. After about the first 30 years, they tend to cause the thick terminal hairs of the scalp to change to small vellus hairs, which produces recession from the forehead and sometimes almost complete male pattern baldness. In females, oestrogens tend to maintain vellus hairs; postmenopausal reduction of oestrogens may permit stronger facial and bodily hair growth. In mid-pregnancy, hair growth may be particularly active but later, often post partum, an unusually large number of hairs enter the telogen phase and are shed before the growth cycle recommences. In older males, growth of hairs on the eyebrows and within the nostrils and external acoustic meatus increases, whereas elsewhere on the body, growth slows and the hairs become much finer.

Measurements of the rate of growth of individual hairs vary considerably, probably because of the influence of the factors mentioned above. A rate of 0.2–0.44 mm per 24 hours in males is usually given; the higher rate occurs on the scalp.

Sebaceous glands

Sebaceous glands are small saccular structures (see Figs 7.1, 7.20; **Fig. 7.23**) found in the dermis. Most associate with the hair follicle and arrector pili muscle to form the pilosebaceous unit. They are present over the whole body except the thick, hairless skin of the palm, soles and flexor surfaces of digits. Typically, they consist of a cluster of secretory acini, which open by a short common duct into the dermal pilary canal of the hair follicle. They release their lipid secretory product, sebum, into the canal by a holocrine mechanism (see below). In some areas of thin skin that lack hair follicles, their ducts open instead directly onto the skin surface, e.g. on the lips and corners of the mouth, the buccal mucosa, nipples (Montgomery's glands), areolae of the female breast, penis, inner surface of the prepuce, clitoris and labia minora. At the margins of the eyelids, the large, complex palpebral tarsal glands (Meibomian glands) are of this type. They are also present in the external acoustic meatus (ceruminous glands).

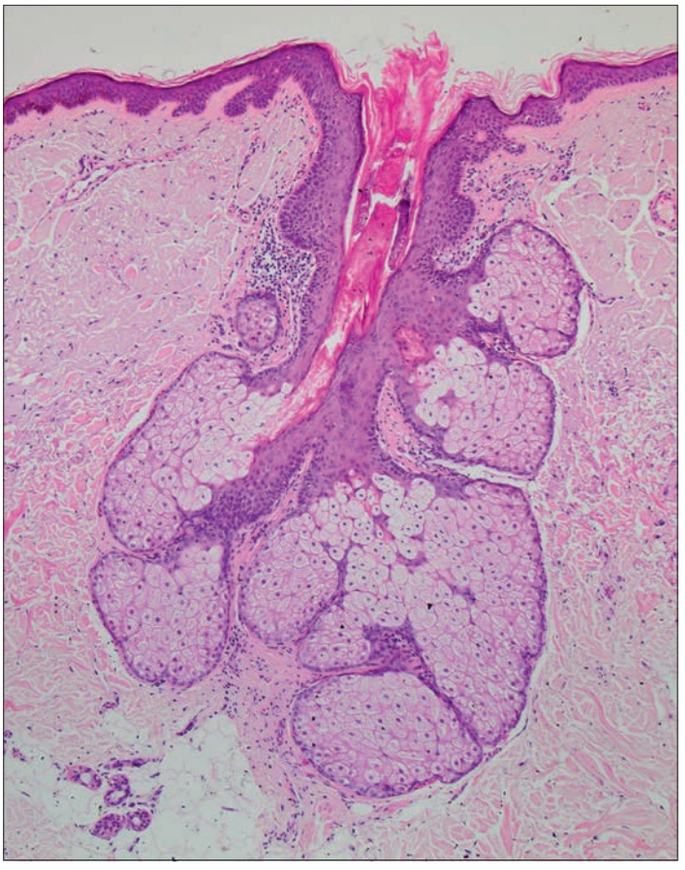

Fig. 7.23 A sebaceous gland, showing a group of secretory acini opening into a hair follicle (top). The distended sebocytes are filled with their oily secretion (sebum), which is discharged into the hair follicle by the holocrine disintegration of secretory cells. (Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

In general, the numbers of sebaceous glands in any given area reflect the distribution of hair follicles, ranging from an average of 100/cm^2 over most of the body to as many as 400–900/cm^2 on the face and scalp. They are also numerous in the midline of the back. Individual sebaceous glands are particularly large on the face, around the external acoustic meatus, chest and shoulders, and on the anogenital surfaces. Those on the face are often related to very small vellus hairs whose follicles have particularly wide apertures (Zouboulis et al 2016).

Microscopically, the glandular acini are enclosed in a basal lamina supported by a thin dermal capsule and a rich capillary network. Each acinus is lined by a single layer of small, flat, polygonal epithelial cells (sebocytes), which, when terminally differentiated, produce and accumulate sebum. They possess euchromatic nuclei and large nucleoli, scattered keratin filaments, free ribosomes, smooth endoplasmic reticulum and rounded mitochondria, and are attached to each other by desmosomes. Mitotically active cells give rise to progeny that move gradually towards the centre of the acinus, increasing in volume and accumulating increasingly large lipid vacuoles. The nuclei become pyknotic as the cells mature. The huge distended cells ultimately disintegrate, filling the central cavity and its duct with a mass of fatty cellular debris (holocrine secretion; see Figs 2.6, 7.23). The process takes 2–3 weeks. The secretory products pass through a wide duct lined with keratinized stratified squamous epithelium into the infundibulum of the hair follicle and then to the surface of the hair and the general epidermis.

While its full range of functions in the skin remains to be clarified, sebum is a key component of the epidermal barrier, as well as having a key role in the skin's immune system. Sebum also contributes to a characteristic body odour. When first formed, sebum is a complex mixture of over 50% di- and triglycerides, with smaller proportions of wax esters, squalene, cholesterol esters, cholesterol and free fatty acids. At birth, sebaceous glands are quite large, regressing later until stimulated again at puberty. At that time, sebaceous gland growth and secretory activity increase greatly in both males and females, under the influence of androgens (testicular and suprarenal), which act directly on the gland. Excessive amounts of sebum may become impacted within the duct and this, associated with hyperkeratinization, may lead to blockage and formation of a comedone. This may become inflamed, and is the primary lesion of acne. Acne is the most common disease caused by dysfunction of the sebocyte. Oestrogens have an effect opposite to that of androgens; sebum secretion is considerably lower in women, and usually decreases significantly after the menopause (Piérard-Franchimont and Piérard 2002).

Apocrine glands

Apocrine glands are particularly large glands found in the dermis or subcutaneous fat. They are conventionally classed as a type of sweat gland. In the adult, they are present in the axillae, perianal region, areolae, periumbilical skin, prepuce, scrotum, mons pubis and labia minora.

An apocrine gland consists of a basal secretory coil and a straight duct that opens into either the pilary canal above the duct of the sebaceous gland, or directly onto the skin surface if there is no associated hair. The secretory region may be as much as 2 mm wide and its coils often anastomose to form a labyrinthine network. Each coil is lined by cuboidal secretory cells whose apical cytoplasm projects into the lumen and basally is in contact with a layer of myoepithelial cells within a thick basal lamina. The secretory cells contain vacuoles, vesicles and dense granules of varying size and internal structure; the numbers and character vary with the cycle of synthesis and discharge. The mechanism of secretion is still not clear but may involve merocrine secretion of granules, apocrine secretion or complete holocrine disintegration of the cells (see Fig. 2.6).

Apocrine activity is minimal before puberty, after which it is androgen-dependent and responsive to emotional stimuli. It is controlled by adrenergic nerves and is sensitive to adrenaline (epinephrine) and noradrenaline (norepinephrine). The secretion is initially sterile and odourless, but it undergoes bacterial decomposition to generate odorous and musky compounds, including short-chain fatty acids, and steroids such as 5α-androstenone. In many animals these are potent pheromonal signals but their role in humans is less certain.

Arrector pili muscles

The arrector pili muscles are small bundles of closely packed smooth muscle cells that form oblique links between the dermal sheaths of hair

follicles and the papillary layer of the dermis (see Figs 7.1, 7.20). They show the typical features of smooth muscle cells and are separated by narrow spaces containing collagen fibres and unmyelinated noradrenergic sympathetic axons. The muscles are attached to the bulge region of the follicles by elastin fibrils, and are directed obliquely and towards the side to which the hair slopes superficially. The sebaceous gland occupies the angle between the muscle and the hair follicle: muscle contraction helps to expel the gland contents. Contraction tends to pull the hair into a more vertical position and to elevate the epidermis surrounding it into a small hillock (goose bump), dimpling the skin surface where the muscle is inserted superficially. Arrector pili muscles are absent from facial, axillary and pubic hairs, eyelashes and eyebrows, and from the hairs around the nostrils and the external acoustic meatus.

Sweat glands

The vast majority of sweat glands (**Figs 7.24–Fig. 7.25**) are classically termed eccrine, although their mode of secretion includes typical merocrine mechanisms. The glands are long, unbranched, tubular structures, each with a highly coiled, secretory portion up to 0.4 mm in diameter, situated deep in the dermis or hypodermis. From there, a narrower, straight or slightly helical ductal portion emerges (see Fig. 7.1). The walls of the duct fuse with the base of an epidermal rete peg and the lumen passes between the keratinocytes, often in a tight spiral, particularly in thick hairless skin (**Fig. 7.26**), and opens via a rounded aperture (pore) onto the skin surface (see Fig. 7.7). In thick hairless skin, sweat glands discharge along the centres of friction ridges, incidentally providing fingerprint patterns for forensic analysis. Sweat glands have an important thermoregulatory function, and their secretion enhances the grip and sensitivity of the palms and soles (Shiohara et al 2016).

Eccrine sweat glands are absent from the tympanic membrane, margins of the lips, nail bed, nipple, inner preputial surface, labia minora, penis and clitoris, all sites where apocrine glands are located. They are numerous elsewhere, their frequency ranging from 80 to over 600/cm^2, depending on position and genetic variation. The total number is estimated to be between 1.6 and 4.5 million, with the greatest density in plantar skin.

Microscopically, the secretory coil consists of a pseudostratified epithelium enclosing a lumen. Three types of cell have been described: clear cells, from which most of the secretion is derived; dark cells, which share the same lumen; and myoepithelial cells. Clear cells are approximately pyramidal in shape, and their bases rest on the basal lamina or are in contact with the myoepithelial cells. Their apical plasma membranes line lateral intercellular canaliculi that connect with the main lumen. The basolateral plasma membranes are highly folded, and interdigitate with apposed clear cells; they have the basal membrane infoldings typical of cells involved in transcytotic fluid and ion transport from the interstitial fluid to the glandular lumen. Their cytoplasm contains glycogen granules, mitochondria, rough endoplasmic reticulum and a small Golgi complex, but few other organelles. The nucleus is round and moderately euchromatic. Dark cells are pyramidal and lie closer to the lumen, such that their broad ends form its lining. Their cytoplasm contains a well-developed Golgi complex, numerous vacuoles and vesicles, and dense glycoprotein granules, which they secrete by a typical merocrine mechanism. Myoepithelial cells (see Figs 2.3–2.4) resemble those associated with secretory acini of the salivary glands and breast, and contain abundant myofilaments.

The intradermal sweat duct is composed of an outer basal layer and an inner layer of luminal cells connected by numerous desmosomes. The intraepidermal sweat duct (acrosyringium) is coiled and consists of two layers of cells, which, developmentally, are different from the surrounding keratinocytes and can be distinguished from them by the presence of keratin K19. The outer cells near the surface contain keratohyalin granules and lamellar granules, and undergo typical cornification. The inner cells, from a mid-epidermal level, contain numerous vesicles, undergo an incomplete form of cornification, and are largely shed into the lumen at the level of the cornified epidermal layer. For further details of the structure and immunocytochemical profile of sweat glands, see Kurata et al (2017).

Sweat is a clear, odourless fluid, hypotonic to tissue fluid, and contains mainly sodium and chloride ions, but also potassium, bicarbonate, calcium, urea, lactate, amino acids, immunoglobulins and other proteins. Excessive sweating can lead to salt depletion. Heavy metals and various organic compounds are eliminated in sweat. When first secreted, the fluid is similar in composition to interstitial fluid. It is modified as it passes along the duct by the action mainly of the basal cells, which resorb sodium, chloride and some water: the hormone aldosterone enhances this activity. The sweat glands are capable of producing up to 10 litres of sweat per day, in response to thermal, emotional and taste stimuli, mediated by unmyelinated sympathetic cholinergic fibres. The glands also respond to adrenaline (epinephrine). Thermoregulation is coordinated via a heat centre in the preoptic region, in and near the rostral hypothalamus, which reacts to changes in blood temperature and afferent stimuli from the skin by initiating appropriate responses such as controlling cutaneous blood supply, the rate and volume of sweat secretion (for evaporation at the surface) and shivering.

Nail apparatus

Nails (**Fig. 7.27**) are homologous with the cornified layer of the general epidermis. They consist of compacted, anucleate, keratin-filled squames in two or three horizontal layers. Ultrastructurally, the squames contain closely packed filaments that lie transversely to the direction of proximodistal growth, and are embedded in a dense protein matrix. Unlike the general epidermis, squames are not shed from the nail plate surface. A variety of mineral elements including calcium are present in nail. The hardness of nail is determined by the arrangement and cohesion of the layers of squames and their internal fibres, and not by the calcium content. Although the water content of nail is low, nail is 10 times more permeable

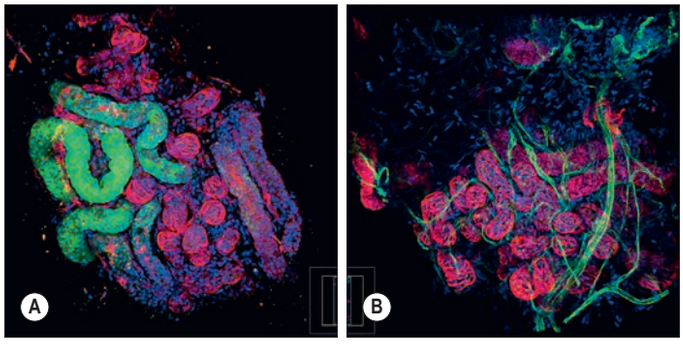

Fig. 7.25 Whole mount, 3D images of human sweat glands. **A**, The coiled secretory portion is identified by the presence of elongated myoepithelial cells labelled with anti-smooth muscle actin (red). Ducts are labelled with anti-calcium binding protein (S100) A2 (green). Nuclei are stained blue with Hoechst 33342 dye. **B**, Elongated myoepithelial cells, labelled with anti-keratin 5 (red) wrap around the coiled secretory portion of the gland. Blood vessels are labelled with anti-CD31 (green). Nuclei are stained blue, as above. (Courtesy of Dr Ryuichiro Kurata and Professor Kiyotoshi Sekiguchi, Osaka University.)

to water than the general epidermis: the softness and elasticity of the nail plate are related to its degree of hydration.

The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed and hyponychium.

Nail plate

The nail plate is embedded within the proximal and lateral nail folds. It is approximately rectangular in shape and is mostly convex in both longitudinal and transverse axes. There is considerable inter- and intra-individual variation (see Fig. 7.27). The thickness of the plate increases proximodistally from about 0.7 mm to 1.6 mm, although the terminal thickness varies between individuals. The surface of the nail plate may show fine longitudinal ridges, and its undersurface is grooved by corresponding ridges in the nail bed. Disturbances of growth pattern or disease may lead to transverse ridging or grooves. Minute trapped air bubbles may produce white flecks that move distally with the growth of the nail plate.

The nail plate arises from compacted cornified epithelial cells derived from the dorsal, intermediate and ventral nail matrices. It is densely adherent to the matrices on its undersurface but becomes a free structure distal to the onychodermal band, where it separates from the nail bed. The dorsal aspect of the nail plate originates from the more proximal regions of the germinal matrix, i.e. dorsal and intermediate matrices, whereas the deeper, palmar (volar) aspect of the plate originates from the ventral matrix.

Nail folds

The sides of the nail plate are bordered by the lateral nail folds, which are continuous with the proximal fold (see Fig. 7.27). They are bounded by the attachment of the skin to the lateral aspect of the distal phalanx margin and the lateral nail. The proximal nail fold provides the visible proximal border to the nail apparatus. It consists of superficial and deep epidermal layers separated by a core of dermis. The epidermis of the superficial layer lacks hair follicles and epidermal ridges, and its cornified distal margin extends over the nail plate as the cuticle or eponychium. The deep layer merges with the nail matrix. The eponychium is bounded by the fascial attachment of the skin to the base of the distal phalanx, distal to the insertion of the extensor tendon, and its distal free edge. It adheres to the dorsal aspect of the nail plate and overlies the root of the nail.

Nail matrix

The nail matrix is the main source of the nail plate and can be subdivided into three parts. Proximally, it is defined as the palmar or volar surface (undersurface) of the proximal nail fold. The intermediate matrix (germinal matrix) starts where the dorsal matrix folds back on itself and extends as far as the distal portion of the lunula (lunule). The ventral matrix (sterile matrix) is the remainder of the nail bed; it starts at the distal border of the lunula and ends at the hyponychium.

The matrix epithelium consists of typical basal and prickle layer keratinocytes, among which are scattered melanocytes and Langerhans cells. Cornified cells of the dorsal and ventral aspects of the matrix are steadily extruded distally to form the nail plate. The proximal 50% of the nail matrix contributes approximately 80% of the nail plate. This process continues into the nail bed at the distal edge of the lunula, which is formed where the distal portion of the ventral matrix underlies the nail plate.

The lunula is pale, opaque and convex, and is most prominent in the thumb nail. It is not known why the lunula is so pale compared with the more distal translucent pink nail bed. The lack of colour may reflect the thickness of the epidermis in the lunula and/or a paucity of capillaries in the dermis of the lunula.

Nail bed

The epidermis of the nail bed extends from the distal margin of the lunula to the hyponychium. The distal margin of the nail bed, which is the point where the nail plate becomes free of the nail bed, is called the onychodermal band. The surface of the nail bed is ridged and grooved longitudinally, corresponding to a similar pattern on the undersurface of the nail plate. This arrangement results in a tight interlocking between the nail plate and the underlying nail bed, protecting against microbial invasion and the collection of debris underneath the nail. The epidermis of the nail bed is thin and lacks a granular layer. It consists of 2–3 layers of nucleated cells that lack keratohyalin granules, and a thin cornified layer that moves distally with the growing nail plate. It contains an occasional sweat gland distally.

The dermis of the nail bed is anchored to the periosteum of the distal phalanx without an underlying subcutaneous layer. It forms a tight compartment, which means that infections involving the nail bed or an increase in pressure, e.g. resulting from a haematoma, may cause severe pain that may be relieved by the removal of part or all of the nail plate. The dermis of the nail bed is richly vascularized. The blood vessels are arranged longitudinally and display numerous glomus bodies, which are encapsulated arteriovenous anastomoses involved in the physiological control of peripheral blood flow in relation to temperature. The dermis of the nail bed is well innervated by numerous sensory nerve endings, including Merkel endings and Meissner's corpuscles. Nail bed cells differentiate towards the nail plate and contribute to its thickness ventrally.

Hyponychium

The hyponychium is the area under the free nail between the onychodermal band proximally and the distal groove. It is an epidermal ridge that demarcates the junction between the finger pulp and the subungual structures.

Nail growth

Nail growth is determined by the turnover rate of the matrix cells, which varies with digit, age, environmental temperature and season, time of day, nutritional status, trauma and various pathologies. Generally, the rate of growth is related to the length of the digit, being fastest in the middle finger of the hand (approximately 0.1 mm per day) and slowest in the little finger. Fingernails grow 3–4 times faster than toenails, more quickly in summer than in winter, and faster in the young than in the old. A fingernail grows out in about 6 months, whereas a toenail is replaced, on average, in 18 months.

VASCULAR SUPPLY, LYMPHATIC DRAINAGE AND INNERVATION

Vascular supply and lymphatic drainage

Cutaneous blood flow amounts to approximately 5% of the cardiac output. The cutaneous circulation has an important thermoregulatory function, and is organized so that its capacity can be rapidly increased or decreased by as much as 20 times, in response to a need to lose or conserve body heat. The ability to control skin blood flow decreases with ageing, making older adults less able to thermoregulate adequately. Lifestyle factors, such as physical activity, diet and smoking, might interact with the ageing process to modulate 'normal' age-associated changes in the cutaneous microcirculation.

The blood supply to the skin originates from the direct cutaneous, musculocutaneous and fasciocutaneous systems. The direct cutaneous system of vessels is derived from the main arterial trunks and accompanying veins. These vessels course in the subcutaneous fat parallel to the skin surface and are confined to certain areas of the body, e.g. the supraorbital artery, the superficial circumflex iliac artery and the dorsalis pedis artery. The musculocutaneous perforators arise from the intramuscular vasculature, pass through the surface of the muscle, and pierce the deep fascia to reach the skin by spreading out in the subcutaneous tissues. The fasciocutaneous system consists of perforating branches from deeply located vessels (deep to the deep fascia) that pass along intermuscular septa and then fan out at the level of the deep fascia to reach the skin. Examples include the fasciocutaneous perforating vessels from the radial and ulnar arteries.

The direct cutaneous vessels, musculocutaneous perforators and fasciocutaneous perforators each contribute to six anastomosing horizontal reticular plexuses of arterioles (Fig. 7.28), which have vascular connections between them and which ultimately provide the blood supply to the skin. Three plexuses are located in the skin itself and supply all elements including the sweat glands and pilosebaceous units. The subpapillary plexus is located at the junction of the papillary and reticular layers of the dermis and gives off small branches that form perpendicular capillary loops in the dermal papillae (usually one loop per papilla) (see Figs 7.1, 7.4; Fig. 7.29). The reticular dermal plexus is located in the middle portion of the dermis and is primarily venous. The deep dermal plexus is located in the deepest part of the reticular dermis and on the undersurface of the dermis. The close association between arteriolar and venous plexuses allows countercurrent heat exchange between bloods at different temperatures.

The remaining three plexuses are the subcutaneous plexus, and two plexuses associated with the deep fascia. The deep fascia has a plexus on its deep surface and a more extensive plexus superficially, an arrangement that is much more pronounced in the limbs than it is in the trunk.

The general structure and arrangement of the microvasculature is described in detail in Chapter 6 and so only features particular to skin will be considered here. In the deeper layers of the dermis, arteriovenous anastomoses are common, particularly in the extremities (hands, feet, ears, lips, nose), where vessels are surrounded by thick muscular coats. Under autonomic vasomotor control, these vascular shunts, when relaxed, divert blood away from the superficial plexus and so reduce heat loss, while at the same time ensuring maintenance of some deep cutaneous circulation and preventing anoxia of structures such as nerves. Extensive capillary anastomoses are present. Generally, cutaneous blood flow is regulated according to thermoregulatory need and also, in some areas of the body, according to emotional state. In very cold conditions, the peripheral circulation is greatly reduced by vasoconstriction, but intermittent spontaneous vasodilation results in periodic increases in temperature that prevent cooling to the level at which frostbite might occur.

The lymphatics of the skin, as elsewhere, are small terminal vessels that collect interstitial fluid and macromolecules for return to the circulation via larger vessels. They also convey lymphocytes, Langerhans cells and macrophages to regional lymph nodes. They begin as blind-ended, endothelial-lined tubes or loops just below the papillary dermis. These drain into a superficial plexus below the subpapillary venous plexus, which drains via collecting vessels into a deeper plexus at the junction of the reticular dermis and subcutis, and this, in turn, drains into larger subcutaneous channels.

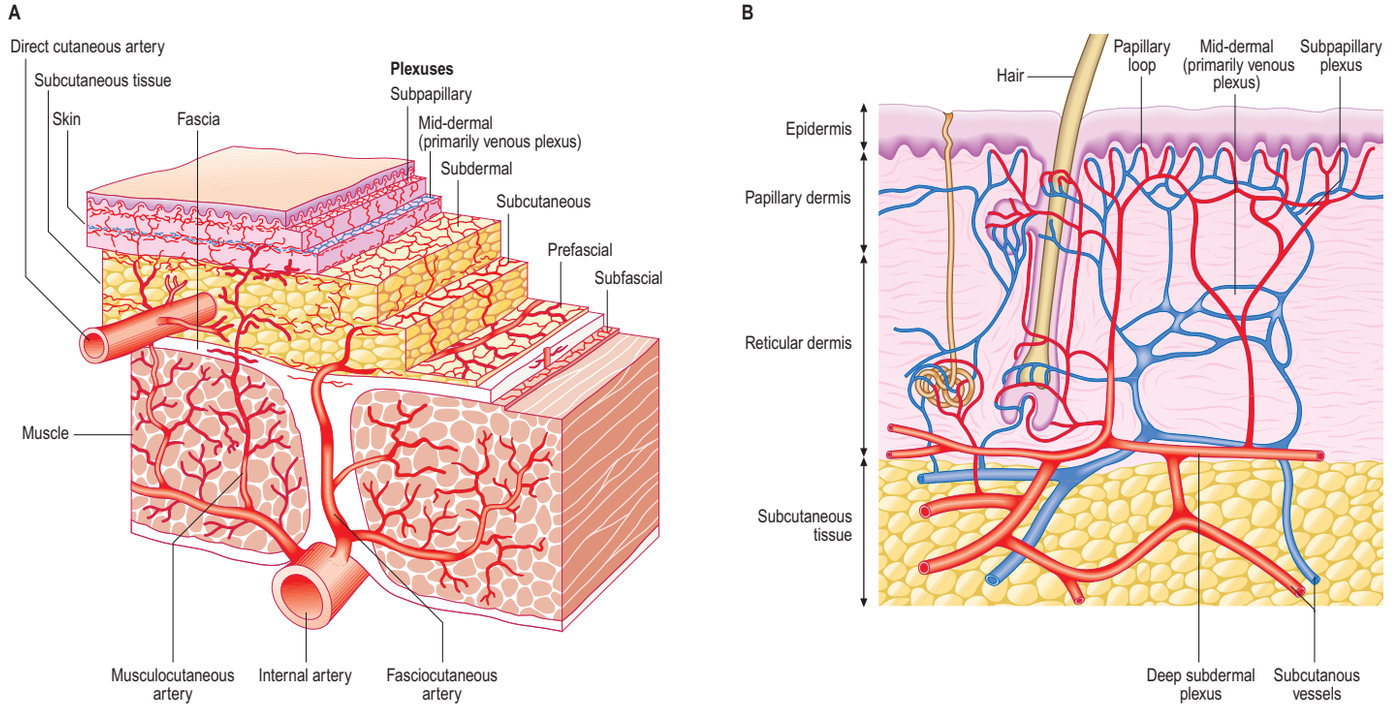

Fig. 7.28 Vascular supply to the skin. **A**, Note the various horizontal plexuses fed by direct cutaneous, fasciocutaneous and musculocutaneous arteries. **B**, Higher magnification of vascular supply. (A, Adapted with permission from McCarthy JG (ed) 1990 Plastic Surgery, Vol 1: ch. 9. Philadelphia: Saunders. B, Adapted with permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd ed. Edinburgh: Churchill Livingstone.)

Genetic keratin disorders (Knöbel et al 2015) may lead to nail dystrophies such as pachyonychia congenita, where the nails become grossly thickened. Germline mutations in the *RSPO4* gene, which encodes R-spondin 4, have been shown to cause recessive anonychia (absence of all fingernails and toenails). Mutations in the *FZD6* gene, which encodes the Wnt receptor protein frizzled 6, have been shown to underlie the molecular basis of autosomal recessive nail dysplasia, as well as twenty-nail dystrophy (a condition that affects the nails of all the fingers and toes).

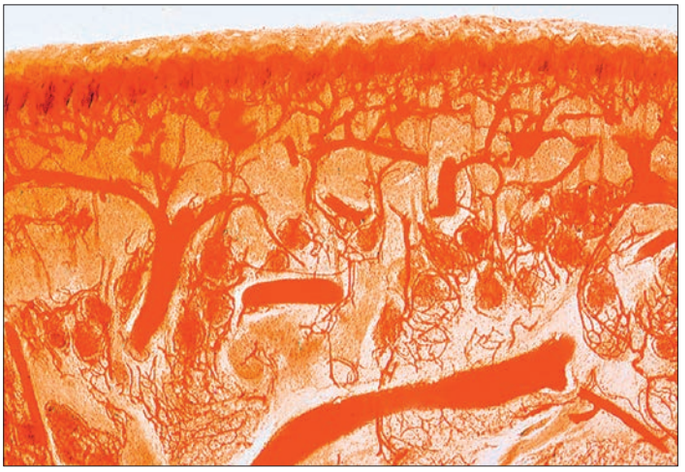

Fig. 7.29 A thick vertical section through palmar skin: the arteries, arterioles and capillaries have been injected with red gelatin to demonstrate the pattern of dermal vascularization. At the base of the dermis a broad, flat arterial plexus supplies a more superficial papillary plexus, which in turn gives off capillary loops that enter the dermal papillae.

Innervation

Skin is a richly innervated, major sensory organ. Information about the external environment is relayed through receptors responsive to various stimuli, whether mechanical (rapid or sustained touch, pressure, vibration, stretching, bending of hairs, etc.), thermal (hot or cold) or noxious (perceived as itching, discomfort or pain). Pacinian corpuscles detect deep pressure and vibrational sensation, and are located deep in the dermis or in the hypodermis, particularly of the digits. Meissner's corpuscles are rapidly adapting mechanoreceptors found in hairy and hairless skin in dermal papillae close to the dermal–epidermal junction. They are responsible for sensing light touch, and are numerous in the finger pads, being particularly suited to detecting shape and texture during active exploratory touch (Ch. 3).

Afferent sensory nerves may be myelinated or unmyelinated and are derived from neuronal cell bodies in cranial or spinal sensory ganglia. On reaching the dermis, nerve fasciculi branch extensively to form a deep reticular plexus that innervates much of the dermis, including most sweat glands, hair follicles and the larger arterioles. Many small fasciculi pass from this plexus to ramify in another superficial papillary plexus at the junction between the reticular and papillary layers of the dermis. Branches from this pass superficially into the papillary layer, ramifying horizontally and vertically, and terminate either in relation to encapsulated receptors, or as terminals reaching the level of the basal lamina. In some instances, they enter the epidermis as free endings that are responsive to light pressure and touch sensation or to nociceptive stimuli. As these fasciculi terminate, they lose their epineurial and perineurial sheaths, leaving the Schwann cell–axonal complexes or naked axons enveloped only by basal lamina, in direct contact with the matrix. These naked distal axonal terminals may be vulnerable to pathogens entering via a skin abrasion. The structure and classification of sensory endings are described in detail on p. 62.

The segmental arrangement of the spinal nerves is reflected in the sensory supply of the skin: a dermatome is the area supplied by all the cutaneous branches of an individual spinal nerve through its dorsal and ventral rami (see Fig. 24.10). Typically, dermatomes extend round the body from the posterior to the anterior median line, the upper half of each zone being supplemented by the nerve above, the lower half by the nerve below. Dermatomes of adjacent spinal nerves overlap markedly, particularly in the segments least affected by development of the limbs. In marked contrast, in the upper and lower limbs, discontinuous dermatomes meet along discrete sensory boundaries (axial lines) (Ladak et al 2014).

Efferent autonomic fibres are unmyelinated and can be either noradrenergic or cholinergic. They innervate the arterioles, arrector pili muscles, and the myoepithelial cells of sweat and apocrine glands. In the scrotum, labia minora, perineal skin and nipples they also supply the smooth muscle fasciculi of the dermis and adjacent connective tissue. Except in the nipples and genital area, the activity of the autonomic efferent nerves is mainly concerned with regulation of heat loss by vasodilation and vasoconstriction, sweat production and pilo-erection (although this is a minor function in humans).

DEVELOPMENT OF SKIN AND SKIN APPENDAGES

The skin develops from the surface ectoderm and its underlying mesenchyme. The surface ectoderm gives rise to the epidermis and its appendages such as the pilosebaceous units, sweat glands and nail units. Interactions between ectoderm and mesenchyme give rise to the oral and nasal epithelia, as well as teeth. Ectodermal cells differentiate mainly into the keratinocytes and probably Merkel cells. Melanocytes are derived from the neural crest while Langerhans cells and lymphocytes originate from the bone marrow.

The dermis is derived from the somatopleuric mesenchyme (in the limbs and trunk), and possibly the somitic mesenchyme (covering the epaxial musculature), and from the neural crest (in the head). Angiogenic mesenchyme gives rise to the blood vessels of the dermis. Nerves and associated Schwann cells, which are derived from the neural crest, enter and traverse the dermis during development.

Epidermis and appendages

General (interfollicular) epidermis

In postfertilization weeks 4–5, embryonic skin consists of a single layer of ectodermal cells overlying a mesenchyme containing cells of stellate dendritic appearance interconnected by slender processes and sparsely distributed in a loosely arranged microfibrillar matrix (Fig. 7.30). By postfertilization week 7, two epidermal cell layers are present and the highly cellular nature of the developing dermis, containing fibroblasts and stellate cells, is evident (Fig. 7.31). The interface between ectoderm and mesenchyme, known as the basement membrane zone (BMZ), is an important site of mutual interactions on which the maintenance of the two tissues depends, both in prenatal and postnatal life. Ectodermal cells, which characteristically contain glycogen deposits, contact each other at gap and tight junctions (occluding junctions, zonae occludentes). The layer so formed soon develops into a bilaminar epithelium, and desmosomes also appear. The basal germinative layer gives rise to the postnatal epidermis, and the superficial layer to the periderm, a transient layer confined to fetal life. The periderm maintains itself, expresses different keratin polypeptides, and grows by the mitotic activity of its own cells, independent of those of the germinative layer. Originally flattened, the periderm cells increase in depth; the central area containing the nucleus becomes elevated and projects as a globular elevation towards the amniotic cavity (Fig. 7.32). The plasma membrane develops numerous surface microvilli with an extraneous coat of glycosaminoglycans, and cytoplasmic vesicles become prominent deep to it. These developments reach a peak between postmenstrual weeks 12–18, at which time the periderm is a major source of the amniotic fluid to which it may contribute glucose; it also has an absorptive function. From about postmenstrual week 20 onwards, the globular protrusions become undermined and pinched off to float free in the amniotic fluid. The now-flattened periderm cells undergo terminal differentiation to form a temporary protective layer for the underlying developing epidermis, against an amniotic fluid of changing composition as a result of the accumulation of products of fetal renal excretion. Up to parturition, the periderm squames continue to be cast off into the amniotic fluid and they contribute to the vernix caseosa, a layer of cellular debris that covers the fetal skin at birth.

Proliferation in the germinative layer leads to a stratified appearance with successive layers of intermediate cells between it and the periderm. From an early stage, cells of all layers are packed with glycogen granules. Differentiation of these layers is not synchronous throughout all regions of the developing skin, being more advanced cranially than caudally, and progressing on the body from the mid-axillary line ventrally. Reduction in glycogen content of the cells is associated with a shift towards biosynthetic activity connected with terminal (cornifying) differentiation, manifested by the presence of different enzymes and expression of keratins. Simple epithelial keratins present from before implantation (K8 and K18) are replaced by typical keratinocyte basal cell keratins (K5 and K14), followed in the first suprabasal cell layer by those of higher molecular weight associated with differentiation (K1 and K10) at postfertilization weeks 10–12. This is soon followed by the expression of profilaggrin and filaggrin, and the appearance of keratohyalin granules among filamentous bundles of the uppermost intermediate layer cells at approximately postmenstrual week 20. The first fully differentiated keratinocytes appear shortly afterwards. By postmenstrual weeks 24–26, a definite cornified layer exists in some areas, and by approximately postmenstrual week 30, apart from some residual glycogen in intermediate cells, the interfollicular epidermis is essentially similar to its postnatal counterpart.

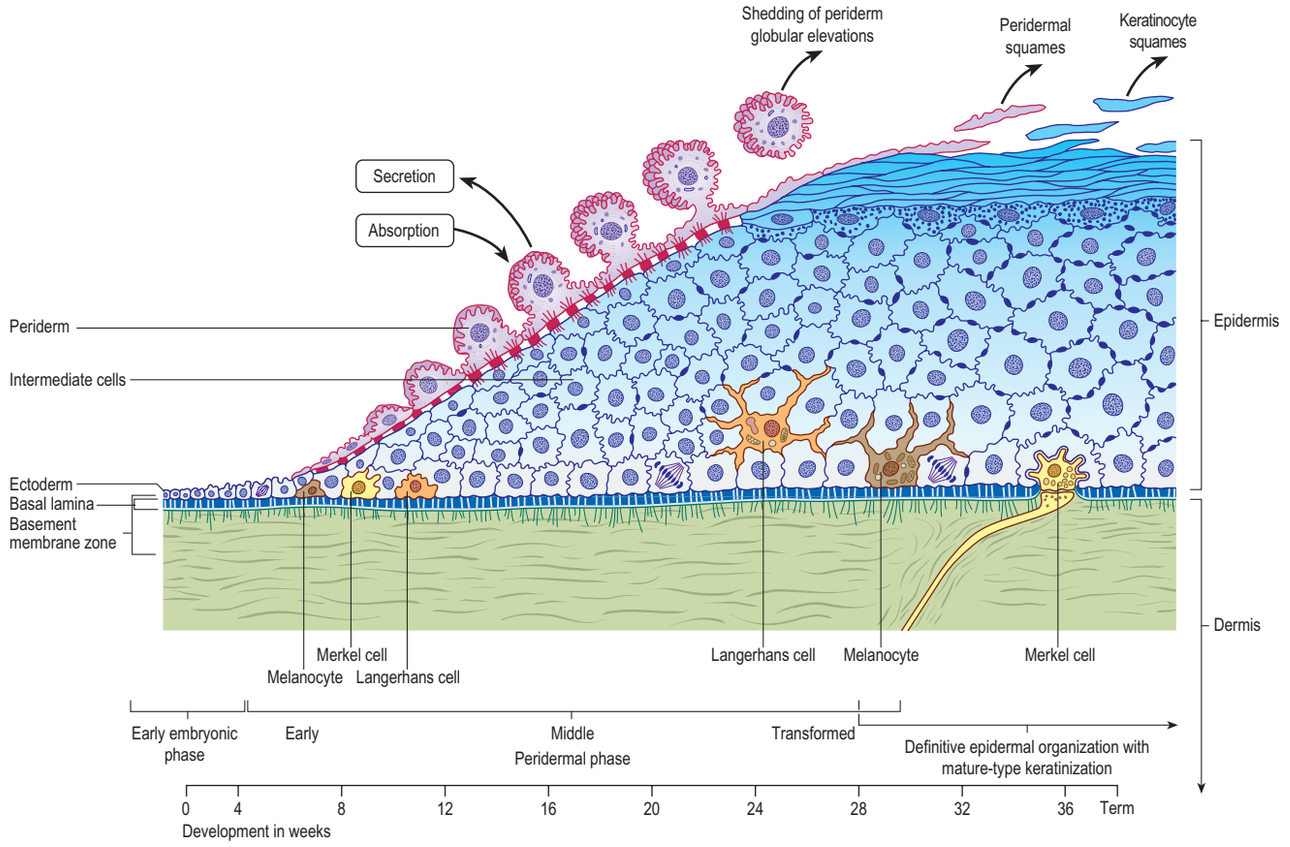

Fig. 7.30 Development of the skin.

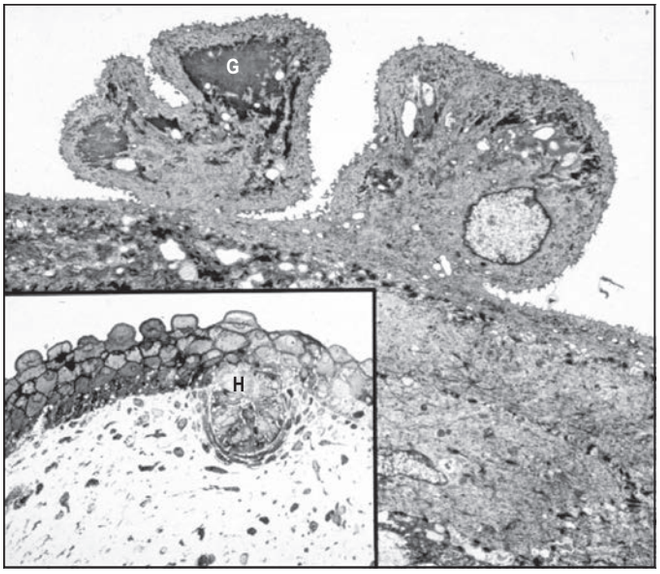

Fig. 7.32 Transmission electron micrograph of human fetal skin at postmenstrual week 21, showing the outer periderm layer (cell contents include glycogen, G); the inset shows early human hair follicle formation with a hair peg (H) projecting from the epidermis and extending into the dermis. The pale area above each photo contains amniotic fluid. (Courtesy of Dr James McMillan, St John's Institute of Dermatology.)

Non-keratinocytes are present in developing epidermis from about postfertilization week 8. Langerhans cells can be seen in the epidermis by postfertilization weeks 5–6 and are fully differentiated by postfertilization weeks 12–14. Their numbers increase at least partially by mitotic division *in situ*, but at 6 months are only 10–20% of those in the adult. It is not known if Langerhans cells function in immune surveillance in fetal skin. Melanocytes are present in the bilaminar epidermis of cephalic regions as early as postfertilization week 8. By postfertilization weeks 12–14 they can reach a density of 2300 per mm^2, reducing to 800 per mm^2 just before birth. Keratinocytes regulate the final ratio between themselves and melanocytes via growth factors, cell-surface molecules and other signals. Fetal melanocytes produce melanized melanosomes and transfer them to keratinocytes. This is an intrinsic activity independent of UV irradiation and suggests that melanin has functions other than photoprotection.

Merkel cells begin to appear in the epidermis of the palm and sole of the foot between postfertilization weeks 8 and 12, and later in association with some hairs and with dermal axonal–Schwann cell complexes.

Pilosebaceous unit

Pilosebaceous units develop in a cranio–caudal direction from about postfertilization week 9, first in the regions of the eyebrows, lips and chin. The hair placode is a collection of cells in the basal layer of the epidermis and develops adjacent to a local concentration of mesenchymal cells, which will eventually become the dermal papilla. Further proliferation and elongation of the cells lead to a hair germ, which protrudes downwards into the mesenchyme in association with the primitive dermal papilla around postmenstrual weeks 13–15. The hair germ becomes a hair peg as it migrates downwards within the developing skin, and when its bulbous lower portion envelops the dermal papilla it becomes known

as a bulbous peg. Melanocytes are individually present at the hair peg stage, and abundantly so and quite active in the bulbous peg. At this stage (approximately postmenstrual week 15), two or three swellings appear on the posterior wall. The uppermost is the rudiment of the apocrine gland (present only in some follicles), the middle forms the sebaceous gland and the lower swelling is the bulb, to which the arrector pili muscle (arising from underlying mesenchyme) later becomes attached. The cells of the lowermost region of the bulb, the matrix, divide actively and produce a pointed hair cone. This grows upwards to canalize a developing hair tract, along which the fully formed hair, derived by further differentiation of cells advancing from the matrix, reaches the surface at approximately postmenstrual week 18. The hair of the scalp lengthens during postmenstrual weeks 25–28, and the eyebrow hairs and eyelashes are well developed.

Sebaceous glands develop independently of hair follicles in the nostrils, eyelids (as tarsal glands) and the anal region. Apocrine sweat glands are formed at the same time as eccrine (merocrine) sweat glands and are at first widely distributed over the body. Their number diminishes from about postmenstrual week 20, producing the distribution seen in adult skin, and they become active at this time. The sebum that is created blends with the desquamated epidermal cells to form a cheesy covering over the skin, the vernix caseosa, which is usually considered to protect the skin from maceration by the amniotic fluid.

Hairs produced prenatally are called lanugo hairs, which are short and downy, lack a medulla, and in certain parts of the body are arranged in a vortex-like manner into tracts (Domagala et al 2017). During postmenstrual weeks 21–24 (6 months), the lanugo darkens, the vernix caseosa is more abundant and the skin becomes markedly wrinkled. Throughout the remaining postmenstrual weeks, there is a progressive loss of lanugo, except for the hairs on the eyelids (eyelashes), eyebrows and scalp. Just prior to birth, lanugo hairs are replaced by vellus hairs, and these are replaced in turn by intermediate hairs, which are the predominant type until puberty. New follicles do not develop in postnatal skin.

Eccrine sweat glands

Eccrine (merocrine) sweat glands are one type of sudoriferous gland. Sweat gland rudiments appear late in the first trimester as cell buds associated with the primary epidermal ridges of the finger and toe pads of the terminal segments of the digits. They elongate into the dermis and by postmenstrual week 16 the lower portion begins to form the secretory coil; secretory and myoepithelial cells are present within the secretory coil by postmenstrual week 22. The solid cord of cells connecting the coil to the epidermis becomes the intradermal duct, and the lumina of both are formed by dissolution of desmosomal contacts between the cells. The intraepidermal duct is foreshadowed by a column of concentrically arranged inner and outer cells within which a lumen is formed that opens on the surface at postmenstrual week 22. As with hair follicles, no new eccrine sweat glands develop postnatally. Emotional sweating occurs in preterm infants from 29 postmenstrual weeks.

Epidermal ridges

The primary epidermal ridges develop as regularly spaced, small downgrowths of epidermal cells separated by corresponding dermal ridges during the second and third months of gestation. From postmenstrual week 20, secondary ridges develop; the pattern becomes evident on the surface and is finalized through further remodelling postnatally.

Nails

Fields of proliferative ectoderm appear on the tips of the terminal segments of the digits. They progressively reach a dorsal position, where, at approximately postfertilization week 9, a flattened nail field limited by proximal, distal and lateral nail grooves is apparent. The nail field ultimately forms the nail bed, and the primordium of the nail is formed of a wedge of cells that grows diagonally, proximally and deeply into the mesenchyme from the proximal groove towards the underlying terminal phalanx. The deeper cells of this wedge form the primordium of the matrix, which gives rise to the nail plate. The latter emerges from under the now proximal nail fold at about postmenstrual week 14 and grows distally over an already keratinized nail bed. The nail matrix is usually considered to have dorsal and ventral (intermediate) components, but there are conflicting opinions as to the extent to which each contributes to the nail, both in ontogeny and postnatally. It is generally agreed that the ventral matrix contributes the major part.

At postmenstrual week 20, the nail plate entirely covers the nail field (nail bed), now limited distally by a distal ridge, which, when the plate projects beyond the tip, becomes the hyponychium beneath it. At birth, the microstructure of the main nail unit components is similar to that postnatally.

Dermis

The embryonic dermis is more cellular than the adult dermis, and many of these mesenchymal cells are involved in signalling pathways that regulate ectodermal differentiation. The mesenchymal cells underlying the surface ectoderm and early bi- and trilaminar epidermis contact each other by slender processes to form an intercommunicating network. They secrete a matrix that is rich in ions, water and macromolecules, proteoglycan/glycosaminoglycans, fibronectin, collagenous proteins of various types and elastin. Further development of these intrinsic components involves the differentiation of individual cell types, fibroblasts, endothelial cells, mast cells and the assembly of matrix components into organized fibrillar collagen fibres and elastic fibres. During embryogenesis, the matrix is heterogeneous with regard to its biochemical and macromolecular components. The main glycosaminoglycans of embryonic and fetal skin are glycuronic acid and dermatan sulphate. Types I, III, V and VI collagens are distributed more or less uniformly, regardless of fetal age, with some local concentrations of type III and V collagens, the levels of which are higher than in postnatal skin. Collagens of types IV and VII are found predominantly in the BMZ.

The progressive morphological differentiation of the dermis involves its separation from the subcutis at about the end of the first trimester; changes in the composition and size of collagen fibrils and their organization into bundles, amongst which cells become relatively fewer; downgrowth of epidermal appendages; the organization of nervous and vascular plexuses; and the relatively late appearance of elastic networks. The papillary and reticular regions are present as early as postmenstrual week 14 and the formation of the two layers of the dermis could be the result of two lineages of dermal fibroblasts (Driskell et al 2013). One lineage forms the papillary dermis and the dermal papillae that regulate hair follicle growth and arrector pili muscles, while the second fibroblast lineage forms the reticular dermis and the underlying subcutis.

Vascular supply and lymphatic drainage

The dermal vasculature is generally thought to be developed *in situ* by the transformation of angiogenic mesenchymal cells. Closed channels lined with endothelium and containing nucleated red cells are present by about postfertilization week 6 underneath the ectoderm, and by postfertilization week 8 are arranged in a single plane parallel to the epidermis: they ultimately form the subpapillary plexus. A second, deeper horizontal plexus is evident by postmenstrual weeks 12–13. Both plexuses extend by budding and give rise to the final patterns of arterioles, venules and capillaries that are established shortly after birth. Pericytes also develop from mesenchymal cells. Lymphatic vessels are formed by mesenchymal cells, which become organized to enclose pools of proteinaceous fluid leaking from the developing capillaries.

Innervation

Sensory cutaneous nerves (axons and Schwann cells) are derived from the neural crest (via dorsal root and cranial sensory ganglia). Motor fibres to vessels and glands arise from postganglionic neurones in sympathetic ganglia. As individual parts of the embryo grow, the nerves grow and lengthen with them. Small axons are present superficially at a stage when the epidermis is bilaminar. By postfertilization week 8, a functioning cutaneous plexus is already present, and by about postmenstrual week 16, the dermal plexuses are richly developed and Meissner and Pacinian corpuscles have appeared.

Epithelial–mesenchymal interactions in developing skin

Epidermal–mesenchymal (dermal) interactions at the BMZ occur during development and throughout life. At the ectodermal stage, the BMZ consists of the basal plasma membrane of an ectodermal cell, paralleled on its cytoplasmic side by various cytoskeletal filaments, and beneath it by a layer (0.1–0.2 μm) of microfibrillar amorphous material deposited by the cell. At the bilaminar stage, a continuous lamina densa is present, separated from the basal plasma membrane by a lamina lucida traversed by loosely fibrillar material; similar filaments extend from the lamina densa into the mesenchymal matrix.

Hemidesmosomes (see Fig. 1.27C) begin to appear at postfertilization week 8 as stratification begins, and anchoring fibrils appear at postfertilization weeks 9–10. By the end of the first trimester, the basic

morphology of the interfollicular BMZ is essentially similar to that of the postnatal BMZ.

Laminin and type IV collagen are present in the developing basal lamina at postfertilization week 6; bullous pemphigoid antigen (BPAG, in hemidesmosomes) and anchoring fibril proteins are expressed later. These immunocytochemical and morphological observations are of importance for the prenatal diagnosis of genetically determined diseases such as epidermolysis bullosa. The basal lamina provides a physical supporting substrate and attachment for the developing epidermis, and is thought to be selectively permeable to macromolecules and soluble factors regulating epidermal–dermal morphogenetic interactions. For details of the conserved signalling pathways operating in the development of skin, see Driskell et al (2013) and Veltri et al (2017).

Neonatal growth

The surface area of the skin increases with growth. It is estimated that the surface area of a premature neonate weighing 1505 g is approximately 1266 cm^2, whereas a neonate of 2980 g has a surface area of 2129 cm^2. The skin of the neonate is thinner than that of older infants and children: it cornifies over a period of 2–3 weeks, which provides protection. In the premature infant the even thinner epidermal layer allows absorption of a variety of substances such as chlorhexidine and permits a significantly higher transepidermal water loss than occurs in full-term neonates.

At birth the skin is richly vascularized by a dense subepidermal plexus. The mature pattern of capillary loops and the subpapillary venous plexus is not present but it develops as a result of capillary budding with migration of endothelia at some sites and the absorption of vessels from other sites. Some regions mature faster than others. With the exception of the palmar and plantar skin and nail beds, the skin of the neonate has almost no papillary loops, unlike the adult (**Fig. 7.28B**). Instead, it has a disordered capillary network, which becomes more orderly from postnatal week 2 when papillary loops appear; defined loops are not present until postnatal weeks 4–5, and all areas possess loops by postnatal weeks 14–17.

Neonates exhibit a regional sequence of eccrine gland maturation. The earliest sweating occurs on the forehead, followed by the chest, upper arm and, later, more caudal areas. Acceleration of maturation of the sweating response occurs in premature babies after delivery. The postnatal maturation of skin and differences from adult skin are given in Stamatas et al (2011) and Liu et al (2018).

The skin microbiome rapidly becomes established in the neonate, although in hospitalized preterm infants the range of species is lower and shaped by the microbiota acquired from the hospital environment (Pammi et al 2017, Younge et al 2018).

NATURAL SKIN CREASES AND WRINKLES

Skin lines

The surface of the skin and its deeper structures show various linear markings, seen as grooves, raised areas and preferred directions of stretching.

Surface pattern lines, tension lines and skin creases

Externally visible skin lines are related to various patterns of epidermal creasing, ridge formation, scarring and pigmentation. A simple lattice pattern of lines occurs on all major areas of the body except the thick palmar and plantar skin. The lattice pattern typically consists of polygons formed by relatively deep primary creases visible to the naked eye that are irregularly divided by finer secondary creases into triangular areas (**Fig. 7.33**). These, in turn, are further subdivided by tertiary creases limited to the cornified layer of the epidermis and, finally, at the microscopic level, by quaternary lines, which are simply the outlines of individual squames (see Fig. 7.7). Apart from the quaternary lines, all the others increase the surface area of the skin, permit considerable stretching and recoil, and distribute stresses more evenly. Details of the patterns vary according to the region of the body, e.g. primary creases radiate from the hair follicles on the cheek, form hexagons on the scalp, and form parallelograms on the calf and thigh. There is a relationship between the type of pattern and the range of local skin extensibility.

Wrinkle lines

Wrinkle lines are caused by the contraction of underlying muscles and are usually perpendicular to their axis of shortening. On the face they are known as lines of expression; they become permanent with age as the skin progressively loses its elasticity. Occupational lines are creases produced by repeated muscular contractions associated with particular trades or skills. Contour lines are lines of division at junctions of body planes, e.g. the cheek with the nose. Lines of dependency are produced by the effect of gravity on loose skin or fatty tissue, e.g. the creases associated with the pendulous fold beneath the chin in older age.

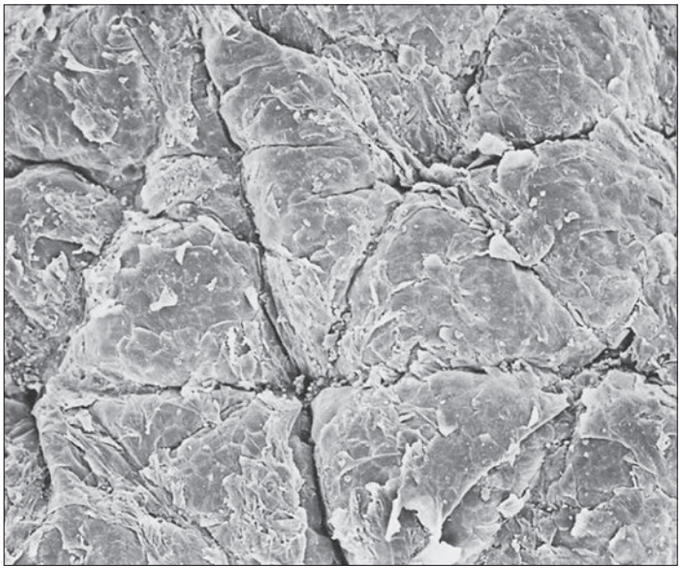

Fig. 7.33 A scanning electron micrograph of the surface of thin skin of the back, showing an interlacing network of fine creases and predominantly triangular areas between them.

Fig. 7.34 The surface of hairless skin from the palm of the hand, showing epidermal friction (papillary) ridges and larger flexure lines (left).

Flexure (joint) lines

Flexure (joint) lines are major markings found in the vicinity of synovial joints, where the skin is attached strongly to the underlying deep fascia (**Fig. 7.34**). They are conspicuous on the flexor surfaces of the palms, soles and digits: in combination with associated skin folds they facilitate movement. The skin lines do not necessarily coincide with the associated underlying joint line. For example, the flexure lines demarcating the extended fingers from the palm lie approximately 12 mm distal to the metacarpophalangeal joints, the positions of which are more closely related to the distal palmar crease. The patterns of flexure lines on the palms and soles may vary and are, to some extent, genetically determined.

Papillary ridges

Papillary ridges are confined to the palmar and plantar skin and the flexor surfaces of the digits, where they form narrow parallel or curved arrays separated by narrow furrows (**Figs 7.35–7.36**). The apertures of sweat ducts open at regular intervals along the summit of each ridge. The epidermal ridges correspond to an underlying interlocking pattern of dermal papillae, an arrangement that helps to anchor the two layers firmly together. The pattern of dermal papillae determines the early development of the epidermal ridges. This arrangement is stable

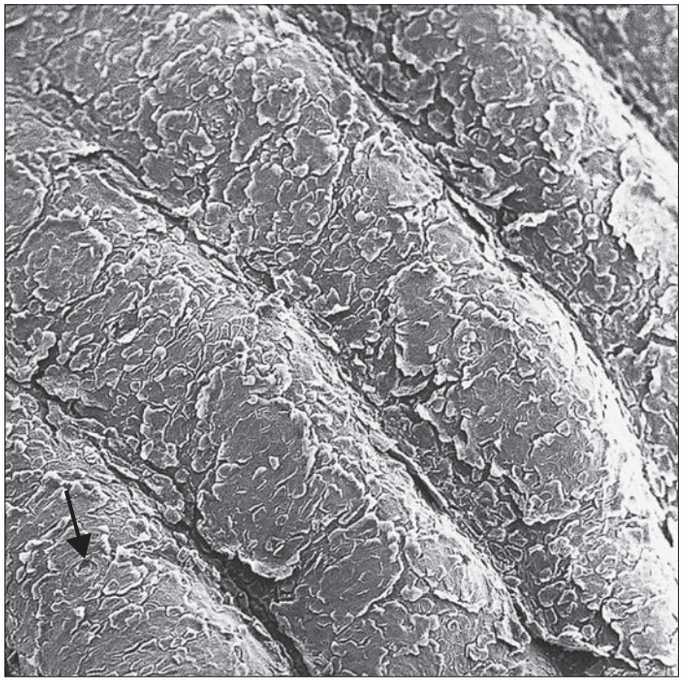

Fig. 7.36 A scanning electron micrograph of the surface of thick hairless skin from the palmar (volar) surface of a human digit, showing friction ridges along which lines of sweat ducts open as pores (one pore is arrowed). (Courtesy of Professor Lawrence Bannister and Dr Caroline Wigley.)

Fig. 7.35 The palmar aspect of a terminal phalanx to show fingerprint ridges. Note the interphalangeal flexure line (IPFL).

throughout life, unique to the individual, and therefore significant as a means of identification. The ridge pattern can be affected by certain abnormalities of early development, including genetic disorders such as Down's syndrome, and skeletal malformations such as polydactyly: absence of epidermal ridges is extremely rare. Functionally, epidermal ridges increase the gripping ability of hands and feet, preventing slipping. The great density of tactile nerve endings beneath them means that they are also important sensory structures.

If the mechanical demands placed on the skin are greater than the skin creases and the dermis can accommodate, the lateral cohesion of dermal collagen fibres becomes disrupted with associated haemorrhage and cellular reaction, and, eventually, the formation of poorly vascularized scar tissue. These changes are termed intrinsic to distinguish them from scars formed by external wounding. Sites of dermal rupture are visible externally as lines or striae. They are initially pink in colour, later widen and become a vivid purple or red (striae rubrae), and eventually fade, becoming paler than the surrounding intact skin (striae albae). They sometimes develop on the anterior abdominal wall during pregnancy, when they are termed striae gravidarum (stretch marks).

Lines detectable after manipulation or incision

In certain regions of the body, surgical wounds heal with a better and less conspicuous scar if they are orientated in a particular direction. This finding is related to a number of factors including skin tension and naturally formed wrinkle lines. Skin is normally under tension; the direction in which the tension is greatest varies regionally. Tension is dependent on the protrusion of underlying structures, the direction of underlying muscles, and on joint movements. Many anatomists and surgeons have therefore attempted to produce a body map to indicate the best direction in which to make an elective incision to obtain the most aesthetic scar. These maps frequently differ, especially in the region of the face. Out of the multitude of described cleavage lines, the most commonly referred to are relaxed skin tension lines (RSTLs), Langer's lines and Kraissl's lines (see Fig. 36.1). Of these, the RSTLs and Kraissl's lines are probably more appropriate lines for surgical incision.

Relaxed skin tension lines

Relaxed skin tension lines (RSTLs) are those that correspond to the directional pull (which forms furrows) when the skin is relaxed; they do not always correspond to wrinkle lines. The tension across RSTLs is constant even during sleep, but can be altered (increased, decreased or abolished) by underlying muscle contraction. The direction of the RSTLs can be determined by pinching the skin in different directions. Pinching at right-angles to the RSTLs will result in fewer and higher furrows than pinching parallel to these lines.

Blaschko's lines

Blaschko's lines represent a pattern of cutaneous mosaicism that can be observed in a range of congenital and acquired skin conditions. They do not appear to correspond to the distribution of the cutaneous vessels or nerves, and may be related to earlier developmental boundaries of a 'mosaic' nature.

Age-related skin changes

Two main factors, chronological and environmental, are involved in skin ageing (Orioli and Dellambra 2018). Chronological changes are physiological or intrinsic in origin. A major environmental factor is chronic exposure to the sun, photoageing, which is to some extent preventable.

Intrinsic ageing

From about the third decade onwards, gradual changes occur in the appearance, microstructure and mechanical properties of the skin as a result of epidermal and dermal atrophy. They become very marked in old age. Alterations include wrinkling, dryness, loss of elasticity, thinning and easy bruising. Epidermal atrophy is manifested by general thinning and loss of the basal rete pegs and flattening of the dermal–epidermal junction. Flattening of the junction decreases resistance to shear, leading to poor adhesion of epidermis and its separation following minor injury. The thickness of the cornified layer is not reduced in old age, and its permeability characteristics seem little affected. Epidermal proliferative activity and rate of cell replacement decline with age, being reduced by up to 50% in elderly skin. Synthesis of vitamin D is also reduced. After middle age, there is a 10–20% decline in the number of melanocytes, and Langerhans cells become sparser, a change associated with a reduction in immune responsiveness. Depigmentation and loss of hair, as well as some local increases (eyebrows, nose and ears in males, and face and upper lip in females), are commonly observed. Alterations in non-keratinocytes may be aggravated by chronic exposure to UV irradiation.

Dermal changes are mainly responsible for the appearance of aged skin, particularly its stiffness, flaccidity and wrinkling, as well as loss of extensibility and elasticity. Its general, thickness diminishes as a result of the decline in collagen synthesis by a reduced population of fibroblasts, though the relative proportion of type III collagen increases. Senile elastosis is a degenerative condition of collagen, which may be partly due to excessive exposure to sun. Vascularization of the skin is reduced, the capillary loops of the dermal papillae are particularly affected, and the tendency towards small spontaneous purpuric haemorrhages indicates a general fragility of the cutaneous microvasculature. There is a decrease in the sensitivity of sensory perception, associated with some loss of specialized receptors. Ageing is also associated with fat redistribution, which may contribute to the physical characteristics of loose, sagging skin.

Photoageing

Skin ageing is also influenced by external factors, such as tobacco exposure, malnutrition, airborne particulate matter and UV radiation. Photoageing, also known as extrinsic skin ageing, occurs as a result of the hazardous effect of UV radiation on human skin, and is a major concern because of an association with skin cancer. Ultraviolet light B (UVB) is primarily absorbed in the epidermis and has been shown to induce angiogenesis and lymphatic dysfunction in skin. It causes DNA damage by generating cyclobutane pyrimidine dimers and 6,4-photoproducts, all of which are photocarcinogenic. Ultraviolet A is absorbed by cellular chromophores such as melanin, riboflavin and urocanic acid, resulting in the formation of reactive oxygen species, which in turn damage lipids, DNA and proteins (Schuch et al 2017).

CUTANEOUS WOUND HEALING AND SCARRING

The end-point of healing of mammalian skin wounds is usually scar formation. This type of healing is called reparative wound healing as opposed to regenerative wound healing which can be seen in lower animals (such as the newt), where wounds can heal without scarring and with functional skin appendages.

Cutaneous scars result from injury to both the epidermis and the underlying dermis. The epidermis largely regenerates, but dermal architecture is abnormal after repair and the undulating pattern of rete ridges at the dermal–epidermal junction is not reproduced. Scar tissue is biomechanically inferior to unwounded skin. Appendages such as hair follicles, sebaceous and sweat glands, which are derived from the epidermis, do not regenerate after wounding.

The molecular biology of cutaneous repair involves the coordination of numerous cell types, signalling molecules and matrix proteins. Many of these signalling molecules have pleiotropic effects and it is the complex balance of these mediators, rather than their individual action, that determines events in wound repair. Wound healing is often considered in four overlapping temporal phases, haemostasis, inflammation, proliferation and remodelling (**Fig. 7.36**) (Landén et al 2016).

Haemostasis

Haemostasis occurs within minutes to hours of injury. Wounding causes vascular injury and initiates fibrin–fibronectin clot formation. The clot

The analysis of ridge patterns by studying prints of them (fingerprints) is known as dermatoglyphics and is of considerable forensic importance. Measurable parameters include the frequency of ridges in particular patterns and the disposition of tri-radii, which are junctional areas where three sets of parallel ridges meet. Fingerprint ridge patterns can be separated into three major types (see Fig. 7.35): arches (5%), loops (70%) and whorls (25%). Arches have no tri-radii, loops have one tri-radius, and whorls have two or more. Whorl finger patterns are more common on the right hand, and males generally have more whorls and fewer arches than females, in whom the ridges are relatively narrower. The frequency of individual patterns varies with particular fingers. Similar patterns are seen on the toes. Adermatoglyphia is an extremely rare autosomal dominant condition in which fingerprint ridges are absent, and is caused by mutations in the *SMARCAD1* gene. Other genetic disorders may also have reduced or absent dermatoglyphics as part of the clinical features.

Variation in pigmentation can produce visible pigmentary demarcation lines on the skin of the arms and legs. Five types (A–E) have been described. Type A, Futcher's or Voigt's lines, are the most common and occur along the anterior axial lines, extending from the sternum to the wrist, delineating the darker extensor and paler flexor surfaces of the arms.

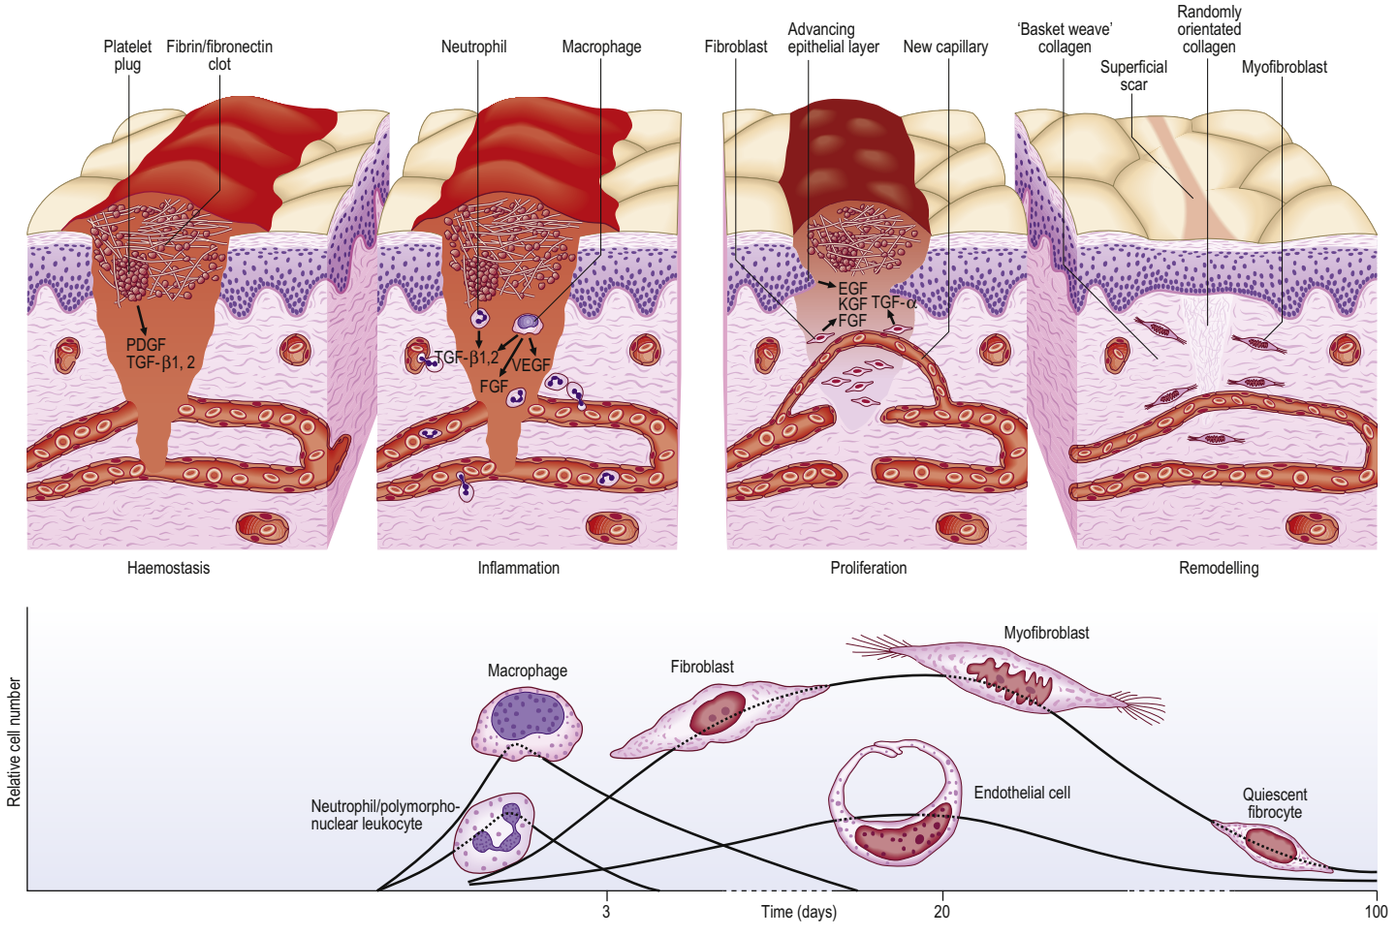

Fig. 7.36 The processes involved in the healing of a normal cutaneous wound. Abbreviations: EGF, epidermal growth factor; FGF, fibroblast growth factor; KGF, keratinocyte growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

consists of platelets (promoted to aggregate by fibrillar collagens type I and III) embedded in a mesh of cross-linked fibrin and fibronectin fibres. It serves as a haemostatic plug, protects the denuded wound with a temporary physical shield, and provides an initial wound bed that allows the surrounding fibroblasts to start laying down new collagen and extracellular matrix proteins to form the neodermis. The clot also acts as a reservoir of growth factors and cytokines that are released as platelets degranulate, and that contribute to inflammatory cell recruitment.

Inflammation

The inflammatory phase of wound healing occurs within the first 72 hours of injury and serves mainly to clear bacteria and debris from the wound and to prepare the wound bed for repair. Neutrophils and monocytes are recruited to wound sites within minutes of injury by a variety of chemotactic signals, including complement factors, bacterial polysaccharides, cytokines and growth factors such as tumour necrosis factor alpha (TNF-α), interleukin (IL)-1, IL-8, platelet-derived growth factor (PDGF), transforming growth factor alpha (TGF-α) and TGF-β1,2, basic fibroblast growth factor (bFGF/FGF-2), serotonin and monocyte chemotactic protein-1 (MCP-1). Complement, thrombin and mast cell mediators cause vasodilatation of the local capillaries and increase blood flow to facilitate the migration of inflammatory cells. Neutrophils are active against contaminating bacteria. Monocytes differentiate into macrophages that phagocytose not only pathogenic organisms, but also expended neutrophils, and cellular and matrix debris. Neutrophils and macrophages act as a source of cytokines and growth factors that amplify stimuli already present in the wound site. Macrophages are also a source of actors such as TGF-α, FGF and vascular endothelial growth factor (VEGF) that activate resident fibroblasts, endothelial cells and keratinocytes, which, in turn, are central to the processes of re-epithelialization and formation of granulation tissue.

Proliferation

The proliferative phase occurs in the first 2–3 weeks, and involves continued re-epithelialization and the formation of granulation tissue to fill the defects caused by the wound.

Re-epithelialization

Re-epithelialization begins within hours of wounding as a result of keratinocyte migration and proliferation from the wound edges and skin appendages. Cytokines such as epidermal growth factor (EGF), FGF, keratinocyte growth factor (KGF/FGF-7), insulin-like growth factor-1 (IGF-1) and TGF-α are released by activated fibroblasts and keratinocytes, and stimulate the re-epithelialization process. Advancing keratinocytes are capable of debriding the wound surface through phagocytosis of debris and dead cells and keratinocyte expression of matrix metalloproteinases (MMPs) appears to be associated with re-epithelialization. During this phase of cutaneous wound healing, keratinocyte proliferation is thought to be upregulated after migration has started; dividing and migrating cells are found in the first suprabasal as well as basal keratinocyte layers. MMP activity is regulated by the production of tissue inhibitors of MMPs (TIMPs). A relative imbalance between MMPs and TIMPs, e.g. upregulation of certain MMPs, may be associated with impaired wound healing. When the denuded wound surface has been covered by a monolayer of keratinocytes, migration ceases. A stratified epidermis with an underlying basal lamina is re-established from the margins of the wound inwards. Anchoring fibrils linking the basal lamina to the underlying connective tissue mark neo-epidermal maturity. For further reading on re-epithelialization see Belokhvostova et al (2018).

Granulation tissue formation

The term granulation tissue refers to the macroscopic appearance of wound connective tissue, which appears pink and granular. It contains numerous capillaries that invade the initial wound clot and become

organized into a microvascular network (angiogenesis), together with the cells and molecules necessary to stimulate neo-matrix deposition. Angiogenesis starts 2 days after injury and is a complex process, promoted by dynamic interactions between endothelial cells, angiogenic cytokines (including FGF-2), VEGF (mainly from keratinocytes), PDGF and TGF-β1,2, MMP and the extracellular matrix environment.

Electron microscopic studies have shown that the epidermis, basal lamina and papillary dermis all develop on the surface of the granulation tissue. Wounds that fail to granulate do not heal satisfactorily, suggesting that granulation tissue formation is a key aspect of wound repair. Excessive granulation is also associated with delayed re-epithelialization.

Activated fibroblasts in the healing wound proliferate in response to growth factors, notably TGF-β1, IGF-1, PDGF, FGF and EGF. Within 72 hours of injury, these fibroblasts synthesize components of the new extracellular matrix, which are deposited in an orderly sequence. The neo-matrix initially includes fibronectin and hyaluronan, which form a provisional substratum for cellular migration. Fibronectin acts as an initiation site for collagen fibrillogenesis, and as anchorage for myofibroblasts to effect wound contraction. Hyaluronan forms a highly hydrated matrix that is easily penetrated by migrating cells. Ultimately this and other neo-matrix components are replaced, first by collagen type III, and subsequently by collagen type I, which imparts strength to the mature scar. Non-structural proteins such as tenascin are also found in the neo-matrix of healing wounds and provide signals that orchestrate the repair process. Cellularity decreases during the evolution of granulation tissue into a mature scar (and during other phases of wound healing), mainly as a result of apoptosis.

Remodelling

Remodelling of the extracellular matrix is important throughout the wound healing process and can last for months to over a year. Fibroblasts are responsible for matrix deposition and remodelling. Initially they replace hyaluronan in the neo-matrix with sulphated proteoglycans, such as decorin, biglycan and versican, which contribute to tissue resilience. Increased wound strength coincides with new collagen deposition. Approximately 3 weeks after injury, collagen breakdown and synthesis equilibrate; subsequent, more gradual increases in wound strength reflect collagen remodelling, with the formation of intermolecular cross-links and larger collagen bundles. Scar maturation is associated with proportional increases in collagen type I relative to collagen type III, associated with more organized orientation of the collagen fibrils. Scarred skin only reaches a maximum tensile strength of about 70% that of unwounded skin.

Wound contraction

An important part of remodelling is wound contraction. Once granulation tissue has been laid down, a proportion of activated fibroblasts (or other mesenchymal cells) transform into myofibroblasts, which play a key role in wound contraction; they are thought to generate forces that pull normal dermal and adipose tissue into the wound defect.

Scarless wound healing

Wounds heal with reduced or absent scarring in certain circumstances, notably cutaneous wounds in the early fetus. The transition from scarless to scarring healing is seen at 24 weeks of gestation. The development of a major inflammatory response at a wound site appears to be a significant determinant of whether scarring occurs. Scarless fetal wound healing is characterized by fewer inflammatory cells (which are less differentiated than their adult counterparts and which remain in the wound for a shorter time), rapid re-epithelialization, reduced angiogenesis and restoration of the connective tissue architecture in which collagen is arranged in the normal reticular pattern. Fetal healing is characterized by low levels of IL-6, IL-8, TGF-β1 and TGF-β2, and high levels of IL-10 and TGF-β3. TGF-β1 and 2 are produced from degranulating platelets and subsequently from monocytes and macrophages: the low levels of TGF-β1 seen in fetal wounds have been attributed to a relative lack of platelet degranulation and fibrin clot formation. The main sources of TGF-β3 are fibroblasts and keratinocytes.

Excessive scar formation

In some individuals, collagenous scar tissue forms which covers a greater area than the original wound, forming a keloid scar or keloid. This is an area of raised, hairless skin overlying the site of a wound which may have been relatively minor. Keloids are more common in darker-pigmented skins, on the upper body and in those with a familial history of keloid formation.

SKIN GRAFTS AND FLAPS

A graft is a piece of tissue that has been detached from its blood supply and therefore needs to regain a blood supply from the bed in which it is placed in order to survive. A flap is a piece of tissue that is surgically raised and transferred from one location in the body to another while maintaining its blood supply.

Grafts

Grafts can be composed of skin, fat, fascia or bone, either separately or together as a composite piece of tissue. Skin grafts can be either full-thickness grafts or split-thickness grafts. Full-thickness grafts consist of the epidermis and the full thickness of the dermis. Split-thickness grafts consist of the epidermis and a variable quantity of the dermis. An essential difference is that the donor site following the harvest of a full-thickness graft has no epidermal elements from which new skin can regenerate. These grafts therefore tend to be taken from sites of the body where the donor defect can be primarily closed. The donor site from split-thickness grafting contains adnexal remnants (hair follicles in particular), that have the propensity to divide and regenerate new epidermis, and so resurface the donor defect.

Revascularization of grafts is dependent on early and direct connection between host and graft vessels (inosculation); in the time that elapses before this occurs, graft survival depends on fluid absorption (imbibition). Revascularization, which occurs as early as 48 hours post-transplantation, is achieved by anastomosis, where the severed ends of pre-existing graft vessels are sutured to vessels of the underlying host wound bed, and/or by neovascularization, which involves the *de novo* angiogenic ingrowth of vessels from the wound bed into the graft. During the first two weeks, blood vessels from the recipient (host) site invade the graft edges along previous vascular channels in the direction of an ischaemic stimulus, while the donor graft vasculature begins to regress. Endothelial progenitor cells appear to play an important role in blood vessel formation, attracted by ischaemic gradients. Inosculation occurs, restoring blood flow to the graft microcirculation. By the start of the third week, complete blood flow in the graft vasculature has been established and, in the absence of a continuing ischaemic stimulus, neovascularization ends.

Flaps

Flaps are named according to the type of tissue transferred, e.g. a fasciocutaneous flap contains skin and fascia, and a musculocutaneous flap contains both muscle and the overlying skin, whereas a skin flap, fascial flap and muscle flap contain only the separate elements that their names imply. The blood supply to a skin flap can be randomly orientated, which limits the flap length-to-breadth proportions to no more than 2:1 (except on the face, where longer flaps can be performed). Much longer skin flaps can be raised elsewhere if the blood supply to the flap is a direct cutaneous artery and vein (axial pattern flaps) and are usually based on the local angiosome. An angiosome is an anatomical territory supplied by a source artery and drained by accompanying veins and lymphatic vessels (Taylor et al 2011) (see p. 135). It may include fascia, nerve, muscle and bone, as well as skin. The concept is important in the analysis of patterns of ischaemia and in planning incisions, and enables the raising of free, composite, vascularized tissue flaps.

A free flap (free tissue transfer) is a specific type of flap in which the tissue, whether skin, fascia, muscle or bone, or a combination of these, is completely removed from its original location in the body along with a single identifiable artery and vein, and transferred to a remote site. The blood vessels in the flap are anastomosed to vessels located in the new site using microsurgical techniques. This often allows for greater flexibility in performing reconstructive surgery.

SKIN STEM CELLS

To maintain, repair and regenerate itself, the skin contains stem cells that reside in various parts of the hair follicles, including the bulge area and isthmus; the basal layer of the interfollicular epidermis; the base

of sebaceous glands and within sweat glands. Epidermal stem cells are able to self-renew, as well as give rise to differentiating cells. However, it is not clear whether every basal keratinocyte, or only a proportion of these cells, is a stem cell. Two hypotheses have emerged concerning epithelial renewal. One theory, known as symmetric cell division, envisages basal keratinocytes within epidermal proliferation units that contain one self-renewing stem cell and about 10 tightly packed transit amplifying cells, each of which is capable of dividing a limited number of times before exiting the basal layer to undergo terminal differentiation. This unit gives rise to a column of larger and flatter cells that culminates in a single hexagonal surface. The alternative theory, known as asymmetric cell division, is that some interfollicular stem cells (perhaps up to 70% of cells) can shift their spindle orientation from lateral to perpendicular, such that one daughter cell is committed to terminal differentiation while the other maintains its proliferative capacity, thus obviating the need for transit amplifying cells.

Hair follicle stem cells are found in the bulge regions below the sebaceous glands but also in other parts of the hair follicle (Fuchs 2018). These stem cells undergo varying degrees of growth, degeneration and rest, which are governed, in part, by Wnt signalling and bone morphogenetic protein (BMP) inhibition. The bulge area stem cells generate cells of the outer root sheath, which drive the highly proliferative matrix cells next to the mesenchymal papillae. After proliferating, matrix cells differentiate to form the hair channel, the inner root sheath and the hair shaft. Hair follicle stem cells can also differentiate into sebocytes and interfollicular epidermis. Despite this multipotency, the follicle stem cells only function in pilosebaceous unit homeostasis and do not contribute to the interfollicular epidermis unless the skin is wounded. Stem cells are also found in the base of sebaceous glands: their progeny differentiate into lipid-filled sebocytes. Stem cells in sweat glands can differentiate into epithelial, luminal or myoepithelial daughter cells to maintain skin integrity and homeostasis.

Other cells in the dermis and subcutis may have stem cell-like properties. Dermal sheath cells lie close to hair follicles; MUSE (multi-lineage differentiating stress-enduring) cells are pluripotent progenitor cells. Trauma and/or hypoxia in the skin, e.g. during wound healing or skin grafting, may induce recruitment of epithelial and endothelial progenitors from stem cell sources beyond the skin, such as the bone marrow, predominantly from the mesenchymal stromal cell pool; this is an area of much debate and current research.

Fluorescence microscopy today: a perspective

Dylan M. Owen, M. Makarova

Fluorescence microscopes are some of the most widely used tools in current cell biology, either as systems within individual laboratories, or increasingly commonly, within centralized core facilities. The largely non-invasive nature of fluorescence imaging is its major strength, in that it allows the distribution of individual, specific protein species to be mapped at submicron resolution in living cells, tissues and even whole living organisms. Techniques developed in the 1990s and early years of the twenty-first century, including the development of fluorescent fusion protein constructs based on genetically encoded fluorescent proteins, advances in excitation and detector technology allowing new levels of specificity, speed and signal-to-noise ratio, and new image analysis and computing techniques for the manipulation and quantification of the resulting data, the most modern of which now use artificial intelligence and machine learning approaches, have collectively made fluorescence a standard research tool found within most laboratories working in the biological sciences.

A new wave of technological developments that have appeared in the past decade is being adopted by the biological sciences community. New fluorescent probes, optical technology and image processing algorithms have underpinned the development of super-resolution microscopy in which fluorescence images can be obtained with resolution approaching the molecular scale. In effect, this allows the mapping of all fluorescent molecules in a sample with nanometre accuracy, a possibility that is changing the way we think about what microscope images mean. Another major advance has been light-sheet-based imaging (**Fig. 1.1.1**). Its fundamental origins go back decades, but it is only now that light-sheet technology is becoming a vital tool that is especially useful for imaging large samples such as embryos and whole organisms, and in so doing, is threatening the status of the confocal microscope as the go-to system for most bio-imaging.

Fluorescent fusion constructs allow a protein species of interest to be genetically fused to a fluorescent protein so that it can be visualized in a microscope (Chudakov et al 2010). Originally, this meant fusion to the green fluorescent protein (GFP) from the Pacific jellyfish *Aequoria victoria* (Tsien 1998). For the development of this technology, the 2008 Nobel Prize for Chemistry was shared between Osamu Shinomura, who identified and purified GFP; Martin Chalfie, who created and imaged the first fluorescent fusion (Chalfie et al 1994); and Roger Tsien, who mutated GFP to create a whole palate of possible colours – a palate that is now vast (Shaner et al 2005, Giepmans et al 2006). Unlike immunostaining, in which fluorescently tagged antibodies to the protein of interest are introduced into a cell, GFP is genetically encoded and is therefore compatible with live cell imaging, so allowing the investigation of protein dynamics under physiological conditions. The newest fluorescent protein technology includes photoactivatable and colour-switchable proteins, which are useful for tracking intracellular events (Patterson and Lippincott-Schwartz 2002). In parallel with the advances in fluorescent protein technology, work is ongoing on new, small organic dye molecules for use in immunostaining and other applications: the Janelia series of JF dyes are excellent examples of rationally designed fluorophores with superior photophysical properties that have largely rendered traditional dyes, such as FITC, obsolete.

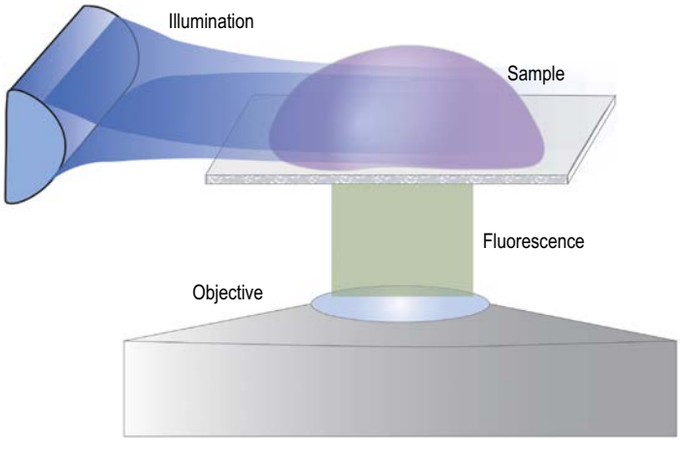

Fig. 1.1.1 Light-sheet microscopy, where the whole plane, and only that plane, is illuminated at any time; the imaging is fast but there is minimal toxicity from the laser because the peak power density is low.

Concomitant with the developments in labelling technology, detectors have become faster and more sensitive. The charge-coupled device (CCD) camera evolved into the electron-multiplying CCD (EM-CCD) camera, sensitive enough to detect individual photons and therefore to image and track single molecules within cells. Currently, compound metal-oxide semiconductor (CMOS) camera technology with very high frame rates and huge fields of view is transforming microscopy. Increases in sensitivity mean that scientific CMOS cameras are now even replacing EM-CCDs for single-molecule imaging applications. For point detectors such as those used on confocal and multiphoton systems, new hybrid detectors are being implemented, offering the Holy Grail of extremely high sensitivity and large dynamic range.

In conventional fluorescence microscopy methods (widefield epifluorescence, confocal, spinning disk, total internal reflection, etc.), the resolution of the final fluorescence image is limited to 200–300 nm by the diffraction of light, which means that two fluorescent objects separated by less than this distance would not be distinguishable as two separate entities. In 2014, the Nobel Prize for Chemistry was awarded to W. E. Moerner, Eric Betzig and Stefan Hell for developing super-resolution fluorescence microscopy methods. The diffraction limit was circumvented by three new methodologies that combined new fluorophores, optics and image analysis. Broadly speaking, these techniques are based on structured illumination microscopy (SIM) (**Fig. 1.1.2A**), in which a grid pattern of excitation light is projected on to the sample (Gustafsson 2000); stimulated emission depletion (STED) microscopy (**Fig. 1.1.2B**), in which a 'doughnut'-shaped depletion beam is used to de-excite fluorophores and narrow the excitation spot used in confocal microscopy (Hell and Wichmann 1994, Vicidomini et al 2011); or single-molecule localization microscopy (SMLM) techniques (**Fig. 1.1.2C**) in which individual molecules are imaged and localized in sequence (Betzig and Chichester 1993). SMLM can be subdivided depending on the types of fluorophore used and how the signal is separated from the ensemble in order to achieve single-molecule imaging.

SIM achieves resolutions of around 100 nm and is compatible with conventional fluorophores and live cell imaging. STED typically achieves 50–100 nm resolution in biological samples, but is more challenging for live cell imaging because of the damaging laser powers used. SMLM delivers the highest resolution of 20–30 nm, but is relatively slow and therefore mainly used on fixed cells where new switchable fluorophores allow fluorescent molecules to be turned on stochastically. Individual molecules are then imaged and their coordinates recorded before the fluorophores are bleached and a new subset of molecules is activated. In this way, all molecules in the sample can be imaged in sequence, circumventing the diffraction limit. Using SMLM, the ability to acquire tables of the x, y and z coordinates of all individual fluorescent molecules, rather than images *per se*, requires new ways of thinking about the analysis and quantification of data sets, a challenge that is only just beginning. One of the newest implementations of SMLM uses complimentary DNA oligos to label molecules in the sample with fluorophores. Termed DNA points-accumulation for imaging by nanoscale topography (DNA-PAINT), it allows the serial imaging of target species and hence many-colour SMLM (Schnitzbauer et al 2017).

The newest developments in *in vivo* imaging are based on light-sheets (see Fig. 1.1.2). Originally termed SPIM (selective plane illumination microscopy), a flat sheet of excitation light is projected through

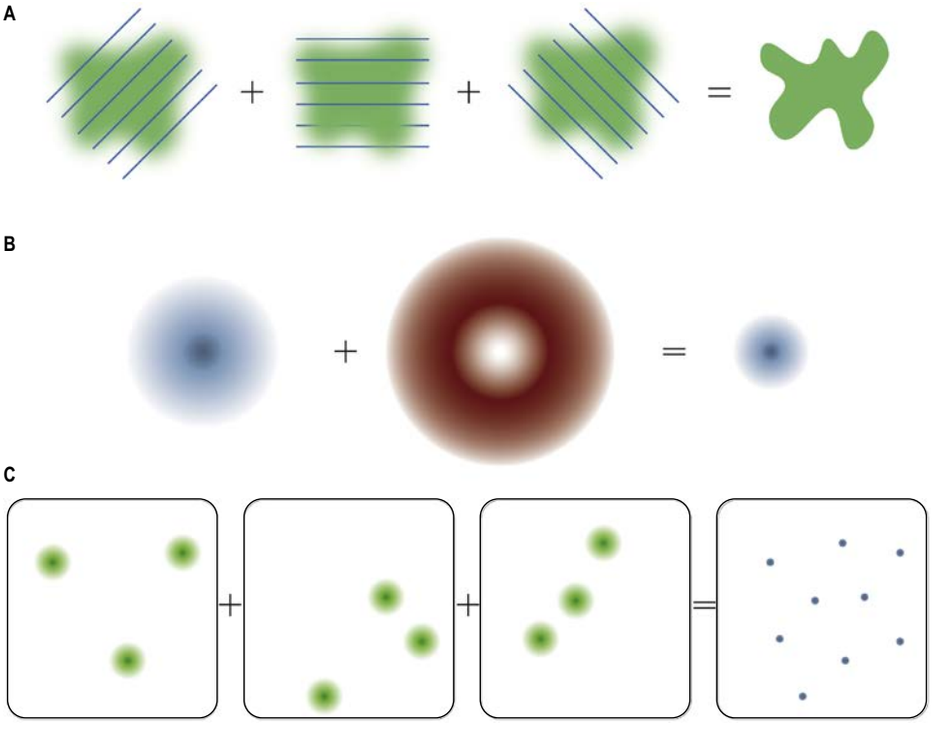

Fig. 1.1.2 In SIM, the sample is illuminated with a stripe or grid pattern which is then rotated and shifted over the sample. **A**, Mathematical reconstruction can combine these individual raw images to create a sharper picture with double the original resolution. **B**, STED works on confocal microscopes and uses a red, doughnut-shaped 'depletion beam' to shrink the size of the original illumination spot, creating a sharper image with a spot size that is dependent on the red laser power. **C**, In SMLM, molecules are imaged a few at a time, sparsely separated so that the location of each can be pinpointed with nanometre accuracy; these are then summed over thousands of frames until the position of every fluorescent molecule has been mapped.

the sample and imaged by a perpendicularly arranged lens (Huisken et al 2004), allowing high-resolution three-dimensional imaging at high speed and with minimal photo-damage to the sample. Modern implementations of light-sheet offer the advantages of confocal microscopy (e.g. optical sectioning) but with dramatically increased imaging speeds and low phototoxicity. Light-sheet therefore has numerous applications in whole, live organism imaging such as in fly embryos, nematodes and zebrafish development (Chen et al 2014). Light-sheet-based imaging is now being combined with super-resolution methods such as SIM and SMLM, with improvements in resolution, image quality, live-cell compatibility and imaging speed.

While work on new improved fluorophores, laser technology, optical components and processing algorithms continues, more radical breakthroughs in microscopic techniques and data analysis are likely. They will focus on further enhancements to resolution, e.g. the recently developed MINimal emission FLUXes (MINFLUX) method (Balzarotti et al 2017), imaging speeds and applicability to whole-organism imaging, e.g. Photoactivated Localization Microscopy (PALM), which is beginning to be applied to live cells when the biological structure is relatively stable (Shroff et al 2008) and the speed of STED has been greatly improved (Chmyrov et al 2013). There is no doubt that these advances will make fluorescence microscopy an even more valuable tool within the biological sciences.

Electron microscopy in the twenty-first century

Roland A. Fleck

INTRODUCTION

Biological electron microscopy (EM) is pivotal in life science research. A measure of its ubiquity is the diversity of its capacity, e.g. three-dimensional structural information about proteins and viruses at Å resolution; three-dimensional reconstructions of cellular organelles and tissues (from a few tens of nanometres to hundreds of micrometres); and two-dimensional and topographic information and elemental microanalysis at subcellular resolution. The capacity of EM can be further enhanced by correlative light and electron microscopy (CLEM) workflows, where light microscopy (LM) events are co-localized with underlying ultrastructure. In its simplest form, LM generates a 'Google Earth'-like map to identify areas of interest, which are then studied at the ultrastructural level by EM, so overcoming both the physical size limitations imposed on samples by EM and the diffraction limits of resolution imposed by LM (Williams and Carter 2009). CLEM can also be combined with advanced EM sample preparation and imaging techniques to provide previously unheralded levels of cytoarchitectural insight into biological systems (Sartori et al 2007, McDonnald 2009, Plitzko et al 2009). Pioneering groups now employ correlation in workflows which allow single particle cryo-EM techniques to be applied directly to structures in cells and tissues. Electron tomography is required to first determine the 3D structures of irregular samples such as cells and organelles. Once good tomograms are available, it is possible to extract multiple copies of a structure of interest and then apply single particle methods to obtain averages with greatly improved signal-to-noise ratios.

However, biological EM is not without its challenges. The electron beam is generated under vacuum at pressures and temperatures that are nominally incompatible with liquid water, yet water is the most abundant cellular constituent. Moreover, carbon-based life forms also have poor contrast in the electron microscope because they are composed mainly of light elements. In fact, carbon is so 'transparent' in the electron microscope that it is often employed as a film to support biological samples. To overcome these caveats, hydrated 'live' tissue is converted to a 'fixed' state; conventional protocols employ a series of steps, including chemical fixation, alcohol dehydration and resin infiltration. Heavy metal salts are added for positive staining of fixed and embedded specimens or as negative stains of whole structures that have been deposited on a support film (Glauert and Lewis 1998). More recently, cryo-fixation has been adopted to allow the 'solidification of a biological specimen by cooling with the aim of minimal displacement of its components' (Steinbrecht and Zierold 1987). By using low temperature as a physical fixation strategy, the morphology and dimensions of the living material are retained and soluble cellular components are not displaced, which means that processing artefacts commonly encountered in more conventional room-temperature EM techniques are either reduced or removed. Cryo-EM often allows direct observation of specimens that have not been stained or chemically fixed.

EM IN PATHOLOGY

Although the use of EM in diagnostic histopathology has declined from the height of its popularity in the 1980s, EM remains an important diagnostic tool in several well-defined areas. Indeed, guidance issued by the UK's Royal College of Pathologists cites and supports the Association of Clinical Pathologists Best Practice No. 160, which states that 'Many respondents [to a review of laboratory practice in renal pathology] expressed the opinion that to carry out evaluation of renal biopsy specimens without at least having the availability of electron microscopy is negligent' (de Haro and Furness 2012). Other specialized areas include the diagnosis of primary ciliary dyskinesia; certain skin/connective tissue disorders, e.g. inherited bullous lesions and Ehlers–Danlos syndrome; and specialized areas of ophthalmic pathology (de Haro and Furness 2012). Despite its continued value and capacity to inform, diagnostic transmission electron microscopy (TEM) has been largely stagnant in the clinical setting; there has been little change in procedures or application for decades. In marked contrast, TEM in the research setting has experienced an explosion in capacity and capability: there is a considerable opportunity for twenty-first century EM to translate to, and to advance, clinical research and diagnostic pathology (**Fig. 1.2.1**, **Video 1.2.1**).

LIMITATIONS OF TRADITIONAL PROCESSING TECHNIQUES AND CURRENT PROTOCOLS

Traditional EM processing strategies introduce artefacts (perturbations to structure) (**Fig. 1.2.2**) that affect tissue structure, e.g. by shrinkage or swelling of the tissue under examination, the shrinkage of cellular organelles, and/or the extraction or redistribution of cellular constituents such as lipids, proteins and DNA (Boyde and Maconnachie 1979). Most chemical fixatives react with proteins and cross-link peptide chains as part of their action (Glauert and Lewis 1998). These reactions can be highly deleterious to epitopes, significantly compromising immunohistochemical studies.

Cryo-fixation has two distinct advantages over chemical fixation (Nermut and Frank 1971, Nermut 1991). It is rapid (measured in milliseconds), which means that the sample is preserved, hydrated and in a 'close-to-life' state at the point of initiating fixation, and it ensures simultaneous immobilization of all macromolecular components (Robards and Sleytr 1995). Many protein networks are labile and prone to disruption with even a slight osmotic or temperature change; cryo-fixation minimizes these deleterious effects. Cryo-techniques allow the study of biological samples with improved ultrastructural preservation and may facilitate the study of dynamic processes. Rapid freezing prevents artefactual aggregations of proteins because tissue fixation and processing can be performed with no or minimal use of cross-linking fixatives, which means that samples retain higher antigenicity (Kellenberger 1991, Hayat 2000, Claeys et al 2004).

This level of preservation relies on vitrification (the transformation of water from a liquid to an amorphous state without inducing the nucleation of ice crystals). The nucleation of ice crystals is

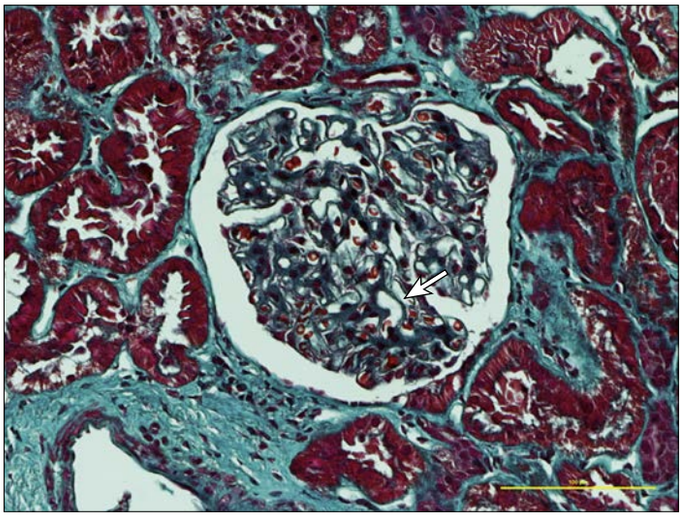

Fig. 1.2.1 A Masson trichrome stain of a renal biopsy taken for diagnostic histopathology. The arrow highlights a glomerular capillary, fringed with foot processes, which would be selected for investigation at higher resolution by transmission electron microscopy (see Video 1.2.1). For diagnostic pathology, the whole glomerulus would be examined. Key: red, keratin; blue/green, collagen; light red/pink, cytoplasm. (Courtesy of M Balys.)

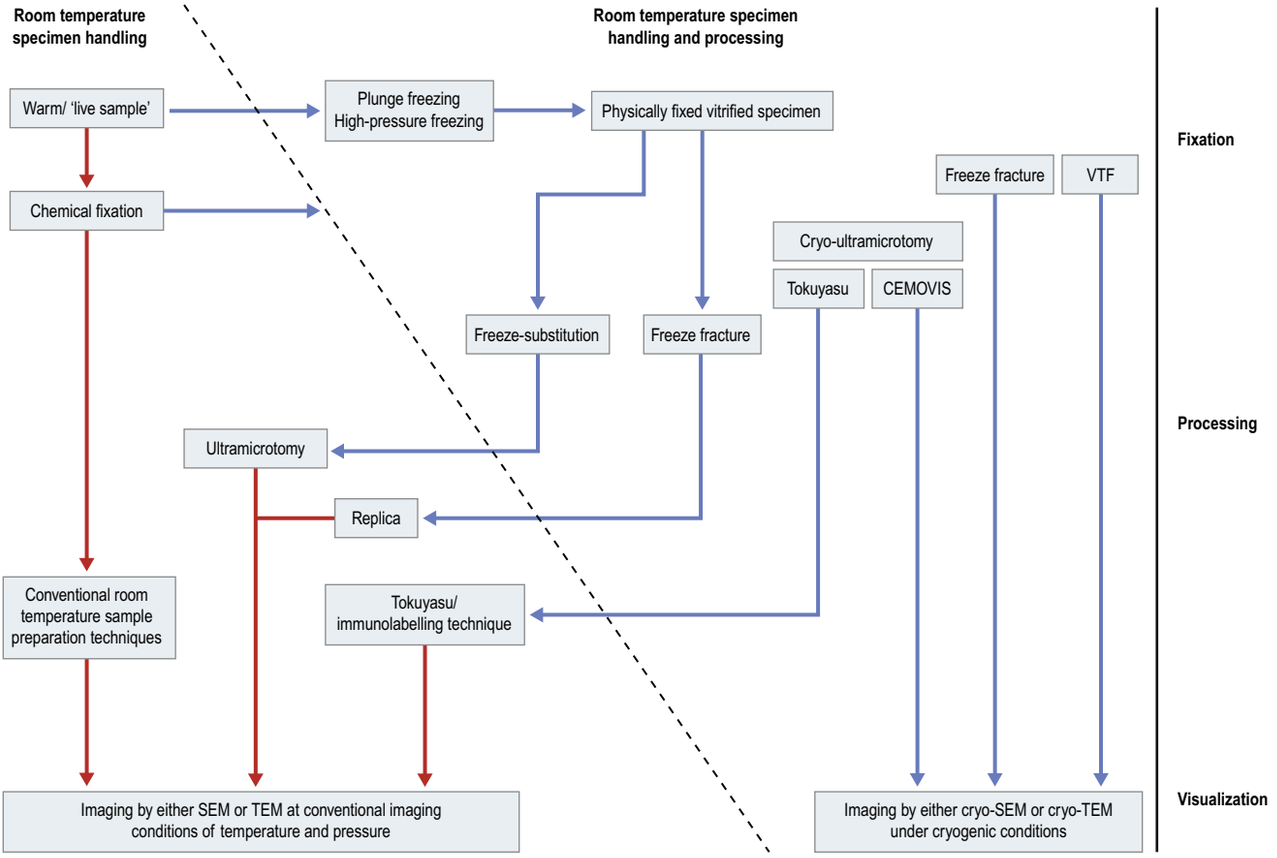

Fig. 1.2.2 An overview of electron microscopy specimen preparation workflow. Areas to the left of the dashed line are at room temperature, indicating that samples can be handled without the requirement for specialist cryo-operating procedures. Samples to the right of the dashed line must be handled in a manner suitable for vitreous biological samples, taking specific care to pre-cool tools before approaching or manipulating samples. Arrows denote the direction of workflow and key stages required to process a sample from 'living/close to life' state to final image. Vitreous thin film (VTF) is a technique in which a liquid sample is pipetted (4–6 µl) onto a transmission electron microscopy (TEM) grid and blotted to create a thin, even liquid film across the surface of the grid. Ideally, the TEM grid should have a holey carbon film and, following blotting, the liquid sample will be held as a monolayer (approximately 12 nm thick) of particles supported within the holes. This film is then plunged rapidly into a liquid cryogen (ethane) to vitrify the sample, generating a vitreous ice film that is amorphous (no long-range structure) and thus a desirable support phase for cryo-electron microscopy of the encased particles (Cheng et al 2012). Other abbreviations: CEMOVIS, cryo-electron microscopy of vitreous sections; SEM, scanning electron microscopy. (Adapted with permission from Fleck RA 2015 Low-temperature electron microscopy. In: Wolkers W, Oldenhof H (eds) Methods in Cryopreservation and Freeze-Drying Protocols. Methods in Molecular Biology. Berlin: Springer.)

temperature- and pressure-dependent. Crystallization depends on the cooling rate, itself dependent on the thermal properties of water, the sample thickness and the heat extraction flow at the surface of the specimen. Freezing is a time-dependent process. Vitrification sits at the beginning of a workflow where the sample is either subsequently processed to a stable room-temperature state for imaging or maintained in its vitreous state throughout (see Fig. 1.2.2) (Fleck 2015).

There are a variety of methods for rapid freeze fixation of tissues. However, the depth of vitrification is often limited (e.g. a few microns for samples plunged into liquid cryogen). Of the available technologies, high-pressure freezing (HPF) is by far the most effective. First introduced by Moor and Riehle in 1968, HPF exploits the physical benefit of high pressure (210 MPa) to reduce the cooling rate required for the vitrification of water from several 100,000 $K.s^{-1}$ to a few 1,000 $K.s^{-1}$, making vitrification of relatively thick samples practicable (Moor and Riehle 1968, Studer et al 2008). HPF machines synchronize the pressurization and cooling of a sample to below the glass transition temperature (Tg) within 20 ms, in a highly reproducible manner (Müller and Moor 1984, Riehle 1968, Studer et al 2001), extending the depth of vitrification to as much as 200 µm (Studer et al 1995, Studer et al 2008). These machines are now incorporating added functionality to achieve a high degree of temporal resolution. For example, light-sensitive cation channels can be expressed in cells and tissues, stimulated in the HPF pressure chamber at different time intervals (ranging from ms to s) and immediately cryo-immobilized. Electron micrographs acquired from many time points reveal in minute detail sequences of morphological changes with ms precision. Using this approach, the process of ultrafast endocytosis has been characterized during neurotransmission (Watanabe 2016). Electrical stimulation has also been adapted to HPF technology, allowing electron microscopy to reveal complex events previously identified by electrophysiology.

Tissue samples prepared in this way require further modification to make them compatible with the transmission electron microscope. They must either be converted to a room-temperature stable state (e.g. by freeze substitution into a resin), or be sectioned whilst remaining below the glass transition temperature (T_g); when this is achieved, images close to the native structure of biological specimens can be obtained. Despite its benefits, cryo-electron microscopy of vitreous sections (CEMOVIS) has not been routinely adopted, principally because of the technical difficulty in producing a ribbon of frozen sections and transferring it to an EM grid. A double micromanipulator tool that guides the ribbon using an electrically conductive fibre, and then positions and attaches the ribbon to an EM grid has been developed (Studer et al 2014) (**Fig. 1.2.3**).

ADVANCES IN INSTRUMENTATION AND DETECTOR TECHNOLOGY

EM has undergone a revolution in recent years, largely coincident with the advent of digital charge-couple device (CCD) cameras and increasing personal computer (PC) processing power. What was principally a two-dimensional technique now readily embraces three dimensions by electron tomography (Gan and Jensen 2011). In this technique, a specimen is tilted through the incident beam, sequential images are acquired, and, after alignment, a weighted back-projection is used to generate a three-dimensional tomographic volume (see Video 1.2.1). These techniques have stimulated instrument changes. In conventional TEM, low

Fig. 1.2.3 Cryo-electron microscopy of vitreous sections (CEMOVIS) performed using a cryo-ultramicrotome. The cryo-chamber (Leica EM FC6, Leica Microsystems, Austria) is mounted on a conventional room-temperature ultramicrotome (Leica EM UC6, Leica Microsystems, Austria). The double manipulators (Manip, Diatome, Switzerland) are then attached to the top of the cryo-chamber, allowing precise control of both the vitreous ribbon and the transmission electron microscopy grid. The system is located within a glove box to maintain a low-humidity environment around the sample that will reduce contamination during sectioning.

accelerating voltages (80–120 keV) provide a strong beam-to-specimen interaction in order to increase contrast from electron scattering. Cryo-TEM and tomography require higher accelerating voltages (200–300 keV), which reduce the beam-to-specimen interaction; the contribution of chromatic aberration to the image is also reduced, theoretically improving resolution (Williams and Carter 2009).

Changing the emission source has been another major technical advance. A field emission gun (FEG) is becoming the preferred source of the electron beam because it provides a beam of smaller diameter, higher coherence and a current density (brightness) of up to three orders of magnitude greater than was achieved with conventional thermionic emitters (e.g. tungsten or lanthanum hexaboride (LaB_6)-tipped filaments) (Kersker 2001). The net results for both scanning electron microscopy (SEM) and TEM have been greatly improved signal-to-noise ratio and spatial resolution, coupled with a significant increase in emitter life and reliability. FEG has had a major impact on the practicality of cryo-SEM and resolution in cryo-TEM studies, although these higher accelerating voltages carry the penalty of decreased contrast.

Overcoming the challenges of contrast in the transmission electron microscope

Zero-loss energy filtering is employed to improve image contrast in the transmission electron microscope. The filter may be positioned either in-column or post-column. Increased scattering contrast and the exclusion of the blurred background (as a consequence of the interception of inelastically scattered electrons) allow specimens to be imaged closer to focus, and increase high-resolution contrast and image resolution (Grimm et al 1997, Grimm et al 1998).

Energy-filtered transmission electron microscopy (EFTEM) imaging to remove the contributions of inelastically scattered electrons is advantageous when imaging thick biological samples. Han et al (1995) demonstrated that only elastically scattered electrons contributed to the coherent image component when imaging biological specimens of more than 0.5 µm thick at 200 keV; optimization of the zero-loss signal required operation at intermediate to high primary accelerating voltages (over 200 keV). The gain due to EFTEM increases with specimen thickness, with a linear dependence for light-scattering elements (Grimm et al 1998). These results are important for the accurate recording of images of thick biological specimens by tomography and to demonstrate the increasing importance of high accelerating voltages in biological TEM (Grimm et al 1998).

New technologies are overcoming previous limitations imposed by low contrast in the transmission electron microscope. Zernike phase plates (ZP), which are well accepted for imaging with the light microscope, represent a novel approach to imaging in the transmission electron microscope. Despite technical hurdles in their use, the potential reward in greater contrast has driven research into this technology (Fukuda et al 2009, Glaeser 2013). An approximate five-fold increase in contrast is possible with a $\{\pi/2\}$ ZP that shifts the phase of only the scattered electrons (these phase-shifted electrons interfere with the unscattered electrons in the image plane), resulting in amplitude contrast rather than phase contrast. Indirect scintillator-coupled charge-coupled device (SCCD) cameras replaced film cameras and revolutionized EM because they provided a near-instant digital readout and obviated the physical limitation of a fixed number of image plates. Direct detection devices (DDD) avoid the fundamental inefficiencies of the electron-to-light conversion process of a scintillator and achieve unmatched sensitivity and resolution with superior detective quantum efficiency (DQE) relative to a conventional CCD camera (Milazzo et al 2010). Moreover, direct exposure to the incident electron beam significantly improves the signal-to-noise ratio in comparison to a SCCD (Milazzo et al 2010). Perhaps more importantly, DDD allow images to be recorded as movies, which means that movement caused by the electron beam can be corrected computationally (Grigorieff 2013). As an example, images of ribosomes of sufficient quality to permit alignment at an accuracy that approaches near-atomic resolution have been obtained using approximately 30,000 images (Bai et al 2013).

When combined, ZP, EFTEM and DDD offer a paradigm shift in the capability of the transmission electron microscope and are likely to drive further advances in EM-based research. Whether in isolation or combination, these techniques will translate from cutting edge to routine instrumentation, heralding generic benefits to the field. Phase contrast electron microscopy utilizing ZP has already been applied to histochemically stained strong-phase (high-contrast heavy-metal-stained) biological specimens (Atsuzawa et al 2009). In sections of various thicknesses specifically stained for the Golgi apparatus, a high-contrast gain was observed even for strong-phase objects, indicating that phase contrast electron microscopy has an application for traditional strong-phase-contrasted biological specimens (Atsuzawa et al 2009), as well as for low-phase cryo-fixed biological specimens (e.g. the visualization of cyanophage Syn5 inside its host, *Synechococcus*, using ZP in combination with cryo-tomography (cryo-ET) to enhance image contrast over conventional cryo-ET) and will permit direct identification of subcellular components (Dai et al 2013).

ADVANCES IN THE SCANNING ELECTRON MICROSCOPE

Cryo-FEGSEM has become well established as a research tool. The stability and emitter life of a FEG source, coupled with the stability and low keV sensitivity of a modern scanning electron microscope, is a powerful tool (Fleck and Humbel 2019). Unlike TEM, in which high accelerating voltages are used to transmit the electrons through the specimen, SEM benefits from low accelerating voltages that limit beam interaction with the specimen. This is key to successful cryo-SEM but creates a challenge around generating sufficient signal for high-resolution imaging. Modern FEGSEM systems (with improved detector sensitivity and signal-to-noise ratios) are now achieving sub-nm resolution at 1 keV, making them highly capable tools for life science research, particularly when combined with high-resolution coating and fracture techniques (Fleck 2015) (see Fig. 1.2.2; **Fig. 1.2.4**).

Large three-dimensional volumes may be generated by the assembly of sequential two-dimensional images acquired in the scanning electron microscope. There are essentially three strategies, each with unique strengths and weaknesses: focused ion beam (FIB), serial block face SEM (SBFSEM) and array tomography (AT). FIB involves milling of material in a dual-beam scanning electron microscope using a focused beam of gallium ions to cut (mill) away layers of material. After each cut, the surface is imaged, ultimately producing a stack of two-dimensional images that can be aligned to generate a three-dimensional volume. Although FIB can be combined with cryo-preparation techniques, elemental microanalysis and the range of imaging modes available within the SEM, it can be challenging (problems include achieving registry between slices, gallium contamination of the sample, and damage to structural information caused by the milling process).

SBFSEM takes a different approach from FIB and incorporates a microtome within the scanning electron microscope chamber (Denk and Horstmann 2004). The microtome cuts a thin section from the block, an image is taken and the procedure is repeated until a three-dimensional volume is generated (**Video 1.2.2**). SBFSEM is less prone to registration issues because the sample essentially remains locked in position below the detector. However, like FIB, this technique is destructive since, once sectioned, the sample is lost. SBFSEM uses room

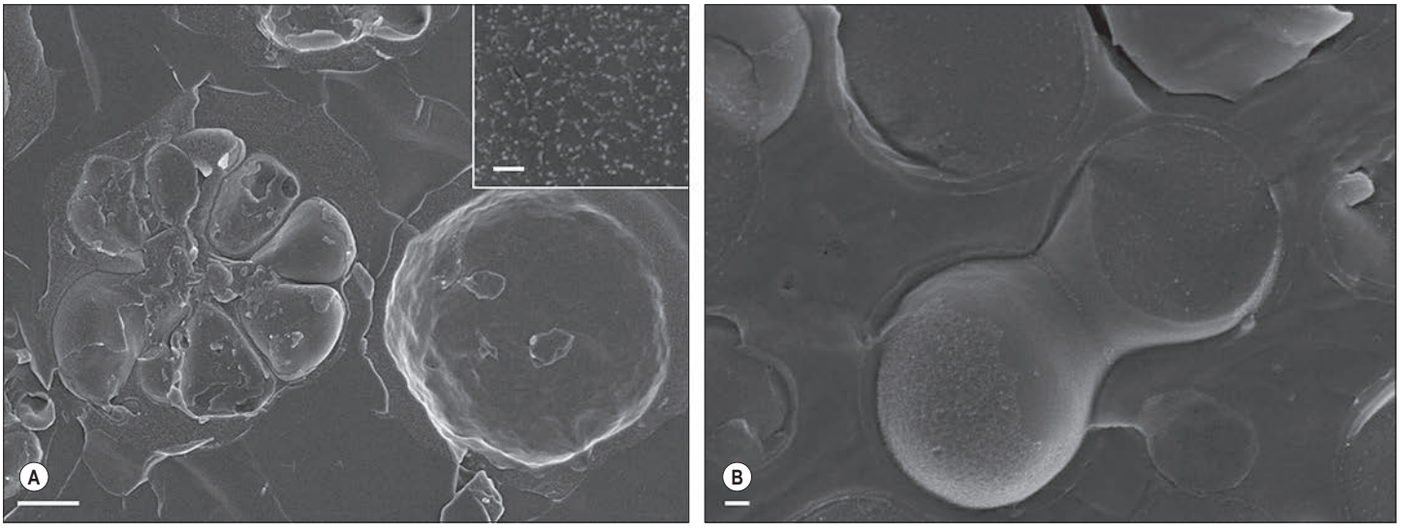

Fig. 1.2.4 Cryo-scanning electron microscopy (SEM) images. **A**, Fractured *Plasmodium falciparum*-infected erythrocytes. A cross-fractured infected erythrocyte is shown; the insert depicts a high-magnification image of the p-face of the infected erythrocyte with membrane proteins visible on the fracture plane. The scale bar represents 1 μm (main image) and 100 nm (inset). **B**, Cross-fractured *Neisseria meningitidis* showing surface membrane protein organization and polysaccharide coat. The scale bar represents 100 nm. Images were taken with a cold-field emission gun cryo-SEM (JSM-7401F, JEOL, Japan), equipped with a Baltec/Leica VCT100 vacuum transfer system and cryo-stage. Coating was applied after fracturing (3 nm Pt/C) using multi-angle rotational coating (BAF060, Baltec/Leica Microsystems, Austria).

temperature processing techniques with high levels of *en bloc* heavy metal staining that are required to generate a sufficiently robust back-scattered electron signal to form an image. The processing steps, and the limitations of the back-scattered electron detector, mean that SBFSEM is currently incompatible with elemental microanalysis or cryo-techniques. However, this is a nascent technology that is advancing rapidly. Novel applications will emerge with advances in detectors, improved resins (e.g. conductive resins) and the exploitation of charge suppression approaches in the SEM (e.g. beam deceleration).

Unlike FIB and SBFSEM, AT is not destructive and material may be recovered and re-imaged. The technique allows samples to be prepared by any TEM preparation strategy. Material is sectioned at room temperature by ultramicrotomy; the sections are collected in order as a ribbon and may then be stained to enhance contrast, or are immunolabelled. Ribbons may be imaged by LM or SEM; individual sections can be identified, recovered and imaged at the higher spatial resolution of the transmission electron microscope. Successful AT requires high-precision x-y-z sample stages that can perform programmed, sequential (in focus) imaging of serial sections. Arguably the most challenging aspect of the workflow is the serial sectioning of the sample; to date, this is undertaken almost exclusively by highly skilled operators. To simplify the process of collecting a large number of sequential sections a number of innovative solutions have been developed. The ATUMtome (RMC, USA) employs a tape system to automate the serial sectioning process by collecting hundreds of individual sections sequentially on a tape (**Fig. 1.2.5**) and the ARTOS3D (Leica-microsystems, Vienna) automatically creates and collects hundreds of serial-section ribbons on a carrier (silicon wafer or slide) ready for AT using a SEM equipped with software able to automate imaging of each section (or region of interest contained within a section) for all the sections loaded into the SEM. New multibeam-multidetector SEMs (e.g. 61 concurrent beams) have been developed that allow images of up to 1.2 billion pixels to be acquired in 1 s (Marx 2013) further speeding data acquisition.

Access to the cell interior enables structural studies *in situ* within otherwise unperturbed cellular environments and is an emerging frontier of life science electron microscopy. Although FIB milling is slow, it is uniquely able to produce, in a precise and controlled way, undistorted layers of suitable thickness for electron tomography. The alternative method for thinning specimens, cryo-sectioning of vitrified samples (CEMOVIS), is limited by knife damage, which compresses cryo samples by ~30% and limits usable section thickness to 50–80 nm, barely retaining any relevant 3D context. A cryo TEM operating at 200 or 300 kV or in STEM mode can readily acquire tomograms from sections up to 600 nm thickness. A minimum section depth of at least 200 nm is required to completely include major cell structures such as the nuclear pore complex (~120 nm), and malarial knob structures (~150 nm). A cryo-focused ion beam field emission scanning electron microscope (cryo FIB SEM) can be used for the preparation of vitrified lamellae of cellular material to be imaged by cryo-electron tomography in a cryo TEM. This allows three-dimensional (3D) structures of cell and tissue regions at nanoscale resolution to be determined, in order to understand biological machinery in its native, cellular context. Electron tomography generates the 3D structures of irregular samples such as cells and organelles. Once good tomograms are available, it is possible to extract multiple copies of a structure of interest and apply single particle methods to obtain high resolution 3D structures. This approach has been demonstrated for membrane coat complexes in FIB lamellae (Bykov et al 2017). There are few currently published tomography studies of FIB milled cells, however, each is reinforcing cryo FIB milling as a key preparative step in the workflow for cellular structural biology (Engel et al 2015, Mahamid et al 2015, Arnold et al 2016, Mahamid et al 2016). Its ability to precisely target and prepare electron-transparent volumes, from areas identified using CLEM approaches that harbour molecular machines in their functional context, is becoming increasingly important for cell biology. When combined with automated tomographic data acquisition in the TEM, the potential for quantitative investigation of 3D cellular structures is truly realized.

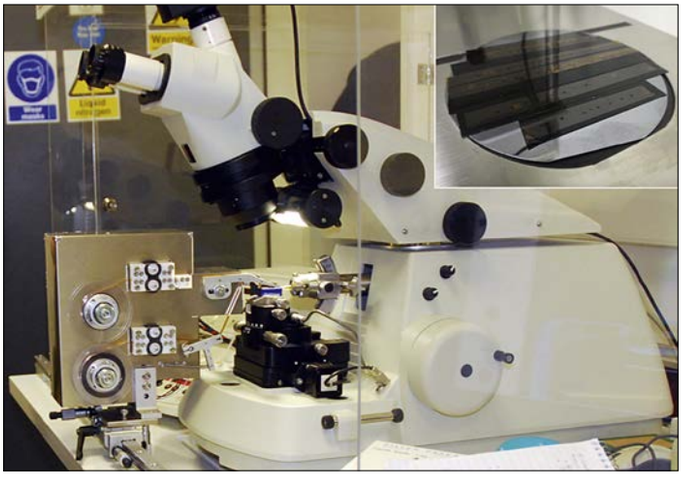

Fig. 1.2.5 ATUMtome and tape. The ATUMtome is mounted on a PT-PC PowerTome (RMC, USA), showing the tape being transferred from a delivery spool (top) to receiving spool (bottom) through the boat, which maintains a water reservoir behind the edge of the diamond knife (blue) to float the sections and allow their capture by tape. Tape tension is maintained throughout by a series of tensioning springs and guides. The inset shows individual sections on tape mounted on carbon tape and silicon wafer (to help dissipate specimen charging during imaging) ready for viewing in the scanning electron microscope.

Future trends

Developments in thin-film technology and microfabrication are facilitating the design of liquid cells that will permit improved imaging of samples in the liquid phase (de Jonge and Ross 2011). In combination with recent advances in ZP, EFTEM and DDD, the new generation of liquid cells offers considerable potential for the study of complex dynamic cellular processes. These may be further enhanced by the translation of emerging trends in material science to the life sciences which proffer higher resolution and a capacity to address transient structures. These include pulsed source TEM, compressive sensing, 4D STEM, ptychographic phase reconstruction (Dömer and Bostanjoglo 2003, Barwick et al 2008, Zewail 2010, Browning et al 2012, Stevens et al 2014, Yang et al 2015).

COMMENTARY

1.3 Metaplasia

Jonathan M.W. Slack

Metaplasia is the appearance, in adult life, of a patch of tissue that normally belongs elsewhere in the body (Slack 1985, 2007). Generally it is understood that a metaplasia has originated *in situ* and has not migrated from elsewhere; so, for example, metastatic tumour deposits are not considered to be metaplasias, nor are tissues misplaced during embryonic development, such as thyroid residues in the thyroglossal duct.

Metaplasias are very diverse (Willis 1962). They include ectopic bone and cartilage arising from connective tissue, squamous metaplasia of glandular epithelia, and substitution of one glandular epithelial tissue for another. The latter group is of particular interest from a biological point of view. These transformations are normally between tissue types that originated in embryonic development as neighbours in a common cell sheet. Such tissues may remain neighbours into adult life or may become separated. An example of metaplasia between tissues that are still neighbours in the adult is intestinal metaplasia of the stomach, involving patches of small intestine-like epithelium which are found in the stomach (Stemmerman and Hayashi 1968, Gutierrez-Gonzalez and Wright 2008). An example of metaplasia between tissues that have become anatomically separated is intestinal metaplasia found in the urinary bladder that typically comprises cell types and markers normally found in the colon (Sung et al 2006). The bladder is no longer part of a common cell sheet with the intestine in the adult, but it is in the embryo, where it originates from the allantoic diverticulum of the hind gut. Metaplasias of glandular epithelia are particularly common in the gastrointestinal tract and in the female reproductive tract (Kurita 2011), perhaps because these are both examples of structures in which a number of different tissue types arise from a simple epithelial tube in the embryo.

The metaplasias are clinically important because they often predispose to cancer: for example, carcinomas of the bronchus usually arise within areas of squamous metaplasia (Auerbach 1961, Rigden 2016) and carcinomas of the stomach usually arise in regions of intestinal metaplasia (Correa 1992, Busuttil and Boussioutas 2009, Spence et al 2017). Metaplasias arise because the combination of gene activities that normally defines the tissue type in embryonic development becomes altered in adult life. The genes in question encode a limited number of key transcription factors. For example, the transcription factor p63 is essential for the formation of squamous epithelia (Koster et al 2004) and is always found to be expressed in patches of squamous metaplasia. The transcription factor CDX2 is required for the formation of intestinal epithelium, and is expressed in patches of intestinal metaplasia (Barros et al 2012). Epithelial tissues like these are maintained by continuous renewal from a population of stem cells, and the initiating event, which may be a somatic mutation or an epigenetic change of gene expression, changes the character of the stem cells: once the change has occurred, it is normally irreversible.

Barrett's metaplasia, also known as Barrett's oesophagus, is a well-studied example of metaplasia (Falk 2002, Gilbert et al 2011, Naini 2016, Colleypriest et al 2017) (**Fig. 1.3.1**). It is characterized by the

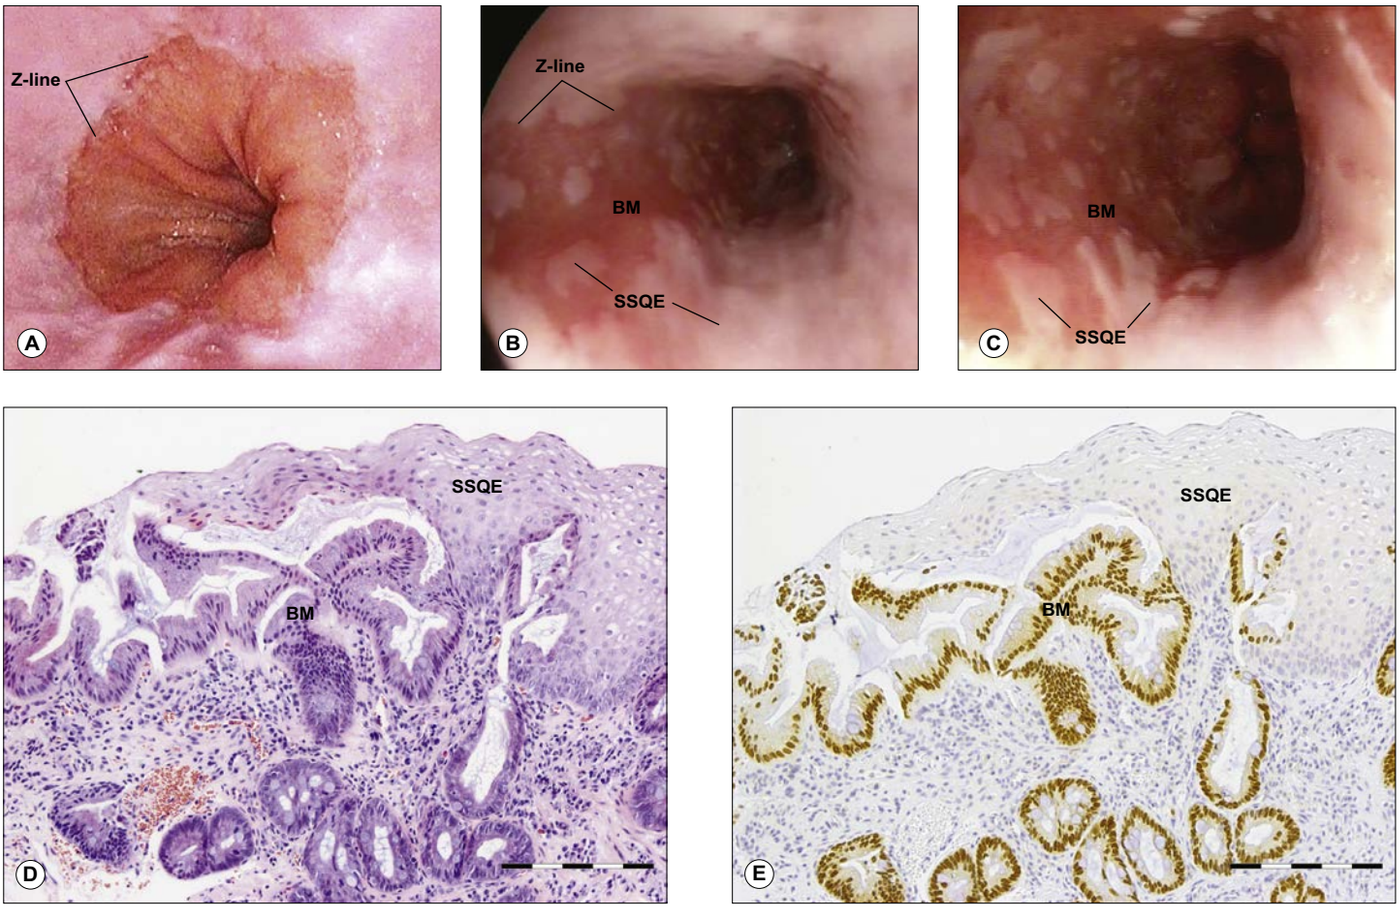

Fig. 1.3.1 Barrett's metaplasia. **A–C**, Endoscopy. **A**, Normal appearance showing the junction between gastric columnar and oesophageal squamous epithelium (Z-line). **B–C**, Two cases of Barrett's oesophagus. The Z-line has moved proximally and is very irregular. There are islands of squamous tissue within the columnar region. Abbreviations: SSQE, squamous epithelium; BM, metaplastic epithelium. **D–E**, Histological views. **D**, Hematoxylin and eosin staining. **E**, Immunostained for CDX2 (brown). Scale bar 200 μm.

presence of columnar epithelium in the distal oesophagus, some of which resembles intestinal epithelium because of the presence of goblet cells. Barrett's metaplasia is a risk factor for the development of oesophageal adenocarcinoma, a cancer whose incidence rose considerably in the late twentieth century (Hvid-Jensen et al 2011). In less developed countries most oesophageal cancers are squamous cell carcinomas, arising from the normal squamous lining of the oesophagus, but in the Western world adenocarcinomas are now more common.

Some metaplasias are monoclonal, meaning that a particular focus of ectopic tissue is derived exclusively from a single cell, as would be expected if the cause is the somatic mutation of key transcription factor genes. Monoclonality has been demonstrated for individual foci of intestinal metaplasia of the stomach, where neighbouring metaplastic crypts arise by fission (Gutierrez-Gonzalez et al 2011). In Barrett's metaplasia, patches of crypts are also monoclonal (Nicholson et al 2012) although the lesion as a whole is polyclonal, being derived from several original progenitors, with various combinations of abnormalities arising from somatic mutation (Leedham et al 2008). A key property of metaplastic foci is that the new tissue is in a situation of competitive growth with the old tissue that surrounds it. Unless the metaplastic tissue can outgrow the surrounding tissue then the transformation of a single stem cell would not give rise to a macroscopic lesion: this aspect of epithelial biology remains poorly understood.

The exact cell of origin of Barrett's metaplasia is still not known (McDonald et al 2015). Theories include a migration of glandular tissue from the stomach; an origin from transitional or primitive cells located at the squamo-columnar junction; metaplasia of the squamous epithelium of the oesophagus; an origin from submucosal oesophageal glands. The plausibility of transformation of the squamous epithelium or the oesophageal glands is increased by the fact that the normal oesophagus originates from an endodermal tube lined with columnar epithelium that becomes squamous between about 6–7 weeks of gestation (Yu et al 2005, Zhang et al 2017).

The predisposing cause of Barrett's metaplasia is gastro-oesophageal reflux, in which stomach acid and bile from the intestine enters the oesophagus (Souza 2010). It is known that this environment can induce expression of some of the key genes involved in intestinal development, such as those encoding CDX factors and hepatocyte nuclear factors, in oesophageal cells (Eda et al 2003, Debruyne et al 2006, Piessen et al 2007). Obesity is a well-known risk factor for reflux, partly because of effects on intra-abdominal pressure and probably also through the effects of cytokines released from fat (Corley et al 2007). Barrett's metaplasia may progress to dysplasia and to adenocarcinoma. Progression is associated with loss of the tumour suppressor gene *CDKN2A*, encoding the protein p16 which is an inhibitor of cell division, and *TP53*, encoding the protein p53 required for death of abnormal cells (Spechler et al 2010, Chen et al 2011).

Gastro-oesophageal reflux is normally treated with proton pump inhibitors that reduce the levels of stomach acid. This improves associated oesophagitis but does not usually result in regression of any Barrett's metaplasia. Barrett's metaplasia as such is not normally treated: if it progresses to dysplasia, it may be extirpated by a variety of endoscopic techniques of which radiofrequency ablation has become the most usual (Lim and Fitzgerald 2013, Spechler and Souza 2014).

COMMENTARY

1.4 Merkel cells

Ellen A. Lumpkin

The epidermis, our outermost layer of skin, serves as a protective barrier and sensory interface with the world. In vertebrates, these functions are accomplished through the work of only four conserved cell types. Keratinocytes form a water-tight barrier, melanocytes protect against ultraviolet damage and Langerhans cells perform immune surveillance. Merkel cells, which constitute less than 1% of the epidermis, are an enigmatic cell type whose function and developmental origin have long been debated; however, recent advances show that mammalian Merkel cells are epithelial derivatives that signal to sensory neurones to initiate touch sensation.

As early as the nineteenth century, Merkel cells were proposed to contribute to skin's sensory function. These cells were first described by Friedrich Sigmund Merkel, who named them touch cells (*Tastzellen*), based on contacts with nerve terminals (Merkel 1875). Merkel cells cluster in highly touch-sensitive skin areas, including glabrous (hairless) skin of fingertips and lips, some hair follicles and touch domes on the trunk (**Fig. 1.4.1**). Most Merkel cells are innervated by a particular class of myelinated (Aβ) sensory neurones called slowly adapting type I (SAI) afferents (Iggo and Muir 1969). These touch receptors are unusual because they produce biphasic discharges of electrical impulses that send two types of information to the brain (see Fig. 1.4.1): dynamic responses to moving stimuli represent an object's spatial features (e.g. edges and curvature), whereas sustained volleys of electrical activity signify steady pressure (e.g. contact with clothing; Johnson 2001).

Merkel cells were initially proposed to serve as sensory receptor cells based on their synapse-like contacts with nerve terminals and dense-core vesicles filled with neurotransmitters (Halata et al 2003). Sensory receptor cells, such as taste-bud cells or hair cells of the inner ear, transduce the energy of a sensory stimulus into electrical signals, which then trigger neurotransmitter release to excite sensory afferents. The hypothesis that Merkel cells are mechanosensory receptors was challenged by neurophysiological studies that reported touch sensitivity after Merkel cell loss, which suggested that Merkel cells act in a non-sensory capacity. Studies in rodent models have reconciled these views by demonstrating that Merkel cells and their sensory afferents are mechanosensory cells. Three lines of evidence support this two-receptor-site model, which was proposed almost three decades ago (Yamashita and Ogawa 1991).

First, Merkel cells are touch-sensitive. Like hair cells in the inner ear, Merkel cells display fast mechanotransduction currents that convert cellular movement into electrical signals (Ikeda et al 2014, Maksimovic et al 2014, Woo et al 2014). These currents are mediated by Piezo2 mechanosensitive ion channels, which are essential for touch and proprioception (Ranade et al 2014, Woo et al 2015, Chesler et al 2016; see Fig. 1.4.1).

Second, Merkel cells are excitatory cells. This was established with optogenetics, a technique that uses light-activated molecules derived from *Archea* to stimulate or inhibit electrical signalling in specific cells. Transgenic mice were engineered to selectively express light-activated membrane proteins in Merkel cells (Maksimovic et al 2014): when their skin is illuminated, Merkel cells are activated and their sensory afferents produce sustained trains of electrical impulses that mimic the response to pressure (see Fig. 1.4.1). Conversely, neuronal firing is inhibited when Merkel cells are optogenetically silenced. These results confirm that Merkel cells are sensory cells capable of exciting afferents.

Third, Merkel cells are necessary for sustained, but not for dynamic, firing in SAI afferents. Prototypical SAI responses are abolished in transgenic mouse strains that lack either Merkel cells or epidermal PIEZO2 expression (Maricich et al 2009, Maksimovic et al 2014, Woo et al 2014). Inhibiting the release of neurotransmitter-containing vesicles from Merkel cells also attenuated touch-evoked neural activity (Chang et al 2016, Hoffman et al 2018). In all cases, sustained touch produced only transient bursts of neuronal impulses (see Fig. 1.4.1). These findings indicate that mechanosensory signalling from Merkel cells is essential for conveying information about pressure to the nervous system. Touch-driven behaviours are compromised in rodents lacking

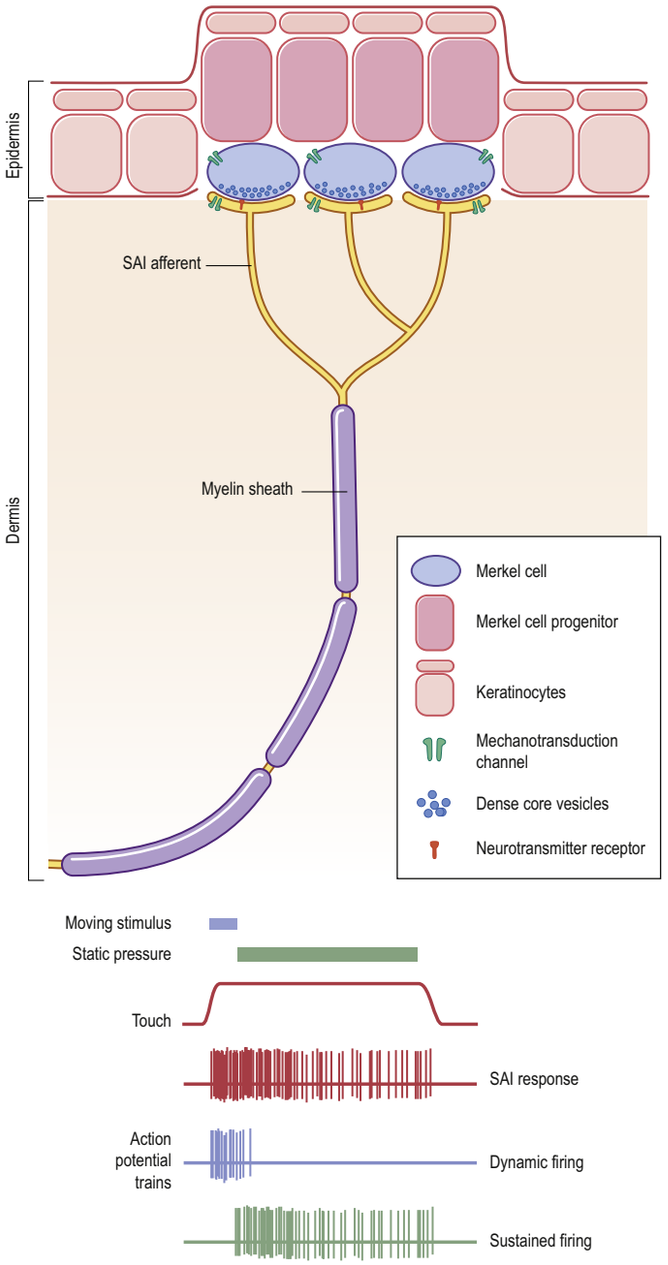

Fig. 1.4.1 The Merkel cell–neurite complex is a compound touch receptor. The schematic shows the innervation of a touch dome. Merkel cells (blue) cluster in these highly touch-sensitive spots in humans and other mammals. Merkel cells are mechanosensory receptor cells derived from epidermal progenitors. Adjacent Merkel cells are innervated by a myelinated sensory afferent fibre (yellow) that produces slowly adapting type I (SAI) responses (black electrical impulses). This response has two phases: (1) *Dynamic firing*: During a moving stimulus (blue bar), Piezo2 mechanotransduction channels (magenta) in the sensory afferent stimulate transient neuronal volleys (blue impulses). (2) *Sustained firing*: Static pressure (green bar) activates the Merkel cells' Piezo2 channels (magenta) to excite electrical signalling. Merkel cells then release monoamine-containing vesicles (black dots) to stimulate sustained electrical impulses in SAI afferent terminals (green). The intracellular signalling pathways that link G-protein coupled monoaminergic receptors (orange) to neural excitation have not been identified. (Receptor and channel symbols © motifolio.com.)

functional Merkel cells, again indicating that Merkel cells are important for the perception of touch (Maricich et al 2012, Ikeda et al 2014, Woo et al 2014). Taken together, these studies demonstrate that the Merkel cell–neurite complex is a compound touch receptor with two mechanosensory cell types arranged in series (see Fig. 1.4.1).

Which neurotransmitters convey information between Merkel cells and sensory afferents remains a key open question. In rodents, it has been proposed that whisker follicle Merkel cells signal through serotoninergic receptors (Chang et al 2016), whereas touch-dome Merkel cells have been reported to employ adrenergic synapses (Hoffman et al 2018). Both findings support the model that Merkel cells use vesicular release of monoamine neuromodulators rather than classical excitatory neurotransmitters to excite the nervous system (see Fig. 1.4.1). Since drugs that target monoamine signalling are widely used for treatment of depression (selective serotonin reuptake inhibitors) and cardiovascular disease (beta-blockers), these basic science findings may have clinical implications by suggesting new treatment avenues for peripheral sensory disturbances such as numbness and tingling.

Transgenic mouse studies have also clarified the ontogeny of the Merkel cell, which expresses an unusual assortment of epithelial and neuronal markers (Moll et al 1984, Halata et al 2003, Haeberle et al 2004). For example, although embedded in a stratified epithelium, Merkel cells express simple epithelial keratins. It was therefore unclear whether Merkel cells are derived from epithelial precursors or neural crest. These competing models were tested in transgenic mice by genetically marking specific cell lineages based on selective expression of *Cre* recombinase. $Wnt1^{Cre}$, which marks all neural crest cells, failed to label Merkel cells, whereas $Krt14^{Cre}$, a marker of keratinocyte-derived cells, labelled Merkel cells in all skin areas (Morrison et al 2009, Van Keymeulen et al 2009). Moreover, Merkel cell specification is disrupted by epithelial-specific deletion of developmental transcription factors (Morrison et al 2009, Van Keymeulen et al 2009, Bardot et al 2013, Lesko et al 2013, Perdigoto et al 2014), and Merkel cells are replenished from epidermal progenitors in mature skin (Van Keymeulen et al 2009, Woo et al 2010, Doucet et al 2013, Wright et al 2017).

The embryonic progenitor of the Merkel cell remains a matter of debate, although recent studies have identified developmental pathways that bestow this neurosensory fate in epidermis. It has been proposed that Merkel cells in mouse hair-bearing skin are derived from hair-follicle placodes, but genetic lineage tracing of hair follicle progenitors has called this model into question (Xiao et al 2016, Jenkins and Lumpkin 2017). Merkel cell progenitors have distinct molecular phenotypes in mouse hairy and glabrous skin (Nguyen et al 2019).

Despite remarkable progress in Merkel cell biology, key questions about human Merkel cells remain unanswered. Do Merkel cells serve additional, non-sensory functions? This is particularly important in human skin, where many Merkel cells lack innervation. Are human Merkel cells derived from epidermis and renewed throughout life? If so, how are these processes disrupted during ageing, which is accompanied by loss of touch receptors in extremities? This loss is thought to contribute to the decline of tactile acuity, grip strength and postural stability in the elderly. Intriguingly, a recent study linked age-related loss of Merkel cells to chronic itch, which is a prevalent clinical problem in the elderly (Feng et al 2018).

Mechanisms of Merkel cell specification may also be important in Merkel cell carcinoma (MCC). This highly aggressive, non-melanoma skin cancer has been linked to Merkel cells on the basis of ultrastructure and molecular markers (Haeberle et al 2004, Bhatia et al 2011, Harms et al 2013). An important unresolved question is whether Merkel cells or their progenitors act as cells of origin for MCC. Distinct molecular pathways appear to give rise to MCC downstream of two risk factors, namely ultraviolet (UV) irradiation or infection with Merkel cell polyoma virus (MCPyV; Feng et al 2008, Harms et al 2018). In most cases of MCC, integration of MCPyV and subsequent inhibition of retinoblastoma tumour suppressor protein give rise to MCPyV-positive tumours with a low mutational burden. By contrast, virus-negative tumours display UV mutational signatures and inactivation of tumour suppressor genes. Despite different aetiologies, virus-positive and virus-negative tumours share similar clinical presentations and treatment guidelines (Harms et al 2018).

Immune checkpoint inhibitors targeting the PD-1 pathway have been a game changer in the clinical care of MCC (Harms et al 2018, Nghiem and Park 2019). These agents are beneficial in almost half of patients with advanced MCC and overall survival at three years is dramatically improved in patients receiving immune checkpoint inhibitors compared with conventional chemotherapies (Nghiem et al 2019). Such promising clinical results have led to rapid changes in treatment guidelines, with immune checkpoint inhibitors now the recommended first-line therapy for advanced MCC in appropriate patients. Nonetheless, new therapies are needed for patients who are immunosuppressed or otherwise resistant to immune checkpoint inhibitors.

ACKNOWLEDGEMENTS

COMMENTARY 1.5

The reaction of peripheral nerves to injury

Rolfe Birch, Praveen Anand

Main nerve trunks contain many thousands of axons. When a trunk is stretched, but not ruptured, by dislocation of, say, the femoral or humeral heads, or by the nearby passage of a bullet, the axons within that nerve may respond in different ways. The degree of injury may vary along the length of a particular nerve or transversely across its cross-section: some axons will remain intact, some will sustain conduction block but recover rapidly, and yet others will degenerate throughout their entire extent distal to the injury because they have been ruptured. A proportion recover spontaneously whilst the remainder never recover.

Seddon (1943) introduced the terms neurapraxia for conduction block, axonotmesis for a degenerative lesion of favourable prognosis, and neurotmesis for a degenerative lesion of unfavourable prognosis. Sunderland (1951) expanded this classification to five degrees of peripheral nerve injury by subdividing neurapraxia according to the degree of connective tissue disruption, and Mackinnon and Dellon (1988) subsequently added a sixth category. However, the fundamental distinction between neurapraxia and either axonotmesis or neurotmesis remains the persistence of conduction in the distal segment of the nerve in neurapraxia, and the absence of conduction in axonotmesis or neurotmesis. In clinical practice, neurotmesis usually signifies transection of an entire nerve trunk, its constituent fascicles and their surrounding investments of perineurium and epineurium; the proximal and distal nerve stumps are frequently separated by an inter-stump gap of varying length (**Fig. 1.5.1**). The early disappearance of conduction indicates impending or actual critical ischaemia and is probably the most important indicator that a lesion is deepening (see below).

Neurapraxia/conduction block

Conduction block exhibits certain characteristic features: paralysis exceeds loss of sensation; proprioceptive nerves are more deeply affected than those responsible for light touch; sympathetic nerves to the smooth muscles of the blood vessels and sweat glands are least affected. There are distinct patterns of conduction block. Anoxia is important in all of them and there are often elements of mechanical deformation, inducing alterations of the nodal and paranodal apparatus in myelinated axons, and subsequent demyelination of whole internodes or of paranodes.

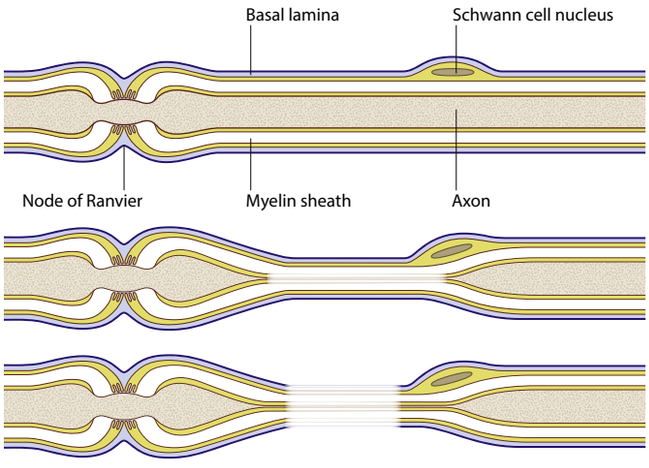

Fig. 1.5.1 Axonotmesis (centre) and neurotmesis (bottom) at the moment of injury. Note the preservation of the Schwann cell basal lamina in axonotmesis. Transient ischaemia

Lying in one position without moving for a long time (e.g. during coma, inebriation or anaesthesia), prolonged sitting with the legs crossed or prolonged leaning on the elbows are all situations in which a limb nerve may be transiently compressed against a bone or a hard surface. The ischaemia thus induced in the compressed nerves causes an anoxic, physiological, block of both axoplasmic transport and ion channel functions along affected axons. This is seen during operation for the exposure of limb nerves with an inflated cuff in position: stimulation of a nerve evokes a brisk muscular response by transmission through the neuromuscular junction, which then diminishes before disappearing after about 30 minutes, whereas conduction within the nerve itself can be detected for about another 30 minutes. On the other hand, direct stimulation of the muscle provokes a twitch that can be elicited for about another 2 hours; loss of this direct response signals impending muscle death. The selective vulnerability of different populations of nerve fibres is demonstrated by the classical experiment of applying an inflated cuff about the arm (Lewis et al 1931). The observer experiences first a loss of superficial sensibility, then a graduated loss of muscle power. The first pain response is lost soon after superficial sensibility fails; the delayed pain response is still detectable after 40 minutes of ischaemia. Large myelinated axons are first affected; unmyelinated axons and autonomic fibres escape, and pilomotor and vasomotor functions are scarcely affected. All modalities recover within a few minutes of release of the cuff; the unpleasant quality of the residual delayed pain sensation, and the burst of painful 'pins and needles' after release of the cuff, give an insight into the feelings of patients affected by dysaesthesiae.

Slowly progressing ischaemia

Conduction block caused by a haematoma or aneurysm, or by bleeding into compartments, produces early and deep autonomic paralysis and loss of power that extends over hours or days, whilst deep pressure sense and some joint position sense persist. These symptoms are seen in war wounds, when nerves become compressed and strangled by scar tissue or by the cicatrix deep to split skin grafts, and may progress over a period of weeks or months. The recovery of function and relief of pain are rapid – at times, dramatic – after removal of the cause in most of these cases.

Prolonged conduction block associated with focal demyelination

Severe prolonged pressure causes local demyelination and a conduction block that is not directly attributable to anoxia and that may last for weeks or months (**Fig. 1.5.2**). Compression-induced focal paranodal myelin deformation may be involved; experimental studies using a cuff inflated to high pressure around a limb produced slippage of paranodal myelin at nodes of Ranvier lying under the edges of the cuff, i.e. where the pressure gradient between compressed and non-compressed portions of the nerve was likely to be greatest (Ochoa et al 1972, Dyck et al 2005). Clinically, local demyelination and conduction block will persist until the source of the external irritation, e.g. a bony projection, is removed (Birch and St Clair Strange 1990). Relief of pain and recovery follow rapidly in lesions that have persisted for many months, or even years. Mechanical deformation is the likely explanation for the conduction block seen in cases of 'hourglass' constriction of fascicles within a nerve trunk, where axons may be focally constricted within affected fascicles (**Fig. 1.5.3**).

Prolonged conduction block of war wounds

The characteristic features of classical neurapraxia (see above), caused by the nearby passage of a missile, are likely to be provoked by a momentary displacement or stretching of the nerve trunks. However, a different pattern of conduction block may occur in recent conflicts, where the patient is exposed, at close range, to the shock wave of an explosion (e.g. blast injury), in addition to penetrating injury to the bony and soft tissues at the level of the nerve lesion. In these cases, the smallest fibres are most deeply affected and they may not recover. Pain may vary in both of these variants of conduction block (Birch et al 2012).

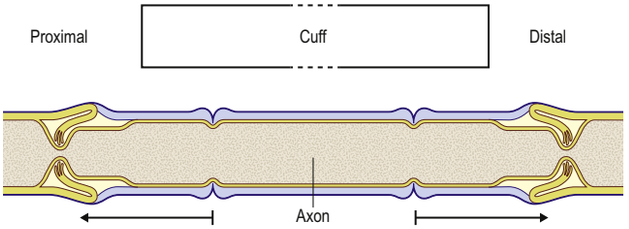

Fig. 1.5.2 The effect of mechanical compression: paranodal and juxtaparanodal myelin slippage under the edges of an inflated pressure cuff. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Non-freezing cold injury (trench foot)

Trench foot, or non-freezing cold injury (NFCI), is caused by exposure to cold of sufficient severity and duration but above the freezing point. It results in abnormalities of the small sensory nerve fibres and associated vascular abnormalities which may persist for years. Based on observations of trench foot in World Wars I and II, the condition was described as a vaso-neuropathy (Ungley et al 1945). It is associated with marked degeneration of cutaneous intraepidermal nerve fibres with regeneration of disproportionate and abnormal nerve fibres along subepidermal blood vessels, causing a 'painful vaso-neuropathy' (Anand et al 2017).

Degenerative lesions

There are essentially two types of degenerative lesion, with very different potentials for recovery. In the first, which approximates to axonotmesis, the tubes of Schwann cell basal lamina that surround each axon–Schwann cell unit remain intact, which means that axons may regenerate in an orderly fashion across the lesion site and into the distal stump, providing that the causative agent is removed and that the length of the distal stump (i.e. the distance from the site of injury to the end organ) is not so long that it compromises axonal regrowth. In the second, which approximates to neurotmesis, not only the Schwann cell basal lamina tubes, but also the connective tissue sheaths around the fascicle are interrupted; spontaneous axonal regeneration following this type of injury will be imperfect and disorderly, and may not occur at all.

Deepening of a lesion in a nerve that has not been divided

Unrelieved activity of a noxious agent on an intact nerve is signified by pain and increasing neurological deficit, indicating that the lesion is deepening. Nerves within a swollen ischaemic limb or tense compartment become compressed and anoxic. Nerves displaced by an expanding haematoma become stretched and anoxic. Nerves that have become displaced into a fracture or joint are tethered and become subjected to

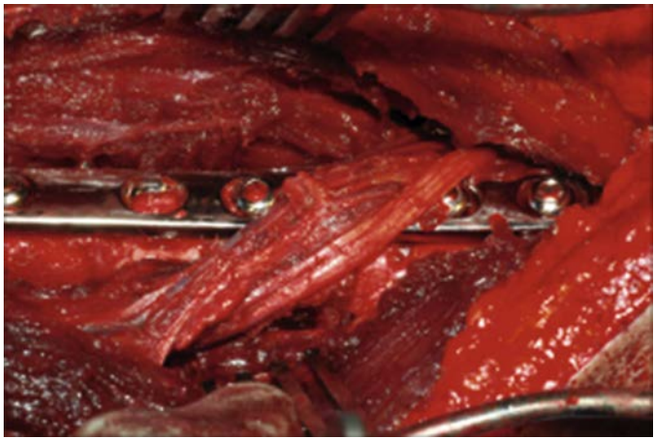

Fig. 1.5.4 The appearance of a radial nerve after extrication from beneath a compression plate 48 hours after the first operation. There was relief of pain but only incomplete recovery so that subsequent flexor to extensor transfer was necessary. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

compression, stretching and anoxia. These nerves are not severed by the initial injury; the first lesion is axonotmesis and spontaneous recovery is probable if the cause is removed. However, if this does not happen, the lesion continues to deepen into that of neurotmesis and spontaneous recovery will not occur. The speed of deepening of a lesion is related to the cause: (i) a nerve crushed by a plate or strangled by an encircling suture may recover if the cause is removed within a few minutes (Fig. 1.5.4); (ii) a nerve that has become compressed and anoxic within a swollen ischaemic limb will recover if perfusion of the tissues is restored within 3 hours; the likelihood of full spontaneous recovery diminishes with the passage of every hour after that time (Fig. 1.5.5); (iii) a nerve displaced into a fracture or joint will usually recover if it is extricated within a few days, but will be destroyed if a compression device has been used to stabilize the skeleton without retrieving the nerve (Fig. 1.5.6); (iv) function may be retained for a long time in a nerve exposed to continuing traction from a malunited fracture; (v) nerves may continue to work for months or years before failing when they are exposed to the progressing fibrosis caused by radiotherapy, by overlying split-skin graft or by other examples of deep scar; (vi) pain is the cardinal symptom of the unrelieved action of a noxious agent.

Wallerian degeneration

Trauma that physically separates axons from their cell bodies produces Wallerian degeneration (WD). All affected axons in the extreme tip of the proximal stump and throughout the distal stump degenerate, irrespective of their calibre or functional modality; recovery is often slow and incomplete, and there may be considerable residual loss of function. Moreover, although research has tended to address issues associated with the molecular and cellular events that occur at the lesion site and target tissues, it is important to remember that injury to a peripheral nerve that induces WD also initiates significant and often long-lasting central changes in sensory ganglia and ascending and descending pathways within the spinal cord and brain; these changes also have a significant impact on the likelihood of recovery. Studies of cell bodies of human dorsal root ganglia (DRG) have revealed changes in the expression of a wide range of receptors and a remarkable alteration in the expression of genes regulating neuronal activity (Rabert et al 2004, Lawson 2005, Anand et al 2008). There is an extensive literature on WD in both central and peripheral nervous systems, and only a brief summary of the response in the peripheral nervous system is presented here (see Gordon 2015).

Neuronal cell body and proximal stump

The central and the peripheral effects of WD are profound and, in neurotmesis, ultimately irreversible. Not only is the neuronal cell body separated from its continual supply of retrogradely transported neurotrophins, but also its central connections rapidly alter; many neurones thus isolated will die. Amputation provides a model of the effect of permanent division of axons on the spinal cord: there is extensive loss of neurones in the dorsal root ganglia and in the ventral horn, and a diminution of the large myelinated axons in the ventral and dorsal roots (Dyck et al 1984, Suzuki et al 1993). Neuronal death is more severe in more proximal neurotmesis, and less marked after

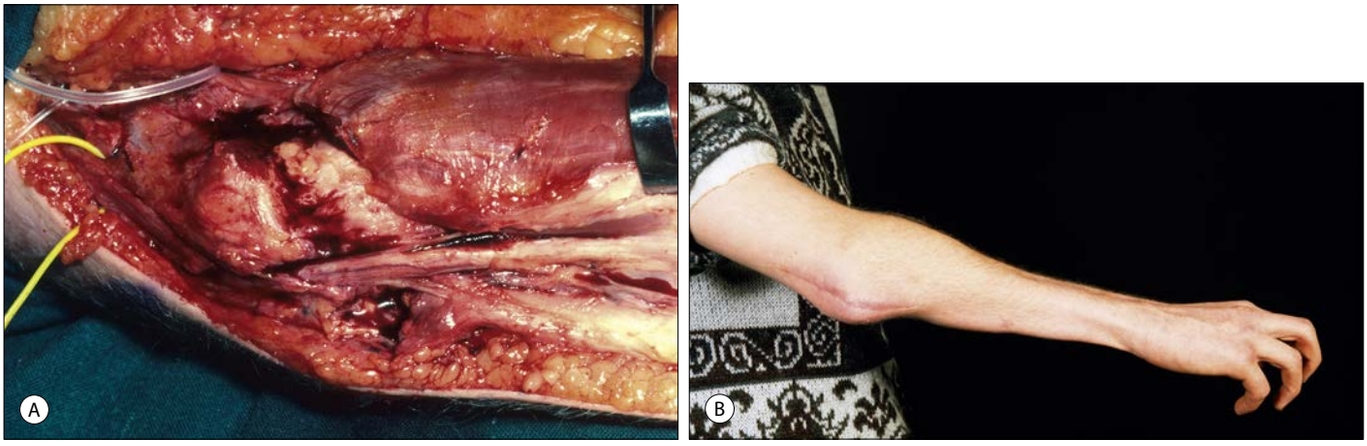

Fig. 1.5.5 Volkmann's ischaemic contracture. **A**, The ulnar nerve exposed during flexor muscle slide 8 weeks after supracondylar fracture. The epineurial vessels and also the ulnar recurrent collateral vessels are occluded, and the nerve is compressed by the swollen infarcted muscle. **B**, The appearance of the hand 14 years later. Fig. 1.5.6 Deepening of a lesion. **A**, A median nerve extricated from a supracondylar fracture in a 9-year-old girl 3 days after injury; there was complete recovery. **B**, A median nerve extricated from a supracondylar fracture in a 13-year-old girl 8 weeks after injury; there was no recovery. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

axonotmesis than after neurotmesis. Neurotmesis in the neonate produces a more rapid and much greater incidence of sensory and motor neurone death than in the adult. Surviving neurones rapidly upregulate a series of genes involved in repair and neuroprotection mechanisms following injury (repair-associated genes, RAGs), which direct many of the changes seen during WD and subsequent recovery (e.g. Calenda et al 2012). (For a review of the molecules involved in retrograde signalling to initiate expression of RAGs, particularly the family of glycoprotein 130 (gp130) cytokines, see Zigmond (2011).) Changes in the expression of ion channels and receptors in the neuronal cell bodies in human DRGs can be detected within a few minutes of an injury to the nerve (Lawson 2005).

Tip of proximal stump

Within a few hours of injury, the cut ends of a transected axon seal off, forming end bulbs. The end bulb that forms at the proximal tip of an axon in the proximal stump is transformed into a growth cone from which multiple needle-like filopodia and broader sheet-like lamellipodia grow out. The filopodia are rich in actin, and may extend or retract within a matter of minutes. Each axon forms new branches or sprouts: collateral sprouts arise from nodes of Ranvier at levels where the axons are still intact, and terminal sprouts arise from the tips of the surviving axons. The axon sprouts and fine cytoplasmic processes derived from their associated Schwann cells form clusters, regenerating units, surrounded by Schwann cell basal laminae. Sprouts within one regenerating unit represent the regenerative effort of one neurone and its axon. Within a few days of injury, the calibre of axons in the proximal stumps is reduced and nerve conduction velocity in the proximal segment falls.

Distal stump

During the first 2 or 3 weeks after injury, the constitutive tissue response within a denervated distal stump involves numerous events: some sequential, others consecutive. These include the production of debris, as axons and their myelin sheaths are degraded; an increase in local blood flow; activation of resident macrophages, and recruitment and influx of exogenous macrophages; and proliferation of fibroblasts and Schwann cells. The gliotic response produces a population of dedifferentiated daughter Schwann cells that remain within the basal lamina tubes secreted by their parent cells, forming what are now called Schwann tubes but which were previously known as bands of Büngner. They behave acutely as the 'presumed targets' of the regrowing axons until the actual targets (muscle or sensory end organ) have been reinnervated: they secrete proteins that collectively facilitate axonal regrowth, whether by providing trophic support or by establishing a supportive growth matrix (for further reading on these interactions, see Hall (2005), Webber et al (2011), Arthur-Farraj et al (2012), Gordon (2015)). There is a growing consensus that Schwann cells express distinct motor and sensory phenotypes, and that this fundamental difference affects the ability of Schwann cell tubes to selectively support regenerating neurones. For example, expression of osteopontin and clusterin is upregulated in Schwann cells in transected peripheral nerves: the two secreted factors appear to facilitate regeneration of motor or sensory neurones, respectively (Wright et al 2014).

While the microenvironment of an acutely denervated distal stump facilitates axonal regrowth because it provides a vascularized segment of longitudinally orientated, laminin-rich basal lamina tubes filled with axon-responsive Schwann cells, a chronically denervated distal stump is associated with poor axonal regeneration and poor functional recovery (Sulaiman and Gordon 2009). Biopsies taken during late repairs, especially when the injury has been complicated by arterial injury or by sepsis, often show remarkably few Schwann cells lying within a densely collagenous matrix. Myelin fragments are detectable in such cases many months after the injury. The residual Schwann cells become progressively less receptive to ingrowing regenerating axons with time; experimental studies have shown that they downregulate expression of axon-responsive receptors that are normally important in Schwann cell–axon signalling (Li et al 1997, Li et al 1998). Accordingly, injured nerves show decreased expression over time of the key Nerve Growth

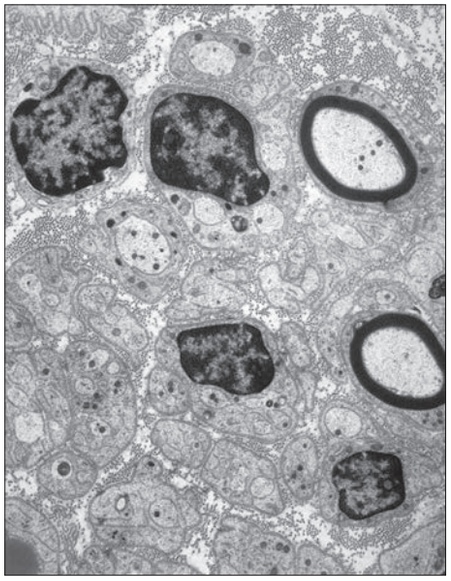

Fig. 1.5.7 Intact (afferent) myelinated and unmyelinated fibres in a suprascapular nerve, 6 weeks after an avulsion lesion of the brachial plexus; efferent fibres have degenerated. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Factor (NGF) in the residual Schwann cells of the distal stump (Anand et al 1997), which may explain, at the molecular level, the unfavourable clinical outcomes of delayed surgical nerve repair. These findings underscore the clinical observation that there is a relatively narrow window of opportunity when surgical intervention is most likely to produce positive results (Lundborg 2000, Dahlin and Wiberg 2017).

The special case of preganglionic injury

The preganglionic lesion is all too common in severe traction injuries to the brachial and lumbosacral plexuses. The roots of the spinal nerves are torn (avulsed) from the spinal cord, which means that the somatic afferent pathway is interrupted between the dorsal root ganglion and the spinal cord (see Fig. 1.5.6). The neuronal cell bodies and their axons, investing Schwann cells and associated basal laminae remain intact, healthy and conducting for a long time after the injury. The surviving axons include all those with cell bodies in the dorsal root ganglion, including many 'recurrent' fibres in the ventral root that derived from cells in the dorsal root ganglion (**Figs 1.5.7–1.5.9**). Somatic efferent fibres, being separated from their cell bodies, degenerate; postganglionic autonomic efferent axons also degenerate, as a result of damage to their grey rami communicantes. Carlstedt (2007) reckons that about one-half of all motor neurones in the affected spinal cord segment have disappeared by 2 weeks after avulsion of the ventral root and he urges 'a swift intervention to re-establish contact between the injured nerve cells and the periphery with its supply of neurotrophic substances to counteract nerve cell loss'. After avulsion injury, human dorsal root ganglion neurones show dramatic changes in the expression of genes involved in neurotransmission, trophism, cytokine function, signal transduction, myelination, transcription regulation and apoptosis (Rabert et al 2004).

Regeneration and recovery of function

> *But the journey of the axon tip to an end organ is only the most dramatic of the phases in the process of regeneration, and its arrival is alone no guarantee of the return of useful function.* **Young (1942)**

The cellular microenvironment of a normal peripheral nerve does not ordinarily support axonal regrowth; indeed, there appear to be 'molecular brakes' that prevent axonal sprouting. Somewhat counterintuitively, it appears that their expression may be upregulated after injury. WD transforms the environment throughout the distal stump of a transected nerve to one that facilitates axonal regrowth, albeit for a relatively short period (Christie and Zochodne 2013). Manipulating the many cellular and molecular responses that occur during the injury response in the peripheral nervous system remains an unachieved goal of reconstructive surgery.

Fig. 1.5.8 Wallerian degeneration in the ventral root of the eighth cervical nerve, 6 weeks after avulsion from the spinal cord. A degenerate efferent myelinated fibre (right) compared with a healthy myelinated afferent fibre (left). (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

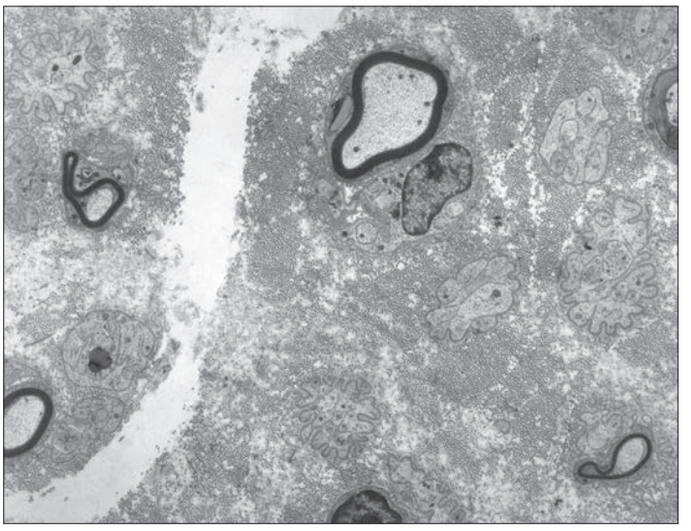

Fig. 1.5.9 Afferent and efferent fibres in a ventral root. Healthy myelinated and unmyelinated fibres in the ventral root of the eighth cervical nerve avulsed from the spinal cord 6 weeks previously. The myelinated efferent fibres have undergone Wallerian degeneration and there is a notable increase in the amount of endoneurial collagen. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Regeneration of end organs

Reinnervation of muscle spindles and Golgi tendon receptors is generally good after crush lesions (axonotmesis). Regeneration after repair of a divided nerve is much less orderly. A muscle spindle may become reinnervated by afferents normally destined for the Golgi tendon organ; many tendon organs remain denervated and the regenerated endings are frequently abnormal in appearance. The reorganization of motor units after repair causes significant alterations in the mechanical input to an individual tendon organ.

Muscles usually exhibit weakness, impaired coordination and reduced stamina after nerve repair. There may be selective failure of regeneration of the largest-diameter fibres and of co-activation of the α and γ efferents. The normal movement of joints is brought about by smoothly coordinated and controlled activity in muscles that is precisely and delicately regulated by inhibition and facilitation of the motor neurones. The conversion of an antagonist to an agonist is the basis of musculotendinous transfer; it is common to see patients actively extending the knee or the ankle and toes as soon as the postoperative splint is removed after hamstring to quadriceps transfer or anterior transfer of tibialis posterior. Reinnervated muscles usually fail to convert after muscle transfer, irrespective of their power. Perhaps the defective reinnervation of the deep afferent pathways from the muscle

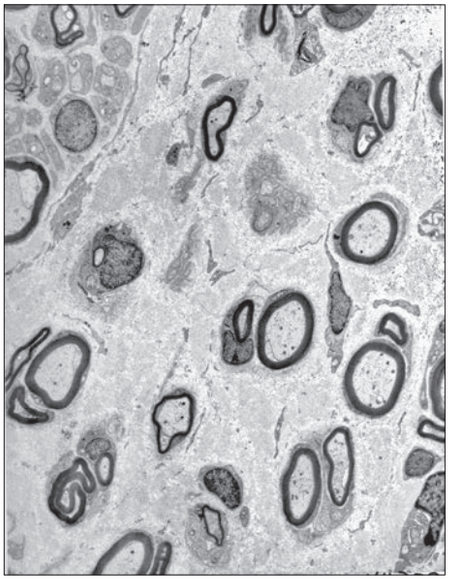

Fig. 1.5.10 Useless regeneration in a median nerve sutured 3 years previously. Proximal to the suture line, the endoneurium contains thinly remyelinated axons, some in regenerating clusters, and extensive collagenization; there was no recovery of function. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

spindles and the tendon receptors blinds muscles, which are, after all, sensory as well as effector organs.

Cutaneous sensory receptors similarly undergo a slow degenerative change after denervation and after 3 years they may disappear. Reinnervation tends to reverse these changes, although the longer the period of denervation, the less complete will be the regeneration. It is usual to find numerous myelinated axons in the tissues bridging nerve stumps in the human, even in failed sutures or in grafts coming to revision (Fig. 1.5.10) (Terenghi et al 1998); these findings encapsulate the difference between regeneration and recovery of function.

Plasticity in the central nervous system

Nerve transfer involves connecting the proximal stump of a healthy nerve to the distal stump of one that has been injured in such a way that direct repair is not possible.

There is considerable adaptation of the central receptor and effector mechanisms after nerve transfer (Fig. 1.5.11). Independent flexion of the elbow without associated activity in the flexor muscles of the forearm is usual by 24 months after transfer from the ulnar nerve to the nerve to biceps brachii. Reinnervation of the muscle spindles and corresponding reorganization and remapping of the somatosensory cortex have been confirmed after transfer of intercostal nerves to the musculocutaneous nerve in adult patients with severe lesions of the brachial plexus (Sai et al 1996, Malessy et al 2003). These central phenomena may explain the remarkably good recovery of sensation within the hand after repair of severe birth lesions of the brachial plexus. The sensory recovery is far better than that of skeletal muscle and sympathetic function: there is accurate localization to the dermatomes of avulsed spinal nerves that had been reinnervated by intercostal nerves transferred from remote spinal segments (Anand and Birch 2002).

Case report

Operation in a 6-month-old boy confirmed rupture of C5 with avulsion of C6–C8 and T1. The lesion was repaired by transfers of the accessory nerve to the suprascapular nerve, of C5–C8 and T1, and of intercostal nerves T3–T5, to the lateral cord of the brachial plexus. At the age of 5 years he was able to localize cotton wool and pinprick sensation accurately in both hands and was able to feel a pin in the affected side. Monofilament, vibration thresholds and joint position sense were identical in both hands. The thresholds for warming were 3.1 °C (C5), 0.8 °C (C6), 4.1 °C (C7), 3.6 °C (C8) and 3.3 °C (T1) on the affected side. The thresholds for cooling were 2 °C (C5), 3.9 °C (C6), 3.8 °C (C7), 2.3 °C (C8) and normal in T1. In the unaffected hand, the thresholds were less than 3.4 °C for warm sensation and less than 2.2 °C for cool sensation. Sweating was 70% of that of the intact palm. It seems likely that afferent impulses from the thumb, index and probably the middle fingers entered the spinal cord through the three intercostal

Fig. 1.5.11 A 13-year-old boy with a right-sided lesion: avulsion of C5–C7. Repair was undertaken at 2 months as follows: accessory to suprascapular transfer; one bundle of the ulnar nerve to the nerve to biceps and the nerve to the medial head of triceps; medial cutaneous nerve of the forearm to the lateral root of the median nerve. Results at 18 months show a full range of lateral rotation; abduction to 60°; power of elbow flexion, Medical Research Council (MRC) grade 4; power of elbow extension, MRC grade 3+. There is a full range of active flexion and extension without obvious co-contraction. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

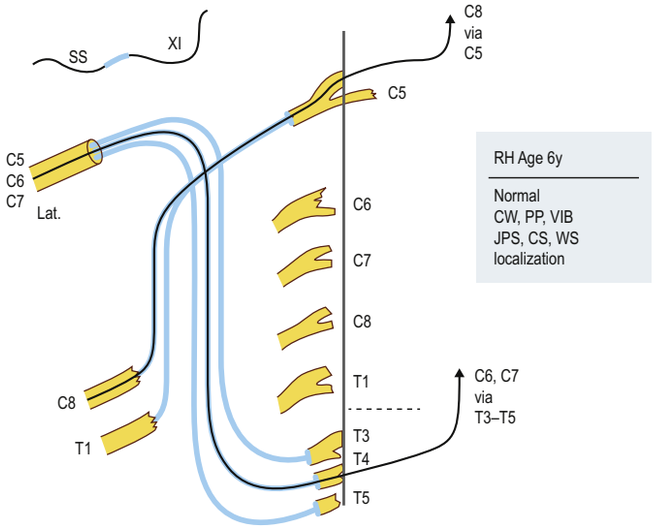

Fig. 1.5.12 The method of repair and the likely pathways for afferent function. Abbreviations: CS, cool sensation; CW, cotton wool; JPS, joint position sense; PP, pinprick; SS, suprascapular nerve; Vib, vibration threshold; WS, warm sensation; XI, accessory nerve. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

nerves, whilst afferent impulses from the little and probably the ring fingers entered the spinal cord through the fifth cervical nerve as shown in Fig. 1.5.12. Similar findings have been observed in four other cases after transfer of intercostal nerves to the lateral cord (Fig. 1.5.13). The situation in the adult is very different. After transfer of the intercostal nerves to the lateral or medial cords, it is usual to find that stimulation of the reinnervated skin is referred to the chest wall and only rarely to the skin of the hand (Htut et al 2006). Concepts of the mechanisms underlying cortical plasticity following nerve injury and the importance of maintaining an active sensory map of the affected part in the somatosensory cortex during the deafferentation period are considered further by Lundborg (2003), Rosén and Lundborg (2007), Björkman et al (2009), Rosén et al (2011) and Knox et al (2015).

Laboratory and clinical studies

There are major differences between a laboratory investigation, in which a controlled, precise and limited lesion is inflicted on a peripheral nerve in an anaesthetized experimental animal, and the situation faced by the clinician presented with a patient with a massive wound involving soft tissues (including blood vessels and muscles) and skeletal elements, and sometimes with other injuries that threaten life and limb. That said, the fundamental cellular processes that underlie subsequent regeneration are similar in the laboratory, in the injuries of civilian practice and in the wounds of war, although in clinical practice they are

Fig. 1.5.13 Birth lesions of the brachial plexus. This boy had a group 4 lesion with rupture of C5 and avulsion of C6–C8 and T1 at birth. At 10 weeks of age, C5 was grafted to the upper trunk and to the ventral root of C8 and T1; accessory nerve was transferred to the ventral root of C7; the sensory divisions of intercostal nerves T3 and T4 were transferred to the lateral root of the median nerve. He regained a useful grasp between thumb and index finger, and is an extremely well-adjusted sportsman and musician. The photograph was taken at 10 years of age. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

modified by the violence of the injury, by the effects of injury on associated tissues and, in particular, by ischaemia and by delay before repair. Some general conclusions may be drawn from extensive clinical and laboratory studies.

The concept of retrograde degeneration of the axon extending to the first internode applies only to the most benign lesion: that of experimentally crushing the nerve between the tips of a jeweller's forceps. The extent of longitudinal damage to a nerve is greater in a rupture caused by traction than it is in 'tidy' transections caused by knife or glass; this effect worsens with increasing delay before repair, is worse still when healing has been complicated by sepsis, and worst of all in neglected ischaemia.

Failure to repair main vessels and to ensure perfusion of tissues is profoundly deleterious to regeneration and rules out worthwhile recovery of function.As time goes by, the cellular response in both stumps changes from one that facilitates regeneration to one that is less favourable. Dense collagenization, a profusion of fibroblasts and a loss of Schwann cells are characteristics of the chronically denervated distal stump and are typical of late cases. The normal architecture of a nerve is most closely restored to normal in a well-executed, tension-free primary suture. Regeneration through a graft falls away along its length and not solely at the suture lines. Delay before repair leads to increasing fibrosis and to shrinking of the distal segment so that it becomes impossible to ensure an accurate topographical match. Destruction of the target tissues, of muscle and skin, limits function even when there is strong regeneration. Chronological age plays an important role: for example, signalling mechanisms involved in the reinnervation of skeletal muscle may become impaired with age (Kawabuchi et al 2011).

COMMENTARY

1.6 A critical evaluation of the current status of myofascial chains

Jan Wilke, Winfried Banzer

INTRODUCTION

From a morphological point of view, most anatomy textbooks have described the skeletal muscles of the human body as being discrete actuators with clear origins and insertions (van der Wal 2009). Recent analyses of published anatomical cadaveric studies have challenged this assumption, revealing that the active components of the locomotor system are directly linked by fibrous connective tissue (Wilke et al 2016c) (**Fig. 1.6.1**). The bridging structures include: ligaments (hamstrings – sacrotuberous ligament – erector spinae muscle) (Martin 1968, Vleeming et al 1995); fasciae[1] (gastrocnemius muscle – hamstrings) (Tuncay et al 2009); aponeuroses (gluteus maximus/tensor fasciae latae – iliotibial tract – calf muscles) (Wilke et al 2016b); tendons (gastrocnemius muscle – Achilles tendon – plantar aponeurosis – toe abductors) (Snow et al 1995, Stecco et al 2013).

A common feature of the listed elements is their considerable tensile strength, conferred by a large quantity of collagen type I fibres. Moreover, comparisons between samples of the fascia lata and different tendons located around the knee joint revealed that these structures share similar biomechanical, biochemical and histological properties (Butler et al 1984, Derwin et al 2008). Therefore, in addition to the classical distinctive terminology, it has been suggested that the entirety of soft collagenous connective tissues should be grouped under the umbrella terms 'fascial tissues/fascial system' when describing the body from a holistic and functional point of view (Adstrum et al 2017).

MYOFASCIAL CHAINS

Concepts of myofascial chains assume that the connectivity of muscles and stretch-resistant soft tissue creates systemic lines of pull with the potential to transmit mechanical force to distant body regions. The selection of the components of a myofascial chain is based on the criterion of continuity between their longitudinal axes (**Fig. 1.6.2**): it is assumed that this construction maximizes the amount of transmittable force. Another relevant factor is the common fibre orientation of neighbouring myofascial chain components. In tendons, the collagen fibrils are oriented parallel to each other, almost directly following the muscle's line of pull. A similar architecture with mostly parallel fibres running in a longitudinal direction can be found in ligaments. Although the investing fasciae often display a bidirectional, lattice-like fibre arrangement, biomechanical studies reveal a markedly higher longitudinal stiffness (Eng et al 2014), which might indicate a more pronounced strain transmission capacity in this direction.

Based on these thoughts, a variety of concepts have suggested body maps with hypothesized myofascial chains (**Fig. 1.6.3**) (for an overview, see Richter (2012)). Only three continuous lines, the posterior longitudinal chain, the posterior diagonal chain and the anterior diagonal chain, have been systematically verified so far (**Fig. 1.6.4A**, **Table 1.6.1**) (Wilke et al 2016c). Two other possible chains, the lateral longitudinal chain and the spiral chain, still exhibit some unresolved inconsistencies but are at least partially backed by scientific evidence (**Fig. 1.6.4B**, **Table 1.6.2**).

Limitations and perspectives

Myofascial continuity is not restricted to in-series coupling as at first glance might be implied by chain concepts. Direct morphological linkages have also been clearly documented between muscles lying parallel to each other, e.g. synergists or antagonists (Yucesoy 2010). Myofascial continuity therefore represents a global feature of body architecture, rather than a distinct hallmark of serially arranged skeletal muscles. The factors determining and influencing the amount of structural continuity are a matter of debate. While the plantar aponeurosis – also called plantar fascia or plantar ligament by other authors – fuses strongly with the Achilles tendon in young individuals, no (or only a few) bridging fibres can be detected in older persons (Snow et al 1995, Stecco et al 2013). Besides age, physical activity and gender represent other potential predictors of the degree of myofascial force transmission, but as yet have not been investigated.

MYOFASCIAL FORCE TRANSMISSION

The existence of myofascial continuity does not necessarily imply mechanical significance. Clinical relevance depends on whether or not substantial amounts of force can be transferred across the connections. In fact, although considerable inter-individual variation exists, results of biomechanical cadaveric studies suggest notable mutual interactions between serially arranged muscles and/or their connective tissue, respectively (Krause et al 2016). In the low back region, this appears

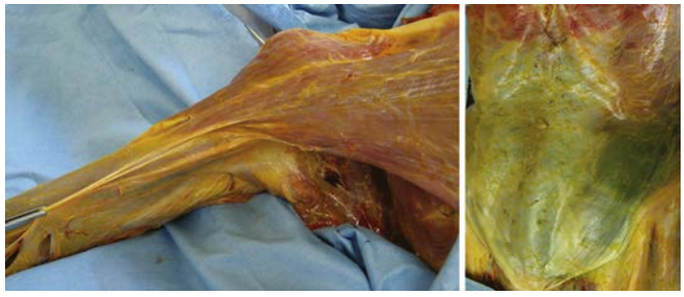

Fig. 1.6.1 The myofascial continuities of pectoralis major, which is connected to the brachial fascia (left) and the rectus abdominis sheath (right). Note that in contrast to sharply dissected muscles, no clear insertions and origins of the connective tissue can be identified. (With permission from Stecco A, Macchi V, Stecco C et al 2009 Anatomical study of myofascial continuity in the anterior region of the upper limb. J Bodyw Mov Ther 13:53–62; Stecco A, Masiero S, Macchi V et al 2009 The pectoral fascia: anatomical and histological study. J Bodyw Mov Ther 13:255–261.)

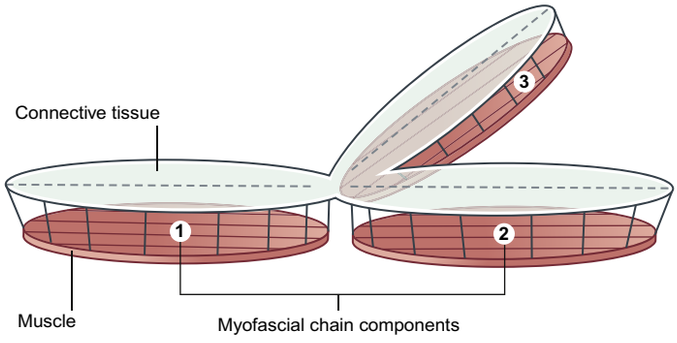

Fig. 1.6.2 A schematic drawing illustrating the selection of myofascial chain components. Although muscle 1 is connected to two other muscles (in this case through the overlying investing fasciae), the transition to muscle 2 would be preferred due to the common fibre course and the linear continuation of the longitudinal axes (grey dotted lines). Note that in this idealized model, similar tensional stiffness is assumed in all three components. If muscle 2 and its overlying connective tissue were in a slack position, force transmission could be superior between muscles 1 and 3.

[1]In this Commentary, the term fascia refers to the connective tissue investing the skeletal muscles, sometimes also called 'deep fascia'.

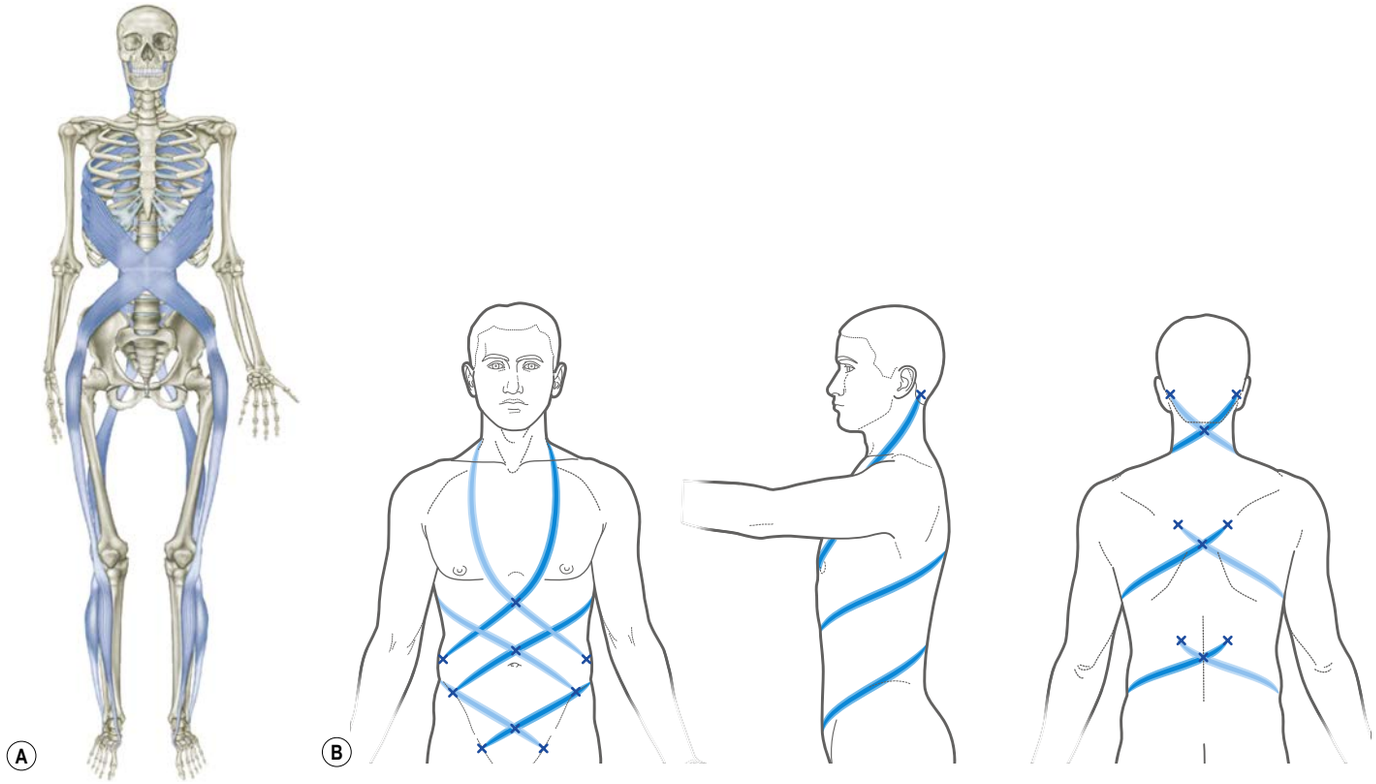

Fig. 1.6.3 Different courses and components of myofascial chains have been proposed. This figure shows two possible versions of a spiral chain wrapping around the body. **A**, Myers (1997). **B**, Dart (1950), did not include the lower leg muscles. (Adapted from Dart 1996 and reproduced with permission from Myers TW Anatomy Trains. Elsevier, Churchill Livingstone. Copyright 2014.)

to be of particular relevance: the lumbar fascia represents the mechanical hub of the posterior diagonal myofascial chain and can receive tension from both latissimus dorsi and the contralateral gluteus maximus muscle (Vleeming et al 1995, Barker et al 2004). In the posterior longitudinal chain, the lumbar fascia and erector spinae may be affected by the hamstring muscles via connectivity with the sacrotuberous ligament (Vleeming et al 1989a, 1989b, 1995). Further interactions for this chain have been demonstrated concerning the more caudal transitions between (1) the hamstrings and gastrocnemius (Cruz-Montecinos et al 2015) and (2) gastrocnemius and the plantar aponeurosis (Carlson et al 2000, Erdemir et al 2004). A mechanical force transmission has been observed between rectus abdominis and adductor longus in the anterior diagonal myofascial chain (Norton-Old et al 2013).

Limitations and perspectives

Myofascial continuity includes both parallel and serial linkages of skeletal muscles. There is evidence of mechanical force transmission in the course of myofascial chains. Numerous studies suggest strong interactions between several lower leg muscles (Wilke et al 2018). For instance, length changes of gastrocnemius at fixed ankle position are associated with substantial strains in soleus and the fibular muscles (Yaman et al 2013), indicative of a mutual interaction between these muscles. It is yet to be elucidated if in-series force transmission across myofascial chains exceeds that of structures located in parallel (**Fig. 1.6.5**).

REMOTE EXERCISE EFFECTS AND NON-LOCAL SYMPTOM MANIFESTATIONS

A few studies have attempted to translate the findings of cadaveric trials into *in vivo* conditions. Initial evidence suggests that exercise protocols based on the concept of myofascial chains lead to non-local effects: stretching of the gastrocnemius and hamstring muscles, both of which represent a part of the longitudinal posterior chain, increases the cervical range of motion (ROM) (Wilke et al 2016a, Wilke et al 2016d). Similarly, self-massage of the plantar aponeurosis enhances hamstring extensibility (Grieve et al 2015, Wilke et al 2019).

Limitations and perspectives

In most cases, non-local exercise effects have been examined using functional outcomes (e.g. ROM of neighbouring joints), which are paramount in order to estimate clinical significance. However, there is a caveat: although likely, without simultaneous imaging it cannot be concluded without doubt that a passive myofascial force transmission caused the remote effects. Alternative explanations include cortical adaptations (e.g. reduced systemic stretch tolerance) or a mechanical force transfer via peripheral neurovascular bundles that also cross multiple joints (Ellis et al 2012).

THE ROLE OF MYOFASCIAL CHAINS IN MUSCULOSKELETAL DISORDERS

Besides optimizing motor function, e.g. through enhanced ROM, force transmission across myofascial chains might contribute to musculoskeletal diseases. In some disorders, remote functional or tissue-related abnormalities can be found in addition to the typical local symptoms. Patients with sacroiliac and chronic low back pain may display hyperactivity of latissimus dorsi and the contralateral gluteus maximus, which represent the major muscular parts of the diagonal posterior chain (Mooney et al 2001, Kim et al 2014). Furthermore, although the relationship between the viscoelastic properties of the posterior thigh

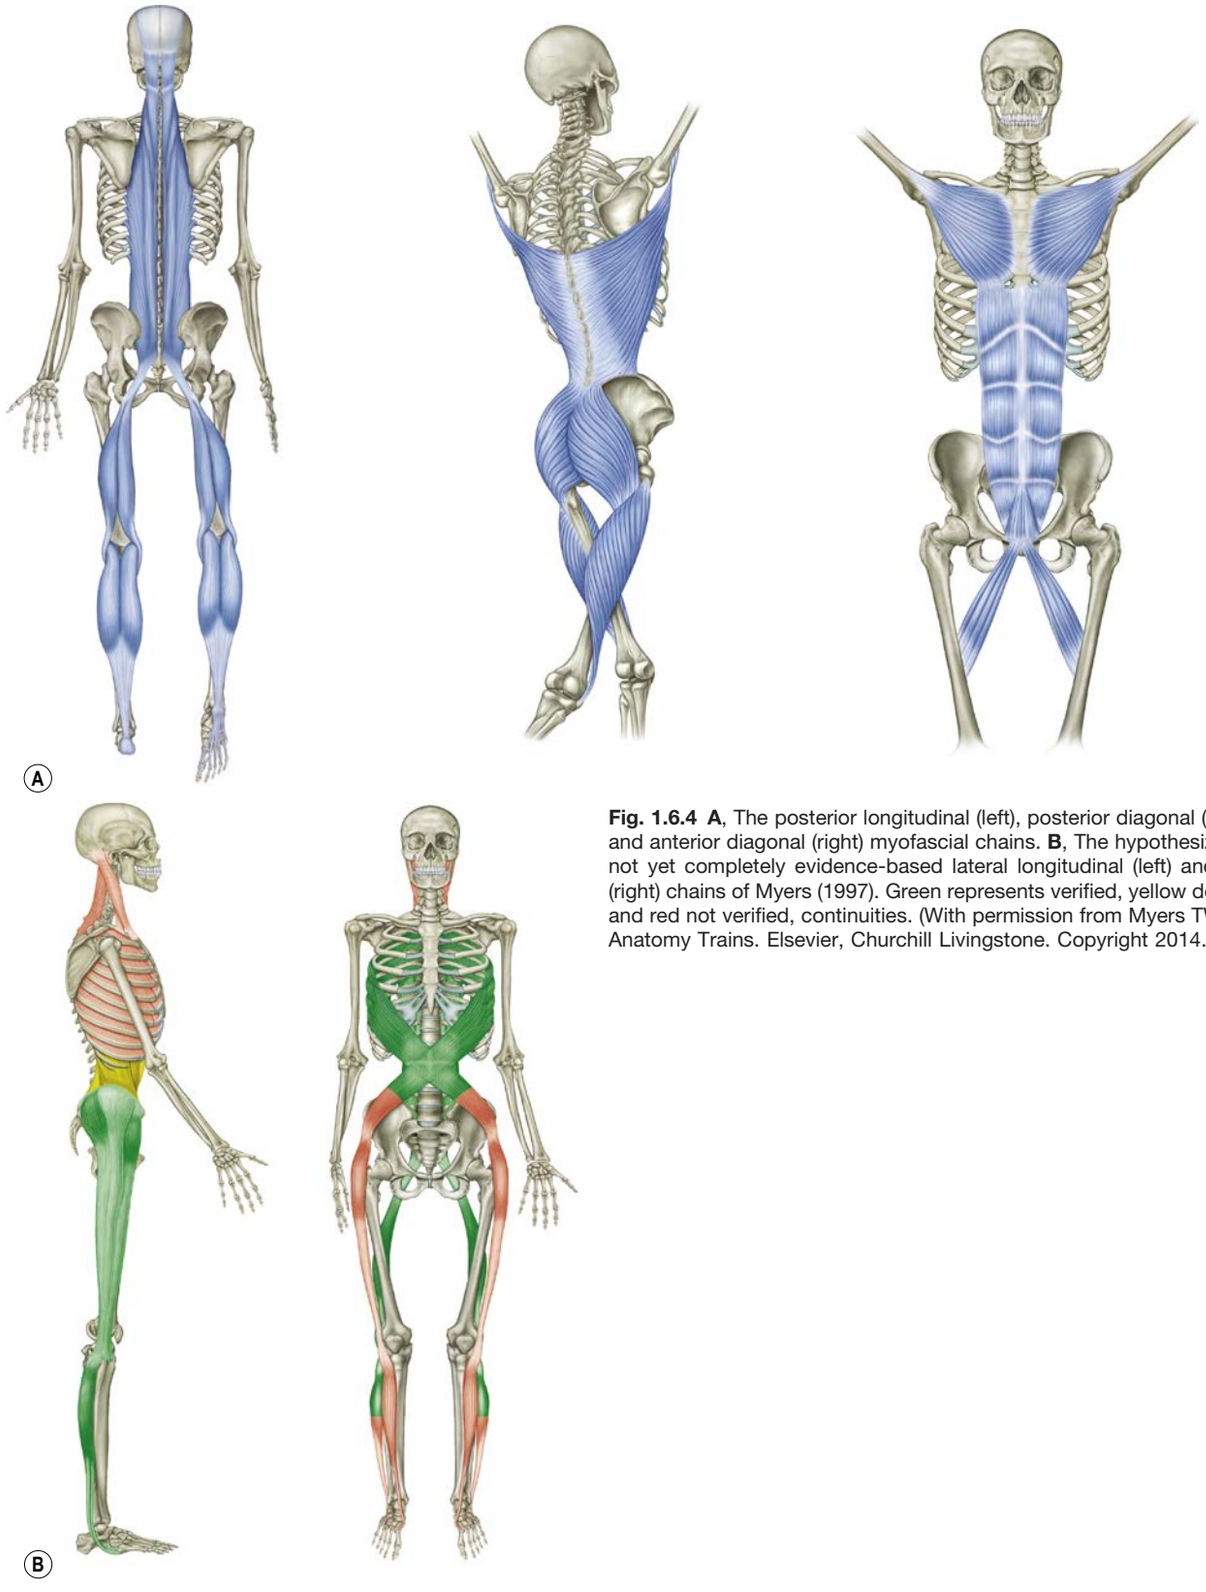

Fig. 1.6.4 **A**, The posterior longitudinal (left), posterior diagonal (middle) and anterior diagonal (right) myofascial chains. **B**, The hypothesized but not yet completely evidence-based lateral longitudinal (left) and spiral (right) chains of Myers (1997). Green represents verified, yellow doubtful, and red not verified, continuities. (With permission from Myers TW 2014 Anatomy Trains. Elsevier, Churchill Livingstone. Copyright 2014.)

muscles and back pain remains controversial (Halbertsma et al 2001), individuals with chronic lumbar pain have been reported to display decreased extensibility and increased stiffness of the hamstrings (Marshall et al 2009), a muscle group belonging to the longitudinal posterior chain. The latter chain might also be of importance in plantar fasciitis, a condition in which increased stiffness of the hamstrings and gastrocnemius has been observed (Labovitz et al 2011, Bolívar et al 2013).

Limitations and perspectives

Although cross-sectional studies indicate several non-local symptom manifestations in the course of myofascial chains, little knowledge exists regarding the success of corresponding interventions. Randomized, controlled trials of treatments of musculoskeletal disorders based on the concept of myofascial chains are therefore warranted.

TABLE 1.6.1 Components and possible functions of the three verified myofascial chains. Muscular parts include the respective investing fasciae

Myofascial chain	Soft tissue components	Assumed function	Remarks
Posterior longitudinal chain	Plantar aponeurosis Achilles tendon Gastrocnemius 'Hamstring' muscles Sacrotuberous ligament Lumbar fascia/erector spinae	Resistance to gravity, control and support of posture in the sagittal plane (e.g. upright and slumped spine), initiation and stabilization of linear vertical movements (e.g. jumps)	Continuity of plantar aponeurosis and Achilles tendon decreases with age
Posterior diagonal chain	Vastus lateralis Gluteus maximus Lumbar fascia Contralateral latissimus dorsi Brachial fascia	Connection of both body sides, interaction between upper and lower extremity, initiation and control of cross-sided movements (e.g. throwing)	In contrast to pectoralis major, the brachial fascia does not adhere strongly to the underlying muscles. This might reduce force transfer, e.g. to biceps brachii
Anterior diagonal chain	Adductor longus Rectus abdominis Pectoralis major Brachial fascia	Connection of both body sides, interaction between upper and lower extremity, initiation and control of cross-sided movements (e.g. throwing)	In contrast to latissimus dorsi, the brachial fascia does not adhere strongly to the underlying muscles. This might reduce force transfer, e.g. to triceps brachii

TABLE 1.6.2 Hypothetical components and possible functions of two not yet entirely evidence-based myofascial chains (based on the proposal of Myers 1997a, 1997b). Muscular parts include the respective investing fasciae. Unverified continuities are indicated in bold font

Myofascial chain	Soft tissue components	Assumed function
Lateral longitudinal chain	Fibularis longus/brevis/crural fascia – iliotibial tract/gluteus maximus/tensor fasciae latae Iliotibial tract/gluteus maximus/tensor fasciae latae – external/internal abdominal oblique **External/internal abdominal oblique – intercostal muscles** **Intercostal muscles – splenius capitis/sternocleidomastoid**	Stabilization and control of ankle, knee, hip and spine in the frontal plane (e.g. knee alignment/valgus/varus)
Spiral chain	Erector spinae – sacrotuberous ligament/biceps femoris Biceps femoris – fibularis longus **Fibularis longus – tibialis anterior** **Tibialis anterior – iliotibial tract/tensor fasciae latae** **Tensor fasciae latae – internal abdominal oblique** Internal – external abdominal oblique External abdominal oblique – serratus anterior Serratus anterior – rhomboid minor/major **Rhomboid minor/major – splenius capitis/cervicis**	Production and control of rotational forces (e.g. torsion of the spine or throwing in sports), stabilization and control of ankle, knee, hip and spine in the frontal plane (e.g. knee alignment/valgus/varus)

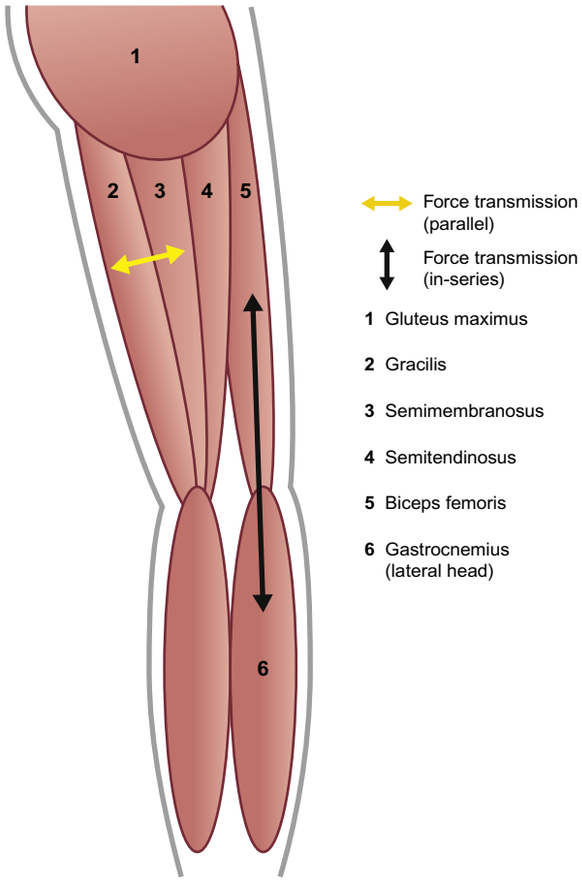

Fig. 1.6.5 A schematic representation of lower leg mechanical force transmission. In myofascial chains, mutual interactions occur between the skeletal muscles arranged in series (black arrows). However, this does not represent the only relevant pathway: forces are also transmitted to tissues located in parallel (yellow arrows).

CONCLUSION

The classical conception of skeletal muscles as independent actuators requires a thorough revision. Fascial tissue links the skeletal muscles of the body and acts as a mechanical force transmitter. Although it is not known (1) to what degree cortical adaptations play a role in the genesis of non-local exercise effects under *in vivo* conditions; and (2) whether the extent of mutual interaction between serially connected muscles exceeds that of muscles arranged parallel to each other, it is reasonable to suggest that clinical focus should not be restricted to one joint or soft tissue.

CHAPTER
8

Preimplantation development

Understanding the spatial and temporal developmental processes that take place within an embryo as it develops from a single cell into a recognizable human is the challenge of embryology. The control of these processes resides within the genome; fundamental questions remain concerning the genes and interactions involved in development.

STAGING OF EMBRYOS

For the purposes of embryological study, prenatal life is divided into an embryonic period and a fetal period. The embryonic period covers the first 8 weeks of development (weeks following ovulation and fertilization resulting in pregnancy). The ages and stages of early human embryos were initially estimated by comparing their development with that of other embryos or with those of monkey embryos of known postovulatory ages. Because the external and internal development of embryos at any specified time may be different, a classification of human embryo development into 23 stages based on the internal and external features of embryos was developed by Streeter (1942), and continued by O'Rahilly and Müller (1987), from detailed histological study of approximately 600 sectioned embryos in the Carnegie collection. On the basis of correlating particular maternal menstrual histories and the known developmental ages of monkey embryos, growth tables were constructed so that the size of an embryo (specifically, the greatest length) could be used to predict its presumed age in postovulatory days (synonymous to postfertilizational days). O'Rahilly and Müller (2000, 2010) emphasize that the Carnegie embryonic stages are based on external and internal morphological criteria and are not founded on length or age. Ultrasonic examination of embryos *in vivo* has necessitated the revision of some of the ages related to stages, and embryos of stages 6–16 are now thought to be up to 3–5 days older than the embryological estimates used previously (O'Rahilly and Müller 1999, 2010). Within this staging system, embryonic life commences with fertilization at stage 1; stage 2 encompasses embryos from two cells, through compaction and early segregation, to the appearance of the blastocoele. The developmental processes occurring during the first 10 stages of embryonic life are shown in **Fig. 8.1**.

Knowledge of the early molecular processes of development is derived from experimental studies on amniote embryos, particularly the chick, mouse and rat. **Figure. 8.2** shows the comparative timescales of development of these species and human development up to stage 12 and illustrates the differences in heterochrony between the species (Ch. 11). The length and age, in post fertilization days, of human development during stages 10–23 is given in **Fig. 8.3**, the external appearance of embryos over this time is shown in Fig. 23.1 and stage is correlated to days and weeks in Fig. 23.3.

Information on developmental age after stage 23 (postfertilization days 53–58) is shown in Fig. 23.4, where the developmental staging used throughout this book is juxtaposed with the clinical obstetric estimation of pregnancy based on maternal last menstrual period. Great care should be taken when reading developmental papers to clarify the staging system used to confer age in days on any embryos. All developmental publications using the Carnegie collection prior to 2010 use earlier estimations of age. Many of the publications since 2010, when O'Rahilly and Müller revised their correlation of age in days to stage, are still using the older unrevised ages. Publications noting changes correlated to Carnegie stage (not age) still match Streeter and O'Rahilly and Müller publications. All embryonic stages in this book are corrected to postfertilization days based on O'Rahilly and Müller (2010).

FERTILIZATION

The central feature of reproduction is the fusion of the two gamete pronuclei at fertilization. In humans, the male gametes are spermatozoa, which are produced from puberty onwards. Female gametes are released as secondary oocytes in the second meiotic metaphase, usually singly, in a cyclical fashion. The signal for the completion of the second meiotic division is fertilization, which stimulates the cell division cycle to resume, completing meiosis and extruding the second polar body (the second set of redundant meiotic chromosomes).

Fertilization normally occurs in the ampullary region of the uterine tube, probably within 24 hours of ovulation. Very few spermatozoa reach the ampulla to achieve fertilization. They must undergo capacitation, a process that is still incompletely understood, and that may involve modifications of membrane sterols or surface proteins. They traverse the cumulus oophorus and corona radiata, then bind to specific glycoprotein receptors on the zona pellucida, ZP3 and ZP2. Interaction of ZP3 with the sperm head induces the acrosome reaction, in which fusion of membranes on the sperm head releases enzymes, such as acrosin, that help to digest the zona around the sperm head, allowing the sperm to reach the perivitelline space. In the perivitelline space, the spermatozoon fuses with the oocyte microvilli, possibly via two disintegrin peptides in the sperm head and integrin in the oolemma (**Figs 8.4, 8.5A**).

Fusion of the sperm with the oolemma causes a weak membrane depolarization and leads to a calcium wave, triggered by the sperm at the site of fusion, that crosses the egg within 5–20 seconds. The calcium wave amplifies the local signal at the site of sperm–oocyte interaction and distributes it throughout the oocyte cytoplasm. The increase in calcium concentration is the signal that causes the oocyte to resume cell division, initiating the completion of meiosis II and setting off the developmental programme that leads to embryogenesis. The pulses of intracellular calcium that occur every few minutes for the first few hours of development also trigger the fusion of cortical granules with the oolemma. The cortical secretory granules release an enzyme that hydrolyses the ZP3 receptor on the zona pellucida and so prevents other sperm from binding and undergoing the acrosome reaction, thus establishing the block to polyspermy. The same cortical granule secretion may also modify the vitelline layer and oolemma, making them less susceptible to sperm–oocyte fusion and providing a further level of polyspermy block.

The sperm head undergoes its protamine to histone transition as the second polar body is extruded. The two pronuclei form, the female one cortically near the site of emission of the second polar body. They move together and are juxtaposed prior to pronuclear membrane breakdown/syngamy and cleavage after approximately 24 hours after sperm and oocyte association (Coticchio et al 2018) (**Fig. 8.5B**). Pronuclear fusion as such does not occur; no true zygote containing a membrane-bound nucleus forms. The two pronuclear envelopes disappear and the two chromosome groups move together to assume positions on the first cleavage spindle. Nucleolar ribosomal ribonucleic acid (rRNA), and perhaps some messenger RNA (mRNA), are synthesized in pronuclei. A succeeding series of cleavage divisions produces eight even-sized blastomeres by approximately 55 hours, when embryonic mRNA is transcribed.

The presence of the pronuclei from both parental origins is crucial for spatial organization and the controlled growth of cells, tissues and organs. In the mouse, embryos in which the paternal pronucleus has been removed and replaced with a second maternal pronucleus develop to a relatively advanced state (25 somites), but with limited development of the trophoblast and extraembryonic tissues. In contrast, embryos in which the maternal pronucleus has been replaced by a second paternal pronucleus develop very poorly, forming embryos of only six to eight somites, but with extensive trophoblast. Thus, it seems that the maternal genome is relatively more important for the development of the embryo, whereas the paternal genome is essential for the development of the extraembryonic tissues that would lead to placental formation.

This functional inequivalence of homologous parental chromosomes is called parental imprinting. It occurs during the maturational phase of production of the haploid gametes in mammals and silences one allele by DNA methylation without changing the DNA sequence (Moore et al

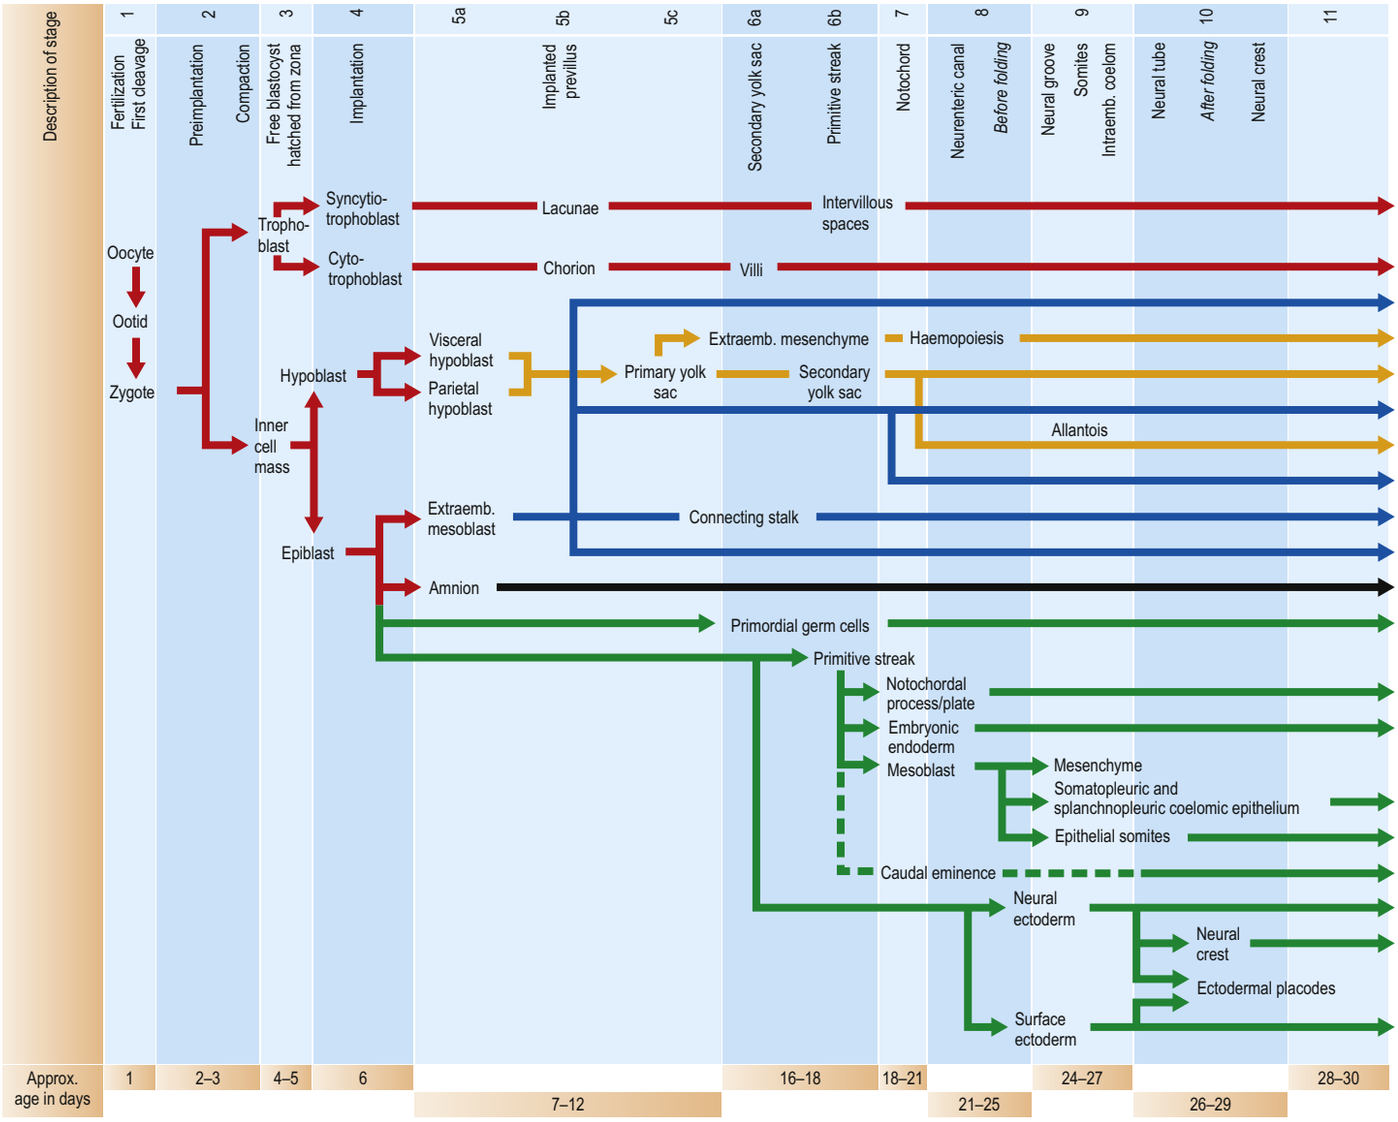

Fig. 8.1 Developmental processes occurring during the first 10 stages of development. In the early stages, a series of binary choices determine the cell lineages. Generally, the earliest stages are concerned with formation of the extraembryonic tissues, whereas the later stages are concerned with the formation of embryonic tissues. The approximate age in days is taken from O'Rahilly and Müller 2010.

2015). Imprinted genes are heritable but in the next generation may be unmethylated during gametogenesis and re-established in the new germline. Between 50 and 90 imprinted genes expressed in the placenta and embryo have been identified, many concerned with embryogenesis and growth (Hanna et al 2018). Although imprinted genes represent a small proportion of the genome, they are particularly important in blastocyst implantation, placentation, developmental growth rates and the embryonic nervous system. Some epigenetic modifications can lead to congenital anomalies and syndromes (Butler 2009, Batcheller et al 2011, Fauque 2013). For example, changes to the 15q11-13 domain if paternally imprinted lead to Prader–Willi syndrome (a disorder of growth) and if maternally imprinted cause Angelman syndrome (a neurological disorder); changes to the domain 11p15 affect IGF2 if paternally expressed and H19 if maternally expressed; both of these imprinted conditions affect growth regulation and trajectory in early development, Beckwith-Wiedemann syndrome results if the region is maternally imprinted (Moore et al 2015). Generally, paternally expressed genes enhance growth and maternally expressed genes suppress growth (Butler 2009).

In vitro fertilization

In vitro fertilization (IVF) of human gametes is a successful way of overcoming most forms of infertility (**Video 8.1**). Controlled stimulation of the ovaries (e.g. pituitary downregulation using gonadotrophin-releasing hormone superactive analogues, followed by stimulation with purified, or recombinant, follicle stimulating hormone or urinary menopausal gonadotrophins) enables many preovulatory oocytes (often 10 or more) to be recruited and matured, and then aspirated transvaginally using ultrasound guidance, 34–38 hours after injection of human chorionic gonadotrophin (which is given to mimic the luteinizing hormone surge). These oocytes are then incubated overnight with motile spermatozoa in a specially formulated culture medium, in an attempt to achieve successful *in vitro* fertilization. In cases of severe male-factor infertility, in which there are insufficient normal spermatozoa to achieve conventional *in vitro* fertilization, individual spermatozoa can be directly injected into the oocyte in a process known as intracytoplasmic sperm injection (ICSI), which is as successful as routine IVF. In cases in which there are no spermatozoa in the ejaculate, suitable material can sometimes be directly aspirated from the epididymis or surgically retrieved from the testes, and the extracted sperm are then used for intracytoplasmic injection.

It is also now sometimes possible to assess embryos by preimplantation genetic testing (PGT) for the presence of monogenic/single gene diseases (PGT-M) or for structural chromosomal rearrangements (PGT-SR). A sample (biopsy) is removed from either the oocyte (polar bodies), the early cleavage stage embryo (a blastomere) or the blastocyst (small piece of trophectoderm), and subjected to specific genetic testing. Oocytes and embryos can also be biopsied and screened for errors in chromosome copy numbers using preimplantation genetic testing for aneuploidy (PGT-A). Unaffected embryos can then be identified for transfer to the recipient. Although increasingly utilized across all ages of IVF patients, there is debate over the efficacy of PGT-A. It is considered most clinically appropriate for women over 37 years of age due to increased aneuploidy levels in their oocytes. Embryos that are surplus to immediate therapeutic requirements can also be cryopreserved in liquid nitrogen for later use. Propanediol or dimethylsulphoxide are commonly used as cryoprotectants for human embryos at all stages. Conception rates per cycle using ovarian stimulation, IVF and successive transfers of fresh and cryopreserved embryos exceed those obtained during non-assisted, or natural, conception.

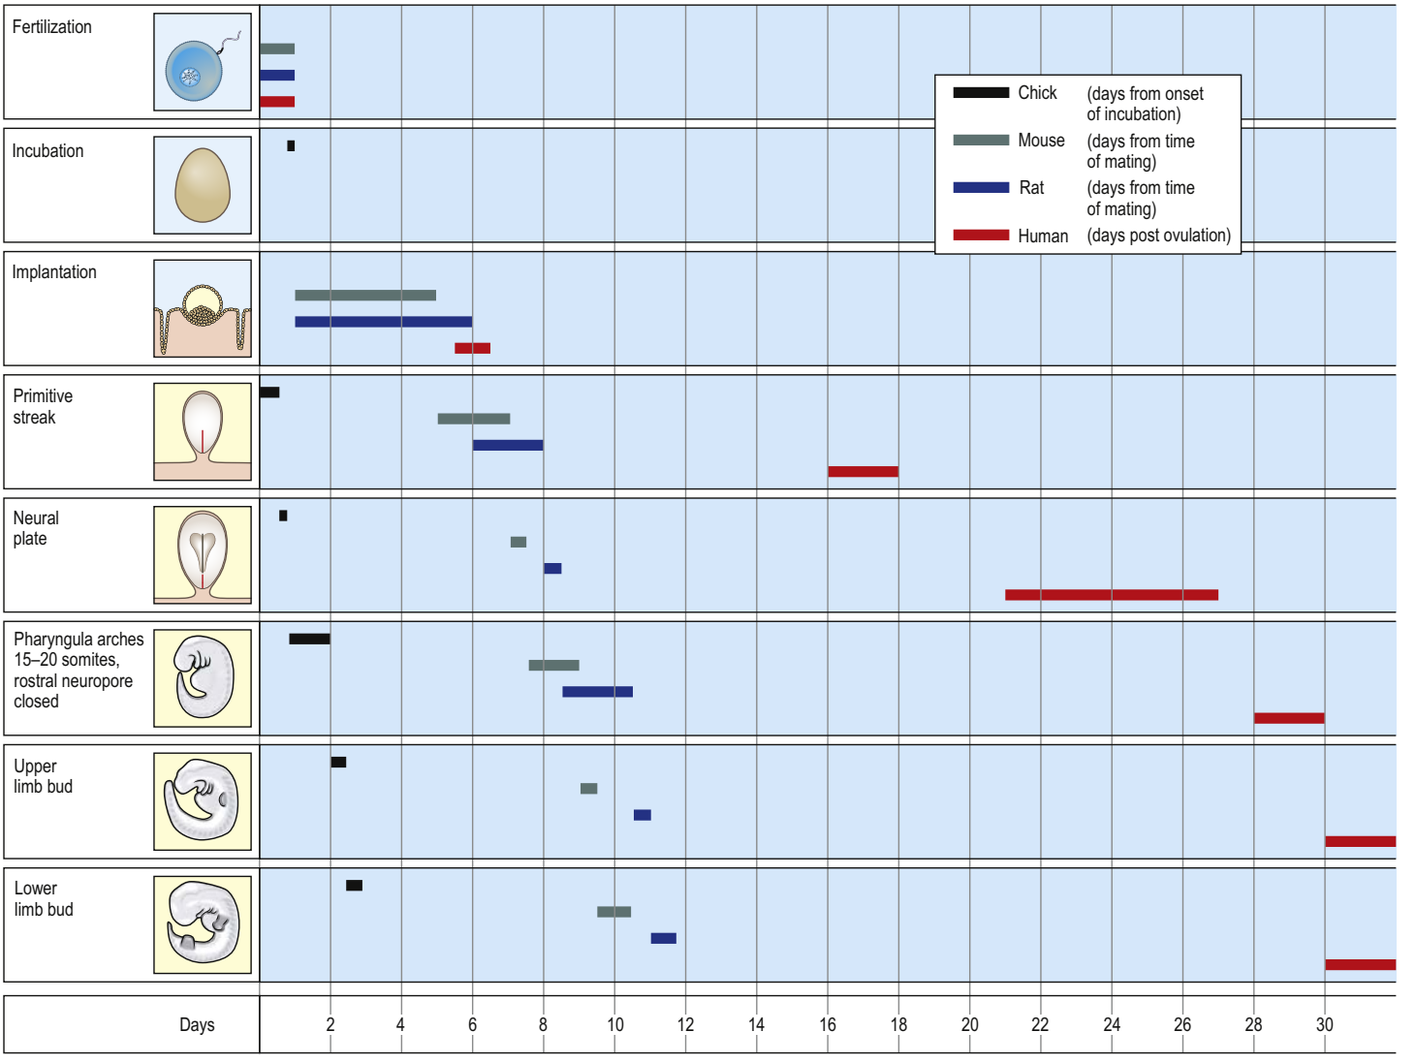

Fig. 8.2 Within developmental biology, evidence concerning the nature of developmental processes has come mainly from studies in vertebrate embryos, most commonly amniote embryos of the chick, mouse and rat. This chart illustrates the comparative timescale of development in these animals and in humans.

In 2014, some 40 years after the first IVF infant was born, more than 200,000 assisted reproductive technologies (ART) cycles were performed in the United States leading to nearly 60,000 live births. Worldwide the prevalence of ART is now extensive. For details of ART the reader should consult Kaser et al (2019).

Data collected on the longer-term effects of ART have indicated an associated increased risk of imprinting syndromes (Hanna et al 2018, Kaser et al 2019). The complexities of ART, i.e. the processes involved in collection of oocytes and sperm, *in vitro* fertilization and blastocyst culture, and the manipulation of the maternal endometrium for successful implantation, challenge many developmental conceptus–maternal interactions. It is now appreciated that the temporal conversations between oocyte/zygote/blastocyst and the mother are informed by dynamic exchange of environmental information some days before the close juxtaposition of the tissues seen in implantation, and that their effects extend into fetal growth and postnatal life (Ch. 23). These periconceptual influences are now being investigated (Moore et al 2015, Fleming et al 2018).

PREIMPLANTATION DEVELOPMENT

Cleavage

The first divisions of the zygote are termed cleavages. They distribute the cytoplasm approximately equally among daughter blastomeres, so that although the cell number of the preimplantation embryo increases, its total mass actually decreases slightly (Fig. 8.6). Cell division can be asynchronous and daughter cells may retain a cytoplasmic link through much of the immediately subsequent cell cycle via a midbody, as a result of the delayed completion of cytokinesis. No centrioles are present until 16–32 cells are seen, but amorphous pericentriolar material is present and serves to organize the mitotic spindles, which are characteristically more barrel-shaped than spindle-shaped at this stage.

All cleavage divisions after fertilization are dependent on continuing protein synthesis, whereas passage through the earliest cycles, up to eight cells, is independent of mRNA synthesis. Thereafter, experimental inhibition of transcription blocks further division and development, indicating that activation of the embryonic genome is required. There is also direct evidence for the synthesis of embryonically encoded proteins at this time. As the genes of the embryo first become both active and essential, the previously functional maternally derived mRNA is destroyed, although protein made on these maternal templates does persist at least during blastocyst growth. Spontaneous developmental arrest of embryos cultured *in vitro* seems to occur during the cell cycle of gene activation, but it is not caused by total failure of that activation process. Early cleavage, up to the formation of eight cells, requires pyruvate or lactate as metabolic substrates, but thereafter more glucose is metabolized and may be required. Pyruvate availability in maternal uterine tube secretions may function as an extrinsic mechanism for embryonic genome activation (Pfeffer 2018).

The earliest time at which different types of cells can be identified within the cleaving embryo is when 8–16 cells are present. Before that time cells are essentially spherical, touch each other loosely, have no specialized intercellular junctions or significant extracellular matrix and the cytoplasm in each cell is organized in a radially symmetric manner around a centrally located nucleus. Once eight cells have formed, a process of compaction occurs that creates tension between adjacent cells. Cells flatten on each other maximizing intercellular contact, this initiates the formation of gap and focal tight junctions, and radically reorganizes their cytoplasmic conformation from a radially symmetric to a highly asymmetric phenotype. This latter process includes the migration of nuclei towards the centre of the blastocyst,

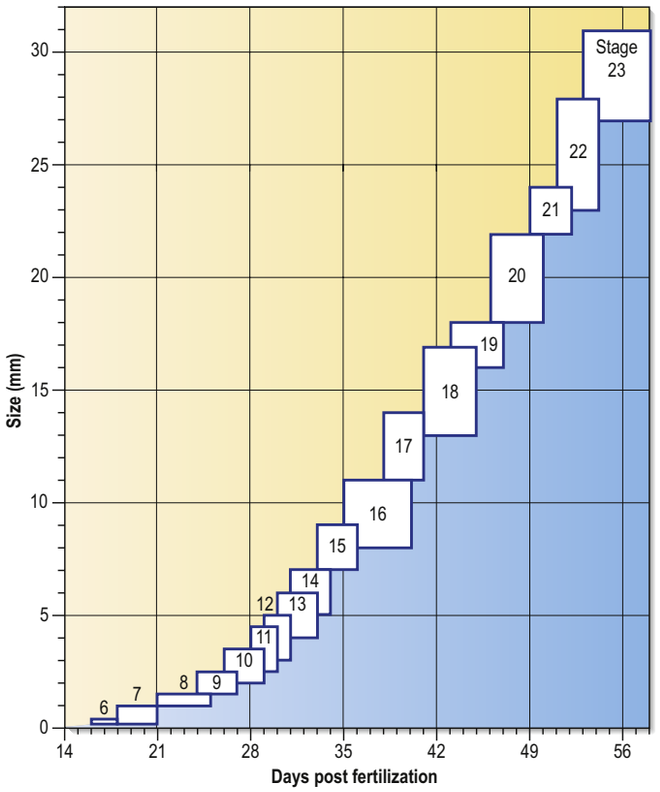

Fig. 8.3 Human developmental stages 10–23. The greatest embryonic length in mm (ordinate) is plotted against age in postfertilizational weeks (abscissa), with the stages superimposed according to current information. (Data provided by courtesy of Professor R O'Rahilly. See also O'Rahilly and Müller (2010).)

the redistribution of surface microvilli and an underlying mesh of microfilaments and microtubules to the exposed surface, and the localization of endosomes beneath the apical cytoskeletal mesh. In the mouse, blastomeres extend filopodia onto the apical surfaces of neighbouring cells between cell divisions (Fierro-González et al 2013). As a result of the process of compaction, the embryo forms a primitive proto-epithelial cyst consisting of eight polarized cells, in which the apices face outwards and basolateral surfaces face internally. The focal tight junctions, which align to become increasingly linear, are localized to the boundary between the apical and basolateral surfaces. Gap junctions form between apposed basolateral surfaces and become functional.

The process of compaction involves the cell surface and the calcium dependent cell–cell adhesion glycoprotein, E-cadherin (also called L-CAM or uvomorulin). Neutralization of its function disturbs all three elements of compaction. The entire process can function in the absence of both mRNA and protein synthesis. Post-translational controls are sufficient and seem to involve regulation through protein phosphorylation. Significantly, although E-cadherin is not synthesized and present on the surface of cleaving blastomeres, it first becomes phosphorylated when eight cells are visible, at the initiation of compaction.

Compaction is important for the generation of cell diversity in the early embryo. As each polarized cell divides, it retains significant elements of its polar organization, so that its daughter cells inherit cytocortical domains, their nature reflecting their origin and organization in the original parent cell in the eight-celled embryo. Thus, if the axis of division is aligned approximately at right-angles to the axis of cell polarity, the more superficially placed daughter cell inherits all the apical cytocortex and some of the basolateral cytocortex and is polar, whereas the more centrally placed cell inherits only basolateral cytocortex and is apolar. In contrast, if the axis of division is aligned approximately along the axis of the cell polarity, two polar daughter cells are formed. In this way, two-cell populations are formed in the 16-cell embryo that differ in phenotype (polar, apolar) and position (superficial, deep). The number of cells in each population in an individual embryo will be determined by the ratio of divisions along, and at right-angles to, the axis of eight-cell polarity. The theoretical and observed limits of the polar to apolar ratio are 16:0 and 8:8 respectively. The outer polar cells contribute largely to the trophectoderm, whereas the inner apolar cells contribute almost exclusively to the inner cell mass in most embryos.

In cleavage, the generation of cell diversity and commitment to either trophectoderm or inner cell mass, occurs in the 16-cell morula and precedes the formation of the blastocyst. During the 16-cell cycle, the outer polar cells continue to differentiate an epithelial phenotype, and display further aspects of polarity and intercellular adhesion typical of epithelial cells, while the inner apolar cells remain symmetrically organized. During the next cell division (16–32 cells), a proportion of polar cells again divide asymmetrically, as in the previous cycle, each yielding one polar and one apolar daughter cell displaying differentiation of the phenotype of the trophectoderm and inner cell mass respectively. Although such differentiative division at this time is less common than at the 8- to 16-cell transition, it has the important function of regulating an appropriate number of cells in the two cell phenotypes of the blastocyst. Thus, if differentiative divisions were relatively infrequent at the 8- to 16-cell transition, they will be more frequent at the 16- to 32-cell transition, and *vice versa*.

After division to 32 cells, the outer polar cells complete their differentiation into a functional epithelium, display structurally complete zonular tight junctions and begin to form desmosomes. The nascent trophectoderm engages in vectorial fluid transport in an apical to basal direction to generate a cavity that expands in size during the 32- to 64-cell cycles and converts the ball of cells, the morula, to a sphere, the blastocyst (**Fig. 8.7B**).

Blastocyst

Blastocysts can be broadly described by the number of cells and the extent of the blastocoele, and these can be correlated to developmental day/stage. The free, unattached blastocyst is assigned to stage 3 of development at approximately 4 days postfertilization. Early blastocysts have >35 cells and a cavity occupying <30% of the blastocyst volume; mid-blastocysts have 64–100 cells, and a cavity occupying 30–70% of the blastocyst volume; late blastocysts have 128–256 cells and the maximum cavity size within the zona pellucida. A hatched blastocyst, has >256 cells and an expanding blastocoele (Pfeffer 2018). Blastocyst 'hatching' from the zona pellucida occurs at 6–7 days, possibly assisted by an enzyme similar to trypsin (**Figs 8.7C, 8.8**). Trophoblast oozes out of a small slit and the cells assume a flattened polyhedral shape with ultrastructural features typical of a transporting epithelium. At hatching, many embryos form a figure-of-eight shape bisected by the small zona pellucida opening, especially if the zona pellucida has become hardened during oocyte maturation and cleavage. Such half-hatching could result in the formation of identical twins. Hatched blastocysts expand and differentiation of the inner cell mass proceeds.

Analysis of the transcriptome from single-cell embryo data, shows that three cell lineages are produced by blastocyst formation. Differentially expressed genes can be identified in the trophoblast (*GATA3*, *GATA2*, *KRT18*, *TEAD3*) but not in the inner cell mass. Once the inner cell mass is defined the epiblast that forms an ('upper') layer closest to the polar trophoblast expresses different genes (*NANOG*, *SOX2*, *KLF17*, *TDFG-1*) to the subjacent hypoblast (*PDGFRA*, *GATA6*, *GATA4*, *SOX17*) that gives rise to the yolk sac (Stirparo et al 2018). The appearance of epiblast and hypoblast layers in a bilaminar arrangement confers the dorsoventral axis of the developing embryo. The earliest primordial germ cells may also be defined at this stage (Chs 10, 22).

In mammals, the trophoblastic lineage becomes committed at species-specific time points related to the time of implantation, and differentiation has started by the time the blastocyst reaches the endometrial cavity. Human trophoblast commitment is noted in late blastocysts with >180 cells (Pfeffer 2018). After hatching, the trophoblast (also termed trophectoderm) surrounding the blastocyst cavity is termed mural trophoblast (cytotrophoblast) and that adjacent to the inner cell mass is termed polar trophoblast (composed of both cytotrophoblast and syncytiotrophoblast) (Ch. 9). Syncytiotrophoblast releases human chorionic gonadotrophin (hCG), which is detectable in maternal serum by 6–8 days after fertilization.

Human pregastrulation development has been studied by *in vitro* culture of donated embryos and also by culture of human embryonic stem cells derived from human embryos. The cultured cells are transcriptionally distinct from human epiblast and lose the imprinting usually established during blastocyst development. Stem cell lines of trophoblast and early endoderm are being studied and trophoblast spheroids have been generated from human embryonic stem cells (Wamaitha and Niakan 2018).

Attachment to the uterine wall

On the sixth postovulatory day, after about 72 hours in the uterine lumen, the blastocyst adheres to the uterine mucosa and the events

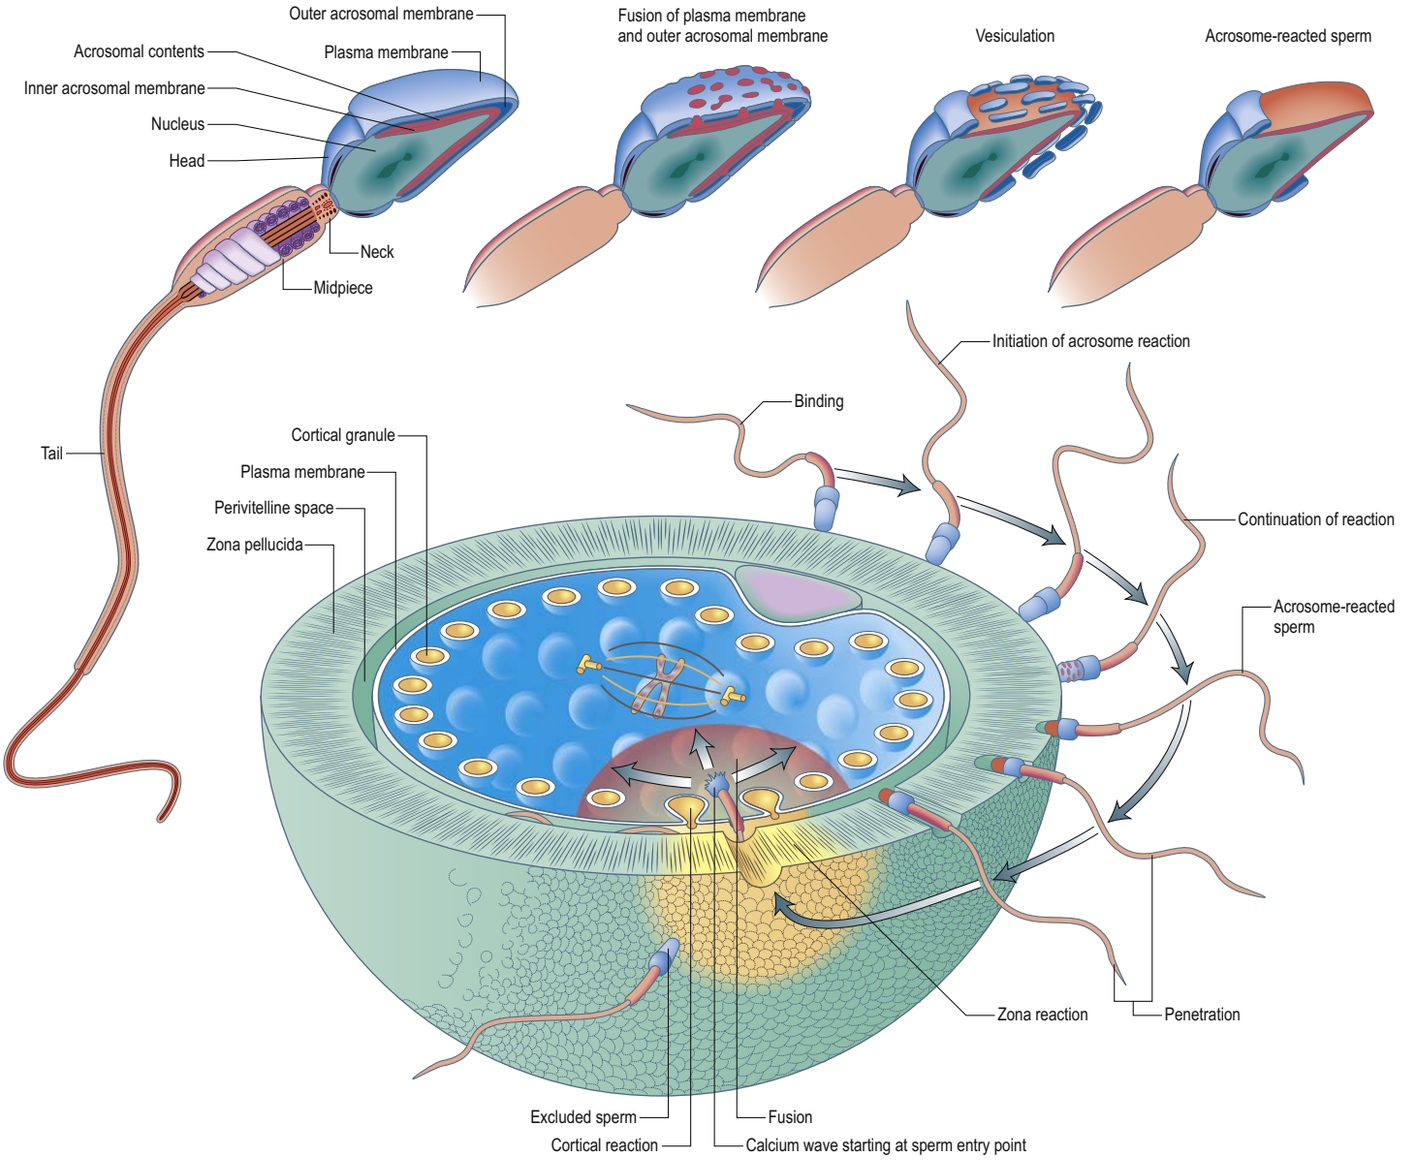

Fig. 8.4 The fertilization pathway: a succession of steps. After a sperm binds to the zona pellucida, the acrosome reaction takes place (see detail at top). The outer acrosomal membrane (blue), an enzyme-rich organelle in the anterior of the sperm head, fuses at many points with the plasma membrane surrounding the sperm head. Then those fused membranes form vesicles, which are eventually sloughed off from the head, exposing the acrosomal enzymes (red). The enzymes digest a path through the zona pellucida, enabling the sperm to advance. Eventually, the sperm meets and fuses with the secondary oocyte plasma membrane and this triggers cortical and zona reactions. First, enzyme-rich cortical granules in the oocyte cytoplasm release their contents (yellow) into the zona pellucida, starting at the point of fusion and progressing right and left. Next, in the zona reaction, the enzymes modify the zona pellucida, transforming it into an impenetrable barrier to sperm as a guard against polyspermy (multiple fertilization).

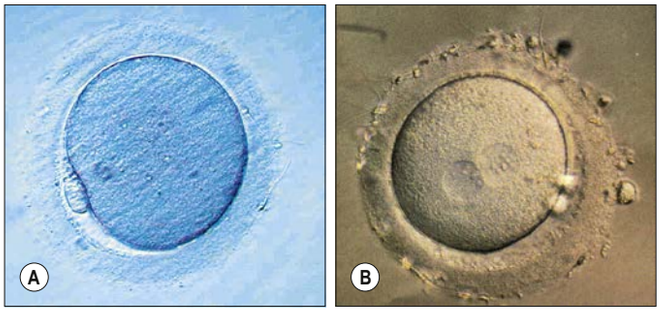

Fig. 8.5 A, An unfertilized human secondary oocyte surrounded by the zona pellucida; the first polar body can be seen. Spermatozoa are visible outside the zona pellucida. **B**, A fertilized human ootid before fusion of the pronuclei. Two polar bodies can be seen beneath the zona pellucida.

leading to the specialized, intimate contact of trophoblast and endometrium begin. Implantation, which is the term used for this complicated process, includes the following stages: dissolution of the zona pellucida; orientation and adhesion of the blastocyst onto the endometrium; trophoblastic penetration into the endometrium; migration of the blastocyst into the endometrium; spread and proliferation of the trophoblast, which envelops and specifically disrupts and invades the maternal tissues (Ch. 9). The interactions between the hatched blastocyst and the maternal endometrium are not well understood. Developmentally competent embryos appear to enhance the uterine environment and promote their own implantation (Brosens et al 2014, Macklon and Brosens 2014). Endometrial stromal cells and their decidualization are important for successful implantation and the interaction between the uterine wall and the blastocyst (Makieva et al 2018, Zhang et al 2018).

The site of implantation is normally in the endometrium of the posterior wall of the uterus, nearer to the fundus than to the cervix. It may be in the median plane or to one or other side, or may occur elsewhere in the uterus, or in an extrauterine or ectopic site.

Ectopic implantation

An ectopic pregnancy occurs when the blastocyst implants at a location other than the uterine endometrium. The syncytiotrophoblast and cytotrophoblast will invade any subjacent tissue, continue development and secrete hCG, with maternal serum levels lower than expected for a uterine implantation.

Almost all (95%) of ectopic implantations occur in the uterine tubes, either close to the fimbriae (11%), in the ampullae (70%), in the

Formation of a morula and blastocyst within the zona pellucida and blastocyst hatching from the zona pellucida. **A**, A ball of cells, the morula, with the cells undergoing compaction. **B**, The blastocyst cavity is developing and the inner cell mass can be seen on one side of the cavity. **C**, The blastocyst is beginning to hatch from the zona pellucida.

isthmus (2%) or in the interstitial portion of the tubes where the tubal mucosa is adjacent to the uterine myometrium (2–4%) (Coady 2011, Baltarowich and Scoutt 2017). Uterine implantations are often ipsilateral to the ovarian corpus luteum. Previous pelvic inflammatory disease, salpingitis or tubal surgery may predispose to blastocyst delay in tubal transport. The presence of an intrauterine contraceptive device or the use of progesterone-based oral contraceptives may also predispose to ectopic pregnancy, probably because of alteration in the normal tubal transport mechanisms.

Fig. 8.8 A human blastocyst nearly completely hatched from the zona pellucida. The blastocyst can now expand to its full size.

Ovarian or abdominal pregnancies are exceptionally rare. Apart from their important clinical implications, these conditions emphasize the fact that the blastocyst can implant successfully into tissues other than a normal progestational endometrium. Prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident and not by a fundamental nutritive or endocrine insufficiency or by an immune maternal response. Abdominal implantation may occur on any organ, e.g. bowel, liver or omentum. If such a pregnancy continues, this makes removal of the placenta at delivery or abortion hazardous as a result of haemorrhage and so the placenta is usually left *in situ* to degenerate spontaneously.

Most ectopic pregnancies are anembryonic. Ectopic pregnancies with a live embryo are the most dangerous because they grow rapidly and may be detected as early as 8 weeks of pregnancy only when they have eroded the uterine tube wall and surrounding blood vessels.

In the United States approximately 2% of all pregnancies are ectopic (Baltarowich and Scoutt 2017). In the UK in 2011 the incidence was 11/1000, twice that noted between 1973–1999 (4.9/1000 (Coady 2011)). The increase in incidence is associated with an increased incidence of pelvic inflammatory disease as well as greater diagnostic accuracy. The rate of recurrent ectopic implantation is 5–20% after a single prior ectopic implantation and more than 30% after two consecutive ectopic implantations. ARTs are particularly associated with ectopic implantation. Approximately 50% of patients with ectopic implantation have no risk factors. (For details consult Baltarowich and Scoutt (2017).)

Twinning

Spontaneous twinning occurs once in approximately every 80 births. Monozygotic twins arise from a single ovum fertilized by a single sperm. At some stage up to the establishment of the axis of the embryonic area and the development of the primitive streak, the embryonic tissues separate into two parts, each of which gives rise to a complete embryo. The process of hatching of the blastocyst from the zona pellucida may result in constriction of the emerging cells and separation into two discrete entities. There is a gradual decrease in the average thickness of the zona pellucida with increasing maternal age, that may be causally related to the increase in frequency of monozygotic twinning with increased maternal age. The resultant twins have the same genotype but the description 'identical twins' is best avoided, since most monozygotic twins have differences in phenotypes. Late separation of twins from a single conceptus may result in conjoined twins; these may be equal or unequal, as in acardia. After twinning, monozygotic embryos enter a period of intense catch-up growth. Despite starting out at half the size, each twin embryo or fetus is of a size comparable to a singleton fetus in the second trimester of pregnancy, but declines in relative size in the last 10 weeks of pregnancy. The sex of monozygotic twins will be the same. Monoamniotic, monochorionic, monozygotic twins are most likely to be female, as are acardiac twins. The male to female ratio for all monozygotic twins is 0.487, and for monoamniotic, monochorionic twins it is 0.231.

Dizygotic twins represent the most frequent form of twinning. They result from multiple ovulations, which can be induced by gonadotrophins or drugs commonly used in patients with infertility. Dizygotic twins may be different sexes; like-sex pairs are more common. The male to female ratio is 0.518. The presence of two gestation sacs can be

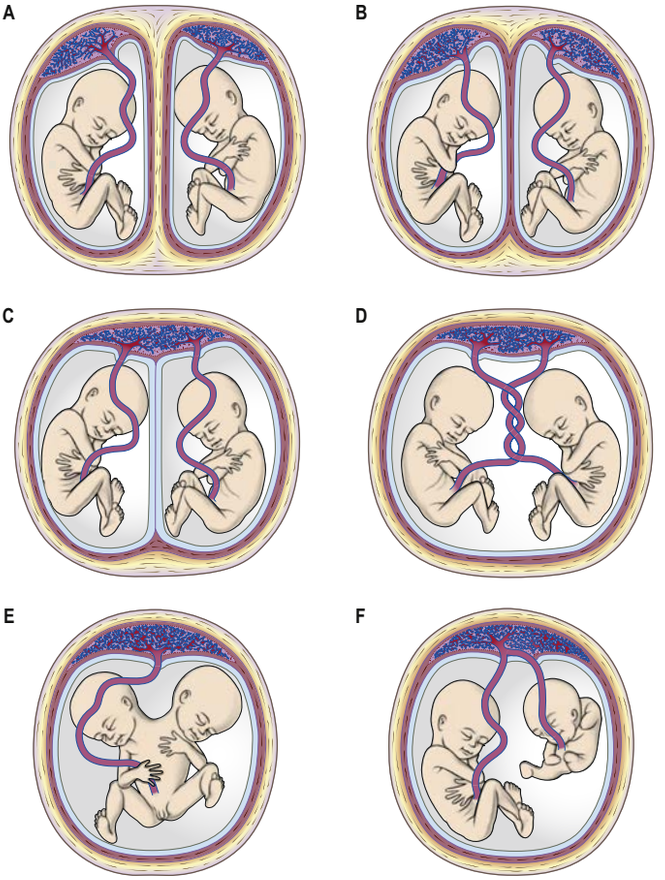

Fig. 8.9 Relationships of the extraembryonic membranes in different types of twinning. **A**, Diamnionic, dichorionic separated; i.e. separation of the first two blastomeres results in separate implantation sites. **B**, Diamnionic, dichorionic fused; here the chorionic membranes are fused but the fetuses occupy separate choria. **C**, Diamnionic, monochorionic; reduplication of the inner cell mass can result in a single placenta and chorionic sacs but separate amniotic cavities. **D**, Monoamnionic, monochorionic; duplication of the embryonic axis results in two embryos sharing a single placenta, chorion and amnion. **E**, Incomplete separation of the embryonic axis results in conjoined twins. **F**, Unequal division of the embryonic axis or unequal division of the blood supply may result in an acardiac monster.

identified on ultrasound examination at 4.5–5 postmenstrual weeks, but amniotic cavities cannot be seen clearly until 8 postmenstrual weeks. Multiple births greater than twinning, such as triplets or quadruplets, can arise from multiple ovulations, or from a single ovum, or both. It is most likely to be seen in women treated with drugs to stimulate ovulation.

The range of separation of twin embryos is reflected in the separation of the extraembryonic membranes. The types of placentation that can occur are shown in Fig. 8.9. Monoamniotic, monochorionic placentae are associated with the greatest perinatal mortality (50%), caused both by entanglement of the umbilical cords impeding the blood supply and by various vascular shunts between the placentae, which may divert blood from one fetus to the other. Artery–artery anastomoses are the most common, followed by artery–vein anastomoses. If the shunting of blood across the placentae from one twin to the other is balanced by more than one vascular connection, development may proceed unimpaired. However, if this is not the case, one twin may receive blood from the other, leading to cardiac enlargement, increased urination and polyhydramnios in the recipient, and anaemia, oligohydramnios and atrophy in the donor.

Dizygotic twins have either completely separate chorionic sacs or sacs that have fused. Such placentae are separated by four membranes, two amnia and two choria; in addition, these placentae have a ridge of firmer tissue at the base of the dividing membranes, caused by the abutting of two expanding placental tissues against each other.

FORMATION OF EXTRAEMBRYONIC TISSUES

The earliest developmental processes in mammalian embryos involve the production of those extraembryonic structures that will support and nourish the embryo during development. Production of these layers begins before implantation is complete. At present, it is unclear where the extraembryonic cell lines arise. Both trophoblast and inner cell mass contribute cells. Fig. 8.1 shows the sequence of development of embryonic and extraembryonic tissues in the early embryo.

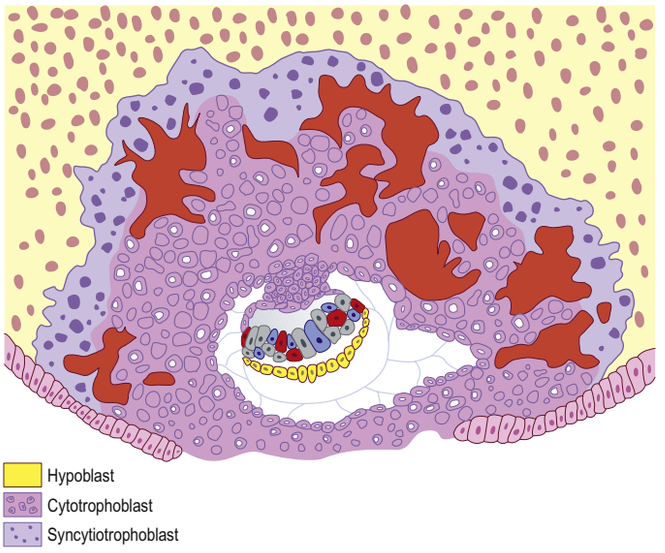

Fig. 8.10 The implanting conceptus at stage 5b. The embryo at this stage is composed only of the abutting epiblast and hypoblast layers. It is suspended within the blastocyst cavity (chorionic cavity) and surrounded by a layer of cytotrophoblast. A large mass of syncytiotrophoblast, with interconnecting lacunae, is penetrating the maternal endometrium.

Epiblast and amniotic cavity

Epiblast cells are closest to the implanting face of the trophoblast and have a definite polarity. They are arranged in a radial manner with extensive junctions near the centre of the mass of cells, supported by supranuclear organelles. A few epiblast cells are contiguous with cytotrophoblast cells: apart from this contact, a basal lamina surrounds what is initially a spherical cluster of epiblast cells isolating them from all other cells. Those epiblast cells adjacent to the hypoblast become taller and more columnar than those adjacent to the trophoblast, causing the epiblast sphere to flatten and shifting the centre of the sphere towards the polar trophoblast. Amniotic fluid accumulates at the eccentric centre of the now lenticular epiblast mass, which is bordered by apical junctional complexes and microvilli. As further fluid accumulates, an amniotic cavity forms, roofed by low cuboidal cells that possess irregular microvilli. The cells share short apical junctional complexes and associated desmosomes, and rest on an underlying basal lamina. The demarcation between true amnion cells and those of the remaining definitive epiblast is clear. The columnar epiblast cells are arranged as a pseudostratified layer with microvilli, frequently a single cilium, clefted nuclei and large nucleoli, and they have a distinct, continuous basal lamina. Cell division in the epiblast tends to occur near the apical surface, causing this region to become more crowded than the basal region. At the margins of the embryonic disc, the amnion cells are contiguous with the epiblast: there is a gradation in cell size from columnar to low cuboidal within a two- to three-cell span (Fig. 8.10; see Fig. 9.1). Further development of the amnion and amniotic fluid is described in Chapter 9.

Hypoblast and yolk sac

Hypoblast is the term used to describe the lower layer of cells of the early bilaminar disc, most commonly in avian embryos: this layer is also termed anterior, or distal, visceral endoderm in mouse embryos. Just before implantation, the hypoblast consists of a layer of squamous cells that is only slightly more extensive than the epiblast. The cells exhibit polarity, in that they show apical junctional complexes and apical microvilli that face the cavity of the blastocyst, but they lack a basal lamina. During early implantation, the hypoblast extends beyond the edges of the epiblast and can be subdivided into visceral hypoblast (cells contact the epiblast basal lamina), and parietal hypoblast (cells contact the mural trophoblast). Parietal hypoblast cells are squamous, may share adhesion junctions with the mural trophoblast and, rarely, may also share gap junctions. Visceral hypoblast cells are cuboidal, and have a uniform apical surface towards the blastocyst cavity but irregular basal and lateral regions, with flanges and projections underlying one

another and extending into intercellular spaces. There is no basal lamina subjacent to the visceral hypoblast. The distance between the hypoblast cells and the epiblast basal lamina is variable.

A series of modifications of the original blastocystic cavity develops beneath the hypoblast later than those developing above the epiblast. While the amniotic cavity is enlarging within the sphere of epiblast cells, the parietal hypoblast cells are proliferating and spreading along the mural trophoblast until they extend most of the way around the circumference of the blastocyst, converging towards the abembryonic pole. At the same time, a space appears between the parietal hypoblast and the mural trophoblast that limits the circumference of the hypoblastic cavity. A variety of terms have been applied to the parietal hypoblast layer: extraembryonic hypoblast, extraembryonic endoderm and exocoelomic (Heuser's) membrane. The cavity that the layer initially surrounds is the primary yolk sac (primary umbilical vesicle), and the resultant smaller cavity lined by hypoblast is the secondary yolk sac, seen from stage 6. The method of secondary yolk sac formation may involve: cavitation of visceral hypoblast (a method similar to formation of the amnion); rearrangement of proliferating visceral hypoblast; or folding of the parietal layer of the primary yolk sac into the secondary yolk sac. Further development of the yolk sac is described in Chapter 9.

Visceral hypoblast cells are thought to be important in many aspects of the early specification of cell lines and control of the timing of early development. They induce the formation and position of the primitive streak in the midline of the embryo, thus establishing the first axis of the embryonic disc, and they influence the timing of epiblast epithelial-to-mesenchymal transition at the primitive streak. The cells remain beneath the primitive streak: their experimental removal in avian embryos causes multiple embryonic axes to form. Visceral hypoblast cells are thought to be necessary for successful induction of the head region and for the successful specification of the primordial germ cells. With the later formation of the embryonic cell layers from the epiblast, the visceral hypoblast appears to be sequestered into the secondary yolk sac wall by the expansion of the newly formed embryonic endoderm beneath the epiblast, although there is now evidence that some hypoblast cells may remain in the final endoderm layer and contribute to the gut, and that they may also play a role in the induction of cardiogenesis. For a review of the roles of hypoblast cells, see Stern and Downs (2012).

After the formation of the secondary yolk sac, a diverticulum of the visceral hypoblast, the allantois, forms towards one end of the embryonic region and extends into the local extraembryonic mesoblast. It passes from the roof of the secondary yolk sac to the same plane as the amnion. Further development of the allantois is described in Chapter 9.

Extraembryonic mesoblast

By definition, extraembryonic tissues encompass all tissues that do not contribute directly to the future body of the definitive embryo and, later, of the fetus. At stage 5, blastocysts are implanted but do not yet display trophoblastic villi (see Fig. 8.10); they range from 7 to 12 days in age. A feature of this stage is the first formation of extraembryonic mesoblast, which will eventually cover the amnion, secondary yolk sac and the internal wall of the mural trophoblast, and will form the connecting stalk of the embryo containing the allantoenteric diverticulum. The origin of this first mesoblastic extraembryonic layer has yet to be established: several sources have been proposed, including the caudal region of the epiblast, the parietal hypoblast and subhypoblastic cells. A trophoblastic origin seems unlikely because there is always a complete basal lamina underlying the trophoblast and the migration of cells out of an epithelium is usually associated with previous disruption of the basal lamina. The origin of extraembryonic cells changes over time as new germinal populations are established.

The first mesoblastic extraembryonic layer gives rise to the layer known as extraembryonic mesoblast, arranged as a mesothelium with underlying extraembryonic mesenchymal cells between the mural trophoblast and the primary yolk sac in stage 5. Later extraembryonic mesoblast populations mushroom beneath the cytotrophoblastic cells at the embryonic pole, forming the cores of the developing villus stems, and the villi and angioblastic cells that will give rise to the capillaries within them and the earliest blood cells.

Initially, the extraembryonic mesoblast connects the amnion to the chorion over a wide area. Continued development and expansion of the extraembryonic coelom means that this attachment becomes increasingly restricted until it becomes a connecting stalk between the future caudal end of the embryonic disc and the chorion, forming a permanent pathway along which vascular anastomoses around the allantois establish communication with those of the chorion.

CHAPTER
9

Implantation and placentation

IMPLANTATION

Implantation involves the initial attachment of the trophoblastic wall of the blastocyst to the endometrial luminal epithelium, stimulating the decidual response. The blastocyst is present within the uterine cavity for some 72 hours prior to implantation, and during this time there is an interactive dialogue between the implanting blastocyst and endometrial decidual stromal cells (Makieva et al 2018). *In vitro* culture of human preimplantation embryos shows that normally developed preimplantation human blastocysts actively enhance the uterine environment for their implantation, whereas developmentally impaired embryos induce endoplasmic reticulum stress responses in decidual cells that inhibit implantation (Brosens et al 2014). Reponses from endometrial stromal cells also inform these interactions (Makieva et al 2018, Zhang et al 2018). Uterine surgical scars may have a long-term impact on the interactive dialogue between the implanting blastocyst and endometrial decidual stromal cells (Jauniaux et al 2018).

The trophoblast of the blastocyst gives rise to three main cell types in the human placenta: syncytiotrophoblast that forms the epithelial covering of the villous tree and is the main endocrine component of the placenta; villous cytotrophoblast cells that represent a germinative population that proliferates throughout pregnancy, fusing to generate syncytiotrophoblast; and extravillous trophoblast cells that are non-proliferative and invade the maternal endometrium. The first two cell lines can be seen from stages 4 and 5 onwards. The cytotrophoblast cells that form the mural and polar trophoblast are cuboidal. Following apposition of the blastocyst to the uterine mucosa, the polar trophoblast becomes covered externally with syncytiotrophoblast, a multinucleated tissue that penetrates between the epithelial cells (see Fig. 8.10).

Preimplantation embryos produce matrix metalloproteinases (MMPs) that mediate penetration of the maternal subepithelial basal lamina by the syncytiotrophoblast. Trophoblast cells express L-selectin (usually seen as a mediator of neutrophil rolling and tethering in inflamed endothelium), and the endometrial epithelium upregulates selectin–oligosaccharide-based ligands (Fukuda and Sugihara 2008). Thus, differentiating cytotrophoblast cells appear to use processes that also occur in vasculogenesis and during leukocyte migration from the blood into the tissues. Flanges of syncytiotrophoblast grow between the cells of the uterine luminal epithelium towards the underlying basal lamina without apparent damage to the maternal cell membranes or disruption of the intercellular junctions. Instead, shared junctions, including tight junctions, are formed with many of the maternal uterine epithelial cells.

Implantation continues with erosion of the vascular endothelium of maternal superficial capillaries and glandular epithelium and phagocytosis of the glandular secretions. There is increasing evidence that the endometrial stromal cells grow around and encapsulate the blastocyst until it occupies an uneven implantation cavity in the stroma (interstitial implantation) (**Fig. 9.1**). In the early postimplantation phase, the uterine surface is resealed by re-epithelialization and the formation of a plug that may contain fibrin. As the blastocyst burrows more deeply into the endometrium, syncytiotrophoblast forms over the mural cytotrophoblast, but never achieves the thickness of the syncytiotrophoblast over the embryonic pole.

The syncytiotrophoblast does not express either class I or class II major histocompatibility complex (MHC) antigens, but it secretes numerous hormones: human chorionic gonadotrophin (hCG) can be detected in maternal urine from as early as postfertilization day 10 and forms the basis for tests for early pregnancy. This hCG prolongs the life of the corpus luteum, which continues to secrete progesterone and oestrogens until these essential hormones are produced by the placenta. For details of postfertilization and postmenstrual ages see Fig. 23.3.

Menstruation ceases on successful implantation and the endometrium transforms into the decidua to form a suitable nidus for the conceptus. Decidualization of the endometrial stroma may occur without an intrauterine pregnancy, for example in the presence of an ectopic pregnancy, after prolonged treatment with progesterone, and in the late secretory phase of a non-conception cycle. Decidual differentiation is not evident in the stroma at the earliest stages of implantation, and it may not be until a week later that fully differentiated cells are present. During decidualization, the interglandular tissue increases in quantity (Burton et al 2010). It contains a substantial population of leukocytes (large granular lymphocytes, macrophages and T cells) distributed amongst large decidual cells.

Extracellular matrix, growth factors and protease inhibitors produced by the decidua all probably modulate the degradative activity of the trophoblast and support placental morphogenesis and placental accession to the maternal blood supply. Once implantation is complete, distinctive names are applied to different regions of the decidua (**Fig. 9.2**). The decidua capsularis covers the conceptus; the decidua basalis (where the placenta subsequently develops) lies between the conceptus and the uterine muscular wall; the decidua parietalis lines the remainder of the body of the uterus. Subsets of perivascular and stromal cells in distinct decidual layers probably mediate regulatory interactions that prevent harmful innate or adaptive immune responses at the maternal-fetal interface in early human pregnancy (Vento-Tormo et al 2018).

DEVELOPMENT OF THE PLACENTA

Formation of the human placenta requires a developmental progression that proceeds in a specific chronological order. The development of primary, secondary and anchoring villi, and the local differentiation of haemangioblast cells within them, occur concurrently with the modification of maternal blood vessels to ensure their patency. By embryonic stage 10, with the onset of the embryonic heartbeat, a primitive circulation between the embryo and the secondary yolk sac is established. Blood vessels within the walls of the allantois and connecting stalk connect the embryonic circulation to the developing placenta during postmenstrual weeks 6–12, forming a low-oxygen environment with nutrition from endometrial glands. From postmenstrual week 12, maternal blood flows into the placental intervillous spaces and a feto-placental circulation is fully established.

As the blastocyst implants, the syncytiotrophoblast invades the uterine tissues, including the glands and walls of maternal blood vessels (see Fig. 9.1; **Fig. 9.3**), and increases rapidly in thickness over the embryonic pole (**Fig. 9.4**). Microvillus-lined clefts and lacunar spaces develop within the syncytiotrophoblastic envelope (postfertilization days 9–11) and establish communications with one another. Initially, many of these spaces contain maternal blood derived from dilated uterine capillaries and veins, as the walls of the vessels are partially destroyed. As the conceptus grows, the lacunar spaces enlarge and become confluent to form intervillous spaces.

The projections of syncytiotrophoblast into the maternal decidua are the primary villi. They are invaded initially with cytotrophoblast and then with extraembryonic mesenchyme (days 13–15) to form secondary placental villi. Capillaries develop in the mesenchymal core of the villi during postfertilization week 3. The cytotrophoblast within the villi continues to grow through the invading syncytiotrophoblast and makes direct contact with the decidua basalis, forming anchoring villi. Further cytotrophoblast proliferation occurs laterally so that neighbouring outgrowths meet to form a spherical cytotrophoblastic shell around the conceptus (**Fig. 9.5**; see Fig. 9.3B). Lateral projections from the main stem villus form true villi. Elongation of growing capillaries outstrips that of the containing villi, causing vessels to loop: obtrusion of capillary loops and new sprouts results in the formation of terminal villi.

As secondary villi form, single mononuclear cells become detached from the distal (anchoring) cytotrophoblast and infiltrate the maternal decidua (**Fig. 9.6**; see Fig. 9.3B). These extravillous cells are the third lineage of the original trophoblastic cells. Extravillous trophoblast cells may be interstitial or endovascular. Interstitial extravillous trophoblast cells invade the maternal spiral arteries from their adventitia, whereas the endovascular trophoblast cells migrate along their lumens.

The most numerous are uterine natural killer (NK) cells that accumulate in the endometrium during the secretory phase of the cycle and persist until mid-pregnancy; they interact with invading extravillous trophoblast cells that express human leukocyte antigens G and C (HLA-G, HLA-C).

Decidual cells are stromal cells that contain varying amounts of glycogen, lipid and vimentin-type intermediate filaments in their cytoplasm. They are generally rounded but their shape may vary, depending on the local packing density. They may contain one, two or sometimes three nuclei, frequently display rows of club-like cytoplasmic protrusions enclosing granules, and are associated with a characteristic capsular basal lamina. Decidual cells produce a range of secretory products that may be taken up by the trophoblast, including insulin-like growth factor binding protein 1 (IGF-BP1) and prolactin. Prolactin signals to the endometrial glands to increase their secretions and may play a role in the maintenance and growth of the conceptus in the early phase of postimplantational development via histotrophic nutrition (Turco et al 2017): it can be detected in amniotic fluid in the first trimester of pregnancy.

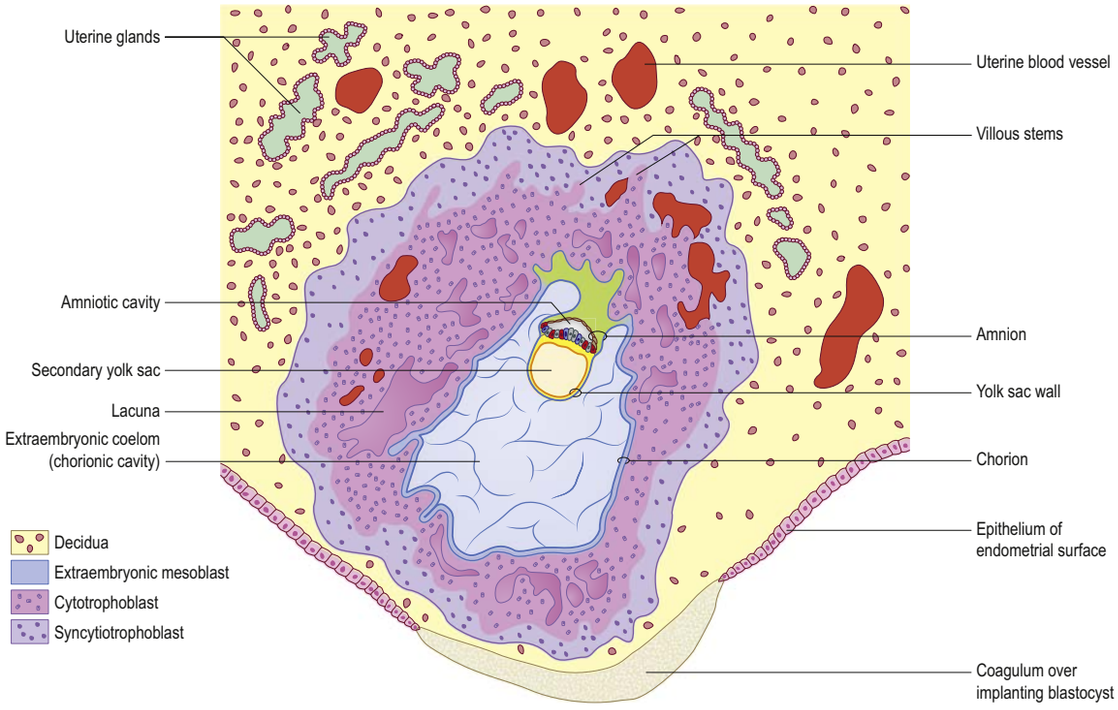

Fig. 9.1 The implanting conceptus at stage 6. The embryo is composed of epiblast, with the amniotic cavity above it, and hypoblast, with the secondary yolk sac below it (see also Figs 8.10, 10.1). Both cavities are covered externally with extraembryonic mesoblast, which also lines the larger chorionic cavity. Primary villi cover the outer aspect of the conceptus and extend into the maternal endometrium, and in places, maternal blood fills the lacunae.

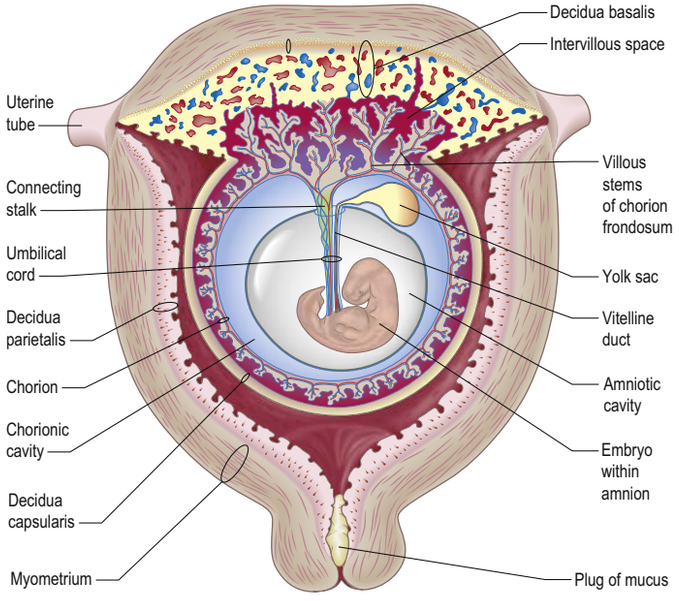

Fig. 9.2 The gravid uterus at about postmenstrual week 9. A placental site precisely in the uterine fundus, as indicated on the figure, is rather unusual; the dorsal, ventral or lateral wall of the corpus uteri is more usual. The maternal endometrium is now termed decidua; different regions are distinguished.

The smooth muscle and internal elastic lamina are replaced with extracellular fibrinoid deposits (see Figs 9.3B, 9.6) (Harris 2010). In the central area of the basal plate, destined to become the definitive placenta, the endovascular trophoblast plugs block the maternal spiral arteries until the end of the first trimester, restricting inflow into the intervillous space. The cells then migrate antidromically, against the flow of maternal blood, along the spiral arteries as far as the inner myometrial region or junctional zone (Huppertz et al 2014).

The definitive placenta is composed of a chorionic plate on its fetal aspect and a basal plate on its maternal aspect, separated by an intervening intervillous space containing villous stems with branches in contact with maternal blood (see Fig. 9.5). During the first trimester, development takes place in a physiologically low-oxygen environment supported by histotrophic nutrition from the endometrial glands which discharge into the intervillous space (see Fig. 9.3A) (Burton et al 2002, Burton et al 2007, Burton and Fowden 2012). When maternal blood bathes the surfaces of the chorion bounding the intervillous space, the human placenta is defined as haemochorial. Different grades of fusion exist between the maternal and fetal tissues in many other mammals (e.g. epitheliochorial, synepitheliochorial, endotheliochorial). The chorion is vascularized by the allantoic blood vessels of the body stalk, and so the human placenta can be termed chorio-allantoic (in some mammals, a choriovitelline placenta exists either alone or supplements the chorio-allantoic variety). It can also be defined as discoidal (in contrast to other shapes in other mammals), and deciduate (because maternal tissue is shed with the placenta and membranes at parturition as part of the afterbirth).

Growth of the placenta

Expansion of the entire conceptus is accompanied by radial growth of the villi and simultaneous integrated tangential growth and expansion of the trophoblastic shell. Eventually, each villous stem forms a complex that consists of a single trunk attached by its base to the chorion, from which second- and third-order branches (intermediate and terminal villi, respectively) arise distally. Terminal villi are specialized for exchange between fetal and maternal circulations; each one starts as a syncytial outgrowth and is invaded by cytotrophoblast cells, which then develop a core of fetal mesenchyme as the villus continues to grow. The core is vascularized by fetal capillaries (each villus undergoes sequential histological differentiation forming primary, secondary and tertiary types). The germinal cytotrophoblast continues to add cells that fuse with the overlying syncytium and so contribute to the expansion of the haemochorial interface. Terminal villi continue to form and branch within the confines of the definitive placenta throughout gestation, projecting in all directions into the intervillous space (see Fig. 9.5).

Up to postmenstrual week 8 (postfertilization week 6; for comparison of postfertilization and postmenstrual ages see Fig. 23.3), the entire chorion is covered with villous stems that are thus continuous peripherally with the trophoblastic shell, which is in close apposition with the decidua capsularis and the decidua basalis. The villi adjacent to the decidua basalis are stouter and longer and show a greater profusion of villi. As the conceptus continues to expand, the decidua capsularis is progressively compressed and thinned, the circulation through it is gradually reduced, and adjacent villi slowly atrophy and disappear. This process starts at the abembryonic pole (opposite to the implantation site): by the first trimester, the abembryonic hemisphere of the conceptus is largely denuded. Eventually, the whole chorion apposed to the decidua capsularis is smooth and is now termed the chorion laeve. It will later become apposed to the amnion, forming the chorio-amnion or placental

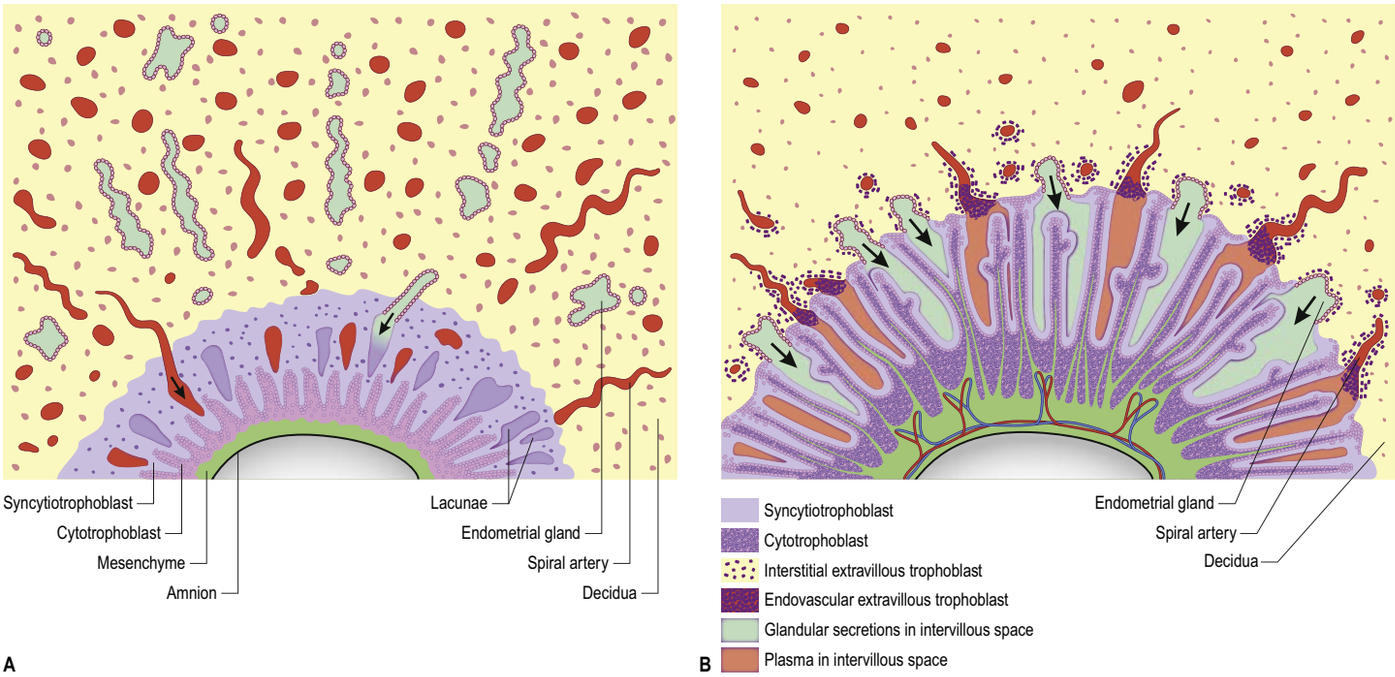

Fig. 9.3 **A**, The growing syncytiotrophoblast erodes decidual glands and spiral arteries, and their contents form lacunae within the syncytiotrophoblast. Cytotrophoblastic cells extend as villi into the syncytiotrophoblast. **B**, Cells originating from the cytotrophoblast move into the decidua, forming interstitial extravillous trophoblast cells, the third line of cytotrophoblastic cells. These surround the opened glands and spiral arteries in the decidua and inner myometrium. Cells that move through the tunicae adventitia, media and interna to enter the lumen of the vessels become endovascular extravillous trophoblast. These cells remodel the walls and plug the lumen of the spiral arteries, permitting only plasma to enter the forming intervillous space. Glandular secretions in the intervillous space provide histiotrophic nutrition to the embryo.

free membranes (see Figs 9.2, 9.10). In contrast, the villous stems of the disc-shaped region of chorion apposed to the decidua basalis increase greatly in size and complexity, and the region is now termed the chorion frondosum (see Fig. 9.4). The chorion frondosum and the decidua basalis constitute the definitive placental site (see Fig. 9.2). Abnormalities in this process may account for the persistence of villi at abnormal sites in the chorion laeve of the gestational sac and the presence of accessory or succenturiate lobes within the membranes of the definitive placenta. The presence of the entire villous ring of the primitive placenta beyond postmenstrual week 8 may lead to the development of placenta membranacea, a giant definitive placental structure surrounding the whole gestational sac during the remainder of pregnancy and covering the entire uterine cavity including the internal os of the cervix.

Coincidentally with the growth of the embryo and the expansion of the amnion, the decidua capsularis is thinned and distended, and the space between it and the decidua parietalis is gradually obliterated. The three endometrial strata recognizable in the premenstrual phase, compactum, spongiosum and basale, are better differentiated and easily distinguished. The glands in the spongiosum are compressed and appear as oblique slit-like fissures lined by low cuboidal cells. By postmenstrual week 9, the decidua capsularis and decidua parietalis are in contact. By postmenstrual weeks 17–20, the decidua capsularis is greatly thinned, and it almost disappears during the succeeding weeks.

When the placenta grows in the area of a previous uterine scar, both the extravillous trophoblast and some of the villi may develop beyond the normal junctional zone of the inner myometrium (Jauniaux et al 2018). The villi may be simply adherent to the myometrium (placenta creta) or invade more deeply inside the uterine wall (placenta increta) or beyond the uterine wall into the pelvis (placenta percreta).

Focal bleeding often occurs in the periphery of the developing placenta at the time of the formation of the membranes (postmenstrual weeks 8–12). This complication, termed threatened miscarriage, is a common clinical complication of pregnancy and can lead to a complete miscarriage if the haematoma extends to the definitive placenta (Jauniaux et al 2006).

At full term (postmenstrual week 40), the placental diameter varies from 200 to 220 mm, the mean placental weight is 500 g, its mean thickness is 25 mm and the total villous surface area is 12–14 m^2, providing an extensive and intimate interface for maternal–fetal exchange (the uteroplacental circulation carries approximately 600 ml of maternal blood per minute). There are no lymph vessels or aggregates of lymphoid cells in the placenta. Systematic evaluation and careful description of the placenta after delivery have been recommended for correlation with later neonatal neurodevelopmental outcomes (Roescher et al 2014).

Chorionic plate

The chorionic plate is covered on its fetal aspect by amniotic epithelium. A connective tissue layer carries the main branches of the umbilical vessels on the stromal side of the epithelium (see Fig. 9.5; Fig. 9.7). Subjacent to this are a diminishing layer of cytotrophoblast cells and then the syncytiotrophoblast lining the intervillous space. The connective tissue layer is formed by fusion between the mesenchyme-covered surfaces of amnion and chorion, and is more fibrous and less cellular than Wharton's jelly (of the umbilical cord), except near the larger vessels. The umbilical vessels radiate and branch from the cord attachment, with variations in the branching pattern, until

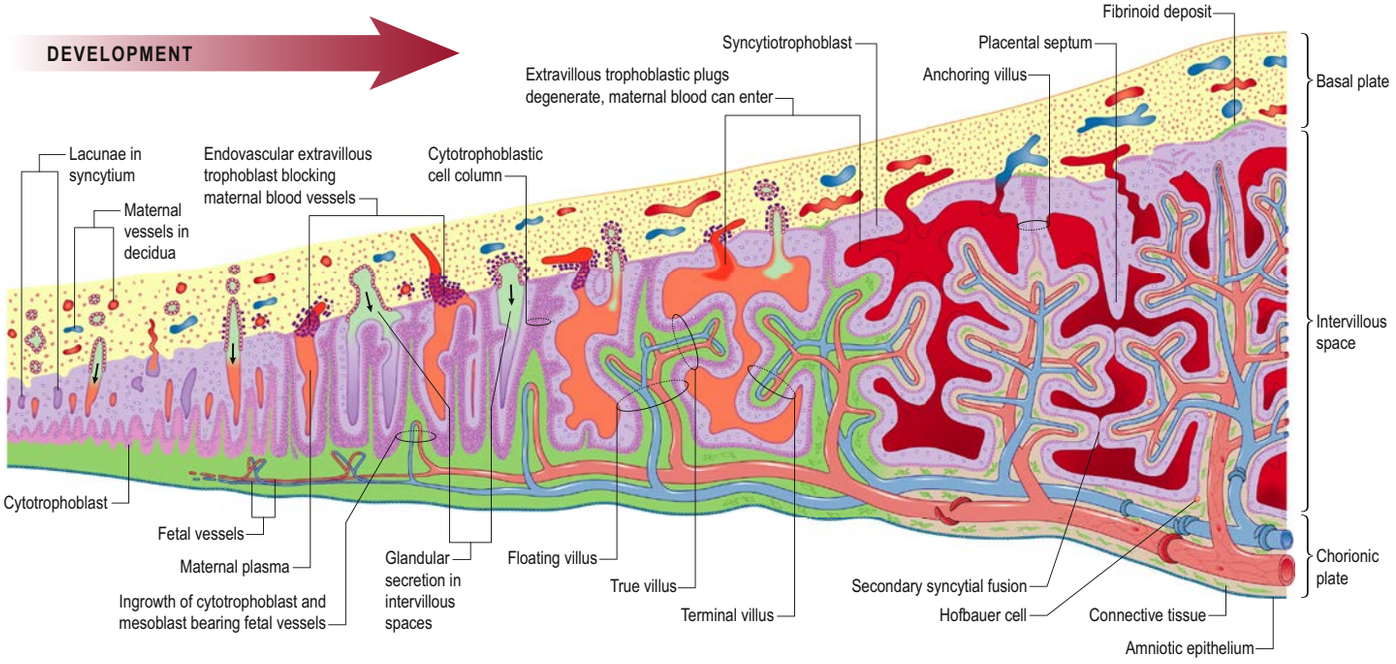

Fig. 9.5 Placental development.

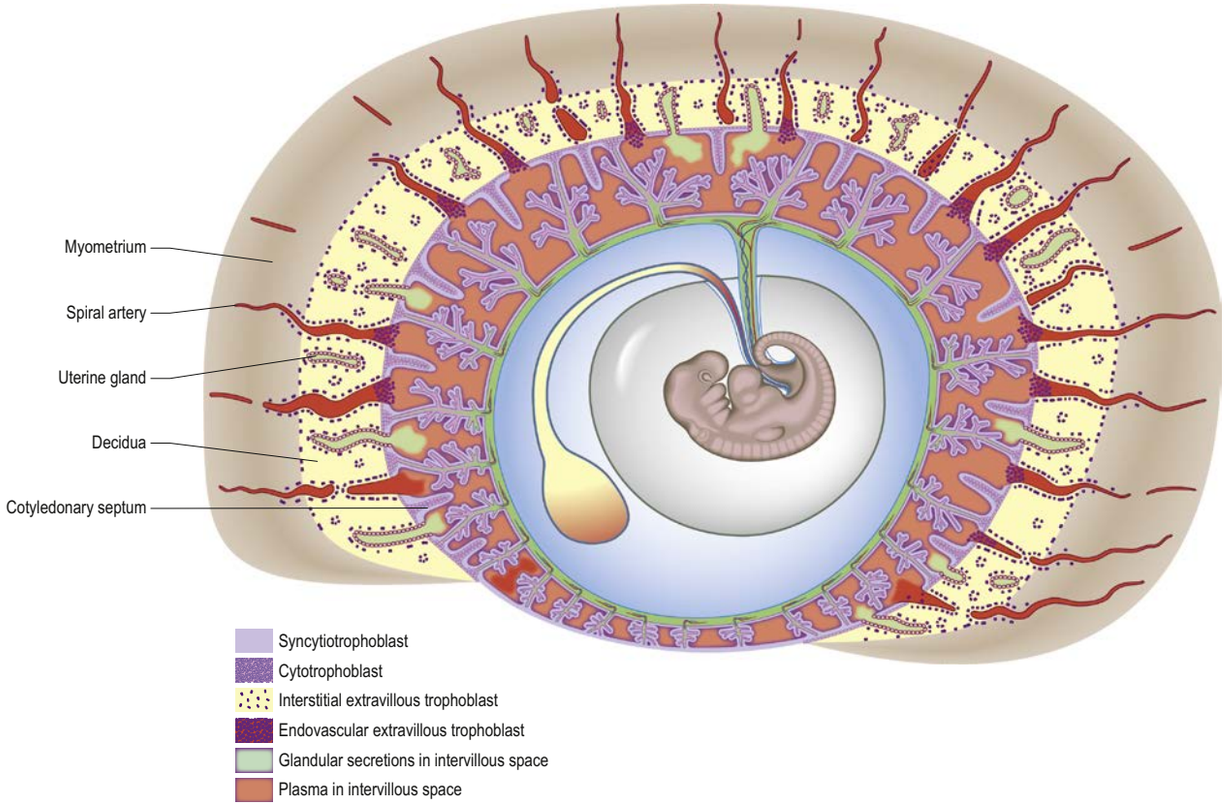

Fig. 9.6 As the placenta grows, the interstitial and endovascular extravillous trophoblast cells continue to remodel the spiral arteries into large-bore, low-resistance uteroplacental vessels. These arteries remain occluded by endovascular extravillous trophoblast until the end of the first trimester, promoting a low-oxygen environment.

they reach the bases of the trunks of the villous stem where they then arborize within the intermediate and terminal villi. The vascular trees of adjacent stems do not anastomose. The two umbilical arteries are normally joined at, or just before they enter, the chorionic plate, by some form of substantial transverse anastomosis (Hyrtl's anastomosis) (Ullberg et al 2001).

Basal plate

The basal plate, from fetal to maternal aspect, forms the outer wall of the intervillous space. The trophoblast and adjacent decidua are enmeshed in layers of fibrinoid and basement membrane-like extracellular matrix to form a complex junctional zone. In different places, the basal plate may contain syncytiotrophoblast, cytotrophoblast or fibrinoid matrix, remnants of the cytotrophoblastic shell, and, at the site of implantation, areas of necrotic maternal decidua (the so-called Nitabuch's stria) (see Figs 9.5, 9.7). Nitabuch's stria and the decidua basalis contain cytotrophoblast and multinucleated trophoblast giant cells derived from the mononuclear extravillous interstitial cytotrophoblast population that infiltrate the decidua basalis up to postmenstrual week 18. These cells penetrate as far as the inner third of the myometrium but can often be observed at or near the decidual–myometrial junction. They are not found in the decidua parietalis or the adjacent myometrium, suggesting that the placental bed giant cell represents a differentiative end stage in the extravillous trophoblast lineage. The striae of fibrinoid are irregularly interconnected and variable in prominence. Strands pass from Nitabuch's stria into the adjacent decidua

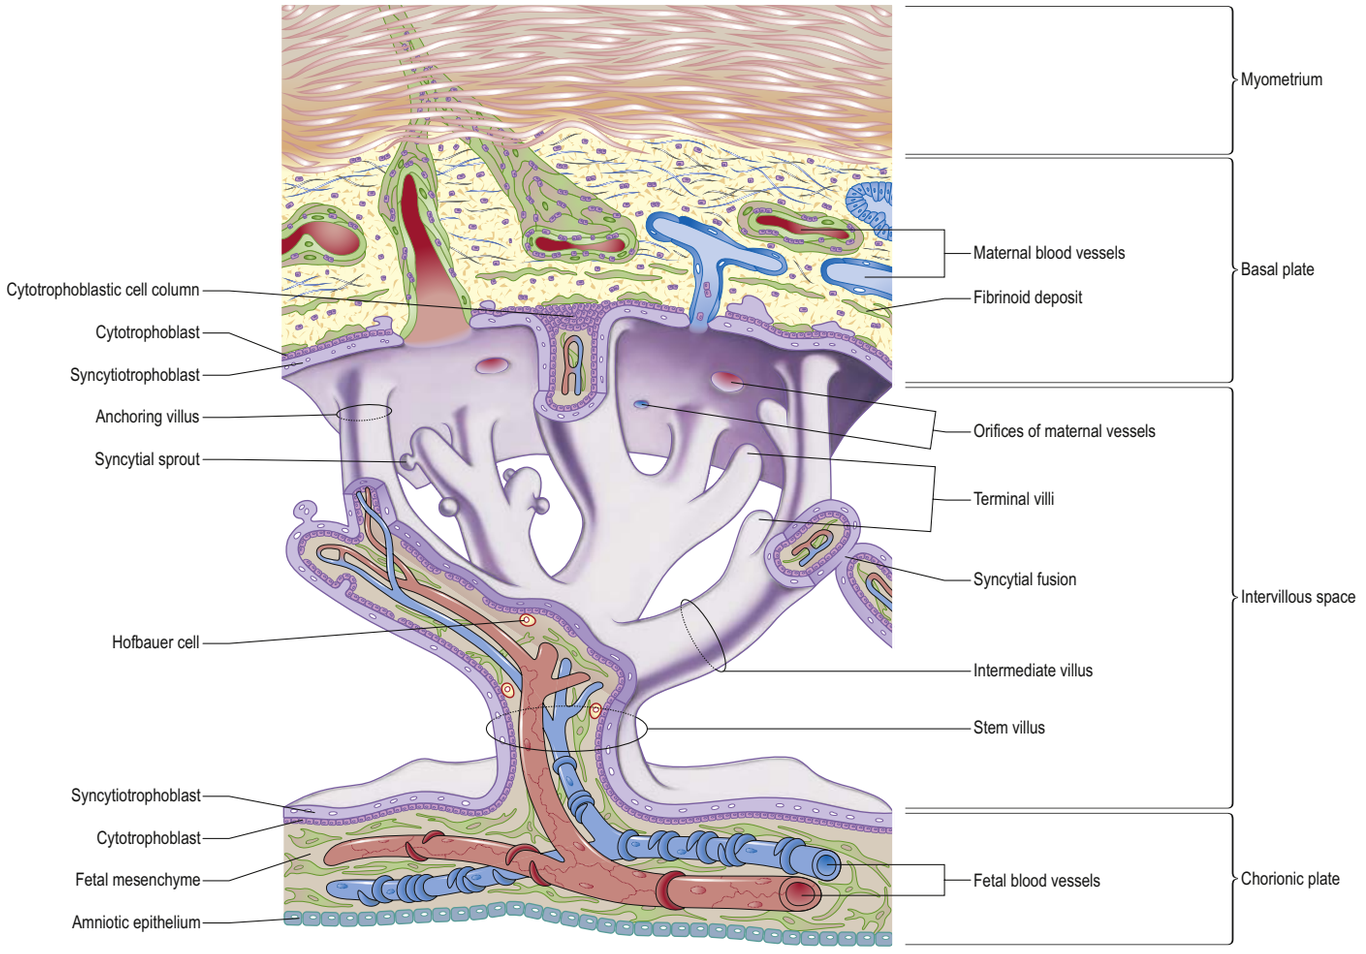

Fig. 9.7 The arrangement of the placental tissues from the chorionic plate (fetal side) to the basal plate or decidua basalis (maternal side).

which contains basal remnants of the endometrial glands and large and small decidual cells scattered in a connective tissue framework that supports an extensive venous plexus.

Initially, only the central area of a placenta contains extravillous trophoblast cells, both within and around the spiral arteries. These cells gradually migrate laterally, reaching the periphery of the placenta around mid-gestation; the extent of invasion is progressively shallower towards the periphery. Invaded maternal vessels show a 5–10-fold dilation of the vessel mouth and altered responsiveness to circulating vasoactive compounds (Hung et al 2001, Burton et al 2009).

The conversion of maternal musculoelastic spiral arteries to large-bore, low-resistance uteroplacental vessels is considered key for a successful human pregnancy. Failure to achieve these changes is a feature of common complications of pregnancy, such as early-onset pre-eclampsia, miscarriage and fetal growth restriction. The area of the basal plate is commonly smaller in these complications of pregnancy (Suri et al 2013).

Between postmenstrual weeks 9 and 12, the placental basal plate develops intercotyledonary septa, ingrowths of the cytotrophoblast covered with syncytium that grow towards, but do not fuse with, the chorionic plate (see Fig. 9.5). These septa circumscribe the uterine surface of the placenta into 15–30 lobes, often termed cotyledons, each surrounding a limited portion of the intervillous space associated with a villous trunk from the chorionic plate. From postmenstrual week 13–14, these septa are supported by tissue from the decidua basalis. Throughout the second half of pregnancy, the basal plate becomes thinned and progressively modified; there is a relative diminution of the decidual elements, increasing deposition of fibrinoid, and admixture of fetal and maternal derivatives.

Intervillous space

The intervillous space contains the main trunks of the villous stems and their arborizations into intermediate and terminal villi (see Figs 9.5, 9.7). A villous trunk and its branches may be regarded as the essential structural, functional and growth unit of the developing placenta.

At term, from the inner myometrium to the intervillous space, the walls of most spiral arteries consist of a fibrinoid matrix and embedded cytotrophoblast. This arrangement allows expansion of the arterial diameter (and so slows the rate of arterial inflow and reduces the perfusion pressure), independent of the local action of vasoconstrictive agents. Endothelial cells, where present, are often hypertrophic. The veins that drain the blood away from the intervillous space pierce the basal plate and join tributaries of the uterine veins.

In vivo studies have shown that in early pregnancy the human placenta is not truly haemochorial (**Video 9.1**) (Jauniaux et al 2003). From the time of implantation, the extravillous trophoblast not only invades the uterine tissues but also forms a continuous shell at the level of the decidua. The cells of this shell anchor the placenta to the maternal tissue and also plug the tips of the uteroplacental arteries (see Figs 9.3B, 9.6) (Burton et al 1999). The shell and the plugs form a labyrinthine interface that filters maternal blood, permitting a slow seepage of plasma but no true blood flow into the intervillous space (Burton et al 2003). This creates a low-oxygen environment that may protect the developing embryo against the deleterious and teratogenic effects of oxygen free radicals and creates a uteroplacental O_2 gradient that exerts a regulatory effect on placental tissue development and function (Jauniaux et al 2003, Burton et al 2017). In particular, it influences cytotrophoblast proliferation and differentiation along the invasive pathway, villous vasculogenesis and the formation of the chorion laeve. An O_2 gradient persists within the placental lobules throughout pregnancy; the central regions are well oxygenated compared to the periphery, reflecting the direction of maternal blood flow (Burton and Jauniaux 2011).

Formation of a well-developed cytotrophoblastic shell at the maternal–fetal interface is crucial for a successful pregnancy. Impaired formation may contribute to reduced extravillous trophoblast invasion and deficient utero-placenta remodelling (Burton and Jauniaux 2017). A thin and fragmentary shell results in premature and disorganized onset of labour and miscarriage, while in less severe cases it may predispose to haemorrhage at the interface and formation of subchorionic haematomas.

At the end of the first trimester (postmenstrual week 12), the endovascular extravillous trophoblastic plugs are progressively dislocated, allowing maternal blood to flow progressively more freely and

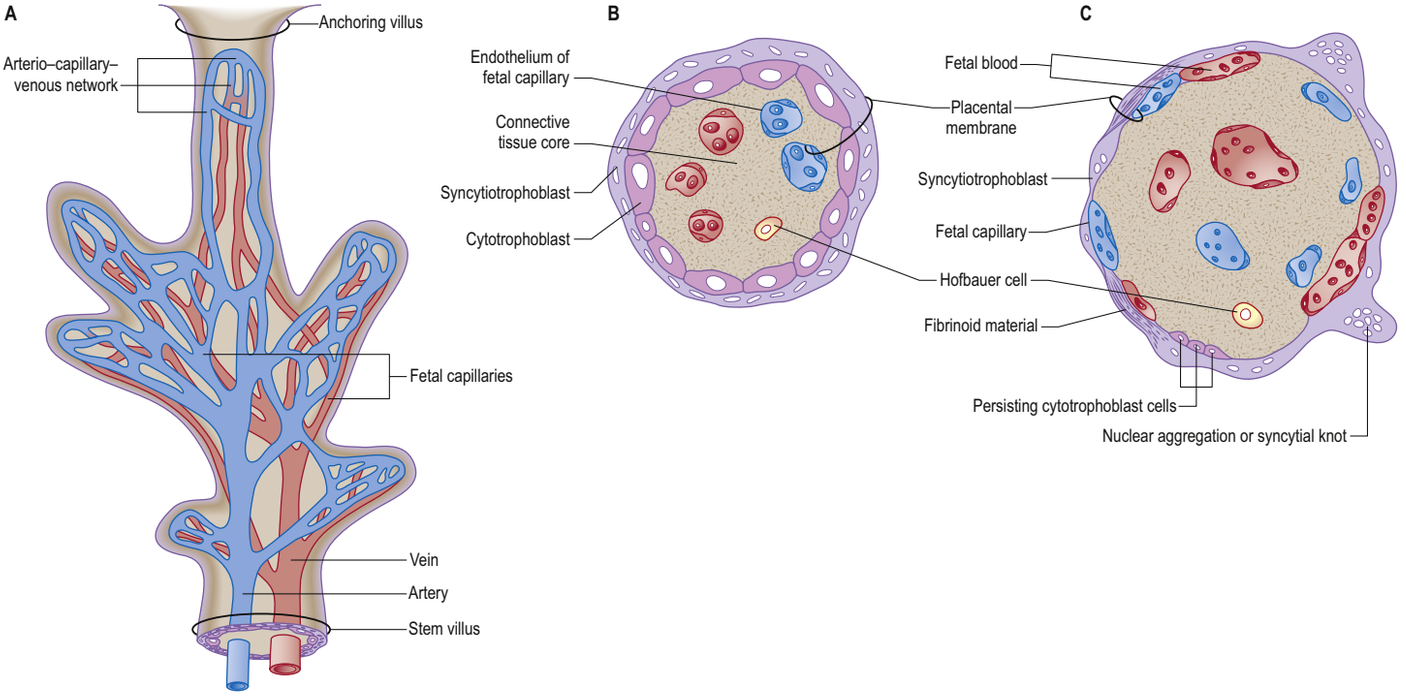

Fig. 9.8 A, A chorionic villus and its arterio-capillary-venous system carrying fetal blood. The artery carries deoxygenated blood and waste products from the fetus, and the vein carries oxygenated blood and nutrients to the fetus. **B–C**, Transverse sections through individual chorionic villi at about postmenstrual week 10 (**B**) and at full term (**C**). The villi would be within the intervillous space, bathed externally in maternal blood. The placental membrane, composed of fetal tissues, separates the maternal blood from the fetal blood.

continuously within the intervillous space (see Figs 9.6, 9.7, **Video 9.1**). During postmenstrual weeks 10–14, two-thirds of the primitive placenta degenerates to form the placental free membranes, the chorionic cavity (corresponding to the extraembryonic coelom) is obliterated by the growth of the amniotic sac, and maternal blood flows progressively throughout the entire placenta (Jauniaux et al 2003). These events bring the maternal blood closer to the fetal tissues, facilitating nutrient and gaseous exchange between the maternal and fetal circulations (Gutierrez-Marcos et al 2012).

Structure of a placental villus

Chorionic villi are the essential structures involved in exchanges between mother and fetus. The villous tissues separating fetal and maternal bloods are therefore crucially important functionally. From the chorionic plate, progressive branching occurs into the villous tree, as stem villi give way to intermediate and terminal villi. Each villus has a core of connective tissue containing collagen types I, III, V and VI, as well as fibronectin. Cross-banded fibres (30–35 nm) of type I collagen often occur in bundles, whereas type III collagen is present as thinner (10–15 nm) beaded fibres forming a meshwork that often encases the larger fibres. Collagens V and VI are present as 6–10 nm fibres closely associated with collagens I and III. Laminin and collagen type IV are present in the stroma associated with the basal laminae that surround fetal vessels and also in the trophoblast basal lamina. Overlying this matrix are ensheathing cytotrophoblast cells and the syncytiotrophoblast, bathed by the maternal blood in the intervillous space (see Figs 9.5, 9.7; **Fig. 9.8**). Adjacent cytotrophoblast cells and cytotrophoblast cells adjacent to the syncytium are joined by numerous desmosomes.

In earlier stages, the cytotrophoblast forms an almost continuous layer on the basal lamina. After postmenstrual weeks 13–16, it gradually expends itself producing the syncytiotrophoblast that comes to lie on the basal lamina over an increasingly large area (56% at term) and it becomes progressively thinner. Cytotrophoblastic sprouts covered in syncytium are present in the first and second trimesters and represent a stage in the development of new villi. Columns of cytotrophoblast at the tips of anchoring villi extend from the villous basal lamina to the maternal decidual stroma. Cytotrophoblastic cells persist until term but, because the increase in villous surface area outstrips their proliferation, they are usually disposed singly.

The syncytiotrophoblast is the multinucleated epithelium of the placenta. It is an intensely active tissue layer, across which most transplacental transport must occur (Ellery et al 2009). It is also a selectively permeable barrier that allows water, oxygen and other nutritive substances and hormones to pass from mother to fetus, and some of the products of excretion to pass from fetus to mother. It secretes a range of placental hormones into the maternal circulation. Syncytial cytoplasm is more strongly basophilic than that of the cytotrophoblast cells, and is packed with organelles consistent with its secretory phenotype. Where the plasma membrane adjoins basal lamina, it is often infolded into the cytoplasm, whereas the surface bordering the intervillous space is set with numerous long microvilli.

Although many nuclei are dispersed within the syncytioplasm, other are aggregated into specializations referred to as syncytial knots and syncytial sprouts (Burton et al 2003). Syncytial sprouts are markers of trophoblast proliferation. In the immature placenta, they represent the first stages in the development of new villi that later become invaded by cytotrophoblast and villous mesenchyme (Fogarty et al 2013). Occasionally, adjacent syncytial sprouts make contact and fuse to form slender syncytial bridges. The sprouts may become detached, forming maternal syncytial emboli that pass to the lungs. It has been computed that some 100,000 sprouts pass daily into the maternal circulation; deported trophoblast may be a mechanism by which the maternal immune system is maintained in a state of tolerance towards paternal antigens (Chamley et al 2011). In the lungs, syncytial sprouts provoke little local reaction and apparently disappear by lysis. However, they may occasionally form foci for neoplastic growth. Syncytial sprouts are present in the term placenta. By contrast, syncytial knots are aggregates of nuclei with particularly condensed heterochromatin, and may represent a sequestration phenomenon by which senescent nuclear material is removed from adjacent metabolically active areas of syncytium.

The core of a villus contains small and large reticulum cells, fibroblasts and macrophages (Hofbauer cells). Early mesenchymal cells differentiate initially into small reticulum cells and then into fibroblasts or large reticulum cells. The small reticulum cells appear to delimit a collagen-free stromal channel system through which Hofbauer cells migrate. Mesenchymal collagen increases from a network of fine fibres in early mesenchymal villi to a densely fibrous stroma within stem villi in the second and third trimesters. After approximately postmenstrual week 14, the stromal channels found in immature intermediate villi are infilled by collagen to give the fibrous stroma characteristic of the stem villus.

Fetal placental vessels include arterioles and capillaries but no lymphatic vessels. Pericytes may be found in close association with the capillary endothelium, and from late first trimester the vessels are surrounded externally by a basal lamina. From the second trimester (and a little later in terminal villi), dilated thin-walled capillaries are found immediately adjacent to the villous trophoblast. Their respective basal laminae apparently fuse to produce a vasculo-syncytial

The cells of the villous cytotrophoblast (Langhans cells) are pale-staining with a slight basophilia. Ultrastructurally, they have a rather electron-translucent cytoplasm and relatively few organelles and contain intermediate filaments, particularly in association with desmosomes. Between the desmosomes, the membranes of adjacent cells are separated by approximately 20 nm. Sometimes, the intercellular gap widens to accommodate microvillous projections from the cell surfaces and occasionally it contains patches of fibrinoid. A smaller population of intermediate cytotrophoblast may also be found in the chorionic villi. This postmitotic population represents a state of partial differentiation between the cytotrophoblast stem cell and the overlying syncytium.

Glycolysis is maintained in placental tissues by re-oxidation of pyridine nucleotides through the polyol pathways. The reliance on glycolysis rather than oxidative phosphorylation preserves carbon skeletons that can be utilized in the synthesis of nucleotides, cell membranes and organelles, and that would otherwise be excreted as carbon dioxide. In the placenta, this reliance may protect the embryo from free radical-mediated teratogenesis (Burton et al 2017). Glycogen is thought to be present in both layers of the trophoblast at all stages, although it is not always possible to demonstrate its presence histochemically.

Lipid droplets occur in both layers and are free in the core of the villus. In the trophoblast, they are found principally within the cytoplasm, but they also occur in the extracellular space between cytotrophoblast and syncytium, and between the individual cells of the cytotrophoblast. The droplets diminish in number with advancing age and may represent fat in transit from mother to fetus, and/or a pool of precursors for steroid synthesis. Membrane-bound granular bodies of moderate electron density occur in the cytoplasm, particularly in the syncytium, and some are probably secretion granules. Other membrane-bound bodies, lysosomes and phagosomes, are involved in the degradation of materials engulfed from the intervillous space.

Fibrinoid deposits are frequently found on the villous surface in areas lacking syncytiotrophoblast. They may constitute a repair mechanism in which the fibrinoid forms a wound surface that is subsequently re-epithelialized by trophoblast. The extracellular matrix glycoprotein tenascin has been localized in the stroma adjacent to these sites.

interface and the distance separating the maternal and fetal circulations may be reduced to as little as 2–3 μm. The endothelial cells are non-fenestrated, display numerous caveolae, and are linked by conspicuous junctional complexes incorporating tight and adherens junctions.

Transport across placental villi

The mechanism of transfer of substances across the placental barrier (membrane) is complex. The volume of maternal blood circulating through the intervillous space has been assessed at 600 ml per minute. Simple diffusion suffices to explain gaseous exchange. Transfer of ions and other water-soluble solutes is by paracellular and transcellular diffusion and transport. The relative importance of each of these for most individual solutes is unknown, and the paracellular pathway is morphologically undefined. Glucose transfer involves facilitated diffusion, while active transport mechanisms carry calcium ions and at least some amino acids. The fat-soluble and water-soluble vitamins are likely to pass across the placental barrier with differing degrees of facility (Jauniaux and Gulbis 2000a, Jauniaux et al 2004, Jauniaux et al 2005). The water-soluble vitamins B and C pass readily. Water is interchanged between fetus and mother (in both directions) at approximately 3.5 litres per hour. The transfer of substances of high molecular weight, such as complex sugars, some lipids and hormonal and non-hormonal proteins, varies greatly in rate and degree and is not well understood; energy-dependent selective transport mechanisms, including receptor-mediated transcytosis, are likely to be involved.

Lipids may be transported unchanged through and between the cells of the trophoblast to the core of the villus. The passage of maternal antibodies (immunoglobulins) across the placental barrier in late pregnancy confers some degree of passive immunity on the fetus; it is widely accepted that transfer is by micropinocytosis. Investigation of transplacental mechanisms is complicated by the fact that the trophoblast itself is the site of synthesis and storage of certain substances, e.g. glycogen.

The placenta is an important endocrine organ. Some steroid hormones, various oestrogens, β-endorphins, progesterone, hCG and human chorionic somato-mammotropin (hCS), also known as placental lactogen (hPL), are synthesized and secreted by the syncytiotrophoblast. The trophoblast contains enzyme systems that are associated with the synthesis of steroid hormones, as well as enzymes that inactivate maternal hormones, allowing the fetus to develop and mature in a protected environment; for example, the fetus is protected from 10 times higher maternal glucocorticoid levels by the placental enzyme 11beta-hydroxysteroid dehydrogenase 2 (11beta-HSD2), that converts biologically active maternal cortisol to inactive cortisone (Murphy et al 1974).

It has been suggested that leukocytes may migrate from the maternal blood through the placental barrier into the fetal capillaries. It has also been shown that some fetal and maternal red blood cells may cross the barrier, especially at the time of delivery. The former may have important consequences, e.g. in Rhesus incompatibility.

The majority of drugs are small molecules and are sufficiently lipophilic to cross the placental barrier from about postmenstrual week 6 in quantities that yield measurable concentrations in both chorionic (extraembryonic coelom) and amniotic fluid. Many are tolerated by the fetus but some may exert grave teratogenic effects on the developing embryo/fetus, depending on the gestational age and the doses used by the mother (e.g. thalidomide, cocaine). A well-documented association exists between maternal alcohol ingestion and/or drug use such as cocaine and fetal anomalies; tobacco smoke and fetal growth; and the fetus can become addicted to heroin. Among pregnant women aged 15–44 years in the United States, 5.9% report illicit drug use; 16–17% report recent cigarette use, and an annual average of about 8.5% report alcohol use during pregnancy (Ross et al 2015, Hoyme and Manning 2017).

A wide variety of bacteria (e.g. *Listeria*), protozoa (e.g. *Toxoplasma gondii*, *Trypanasoma cruzi* and *Plasmodium falciparum*), and viruses (e.g. cytomegalovirus (CMV), Zika virus (ZIKV) and rubella), are known to cross the placental barrier from mother to fetus. By contrast, group B streptococcus (GBS), herpes simplex virus (HSV) and human immunodeficiency virus (HIV) do not cross the placental barrier during pregnancy and are acquired by the fetus during delivery. Toxoplasma and CMV are transferred by cellular invasion of the villous trophoblast during the acute phase of a newly acquired maternal infection. Since the maternal circulation inside the definitive placenta only starts at the end of the first trimester, transmission of *Toxoplasma* to an embryo is rare before that time, but highly damaging to a developing fetus. *Plasmodium falciparum* (malaria) is transferred by villous sequestration of maternal infected erythrocytes or a breakdown of the villous barrier during labour. The presence of maternal rubella in the early pregnancy is of especial importance in relation to the production of congenital anomalies. For further reading about TORCH perinatal infections (**T**oxoplasmosis; **O**thers, including syphilis and listeriosis; **R**ubella; **C**MV; **H**SV) see Stegmann and Carey (2002).

FETAL MEMBRANES

The implanting conceptus consists initially of three cavities and their surrounding epithelia. The original blastocyst cavity, surrounded by trophoblast, is now termed the chorionic cavity (the extraembryonic coelom). It is a large cavity that contains the much smaller amniotic cavity and secondary yolk sac (see Fig. 9.1). The apposition of the latter two cavities delineates the extent of the early embryo. The chorionic cavity becomes lined with extraembryonic mesoblast, which is also reflected over the outer surface of the amnion and yolk sac. A fourth cavity, the allantois, develops later as a caudal hypoblastic diverticulum that becomes embedded within the extraembryonic mesenchyme, forming the connecting stalk of the embryo: it lacks a direct mesothelial covering.

Chorion

The chorion consists of developing trophoblast and extraembryonic mesothelium and varies in thickness during development, both temporally and spatially. It is thickest at the implantation site throughout gestation, initially as the chorion frondosum and then the placenta, and thinner as gestation progresses over the remainder of its surface as the chorion laeve (see Fig. 9.4). At term, the chorion consists of an inner cellular layer containing fibroblasts and a reticular layer of fibroblasts and Hofbauer cells that resembles the mesenchyme of an intermediate villus. The outer layer consists of cytotrophoblast 3–10 cells deep, resting on a pseudo-basement membrane that extends beneath and between the cells. Occasional obliterated villi within the trophoblast layer are the remnants of villi present in the chorion frondosum of the first trimester. Although the interface between the trophoblast and decidua parietalis is uneven, no trophoblast infiltration of the decidua parietalis occurs.

Yolk sac

The yolk sac is thought to be the phylogenetically oldest extraembryonic membrane. The human embryo retains a yolk sac that goes through primary and secondary phases of development. As the secondary yolk sac forms, it delineates a cavity lined with parietal, and perhaps visceral, hypoblast, continuous with the developing endoderm from the primitive streak (Ch. 10; see Fig. 10.10). The secondary yolk sac is the first structure that can be detected ultrasonographically within the chorionic cavity (Jauniaux et al 1991). Its diameter increases slightly between postmenstrual weeks 6 and 10, reaching a maximum of 6–7 mm, after which time it decreases.

The inner cells of the secondary yolk sac (denoted endoderm in many studies, although this layer is restricted to the embryo) display a few short microvilli and are linked by juxtaluminal tight junctions (Jones and Jauniaux 1995). Their cytoplasm contains numerous mitochondria, whorls of rough endoplasmic reticulum, Golgi bodies and secretory droplets, giving them the appearance of highly active synthetic cells. With further development, the epithelium becomes folded to form a series of cyst-like structures or tubules, only some of which communicate with the central cavity. The cells synthesize several serum proteins in common with the fetal lung, kidney and liver, including α-fetoprotein (AFP), α-1-antitrypsin, albumin, pre-albumin and transferrin (Gulbis et al 1998) (**Fig. 9.9**). With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments (Jauniaux and Gulbis 2000b).

The yolk sac becomes coated with extraembryonic mesenchyme, that forms mesenchymal and mesothelial layers. A diffuse capillary plexus develops between the mesothelial layer and the underlying secondary yolk sac wall, and subsequently drains through vitelline veins to the developing liver. The mesothelial layer bears a dense covering of microvilli and numerous coated pits and pinocytotic vesicles, giving it the appearance of an absorptive epithelium (Jones and Jauniaux 1995, Burke et al 2013).

The secondary yolk sac plays a major role in the early embryonic development of all mammals. In laboratory rodents, it has been demonstrated to be one of the initial sites of haemopoiesis. Human data indicate that it has an absorptive role for molecules of maternal and placental origin found in the chorionic cavity (Gulbis et al 1998) and that it mediates the main movement of molecules passing from the chorionic cavity to the embryonic gut and circulation. Conservation of

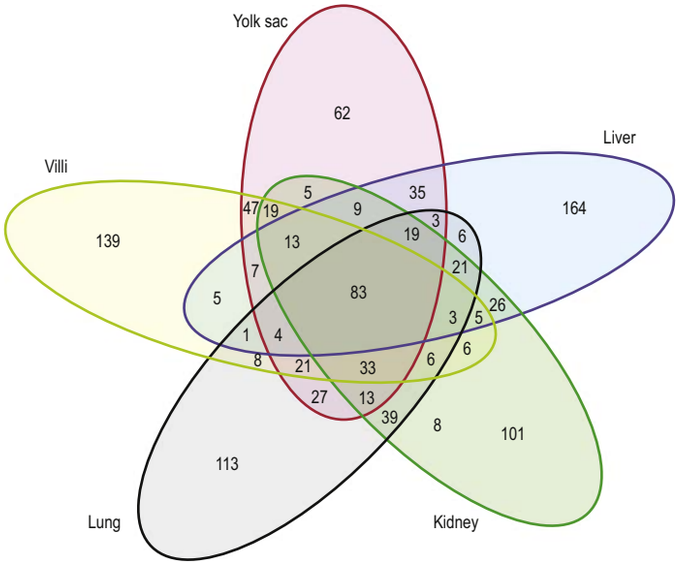

Fig. 9.9 Venn diagram comparing the most abundant 400 transcripts in the human yolk sac with first-trimester placental villi and adult liver, lung and kidney. Transcripts shared by all five tissues (*n* = 83) principally encoded housekeeping proteins, whereas those shared uniquely with liver (*n* = 35) encoded proteins involved in cholesterol and lipid metabolism, suggesting that the yolk sac may perform these functions while the fetal liver develops. By contrast, there are few transcripts shared uniquely with the kidney (*n* = 5), suggesting that the yolk sac plays little role in excretion. (With permission from Cindrova-Davies T, Jauniaux E, Elliot MG et al 2017 RNA-seq reveals conservation of function among the yolk sacs of human, mouse, and chicken. Proc Natl Acad Sci U S A 114: E4753–E4761.)

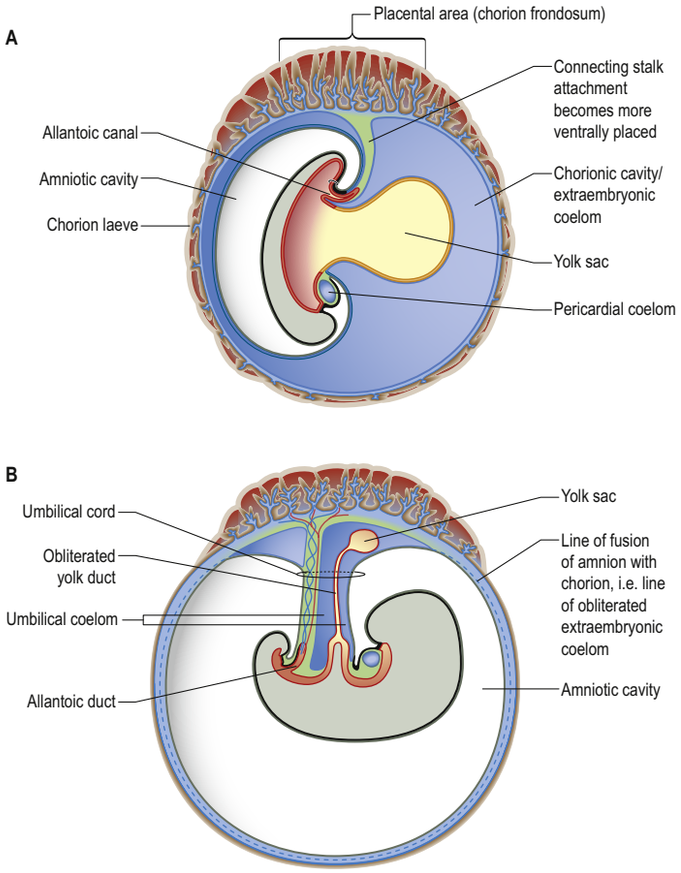

Fig. 9.10 A, A longitudinal section of a conceptus showing the cavities associated with development. The amniotic cavity and yolk sac are both covered with extraembryonic mesoblast and are contained within the larger chorionic cavity, which is lined with extraembryonic mesoblast. The embryo is attached to the chorion frondosum by the connecting stalk into which the allantois projects. **B**, A longitudinal section of a conceptus at a later stage, showing the diminution of the chorionic cavity, expansion of the amniotic cavity, relative attenuation of the yolk sac and the structures that give rise to the umbilical cord.

transcriptomes across the species indicates that the human secondary yolk sac likely performs key functions early in development, particularly uptake and processing of macro- and micronutrients (see Fig. 9.9), many of which are found in the chorionic cavity (Cindrova-Davies et al 2017).

After postmenstrual week 9, the cellular components of the wall of the secondary yolk sac start to degenerate, and their function is subsumed into exchanges at the placental chorionic plate. With embryonic development of the midgut, the connection of the yolk sac to the embryo becomes attenuated to a slender and elongated vitelline intestinal duct. Both the yolk sac and its duct remain within the chorionic cavity (extraembryonic coelom) throughout gestation, located between the amnion and chorion as they fuse near the placental attachment of the umbilical cord.

Allantois

The allantoenteric diverticulum (see Fig. 10.10B,C) arises in stage 7 as a solid, endodermal outgrowth from the dorsocaudal part of the yolk sac into the mesenchyme of the connecting stalk. It soon becomes canalized. When the hindgut develops, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall. The distal (allantoic) part remains as the allantoic duct and is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hindgut (**Fig. 9.10A**). The allantois is a site of angiogenesis, giving rise to the umbilical vessels that connect to the placental circulation. The extraembryonic mesenchyme around the allantois forms the connecting stalk, which is later incorporated into the umbilical cord.

In the fetus, the allantoic duct, which is confined to the proximal end of the umbilical cord, elongates and thins. However, it may persist as an interrupted series of epithelial strands at term, in which case the proximal strand is often continuous at the umbilicus with the median intra-abdominal urachus and this, in turn, continues into the apex of the bladder.

Amnion (chorio-amnion)

The original amniotic cells develop from the edges of the epiblast of the embryonic disc that ultimately form the interface with the skin at the umbilical region. Between postmenstrual weeks 10 and 12, the amniotic cavity expands until it makes contact with the chorion to form the chorio-amnion, an avascular membrane that persists to term. The amniotic membrane extends along the connecting stalk and forms the outer covering of the umbilical cord. After birth, the site of this embryonic/extraembryonic junction is important because the extraembryonic cell lines will die, causing the umbilical cord to degenerate and detach from the body wall. In cases of anomalous development of the ventral body wall, e.g. gastroschisis and exomphalos, the reflections of the amnion along the forming umbilical cord may be incomplete (see below).

The inner surface of the amnion consists of a simple cuboidal epithelium. It has a microvillous apical surface, beneath which is a cortical web of intermediate filaments and microfilaments. There are no tight junctional complexes between adjacent cells and cationic dyes penetrate between the cells as far as the basal lamina. The intercellular clefts present scattered desmosomes, but elsewhere the clefts widen and contain interlacing microvilli. These features are all consistent with selective permeability properties. The epithelium synthesizes and deposits extracellular matrix into the compact layer of acellular stroma located beneath the basal lamina, as well as into the basal lamina.

Towards full term, increasing numbers of amniotic cells undergo apoptosis, become detached from the amnion and are found in the amniotic cavity at full term. The highest incidence is in postmenstrual weeks 40–41, independent of the time of the onset of labour. Apoptosis may play a role in the fragility and rupture of the fetal membranes at term.

Human amniotic epithelial cells are thought to be pluripotent because they arise so early from the conceptus. They can be distinguished from the epiblast cells from postfertilization day 8. Amniotic cells lack the MHC antigen and so the amnion can be exposed to the maternal immune system without eliciting a maternal immune response. Cultured human amniotic epithelial cells express a range of neural and glial markers, including glial fibrillary acidic protein, myelin basic protein, vimentin and neurofilament proteins, suggesting that these cells may supply neurotrophic factors to the amniotic fluid. They also appear to have a hepatocyte gene expression profile, showing albumin production, glycogen storage and albumin secretion in organ culture: they have been shown to secrete 30-fold larger amounts of albumin than in monolayer culture, and to secrete α-1-antitrypsin (Takashina et al 2004). Amnion is used in the repair of corneas after

trauma and as a graft material for reconstructing vaginas in women with cloacal abnormalities.

Prenatal changes to the chorio-amnion

At full term, the surface area of the chorio-amnion is 1000–1200 cm^2, where 30% overlies the placenta and the remaining 70% contacts the decidua (Myatt and Sun 2010). The decidual component of the chorion diminishes and chorionic apoptosis increases towards term at the supracervical site that overlies the cervical os, encompassing the site of rupture (Chai et al 2013). The amnion and choriodecidua show varying degrees of separation over the putative rupture site; the mean rupture strength of the zone is only 60% of that of the remaining membranes, associated with changes in collagen organization and an increase in MMP-9 (Strauss 2013). When compared to fetal membranes from non-labouring, elective caesarean delivery, term vaginal delivery is associated with a three-fold increase in apoptosis in the chorion close to the rupture site (Harirah et al 2012).

In preterm, premature rupture of membranes (PPROM), the chorion is reported to be thinner at all sites (Fortner et al 2014). The presence of bacteria in the chorion at term, ascending via the vagina, has been reported without concomitant chorio-amnionitis. However, chorio-amnionitis rates are higher in preterm labour and so this may be a contributing cause (Harirah et al 2012, Fortner et al 2014). Loss of chorio-amnion intracellular cytokeratins, which become downregulated in infection, is thought to make the amnion vulnerable to apoptosis, shear stress and rupture (Vanderhoeven et al 2014).

There is increasing evidence that infection and inflammation of the chorio-amnion is associated with prenatal changes to the developing brain, especially the cortex, periventricular white matter and the developing cerebral blood vessels (Harteman et al 2013, Roescher et al 2014). This association also extends to the neonatal period and postnatal gut maturation (Wynn and Neu 2012). Histologically confirmed chorio-amnionitis is associated with changes in cerebral blood flow soon after birth; male infants appear to be more affected than female (Koch et al 2014)

AMNIOTIC FLUID

Amniotic fluid (liquor amnii) provides a buoyant medium that supports the delicate tissues of the young embryo, allows free movement of the fetus up to the later stages of pregnancy and diminishes the risk to the fetus of injury from outside. Amniotic fluid is derived from multiple sources throughout gestation including secretions from amniotic epithelium, filtration of fluid from maternal vessels via the parietal decidua and amniochorion, filtration from the fetal vessels via the chorionic plate or the umbilical cord, and fetal urine and fetal lung secretions. In early pregnancy, diffusion from intracorporeal vessels via the non-keratinized fetal skin also provides a source. Once the gut is formed, fetal swallowing of amniotic fluid is a normal occurrence and the fluid is absorbed into the fetal circulation.

Amniotic fluid volume increases logarithmically during the first half of pregnancy, from less than 10 ml at postmenstrual week 8 to 30 ml at postmenstrual week 22 and 770 ml at postmenstrual week 28. After postmenstrual week 30, the volume may remain unchanged until postmenstrual week 36, after which it decreases towards the expected delivery date: volumes decrease sharply in post-term gestation, averaging 515 ml at postmenstrual week 41 (Beall et al 2007, Ross and Beall 2014).

Human fetal urine output from the metanephric kidney increases from 110 ml/kg/day at postmenstrual week 25 to almost 200 ml/kg/day at full term postmenstrual week 40, which corresponds to almost 1000 ml/day. The rate of human fetal lung secretion has not been measured but is presumed to be in the range of 60–100 ml/kg/day near full term (Callen 2008). Experimental animal studies indicate that lung fluid production is about one-third that of urine production, and that half of the fluid leaving the lungs enters the amniotic fluid and half is swallowed (Beall et al 2007, Ross and Beall 2014). It has been estimated that human fetuses swallow up to 760 ml/day of amniotic fluid near term, although this decreases in the days before delivery. The remainder of the amniotic fluid is thought to be absorbed via an intramembranous pathway directly across the amniotic cavity and fetal surface of the placenta into fetal blood vessels (Beall et al 2007, Ross and Beall 2014). Intramembranous flow is thought to reach 400 ml/day at term (Callen 2008).

Amniotic fluid volume is estimated at routine antenatal ultrasound scans, despite some concerns about its objectivity (Beattie and Rich 2007, Callen 2008, Gilbert 2017) and it may be expressed as an amniotic fluid index. A deficiency of amniotic fluid is termed oligohydramnios and absent amniotic fluid is anhydramnios. Oligohydramnios in the second or third trimester is usually the result of urinary tract malformations, e.g. bilateral renal agenesis or obstruction of the lower urinary tract, uteroplacental insufficiency or premature rupture of the membranes. The urachus may play a critical role in the resolution of oligohydramnios in lower urinary tract obstruction by acting as a fistula between the bladder and the amniotic space. The major concern with oligohydramnios at less than postmenstrual week 20 is the significant risk of pulmonary hypoplasia and neonatal death.

A volume of amniotic fluid in excess of 2 litres in the second half of pregnancy is generally considered to be abnormal and constitutes polyhydramnios (see Fig. 23.6A). Maternal causes include cardiac and renal problems and diabetes mellitus, which causes fetal hyperglycaemia and polyuria. Fetal causes include reduced fetal swallowing due to congenital anomalies, e.g. anencephaly, upper intestinal tract obstruction (oesophageal and duodenal atresia), compressive pulmonary disorders (congenital respiratory diaphragmatic hernia) and neuromuscular impairment of swallowing.

For many years amniotic fluid was regarded as a medium that physically supported the developing embryo and fetus. More recently, it has also been conceptualized as part of the embryonic and early fetal extracellular matrix, and its composition throughout pregnancy has been investigated (Tong et al 2009). Techniques for biochemical analysis have compared amniotic fluid, fetal umbilical cord blood and maternal serum. Early in development, amniotic fluid resembles blood plasma, but also demonstrates extremely low oxygen tension, reflecting the physiological placental hypoxia noted in the first trimester (Jauniaux et al 2003, Ross and Beall 2014). In the second and third trimesters, primary electrolytes are similar in amniotic fluid, umbilical cord blood and maternal serum, whereas glucose, cholesterol and some enzymes are markedly lower in amniotic fluid. Umbilical cord blood and maternal serum contain 8 and 12.5 times more protein, respectively, than amniotic fluid (Tong et al 2009). More than 100 metabolites, including cortisol and a range of cytokines, have been detected in amniotic fluid. The concentrations of most cytokines differ from those in maternal blood and reflect the physiological status of the fetus (Tong 2013). Proteomic analysis of human amniotic fluid at postmenstrual weeks 16–18 has identified more than 800 proteins and peptides (Cho et al 2007). It appears that amniotic fluid may be acting as a pathway for the transport of signalling molecules to target cells. In experimental animal studies, substances injected into the amniotic cavity were detected within the embryos within 2 minutes, demonstrating a rapid exchange with all fetal tissues in these models (Tong 2013).

UMBILICAL CORD

The umbilical cord ultimately consists of an outer covering of flattened amniotic epithelial cells and an interior mass of mesenchyme of diverse origins (see Fig. 9.10). It contains two tubes of hypoblastic origin, the vitelline-intestinal and allantoic ducts, and their associated vitelline and allantoic (umbilical) blood vessels. The yolk stalk and continuing duct extend the length of the cord, whereas the allantoic duct extends only into its proximal part. The embryonic development of the umbilical cord is considered further in Chapter 21.

The mesenchymal core is derived from the somatopleuric extraembryonic mesenchyme covering the amniotic folds; splanchnopleuric extraembryonic mesenchyme of the yolk stalk (which carries the vitelline vessels and clothes the yolk duct); and similar allantoic mesenchyme of the connecting stalk (which clothes the allantoic duct and initially carries two umbilical arteries and two umbilical veins). These various mesenchymal compartments fuse and are gradually transformed into the loose connective tissue (Wharton's jelly) that characterizes the more mature cord. The tissue consists of widely spaced elongated fibroblasts separated by a delicate three-dimensional meshwork of fine collagen fibres that contains a variety of hydrated glycosaminoglycans and is particularly rich in hyaluronic acid.

The initially symmetric vitelline and allantoic (umbilical) vessels become modified as a result of changes in the intraembryonic circulation. The vitelline vessels involute, whereas most of the allantoic (umbilical) vessels persist. The right umbilical vein disappears but the two umbilical arteries normally remain. In around 1% of pregnancies, one of the umbilical arteries may not develop or disappears at the end of the first trimester. This anomaly is often found in syndromes such as aneuploidies, acardiac fetuses or sirenomelia and when isolated can be associated with slow fetal growth. The vessels of the umbilical cord are rarely straight and are usually twisted into either a right- or left-handed cylindrical helix. The number of turns involved ranges from a few to over 300. This conformation may be produced by unequal growth of the vessels, or by torsional forces imposed by fetal

A number of clinical markers in amniotic fluid are used as predictors of fetal health, including interleukin (IL)-10, IL-6, cell free fetal DNA and cell free fetal mRNA. Genes and proteins specific to the fetal brain, lung, kidney, blood and heart have been identified in amniotic fluid; differential gene expression investigated in a range of trisomic fetuses; and lung maturity predicted by measurement of lecithin, sphingomyelin and phosphatidylglycerol (Edlow and Bianchi 2012, Ross and Beall 2014). Bacterial species have been isolated from amniotic fluid; and microbial invasion of the amniotic cavity is considered a leading cause of preterm premature delivery (DiGiulio 2012). It is thought bacteria access the amniotic cavity via the vagina and cervix, although many oral bacteria have also been identified, suggesting an alternative haematogenous route. The establishment of pathogenesis is influenced by microbial adhesion, biofilm formation, immune evasion and the maternal and fetal immune systems (DiGiulio 2012).

movements. Its functional significance is obscure: the pulsations and contractions of the helical vessels may assist the venous return to the fetus in the umbilical vein. Autonomic nerves accompanying the arteries from the pelvic plexus do not penetrate more than a third of the length of the umbilical cord.

Anomalies of the fetal anterior abdominal wall, such as exomphalos and gastroschisis can affect the arrangement of the outer covering of amnion cells along the proximal end of the umbilical cord (Ch. 21). Exomphalos arises from a failure of the lateral folds along the ventral surface of the embryo, so that the normal embryonic regression of the midgut from the umbilical stalk into the abdominal cavity fails. The abdominal contents, including intestines and liver or spleen, covered by a sac of parietal peritoneum and amnion, protrude into the base of the umbilical cord. In gastroschisis, the insertion of the umbilical cord is intact and there is evisceration of the intestine through a small abdominal wall defect that is usually located to the right of the umbilical cord, resulting in free loops of bowel in the amniotic cavity.

Mature umbilical vessels, particularly the arteries, have a strong muscular coat that contracts readily in response to mechanical stimuli. The outermost bundles pursue an interlacing spiral course, and when they contract, they produce shortening of the vessel and thickening of the media, with folding of the interna and considerable narrowing of the lumen. This action may account for the periodic sharp constrictions of contour, the valves of Hoboken, that often characterize these vessels.

The fully developed umbilical cord is, on average, some 50 cm long and 1–2 cm in diameter. Its length varies from 20 to 120 cm; exceptionally short or long cords are associated with fetal problems and complications during labour. A long umbilical cord may prolapse through the cervix into the vagina once the fetal membranes rupture and this may be exacerbated by conditions that prevent the fetal head from fully occupying the maternal pelvis, e.g. pelvic tumours (fibroids), ovarian cysts, placenta previa and prematurity. Compression of the cord by the presenting part of the fetus, or an umbilical artery spasm, will lead to fetal hypoxia and death, if untreated.

The distal end of the umbilical cord is usually attached in the central portion of the placenta. In 0.2% of pregnancies, velamentous insertion (i.e. into the membranes) occurs and may be associated with cord vessels running in the free placental membranes (vasa previa): these vessels are vulnerable to injury during delivery and may lead to fatal fetal haemorrhage.

Artificial reproductive techniques, and in particular *in vitro* fertilization and embryo transfer, are associated with a high incidence of placental and cord anatomical anomalies such as bilobate placenta, placenta previa and velamentous insertion of the cord in the membranes. These anomalies probably reflect alterations in the interactions between the blastocyst and the decidua that normally occur in spontaneous pregnancies (Jauniaux et al 1990). Damage to the uterine wall following surgery, mainly after repeat caesarean section, increases the chances of implantation in the scar area and results in a higher incidence of scar pregnancy and placenta previa accreta in subsequent pregnancies (Jauniaux et al 2018).

CHAPTER
10

Cell populations at gastrulation

CONCEPTUS WITH A BILAMINAR EMBRYONIC DISC

At stage 6 the conceptus is composed of the walls of three cavities. The large chorionic cavity is surrounded by a meshwork of trophoblast and developing villi, and lined with extraembryonic mesoblast. The chorion, trophoblast and extraembryonic mesoblast enclose the extraembryonic coelom and contain the much smaller amniotic cavity and yolk sac that abut at the embryonic bilaminar disc where the epithelial epiblast and visceral hypoblast are approximated (see Fig. 9.1). A fourth cavity, the allantois, will form as a hypoblastic diverticulum in stage 7. The 'bilaminar disc' commonly referred to in embryology texts does not yet possess the definitive layers of embryonic ectoderm and endoderm that will give rise to embryonic structures. Only the epiblast will give rise to the embryo and all other layers produced so far are extraembryonic. The amnion and chorion and surrounding extraembryonic mesoblast are part of the extraembryonic somatopleure, whereas the yolk sac, allantois and surrounding extraembryonic mesoblast constitute extraembryonic splanchnopleure. At the junctional zone surrounding the margins of the embryonic area, where the walls of the amnion and yolk sac converge, the somatopleuric and splanchnopleuric layers of extraembryonic mesoblast are continuous.

The terms epiblast and hypoblast are used to make the distinction between the earliest bilaminar disc layers and the later embryonic layers. Epiblast and hypoblast contain mixed populations of cells with little restriction, that establish the placental structures and extraembryonic tissues before the production of embryonic cell lines at gastrulation. The older terminology depicting three germ layers that give rise to the skin, gut lining and intervening tissues is therefore incorrect for the bilaminar and trilaminar embryonic disc. The persistent application of this terminology to descriptions of the early stages of embryogenesis continues to cause confusion and restricts the development of more pertinent language to describe these early events. The earliest three cell lineages, not layers, that give rise to the extraembryonic membranes and the embryo are trophoblast, hypoblast and epiblast (Ch. 8) and each expresses different lineage-specific genes for its establishment, maintenance and differentiation (Pfeffer 2018, Stirparo et al 2018).

At early stage 6 the epiblast is producing extraembryonic mesenchyme from its caudal margin. With the appearance of the primitive streak, a process is started whereby cells of the epiblast pass either deep to the epiblast layer to form the populations of cells within the embryo, or remain on the dorsal aspect of the embryo to become the embryonic ectoderm. Although human embryos do not form a 'gastrula' as such, the term gastrulation is used here to denote an early period of development during which significant rearrangements, migrations and folding of the early embryo occur. The primitive streak is the site of organizer cells analogous to those found in embryos that do undergo gastrulation. The appearance of the primitive streak therefore marks the beginning of a period when gross alterations in morphology and complex rearrangements of cell populations occur. During this time, the epiblast will give rise to a complex multilaminar structure with a defined craniocaudal axis. By the end of gastrulation, cell populations from different, often widely separated, regions of the embryonic disc will become spatially related and the embryonic shape will have been produced.

Primitive streak and node

Seen from the dorsal (epiblastic) aspect at stage 6, the embryonic disc appears elongated. At this stage the primitive streak is first seen in the caudal region of the embryonic disc as a collection of pluripotent cells, orientated along its long axis in the median position and conferring the future craniocaudal axis of the embryo (**Figs 10.1–10.2**). Although the future rostral (cranial) and caudal regions of the embryo are well within the boundaries of the embryonic disc, it has become the practice to term the region of the disc closest to the streak 'caudal', and the region of the disc furthest from the streak 'rostral'. With the development of the streak, the terms medial and lateral can be used. The relative dimensions of the primitive streak and the fates of the cells that pass through it change with the developmental stage. Thus, the streak extends half way along the disc in the stage 6 embryo, reaching its greatest relative length in stage 7 and its maximum length in stage 8.

Formation of the primitive streak is induced by the underlying visceral hypoblast, which remains beneath the streak even at later stages. The primitive streak may be considered to be generally homologous with the blastopore of lower vertebrates (e.g. amphibia), with the nodal region corresponding to the dorsal lip. Experiments clearly show the lip of the blastopore to be a dynamic wave front on which cells are carried into the interior to form the roof of the archenteron, a situation analogous to ingression through the node of the prechordal plate and endoderm. The primitive streak similarly may be considered analogous to the coapted, or fused, lateral lips of the blastopore, and the cloacal membrane and its immediate environs are considered analogous to the ventral lip of the blastopore.

At the primitive streak, epiblast cells undergo a period of intense proliferation, the rate of division being much faster than that of blastomeres during cleavage. Streak formation is associated with the local production of several cell layers, extensive disruption of the epiblast basal lamina: increase in adhesive plaques and gap junctions; synthesis of vimentin; and loss of cytokeratins by the emerging cells.

As the epiblast cells proliferate, two ridges are formed on each side of the primitive streak, which appears to sink between them. The lower midline portion of the streak is termed the primitive groove. The process by which cells become part of the streak and then migrate away from it beneath the epiblast is termed ingression and is an example of epithelial to mesenchymal transformation.

The primitive node, or Hensen's node, is the most rostral region of the primitive streak. It appears as a curved ridge of cells similar in shape to the top of an old-fashioned keyhole. Cells ingressing from the ridge pass into the primitive pit (the most rostral part of the primitive groove), and then migrate rostrally beneath the epiblast. The primitive node has been recorded in all stage 7 human embryos; it produces axial cell populations, the prechordal plate, notochord, embryonic endoderm and the medial halves of the somites. Experimental removal of the node in avian embryos results in complete absence of the notochord and a failure of neurulation.

Studies on the dynamics of ingression at the primitive streak have shown movement of the underlying extracellular tissues as well as of the overlying cells. Re-examination of the processes of cell movement relative to the surrounding extracellular molecules in embryos has found that vertical and convergent extension motion patterns, previously thought to be limited to the epiblast, also occur in sub-epiblastic extracellular matrix fibronectin fibrils (Zamir et al 2008, Szabó et al 2011).

Position and time of ingression through the primitive streak

Studies of cell fate have shown that epiblast cells that will pass through the streak are randomly located within the epiblast layer before their ingression, and that epiblast fate is determined at or before the time of ingression through the streak, indicating that passage through the primitive streak is the most important factor for future differentiation.

The position and time of ingression through either streak or node directly affect the developmental fate of cells. Passage through the streak is specified according to time and position, e.g. via the node, or rostral, middle or caudal regions of the streak. Cells that ingress through the primitive node give rise to the axial cell lines, the prechordal mesenchyme and notochord, and the endoderm and the medial halves of the somites. The rostral portion of the primitive streak produces cells for the lateral halves of the somites, whereas the middle streak produces the lateral plate mesoblast. The adjacent caudal portion of the streak gives rise to the primordial germ cells (which can be distinguished histologically and histochemically) and the most caudal portion of the streak contributes cells to the extraembryonic mesoblast until the somites are visible. A composite of the information on the position of ingression through the streak and node is shown in **Fig. 10.3**. Epiblast cells that do not pass through the streak but remain within the epiblast population give rise to the neural and surface ectoderm of the embryo.

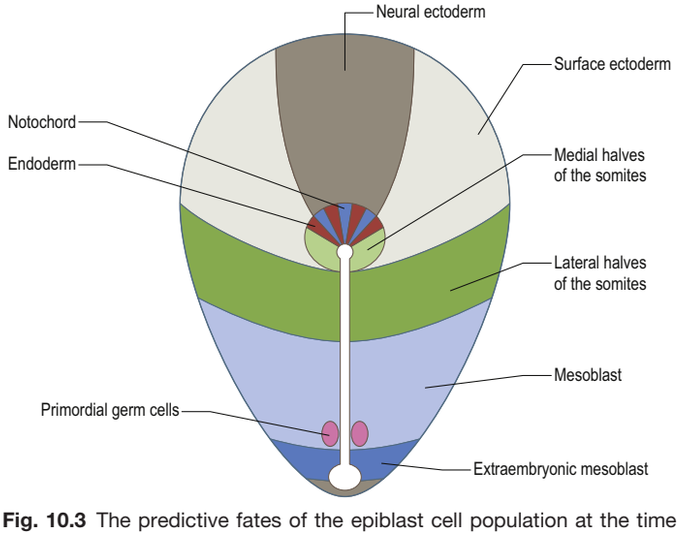

Fig. 10.3 The predictive fates of the epiblast cell population at the time the primitive streak is present.

Prechordal plate

The earliest cells migrating through the primitive node and streak give rise to both the embryonic endoderm and the notochord. The prechordal plate is first seen at stage 7. It has been defined as a localized thickening of the endoderm rostral to the notochordal process, although it is seen as a highly developed mesenchymal mass in contact with the floor of the neural groove, rostral to the notochordal process, rather than as an epithelial layer. The prechordal plate is a temporary collection of cells that underlies the neural plate during stage 9. It is composed of cells that are similar to, or larger and more spherical than, the ingressing endodermal cells (Müller and O'Rahilly 2003). In stage 8 embryos, the prechordal plate is up to eight cells deep and extends along the long axis of the embryonic disc. By stages 9 and 10 the cells at the lateral edge of the plate have begun to migrate laterally as free mesenchymal cells and the plate reduces in height to two cells deep. At stage 11 the migrating prechordal mesenchyme forms bilateral premandibular mesenchymal condensations and is no longer a median structure. The extent of prechordal cells that remain within the endoderm has yet to be established.

Notochord

The notochord (chordamesoderm, the head process or chorda) arises from epiblast cells of the medial part of the primitive node. It passes through several stages during development, i.e. notochordal process and notochordal plate, before the definitive notochord is formed (de Bree et al 2018). The cells of the early notochordal process express myogenic markers transiently as they migrate beneath the epiblast, but later they become epithelial, forming junctions and a basal lamina. The notochordal cells are intimately mixed with endodermal cells, because both cell lines ingress synchronously (see Figs 10.1–10.2; Fig. 10.4). During stage 8 the ingressing notochordal cells remain in the midline along the cephalocaudal axis. They form a rostral part composed of a cell mass continuous with the prechordal mesenchyme; a mid-portion in which cells are arranged in a tube with a central notochordal canal; and a caudal epithelial layer of cells, the notochordal plate, contiguous with the embryonic endoderm, which forms a roof to the secondary yolk sac. There is a transitory opening between the primitive node (and amniotic cavity) and the secondary yolk sac called the neurenteric canal (so named because its upper opening is in the future caudal floor of the neural groove, and its lower opening is into the archenteron, which is the primitive gut). It may still be found at stage 9 and the site of the neurenteric canal can be recognized in stage 10 embryos. The ingression of notochordal cells at the primitive node is matched by specification of the overlying neural ectodermal cells, and the notochordal plate is thus matched in length by the future neural floor plate. Both the notochord and the region of the floor plate of the neural tube may arise from a common progenitor cell. The early notochord is important for the maintenance and subsequent development of the neural floor plate and the induction of motor neurones. Experimental removal of the notochord results in elimination of the neural floor plate and motor neurones and expression of sensory neurones.

Caudal eminence

From stages 9–10 the region between the neurenteric canal and the cloacal membrane (see below), including the primitive streak, is termed the caudal eminence. It consists of the caudal region of the trunk, composed of mesenchyme derived from the primitive streak and epiblast, and covered with surface ectoderm. Whereas ingression of cells through the primitive streak gives rise to the prechordal and notochordal plates, and cells rostral to the neurenteric canal (see above), the cells of the caudal eminence arise from local division of a mesenchymal population positioned caudal to the neurenteric canal. The caudal portions of the notochord, that form later in development when secondary neurulation processes begin, arise from these cell populations, sometimes termed the caudoneural hinge or junction. This tissue is thicker and more advanced in differentiation than the tissues derived from the early primitive streak.

Embryonic endoderm

Before ingression, definitive embryonic endoderm cells are found in the epiblast, located at the primitive node and rostral primitive streak. In the mouse, the endodermal cells lie beneath the epiblast mainly in the midline, interspersed with presumptive notochordal cells, forming the roof of the secondary yolk sac. The ingressing endoderm displaces the visceral hypoblast into the secondary yolk sac wall by a dramatic

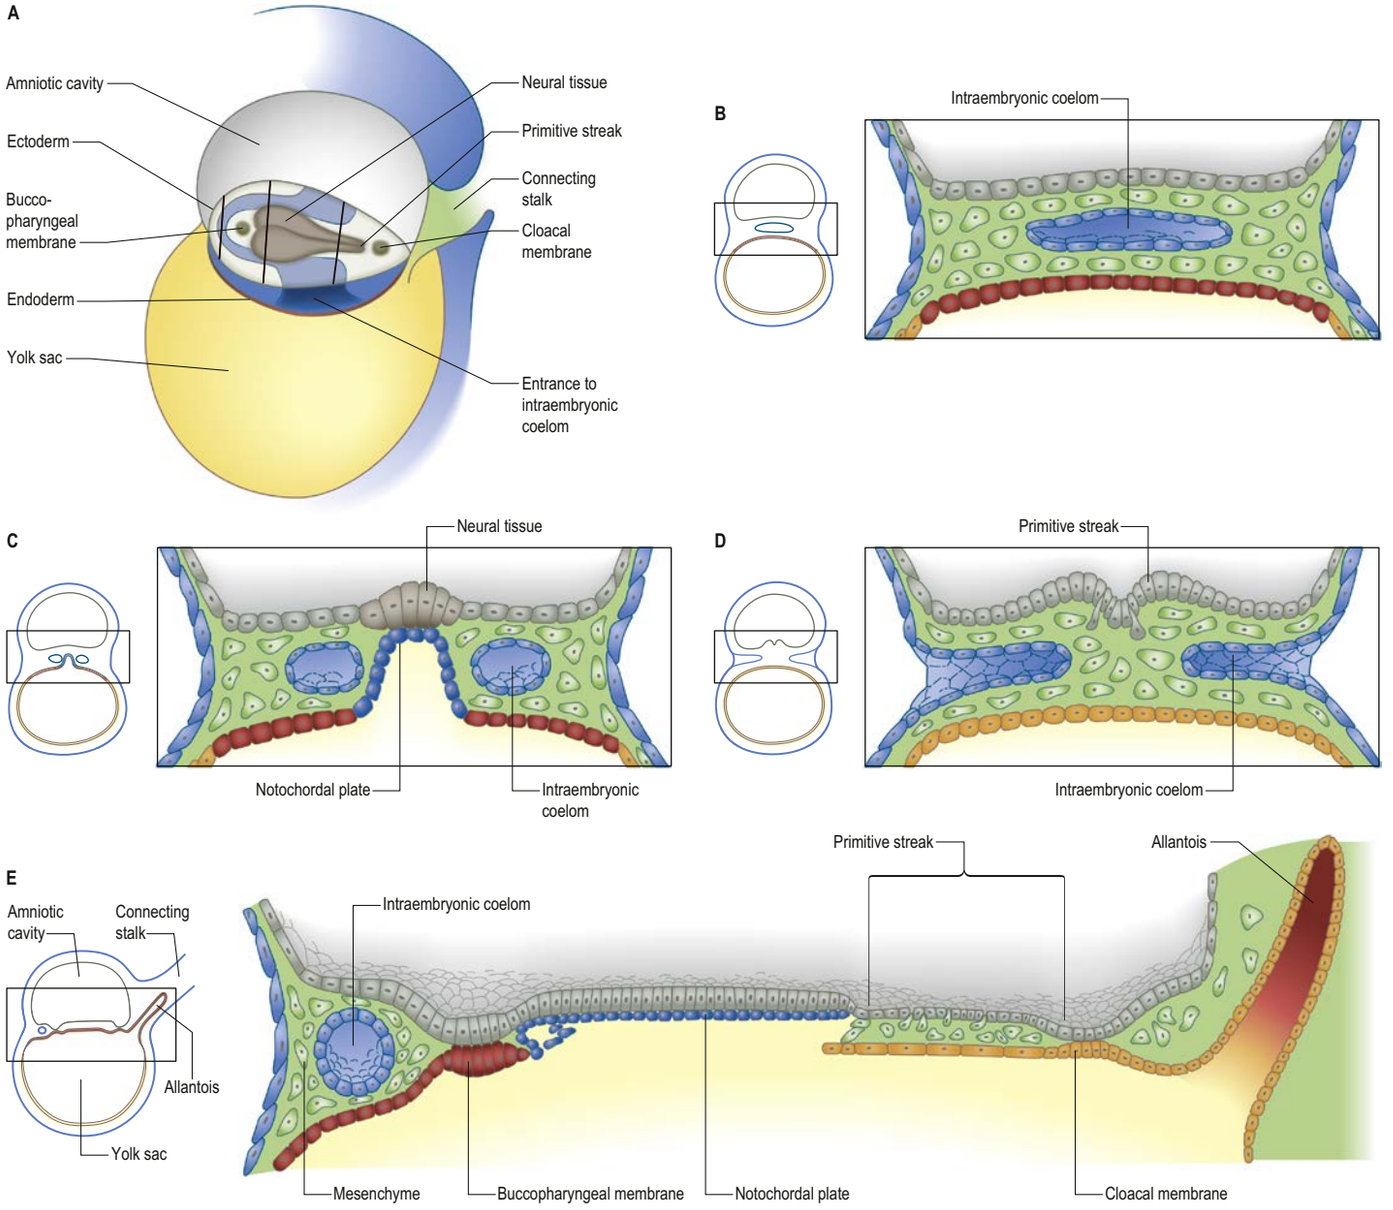

Fig. 10.4 **A**, The unfolded embryo, showing the disposition of the intraembryonic coelom within the embryonic disc. The three lines across the embryo show the level of transverse sections through the disc shown in **B–D**. **E**, A longitudinal section through the disc.

territorial expansion that is brought about by a change in the morphology of the cells (see Figs 10.1–10.2, 10.4). The putative endoderm cells are cuboidal epithelial cells within the node but they become squamous in the endoderm layer; this could result in a four-fold increase in the surface area covered by the cells. A complete replacement of the visceral hypoblast has not yet been confirmed and there may be a mixed population of cells in the endodermal layer in the early stages. Ingression of cells through the streak and node in the human is apparent at stage 6 and, by stage 7, a population of endoderm and notochord cells is present beneath the epiblast (see Figs 10.1–10.2, 10.4). During stages 6–11 the midline roof of the secondary yolk sac becomes populated mainly by the notochordal plate, which remains in direct lateral continuity with the endodermal cells. It is not until stage 11, after the definitive notochord is formed, that the endoderm cells can join across the midline. For the developmental fate of the embryonic endoderm, see Fig. 12.3.

Intraembryonic mesoblast (mesenchyme)

Epiblast cells undergo a transformation of cell phenotype from stage 8, ingressing through the rostral and middle parts of the streak individually, maintaining their apical epithelial contacts while elongating ventrally. The cells become flask-shaped, with thin, attenuated apical necks and broad basal regions. Their basal and lateral surfaces form lamellipodia and filopodia, and their adjacent apical contacts are released. The cells are now free mesoblast cells, their fibroblastic, stellate morphology reflecting their withdrawal from the epithelial layer. Once through the streak, the cells secrete an extracellular matrix that surrounds and separates them. The cells contact one another by filopodia and lamellipodia, with which they also contact the basal lamina of the overlying epiblast, using it for their subjacent migration. Gap junctions have been observed between filopodia and cell bodies. With the generation of mesoblast cells and their secretion of an extracellular matrix rich in glycosaminoglycans, spaces form between the epiblast and visceral hypoblast through which the mesoblast cells can move. Groups of mesoblast cells open up migration routes and the following cells seem to be pulled along behind in a coordinated mass movement. Mesoblast formed by cells migrating through the primitive node and rostral primitive streak forms the paraxial mesenchyme, whereas cells migrating later through the middle to caudal streak form the lateral plate mesenchyme (see Figs 10.1–10.2). Tissue motion of cell and extracellular matrix movement from the primitive streak has been elegantly demonstrated in avian embryos (Loganathan et al 2016).

Embryonic ectoderm

When the ingression of cells through the primitive streak is complete, the epithelial cells remaining in the epiblast layer are termed embryonic ectoderm cells. This layer still contains a mixed population because both surface ectoderm cells and neural ectoderm cells are present. It is believed that these cells were originally in the rostral half of the disc when the primitive streak first appeared, at which time the neural-fated

cells were closest to the streak, and the surface ectoderm cells were most rostral (see Fig. 10.3). The process of primary neurulation relocates most of the neuroepithelial cells (see below).

Primordial germ cells

Although early studies on human embryos reported primordial germ cells, and described their development from the early endoderm of the yolk sac and allantois, results from animal experimentation indicate that primordial germ cells arise from epiblast ingressing at the caudal end of the primitive streak (see Fig. 10.3). It is not known whether these cells originate from rostral regions that migrate to the streak or from local caudal regions. Extremely early segregation of the germ cells, when the epiblast layer consists of only 10–13 cells, has been demonstrated and it has been suggested that the primordial germ cells remain sequestered in the extraembryonic mesenchyme at the caudal end of the embryo until the embryonic endoderm has been produced and gastrulation completed, and that they start to migrate along the allantoic and hindgut endoderm as the folding of the embryo begins. The formation of the tail fold brings the proximal portion of the allantois within the body, so reducing the final distance over which the cells migrate to the genital ridges. Further development of the germ cells is described in Chapter 22.

TRILAMINAR DISC

Although the stage 8 embryo is termed a trilaminar disc, the concept of three epithelial layers forming a trilaminar disc is not correct because the middle, mesoblast, layer is several cells thick with intervening extracellular matrix. The embryo at this stage, approximately 23 days after ovulation, is pear-shaped, and broader rostrally than caudally (**Fig. 10.5**). The upper epiblast cells are tall and form a pseudostratified columnar epithelial layer with a basal lamina, except at the primitive streak, where the cells are ingressing to form the other layers. The more centrally placed epiblast will give rise to neural ectoderm (neurectoderm) and the more laterally placed epiblast will give rise to surface ectoderm. The future neural ectoderm is seen as a neural plate that matches the length of the notochordal plate directly beneath, being slightly wider near the prechordal plate. The lower embryonic endoderm, a simple squamous layer with a developing basal lamina, is not always complete at this stage, particularly in the midline caudal to the prechordal plate, which is still occupied by the notochordal process or plate.

The middle, mesoblast, layer is composed of free cells migrating rostrally, laterally and caudally from the primitive streak and producing extracellular matrix: it separates the epiblast and endoderm of the embryonic area and permits their migration (see Fig. 10.4). The streams of mesoblast extend between the epiblast and endoderm throughout all of the disc area except rostrally at the buccopharyngeal membrane (where the endoderm and ectoderm become apposed once the prechordal mesenchyme has migrated laterally), and caudally at the cloacal membrane (a patch of thickened endoderm, similar to the buccopharyngeal membrane, caudal to the primitive streak). The mesoblast on each side of the notochord is termed paraxial mesenchyme.

Mesoblast that passes in a rostral direction flanks the notochordal plate and passes around the prechordal plate region, converging medially to fuse in the midline beyond its rostral border. This transmedian mass, in which the heart and pericardium will develop, is initially termed the cardiogenic mesoblast. It fuses with the junctional zone of extraembryonic mesoblast around the extreme cephalic margin of the embryonic area. This region will eventually form the septum transversum and primitive ventral mesentery of the foregut. Mesoblast passing laterally from the streak soon approaches and becomes confluent with the extraembryonic mesoblast around the margins of the disc, i.e. at the junctional zone where the splanchnic and somatic strata of extraembryonic mesoblast merge. Mesoblast that streams caudally from the primitive streak skirts the margins of the cloacal membrane and then converges towards the caudal midline extremity of the embryonic disc to become continuous with the extraembryonic mesoblast of the connecting stalk. It is unclear if the lower layer of the cloacal membrane consists of visceral hypoblast, like the more rostral primitive streak (the hypoblast is necessary for maintaining the streak), or if it is replaced by migrating embryonic endoderm, or if there is a region for ingression of endoderm at the caudal end of the streak, similar to the node rostrally.

Still further caudally, the embryonic disc develops a midline diverticulum adjacent to the cloacal membrane. This diverticulum, the allantois, projects into the extraembryonic connecting stalk (see Figs 9.10, 10.4; **Fig. 10.6**). It is unclear whether the allantois is composed of visceral hypoblast, parietal hypoblast or embryonic endoderm. The allantois later develops a rich anastomotic blood supply around it, in the manner of the yolk sac.

The generation of cells at the primitive node produces midline endoderm, notochord and the floor plate of the future neural tube. As the notochord grows and elongates, there is a matched growth of neural floor plate cells until both cell lines extend to the buccopharyngeal membrane. The epiblast lateral to the midline contains both future surface and neural ectoderm. The latter becomes arranged between the primitive node and buccopharyngeal membrane; cells destined to be in the neural plate lie medially, and those destined for the neural crest lie along the junction between the neural plate and surface ectoderm (see Fig. 10.5). A smaller subpopulation of neuronal cells, the ectodermal placodes, are arranged either close to the neural crest or within the rostral limit of the neural plate itself.

FOLDING OF THE EMBRYO

In a diagrammatic representation of the trilaminar disc prior to folding and viewed from the ectodermal aspect, all of the future external surface of the body is delimited (see Fig. 10.5). The ends of the gut tube are specified on the ectodermal surface at the buccopharyngeal and cloacal membranes, regions where the ectoderm and underlying endoderm are apposed without intervening mesoblast. In the midline between these membranes, proliferation of the neural ectoderm matches the underlying migration of mesoblast from the primitive streak, so that the neural plate covers the paraxial mesenchyme on each side of the notochord (see Fig. 10.6E). As the paraxial mesenchyme segments, the formation of the epithelial somites elevates the edges of the neural plate and initiates primary neurulation (see Fig. 10.6F; **Figs 10.7–10.8**). The neural plate itself undergoes concurrent morphological changes. The most medial cells become wedge-shaped, forming the neural groove. Further elevation of the edges of the neural groove permits fusion of the neuronal populations in the dorsal midline to form the neural tube. The surface ectoderm forms the putative dorsal epidermis (see Figs 10.6G, 10.7–10.8). Cells at the lateral edge of the neural plate, neural crest cells, remain as a linearly arranged mesenchymal population between these two epithelia. Fusion of the neural tube begins in the future rhombencephalic region of the embryo and proceeds rostrally and caudally to about the level of somite 29. Neurulation is described further in Chapter 14. A population of neural epithelial cells remain within the surface ectoderm and at this stage they are termed ectodermal placodes.

The representation of a person on the trilaminar disc (**Fig. 10.9**) shows, to some extent, the way in which the positions of the main body structures are already specified in the unfolded embryo. Ectoderm lateral to the neural plate and the paraxial mesenchyme will form structures within the back. The portion of the disc between the buccopharyngeal membrane and the edge of the disc will become the ventral thoracic wall and the ventral abdominal wall rostral to the umbilicus. Further caudally, midway along the neural axis, the lateral portions of the disc will become the lateral and ventral abdominal walls of the trunk. The portion of the disc beyond the cloacal membrane will form the ventral abdominal wall caudal to the umbilicus. The circumference of the disc, where the embryonic tissue meets the extraembryonic membranes, will become restricted to the connection between the ventral abdominal wall and the umbilical cord, i.e. the umbilicus.

Head folding begins at stage 9, when the fusing rostral neural plate rises above the surface ectoderm and the portion of the disc rostral to

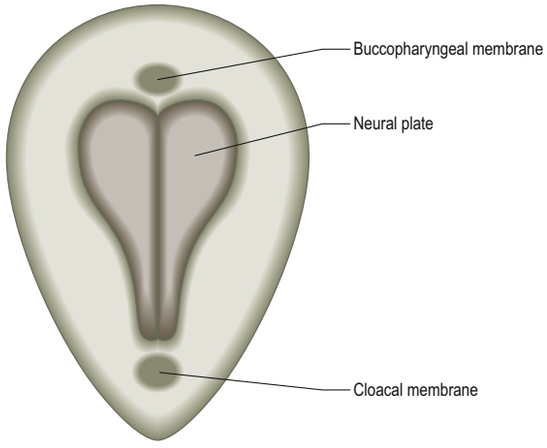

Fig. 10.5 The extent and shape of the neural plate in an unfolded embryo.

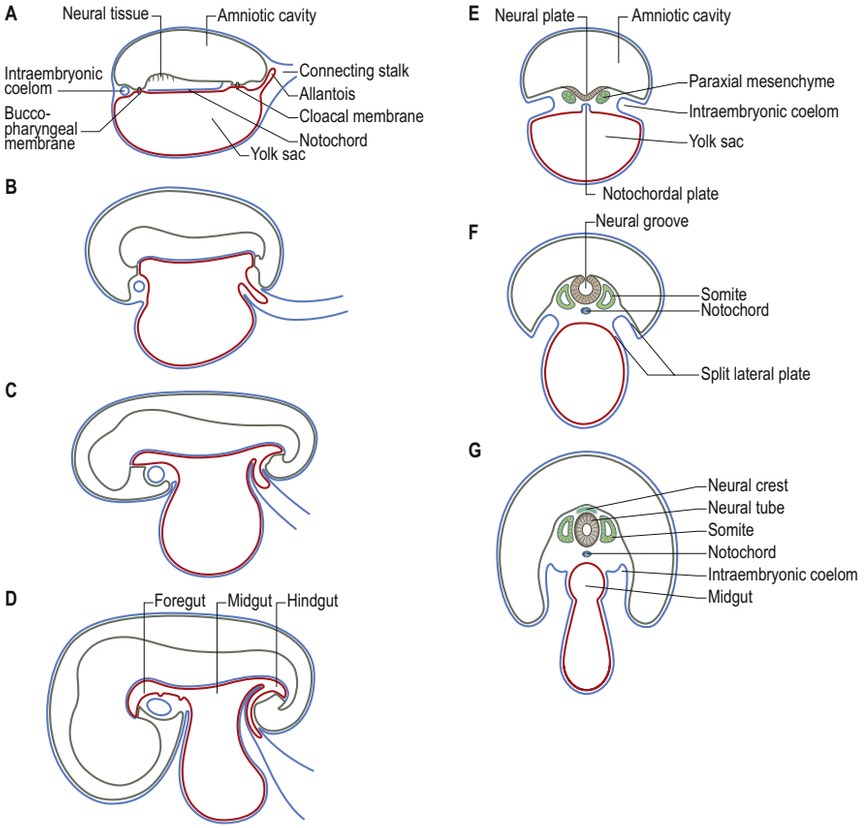

Fig. 10.6 Head and tail (**A–D**) and lateral (**E–G**) folding of the embryo. **A–D**, Median sagittal sections through the embryonic disc at successive stages; the relative positions of the buccopharyngeal and cloacal membranes have been maintained; thus, the movement of the most rostral and caudal portions of the disc can be followed. As these portions of the disc move ventrally, the initially wide-open yolk sac becomes constricted and fore- and hindgut divisions can be seen; the midgut is that region remaining in wide connection to the yolk sac. **E–G**, Transverse sections through the midpoint of the embryonic disc at successive stages to illustrate lateral folding that occurs as neurulation proceeds.

the buccopharyngeal membrane (containing the cardiogenic mesenchyme) moves to lie ventral to the developing brain (see Fig. 10.6). The prosencephalon and buccopharyngeal membrane are now the most rostral structures of the embryo. The previously flat region of endoderm, which may contain cells from the prechordal plate, is now modified into a deep tube, the primitive foregut. Tail folding can be seen in stage 10 embryos, when the entire embryo comes to rise above the level of the yolk sac. Similar movement of the part of the disc caudal to the cloacal membrane results in its repositioning ventral to the neural plate. Generally, as the embryo rises above the edges of the disc, the lateral regions of the disc are drawn ventrally and medially, contributing to the lateral folding of the embryo.

FORMATION OF THE INTRAEMBRYONIC COELOM

At and just before stage 9 (before formation of the head fold), vesicles appear between the mesenchymal cells rostral to the buccopharyngeal membrane and within the rostral lateral plate mesenchyme. At the periphery of the vesicles, the mesenchymal cells undergo mesenchymal to epithelial transformation, developing the apical polarity and junctional complexes typical of the epithelial phenotype. The vesicles become confluent to form a horseshoe-shaped tube, the intraembryonic coelom, that extends caudally to the level of the first somite and laterally into the lateral plate mesenchyme towards the extraembryonic mesenchyme. The lateral plate mesenchyme epithelium subjacent to the ectoderm is termed somatopleuric coelomic epithelium, and that adjacent to the embryonic endoderm is termed splanchnopleuric coelomic epithelium (see Fig. 12.2C(iv)). At this stage, the intra- and extraembryonic coeloms do not yet communicate.

During development of the head fold, the morphological movements that organize the foregut and buccopharyngeal membrane have a similarly profound effect on the shape of the intraembryonic coelom. The midline portion of the originally flat, horseshoe-shaped intraembryonic coelom moves ventrally, leaving the caudal arms of the horseshoe in their original position. In this way, the midline part of the coelom, which was originally just rostral to the buccopharyngeal membrane, comes to lie ventral to the foregut (caudal to the buccopharyngeal membrane), and the two lateral extensions of the coelom pass close to the lateral walls of the foregut on each side. The caudal portions of the coelom (the two arms of the horseshoe), which, in the unfolded disc, communicated laterally with the extraembryonic coelom, turn 90° to lie lateral to the gut, and communicate with the extraembryonic coelom ventrally.

Compartments of the coelom that will give rise to the body cavities later in development can already be seen. The midline ventral portion, caudal to the buccopharyngeal membrane, becomes the pericardial cavity. The canals lateral to the foregut (pericardioperitoneal canals) become the pleural cavities and the uppermost part of the peritoneal cavity. The remaining portion of the coelom becomes the peritoneal cavity. By stage 11 the intraembryonic coelom within the lateral plate mesenchyme extends caudally to the level of the caudal wall of the yolk sac. The intra- and extraembryonic coeloms communicate widely on each side of the midgut along the length of the embryo from the level of the fourth somite (**Fig. 10.10**).

In the early embryo, the intraembryonic coelom provides a route for the circulation of coelomic fluid and, with the beating of the heart tube, functions as a primitive circulation that takes nutritive fluid deep into the embryo until it is superseded by the blood vascular system. The coelomic channel, and the primitive circulation that passes through it, is of paramount importance up to stage 13. Whereas the superficial tissues of the embryo can receive nutrients via the amniotic sac and yolk sac fluids, the deeper tissues are, until the formation of the coelom, under conditions similar to those found in tissue culture. However, from stage 10 exocoelomic fluid, propelled by the first contractions of the developing heart, is brought into contact with the deeply placed mesenchyme. This early 'circulation' ensures that an adequate supply of nutrients reaches the rapidly increasing amount of embryonic tissue, and meets most of the requirements of the deeper mesenchymal derivatives. From stage 12 the endothelial system expands and fills rapidly with plasma, which passes across the locally thinned coelomic epithelium into the large hepatocardiac channels that project into the pericardioperitoneal canals at the level of the seventh somite. Exocoelomic fluid (which is propelled into the intraembryonic coelom) has been collected, via coelocentesis, from the chorionic cavity (see Fig. 10.10)

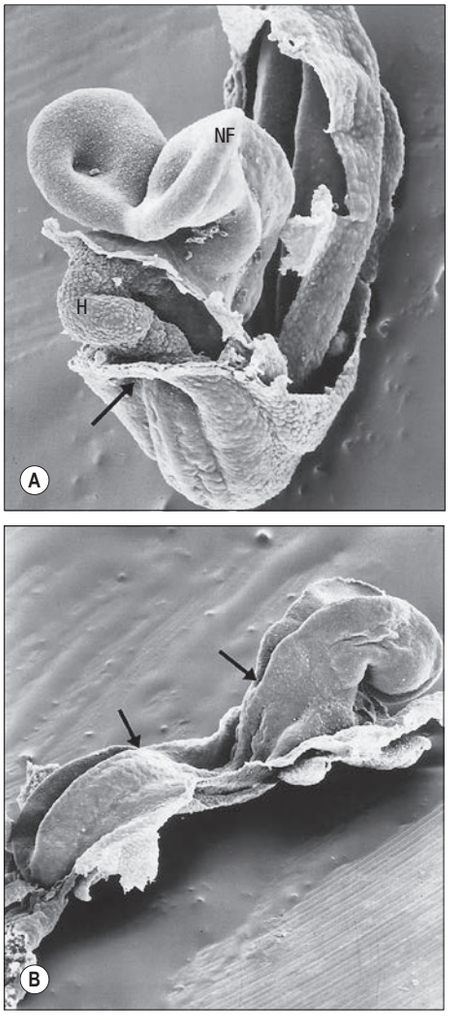

Fig. 10.7 Scanning electron micrographs of rat embryos at the time of neurulation. **A**, Ventral view, showing the neural fold (NF), and the heart (H), with the somatopleuric pericardial membrane and surface ectoderm removed; the arrow indicates the entrance to the foregut via the rostral intestinal portal. **B**, Dorsolateral view; the arrows indicate the extent of rostral (to the right) and caudal (to the left) neural tube formation. (Photographs by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

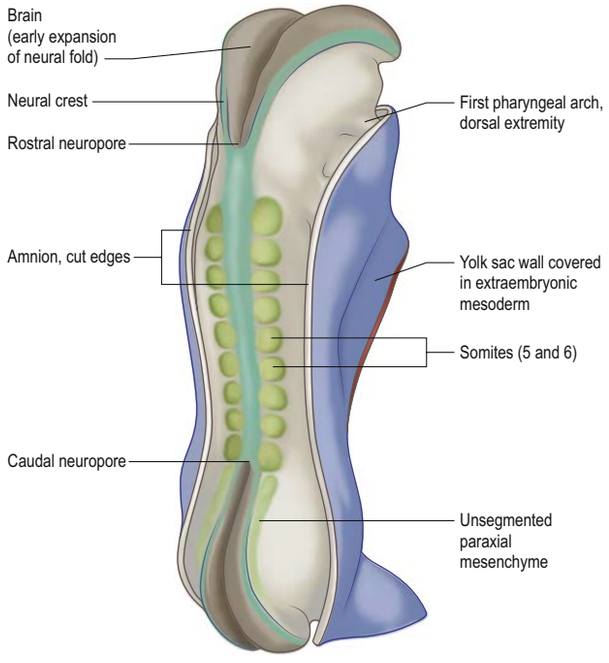

Fig. 10.8 A human embryo at stage 10, 2.1 mm long, with nine somites: right lateral and dorsal aspects. Nearly all the yolk sac and the caudal amnion have been excised.

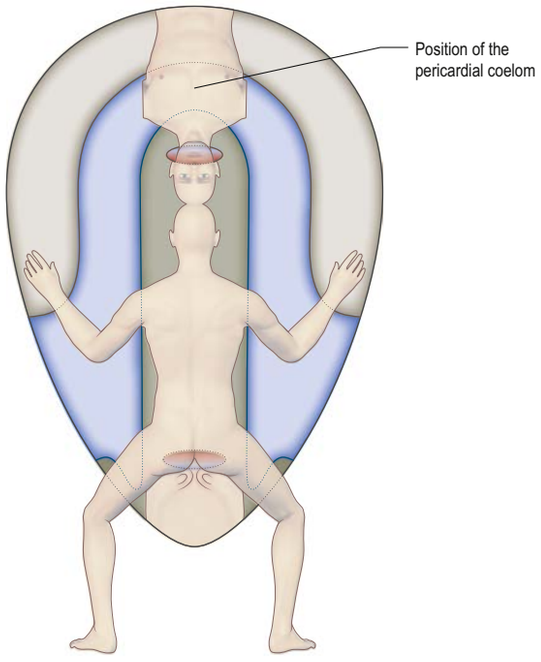

Fig. 10.9 A representation of a person on the flat embryonic disc. The position of the central nervous system has been matched to the dimensions of the neural plate, and the position of the heart in the thorax to the position of the pericardial coelom. The limbs, although represented in this diagram, are not present on the disc at this stage. The usefulness of this diagram lies in its illustration of the extent of the anterior body wall both rostral to the buccopharyngeal membrane and caudal to the cloacal membrane. The future dorsal regions of the body are found medially on the disc, while the ventral regions of the body are situated laterally and peripherally on the disc. After head and tail folding and lateral folding, the peripheral edge of the disc becomes constricted as the edge of the umbilicus.

of embryos at stages 9–14; its total protein content is 54 times higher than that in amniotic fluid, but 18 times lower than in maternal serum (Aiello et al 2018).

In spite of the importance of the coelom in defining the body cavities, and of the coelomic epithelium in the production of the major mesenchymal populations of the trunk (Streeter 1942, Langemeijer 1976, O'Rahilly and Müller 1987) (see Fig. 12.2), until recently the overall contribution of the epithelial coelomic walls to the embryo has received relatively little attention (Carmona et al 2013). The coelom is a single, tubular organ that may be compared to the neural tube, in that it possesses a specialized wall that encloses a cavity. Like neural ectoderm, proliferating coelomic epithelium is a pseudostratified columnar epithelium with a germinal layer displaying interkinetic nuclear migration, matching the timing of the cell cycle, from which cellular progeny migrate. After the germinal phase, which occurs in the fetal period, both epithelia ultimately form the lining of a cavity, ependyma for the neural epithelium, and mesothelium for the coelomic epithelium. Coelomic epithelium, like neural epithelium, produces cells destined for different fates from different sites and at different developmental times. Coelomic cells are like the neural epithelium, in that they have apical epithelial specializations and tapering basal processes that are in direct contact with the underlying mesenchyme, without an intervening basal lamina. The possibility of the tapering processes forming directional signals for migrating progeny, similar to the radial glia of the neural tube, has not been examined.

EMBRYONIC CELL POPULATIONS AT GASTRULATION

After gastrulation, the cells of the embryo contribute to two fundamental types of tissue, epithelia and mesenchyme. Differentiation of specialized circulating blood cells and other cell types occurs in sequence. Embryonic and fetal cell types are replaced later in development or after birth.

Epithelia

Epithelial populations in the embryo have many of the morphological characteristics of differentiated epithelia, i.e. they are composed of

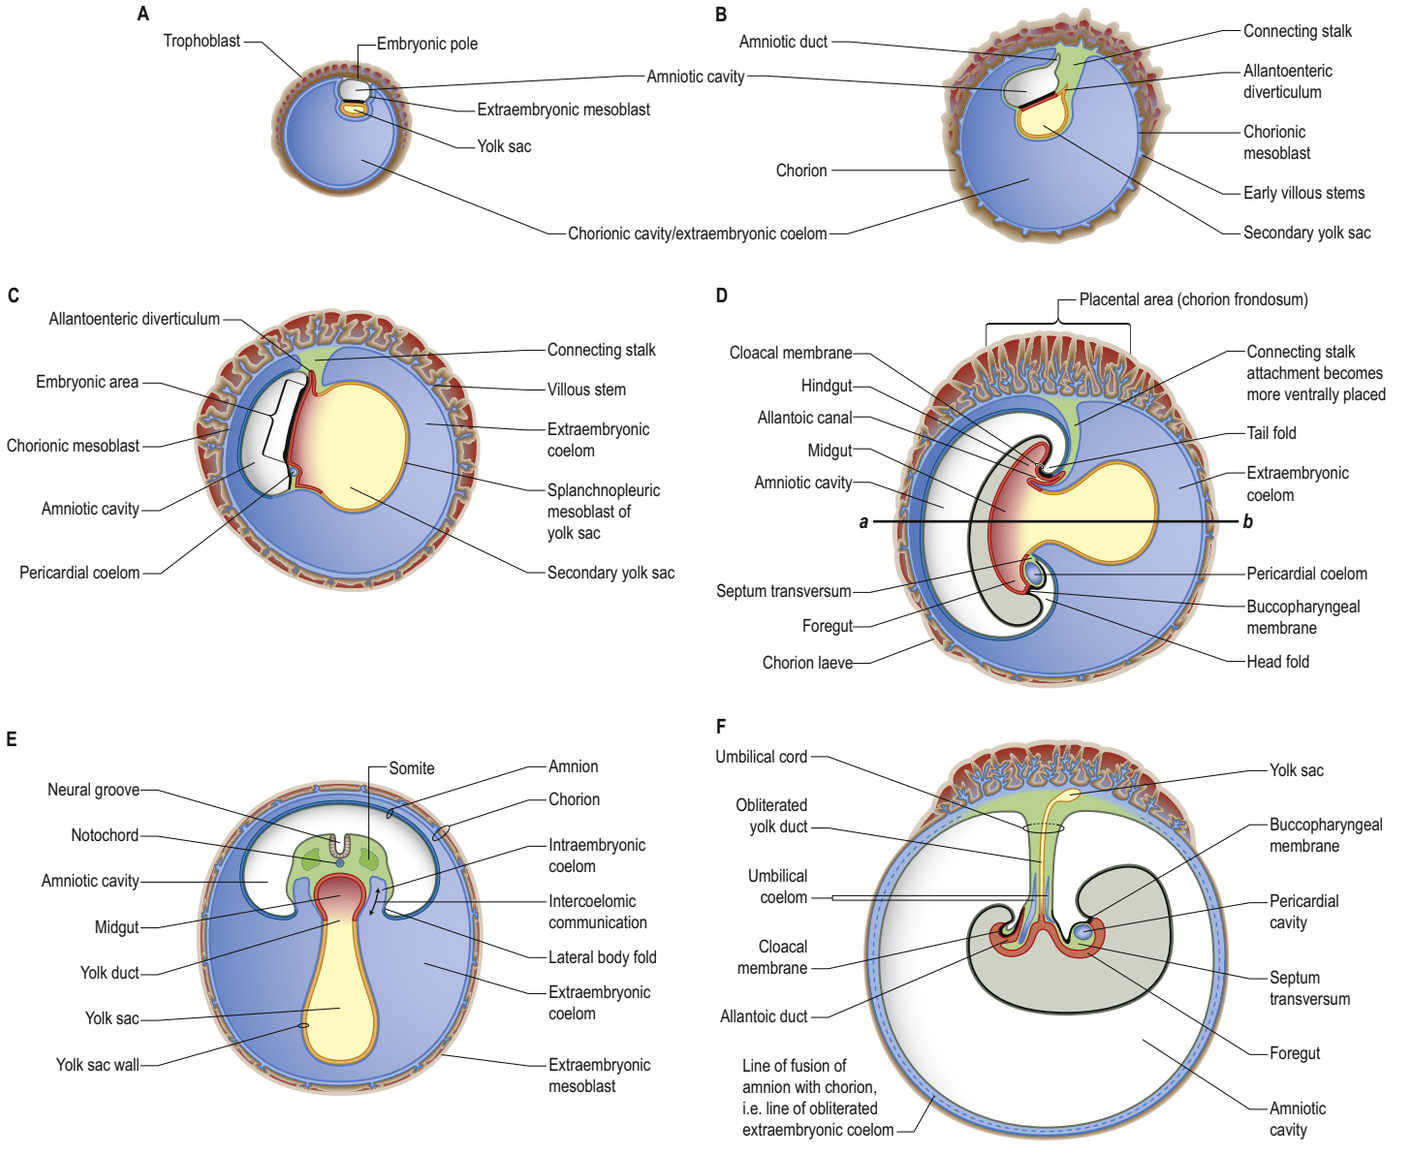

Fig. 10.10 **A**, An early stage in development of a human blastocyst. **B**, A blastocyst sectioned through the longitudinal axis of an embryo, showing the early formation of the allantois and the connecting stalk. **C**, A longitudinal section of an embryo at a later stage of development; the pericardial cavity can be seen at the most rostral part of the embryonic area. **D**, A longitudinal section of an embryo at a later stage, showing formation of the head and tail folds, the expansion of the amnion and the delimitation of the umbilicus. **E**, A transverse section along the line a–b in **D**; observe that the intraembryonic coelom communicates freely with the extraembryonic coelom. **F**, A longitudinal section of an embryo at a later stage, showing full expansion of the amniotic cavity and the umbilical cord.

sheets of closely packed, polarized cells, with narrow intercellular clefts containing minimal extracellular material, and a developed basal lamina containing specific proteins synthesized by the epithelium itself. The cells usually show juxtaluminal lateral surface specializations, (e.g. desmosomes, tight junctions or gap junctions) and specializations of the apical surface (e.g. microvilli or cilia).

Epithelial polarity factors establish the extent of the apical, lateral and basal domains of the individual cells forming an epithelium. Three main control pathways have been identified in maintaining apicobasal polarity (St Jonston and Sanson 2011). The apical domain is specified by the Crumbs transmembrane protein; Baz/PAR-3 specifies the position and extent of the intercellular junction; and Scribble restricts the size of the junctional domains. Once established with an underlying basal lamina, the basal surface displays integrins. Changes in the morphology of an epithelial sheet will involve relative changes in the apical, lateral and basal domains of all the cells in the sheet. Planar polarity of epithelia is driven by intercellular cortical actin and myosin. Epithelial cells are contiguous via actomyosin contractile networks, that contact the lateral cell membrane through E-cadherin adhesion (Gorfinkiel and Blanshard 2011). Wnt/planar cell polarity signalling pathways are involved in these epithelial morphogenetic movements and also in orientated cell division that occurs in epithelial sheets (Tao et al 2009).

Embryonic epithelia differ from those in the fetus and adult. Two distinct types can be identified. Early germinal epithelia, that give rise to epithelial or mesenchymal populations of the embryo and confer their early patterning are termed organizers, e.g. the primitive streak. Later germinal epithelia give rise to system-specific progenitor populations, e.g. the ventricular zone of the neural tube. All epithelia other than special germinal epithelia divide to produce embryonic growth throughout development and may retain stem cells that will divide throughout life.

Characteristically, epithelia clothe internal and external surfaces as simple or compound cellular sheets that separate phases of differing composition (e.g. the external environment and the subepithelial tissue fluids; intravascular and extravascular fluids). Traffic of materials in the intercellular clefts is limited. Traffic occurs across the cells because their limiting membranes, which function as energy-dependent selective barriers, enhance the passage of some materials and impede the passage of others.

Mesenchyme

The terms mesoblast and mesenchyme are used in this text in a specific manner and are not interchangeable. Previously, cells generated by the primitive streak, forming a population between the epiblast and hypoblast were termed mesoderm and, more recently, mesenchyme. The terms primary and secondary mesenchyme have been used to distinguish between those cells that arise from ingression through the primitive streak and those that arise from neural crest ingression from the edges of the

neural plate, respectively. Primary mesenchymal cells revert to epithelia at their destinations. However, whereas some primary mesenchymal cells may become epithelial within a short timeframe, e.g. somites and lateral plate, other cells may transform later, e.g. the epithelium lining blood vessels. To address these terminological conflicts, the mixed population of epiblast cells that ingress through the primitive streak and come to lie between the epiblast and embryonic endoderm is termed mesoblast until the cells have migrated to their final position, at which time the populations of mesenchyme can be identified and their fates inferred.

Mesoblastic and mesenchymal cells have no polarity. They form junctional complexes, which are not exclusively juxtaluminal, and they produce extracellular matrix molecules and fibres from the entire cell surface. Mesenchymal populations are formed from a range of germinal epithelia and by proliferation of mesenchymal cells directly, and occupy all the regions between the various epithelial layers described above. The term mesoderm is reserved for the coelomic epithelia that later form mesothelia.

Mesenchymal cells support epithelia throughout the developing body, both locally where they contribute to the basement membrane and form the lamina propria and smooth muscle of tubes, and generally where they differentiate into connective tissue. Specific mesenchymal populations control the patterning of local regions of epithelium (e.g. the zone of polarizing activity on the postaxial limb border posterior to the apical ectodermal ridge).

Extracellular matrix

The space beneath epithelia and between mesenchyme cells is filled with extracellular matrix. Epithelial and mesenchymal cells synthesize extracellular matrix molecules and their receptors. Epithelial cells produce two-dimensional basal laminae that contain a variety of matrix molecules, including laminin, fibronectin, type IV collagen and various proteoglycans. The particular molecules can vary during development according to spatial and temporal patterns, resulting in changes in the behaviour of the underlying mesenchymal cells (e.g. in patterning of the basal regions of the skull). Mesenchymal cells produce extracellular matrix molecules in three dimensions. Those adjacent to an epithelial layer will connect with its basal lamina, forming a basement membrane that secures the epithelial layer to the underlying tissue. Cells deep within a mesenchymal population may synthesize matrix molecules (fibrillar or granular) to separate cells locally, open up migration routes or leave information within the matrix to act on cell populations passing at a later time (see Fig. 11.1).

Molecules of the extracellular matrix are complex. They include more than 19 individual types of collagen (some capable of being individually spliced to give more than 100 variants), proteoglycans and glycoproteins (which come in a wide variety of forms, with and without binding proteins), and elastic fibres (Ch. 2). Hyaluronic acid, a glycosaminoglycan, has a vast capacity to bind water molecules and so create and structure the space between the mesenchymal cells, thereby producing much of the overall shape of an embryo. Experimental removal of hyaluronic acid prevents the formation of cell migration routes, removes the support for overlying epithelia, and disrupts the normal branching of glandular systems.

Fibronectin deposited extracellularly along a migration pathway will affect cells that touch it later, causing realignment of their intracellular actin filaments and thus of their orientation, and it also induces cell migration. The receptors for extracellular matrix molecules such as fibronectin and laminin were originally termed integrins because they integrate extracellular proteins and intracellular cytoskeletal elements (via α and β subunits that span the cell membrane), allowing them to act together; the binding preference of integrins depends on their combination of subunits and environmental conditions.

Extracellular matrix is structured rather than random. Epithelial and mesenchymal cell populations can structure the space around them by secretion of particular matrix molecules or growth factors, which, in turn, can organize the cells that contact them. Cell–matrix interactions and matrix–cell interactions control the position of migration routes and cellular 'decisions' to migrate or to begin to differentiate. Matrix molecules propagate developmental instructions from cell to cell and form a far-reaching four-dimensional (spatial and temporal) mechanism of communication. Mapping the molecular pathways and the biomechanical processes that underlie morphogenesis, the dynamic epigenetics of early mesenchyme cells and their secreted three-dimensional extracellular matrices, and the mechanisms by which the stiffness of the surrounding matrix affects the actions of the cells within it, and how the specific deposition of fibrillary proteins creates tissue boundaries and zones of tension, remain the subject of ongoing research (e.g. Davidson et al 2010, Loganathan et al 2012, Loganathan et al 2016).

Transition between epithelial and mesenchymal states

Transformations of cell morphology from epithelium to mesenchyme, and *vice versa*, occur in specific places and times during development, and can be seen as ways of dispersing germinal centres with increasing cell restriction. The first epithelial-to-mesenchymal transition occurs at the primitive streak, a germinal epithelium that confers embryonic specification on the resultant mesoblast population. The mesoblast so formed migrates and the cells undergo mesenchymal-to-epithelial transitions when they reach their final destinations. Series of small epithelial germinal centres, the somites, are formed, as are larger, more extensive, germinal epithelial sheets that line the walls of the intraembryonic coelom. The coelomic walls, especially those derived from somatopleure and splanchnopleure, form germinal epithelia that give rise to the major mesenchymal populations that form the viscera. The early epithelial somites undergo further local epithelial-to-mesenchymal transitions to form the sclerotomes, and subsequently form several germinal epithelia in the epithelial plate of each somite. Later mesenchymal-to-epithelial transitions are not associated with the formation of germinal epithelia; the most common involve the transition of mesenchyme into the endothelium of the vascular system. The nephrons of the mesonephric and metanephric systems also form from mesen chymal-to-epithelial transition. The generation of epithelial layers supported by underlying mesenchyme are widespread throughout the developing embryo and important for cellular interactions. The generation of two abutting epithelia with adjoining basal laminae is rare and seen within particular organs (Ch. 11).

CHAPTER
11 Overarching concepts in development

GENES IN DEVELOPMENT

Study of secondary oocytes before and after fertilization, and of the selection of embryos for implantation after *in vitro* fertilization, has identified the range of maternal genes ready for expression to ensure cleavage, morula and blastocyst formation. Embryonic genome activation occurs in the 4–8 cells stage (Niakan et al 2012) when embryonic cells express polarity genes, initiating cell–cell interaction (Mihajlović and Bruce 2017); by 6 days post fertilization the hatched blastocyst is able to interact with maternal tissue. A simplistic but useful concept likens these early developmental processes to a series of binary choices (see Fig. 8.1). Two cell phenotypes, epithelial and non-epithelial cells, are specified during cleavage and early compaction within the zona pellucida. All the relevant genes required to maintain these cell shapes and behaviours are upregulated at these very early stages.

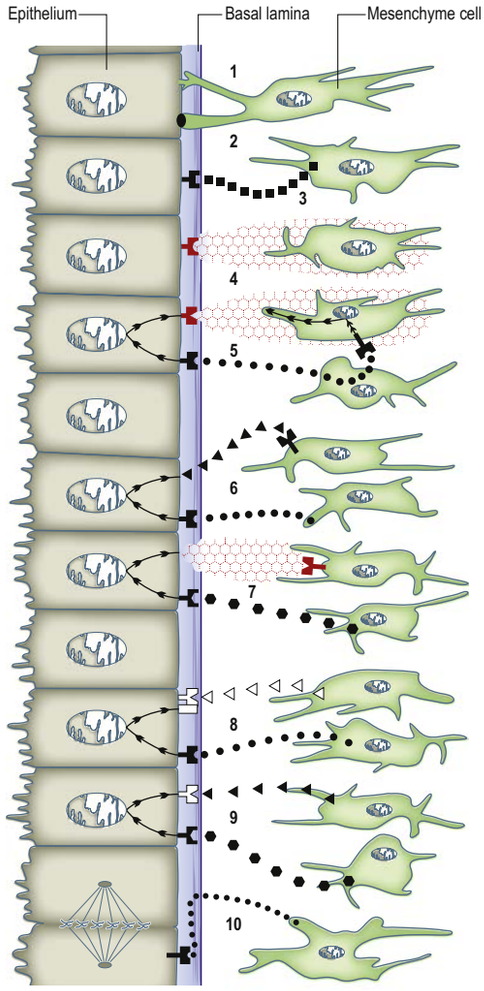
Three lineages are set up at this time with the specification of trophoblast, hypoblast (primitive endoderm) and epiblast. Cells subsequently respond locally to their environment, specifically to other cells that are positioned lateral and basal to them. In the mouse embryo, the genes operating at these early times are given in Takaoka and Hamada (2012). The implanting blastocyst also expresses and secretes miRNAs (involved in post-translational gene expression) involved in interactions with the maternal endometrium which secretes similar molecules (Lian et al 2017): successful embryo–maternal cross-talk is vital for implantation.

Two related themes have emerged from experimental studies of development: the control of embryonic morphology has been highly conserved in evolution between vertebrates and invertebrates; this control involves families of genes coding for proteins that act as transcriptional regulators. Homeobox genes are believed to be responsible, at least in part, for the evolutionary origin of the embryonic body plan (Irie and Kuratani 2014) and for appropriate axial elongation of the embryo and limb specification (Deschamps and Duboule 2017). Experimental studies of transgenic animals in which the homeobox genes have been knocked out provide some evidence of their function. However, because developmental processes permit significant recovery from insult, some of the outcomes cannot be directly interpreted as demonstrating the effect of such gene loss. Other gene families required for normal development include the T-box family (helix–loop–helix transcription factors and *Sox* genes) and the signalling factors transforming growth factor beta (TGF-β), bone morphogenetic proteins (BMPs), fibroblast growth factor family (FGF), the Wnt family and Hedgehog signalling molecules. A range of cell receptor molecules are also required. For details on individual members within this range of factors, see Carlson (2014).

The successful culture of embryonic stem cells, the techniques of single-cell RNA-sequencing, analysis of all proteins expressed by early embryonic cells, the transcription factors they express, the molecules they secrete and those produced as metabolites, have generated extensive data on early genes and the control of sequential expression of genes specific to diverging cell phenotypes (Giacomini et al 2017).

Signalling between embryonic cells and tissues

Within the developing blastocyst, the position of cells relative to each other leads to epigenetic change. The acquisition of cell polarity is fundamental, because this specifies apical and basolateral domains, cell surface specializations, the positioning of intracellular organelles and cytoskeletal elements, and the position and nature of cell–cell junctions. The establishment cell junctional complexes between the outer, polarized, cells of the morula within the zona pellucida are the earliest embryonic cell interactions. The signals received by adjacent cells induces a change in their subsequent behaviour. Cellular signalling between cells and tissues occur via: direct cell–cell contact (gap junctions); cell adhesion molecules and their receptors; extracellular matrix molecules and their receptors; and growth factors and their receptors. The production of a basal lamina by epithelial cells (containing, e.g., laminin and fibronectin) and its attachment to underlying extracellular matrix molecules (collagen, proteoglycans and glycosaminoglycans) synthesized by mesenchyme cells constructs the tissues in which reciprocal signalling occurs (**Fig. 11.1**). In most developing tissues an epithelium and its basal lamina are supported by underlying mesenchymal cells, each contributing to developmental interactions. However, there are a few sites where two epithelial layers, a special epithelium and an endothelium, generate a shared basement membrane to which both epithelial phenotypes contribute. This arrangement is seen between type-1 pneumocytes and endothelium in the developing lung alveoli; between the podocytes and endothelium in the glomerulus of the developing kidney; and between astrocyte end feet and pial-derived endothelium in the developing brain (**Fig. 11.2**).



Combinations of all of these signalling routes are involved in development and their perturbation may result in developmental aberration. The transient production of, e.g., gap junctions is seen as epithelial somites are formed; between neuroepithelial cells within rhombomeres; and in the tunica media of the outflow tract of the heart. Mutations of the genes that code for extracellular matrix molecules give rise to a number of congenital disorders, e.g. mutations in type I collagen produce osteogenesis imperfecta; mutations in type II collagen produce disorders of cartilage; and mutations in fibrillin are associated with Marfan syndrome

Growth factors are distinguished from extracellular matrix molecules. They can be delivered to, and act on, cells in a variety of ways, namely: endocrine, autocrine, paracrine, intracrine, juxtacrine or matricrine (**Fig. 11.3**). Many growth factors are secreted in a latent form, e.g. associated with a propeptide (latency-associated peptide) in the case of transforming growth factor beta, or attached to a binding protein, in the case of insulin-like growth factors.

Other signalling mechanisms occurring between these cell arrangements include the transduction of the biomechanics of mesenchyme cell synthesized matrix. Stiffness of the matrix leads cells towards an osteoblastic developmental phenotype, whereas soft matrix leads to an adipocyte lineage (Heisenberg and Bellaïche 2013). Endogenous electrical fields are also believed to have a role in cell–cell communication and have been demonstrated in a range of amphibian embryos, and in vertebrate embryos during primitive streak ingression. Neuroepithelial cells are electrically coupled, regardless of their position relative to inter-rhombomeric boundaries.

The spatial and temporal distribution of a variety of cell adhesion molecules has been localized in the early embryo and displayed within the 3D tissue arrangement of embryos at a variety of stages (MGI mouse gene expression data search: eMAGE). The temporal appearance of these molecules correlates with a variety of morphogenetic events that involve cell aggregation or disaggregation.

It is important to realize that while developmental studies on laboratory species and *in vitro* studies of animal tissues indicate the range of factors operating in embryos, the spatial and temporal expression of these factors in human embryos will be different. Figure 8.2 illustrates the temporal differences in external features between human and some animal species. Differences in heterochrony (the time at which genes are expressed and specific structures develop), are easily appreciated between mammals and marsupials, where marsupial embryos are born with facial and upper limb development well in advance of mammals of a similar developmental age (Chew et al 2014). Although not so extreme, differences in heterochrony are significant between human and mouse embryos and any extrapolation of animal developmental sequences to human development should be avoided. Somite generation frequency is 5 hours in humans and 2 hours in mice, and other processes, such as progenitor cell population expansion, have different time lines, e.g. generation of motor neurones takes 2–3 weeks in humans but a few days in mice (Ebisuya and Briscoe 2018). The way in which embryonic cells and tissues count time is not yet clear, but analyses and correlation of specific heterochronic interspecies differences are now being investigated at the molecular level.

1 Direct cell–cell contact by gap junctions.

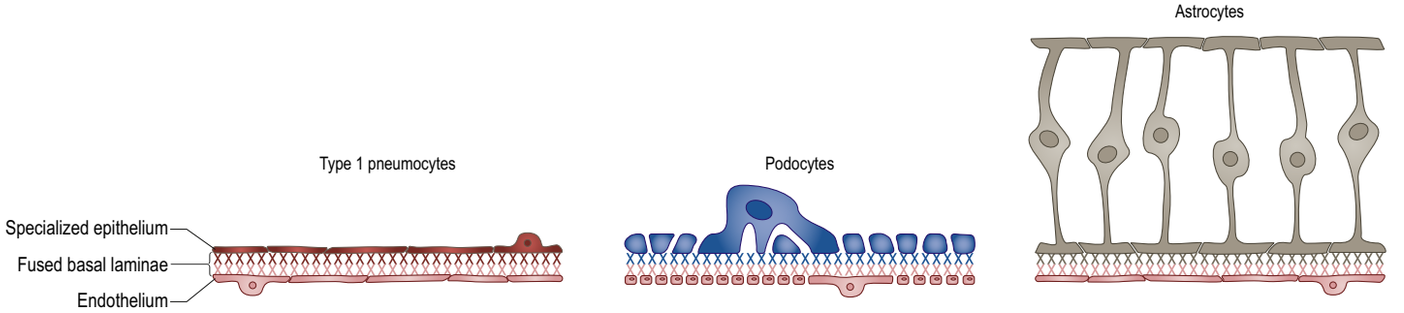
2 Cell–cell contact by cell adhesion molecules.

3 A soluble factor (growth factor) reacting with a receptor for that factor on the epithelial cells.

4 Extracellular matrix molecule secreted by the mesenchyme cells interacting with a receptor on the epithelial cell.

5 A soluble factor (growth factor) secreted by a mesenchymal cell having a biphasic action interacting (i) with a receptor on an epithelial cell, causing it to express a specific extracellular matrix molecule receptor; (ii) with a receptor on a mesenchyme cell, causing it to secrete a specific extracellular matrix molecule which then interacts with the induced epithelial receptor.

6 A soluble factor (growth factor) secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to express a receptor or secrete a factor, which interacts with another factor synthesized, or receptor expressed, by another mesenchyme cell.



7 A soluble factor secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to synthesize an extracellular matrix molecule (or a receptor for such a molecule) which then interacts with a specific receptor for that molecule on another mesenchyme cell.

8 A soluble factor secreted from a mesenchyme cell interacting with a receptor on an epithelial cell, causing it to synthesize a molecule which stabilizes or enhances the interaction between a mesenchymal-derived factor and its epithelial receptor.

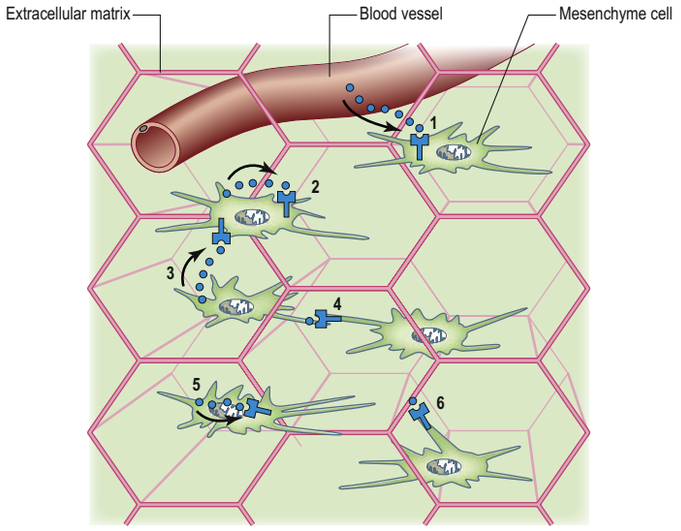
9 A soluble factor secreted by a mesenchyme cell interacting with a receptor on an epithelial cell, causing the inhibition of synthesis/assembly of a factor or receptor.

10 A soluble factor secreted by a mesenchyme cell binding to the extracellular matrix of the basal lamina, where it remains active and subsequently interacts with a receptor on an epithelial cell which appears at a later developmental time.

Fig. 11.1 The many ways by which mesenchyme cells could signal to epithelial cells. Precisely the same mechanisms can operate in reverse, i.e. epithelium to mesenchyme.

Lung alveoli – Fused basal laminae between endoderm-derived Type 1 pneumocytes and pulmonary endothelium forms thin part of interalveolar septa.

Kidney glomeruli – Fused basal laminae between podocytes, derived from mesenchyme to epithelium transformation, and fenestrated systemic endothelium forms the glomerular basement membrane.



Brain – Fused basal laminae between neurectoderm-derived astrocyte end feet and pial-derived endothelium forms part of the blood:brain barrier.

Fig. 11.2 Sites where specialized epithelial cells form shared basal laminae with endothelium.

Induction and interactions

All cell signalling events form the basis of induction and are involved in cell–cell and tissue interactions. The sequential consequents of induction are described using specific terminology. The ability of a cell population (or tissue) to respond to an inductive signal is called *competence* and denotes the ability of the population to alter its initial behaviour as a result of the induction. After a cell population has been induced to develop along a certain pathway, it loses competence and becomes *restricted*. Once restricted, cells are set on a particular pathway of development and after a number of binary choices (further restrictions), they are said to be *determined*. Determined cells are programmed to follow a process of development that will lead to *differentiation*. The determined state is a heritable characteristic of cells and is the final step in restriction. Once a cell has become determined, it will progress to a differentiated phenotype if the environmental factors are suitable.

The process of determination and differentiation within embryonic cell populations is reflected by the ability of these populations to produce specific proteins. Primary proteins (colloquially termed housekeeping proteins) are considered essential for cellular metabolism, whereas proteins synthesized as cells become determined, and are therefore specific to the state of determination, are termed secondary proteins; e.g. liver and kidney cells produce arginase, but muscle cells do not. Fully differentiated cells produce tertiary proteins, that no other cell line can synthesize, e.g. haemoglobin in erythrocytes. The range of housekeeping, regulatory, and tissue-specific proteomes in adult cells is presented in the Human Protein Atlas (www.proteinatlas.org).

1 Endocrine Delivery of growth factor by the blood stream from a distant biosynthetic site to the target mesenchyme cell.

2 Autocrine Synthesis of growth factor by the cell, its secretion, binding and activation of a surface receptor elsewhere on its own surface.

3 Paracrine Synthesis of growth factor by the cell, its secretion and diffusion to an adjacent cell (or group of cells) where it binds to and activates a cell surface receptor.

4 Juxtacrine Synthesis of growth factor by the cell. The growth factor remains on the cell surface and binds to and activates a receptor on an immediately adjacent cell.

5 Intracrine Synthesis of growth factor within the cytoplasm of the cell. The growth factor moves to the nucleus and binds to and activates its own nuclear receptors.

6 Matricrine Synthesis and export of growth factor from the cell. The growth factor binds to the extracellular matrix where it remains active and subsequently binds to and activates a receptor for that growth factor on the same or a different cell.

Fig. 11.3 In addition to the mechanisms described in Fig. 11.1, cells may also communicate by the reception, production and secretion of growth factors. A typical embryonic mesenchyme cell may receive and produce growth factors in this way.

Permissive and instructive tissue interactions

Classically two types of cell and tissue interaction have been described, namely, permissive and instructive (Wessells 1977).

In a permissive interaction, a signal from an adjacent tissue is necessary for the successful self-differentiation of the responding tissue. This means that a particular cell population (or the matrix molecules secreted by the cells that it contains) will maintain mitotic activity in an adjacent cell population. Since a variety of different cell populations may permit a specific cell population to undergo mitosis and cell differentiation, no specific instruction or signal that might limit the developmental options of the responding tissue is involved; this signal therefore does not influence the developmental pathway selected and there is no restriction. The responding tissue has the intrinsic capacity to develop, and only needs appropriate environmental conditions in order to express this capacity. Permissive interactions often occur later in development, when a tissue whose fate has already been determined is maintained and stabilized by another.

An instructive (directive) interaction (induction) changes the cell type of the responding tissue, so that the cell population becomes restricted. Wessells (1977) proposed four general principles in most instructive interactions: in the presence of tissue A, responding tissue B develops in a certain way; in the absence of tissue A, responding tissue B does not develop in that way; in the absence of tissue A, but in the presence of tissue C, tissue B does not develop in that way; and in the presence of tissue A, a tissue D, which would normally develop differently, is changed to develop like tissue B.

These principles are exemplified during induction of the lens vesicle by the optic cup (see Fig. 15.1). An example of D is the experimental association of chicken flank ectoderm with mouse mammary mesenchyme, which results in the morphogenesis of mammary gland-like structures even though chickens do not normally develop mammary glands Wessells (1977).

Tissue interactions continue into adult life and are probably responsible for maintaining the functional heterogeneity of adult tissues and organs, as exemplified by the complex tissue heterogeneity, with sharply compartmentalized boundaries, that occurs in the oral cavity. The junctions between the mucosa of the vestibule and the lip, and between the vermillion border and the facial skin, are distinct boundaries of specific epithelial and mesenchymal differentiation, and are almost certainly maintained by continuing epithelial–mesenchymal interactions in adult life. Perturbation of these interactions throughout the body may underlie a wide variety of adult diseases, including susceptibility to cancer and proliferative disorders.

The interactions between adjacent epithelia and underlying connective tissue continue throughout embryonic and fetal life and extend into postnatal life. In the adult, these interactions also permit the metaplastic changes that tissues can undergo in response to local environmental conditions

Cell fates and stem cells

As populations of cells become progressively determined, they can be described within a hierarchy of cellular development as stem cells, progenitor cells, and terminally differentiated cells.

Stem cells The definition of a *stem cell* has changed as newer methods for producing such cells *in vitro* have expanded. Within an embryo the earliest cells are totipotent and become restricted as development proceeds. In the adult, populations of stem cells remain within most tissues able to replenish the temporal loss of senescent cells and to respond to changes in environmental conditions by asymmetric division, where one daughter cell remains as a stem cell, while the other proceeds along a differentiation pathway. In proliferative cell division, which may be symmetric, the derived cells have identical determination.

Stem cell populations have been developed from a range of embryonic, fetal and adult cells (**Fig. 11.4**) and are now routinely used in *in vitro* culture for exploration of their properties and their reactions to possible therapeutic agents. Human embryonic stem cells (hESC) were first established in culture by Thomson et al (1998); embryonic and adult *induced* pluripotent stem cells (iPSCs) were established by Takahashi and Yamanaka (2006). All stem cells undergo passaging in culture (cells are grown to confluence then split into subcultures and regrown many times); specific growth factors are added to the culture media to promote cell restriction and determination. Precise control of levels of oxygen tension and growth factors *in vitro* (retroviral transduction of OCT4, KLF4m, c-MYC and SOX2), and forced changing of cell phenotype (mesenchyme to epithelial) have been used to produce a range of human *induced* pluripotential stem cell (hiPSC) types, e.g. cardiac myocytes, hepatocytes, neurones etc. (Takahashi and Yamanaka 2016, Chhabra 2017).

Progenitor cells Progenitor cells are already determined along a particular pathway. They may individually follow that differentiation pathway or may proliferate and produce large numbers of similarly determined progenitor cells that subsequently differentiate; neuroblasts or myoblasts are examples of progenitor cells.

Terminally differentiated cells By virtue of their extreme specialization, terminally differentiated cells can no longer divide, e.g. erythrocytes and neurones. Apoptosis is a particular variety of terminal differentiation in which the final outcome is the death of the individual cells or cell populations. It occurs in the developing limb, where cells die along the pre- and postaxial limits of the apical ectodermal ridge, limiting its extent, and also between the digits, permitting their separation (see Ch. 19).

MORPHOGENESIS AND PATTERN FORMATION

The outcomes of embryonic studies show that the process of expression of specific genes and transcription factors, the consequent synthesis of proteins, and movements of local cells or cell populations, is repeated in many different locations and at different times within an embryo. Correlation of these different but related processes informs overarching concepts of development that are applicable to many different cell populations and regions of an embryo. Over time, the meaning and use of some of the terms that describe such concepts have changed: the most recent ways of defining these terms are presented and attributed in what follows.

Interactions between cells are inferred when a change in the initial status of the cell (cells) is noted, e.g. the cell may undergo mitosis or apoptosis, change its glycocalyx protein receptors, or show signs of differentiation. The outcomes of any interaction can be specified by

Initial cell culture studies were usually in 2D systems. Cultured cells are now grown in 3D in specific gels, on microfluidic chips, or in bioprinted shapes, where the culture medium and oxygen tension can be controlled. The metabolic products of such cultures have been analysed through proteomic analysis (metabolome or secretome). Cells grown in 3D culture will form organoids, where epithelial cells, supported by outer mesenchymal cells form hollow spheres. If these self-organizing cell lines are implanted into animals they continue to grow; if maintained in 3D culture they can be used for drug testing or examination of transcription factors they release. Exploration of the cellular interactions in such systems gives insights into how cells self-organize temporally and spatially (Simunovic and Brivanlou 2017). 3D culture of mouse embryonic stem cells with trophoblastic and hypoblastic (extra-embryonic endoderm) cell lines has produced gastrulating embryo-like structures *in vitro* (Sozen et al 2018). These structures allow the exploration of gene expression, spatio-temporal modifications, transcriptional profiling, and comparison with *in vitro* embryonic development.

It is worth reflecting that changes from a perceived 'normal' behavioural repertoire seen in stem cell culture, as a result of changes to the culture conditions may lead to the misinterpretation of experimental results. Undifferentiated embryonic cells are seen only transiently in developing embryos (De Paepe et al 2014), yet hiPSCs, generated by resetting their epigenetic landscapes are used as 'embryonic' stem cells that can be pushed into specific developmental pathways by factors in the culture media. It has been noted that some of the epigenetic memories of such hiPSCs are not eradicated by their preparation and this may obfuscate hypotheses to explain their behaviours (Noguchi et al 2018). Such memory may also include a developmental clock. Heterochronic species-specific differences were conserved when hiPSC-derived neural progenitors were implanted into neonatal mouse brain: the hiPSCs divided for longer and took much longer to differentiate, reflecting their epigentic timeline for *in vivo* human corticogenesis (Espuny-Canacho et al 2013). The results from studies using implanted stem cell-derived tissues or from *in vitro* organoids, or the outcomes of metabolome and secretome analyses of stem cell-derived 'gastrulating embryo-like structures' (Sozen et al 2018), may provide answers to specific questions but these should not be extrapolated to represent what happens in whole embryo development.

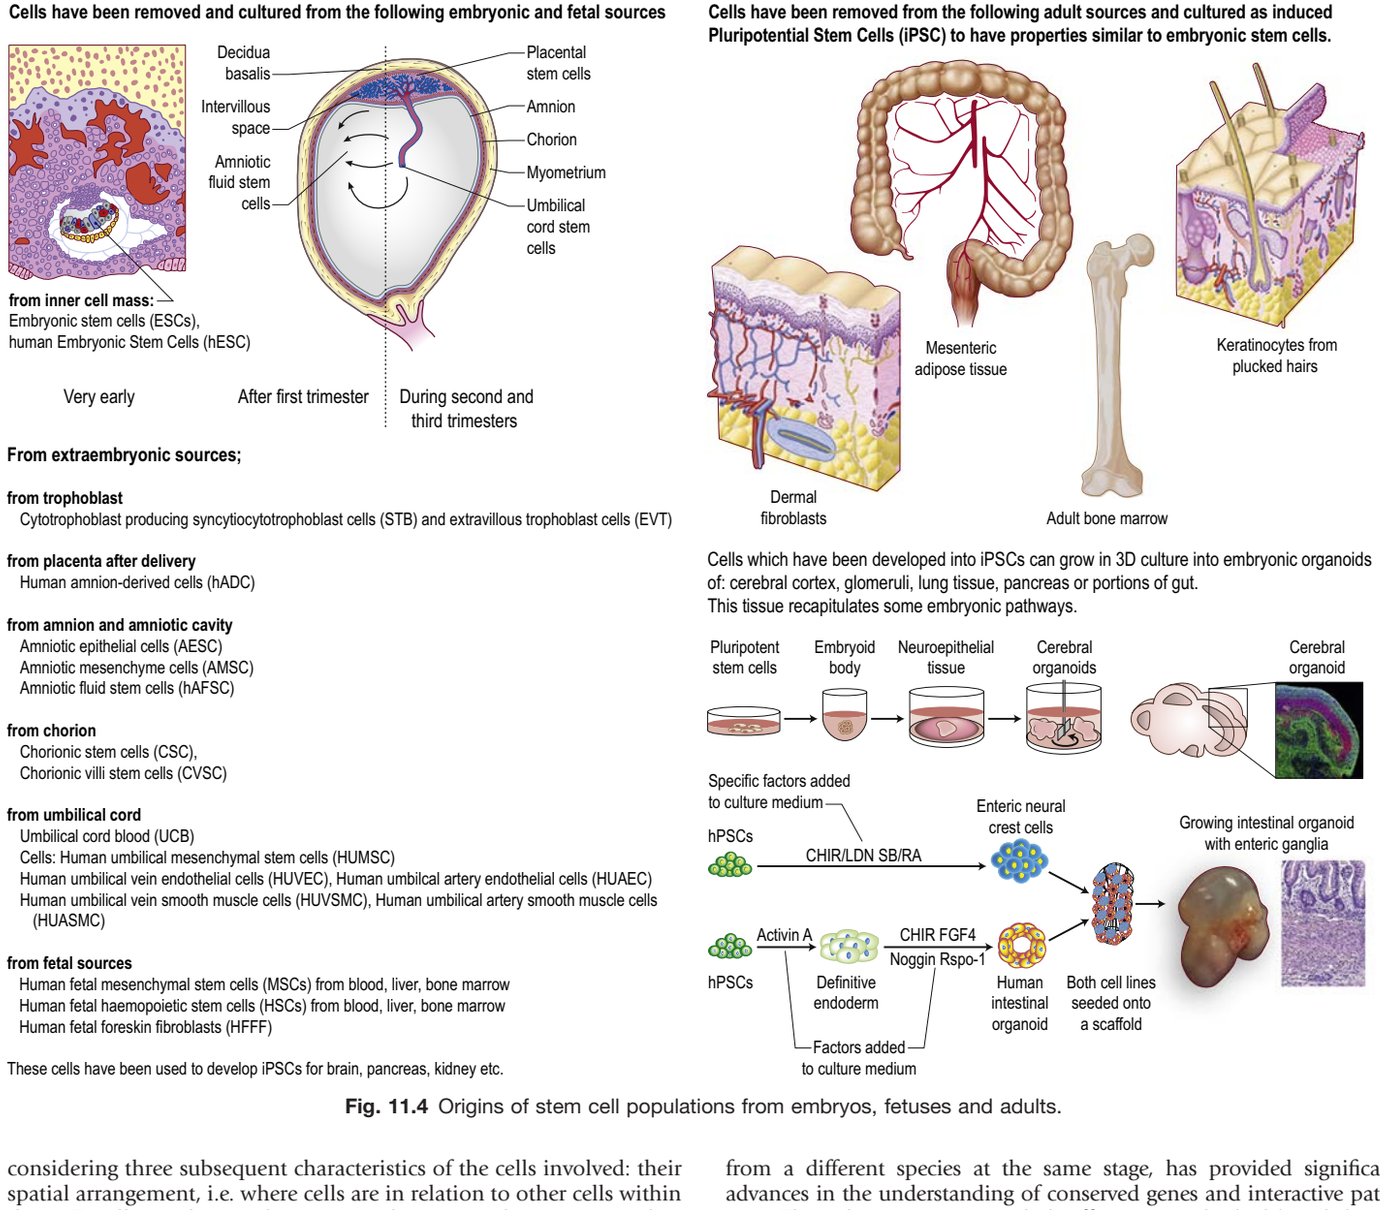


Fig. 11.4 Origins of stem cell populations from embryos, fetuses and adults.

considering three subsequent characteristics of the cells involved: their spatial arrangement, i.e. where cells are in relation to other cells within their 3D cell population; their temporal state, i.e. the time since they were produced or expressed particular factors; their state of restriction or determination, i.e. their individual state at any one time, as a response to their neighbouring cells

Over time, the consequences of interactions are movements of cell populations that change the shape of an embryo. This overarching process is termed morphogenesis. It denotes the assumption of, and change in, form by the whole or part of a developing embryo: it is apparent in the whole embryo during gastrulation and in local cell population movements in branching morphogenesis, which occurs in developing lungs, kidneys and most glandular organs.

The development of branches from a tubular duct occurs over a period of time. Reciprocal interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix results in a series of clefts that produce a characteristic branching pattern (Fig. 11.5). During tubular and acinar development, hyaluronidase secreted by the underlying mesenchymal cells breaks down the basal laminae produced by the epithelial cells, which increases epithelial mitoses locally and results in an expanding acinus. Cleft formation is initiated by the mesenchyme, which produces collagen III fibrils within putative clefts. (If the collagen is removed experimentally, no clefts develop, whereas if excess collagen is not removed, supernumerary clefts appear.) The collagen acts to protect the basal lamina from the effects of the hyaluronidase, which means that the overlying epithelia have a locally reduced rate of mitosis. The region of rapid mitoses at the tip of the acinus is split into two, and two branches develop from this point.

Experimental approaches to embryology

Study of the development of chimeric embryos, where small portions of an embryo are excised and replaced with similar portions of an embryo from a different species at the same stage, has provided significant advances in the understanding of conserved genes and interactive pathways. The technique was particularly effective in early chick/quail chimeric embryonic experiments because the nucleolus is especially prominent in quail but not in chick cells, allowing easy identification of quail cells within a chick embryo (Le Douarin 1969). Chimeric embryo experimentation confirmed the reciprocity of tissue interaction between the embryonic species, a phenomenon that had previously been illustrated, for a limited period, in co-cultures of embryonic avian and mammalian tissues. Somite development and vertebral formation have been studied in mouse–chick chimeras (Fontaine-Pérus 2000). The production, *in vitro*, of human–animal chimeric cell lines has also provided new ways of studying cellular pathways, as has the introduction of human artificial chromosome vectors into animal cells to study their interaction.

Techniques in which specific genes were targeted, removed or replaced (knock-out and knock-in studies) provided significant information on the actions of genes and the result of their perturbation in *in vivo* and *in vitro* experimentation. Culture of embryos, embryonic tissues and embryonic cells permitted investigation of the products of cell metabolism via perturbation of the culture media and analysis of culture metabolites, seen in proteomic, metabolome and secretome studies. Such techniques have also been used to study extraembryonic membranes, e.g. amnion and yolk sac.

The current production of human *induced* pluripotent stem cells which can be encouraged along any line of development by the provision of specific growth factors in the culture media has expanded the possibilities of embryonic research. Specified cell phenotypes can be produced in culture and encouraged, within 3D systems, to form organoids with the view to further study of interactive developmental sequences, to implant such organoids back into animals to study their ability to grow *in vivo*, or to promote continued growth *in vitro* to produce portions of organs which could be transplanted into humans as future treatments.

Branching morphogenesis is an example of pattern formation, the process whereby the individual members of a mass of cells follow a number of different responses that are precisely related to each other, in an orderly manner in space and time. Conceptually, two separate components of pattern formation within branching morphogenesis have been noted (Salazar-Ciudad et al 2003): inductive mechanisms, which pattern via cell signalling, and mophogenetic mechanisms, which act on cell populations to change the spatial distribution of cells (a change of form) without changing the cell states (e.g. degree of restriction).

Inductive mechanisms seem to have a hierarchy, based on sequential gene expression; patterns generated in this way are similar to one another and limited in complexity. In contrast, morphogenetic mechanisms, which include the epigenetic context of cell populations, mechanical interactions between cells and also the ECM, and also the local properties of the ECM and its response to the local stresses, appear to generate more complex patterns using fewer genes.

A cell population with equivalent states of gene expression, noted as a genetic territory (Salazar-Ciudad et al 2003) can undergo an overall change in form. This has been termed a morphostatic mechanism: the population follows an autonomous and specific temporal sequence of behavioural changes specified by the expression of a new range of transcription factors, e.g. the meristematic growth of the developing limb bud (Ch. 19).

Morphodynamic mechanisms denote cell populations where genetic territories are changing at the same time as the cells are sending and receiving inductive molecular signals. Inductive and morphogenetic mechanisms are working synchronously and interdependently. Cells are acquiring positional information dynamically and, because of the different relative positions of each cell to its neighbour, the local interpretations of any inductive signals to a cell population is complex, as cells interact with changing molecular and biomechanical microenvironments over time. Such mechanisms can be seen in cerebral development (Ch. 14). For details of patterning in vertebrate development, see Tickle (2003).

The concept of pattern formation is used throughout all branches of embryology and development. It can be identified across species and used to explore the evolution of conserved cell interactions (Schlosser et al 2014). The prediction of patterning described mathematically by Turing (1952) where a cell producing two morphogens with different diffusion rates, one an activator and the other an inhibitor, has been applied to many developmental scenarios such as hair follicle patterning in developing skin, villous patterning in the gut and the development of stripes (Maini et al 2006, Heller and Fuchs 2015). Pattern formation can also be seen within *in vitro* culture of organoids (Deglincerti et al 2016, Ishihara et al 2017), demonstrating that the sequences of interactions, gene expression and signalling of cells in culture continue to follow the epigenetic programming of stem cells within their specified culture microenvironment.

Buckling morphogenesis is a process integrating further complexity, where two epithelia contribute to inductive interactions in three and four dimensions, with the transductive effects of the biomechanical properties of the combined tissues effecting subsequent developmental outcomes. This type of interaction is seen particularly in gut development, where joined linear sequences of epithelial: mesenchyme interactions are covered by a second epithelium. The elongation of the first tube is informed by its own genetic programme and also confined by the dynamic relationship with the outer epithelium. The biomechanical tension produced in the system informs regional lengthening, rate of growth of the original epithelial–mesenchyme interaction, and the local formation of complex looping. Differential growth between the epithelial layers in this system can give rise to complex coiling of the gut which can then slide into and pack closely within a restricted space. Although aspects of buckling morphogenesis can be predicted mathematically, the parameters for inclusion are extremely complex and not all of the mechanical properties of the tissues involved can yet be specified (Nerurkar et al 2017, Nerurkar et al 2019).

Co-culture of different embryonic cell phenotypes has provided further information on the factors involved in instructive interactions between epithelial and mesenchymal cells, and has also allowed experimental examination of the extracellular matrix and its biomechanical properties (Hadden et al 2017). Three-dimensional cell culture has highlighted the self-organizing properties of mixed phenotypic embryonic cell populations and given rise to a plethora of studies where portions of embryos or embryonic stem cells are grown in mini-culture conditions with full control of the liquid and gaseous environment. Such ‘organ on chips’ culture systems are producing high volumes of data on the conditions under which such cell systems will flourish and the metabolites that are produced. However, these experimental results cannot be extrapolated to any *in vivo* embryonic development and care must be taken in generalizing the knowledge gained from them.

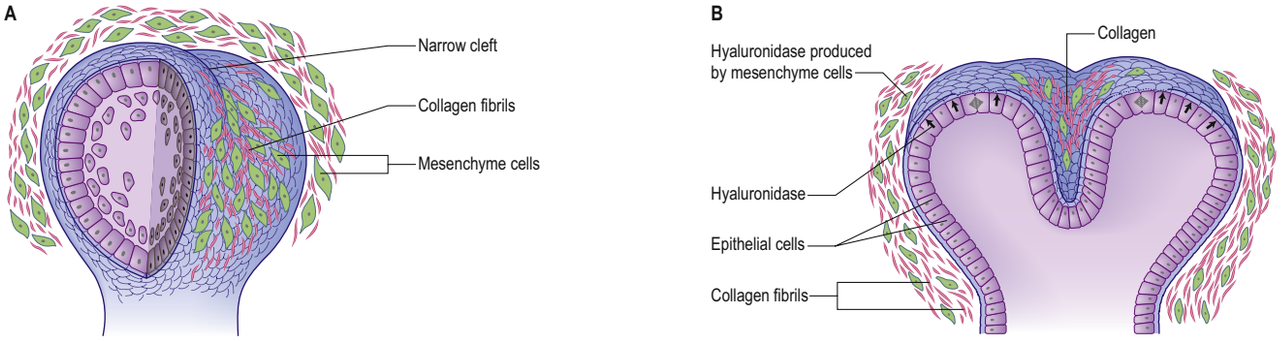

Fig. 11.5 Branching of a tubular duct may occur as a result of an interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix. **A**, Mesenchymal cells initiate cleft formation by producing collagen III fibrils locally within the development clefts and hyaluronidase over other parts of the epithelium. Collagen III prevents local degradation of the epithelial basal lamina by hyaluronidase and slows the rate of mitosis of the overlying epithelial cells. **B**, In regions where no collagen III is produced, hyaluronidase breaks down the epithelial basal lamina and locally increases epithelial mitoses, forming an expanded acinus (arrows). (Adapted with permission from Gilbert SF 1991 Developmental Biology. Sunderland, MA: Sinauer Associates.)

Answers from these studies should not be assumed to add to our knowledge of normal development. Human embryos must not be grown *in vitro* for longer than 14 days after the point of fertilization; the present 14-day rule advocated in the UK by the Warnock Committee (Department of Health and Social Security 1984) was established at a time when human embryos could only be grown *in vitro* for a few days. Today, the purposeful culture of '*synthetic human entities with embryo-like features*' (SHEEFs) (Aach et al 2017), multi-phenotype self-organizing gastruloids/organoids of gut, kidney or cerebral cortex (which can model diverse brain regions) created from hiPSCs, with the very real possibility of maintaining growth beyond the 14-day limit, poses significant ethical problems (Chan 2018). The International Society for Stem Cell Research (ISSCR) produced guidelines for the review, by a proposed human Embryo Research Oversight (EMRO) process, of '*embryo-like structures that might manifest human organismal potential*' (ISSCR 2016). The production of these organoids enables researchers to study portions of embryos, in effect, at developmental stages much later than those at present permitted (Aach et al 2017). How the transnational dimension of any regulatory change ought to be managed and how this would affect the global dynamic of science needs careful thought and discussion (Chan 2018).

DEVELOPMENT OF HIERARCHICAL ONTOLOGIES AND COMPUTER MODELLING OF DEVELOPMENT

Bioinformatic databases use embryological ontologies to trace the lineage of organs and tissues to the earliest time and provide a temporal and spatial framework against which the sequential activation of genes preceding changes in cell and tissue morphology can be matched. They also provide a means of viewing all of the complex partonomy, lineage data and temporal information occurring within embryos within a specific timeframe and of linking these to adult anatomical tissue types. As understanding of the complexity of early developmental events expands, the use of ontological databases provide methods to correlate embryological information (limitations are discussed in Bard 2012).

Computer models have so far focused on single attributes of cells, such as their position, movement or forces transmitted through layers, e.g. cell position relative to a lattice, or the contact surfaces of a cell with other cells in 3D. Such models are more suited to densely packed epithelial cell populations than to mesenchymal populations where the viscoelastic properties of the glycosaminoglycans can be changed in three dimensions by mesenchymal cell–cell interaction or epithelial–mesenchymal interaction. Quantifying the development of complexity time in specific embryonic regions offers the opportunity to compare features such as gene expression, cell lineage and territories (Salvador-Martinez and Salazar-Ciudad 2017).

The exploration of data derived from analysis of the genomes of a range of animals including humans has benefited from ontologies and powerful computing algorithms. Internet websites contain the databases of genomes, spatial and temporal gene expressions, metabolomes and secretomes throughout the development of a range of invertebrate and vertebrate species (including Wormbase, Flybase, Mouse eMAP, KOMP (Knockout Mouse Project), and Human Developmental Studies Network – HUDSEN). Such ontologies assist embryological study, reveal explicit similarities in interspecies developmental processes and enhance the production of taxonomies of vertebrate evolution.

Outcomes of studies based on analyses of Big Data in embryological studies and how they fit into the sum of knowledge may need caution in their interpretation (Hutter and Moerman 2015). If the input data (and underlying concepts) used to solve a problem are based on obfuscated and confused understanding, then the output may not answer the question investigated.

Until fairly recently the study of embryology has been based on detailed examination of histological sections of embryos at different developmental stages: an understanding of cells, tissues and extracellular spaces in 3D; and the use of specific staining techniques to compare sections of normal, perturbed or chimeric embryos. Today many computer programs based on cell or gene ontologies, devised and specified some years ago, are making predictions about developmental mechanisms. New research outcomes are curated and updated in the main by other computer algorithms, with human curation of only a small proportion of the uploaded data. The concepts used to explain developmental processes have evolved in step with an increased understanding of gene expression, common embryonic mechanisms, cell–cell and cell–matrix interactions, and newly discovered transitory embryonic cell populations. However, it is perhaps now no longer possible to modify how embryonic processes are (re) conceptualized in the light of new knowledge, because the language used when computer ontologies were first devised cannot be revised. The earlier freedom for exploration of concepts and theories, their revision in the light of new discoveries and the development of new thoughts and language, may no longer be possible. As computers are now able to devise their own algorithms, learning from their past searches, the original concepts and thoughts concerning embryological mechanisms and interaction may become changed in ways not yet apparent, and certainly not transparent.

CHAPTER 12

Cell populations at the start of organogenesis

SPECIFICATION OF THE BODY AXES AND THE BODY PLAN

Embryos can be thought of as being constructed with three orthogonal spatial axes (cephalocaudal, dorsoventral and laterolateral), plus a temporal axis. In mammalian embryos, axes cannot be specified at very early stages: embryonic axes can be defined only after the early extraembryonic structures have been formed and the inner cell mass can be seen. The position of the future epiblast can be predicted in human embryos when the hollow blastocyst has formed. The inner cell mass becomes (seemingly) randomly located on the inside of the trophectoderm and forms a population of epiblast cells subjacent to the trophoblast. This region implants first. It is not known whether the trophectoderm in contact with the inner cell mass initiates implantation, so that the future dorsal surface of the embryo is closest to the disrupted maternal vessels at the implantation site, or whether the inner cell mass can travel around the inside of the trophoblast to gain a position subjacent to the implantation site once implantation has started.

Axes may be conferred on the whole embryonic disc, which is initially flat and mainly two-dimensional. However, their subsequent orientation in the folded three-dimensional embryo will be completely different. The dorsal structures of the folded embryo form from a circumscribed central ellipse of the early flat embryonic disc (see Fig. 10.5). Lateral and ventral structures form from the remainder of the disc, and the peripheral edge of the disc eventually becomes constricted at the umbilicus (see Figs 10.9–10.10). Although the appearance of part of the epiblast is taken to specify the dorsal surface of the embryo, the inner layer, i.e. the hypoblast, is not, by default, a ventral embryonic structure.

The primary, cephalocaudal, axis is conferred by the appearance of the primitive streak in the bilaminar disc. The primitive streak patterns cells during ingression, and so also specifies the dorsoventral axis, which becomes apparent after embryonic folding. The position of ingression through the streak confers axial, medial or lateral characteristics on the forming mesenchyme cells. The axial and medial populations remain as dorsal structures in the folded embryo, and the surface ectoderm above them will exhibit dorsal characteristics. The lateral plate mesenchyme will assume lateral and ventral positions after embryonic folding, and the surface ectoderm above this population will gain ventral characteristics. The third and last spatial axis is the bilateral, or laterolateral, axis, which appears as a consequence of the development of the other two axes. Initially, the right and left halves of the embryonic body are bilaterally symmetric. Lateral projections, the upper and lower limbs, develop in two places on each side of the body wall (somatopleure).

With the last axis established, the temporal modification of the original embryonic axes can be seen. The segmental arrangement of the cephalocaudal axis is very obvious in the early embryo and is retained in many structures in adult life. Similarly, dorsal embryonic structures remain dorsal and undergo relatively little change. However, structures that were originally midline and ventral, especially those derived from splanchnopleuric mesenchyme, e.g. the cardiovascular system and the gastrointestinal tract and its adnexae, are subject to extensive shifts, and change from a bilaterally symmetric arrangement to an entire body that is now chiral, i.e. has distinct left and right sides.

Organogenesis, the development of all the body organs and systems, begins after the dramatic events of gastrulation, when the embryo has attained a recognizable body plan. In human embryos, this corresponds to the end of stage 10 (**Fig. 12.1**). The head and tail folds are well formed, with enclosure of the foregut and hindgut (proenteron and metenteron), although the midgut (mesenteron) is only partly constricted from the yolk sac. The forebrain projection dominates the cranial end of the embryo, and the buccopharyngeal membrane and cardiac prominence are caudal and ventral to it. The cardiac prominence contains the transmedian pericardial cavity, which communicates dorsocaudally with right and left pericardioperitoneal canals. These pass dorsally to the transverse septum mesenchyme and open caudally into the extraembryonic coelom on each side of the midgut. The intraembryonic mesenchyme has begun to differentiate and the paraxial mesenchyme is being segmented into somites. Neural groove closure is progressing caudally, so that a neural tube is forming between the newly segmenting somites. Rostrally, the early brain regions, which have not yet fused, can be discerned. The neuroepithelium is separated from the dorsal aspect of the gut by the notochord. The earliest blood vessels have appeared and a primitive tubular heart occupies the pericardium. The chorionic circulation is soon to be established, after which the embryo rapidly becomes completely dependent on the maternal blood stream for its requirements. The embryo is connected to the developing placenta by a mesenchymal connecting stalk in which the umbilical vessels develop, and that also contains the allantois, a hindgut diverticulum. The lateral body walls are still widely separated. The embryo has contact with three different vesicles, namely, the amnion, which is in contact with the surface ectoderm; the yolk sac, which is in contact with the endoderm; and the chorionic cavity, containing the extraembryonic coelom, which is in contact with the intraembryonic coelomic lining (see Fig. 10.10).

The early body plan of the embryo is segmented. The boundaries between the segments are maintained by the differential expression of genes and proteins that restrict cell migration in these regions. Organogenetic processes either retain the segmental plan, e.g. spinal nerves, or replace it locally, e.g. the modifications of somatic intersegmental vessels by the development of longitudinal anastomoses. Anomalies may result from improper specification of segments along the cephalocaudal axis and may fail to produce the appropriately modified segmental plan.

The degree to which vertebrate embryos are developmentally constrained at this period of development is controversial. Comparative studies on the timing at which specific embryonic structures appear, heterochrony, have shown that other embryonic species do not follow the same developmental sequence as humans (Richardson and Keuck 2002). Although some developmental mechanisms are highly conserved, e.g. the homeobox gene codes, others may have been dissociated and modified in different vertebrate species during evolution.

Organogenesis, the further development of body regions and organs that is described in this Section, starts from about stage 10 (postfertilization days 28–29). Although it is both conventional and convenient to consider the further development of each body system on an individual basis, not only do all systems develop simultaneously, but also they interact and modify each other as they develop. This necessary interdependence is supported by the evidence of experimental embryology and reinforced by the phenomena of growth anomalies, which cut across the artificial boundaries of systems in most instances. For these reasons, it is recommended that the development of an individual system or body region should be studied in relation to others, especially those most closely associated with it, whether spatiotemporally or causally.

EMBRYONIC CELL POPULATIONS AT THE START OF ORGANOGENESIS

The developmental processes operating in the embryo between stages 5 and 9 enabled the construction of the bi- and trilaminar embryonic disc, the intraembryonic coelom and new proliferative epithelia. From the end of stage 10 a range of local epithelial and mesenchymal populations now interact to produce viscera and appendages. The inductive influences on these tissues and their repertoire of responses are very different from those seen at the onset of gastrulation. The range of tissues present at the start of organogenesis, when the body plan is clear, is given below (see Fig. 12.1; **Fig. 12.2**). A summary of the fates of the embryonic cell populations is given in **Fig. 12.3**.

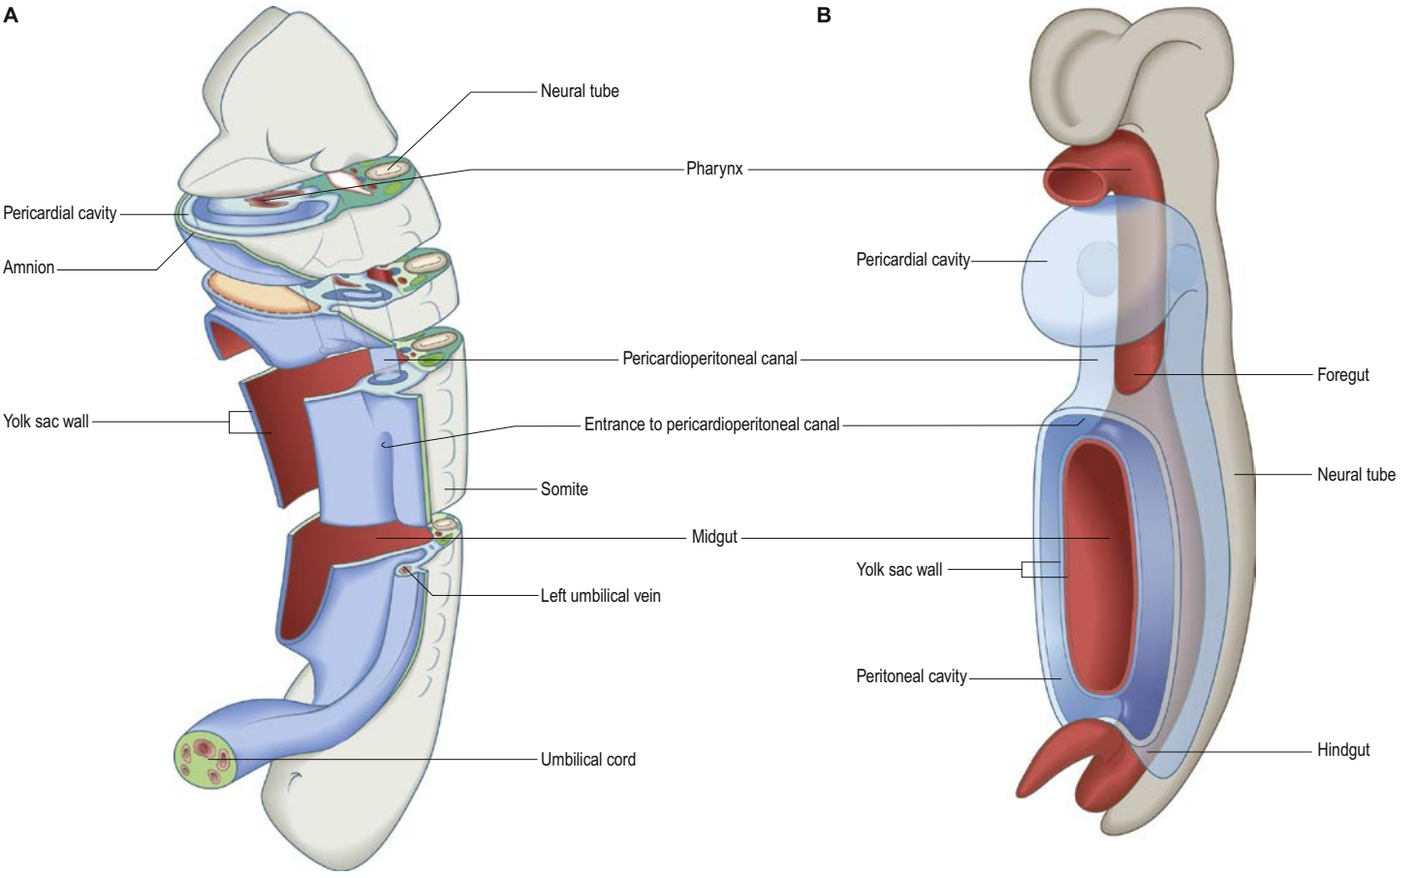

Fig. 12.1 **A**, The embryo at stage 11, showing the position of the intraembryonic coelom (contained by the walls coloured blue). **B**, The three major epithelial populations within a stage 11 embryo, viewed from a ventrolateral position. The neural tube lies dorsal to the gut. Ventrally, the intraembryonic coelom crosses the midline at the level of the foregut and hindgut, but is lateral to the midgut and a portion of the foregut.

Epithelial populations in the embryo

All epithelial populations express the cell polarity genes *Crumbs*, *Scribble* and *Baz/PAR-3* (Ch. 10). They all display apical specializations, including primary cilia and microvilli, juxtaluminal junctions and, when not actively dividing, temporally and spatially specified basal laminae. Movement of fluid or proteins is limited between epithelial populations, creating barriers between developing tissues and organs.

Surface ectoderm

During embryogenesis, the surface ectoderm shows regional differences in thickness. Ectoderm over the dorsal region of the head and trunk is thin, as is the pericardial covering; this has been interpreted as a consequence of the expansion of this epithelium over structures that are enlarging rapidly as development proceeds. After the surface ectoderm has completed a number of early interactions it forms an upper layer, the periderm, which remains throughout fetal life, and a lower layer which differentiates into epidermis.

Ectodermal ring and ectodermal placodes

The ectoderm on the head and lateral borders of the embryo shows a zone of epithelial thickening, the ectodermal ring, which can be discerned from stage 10 and is completed by stage 12. Rostrally, it contains populations of neuroectoderm that remain in the ectoderm after primary neurulation and are termed ectodermal placodes. The latter may be considered to be neuroepithelial cells that remain within the surface ectoderm until central nervous system development has progressed sufficiently for their inclusion into sensory epithelia and cranial nerve ganglia. The neuronal placodes may either invaginate *in toto* to form a vesicle, or remain as a neuronal layer, or contribute individually to neuronal structures with cells of other origins. A midline ectodermal thickening, the adenohypophysial placode, invaginates as Rathke's pouch and forms a vesicle immediately rostral to the buccopharyngeal membrane. The ectodermal ring then passes bilaterally to encompass the olfactory and optic placodes, which give rise to the olfactory sensory epithelium and the lens of the eye, respectively. It then overlays the pharyngeal arches, where it gives rise to epibranchial placodes which remove themselves individually from the ectoderm at stage 10–11 and become associated with the neural crest cells within the cranial sensory ganglia supplying the arches. It also forms specializations of the ectoderm on the frontonasal, maxillary and mandibular processes, which give rise to the tooth buds and the outer coating of the teeth. The paired otic placodes overlying the rhombencephalon at the lateral portion of the second pharyngeal arch invaginate to form the otic vesicles, which give rise to the membranous labyrinth of the ear. The ectodermal ring then passes over the occipital and cervicothoracic parts of the embryo, superficial to the four occipital somites and later to the occipitocervical junction. Further caudally, it is associated with the upper limb field, where it will give rise to the apical ectodermal ridge. O'Rahilly and Müller (1985) have called the portion of the ring between the upper and lower limbs the intermembral part. It overlies the underlying intraembryonic coelom, and later (between stages 12 and 13), the mesonephric duct and ridge. In stages 14–15 this portion of the ectodermal ring gives rise to the mammary line. In the unfolded embryo, caudal to the lower limb field, the ring passes distal to the cloacal membrane. In the folded embryo, this region becomes superior to the cloacal membrane and corresponds to the ectoderm associated with the external genitalia, particularly the genital tubercle and urogenital swellings, where it influences the internal and external descent of the testis and the formation of the inguinal canal.

Neural ectoderm

The neuroepithelium at the time of primary neurulation is pseudostratified. It has a midline hinge region, which, with concomitant wedging of the cells in the lateral wall of the neural groove, promotes neural tube formation. The processes of the neuroepithelium abut on to internal and external limiting membranes. This epithelium proliferates to form all the cell lines of the central nervous system and, via the production of neural crest, all the cell lines of the peripheral nervous system.

Notochord

During stage 10 the notochordal plate undergoes a process that is similar to, but a mirror image of, neurulation, and forms an epithelial tube from caudal to rostral, ending with the pharynx. The notochordal plate forms a deep groove, the vertical edges of the groove move medially and touch, and then the endodermal epithelium from each side fuses ventral to the notochord. The cells swell and develop an internal

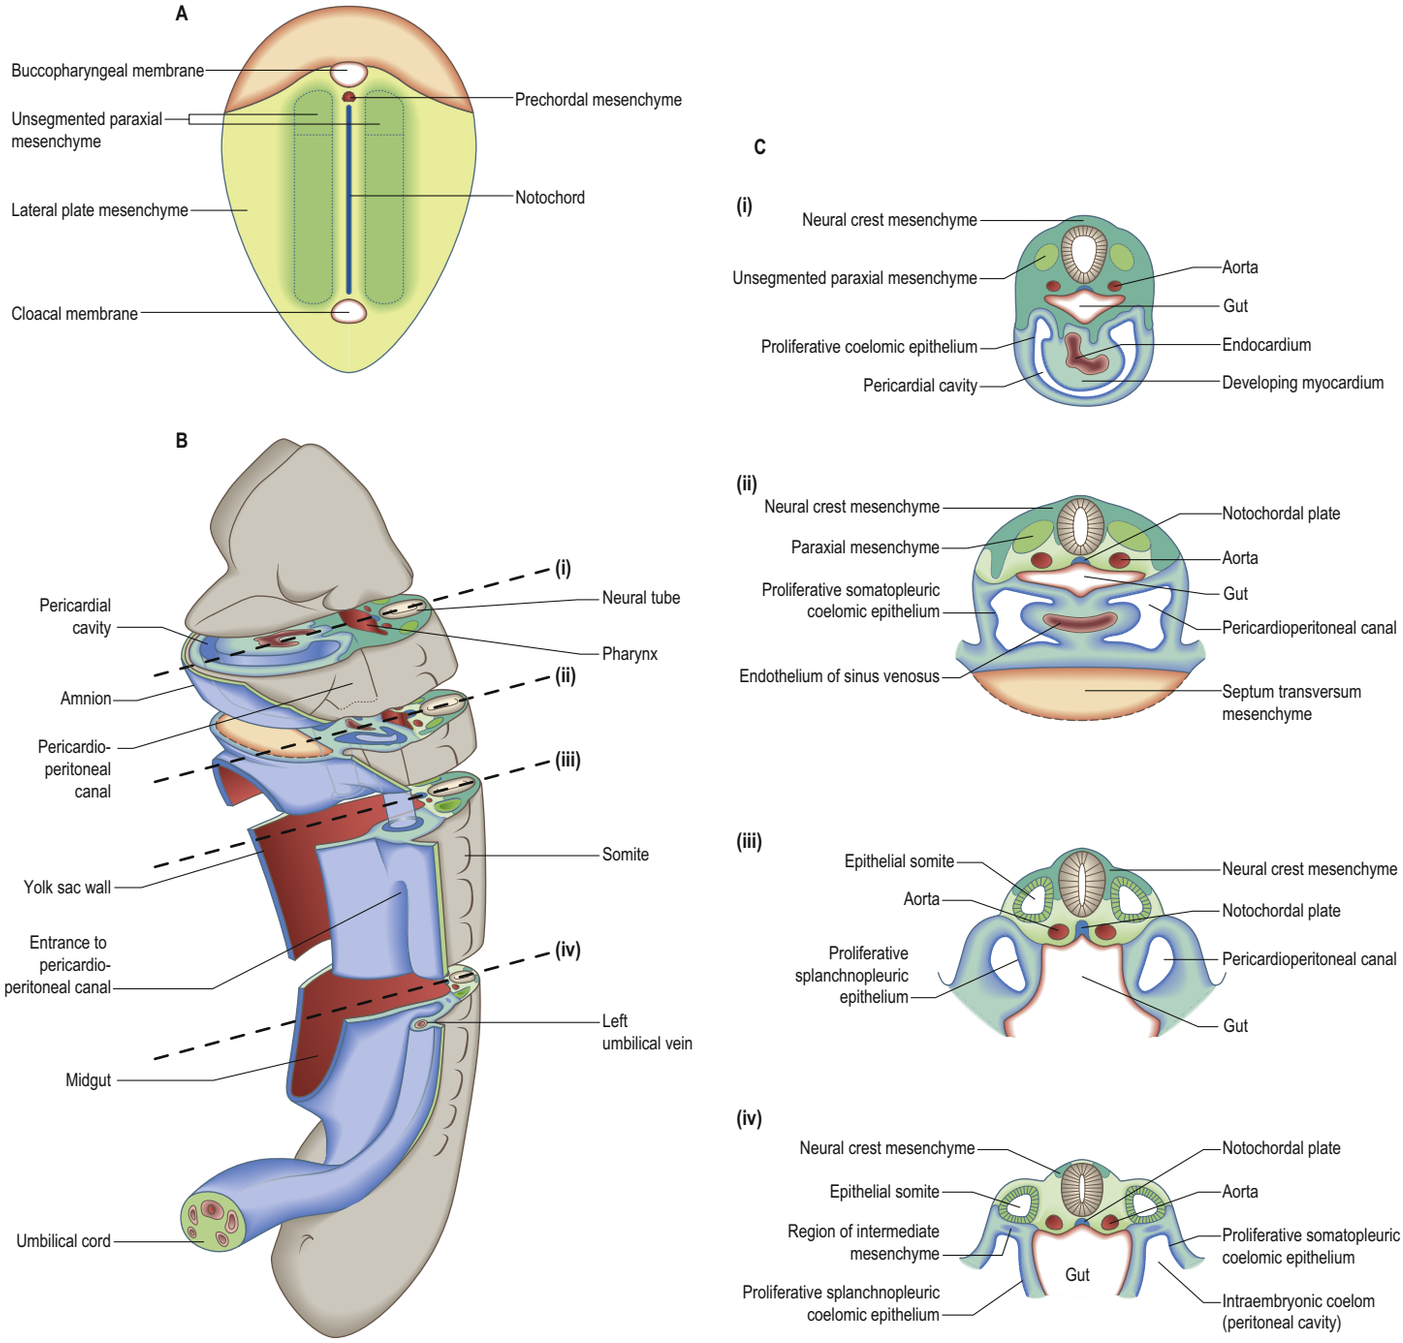

Fig. 12.2 A, Mesoblast populations within the early embryonic disc. **B**, A stage 11 embryo, showing the position of the intraembryonic coelom (contained by the walls coloured blue) and the positions of the sections (i)–(iv) shown in **C**. **C**, Transverse sections, arranged cranial to caudal, from a stage 11 embryo; the populations of mesenchyme and the sites of mesenchymal proliferation are indicated.

pressure (turgor) that confers rigidity on the notochord. The notochord is surrounded by a basal lamina, which is initially connected to a basement membrane, referred to as a perinotochordal sheath (Trapani et al 2017); this term is subsequently applied to mesenchymal populations that surround the notochord. After stage 11 the tubular notochord is in contact with the neural tube dorsally and the endoderm ventrally. It is not a proliferative epithelium, but it has inductive effects on the overlying neural tube and the adjacent somites, and later provides a focus for sclerotomal migration.

Endoderm

The craniocaudal progression of development means that the endoderm of the early stomodeum develops ahead of other portions of the endodermal epithelium. The development of the pharyngeal arches and pouches (Ch. 17) is closely associated with the development of the neural ectoderm and proliferation of the neural crest. The respiratory diverticulum arises slightly later, when the postpharyngeal gut may also be distinguished. The endoderm gives rise to the epithelial lining of the respiratory and gastrointestinal tracts, the biliary system, and the urinary bladder and urethra.

Coelomic epithelium

The coelomic epithelium lines the intraembryonic coelom, which is subdivided into a midline pericardial cavity, two bilateral pericardioperitoneal canals, and (initially bilateral) peritoneal cavities which are continuous with the extraembryonic coelom. The coelomic epithelium is a germinal epithelium. It produces the myocardium and connective tissue populations for the viscera, and gives rise to the supporting cells for the germ cells, the epithelial lining of the urogenital tracts, and the mesothelial lining of the pericardial, pleural and peritoneal cavities.

Somites

Somites are discrete epithelial spheres formed by the transformation of paraxial mesoblast cells to epithelium once their migration is complete. Specific regions of somitic epithelium form local proliferative centres. Like neural and coelomic epithelium, somatic epithelium produces cells destined for different fates, at different developmental times. Somites can be seen on each side of the fusing neural tube in the human embryo from stage 9. Development proceeds in a craniocaudal direction: the original epithelial somites form the base of the skull and the vertebral

Endoderm epithelium	Coelomic wall epithelium	Mesenchyme
Primitive gut **Foregut** – recesses, diverticula and glands of the pharynx. General mucous glandular and duct-lining cells and the main follicular cells of the thyroid. Epithelium of pharyngeal pouches (tonsil, middle ear cavity, thymus, parathyroids 3 and 4, C cells of thyroid), adenoid, epithelial lining of the auditory tube, tympanic cavity, tympanic antrum, internal lamina of the tympanic membrane. **Respiratory tract** – epithelial lining, secretory and duct-lining cells of the trachea, bronchi, bronchioles and alveolar sacs. Epithelial lining, secretory and duct-lining cells of the oesophagus, stomach and duodenum. Hepatocytes of liver, biliary tract, exocrine and endocrine cells of the pancreas. **Midgut** – epithelial lining, glandular and duct-lining cells of the duodenum, jejunum, appendix, caecum, part of transverse colons. **Hindgut** – epithelial lining, glandular and duct-lining cells of part of the transverse, descending and sigmoid colons, rectum, upper part of anal canal. **Allantois** – urinary bladder, vagina, urethra, secretory cells of the prostate and urethral glands.	**Walls of intraembryonic coelom** **Primitive pericardium** – myocardium, parietal pericardium. **Pericardioperitoneal canals** – visceral, parietal and mediastinal pleura, pleuroperitoneal membranes contributing to diaphragm. *Splanchnopleuric epithelium* – visceral peritoneum of stomach, peritoneum of lesser and greater omenta, falciform ligament, lienorenal and gastrosplenic ligaments. *Somatopleuric epithelium* – parietal peritoneum. **Primitive peritoneal cavity** Splanchnopleuric epithelium – visceral peritoneal covering of mid- and hindgut, the mesentery, transverse and sigmoid mesocolons. Pronephros, epithelial lining of mesonephric ducts, vas deferens, epididymis, seminal vesicles, ejaculatory duct, ureters, vesical trigone. Müllerian ducts, epithelial lining of uterine tubes, body and cervix of uterus, vagina, broad ligament of uterus. Germinal epithelium of gonad (note the germ cells are not included on this chart because of their early sequestration into the extraembryonic tissues). Germinal epithelium forming cortex of suprarenal gland. *Somatopleuric epithelium* – parietal peritoneum, tunica vaginalis of testis.	**Paraxial mesenchyme** **(somites and somitomeres)** *Sclerotome* – vertebrae and portions of the neurocranium, axial skeleton. *Myotome* – all voluntary muscles of the head, trunk and limbs. Dermatome – dermis of skin over dorsal regions. **Intermediate mesenchyme** – connective tissue of gonads, mesonephric and metanephric nephrons, smooth muscle and connective tissues of the reproductive tracts. **Septum transversum** – epicardium, fibrous pericardium, portion of diaphragm, oesophageal mesentery, sinusoids of liver, tissue within lesser omentum and falciform ligament. **Lateral plate mesenchyme** *Splanchnopleuric layer* – smooth muscle and connective tissues of respiratory tract and associated glands. Smooth muscle and connective tissues of intestinal tract, associated glands and abdominal mesenteries. Smooth muscle and connective tissue of blood vessels (also see below). *Somatopleuric layer* – appendicular skeleton, connective tissue of limbs and trunk, including cartilage, ligaments and tendons. Dermis of ventral body wall and limbs. Mesenchyme of external genitalia. **Angiogenic mesenchyme** Endocardium of heart, endothelium of blood and lymphatic vessels, vessels of choroid plexus, sinusoids of liver and spleen, circulating blood cells, microglia, tissue macrophages.

Surface ectoderm epithelium	Neural plate epithelium	Neural crest
Ectodermal placodes Adenohypophysis. Sensory neurones of the cranial ganglia V, VII, VIII, IX, X. Olfactory receptor cells and olfactory epithelium. Epithelial walls of the membranous labyrinth, the cochlear organ of Corti. Lens of the eye. Enamel organs of the teeth. **Cranial structures** Secretory and duct-lining cells of the lacrimal, nasal, labial, palatine, oral and salivary glands. Epithelia of the cornea and conjunctiva. Epithelial lining of the external acoustic meatus and external epithelium of the tympanic membrane. Epithelial lining of the lacrimal canaliculi and nasolacrimal duct. Epithelial lining of the paranasal sinuses, lips, cheeks, gums and palate. **Epidermal structures** Most of the cutaneous epidermal cells, the secretory, duct-lining and myoepithelial cells of the sweat, sebaceous and mammary glands. Hair and nails. Proctodeal epithelium and epithelium of the terminal male urethra.	**CNS – Brain and spinal cord** Neurohypophysis. Prosencephalon (telencephalon and diencephalon) – cerebral hemispheres, basal nuclei. Mesencephalon – cerebral peduncles, tectum, tegmentum. Rhombencephalon (metencephalon and myelencephalon) – cerebellum, pons, medulla oblongata. Spinal cord. All cranial and spinal motor nerves. All CNS neurones, including preganglionic efferent neurones, that have somata within the CNS. Astrocytes and oligodendrocytes. Ependyma lining the cerebral ventricles, aqueduct and central canal of the brain and spinal cord, tanycytes, cells covering the choroid plexuses, circumventricular cells. Retina and optic nerve (II), epithelium of the iris, ciliary body and processes.	**Neural derivatives** Sensory neurones of the cranial ganglia V, VII, VIII, IX, X. Sensory neurones of the spinal dorsal root ganglia and their peripheral sensory receptors. Satellite cells in all sensory ganglia. Sympathetic ganglia and plexuses: neurones and satellite cells. Parasympathetic ganglia and plexuses: neurones and satellite cells. Enteric plexuses: neurones and glial cells. Schwann cells of all the peripheral nerves. Medulla of the suprarenal gland. Chromaffin cells. Carotid body type I cells (and type II, satellite type cells). Calcitonin-producing cells (C cells). Melanocytes. **Mesenchymal derivatives in the head** Frontal, parietal, squamous temporal, nasal, vomer and palatine bones, maxillae and mandible. Meninges. Choroid and sclera of eye. Connective tissue of lacrimal, nasal, labial, palatine, oral and salivary glands. Dentine of teeth. Connective tissues of head, including cartilage, ligaments and tendons. Connective tissues of thyroid gland and of the pharyngeal pouches, i.e. parathyroid glands, thymus. Tunica media of the outflow tract of the heart and the great vessels.

Fig. 12.3 Structures that will be derived from specific epithelial and mesenchymal populations in the early embryo. Abbreviation: CNS, central nervous system.

column and ribs and the dorsolateral portion, the dermomyotome, gives rise to the majority of the skeletal muscle of the body, including that in the limbs.

The relative dispositions of the neural, endodermal and coelomic epithelia are shown in Fig. 12.1.

Mesenchymal populations in the embryo

The term 'mesenchyme' refers to the three-dimensional arrangement of unrestricted and undetermined cell populations (expressing a range of surface signalling molecules and receptors), and the extracellular secretions of these cells (collectively producing the extracellular matrix (ECM), e.g. collagens, elastins, proteoglycans and glycosaminoglycans (GAGs)). The proportions of fibrous extracellular proteins (collagens) and the hydrophilic GAGs are important, because they confer turgidity and stiffness on developing tissues, open migration routes and provide 'signposts' for cellular interactions by facilitating the local deposition of growth factors (Ch. 11) (Loganathan et al 2016). Understanding the interactions between ECM stiffness, the mechanotransduction of forces within early mesenchymal populations, and how these interact in an epigenetic manner during development, has become an important topic of study (Hadden et al 2017).

In a stage 10 embryo the major mesenchymal populations are in place. Mesoblast is still being generated at the primitive streak and moving into the presomitic mesenchymal population adjacent to the notochord and some mesoblast is also contributing to the lateral regions of the embryo. The different mesenchymal populations within the embryo from stage 10 onwards are described below. The relative dispositions of the early mesenchymal populations are shown in Fig. 12.2.

Axial mesenchyme

The first epiblast cells to ingress through the primitive streak form the endoderm and notochord, and initially occupy a midline position. The earliest population of endodermal cells rostral to the notochordal plate is termed the prechordal plate. The notochordal cells remain medially and the endodermal cells subsequently flatten and spread laterally. The population of cells that remain mesenchymal in contact with the floor of the neural groove, just rostral to the notochordal plate, is the prechordal mesenchyme (**Fig. 12.4**). These axial mesenchyme cells are tightly packed, unlike the more lateral paraxial cells but, unlike the notochord, they are not contained in an extracellular sheath. They are displaced laterally at the time of head flexion and form bilateral premandibular mesenchymal condensations. They become associated with the local paraxial mesenchyme. Experimental orthotopic grafting has demonstrated that these cells leave the edges of the prechordal mesenchyme and migrate laterally into the periocular mesenchyme, where they give rise to all of the extraocular muscles.

Paraxial mesenchyme

Mesenchyme adjacent to the notochord and developing neural tube is termed paraxial mesenchyme. It arises from epiblast cells that undergo epithelial to mesenchymal transition and ingress through the primitive streak. This population of cells is termed paraxial mesoblast when migrating; at their final destination the cells form epithelial structures. Those cells ingressing through the primitive node will form the medial part of the paraxial mesenchyme, and cells that ingress through the rostral streak will form the lateral part (see Fig. 10.3). Before somite formation, this mesenchymal tissue is also termed presomitic or unsegmented mesenchyme in mammals (analogous to the segmental plate in birds). Paraxial mesenchyme extends rostrally from the primitive streak to the prechordal plate, which is immediately rostral to the notochord.

Caudal to the otic vesicle, the paraxial mesenchyme on each side of the rhombencephalon segments into somites as the neural folds elevate and neurulation begins; somites are therefore post-otic. During somitogenesis, mesoblastic cells show changes in shape and in cell–cell adhesion. They undergo mesenchymal to epithelial transformation and become organized into epithelial somites: this process begins at the eighth somitomere, just caudal to the midpoint of the notochordal plate (Ch. 18). Somite one is also termed the first occipital somite. The post-otic paraxial cell population is termed paraxial mesoderm in contemporary literature.

Skeletal muscle throughout the body is derived from paraxial mesoblast-derived somatic epithelium, which proliferates to form myoblastic populations that migrate to the head, body and limbs.

Septum transversum

Early mesenchyme that invaginates through the middle part of the primitive streak comes to lie rostral to the buccopharyngeal membrane, where the cells undergo mesenchymal to epithelial transformation to form the wall of the pericardial coelom. As this epithelium proliferates, the visceral pericardial wall gives rise to myocardium. The parietal pericardial wall forms mesenchyme, initially termed precardiac, or cardiac, mesenchyme, which is able to induce proliferation of hepatic endodermal epithelium. With further proliferation, the precardiac mesenchyme forms a ventral mass caudal to the heart, the septum transversum, which separates the foregut endoderm from the pericardial coelom (see Fig. 12.2). By stage 11 the septum transversum extends dorsally on each side of the developing gut and becomes continuous with the mesenchymal populations that proliferate from the walls of the pericardioperitoneal canals. Cells of the septum transversum give rise to the sinusoids of the liver, the central portions of the respiratory diaphragm and the epicardium (visceral layer of serous pericardium).

Neural crest

The neural crest is a unique mesenchymal population. It arises from stage 10 onwards from cells that lie initially at the outermost edges of the neural plate, between the presumptive epidermis and the neural tube, and become committed to a neural crest lineage before the neural plate begins to fold. The neural crest gives rise to neuronal populations in the head and trunk, and provides an extensive non-neuronal mesenchymal population in the head with attributes similar to somatopleuric mesenchyme in terms of patterning. After neurulation, neural crest cells form a transient axial population and then disperse, in some cases migrating over considerable distances, to a variety of different developmental fates. Unlike mesoblast, which is produced from the primitive streak, none of the cells that arise from the neural crest subsequently become epithelial. The development and fate of head and trunk neural crest cells are very different and therefore they will be considered separately.

Head neural crest

Head neural crest migrates before the neural tube closes: the crest cell population arising from the rostral neural plate is larger than that found at any trunk level. Each brain region has its own crest population that migrates dorsolaterally around the sides of the neural tube to reach the ventral side of the head. Crest cells surround the prosencephalic and optic vesicles, and occupy each of the pharyngeal arches (Ch. 17). They provide mesenchyme cells that will produce the connective tissue in parts of the neuro- and viscerocrania: all cartilage, bone, ligament, tendon, dermal components and glandular stroma in the head; and contribute to the tunica media of the aortic arch arteries.

Trunk neural crest

Unlike its counterpart in the head, trunk neural crest is formed as the neural tube closes rostrocaudally, which means that various stages of crest development can be found in the more caudal regions of an embryo. As the neural tube begins to fuse dorsally in the midline, the neural crest cells lose their epithelial characteristics and junctional connections, and form a band of loosely arranged mesenchyme cells immediately dorsal to the neural tube and beneath the ectoderm. Initially, most of the crest cells lie with their long axes perpendicular to the long axis of the neural tube. Later, the cell population expands laterally and around the neural tube as a sheet. Trunk neural crest cells move from their position dorsal to the neural tube via three routes: dorsolaterally, to form dorsal root ganglia throughout the trunk; ventrally, to form sympathetic ganglia, enteric nerves and the suprarenal medulla; and rostrocaudally, along the aorta, to form the pre-aortic ganglia (see Fig. 14.6). In a second migration route, crest cells pass dorsolaterally between the ectoderm and the epithelial plate of the somite into the somatopleure, where they eventually form melanocytes in the skin.

Lateral plate

Lateral plate is the term for the early unsegmented mesoblast population lateral to the paraxial mesenchyme. Mesoblastic cells that arise from the middle of the primitive streak (primary mesenchyme) migrate cranially, laterally and caudally to reach their destinations, where they undergo mesenchymal to epithelial transformation to form a continuous layer subjacent to the ectoderm dorsally and the endoderm ventrally. The epithelium faces a new intraembryonic cavity, the intraembryonic coelom, which becomes confluent with the extraembryonic coelom and provides a route for the circulation of coelomic fluid through the embryo. Once formed, the intraembryonic coelomic wall becomes a proliferative epithelium that produces new populations of mesenchymal cells. The mesenchymal population subjacent to the ectoderm is termed somatopleuric mesenchyme, produced by the somatopleuric coelomic epithelium. The mesenchymal population surrounding the endoderm is termed splanchnopleuric mesenchyme, produced by the splanchnopleuric coelomic epithelium (see Fig. 12.2).

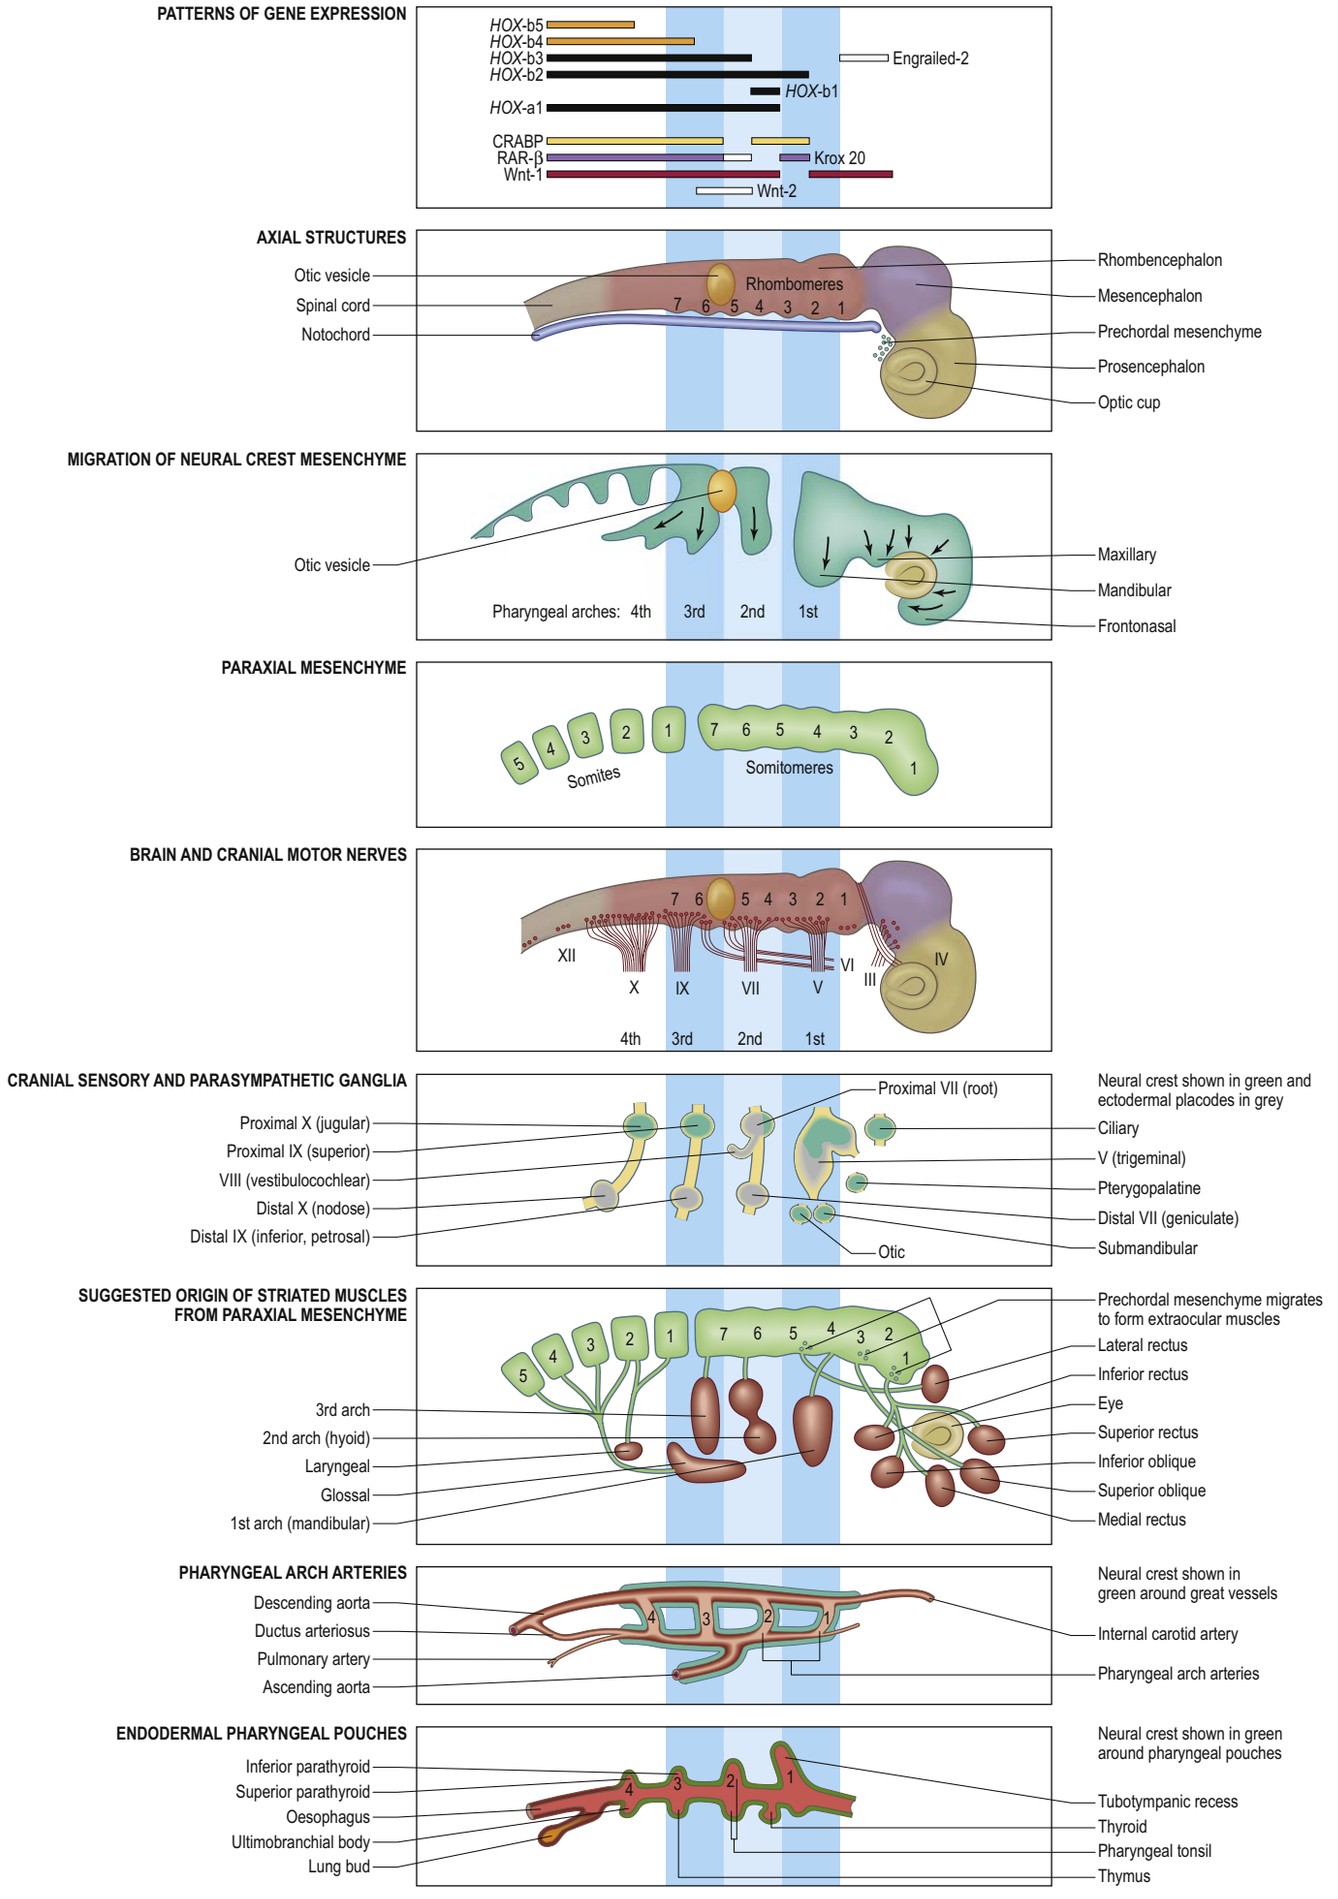

Fig. 12.4 The organization of the head and pharynx in an embryo at about stage 14. The individual tissue components have been separated but are aligned in register through the numbered zones.

It is important to note that these terms are relevant only caudal to the third pharyngeal arch. Rostral to this arch, there is a sparse mesenchymal population between the pharynx and the surface ectoderm prior to migration of the head neural crest, and there are no landmarks with which to demarcate lateral from paraxial mesenchyme. This unsplit lateral plate is believed to contribute to the cricoid and arytenoid cartilages, the tracheal rings and the associated connective tissue.

Somatopleuric mesenchyme

Somatopleuric mesenchyme produces a mixed population of connective tissues and has a significant organizing effect at the level of the developing limbs. The pattern of limb development is controlled by information contained in the somatopleuric mesenchyme. Regions of the limb are specified by interaction between the surface ectoderm (apical ectodermal ridge) and underlying somatopleuric mesenchyme and together these tissues form the progress zone of the limb. The somatopleuric mesenchyme in the limb bud also specifies the postaxial border of the developing limb. Somatopleuric mesenchyme gives rise to the connective tissue elements of the appendicular skeleton, including the bones, cartilages and associated ligaments and tendons of the pectoral and pelvic girdles and the limbs. It also gives rise to the dermis of the skin of the ventral and lateral body walls and of the limbs.

Splanchnopleuric mesenchyme

Splanchnopleuric mesenchyme surrounds the developing gut and respiratory tubes, contributing connective tissue cells to the lamina propria and submucosa, and smooth muscle cells to the muscularis mucosae and muscularis externa. It plays a patterning role in endodermal development, specifying the region and villus type in the gut, and the branching pattern in the respiratory tract.

Intermediate mesenchyme

Intermediate mesenchyme is a loose collection of cells found between the somites and the lateral plate (see Fig. 12.2). Its development is closely related to the progress of differentiation of the somites and the proliferating coelomic epithelium from which it is derived. Intermediate mesenchyme is not present before somitogenesis or the formation of the eighth somite. In embryos with 8–10 somites, it is present lateral to the sixth somite but does not extend cranially. The mesenchyme cells are arranged as layers, one continuous with the dorsal side of the paraxial mesenchyme and the somatopleure, the other with the ventral side of the paraxial mesenchyme and the splanchnopleure.

As development proceeds, the intermediate mesenchyme forms a loosely packed dorsolateral cord of cells that lengthens at the caudal end and ultimately joins the cloaca: it gives rise to the nephric system, gonads and reproductive ducts.

Angioblastic mesenchyme

Mesenchymal cells that give rise to the cellular elements of the blood, the endothelium and the mesenchymal layers of the tunica externa and tunica adventitia of blood and lymphatic vessels, arise initially from extraembryonic and later from intraembryonic sources. Evidence suggests that endodermal tissues are necessary for endothelial differentiation, particularly in the early foregut. Angioblastic mesenchyme forms early in postfertilization week 3 from extraembryonic mesenchyme in the splanchnopleure of the yolk sac, in the body stalk (containing the allantois), and in the somatopleure of the chorion. Later, contiguous islands merge, forming a continuous network of fine vessels. Intraembryonic blood vessels are first seen at the endoderm–mesenchyme interface within the lateral splanchnic mesenchyme at the caudolateral margins of the cranial intestinal portal. Angioblastic competence has been demonstrated within the ventral (splanchnopleuric) mesenchyme with which the endoderm interacts. The notochord and prechordal plate do not contain angiogenic cells and ectodermal tissues do not appear to give rise to angiogenic cells. Somites, derived from paraxial mesenchyme, have been shown to be a source of angioblasts that either differentiate with the somite derivatives, or migrate to the neural tube, ventrolateral body wall, limb buds, mesonephros and the dorsal part of the aorta.

The earliest angiogenic mesenchymal cells form blood vessels by vasculogenesis, a process in which new vessels (e.g. endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels) develop *in situ* (Ch. 13). Later vessels develop by angiogenesis, sprouting and branching from the endothelium of pre-existing vessels; this process is the means by which most other vessels develop. The ultimate pattern of vessels is controlled by the surrounding non-angiogenic mesenchyme: vessels become morphologically specific for the organ in which they develop, and immunologically specific, expressing organ-specific proteins. Blood cells also arise from extraembryonic tissues of the secondary yolk sac, with three overlapping waves of production as intraembryonic regions become seeded with haemopoietic stem cell precursors (Ch. 13). They are not derived from the same precursor populations that produce blood and lymphatic vessels.

CHAPTER
13

Development of the heart and circulation

The early embryonic circulation is symmetric (Fig. 13.1). It is modified throughout development to produce a functioning heart and fetal circulation that is connected to the placenta, and changes rapidly at birth to accommodate disconnection from the placenta and the start of gaseous exchange in the lungs. Major restructuring of early vessels occurs as the embryo grows; anastomoses form and then disappear, capillaries fuse and give rise to arteries or veins, and the direction of blood flow may reverse several times before the final arrangement of vessels is completed. Embryonic cell populations arise and become restricted to a cardiovascular phenotype in spatially and temporally defined interactions during the earliest stages of development.

Cells from mesenchyme derived from the midline splanchnopleuric coelomic epithelium initially form both the myocardium and the endocardial lining. Later, this splanchnopleuric coelomic epithelium is also the source of the epicardium, the coronary arteries and the interstitial fibroblasts of the heart. (The epicardium, sometimes included in descriptions of the myocardium as 'epimyocardium', is not present at early stages of heart development.) A further cell population of head neural crest mesenchyme that arises from the region between the otic vesicle and the caudal limit of somite 3 later migrates to the arterial pole of the heart and contributes to the formation of the valves and aortic arch arteries (see Fig. 17.9).

The position of the developing myocardium is intimately related to the formation of the intraembryonic coelom and the relative movement of that tubular structure during neurulation and somitogenesis. The splanchnopleuric wall of the early midline intraembryonic coelom, directly adjacent to the endoderm, is a horseshoe-shaped proliferative epithelium that produces cardiogenic mesenchyme. It is termed the

At this stage, the arteries and veins are in the process of development and no true circulation is yet established.

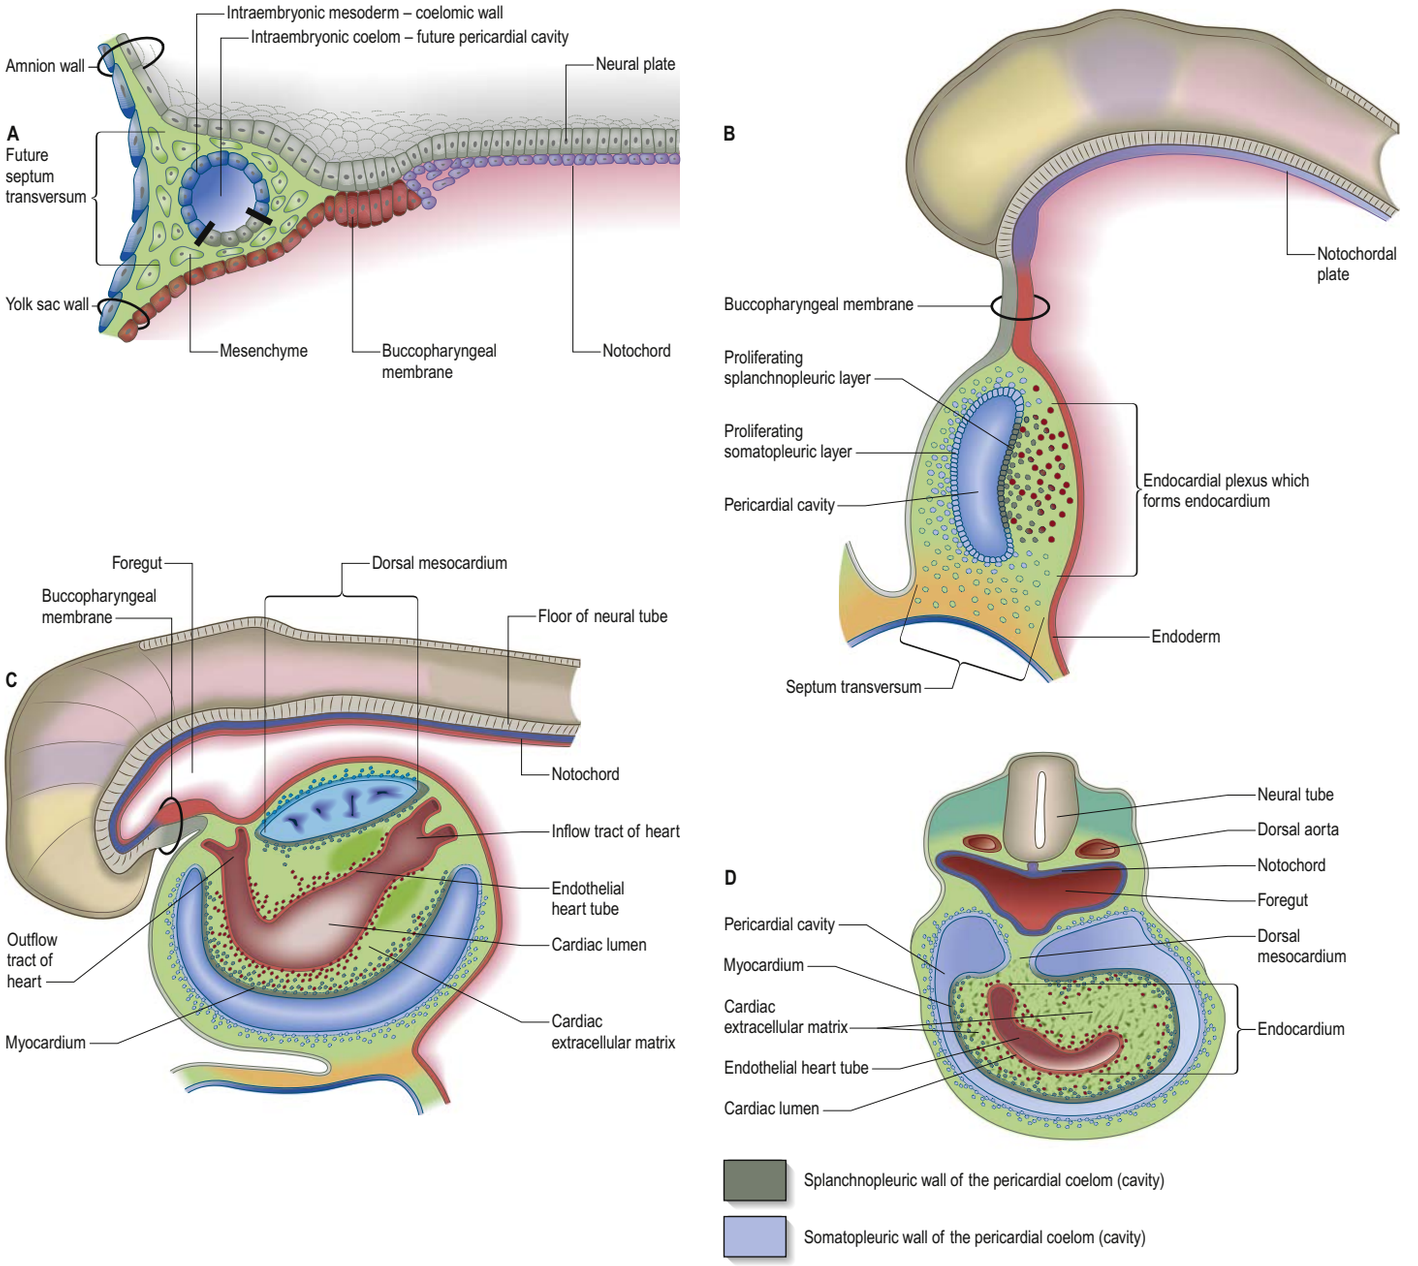

Fig. 13.3 **A**, A median section through part of the embryonic disc to show the position of the future pericardial cavity before head folding. **B**, A median section through the cranial end of a human embryo during early head folding, showing its reversal effect on the position of the pericardium. **C**, A median section through the cranial end of a human embryo after head folding, showing the pericardial cavity and endothelial heart tube now located ventral to the foregut. **D**, A horizontal section through the pericardium and endothelial heart tube shown in **C**. The position of the dorsal mesocardium, a source of secondary heart field mesenchyme, is indicated. Circles and dots denote cells migrating away from proliferating epithelia.

cardiac crescent or primary heart-forming field (Fig. 13.2) and is characterized by the expression of myocardium-specific markers, such as cardiac myosin and the cardiac transcription factor Nkx2-5. The area of the coelomic epithelium dorsomedial to the primary heart-forming field will later also add to the forming heart tube and is therefore named the secondary heart-forming field (see Fig. 13.2). These two myocardial fields may represent distinct myocardial lineages; they both express Islet1 but they sequentially add to different parts of the heart.

The endocardium that lines the cardiac lumen develops from the coelomic splanchnopleuric epithelium during stages 8 and 9. Individual endocardial cells arise from it close to the ventrolateral edges of the cranial intestinal portal and form an endocardial plexus between the splanchnopleuric coelomic epithelium and the foregut endoderm. This plexus of cells, formed initially by vasculogenesis and subsequently from angioblastic mesenchyme, is one of the earliest intraembryonic vascular precursors to appear. The cells express molecular markers of both the myocardial and the endothelial cell lineages, indicating that the endocardium has a different origin than other endothelial populations. The cells of the endocardial plexus aggregate to form two separate endocardial epithelial tubes that fuse across the midline, from the arterial pole to the venous pole, producing a single linear heart tube.

The development of the early heart is described below, followed by the formation of the early compartments of the heart and their later septation.

FORMATION OF THE HEART TUBE

During the process of embryonic head folding, the midline splanchnopleuric coelomic epithelium (now cardiogenic epithelium) becomes positioned ventral to the foregut; the portion of the intraembryonic coelomic cavity it surrounds is the future pericardial cavity (Fig. 13.3). Populations of cardiac myocytes now arise from the ventral proliferating coelomic epithelium and surround the endocardial linear heart tube forming the early myocardium; these cells will have undergone restriction, differentiation and most will have left the cell cycle (Ch. 11). The secondary heart-forming field proliferates and adds cells to this bilaminar heart tube after embryonic head folding. It has been suggested that the secondary heart-forming field only contributes cells to those cardiac components that are required for the pulmonary circulation: namely, the right ventricle and outflow tract at the arterial pole, and the dorsal atrial wall and atrial septum at the venous pole. However, a type of secondary heart-forming field can also be distinguished in zebrafish and other chordates that lack

a pulmonary circulation, implying that it is evolutionarily conserved independent of the presence of a pulmonary circulation (Sizarov et al 2016).

The pericardial cavity and myocardium gradually extend around the forming endocardial tube, leaving the dorsal mesocardium as a transient connection between the forming heart tube and the dorsal pericardial wall, analogous to the mesentery of the intestines (see Fig. 13.3C–D). The dorsal mesocardium is contiguous with the splanchnopleuric mesenchyme that surrounds the embryonic foregut and the developing lung buds and is the site of early mediastinal mesenchyme production. It disappears as a mesenteric entity in embryos with 8–12 somites. The partial breakdown of the dorsal mesocardium creates the transverse sinus of the pericardium that extends across the pericardial cavity from side to side, dorsal to the heart. Persisting dorsal mesocardium at the venous pole remains connected to the splanchnopleuric mesenchyme in which the pulmonary veins will develop; it is also confluent with the septum transversum mesenchyme, in which the liver will later develop.

By stage 10 (28–29 days postfertilization; embryonic stages 10–23 correlated to postfertilization days of development and postmenstrual weeks of pregnancy are shown in Fig. 23.3) a single endocardial tube is established that is almost completely surrounded by myocardial cells. This arrangement of an outer myocardial sleeve containing an inner endocardial tube constitutes the primary heart tube. The primary myocardium will not only give rise to the major parts of the conduction system of the heart, including the sinus node, the atrioventricular node, and the atrioventricular bundle, but also to part of the floor of the right atrium (the vestibule) and the entire atrioventricular canal. An enlarging space between the endocardial tube and the developing myocardium is filled by a meshwork of cardiac extracellular matrix proteins, produced by the cardiac myocytes, which promotes occlusion of some parts of the early heart tube during myocardial contraction and mechanical assistance for the generation of flow of early blood. There are heterochronic differences between species in these processes, for example, in the mouse, cardiac chambers start to form before a distinct linear heart tube has appeared.

Endocardial cushions

The extracellular matrix of the embryonic heart (see Fig. 13.3C–D), historically termed cardiac jelly, is composed of hyaluronic acid, hyaluronidase and fibronectin among other components. Inductive signals originating from the cardiac myocytes, such as BMP2 and TGF-β, lead to the activation of a subset of endocardial epithelial cells that will line the future atrioventricular canal and the proximal outflow tract; in the future left ventricle, endocardial cells do not undergo such an activation. The activated endocardial cells lose their cell-to-cell connections and undergo an epithelial to mesenchymal transition. Their expression of neural cell adhesion molecule (N-CAM) decreases and expression of substrate adhesion molecules such as chondroitin sulphate and fibronectin increases. Expression of type I procollagen is initiated and cytoskeletal re-arrangements facilitate cell migration into the cardiac extracellular matrix where they continue to proliferate. The cells and the locally accumulated extracellular matrix molecules, form the endocardial or cardiac cushions. Endocardial cushions initially function as valves in the embryonic heart: they give rise to the valves of the atrioventricular canal and the outflow tract and also supply the mesenchyme that is needed to complete the septation of the atria, ventricles and the outflow tract. This particular epithelial to mesenchymal transition may be the only example of a mesenchymal population derived from an endothelial lineage; endothelial to mesenchymal transformation may be relevant to later circulatory pathologies (Suzuki et al 2018, Kovacic et al 2019).

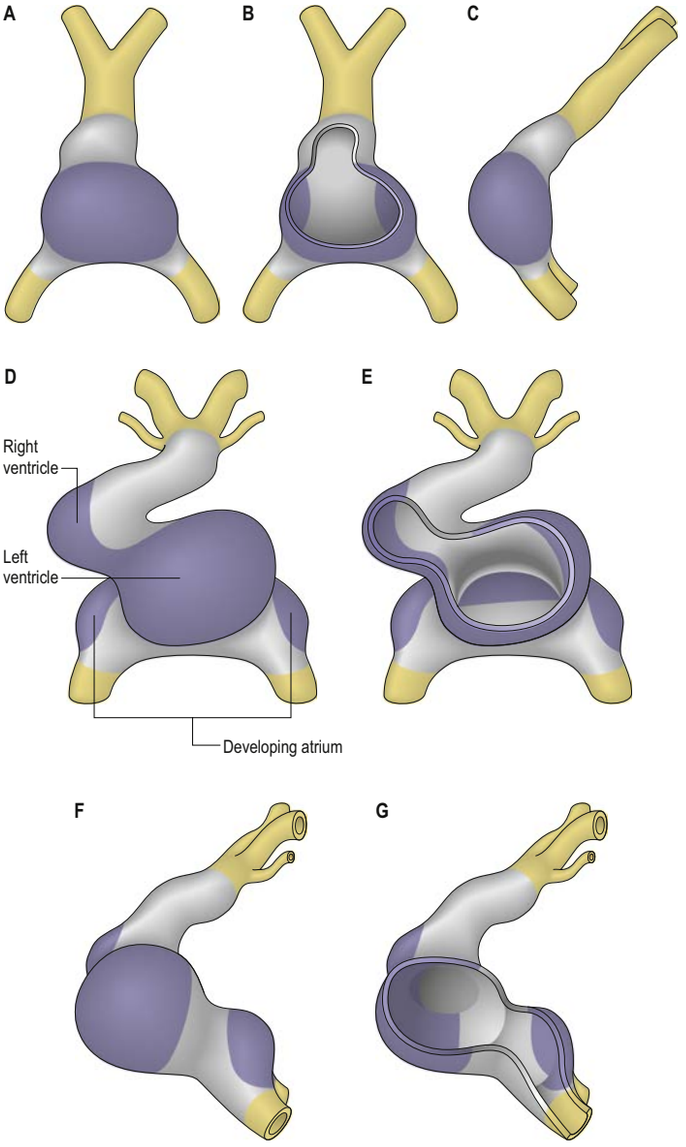

Fig. 13.4 Local expansion of the myocardial wall of the early heart tube and heart tube looping. **A**, Ventral view. **B**, The ventral wall has been removed to show the inner aspect of the early heart tube. **C**, Left lateral view. The early heart tube is shaped like an inverted 'Y'. The legs of the Y pass caudal to each side of the cranial intestinal portal. In the early heart tube, the myocardium of the stem of the Y (purple) contains only precursor cells for the left ventricle. The remaining myocardium (grey) contains only precursor cells for the atrioventricular canal and atria. The precursor left ventricular cells expand first. **D–G**, The later heart tube, showing looping. **D**, Ventral view. **E**, The ventral wall has been removed to show the inner aspect of the folding heart tube. **F**, Left lateral view. **G**, The lateral wall has been removed to show the inner aspect of the heart from the left. In **D** and **E**, the expansion of the right ventricle can be seen and the heart tube has elongated to the right. The developing atrium can be seen dorsolaterally in **D–G**.

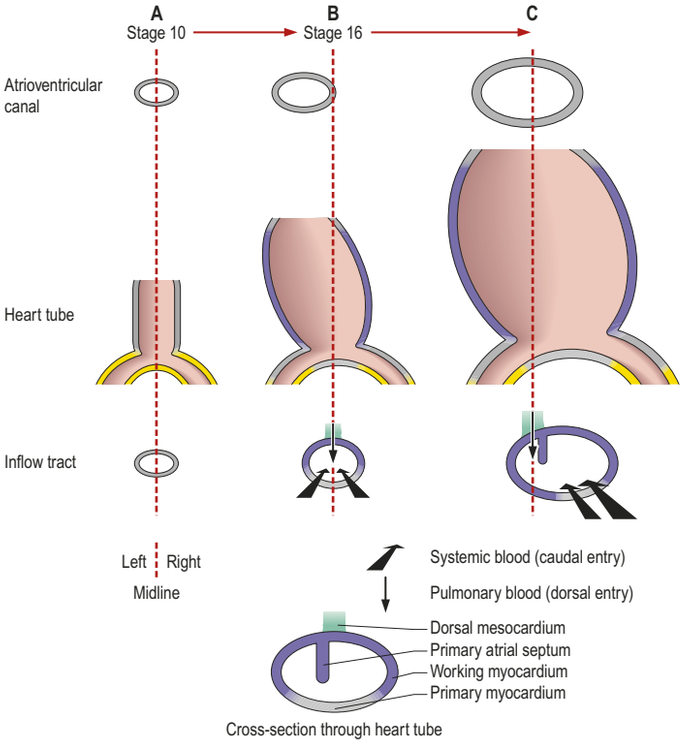
Looping of the heart tube

The early primary heart tube is initially bilaterally symmetric and has the form of an inverted 'Y'. The caudal 'legs' of the Y are positioned on either side of the cranial intestinal portal, where they form the venous pole of the heart (**Fig. 13.4A–C**). The rostral 'stem' of the Y connects cranially with the future aortic arch arteries, forming the arterial pole of the heart. From the start, both poles are connected with the systemic vessels that run from the embryo, yolk sac and placenta. The pulmonary veins form later, their initial venous primordium becoming evident in the dorsal mesocardial mesenchyme. Myocardium from the secondary heart-forming field continues to be added to the heart, forming the smooth dorsal wall of the left atrium, and providing the site where the primary atrial septum will form.

The putative cardiac segments are not present in the early linear heart tube. The definitive cardiac chambers are formed by local differentiation and expansion, or 'ballooning', of the myocardial walls of the primary heart tube, indicating that cardiac myocyte identity is dependent on genetic, spatial and temporal signals and lacks a fixed ontogeny. Genetic fate map studies have shown that the primary heart tube will contribute to only two compartments: the legs of the inverted Y of the primary heart tube contain precursor cells of the atrioventricular canal, while the stem of the inverted Y contains myocardial precursor cells of the left ventricle (van Eif et al 2018). The atrioventricular canal precursors finally reside in the left ventricular free wall and the cells of the original embryonic left ventricle largely end up in the left face of the ventricular septum. The embryonic outflow tract contributes to the right ventricle.

The nodal/pitx2/cited-2 signalling pathway that determines the formation of the morphologically left-sided or right-sided features in the lungs, bronchial tree, liver and spleen is also expressed in the heart outflow tract and atrial appendages (Ocaña et al 2017). The lengthening heart tube bends ventrally and rightwards, concomitant with the partial breakdown of the dorsal mesocardium. This bend is now named the ventricular loop because the left ventricle will balloon from its outer



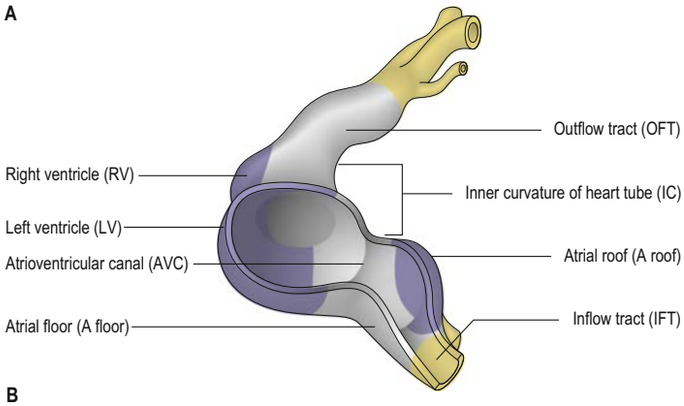


Fig. 13.5 Movements of the atrioventricular canal relative to the midline during early heart development. **A**, The primary heart tube (primary myocardium, grey) is found at the body midline; it receives bilateral veins (yellow) from the body and placenta. **B**, Working myocardium (purple) is present between the inflow tract and the atrioventricular canal. The atrioventricular canal moves to the left; the inflow tract remains in the midline. The pulmonary vein develops within the dorsal mesocardium. **C**, The atrioventricular canal moves to the right, returning toward the midline.

curvature, the original ventral side of the straight tube; the inner curvature of this loop is the original dorsal side.

At the start of stage 10 the venous pole, the atrioventricular canal, the developing left ventricle and the outflow tract are all positioned symmetrically around the midline (Fig. 13.5A). As a result of the subsequent rapid lengthening of the cardiac tube, the atrioventricular canal moves in its entirety to the left (Fig. 13.5B), and the ventricular part of the heart tube loops to the right, thus placing the developing left ventricle on the left and the forming right ventricle on the right side of the midline of the body. The atrial floor, including the developing systemic sinus venosus and the atrioventricular canal moves to the right (Fig. 13.5C). The developing pulmonary vein remains anchored in the midline and after these manoeuvres, the atrioventricular canal again becomes positioned in the midline; these movements facilitate the appropriate connections of the developing muscular ventricular septum with the atrioventricular and outflow cushions. The orifice of the sinus venosus is now positioned to the right. From the outset, the muscular ventricular septum develops in line with the right side of the dorsal atrioventricular cushion so that the right atrium always has direct access to the developing right ventricle.

Cardiac gene expression, differentiation, contraction, conduction and automaticity

Cardiac differentiation and morphogenesis are intimately related processes, achieved by a still obscure transcriptional network. It is known that the cardiac transcription factor Nkx2–5, which has a homogeneous distribution over the embryonic heart tube, is generally important for cardiac-specific gene expression. In the human, mutations in this factor cause atrial septal defects and disturbances of atrioventricular conduction; in *Drosophila*, the heart will not form in its absence. The discovery of the involvement of locally expressed T-box transcription factors, provides some evidence of the further complexity of the patterning of the heart (Fig. 13.6). For example, whereas Tbx5 confers caudocranial positional information over the heart tube, determining the regional development of the cardiac chambers along these axes, Tbx2 and Tbx3 prevent regional formation of the cardiac chambers, permitting the myocardium in these regions to differentiate into the conduction system. Tbx18 is involved in the development of the sinus venosus while Tbx1 is necessary for the development of the outflow tract of the heart.

TABLE 13.1 Basic phenotypes of cardiac myocytes

Feature	Type of myocardium			
	'Primary'	'Nodal'	'Conducting'	'Working'
Automaticity	High	High	High	Low
Conduction velocity	Low	Low	High	High
Contractility	Low	Low	Low	High
Sarcoplasmic reticulum	Low	Low	Low	High

Nodal myocardium as found in the sinus node and AV node derives directly from primary myocardium. The working myocardium as found in the bodies of the atria and ventricles has an opposite phenotype. The conducting myocardium exhibits an intermediate phenotype.

Most cardiac myocytes cease to divide after their differentiation to myocardium (Ahuja et al 2007). The primary heart tube continues to elongate as additional myocytes are recruited from the secondary heart-forming field. Hypertrophy of cardiac myocytes is not thought to be part of the process in this elongation as in mouse embryos, cardiac myocyte volume remains at approximately $2 \times 10^{-3} \mu m^3$ throughout gestation (de Boer et al 2012). Cardiac myocytes share a number of characteristic features that distinguish them from other cells: they are mononuclear, have sarcomeres and a sarcoplasmic reticulum and are joined to adjacent myocytes by the gap-junctional proteins connexin 40 and 43 (van Eif et al 2018). The expression of sarcomeric proteins is seen in primitive cardiomyocytes in stage 9 embryos. All cardiac myocytes share the capacity for producing an intrinsic cycle of electrical activity, i.e. the capacity to generate and conduct a depolarizing impulse that results in contraction (the cells are myogenic): the phenomenon is called automaticity, or pacemaker activity. Because the cells are electrically coupled the fastest pacemaking activity will take the lead. In embryonic hearts, the leading pacemaker is always found at the venous pole which corresponds to the sinuatrial node in the adult heart. There is evidence for the presence of a tertiary heart-forming field specific for pacemaker formation (Liang et al 2017).

All of the cardiac conduction system is myocardial in origin. The nodes, sinuatrial and atrioventricular, and the atrioventricular bundle constitute the central conduction system, while the bundle branches and their terminal ramifications, the Purkinje fibres, represent the peripheral ventricular conduction system. The development of the conduction system of the heart is intimately related to overall heart formation and the blood flow through the heart, embryo and placenta. The underlying gene-regulatory networks have been conserved during vertebrate evolution. Each phase of heart development shows different patterns of spontaneous electrical activation and contraction (Watanabe et al 2016).

Varying degrees of differentiation seen in early populations of cardiac myocytes can be categorized as forming primary, nodal, conducting and working myocardium (**Table 13.1**). There is a relationship between the degree of apparent differentiation and extent of the coupling between myocytes, and the occurrence of slow or fast wave propagation and corresponding contraction. All regions of the early embryonic heart tube have poorly coupled cells and display intrinsic automaticity (**Video 13.1**). This produces slow wave propagation of the depolarizing impulse along the heart tube and matching peristaltic waves of contraction that push the blood in an antegrade direction. That part of the early heart tube wall termed primary myocardium retains this phenotype; it shows poorly developed sarcoplasmic reticulum and sarcomeric structures. Poor electrical coupling and slow conduction seen in nodal myocytes is an absolute requirement for effective pacemaking because it allows the cells to build up sufficient electrical charge, which is then propagated through the surrounding myocardium. Cells that differentiate into working myocardium display virtually no automaticity. They have well developed sarcomeres and sarcoplasmic reticular structures, and contiguous cells show well developed gap junctions expressing connexins 40 and 43. The cells of the putative atrioventricular and peripheral ventricular conduction system have an ambiguous phenotype: they are well coupled, thus allowing fast conduction of the depolarizing impulse, but otherwise retain an embryonic phenotype. Myocytes of the atrioventricular bundles and Purkinje fibres have a phenotype between that of working and primary myocardium. Distinguishing conduction myocardium from working myocardium may suggest that the working myocardium does not conduct, while the conduction system conducts rapidly. However, to produce powerful synchronous contractions, the working myocardium must also conduct rapidly. Unambiguous morphological markers are often lacking in the early embryonic heart, which means that it is not possible to distinguish the various cells phenotypically; automaticity and the speed of conduction have therefore become important functional parameters with which to describe the development of the different parts of the heart.

Peristaltic hearts do not need valves, whereas chambered hearts require the presence of one-way valves at the inlets to, and the outlets from, the chambers. During development, specific regions of mesenchyme and cardiac extracellular matrix fulfil this function. The sequential arrangement of slow and fast conduction portions of the early myocardium is key to its early development. The fast conducting working myocardium of the atrial and ventricular chambers permits nearly simultaneous contraction, increasing the velocity of the forward pressure of blood. The slow conducting primary myocardium within the atrioventricular junction and outflow tract is adjacent to endocardial cushions formed from locally accumulated cardiac extracellular matrix. These regions have longer, slower closure and are thus able to function as sphincteric valves, preventing retrograde flow of blood. The longer closure permits discrete and successive contraction of the atrial chambers followed by the ventricular chambers: contraction in the ventricles at these early stages passes from base to apex. Conduction myocytes originate from part of a primary interventricular ring that becomes positioned at the atrioventricular fibrous ring, close to the interventricular septum in the adult heart (see Fig. 13.10). For further reading about the electrophysiology of the developing chick heart, see Watanabe et al (2016).

COMPARTMENTS OF THE HEART

The future atrial and ventricular components of the developing heart can be distinguished once the primary heart tube has formed its ventricular loop (**Fig. 13.7**; see Figs 13.4, 13.5A). The region where the systemic venous tributaries join the primary heart tube is called the inflow tract of the heart. Within the primary heart tube, the developing atrial and ventricular chambers can be discerned as bulges that are separated by the atrioventricular canal. The ventricles connect to the outflow tract which, in a later stage, will septate and give rise to the pulmonary trunk and the aorta.

Inflow tract

Initially, blood flows into the heart via a sinus venosus, a confluence of bilateral umbilical, vitelline and cardinal venous channels (see Fig. 13.1). The sinus enlarges forming right and left sinus horns; a process under the control of the T-box transcription factor Tbx18. The common cardinal veins, the main contributors to the sinus horns, become surrounded by cardiomyocytes (van den Berg and Moorman 2011). With later development of the septum transversum and hepatic blood vessels, modifications of the cardinal system of veins and the terminal portions of the vitelline and umbilical veins form a main hepatocardiac channel that directs blood from the caudal part of the embryo towards the right horn of the sinus venosus (**Fig. 13.8**; see Figs 13.17, 13.21, 13.22). The sinus wall is thickened dorsally where the right and left sinus horns meet: this is the sinus septum that will give rise to the roof of the orifice of the future coronary sinus.

Inflow tract anomalies

Sinuatrial junction

The sinus venosus becomes incorporated into the right atrium proper (see Fig. 13.8C), distinguished from the common atrium by a sinuatrial valve. The growth of the sinuatrial valve is slower than that of the surrounding myocardium and the valve leaflets lose their competence over

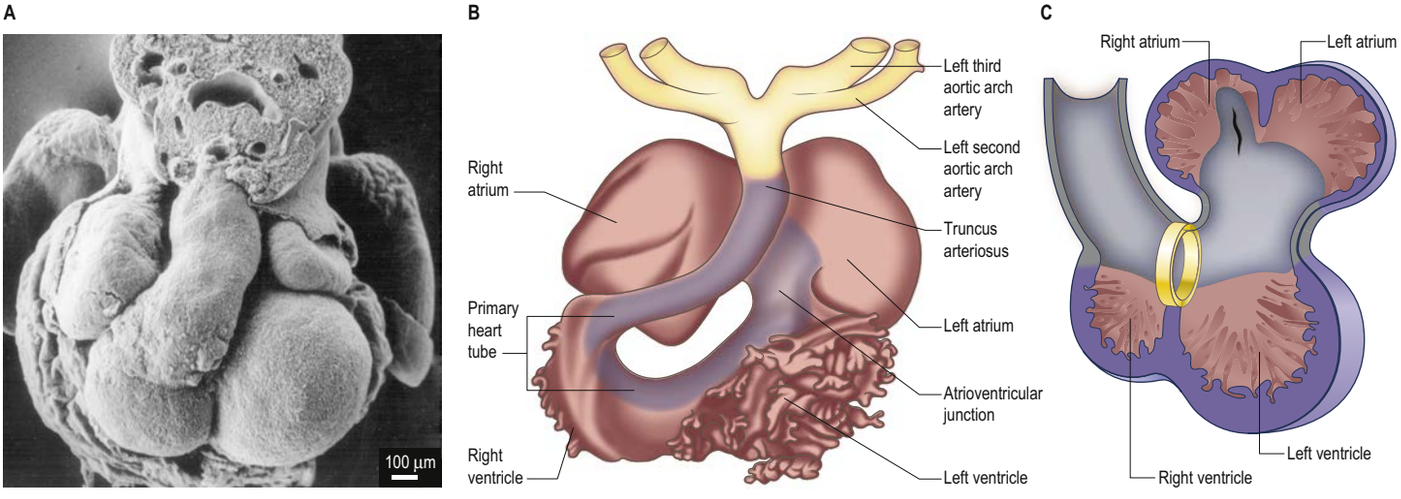

Fig. 13.7 **A**, A scanning electron micrograph of an early developing human heart, showing the external appearance of the myocardium of the right and left ventricles and the right and left atrial appendages. The truncus arteriosus passes between the atria. **B**, A reconstruction of the heart tube at stage 13, showing the endocardium. In the left and right ventricles, the endocardium interdigitates with the myocardium and appears trabeculated; at the atrioventricular canal and in the outflow tract, it is separated from the myocardium by the cardiac extracellular matrix. **C**, The heart at stage 13 with the truncus arteriosus reflected to the right. The opening of the sinus venosus into the right atrium can be seen (yellow). The region of the primary heart tube is indicated by a yellow interventricular ring. (A, With permission from Oostra RJ, Steding G, Lamers WH et al 2006 Steding's and Virágh's Scanning Electron Microscopy Atlas of the Developing Human Heart. New York: Springer-Verlag. B, Modified from O'Rahilly R, Müller F 1987 Developmental Stages in Human Embryos. Washington, DC: Carnegie Institution. Publication 637.)

The most common systemic venous anomaly is a persistent left superior vena cava that drains into the right atrium through an enlarged orifice of the coronary sinus (Povoski and Khabiri 2011): it can be caused by defects in the Robo1 and Robo2 receptors (Mommersteeg et al 2013).

The inferior vena cava can have an interrupted abdominal course and drain to the heart via the azygos or hemiazygos venous system (see Figs 13.4, 13.18), an aberration found most frequently with left isomerism of the atrial appendages.

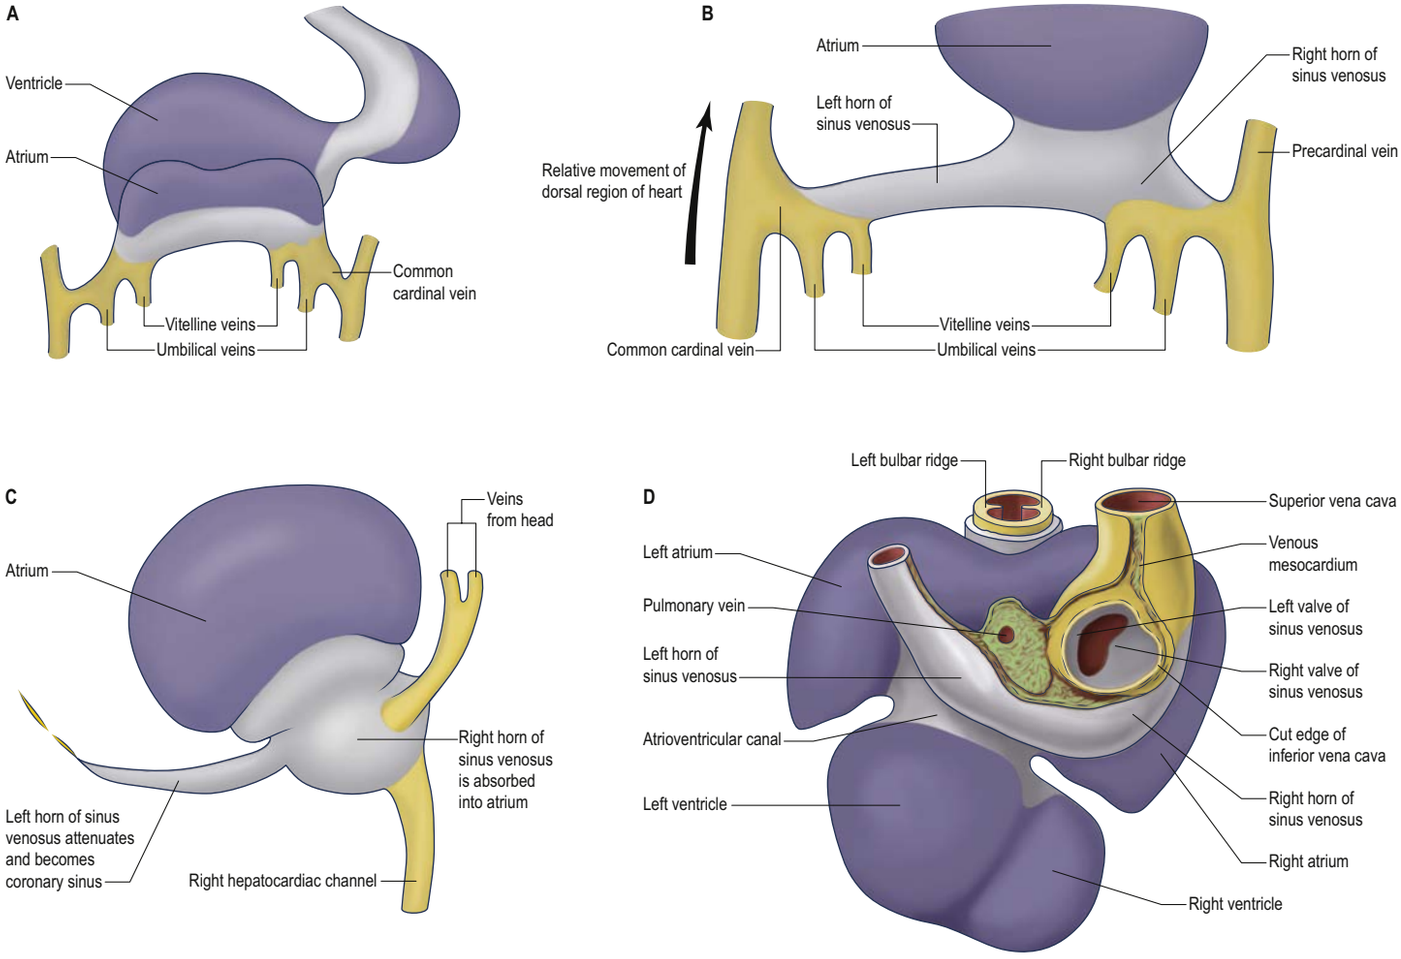

Fig. 13.8 The changes to the sinus venosus. **A**, A dorsal view of the early heart tube shown in Fig. 13.4D. **B**, Changes to the circulation bring the venous circulation to the right, causing enlargement of the right horn of the sinus venosus and atrium, and attenuation of the left horn of the sinus venosus. **C**, The right horn of the sinus venosus becomes incorporated into the atrium. The left horn of the sinus venosus becomes the coronary sinus. **D**, A dorsal view of a stage 16 embryonic human heart, showing the relative changes to the sinus venosus.

time. The sinuatrial orifice becomes elongated and slit-like because of this differential growth. The two sinuatrial valve leaflets that flank it meet cranially to form the septum spurium. Later, a cranial part of the right sinuatrial valve leaflet, caudal to the septum spurium, becomes continuous with the crista terminalis, a ridge that projects from the atrial roof. More caudally, the right sinuatrial valve leaflet forms the valve of the inferior vena cava (Eustachian valve) and of the original left superior vena cava, later the valve of the coronary sinus (Thebesian valve). When this process is disturbed, a venous network (Chiari's network) can develop from the right sinuatrial valve leaflet (Figueras-Coll et al 2017).

As development proceeds, the left-sided systemic venous tributaries diminish in size. The left common cardinal vein (later the left superior vena cava) forms the oblique vein of the left atrium (also known as the oblique vein of Marshall), while the remainder of the left sinus horn is incorporated into the left atrioventricular junction forming the coronary sinus (see Fig. 13.8C). The coronary sinus retains its own myocardial wall, histologically distinct from the left atrial wall, although some merging may take place.

At the sinus venosus side of the sinuatrial junction, cardiac nodal myocytes form a specialized sinuatrial node able to initiate the electrical impulses that activate the atrial myocardium and heart, and lead to its contraction. This node consists of distinct morphological regions and is supplied by a relatively large artery. It forms under the influence of Tbx18 and its differentiation is regulated by Tbx3. Later, when the dorsal wall of the sinus venosus lies in line with the atrial myocardium, lateral to the sinuatrial valve leaflets, and the sinuatrial valve has lost its competence, this region is termed the sinus venarum: it is smooth-walled and forms the dorsal wall of the right atrium. In adult humans, the sinus venosus myocardium contracts simultaneously with that of the right atrium and can therefore be considered to be incorporated functionally into the right atrium.

Sinus venosus anomalies

Available with the *Gray's Anatomy* e-book

Common atrium

The working myocardium of the primitive atrium differentiates at the dorsal and lateral sides of the primary heart tube (Sylva et al 2013) (see Fig. 13.4D–G). The developing atrium then expands, ballooning in dorsal, lateral and cranial directions. The cranial expansion is pouch-shaped and forms the left and right atrial appendage (see Fig. 13.7A–B). Although it is possible to distinguish the left from the right atrial appendage around stage 14, the right being more extensive than the left, the atrium itself contains only a single cavity at this stage. The onset of primary septum formation is initially visible in the atrial roof. During atrial septation, the sinuatrial junction moves from a symmetric, midline position to a right-sided position (see Figs 13.5, 13.8, 13.20).

Right atrium

In the developing right atrium, the united remnants of the sinuatrial valve leaflets, caudal to the valve of the coronary sinus (Thebesian valve), continue to pass through the tissue that separates the orifice of the coronary sinus from the foramen ovale. These remnants form the tendon of Todaro (Ch. 57): the atrioventricular node of the fully formed heart is located at the end of this structure. The left sinuatrial valve leaflet blends with the right side of the atrial septum and there is usually no trace of it in the postnatal heart. The inner aspect of the sinus venosus myocardium and that of the newly forming mediastinal myocardium, derived from the dorsal mesocardium, is smooth, whereas the myocardium of the atrial appendages is ridged on its inner surface, forming the pectinate muscles.

The secondary heart-forming field myocardium of the atrial appendages is working myocardium and expresses the markers atrial natriuretic factor and connexin 40, like the ventricular myocardium at this stage. The mediastinal myocardium is connexin 40-positive but atrial natriuretic factor-negative. Connexin 40-negative primary myocardium marks the inflow to, and the outflow from, the initial atrial

Interatrial communications can occur where the venae cavae join the sinus venosus and are most frequently noted for the superior vena cava (Jensen et al 2016). These defects are usually associated with drainage of the right pulmonary veins into the sinuatrial junction. Known as sinus venosus defects, their essential feature is a bi-atrial connection of the involved vena cava (Keyte et al 2014). Defective signalling by the guidance molecule Semaphorin 3d, which normally ensures that forming pulmonary veins connect to the left atrium, could underlie this malformation (Degenhardt et al 2013). An interatrial communication can occur through the mouth of the coronary sinus when there is a deficiency or absence of the walls that usually separate the left sinus horn or future coronary sinus from the left atrium (Ootaki et al 2003).

chambers as 'rings'. The ring at the inflow defines the sinuatrial junction, and the atrioventricular canal ring forms the atrial outlets during development. The original atrioventricular canal is present within the definitive right and left atrial chambers as the atrial vestibules. These Tbx3-positive, connexin 40-negative rings initially lie parallel in the primary heart tube, but they become separated. The atrial floor or vestibule normally becomes Tbx3-negative and connexin 40-positive as a result of the ingrowth of myocardium from the secondary heart-forming field, while the sinus node and atrioventricular node, derivatives from the primary myocardium, retain their molecular phenotype. Connexin 40-negative remnants of the primary myocardium have been reported in the atrial floor and Tbx3-positive cardiomyocytes are found around the mouth of the coronary sinus: while these cardiomyocytes do not form a separate functional tract, they might be the substrate for arrhythmias.

Left atrium

Following the formation of the left atrial appendage and the primary atrial septum, the left atrium takes shape by the incorporation of mediastinal myocardium. While the tributaries of the sinus venosus approach the right atrium caudally and cranially, the differentiating pulmonary veins gain their entrance to the left atrial cavity through the dorsal mesocardium (see Fig. 13.3). The definitive topographical relationships between vessels and heart seen postnatally are therefore only established once differentiation of the pulmonary venous portal occurs.

Around stage 14, simultaneously with atrial septation, the pulmonary vein develops as a solitary channel from angiogenic cells derived from the dorsal mesocardium. This channel establishes continuity with the vascular plexus formed in the mediastinal mesenchyme around the developing lung buds. The initially solitary pulmonary vein, guided by Semaphorin 3d signals, later opens into the caudo-dorsal wall of the atrium adjacent to the developing atrioventricular junction, where a depression termed the pulmonary pit, flanked by the pulmonary ridges, has already been established (Degenhardt et al 2013).

The primary atrial septum develops from the right pulmonary ridge, confining the pulmonary venous orifice to the developing left atrium (see Fig. 13.11). The pulmonary vein initially branches within the dorsal mediastinal mesenchyme, its tributaries draining blood from the developing lung. With continuing development, the walls of the pulmonary venous channels become surrounded by myocardium; this process occurs up to and beyond the level of the second bifurcation. The veins then expand and their walls become incorporated into the roof of the left atrium, eventually forming the greater part of its cavity. The four pulmonary veins do not achieve their separate opening into the atrial roof until well after septum formation is completed, around postmenstrual week 11. The left half of the primary atrium becomes progressively restricted to the mature appendage. The myocardial sleeves that surround the pulmonary orifices taper off distally and become intermingled with fibrous tissue. In adult life, it is likely that this intermingling of myocardial and fibrous tissues forms the substrate for some forms of atrial fibrillation. Variations in the precise pattern of pulmonary venous drainage are quite common.

Anomalous pulmonary venous connections and cor triatriatum sinistrum

Available with the *Gray's Anatomy* e-book

Ventricles

The ventricles develop from the ventral side of the looping primary heart tube (see Figs 13.4, 13.7). The left ventricle develops from the rostral stem of the inverted, Y-shaped primary heart tube. The right ventricle develops later, downstream relative to the left ventricle, after more myocardium has been added to the cardiac tube from the secondary heart-forming field. As a consequence of the heart tube looping, the right ventricle is positioned to the right of the left ventricle, which is a prerequisite for forming the appropriate connections with the expanding atrial component of the heart. Unlike the atrial chambers, the morphological differences between the right and left ventricles are not part of the general asymmetry between the right- and left-sided organs of the body, but under the control of signalling pathways that determine caudocranial differentiation, such as retinoic acid and its downstream transcription factor Tbx5, which play a crucial role in this process. The Hand transcription factors also play a role in left ventricular growth and endocardial cushion maturation (Vincentz et al 2017).

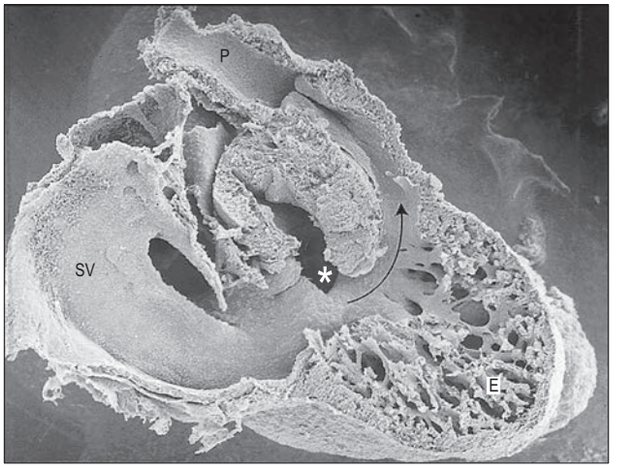

Fig. 13.9 A scanning electron micrograph of a human heart at stage 18 showing the embryonic trabeculae in the right ventricle (E). The right lateral walls of the right atrium, right ventricle and outflow tract have been removed. The sinuatrial valve (SV) is prominent in the right atrium. There is no septal cusp of the tricuspid valve guarding the inlet portion of the right ventricle. The parietal cusp has been removed. The atrioventricular cushions are fused. A small interventricular foramen is indicated (*). There is a well-developed right ventricular outflow tract (curved arrow) culminating in the pulmonary trunk (P).

Formation of the ventricular wall

The myocardium at the inner curvature of the looped heart, which is the original dorsal side of the primary heart tube, remains smooth-walled, whereas the myocardium at the outer curvature of the myocardial tube displays trabeculae as early as stage 10 (see Fig. 13.7C). By stage 17 the trabeculae have achieved a typical spatial organization, giving a sponge-like appearance to the internal aspect of both ventricles. Embryonic trabeculae are a few tens of micrometres in width, and diffusion with early luminal blood is sufficient to maintain cardiac cellular homeostasis, which means that the increase of cardiac mass by trabecular addition can continue in the absence of a coronary circulation (**Fig. 13.9**). Trabecular cardiomyocytes proliferate much less and exhibit more mitochondrial activity than compact wall cardiomyocytes, and are likely to be the main contributor to pressure generation. As development proceeds, a portion of the embryonic trabeculae on the luminal side of the ventricles stops proliferating and differentiates into the fast-conducting peripheral ventricular conduction system that includes the bundle branches and the Purkinje fibres (**Fig. 13.10**). A further portion, from the level of the atrioventricular junction to the apex of the heart, forms thicker adult trabeculae; the trabeculae in the right ventricle are coarser compared to those in the left. Over time the outer layer of ventricular myocardium will become highly proliferative and will form the thick compact layer of the ventricular wall.

Embryonic ventricular myocardium, encompassing both the trabeculae and exterior wall, possesses a specific molecular chamber phenotype: the myocytes express, among other proteins, the fast-conducting gap-junctional proteins connexin 40 and 43, and atrial natriuretic factor. During development, only the peripheral ventricular conduction system retains this molecular phenotype. The ventricular working myocardium loses connexin 40 and atrial natriuretic factor expression while retaining low expression of connexin 43. Changes in the expression of connexin 40 and 43 have been correlated with morphological development of the fetal heart. The increasing complexity of the helical disposition of ventricular myocardial fibres has been studied using high resolution diffusion tensor magnetic resonance imaging (Pervolaraki et al 2017).

Left ventricular noncompaction

Outflow tract

The outflow tract of the heart (truncus arteriosus) is formed by cells derived from the secondary heart-forming field and is confluent with the right ventricle. Initially, the outflow tract myocardium extends

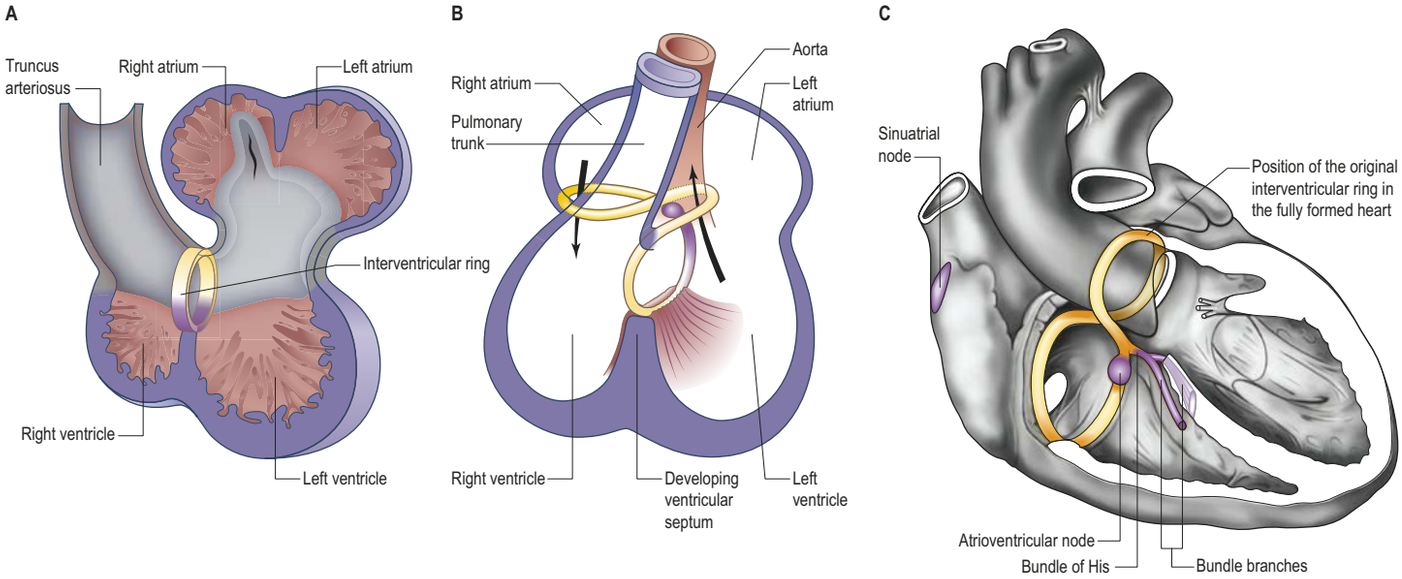

Fig. 13.10 Development of the conduction system of the heart. **A**, At stage 13 with the truncus arteriosus reflected to the right, the interventricular ring marks the region of the primary heart tube. The purple part of the interventricular ring will give rise to the atrioventricular bundle and bundle branches, whereas the yellow part of the interventricular ring will not participate in the formation of the adult conducting system. **B**, The truncus arteriosus, now divided into the pulmonary trunk and aorta, is presented between the right and left atria, which expand lateral to it. The right atrium is now positioned entirely above the right ventricle, and the outflow tract has expanded to the left; the left ventricle has access to the aorta. **C**, The position of the original primary heart tube ring indicated in the formed heart. The pulmonary trunk has been removed.

up to the pericardial reflections. As development proceeds, continuous addition of non-myocardial cells changes the position of the myocardium and cardiac extracellular matrix (cardiac jelly) relative to the outflow tract bend, a conspicuous morphological feature in the embryonic heart. The outflow tract is therefore a highly dynamic structure along which cells pass to contribute to the definitive right ventricle. By definition, the outflow tract is downstream of the ventricular loop, irrespective of the fact that, eventually, it will largely become incorporated within the definitive right ventricle (see Figs 13.4, 13.7). The method of incorporation of the outflow tract into the heart is different to that of the sinus venosus, because it involves movement of a structure, whereas the sinus venosus changes identity but otherwise shows no relative movement.

Within the inner curvature of the ventricular loop, the walls of the outflow tract and atrioventricular canal fade into one another without a clear boundary. It is within this ventricular part of the primary heart tube that the cushions of the atrioventricular canal and the outflow tract must achieve appropriate connections with the ventricular septum in order to separate the pulmonary trunk and the aorta.

Aortic arch anomalies

SEPTATION OF THE EMBRYONIC CARDIAC COMPARTMENTS

The early embryonic heart is an undivided continuous tube. During development, septa are formed within the compartments of the heart. Initially they separate blood draining to the right side of the heart (oxygenated blood from the placenta and venous drainage from the body) and arterial flow from the left side of the heart (to the body and placenta); after birth they permit the smooth transfer of blood flow from the intrauterine to the extrauterine arrangement. Septa develop within the common atrium, in the atrioventricular canal, between the ventricles and within the outflow tract. Initially flow of blood on the right and left sides of the developing heart does not intermingle because flow is laminar. Pressures are similar in the right and left sides of the embryonic and fetal heart.

A number of shunts are open in the early heart and vessels because oxygenation is derived from the placenta and the pulmonary circulation is not functional in the embryo and fetus. Blood flow through the beating heart, the local pressures generated, and the shear forces created within the endocardial tube, form part of the epigenetic processes involved in heart development and the establishment of systemic and placental circulations.

Septation of the atrial chambers

Atrial septation is a process in which a valvular structure develops that initially directs the flow of placental blood to the body and allows separation of the two atrial chambers immediately after birth. It is typically described in terms of two septa that separate the endocardial and myocardial walls of the common atrium and two foramina that ensure continuous blood flow. Atrial septation starts at about stage 13 with proliferation of a crescentic ridge of mesenchyme in the atrial roof. This ridge, the septum primum, grows by active proliferation from the craniodorsal atrial roof towards the atrioventricular canal, just to the right of the entrance of the pulmonary vein (pulmonary pit) (Fig. 13.11A,D). Its leading edge is covered by a mesenchymal cap which is continuous with extracardiac mesenchyme (mediastinal mesenchyme) derived from the dorsal mesocardium that forms a dorsal mesenchymal protrusion. Under the influence of BMP signalling, the ventral horn of the crescentic septum primum will touch the ventral atrioventricular cushion, while the dorsal horn will fuse with the dorsal atrioventricular cushion. The primary atrial foramen (foramen or ostium primum) is therefore entirely surrounded by mesenchyme, subjacent to the atrial endocardium. Caudal to the advancing edge of the septum primum, the developing atrial chambers still communicate through the foramen primum (see Fig. 13.11A,D). The foramen primum diminishes in size as a result of continuous growth of the muscular primary atrial septum and the cranial part of the septum perforates by apoptosis. The perforations coalesce, producing a secondary atrial foramen (foramen, or ostium, secundum) that allows continued shunting of oxygen-enriched blood from the placenta to the left side of the heart and so to the head and brain. The foramen secundum forms during stages 15–17. The foramen primum is occluded in the median plane by stage 17, when the septum primum mesenchyme merges with the fusing atrioventricular (Fig. 13.11B,E). This tissue later differentiates to myocardium and forms a ridge that will become the limbus of the future fossa ovalis.

The secondary atrial septum (septum secundum) is reported to appear during stages 18–21 (O'Rahilly and Müller 1987), signalling the earliest development of the foramen ovale. Anderson et al (2002), however, note that invagination of the roof of the right atrium, forming a myocardial ridge, constitutes the septum secundum, and that this is not present until after stage 23 (see Fig. 13.11B,E). The free edge of the septum secundum overlaps the foramen secundum forming an oblique channel, the

The developing common pulmonary vein migrates towards the heart before connecting to the pulmonary pit, but the correct connection may not occur (van den Berg and Moorman 2011). In total anomalous pulmonary venous connection, which occurs in about 7/100,000 neonates, no pulmonary veins enter the left atrium (Wu et al 2018) and the more primitive connection between the splanchnic plexus that surrounds the lungs with the right atrial inflow tract persists (Kao et al 2017): these vessels do not become surrounded by myocardium (Douglas et al 2009). In case of a partial anomalous pulmonary venous connection, one or more connections with the left atrium will be established alongside this primitive conjunction between cardinal veins and the splanchnic plexus. It has been suggested that these anomalies occur when there is a defect in the Semaphorin 3d signalling that would normally act as a repelling guiding factor (Degenhardt et al 2013).

In cor triatriatum sinistrum, a very rare anomaly, the left atrium is subdivided into two compartments separated by a full or partial membrane. The pulmonary venous confluence is guarded from the rest of the atrial body. There is evidence that mutations in the enzyme HYAL2 can lead to cor triatriatum sinistrum in humans (Muggenthaler et al 2017). The membrane might be an outgrowth of a ridge that is naturally found between the left superior pulmonary vein and the atrial appendage. Often this defect coincides with a septal defect, anomalous pulmonary venous connections or a patent ductus arteriosus.

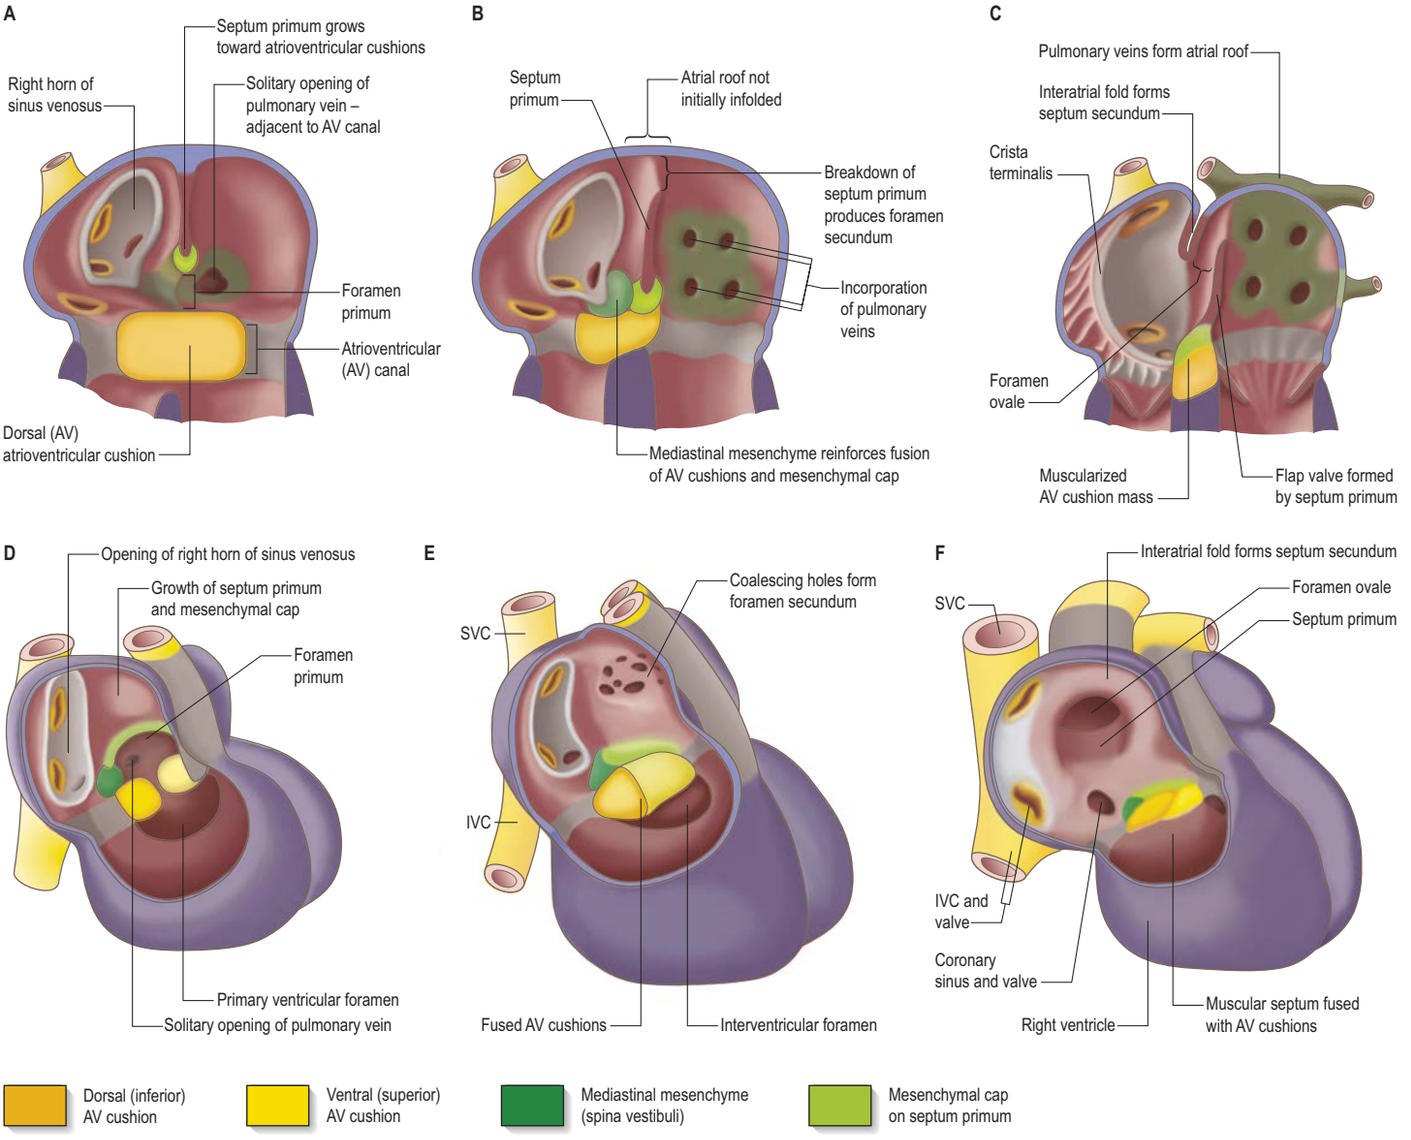

Fig. 13.11 Three representative stages in the development of the atrial septum. **A–C**, Coronal views from the front. **D–F**, Lateral views from the right side. **A** and **D**, At stage 14 the primary atrial septum has not yet obliterated the original communication between the two atria (primary atrial foramen) and the atrioventricular endocardial cushions have not yet fused. The mediastinal mesenchyme starts to protrude into the heart. **B** and **E**, A few days later, the atrioventricular endocardial cushions have fused with each other and with the mediastinal mesenchyme and the mesenchymal cap of the primary atrial septum, which starts to exhibit openings in its cranial part that will form the secondary atrial foramen. **C** and **F**, The secondary atrial septum is forming to the right of the primary atrial septum and overlaps the secondary atrial foramen. The sinuatrial valve has lost its competence and the pulmonary veins have acquired their respective entries to the left atrium. The left superior cava now functions as the coronary sinus. Abbreviations: AV, atrioventricular; IVC, inferior vena cava; SVC, superior vena cava.

foramen ovale, between the now divided atria. Once these septa have formed, blood passes under the crescentic edge or limbus that is the crista dividens of the septum secundum, and flows obliquely towards and through the foramen secundum to the left atrium. This passage through the foramen ovale, persists throughout intrauterine life (see Videos 13.2, 23.1). In postnatal life, when left atrial pressure exceeds that in the right atrium, the septum primum will close against the septum secundum as a type of flap valve, completing atrial septation (Fig. 13.11C,F). On the right side of the foramen ovale, part of the septum primum remains underneath the rim of the septum secundum and becomes the fossa ovalis. Fig. 13.12 summarizes all the anomalies of septation.

Atrial septal defects

Septation and appropriate positioning of the atrioventricular canal

The atrioventricular canal is initially a continuation of myocardium between the common atrium and the primitive ventricle. Four cardiac cushions are formed at the margin of this canal, namely: the left and right cushions, and the much larger ventral and dorsal cushions. The single orifice of the atrioventricular canal is divided by the approximation and later merger of the ventral and dorsal cushions. The dorsal atrioventricular cushion runs along the floor of the atrium. As it extends further dorsally it meets the dorsal mesenchymal protrusion (spina vestibuli) that connects with the mesenchymal cap that runs along the leading edge of the septum primum until it meets the ventral atrioventricular cushion (see Fig. 13.11). The dorsal atrioventricular cushion has a ventricular extension to the inner curvature of the heart tube that comes to lie on top of the developing muscular ventricular septum: much of the membranous septum of the ventricles is derived from this extension.

The two atrioventricular cushions fuse during stages 14–17, at which time they become known as the central fibrous body. Relative to the canal itself, the cushions are large, leaving narrow right and left slits for the passage of blood (Fig. 13.13). At the same time as the cushions fuse, the canal expands. This is seen most clearly on the lateral right side where the size of the right atrioventricular opening increases. Relative to the heart, the entire atrioventricular canal also shifts to the

In left ventricular noncompaction, the left ventricle exhibits particularly prominent trabeculae as compared to the compact wall. Although most cases of left ventricular noncompaction are thought to be developmental in origin, the process behind acquisition of prominent trabeculae is not clear: variation in trabecular prominence is seen during adult life, for example in pregnant women (Gati et al 2014). The condition can reflect failure of the trabeculae to compact, or excessive trabecular formation, or hypoplasticity of the compact wall (Anderson et al 2017, Jensen et al 2017) and can be associated with heart failure. Its uncertain aetiology is reflected in the diversity of current diagnostic criteria (Ivanov et al 2017).

A series of aortic arch arteries develop from the outflow tract and conduct blood through the pharyngeal arches before joining the dorsal aortae; the temporal changes that occur in the arteries are outlined on p. 222 and described in detail in Chapter 17 (see Fig. 17.9). The persistence of a right aortic arch is caused by a failure of resorption of the embryonic fourth right pharyngeal arch artery (Kanne and Godwin 2010), and is found most frequently with Fallot's tetralogy or with a persistent truncus arteriosus. It can also exist, together with a left aortic arch, in various combinations known as arterial rings, which compress the oesophagus, causing so-called dysphagia lusoria. For example, the right subclavian artery can sometimes arise from the arch of the aorta distal to the origin of the left subclavian artery and pass to the right, behind the trachea and oesophagus. This aberrant connection can be explained by the failure of fusion of the right common carotid artery and the right subclavian artery, caused by a fault in the right aortic arch involution.

Worldwide, the reported prevalence of persistent communication between the atrial chambers through the foramen ovale is 1.64/1000 live births (13% of the most common congenital heart disease subtypes) (van der Linde et al 2011). It is often the result of failure of the flap valve (septum primum) to fuse completely with the infolded muscular rim of the septum secundum. This type of atrial septal defect is known as a persistent foramen ovale. When the flap valve is still able to overlap the rim, the communication is of little or no functional significance as long as the left atrial pressure is greater than the right, which is usually the case in healthy individuals. However, when the pressure in the right atrium increases during sneezing, when diving, or in the case of pulmonary hypertension, there is a risk of some blood entering the left atrium directly, bypassing the pulmonary circulation (Briggs et al 2012). If the flap valve (septum primum) does not cover the foramen ovale, or if it is perforated, a true septal defect exists (Geva et al 2014) (see Fig. 13.12A). A foramen secundum defect is present when the lumen of the left atrium is visible from within the right atrium; it can be the result of either a septum secundum that is too small or a foramen secundum in the septum primum that is too large. Foramen primum defects occur when the mesenchymal cap of the septum primum does not fuse with the atrioventricular cushions, resulting in an interatrial communication. Deficient growth of the dorsal mesenchymal protrusion may also result in foramen primum defects: this is an atrioventricular septal defect permitting exclusively atrial shunting (Jensen et al 2016, Wessels 2016).

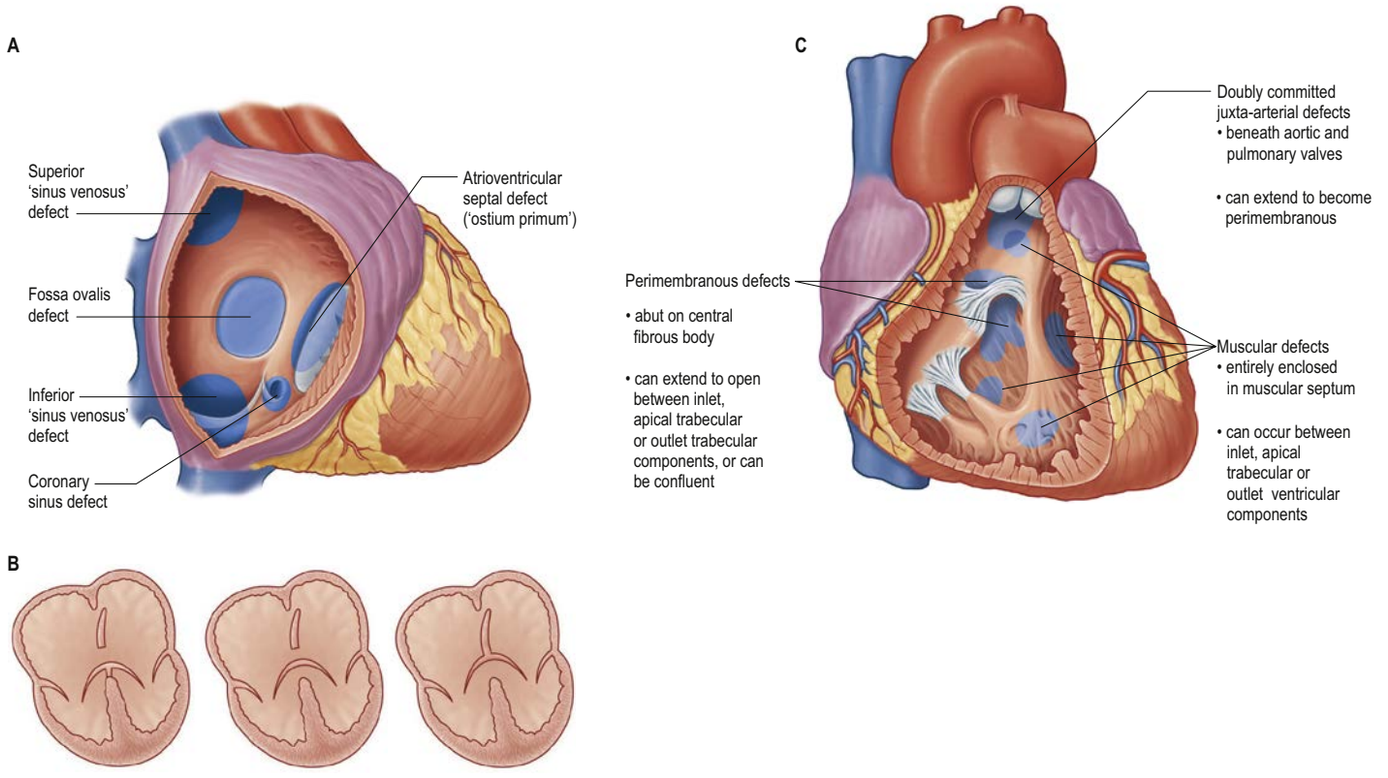

Fig. 13.12 **A**, Location of the defects that produce an interatrial communication. Only defects within the fossa ovalis are true atrial septal defects. **B**, Shunting across an atrioventricular septal defect. This can be atrial (left), ventricular (right) or at both levels (middle), depending on the attachment of the bridging cusps. **C**, Ventricular septal defects. Depending on the structure of the anatomical borders seen from the right ventricle, these defects can be placed into perimembranous, muscular or doubly committed groups. Fig. 13.13 Septation of the ventricles and outflow tract. **A**, A frontal view of the heart at stage 13, with the outflow tract reflected to the right. Lines show the level of the transverse sections through the atrioventricular cushions and outflow tract. Note that blood from both atria has to pass through the embryonic primary myocardial ring at this stage. **B**, A sagittal section of heart along the dotted line in **A**, showing the atrioventricular junctional region as seen from the right side. The atrioventricular cushions extend cranially onto the leading edge of the septum primum where they are fused with the mesenchymal cap.

right (see Fig. 13.5), causing the dorsal cushion to overhang the ventricular septum into the developing right ventricle while the ventral cushion remains mostly on the left side.

Atrioventricular septal defects

Available with the *Gray's Anatomy* e-book

Septation of the ventricles

Three distinct structures contribute to the formation of the ventricular septum: the atrioventricular cushions (including the protrusion of the dorsal atrioventricular cushion that lies on the ventricular septal crest), the muscular ventricular septum and the proximal parts of the outflow cushions. Separation of the right and left ventricles is heralded by the appearance of a caudal crescentic ridge within the ventricular loop (see Fig. 13.7). This is a persisting part of the Tbx3 and G1N2-positive primary heart tube myocardium, which means that the crest of the septum is the oldest portion of the developing ventricular septum. The ventricles (especially those parts that will become the apex of the heart) become enlarged as if they were expanding like balloons on either side of the muscular ventricular septum (see Figs 13.4, 13.7). Later, the dorsal part of the crest of the septum will become the atrioventricular bundle, while the atrioventricular node will form at the dorsal atrioventricular junction (see Fig. 13.10C). The ventral parts will largely disappear except

Atrioventricular septal defects result from a failure of fusion of the endocardial atrioventricular cushions, leading to a common atrioventricular orifice and deficiencies of the adjacent septal structures (see Fig. 13.12B). Two major subgroups of atrioventricular defects are identified. The more frequent is complete atrioventricular defect, characterized by a common atrioventricular orifice and the potential for shunting through the septal defect at both atrial and ventricular levels (see Fig. 13.12B). The common atrioventricular orifice is guarded by a single common valve, with superior and inferior leaflets that bridge the scooped-out ventricular septum. The valve is tethered to both right and left ventricles. Although the left component of this valve is often interpreted as a 'cleft mitral valve', it bears no resemblance to the normally structured mitral valve because it has three leaflets where the 'cleft' forms the zone of apposition between the left ventricular components of the ventral and dorsal bridging leaflets. The less common incomplete atrioventricular septal defect has separate right and left atrioventricular orifices and shunting occurs only at the atrial level. Occasionally, when the bridging leaflets are attached to the underside of the atrial septum, shunting is minor and confined to the ventricular level (Briggs et al 2012).

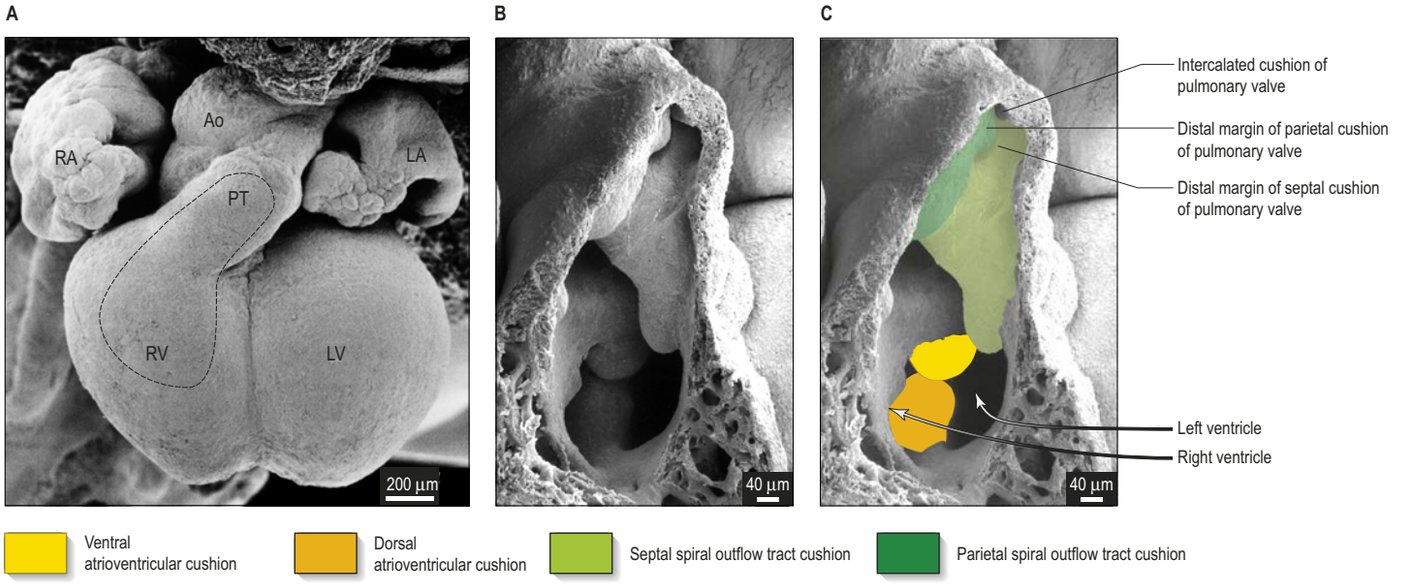

Fig. 13.14 Septation of the outflow tract. **A**, A scanning electron micrograph (SEM) of a human heart at stage 18. The pulmonary trunk is separated from the aorta. **B**, An SEM of the human heart at stage 17, showing the luminal aspect of the right ventricle and the outflow tract. The anterior and parietal walls of the outflow tract have been removed along the dotted line shown in **A**. **C**, An SEM with added colour to show the structures in **B**. The outflow cushions are unfused. The distal margins of both outflow tract cushions are contributing to the developing pulmonary valve: the third leaflet and sinus of this valve are derived from the intercalated cushion. The components of the aortic valve develop from the dorsal aspect of the outflow tract cushions. Abbreviations: Ao, aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle. (Courtesy of Professor G Steding, Göttingen, with permission from Oostra RJ, Steding G, Lamers WH et al 2006 Steding's and Virágh's Scanning Electron Microscopy Atlas of the Developing Human Heart. New York: Springer-Verlag.)

the so-called 'dead-end tract' (Anderson et al 2016, de Vries et al 2016). The crest of the septum, covered by an extension of the dorsal atrioventricular cushion, together with the fused atrioventricular cushions themselves, bounds the ovoid interventricular foramen. The Tbx3 and G1N2-positive myocardium that surrounds this foramen marks a ring composed of primary myocardium which is smooth (see Fig. 13.10). Completion of ventricular septation is seen after a rightward shift of the atrioventricular canal and the positioning of the outflow tract between the separating atrioventricular canals so that it too overrides the developing ventricular septum. The foramen finally closes by formation of the membranous septum that completely separates the right from the left ventricle (see Fig. 13.13). During ventricular septation, transition from the early ventricular base-to-apex conduction activation to an apex-to-base conduction is initiated. Maturation of the ventricular conduction system, with concomitant development of the fibrous rings of the heart, continues throughout fetal development (Watanabe et al 2016).

Ventricular septal defects

Available with the *Gray's Anatomy* e-book

Septation and appropriate positioning of the outflow tract

The appearance of two outflow cushions is key to the separation of the outflow tract (truncus arteriosus). Together with the myocardial wall, the cushions spiral as they extend from their septal and parietal positions at end of the right ventricle to the developing aortic sac (see Fig. 13.13; **Fig. 13.14**). Within the developing aortic sac, a transverse wedge of tissue composed of dorsal mediastinal mesenchyme, the aortopulmonary septum, initially separates the origins of the aorta and the pulmonary trunk before their individual walls are formed. Meanwhile, neural crest cells migrate from the pharyngeal mediastinal myocardium into the outflow cushions. They do not populate the septum itself, but form the larger parts of the walls of the intrapericardial portions of the truncus arteriosus (Keyte et al 2014).

The outflow cushions start to fuse from stage 15. Fusion starts in the distal part of the outflow tract and continues gradually in the direction of the ventricular septum (see Fig. 13.14; **Fig. 13.15A**). Early on, the most proximal parts of the cushions remain unfused. The arterial valves and sinuses develop distally within the myocardial sleeve that surrounds this area. When the most proximal parts of the cushions fuse, they are invaded by cardiac myocytes (myocardium) and become continuous with the muscular ventricular septum, so joining the aorta to the left ventricle. Spread of myocardial cells also gives rise to the greater part of the supraventricular crest. In the right ventricle, the wall of the proximal myocardial outflow tract persists as the smooth-walled muscular sub-pulmonary infundibulum. Some myocardium also persists distal to the pulmonary valve. There is no distinct myocardial outflow tract present within the left ventricle in the postnatal heart: the myocardium that initially surrounded the entire aortic root is lost on the side of the non-coronary leaflet because a fibrous continuity develops between the mitral valve and the aorta.

Outflow tract septal anomalies

Available with the *Gray's Anatomy* e-book

CARDIAC VALVE DEVELOPMENT

Competent mesenchymal valves develop at the atrioventricular junction and between the ventricles and outflow tract. The valvular apparatus is largely composed of endocardium-derived mesenchyme. All leaflets and the chordae tendineae and myotendinous junctions initially form from internal endocardial projections that cover a myocardial basement membrane, matrix and mesenchymal cells.

Atrioventricular valves

The mitral and tricuspid valves are formed at the site of the atrioventricular canal. The endocardial cushions are located on the inside of the canal. The cushions occupy most of the canal, save two tiny lumina that connect the right atrium to the developing right ventricle and the left atrium to the developing left ventricle. On the outside of the heart, at the level of the atrioventricular canal, a groove forms which is covered by the developing epicardium (see p. 220). As the atrioventricular valves develop, the epicardium and the endocardial cushions fuse at the ventricular margin of the canal, disrupting the

Ventricular septal defects account for approximately two-thirds of all cardiac septal defects; the worldwide prevalence is 2.6/1000 live births (34% of the most common congenital heart disease subtypes) (van der Linde et al 2011, Xie et al 2017). The inappropriate formation and connection of the atrioventricular cushions to the muscular ventricular septum results in a perimembranous ventricular septal defect (see Fig. 13.12C). The membranous septum, and by extension a perimembranous ventricular septal defect, is closely associated with the area of insertion of the septal leaflet of the tricuspid valve. A perimembranous defect can also extend further into the ventricular outlet beneath the supraventricular crest that borders the right ventricle from the outflow tract. Perimembranous ventricular septal defects are often associated with the aortic orifice overriding the crest of the muscular septum, i.e. 'overriding aorta'. When combined with pulmonary stenosis or atresia, this forms the basis for the syndrome of Fallot's tetralogy. The last feature of the tetralogy, right ventricular hypertrophy, which developed in infancy in the untreated child, is now usually seen in cases where an affected child does not have timely surgical repair. The condition does not cause important haemodynamic imbalance during fetal life (Wohlmuth and Gardiner 2020). When the pulmonary trunk is normal or even dilated with this combination of anomalies, it is known as the Eisenmenger complex. Perimembranous defects can also occur with abnormal ventriculoarterial connections. Taussig–Bing anomaly occurs when, in a case of transposition of the great arteries, the pulmonary trunk overrides the muscular septum, causing both arteries to connect to the right ventricle and the ventricular septum is also defective. In perimembranous ventricular septal defects, the atrioventricular bundle and its right and left branches are still always found along the dorsal and caudal margins of the defect.

Less commonly, a septal defect may be found in the ventricular outflow tract underneath the conjoined facing leaflets of the aortic and pulmonary valves. Such juxta-arterial defects are doubly committed, in that they open beneath the orifices of both aortic and pulmonary valves. They are the result of the failure of formation of the free-standing muscular sub-pulmonary infundibulum, which links them to persistent truncus arteriosus anomalies, but the ventriculoarterial junctions are appropriately separated. These defects usually have a muscular dorsocaudal rim that protects the atrioventricular bundle: the defect can sometimes extend to the membranous septum.

A third type of ventricular septal defect occurs within the musculature of the septum. Defects may affect all parts of the septum and can be multiple, producing a so-called 'Swiss cheese' septum (Spicer et al 2014).

A number of outflow anomalies may occur if the outflow cushions either fail to develop or fuse in an inappropriate fashion. When the cushions fail to fuse, the result is a persistent truncus arteriosus, represented by an undivided arterial channel, guarded by a common arterial valve, positioned above and astride the free margin of the muscular ventricular septum (**Fig. 13.16**). This anomaly occurs frequently in DiGeorge syndrome and can be a result of a Tbx1 deletion (Rana et al 2014). Persistent truncus arteriosus is also likely linked to abnormal development of the secondary heart-forming field, which, by means of an overall shorter heart tube, leads to poor alignment of the aorta with the left ventricle. In this condition, there is a coexisting juxta-arterial deficiency of the ventricular septum; right and left pulmonary arteries usually arise via a confluent segment but can also take independent origin from the trunk, which continues as the ascending aorta. The common valve usually has three leaflets but may also have two, four or more.

Transposition of the arterial trunks (also referred to as transposition of the great vessels) is a condition in which the aorta arises from the right ventricle and the pulmonary trunk from the left. Better described as having discordant ventriculoarterial connections, such hearts can coexist with deficiencies of cardiac septation. They can also be found with discordant connections at the atrioventricular junctions, producing a congenitally corrected transposition. The developmental history of discordant connections remains unknown but may have similar signalling pathways that are involved in right atrial isomerism, the nodal/pitx2 pathways (Nakajima 2016).

Double outlet ventricle occurs when the greater parts of both arterial valves fall within the same ventricle, almost always the right. In these cases, in order to continue the circulation of oxygenated blood after birth, it is necessary that either the ventricular septum is deficient, or the ductus arteriosus remains patent with medication; in rare cases, the septal defect can close as a secondary event.

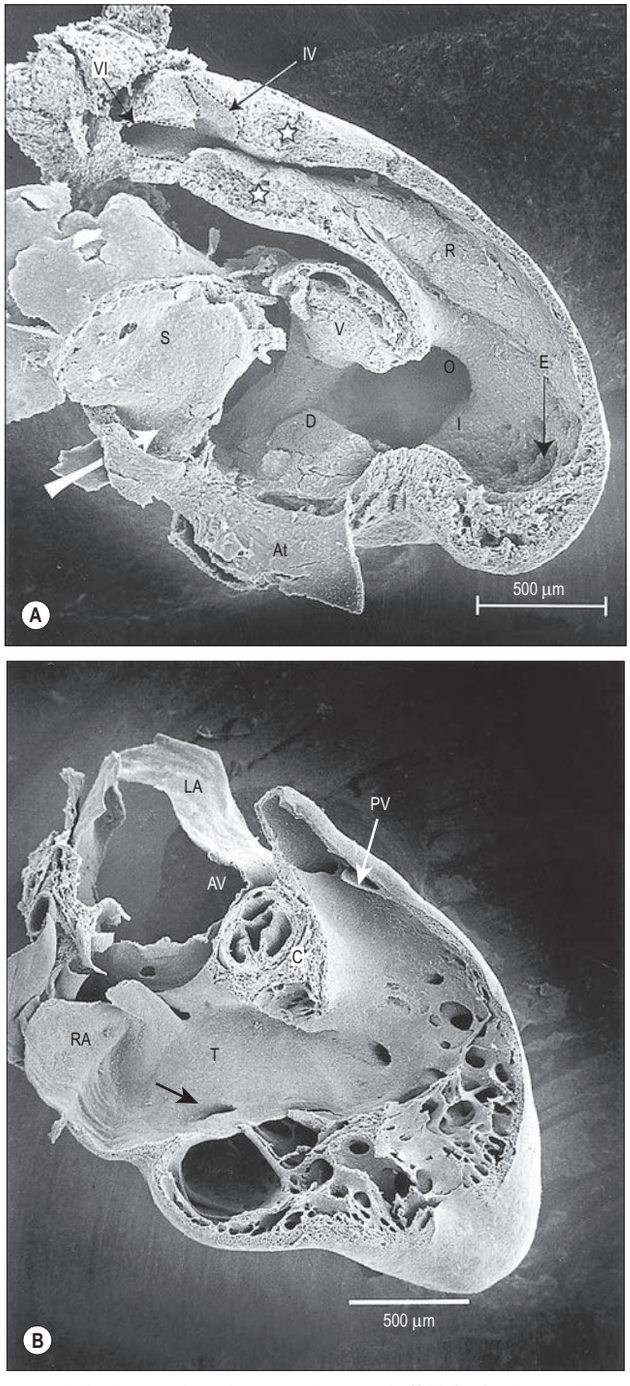

Fig. 13.15 A, A scanning electron micrograph (SEM) of a human heart at stage 15. The right lateral walls of the right atrium, right ventricle and the outflow tract have been removed. The primary atrial septum (S) is at a distance from the unfused ventral (V) and dorsal (D) atrioventricular cushions. There is not yet a membranous ventricular septum, leaving an opening between the left and right ventricle (O). The muscular interventricular septum (I) is visible. Note the left anterolateral ridge (R) and, at the distal margins of the truncus arteriosus, the valve swellings (*) of the putative aorta and pulmonary trunk. The white arrow marks the direction of blood flow from the systemic veins into the right atrium. Other abbreviations: At, atrium; E, embryonic trabeculae; IV, origin of fourth aortic arch; VI, origin of sixth aortic arch. **B**, The septal aspect of the right ventricle of a human heart at stage 23. Delamination of the septal cusp of the tricuspid valve (T) is taking place. A cleft (black arrow) has appeared, marking the posterior margin of the septal cusp. There are no clefts delineating the anterior margins in the region adjacent to the supraventricular crest (C), and the endocardium is continuous. No tension apparatus (chordae tendinae and papillary muscles) is visible. Other abbreviations: AV, aortic valve; LA, left atrium; PV, pulmonary valve; RA, right atrium.

myocardial continuity. Only the prospective atrioventricular conduction axis is spared from disruption. The sites of myocardial disruption later form the anulus fibrosus, a collagenous structure that physically insulates the atria from the ventricles. If anulus fibrosus formation is disrupted, accessory strands of myocardium between the atria and ventricles may persist and can become aberrantly differentiated thereby becoming able to propagate the electrical impulse. This can lead to early excitation of the ventricles and can act as a substrate for re-entry ventricular tachycardias as seen in Wolf–Parkinson–White syndrome.

Although molecular lineage studies in the mouse have demonstrated that the atrioventricular cushions are initially entirely populated by endocardium-derived mesenchymal cells, they later receive a significant epicardial contribution. For example, the fibroblasts that make up the parietal valvular leaflets and the tendinous cords in the formed heart are derived from both the endocardium and the epicardium.

The atrioventricular valves develop as shelf-like projections from the margins of the expanded atrioventricular orifices. These projections contain both myocardium and endocardial cushion mesenchyme. They grow deep into the ventricular cavity initially as trabecular ridges. Part of these trabeculae will later remodel to form papillary muscles. Each valve leaflet develops functionally significant regional variations in surface texture while its core condenses as a collagenous fibrous lamina, supported either by the fibro-fatty tissue of the atrioventricular groove, or by the anulus fibrosus. In the mitral valve, the aortic leaflet forms before the mural leaflet. Both are fully delaminated from the myocardial wall by postmenstrual week 10. The formation of the inferior leaflet of the tricuspid valve is followed by the formation of the septal and, later, the anterosuperior leaflets. This process continues until at least postmenstrual week 13 (see Fig. 13.15B).

Atrioventricular valve defects

Available with the *Gray's Anatomy* e-book

Aortic and pulmonary valves

The aortic and pulmonary valves are derived from the endocardial cushions within the myocardial outflow tract. These cushions become populated by neural crest cells, in addition to endocardial- and pharyngeal-derived mesenchymal cells, which helps them fuse across the tract. The myocardial wall surrounding the cushions then starts to split giving rise to the aortic and pulmonary roots. What remains of the fused cushions in each of the arterial roots will develop into the right and left adjacent pulmonary and coronary leaflets. The developing intercalated cushions, which form on opposite sides of the fused outflow cushions, will give rise to the non-adjacent leaflets of the aortic and pulmonary valve (see Fig. 13.14). In all these cushion-derived intrusions, the distal parts become excavated from the arterial wall to form the valvular leaflets. The valvular sinuses are found between the leaflets and the wall. The anulus fibrosus surrounding the atrioventricular valves also partially surrounds the outflow tract valves: only the pulmonary valve is not fully connected to it. The non-adjacent and left coronary leaflet of the aortic valve and the aortic leaflet of the mitral valve form a fibrous continuity with each other.

Neural crest cells play a role in the spatiotemporal regulation of the division of the outflow tract into the aortic and pulmonary arteries, and therefore of the development of the muscular sub-pulmonary infundibulum. Although proper migration of these cells is crucial for normal development of the outflow tract and the formation of arterial valve leaflets and sinuses, their exact role is largely obscure. Scarcely any neural crest cells remain in the adult heart, either in the leaflets of the arterial valves in the formed heart, or in the muscular sub-pulmonary infundibulum.

Arterial valve defects

Non-myocardial additions to the developing heart

The parietal pericardial wall surrounding the heart is lined with bipotential mesothelium that will either add cells to the venous pole of the heart or differentiate towards the Tbx18-positive epicardial lineage. Bone morphogenetic proteins and fibroblast growth factors influence which lineage is ultimately followed. After heart looping and septation has started, epicardial mesenchyme is added to the external surface of the heart. The epicardium subsequently gives rise to the coronary vasculature and to the population of interstitial

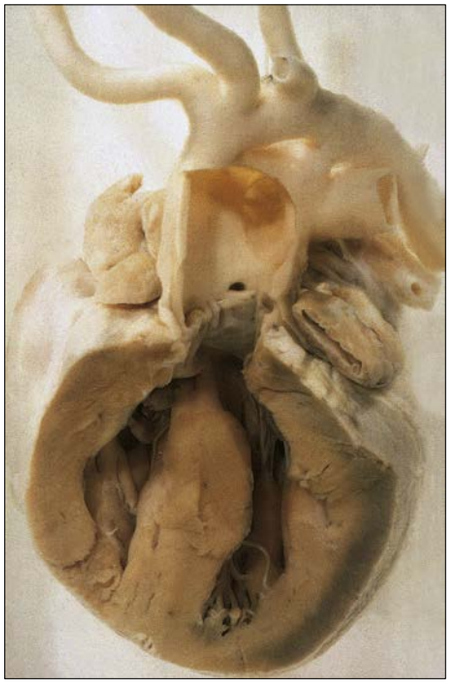

Fig. 13.16 This heart possesses a common arterial trunk, with a common truncal valve overriding a juxta-arterial deficiency of the ventricular septum, the result of failure of septation of the arterial pole of the developing heart. (Courtesy of Professor RH Anderson, Institute of Child Health, University College, London. Specimen prepared by Dr Leon M Gerlis.)

When the right atrioventricular junction (the connection between the right atrium and the right ventricle) does not expand normally during atrioventricular septation, the tricuspid valve remains atretic. Often a small dimple can still be observed within the right atrium where the connection should have been. Atresia of the tricuspid valve coincides with an atrial septal defect and a failure in right ventricle development. The left ventricle supports both the systemic and pulmonary circulation.

In Ebstein's malformation, the septal and inferior tricuspid valve leaflets are attached abnormally deep into the right ventricular chamber (Paranon and Acar 2008). This often leads to right ventricular overload and valve regurgitation (Lombardi and Pluchinotta 2018). In rare cases, Ebstein's malformation can coexist with atresia of the tricuspid valve; it does not coincide with hypoplasia of the right ventricle because the developmental process is different.

The mitral valve can exhibit several anomalies that result either in a valve stenosis or a valve regurgitation (Prakash et al 2017). Often, the papillary muscles or tensor apparatus are involved in these malformations (Séguéla et al 2011).

Bicuspid aortic valve is the most common congenital cardiac anomaly and often results from the aberrant formation of a large leaflet from two leaflets (Hoffman and Kaplan 2002, Yener et al 2002). It is linked with an ascending aorta that is prone to dilatation and dissection later in life. The aetiology is not yet fully understood but may involve different extracellular matrix composition (Siu and Silversides 2010, Rambeau et al 2017).

cardiac fibroblasts which not only produce extracellular matrix but also play a role in tissue repair and homeostasis (Tallquist and Molkentin 2017).

Epicardium

The epicardium develops from a protrusion of mesenchymal cells covered by mesothelium, the pro-epicardial organ (Simões and Riley 2018). This structure arises from the pericardial surface in the region of the sinus venosus during postfertilization week 5. The pro-epicardial cells migrate on the surface of the heart both by proliferation from their original location and by local directional outgrowth. The pro-epicardial cells successively spread over the myocardial surface of the developing atria, atrioventricular canal, ventricles and the proximal part of the outflow tract. The remnants of the pro-epicardium can be found in the area of the developing systemic venous tributaries up to stage 15 before it ultimately regresses.

After the formation of the epicardium, a distinct region, the sub-epicardial space or sub-epicardium, is formed between the developing epicardium and the outer myocardial layer. It is particularly pronounced at the atrioventricular junction and around the outflow regions of the heart tube and is populated by mesenchymal cells that are largely derived from the epicardium and that play an important role in the formation of the coronary vasculature.

Coronary blood vessels

Coronary arteries develop concomitantly with outflow tract septation during stages 14–16, by vasculogenesis from blood islands that coalesce into a plexus within the epicardial mesenchyme (Tomanek 2016). Plexus formation takes place before the formation of the arterial orifices in the aortic sinuses to which the coronary vessels ultimately connect. The coronary veins develop by a similar mechanism of plexus formation and mostly attach to the sinus venosus, although a small subpopulation will drain directly to the atrial chambers (Thebesian veins).

The coronary vessels themselves are formed by several precursor tissues. The endothelium is thought to arise from at least three different sources: the sinus venosus endothelium, the endocardium and, to a lesser extent, the pro-epicardium. The pericytes and smooth muscle cells arise from the epicardium and partially from the cushion endocardium. Neural crest cells can be traced to parts of the smooth muscle layer and fibroblasts arise mainly from the sub-epicardium.

The mature coronary vascular pattern is established by remodelling of the capillary plexuses and reduction in the number of arteriovenous anastomoses. Concomitant with the connection of the arterial plexus to the aorta, those vessels that acquire a tunica media and an adventitial covering persist and their luminal diameter increases (Sharma et al 2017), whereas those lacking a tunica media regress. Between postmenstrual weeks 16–19 the coronary arteries and veins increase in number and show thickening of the tunica media. During postmenstrual weeks 26–34 further expansion of the coronary vasculature occurs and elastic fibres are seen in the thickening tunica adventitia (Tomanek 2016).

Coronary artery anomalies

EMBRYONIC BLOOD, BLOOD VESSELS AND EARLY CIRCULATION

Early formation of blood

Cellular elements

The cellular elements of the blood initially arise from the extraembryonic tissues of the secondary yolk sac (Ch. 8). The yolk sac wall is composed of an epithelial parietal hypoblast layer covered with an epithelial extraembryonic mesodermal layer, derived from extraembryonic mesoblast, and some intervening extraembryonic mesenchyme (Ch. 9). The yolk sac floats freely in the extraembryonic coelom (chorionic cavity) and after head and tail folding is continuous with the developing intraembryonic midgut within the embryo via a narrow vitelline duct (Ch. 10).

Evidence for the temporal phases of blood cell production is based mainly on experimental chick and mouse embryo studies. As both of these laboratory animals have very different developmental timescales and arrangements of extraembryonic tissues, any comparison to human development must be treated with caution. In the chick, the allantois becomes the site for gaseous exchange, and in the mouse, there is an extensive inverted visceral yolk sac and a haemotrichorial labyrinthine placenta. In humans, discoid haemochorial placentation provides gaseous and nutritional exchange and a separate yolk sac, which remains throughout gestation, can be identified at parturition.

Three overlapping waves of blood cell production have been identified, with differences between erythrocyte production and that of other cellular elements (Baron 2013). Lineage analyses of blood cells have revised some of the traditional views of the initial restriction of haemopoietic cell lines, e.g. populations of megakaryocytes and macrophages have been identified in the yolk sac wall at the same time as the earliest erythrocytes (McGrath et al 2015).

Erythrocytes arising in the first haemopoietic wave have conventionally been termed 'primitive', a term that is frequently used to indicate that embryonic cells are different from their adult counterparts: the acronym, EryP, primitive erythrocytes, is more useful. EryPs arise in the yolk sac wall within 3–4 weeks post fertilization in human embryos. The cells are nucleated and, in the mouse, very large (three times larger than fetal erythrocytes and 6 times larger than adult erythrocytes) (Kauts et al 2016). They express the zeta (ζ) and epsilon (ε) globin genes, which are consistently expressed in amniote embryos. EryPs enter the developing extraembryonic and intraembryonic circulations as a transiently amplifying pool of dividing cells, able to transport oxygen and carbon dioxide, and appear to have a role in vascular remodelling. They can leave the circulation, demonstrate surface adhesion molecules and form tight associations with other EryPs in the adjacent mesenchymal tissue surrounding early vessels. Over time, circulating EryPs continue to mature, as their cell diameter decreases and they lose nucleoli. In the mouse, EryPs undergo enucleation in the liver and remain in the fetal circulation until birth. In humans, EryPs are found in the stroma of placental villi at postfertilization week 4, and by week 5 the process of enucleation is first seen. Macrophages are present and proliferating in the chorionic plate before the fetoplacental circulation is established. In the process of EryP enucleation, groups of EryPs surround a macrophage, which contacts them via cytoplasmic projections and appears to engulf and digest their extruded nuclei (Van Handel et al 2010). The enucleated cells, reticulocytes, are found in the circulation, as are blood elements termed pyrenocytes, which are nuclei from EryPs with a surrounding cell membrane (McGrath et al 2008).

The second wave of erythrocyte production, also from the yolk sac wall, gives rise to EryD (definitive erythrocytes) from about postfertilization week 4 in humans. These cells are considered to arise from transient multipotent progenitors which will become restricted to erythroid and myeloid lineages (Baron 2013). In the mouse, EryD cells are found in the yolk sac wall, the developing liver and in the forming bone marrow. EryD cells are smaller than EryPs, they display different gene expression and requirements for erythropoietin, and different oxygen carrying capacities. Both types of early erythrocyte are present in the circulation during the second wave, and EryD cells rapidly outnumber EryPs.

The third wave of erythrocyte production of haemopoietic stem cells (HSCs), arises within the embryo at intraembryonic sites, including mesenchyme adjacent to large blood vessels, within the placental stroma and in the aorta-gonad-mesonephros (AGM) region. This latter region is subjacent to the intraembryonic coelom, particularly the lower ends of the pericardio-peritoneal canals and the upper posterior wall of the peritoneal cavity on either side of the mesentery of the midgut. It forms at the junction between somatopleuric and splanchnopleuric mesenchyme and is referred to as intermediate mesenchyme (Ch. 12).

It was always stated that the embryonic liver develops precociously to become a haemopoietic site before the medullary cavities form in developing long bones. In the mouse, both EryP and EryDs mature and enucleate in the liver. EryDs, (which are zeta-globin negative) have been identified in human embryonic liver from 6.5 weeks post fertilization, equivalent to about stage 19, and enucleating cells have been identified in sub-sinusoidal spaces at 11 weeks post fertilization. These findings suggest that the fetal human liver may not support erythroblast enucleation until later in development than was previously thought (Van Handel et al 2010). Study of haemopoietic stem cells from human fetal liver and cord blood have produced genome-wide maps of the DNA methylation profiles of developing blood cells (Farlik et al 2016).

Ultimately, only solitary right and left coronary arteries remain. There are occasional anomalies in coronary artery morphology: small accessory branches of the coronary arteries take their origin directly from the coronary sinuses in one third of human hearts. For information on coronary artery anomalies see Spicer et al (2015) and Pérez-Pomares et al (2016).

In the mouse there is some evidence that cells with a future haemopoietic lineage arise from the caudal primitive streak (Fraser 2012). Mesoblast cells arising from the caudal primitive streak migrate rostrally and laterally and differentiate into the initial epithelial lining of the intraembryonic coelomic wall (see Fig. 10.3). These cells then proliferate producing the mesenchymal populations (splanchnopleuric, somatopleuric and intermediate). It is possible that the final stem cells for late fetal and future adult haemopoiesis remain in the coelomic wall epithelium until the requisite time. These haemopoietic stem cells do not differentiate *in situ*, but seed precursor cells to the liver, thymus and bone marrow, which subsequently produce all blood lineages; they have been found in human embryos in very small numbers around 5 postfertilization weeks (Baron 2013).

Plasma

It has been suggested that the rapidly expanding early cardiovascular system is filled with plasma, reflecting the movement of fluid from the intraembryonic coelom to the veins. The intraembryonic coelomic wall is largely composed of proliferating cells that produce the splanchnopleuric and somatopleuric mesenchymal populations; when not dividing, adjacent cells form tight junctions, indicating a barrier function of the epithelium (Guo et al 2014). However, the walls of a portion of the pericardioperitoneal canals are thinner, and possibly more permeable to coelomic fluid, at the time when the canals surround the hepatocardiac channels. The latter lie between the hepatic plexus and the sinus venosus; the hepatocardiac channel on the right side is a wider vessel whereas on the left it is more plexiform, with only a transitory connection to the sinus venosus. The differentiation of this specific coelomic region occurs just in advance of the expansion and filling of the right and left atria, at about stage 12. Fluid within the extraembryonic coelomic space, the chorionic cavity, which is continuous with the intraembryonic coelom, has been collected and examined in the early human embryo (Jauniaux and Gulbis 2000). There are few, if any, studies on the synthesis and circulation of proteins including plasma proteins, although both erythropoietin and thrombopoietin are apparently needed for embryonic erythrocyte production (Baron 2013).

Early formation of blood vessels

It was thought that blood cells and blood vessels were derived from the same precursor population, initially in the extraembryonic tissues, but lineage studies have shown that EryPs and endothelial precursors do not share a common progenitor (Baron 2013). Vasculogenesis and angiogenesis are involved in the formation of blood vessels lined with endothelium. Vasculogenesis is the process where vessels arise *in situ* in extra- and intraembryonic sites: vitelline vessels form within the yolk sac wall; umbilical vessels arise within the mesenchyme surrounding the allantois; and the endocardium and dorsal aortae arise from splanchopleuric mesenchyme derived from the epithelial coelomic wall.

Angiogenesis

Further vessel development occurs by a process of angiogenesis in which endothelial precursors, angioblasts, arising in splanchnic and somitic tissues, add endothelial sprouts and branches to earlier vessels. None of the main vessels of the adult arises as a single trunk in the embryo. A capillary network is first laid down along the course of each vessel and the larger arteries and veins are defined by selection and enlargement of definite paths in this network. Lymphatic vessels develop after the main arteries and veins are formed. They arise initially by angiogenesis from the cardinal veins and subsequently by proliferation of lymphangioblasts that form lymphatic capillaries.

Five stages of angiogenesis have been described: endothelial tip cell specification and sprout initiation; sprout elongation and local guidance, where the distal tip cell extends supported by proximal stalk cells that may divide; sprout elongation in response to cues from the extracellular matrix; lumen formation, initially by the confluence of intracellular vacuoles, followed by establishment of apical basal polarity of the cells of the endothelial sprout; and fusion of the tip cell to another sprout tip so that two developing tubes join to form an early vascular plexus (Kuijper et al 2007, Chappell et al 2012). The developmental processes of angiogenesis are similar to those seen in both neoplasia and acute inflammation in adult tissue. The literature on angiogenesis is extensive and the process will not be considered in detail here; the interested reader is directed to Herbert and Stainier (2011), Senger and Davis (2011), Beets et al (2013), Eichmann and Pardanaud (2014) and Hashimoto et al (2016).

Studies have considered the development of capillary beds within the surrounding mesenchymal tissues destined to become laminae propriae, but few have looked at how capillary beds form within tissues undergoing morphogenetic movements. Czirok et al (2011) discussed the temporal imperative for free-living embryos to develop rapidly in contrast to amniote embryos, which do not have to fend for themselves. They concluded that prior to the establishment of a circulation, amniote vascular patterns of development are not predetermined by a network of patterning genes and cell signalling pathways, but rather that the tissue movements during organogenesis and the realignment and tension that develop within extracellular matrix fibres may guide cell migration and the position of early vessels.

Extracellular matrix plays a critical role in angiogenesis and vessel stabilization in the embryo and in the adult. Differences in the composition and abundance of specific extracellular matrix components between the embryo and adult mean that there are likely to be significant differences in the process at different ages. Fibronectin is required for normal vascular development; its deposition is related to interactions between endothelial cells and pericytes, and local tensional forces that occur between blood vessel basement membrane and local extracellular matrix assembly (Davis and Senger 2005, Senger and Davis 2011). Early blood vessels are initially surrounded by a fibronectin-rich matrix that is later incorporated into the endothelial basal lamina along with laminin, a particularly early constituent. Several layers of fibronectin-expressing cells are seen around larger vessels, such as the dorsal aortae. The endothelium does not synthesize a basal lamina in those regions where remodelling and angiogenesis are active, and the mesenchyme around such endothelium does not express α-actin or laminin until branching has stopped and differentiation of the tunica media begins (after a stable vascular pattern has formed). It is not known how differentiation of pericytes and smooth muscle cells is induced; the majority of arteries accumulate medial smooth muscle from the surrounding mesenchyme.

In early development, the early vessels of the embryo are disproportionately large and their walls consist of little more than a single layer of endothelium. The cardiac orifices are also relatively large and the force of the cardiac contraction is weak and, consequently, the circulation is sluggish, despite the rapid rate of contraction of the developing heart. However, the tissues are able to draw nourishment not only from the capillaries but also from the large arteries and the intraembryonic coelomic fluid. The earliest blood cells are also very large; as the embryo grows the early vascular beds become more complex and narrowed and erythrocytes also become smaller.

There is an ongoing relationship between developing blood vessels, their response to haemodynamic forces and the mechanotransduction pathways involved. The flow of blood exerts pressure on the developing vessel walls; circumferential stress is generated when vessels stretch in response to pressure, and shear stress, the tangential frictional force of flowing blood against the endothelium, is detected by and produces epigenetic changes in that epithelium (Culver and Dickinson 2010). Three principles operate in embryonic vasculature: if the flow increases or decreases the blood vessel calibre increases or decreases to normalize the shear stress; if the blood pressure in the vessel increases or decreases the vessel wall thickens or thins respectively, mainly by the modulation of the amount of smooth muscle; increase in capillary pressure leads to new capillary growth (Roman and Pekkan 2012). Endothelial cells are mechanosensitive, they are able to respond to laminar and disturbed blood flows and are sensitive to blood viscosity. Very complex interactions occur throughout the development of the circulation; cardiac rate increases with development and cardiac output increases in proportion to the weight of the embryo, so that when dorsal aortic blood flow is matched to embryonic weight, blood flow remains constant over a more than 150-fold change in the mass of the embryo. The influence of blood flow on cardiac development, and the ways that computational fluid dynamics can be used to determine developmental responses to blood flow have been studied (Courchaine and Rugonyi 2018, Courchaine et al 2018). Routine postmenstrual week 20 4D ultrasound assessments have been correlated with fluid mechanics of blood flow through fetal hearts (Wiputra et al 2016). For further information on haemodynamic forces in vascular development, remodelling and vessel specification see Culver and Dickinson (2010) and Roman and Pekkan (2012).

Embryonic arteries

Early arteries

After head folding, the embryo has bilateral primitive aortae, each consisting of ventral and dorsal parts that are continuous through the first embryonic aortic arches. The ventral aortae are fused and form a dilated aortic sac. The dorsal aortae run caudally, one on each side of the notochord, and fuse from about the level of the fourth thoracic to the fourth lumbar segment to form a single definitive descending aorta in stage 10 (**Fig. 13.17B**). In general, more mature endothelial channels are seen in the rostral, more advanced regions of the embryo. More caudally, a changing capillary plexus constantly remodels, becoming confluent with the extraembryonic vascular channels developing in the walls of the yolk sac and allantois (within the connecting stalk). The dorsal continuation of the primitive dorsal aortae forms anastomoses with the vitelline vessels around the yolk sac, and more caudally with anastomoses forming around the allantois.

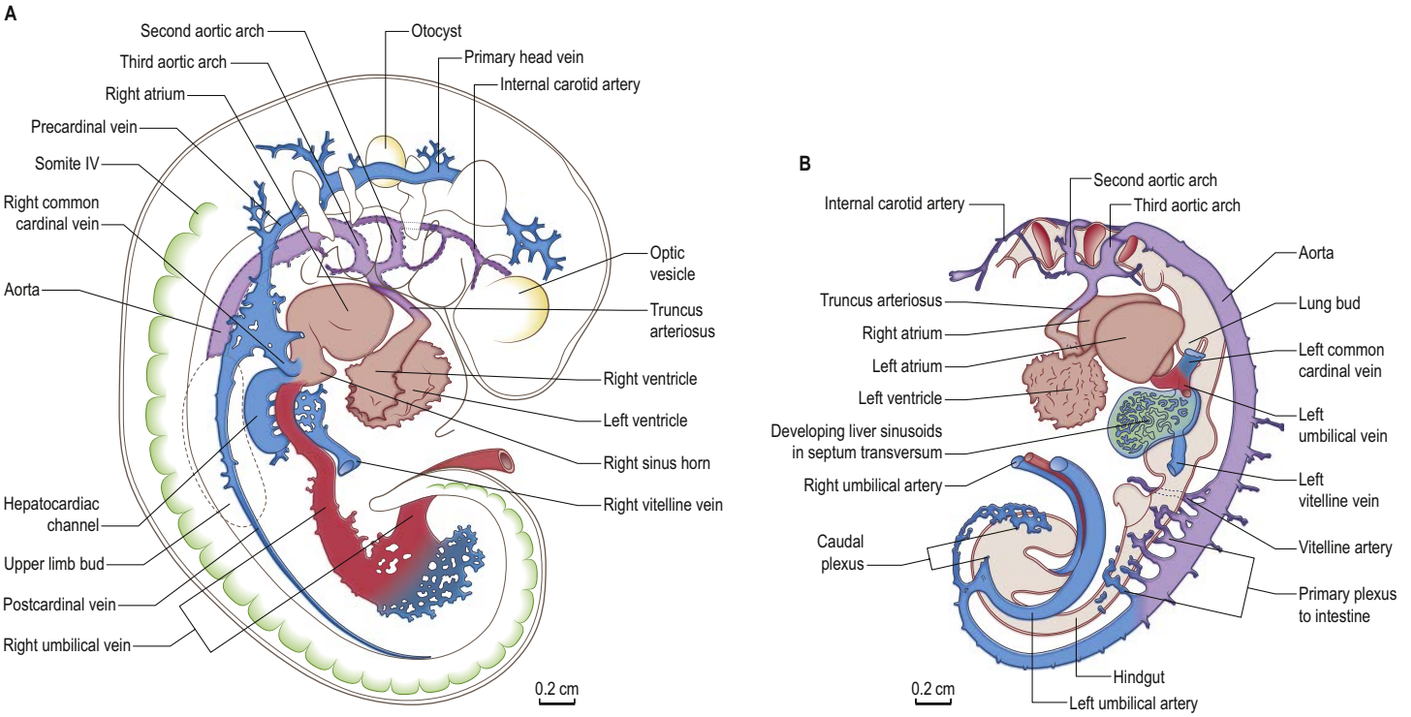

Fig. 13.17 Profile reconstructions of the blood vascular system of a stage 13 human embryo. The early circulation is now asymmetric; the venous vessels are enlarging on the right and diminishing on the left. **A**, Seen from the right side, showing the main venous channels to the heart. **B**, Seen from the left side, showing the aortic arch arteries, the main vessels arising from the dorsal aorta and umbilical arteries. Note that only the endothelial lining of the heart chambers is shown and, because the muscular wall has been omitted, the pericardial cavity appears much larger than the contained heart.

Initially, the dorsal aortae are the only longitudinal vessels present. Their branches all run at right-angles to the long axis of the embryo. Later, these transverse arteries become connected by longitudinal anastomosing channels that persist in part, forming arteries such as the vertebral, internal thoracic, superior and inferior epigastric, and gastro-epiploic (gastro-omental). Each primitive dorsal aorta gives off somatic arteries (intersegmental branches to the body wall), a caudal continuation that passes into the body stalk (the umbilical arteries), lateral splanchnic arteries (paired segmental branches to the mesonephric ridge), and ventral splanchnic arteries (paired segmental branches to the digestive tube).

Aortic arch arteries

The aortic arch arteries arise from the truncus arteriosus and pass bilaterally around the developing pharynx, to join bilateral dorsal aortae (Fig. 13.17). Details of the fates of the aortic arteries are given in Chapter 17, Fig. 17.9. The arterial vessels supplying the head and brain in stage 17 are illustrated in Fig. 17.8 and details of the maturation of cerebral arteries are given in Chapter 14 (see Fig. 14.36).

Somatic arteries

The somatic arteries are intersegmental in position. They persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal ramus that passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (Fig. 13.18). The dorsal ramus also gives off a spinal branch that enters the vertebral canal and divides into a series of branches that supply the walls and joints of the osteoligamentous canal, and neural branches to the spinal cord and spinal nerve roots. After giving off its dorsal ramus, each intersegmental artery runs ventrally in the body wall, gives off a lateral branch and terminates in muscular and cutaneous rami.

Lateral splanchnic arteries

On each side the lateral splanchnic arteries supply the mesonephros, metanephros (see Fig. 22.2), testis or ovary and the suprarenal gland. All these structures develop, in whole or in part, from the intermediate mesenchyme, later termed the aorta–gonad–mesonephros region. One testicular or ovarian artery and three suprarenal arteries persist on each side. The phrenic artery branches from the most cranial suprarenal artery, and the renal artery arises from the most caudal. Additional renal arteries are frequently present and may be regarded as branches of persistent lateral splanchnic arteries.

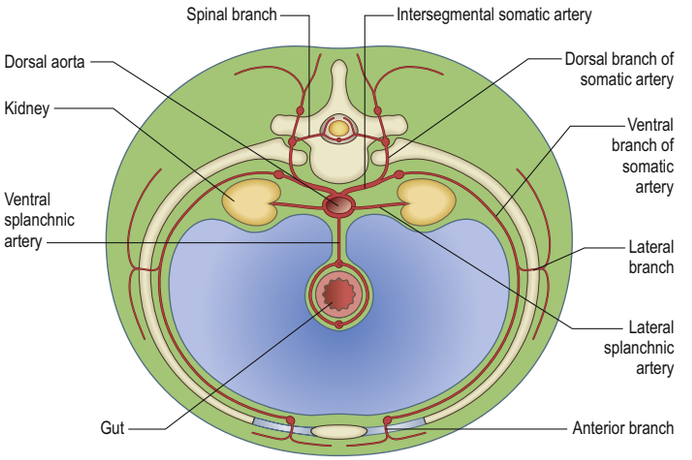

Fig. 13.18 The segmental and intersegmental arteries. The small red dilations indicate the positions of the longitudinal anastomoses.

Ventral splanchnic arteries

The ventral splanchnic arteries are originally paired (vitelline) vessels distributed to the capillary plexus in the wall of the yolk sac. After fusion of the dorsal aortae, they merge as unpaired trunks that are distributed to the increasingly defined and lengthening primitive digestive tube. Longitudinal anastomotic channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (see Figs 13.17, 13.18). Above the respiratory diaphragm, a variable number of ventral splanchnic arteries persist, usually four or five, and supply the thoracic oesophagus. The dorsal splanchnic anastomosis persists in the gastro-omental (gastroepiploic), pancreaticoduodenal and primary branches of the colic arteries, whereas the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries. Below the diaphragm, the ventral splanchnic arteries are reduced to three: the coeliac trunk and the superior and inferior mesenteric arteries. As the viscera supplied descend into the abdomen,

their origins migrate caudally by differential growth. Thus the origin of the coeliac artery is transferred from the level of C7 to the level of T12; the superior mesenteric from T2 to L1; and the inferior mesenteric from T12 to L3. The superior mesenteric artery extends along the axis of the midgut loop into the extraembryonic coelom from stage 14 until 9 postfertilization weeks. As the proximal limb of the midgut loop develops secondary and tertiary loops, the artery gives rise to a series of branches. At stage 23 eight branches have arisen from the intra-abdominal portion of the artery, with the first three supplying the most proximal portion of the midgut loop. The third branch is bifurcated and supplies the midgut at the umbilical opening. The distal parts of the intra-abdominal branches 5–8 extend into the mesentery within the extraembryonic coelom, and all of the remaining branches, 9–14, supply that part of the midgut loop outside the embryonic body. The distance between the individual branches 9–14 are longer than those between branches 5–8. A colic branch arises consistently on the cranial side of the artery between branches 7 and 9 (Hikspoors et al 2015).

Early vitelline arteries

Vitelline arteries form in the vitelline arterial plexus around the secondary yolk sac and become confluent with the dorsal aortae in stage 12. By stage 13 communication between the embryonic body and yolk sac is limited to a single vitelline artery arising from the splanchnic branches of the dorsal aorta and running rostral to the narrowing vitelline duct (see Fig. 13.17). During stage 14 the artery with the vitelline duct is a landmark for the apex of the midgut loop within the splanchnopleuric mesenchyme of the dorsal mesentery. The vitelline artery is not a patent vessel at stage 16: its proximal origin becomes the origin of the superior mesenteric artery (Hikspoors et al 2015).

Early umbilical arteries

Initially, the umbilical arteries are the direct caudal continuation of the primitive dorsal aortae (see Fig. 13.17). They are present in the body stalk (connecting stalk) before any vitelline or visceral branches emerge, indicating the dominance of the allantoic over the vitelline circulation in the human embryo. (On a comparative basis, the umbilical vessels are chorio-allantoic and therefore 'somatovisceral'.) After the dorsal aortae fuse, right and left umbilical arteries arise from their ventrolateral aspects and pass lateral to the allantois in the connecting stalk (see Figs 13.17, 22.1). Later, the proximal part of each umbilical artery is joined by a new vessel that leaves the aorta at its termination and passes lateral to the allantois. This, possibly the fifth lumbar intersegmental artery, constitutes the dorsal root of the umbilical artery (the original stem forms the ventral root). The dorsal root gives off the axial artery of the lower limb, branches to the pelvic viscera and, more proximally, the external iliac artery. The ventral root disappears entirely and the umbilical artery now arises from that part of its dorsal root distal to the external iliac artery, i.e. the internal iliac artery.

Embryonic veins

Early veins

The early embryonic veins are often segregated into two groups, visceral and somatic, for convenience and apparent simplicity. The visceral group contains the derivatives of the vitelline and umbilical veins, and the somatic group includes all remaining veins. It should be noted that, with time, embryonic veins change the principal tissues they drain. They may receive radicles from obviously parietal tissues, which become confluent with drainage channels that are clearly visceral, and so form a compound vessel. The arrangement of the early embryonic veins is initially symmetric (see Fig. 13.17). The primitive tubular symmetric heart receives its venous return through the right and left horns of the sinus venosus, which are initially embedded in the mesenchyme of the septum transversum. Each horn receives vitelline, umbilical and the common cardinal veins (see Fig. 13.8). This symmetric pattern changes as the heart and gut develop and cardiac return is diverted to the right side of the heart.

Cardinal veins and somatic venous complexes

The initial venous channels in the early embryo have conventionally been termed cardinal because of their importance at this stage. The cardinal venous complexes are first represented by two large vessels on each side, the precardinal portion is rostral and the postcardinal is caudal to the heart. The two vessels unite to form a short common cardinal vein which passes ventrally to open into the corresponding horn of the sinus venosus (see Figs 13.1B, 13.17A; **Fig. 13.19B**). Further development of the precardinal veins directing the venous drainage of the head and arms to the right gives rise to the superior vena cava. Caudally, the postcardinal veins connect to a range of bilateral longitudinal anastomoses and venous confluences that cross the midline and successively direct the venous drainage from the lower limbs and body to the right, forming the inferior vena cava.

The precardinal veins join across the midline via an oblique interprecardial anastomosis (see Fig. 13.19B(i)) and undergo further remodelling as the head develops to form the dural venous sinuses (Ch. 17, p. 279; see Fig. 17.10). As the embryo increases in size, the postcardinal veins are insufficient channels to carry the venous return from the body wall and the developing mesonephros and gonads, and are supplemented by the bilateral longitudinal channels that anastomose with each other and with the posterior cardinal system. These channels are the subcardinal veins ventrally, and the subcentral, supracardinal, azygos line, and precostal veins more dorsally (**Fig. 13.19A**).

Postcardinal veins

The early postcardinal veins communicate across the midline via an interpostcardinal anastomosis (see Fig. 13.19B(ii)). This remains as an oblique transverse anastomosis between the iliac veins, and becomes the major part of the definitive left common iliac vein. It diverts an increasing volume of blood into the right longitudinal veins, which accounts for the ultimate disappearance of most of those on the left.

Subcardinal veins

Subcardinal veins (see Fig. 13.19B(i)) form in the ventromedial parts of the mesonephric ridges and become connected to the postcardinal veins by a number of vessels traversing the medial part of the ridges. They communicate by a pre-aortic intersubcardinal anastomotic plexus (the renal collar), which later forms the part of the left renal vein that crosses anterior to the abdominal aorta. On the right side, the subcardinal vein comes into intimate relationship with the developing liver. A cranial extension of the vessel establishes continuity with a corresponding new formation that is growing caudally from the right vitelline hepatocardiac (common hepatic) vein. In this way, on the right side, a more direct route is established to the heart and the prerenal (cranial) segment of the developing inferior vena cava.

Supracardinal veins

Supracardinal veins (see Fig. 13.19B(ii)) form dorsolateral to the aorta and lateral to the sympathetic trunk and take over the intersegmental venous drainage from the posterior cardinal vein. The supracardinal veins are also referred to as lateral sympathetic line veins or the thoracolumbar line. They receive the larger venous drainage of the growing body wall and communicate with the iliac veins caudally and with each other via the azygos lines and subcentral veins. The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava. The continuity of the vessel is maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the renal collar, a complete venous ring around the aorta below the origin of the superior mesenteric artery. The left supracardinal disappears, but some of the renal collar formed by the left supracardinal–subcardinal anastomosis persists in the left renal vein. Both supracardinal veins drain cranially into the subcardinal veins.

Azygos line veins

Azygos line veins form dorsolateral to the aorta and medial to the sympathetic trunk (see Fig. 13.19B(ii)). These channels, also referred to as the medial sympathetic line veins, gradually take over the intersegmental venous drainage from the supracardinal veins. The intersegmental veins now reach their longitudinal channel by passing medial to the sympathetic trunk, a relationship that the lumbar and intercostal veins subsequently maintain. Cranially, the azygos lines join the persistent cranial ends of the posterior cardinal veins.

Subcentral veins

Subcentral veins form directly dorsal to the aorta in the interval between the origins of the paired intersegmental arteries (see Fig. 13.19A). These veins communicate freely with each other and with the azygos line veins: these connections ultimately form the retro-aortic parts of the left lumbar veins and of the hemiazygos veins.

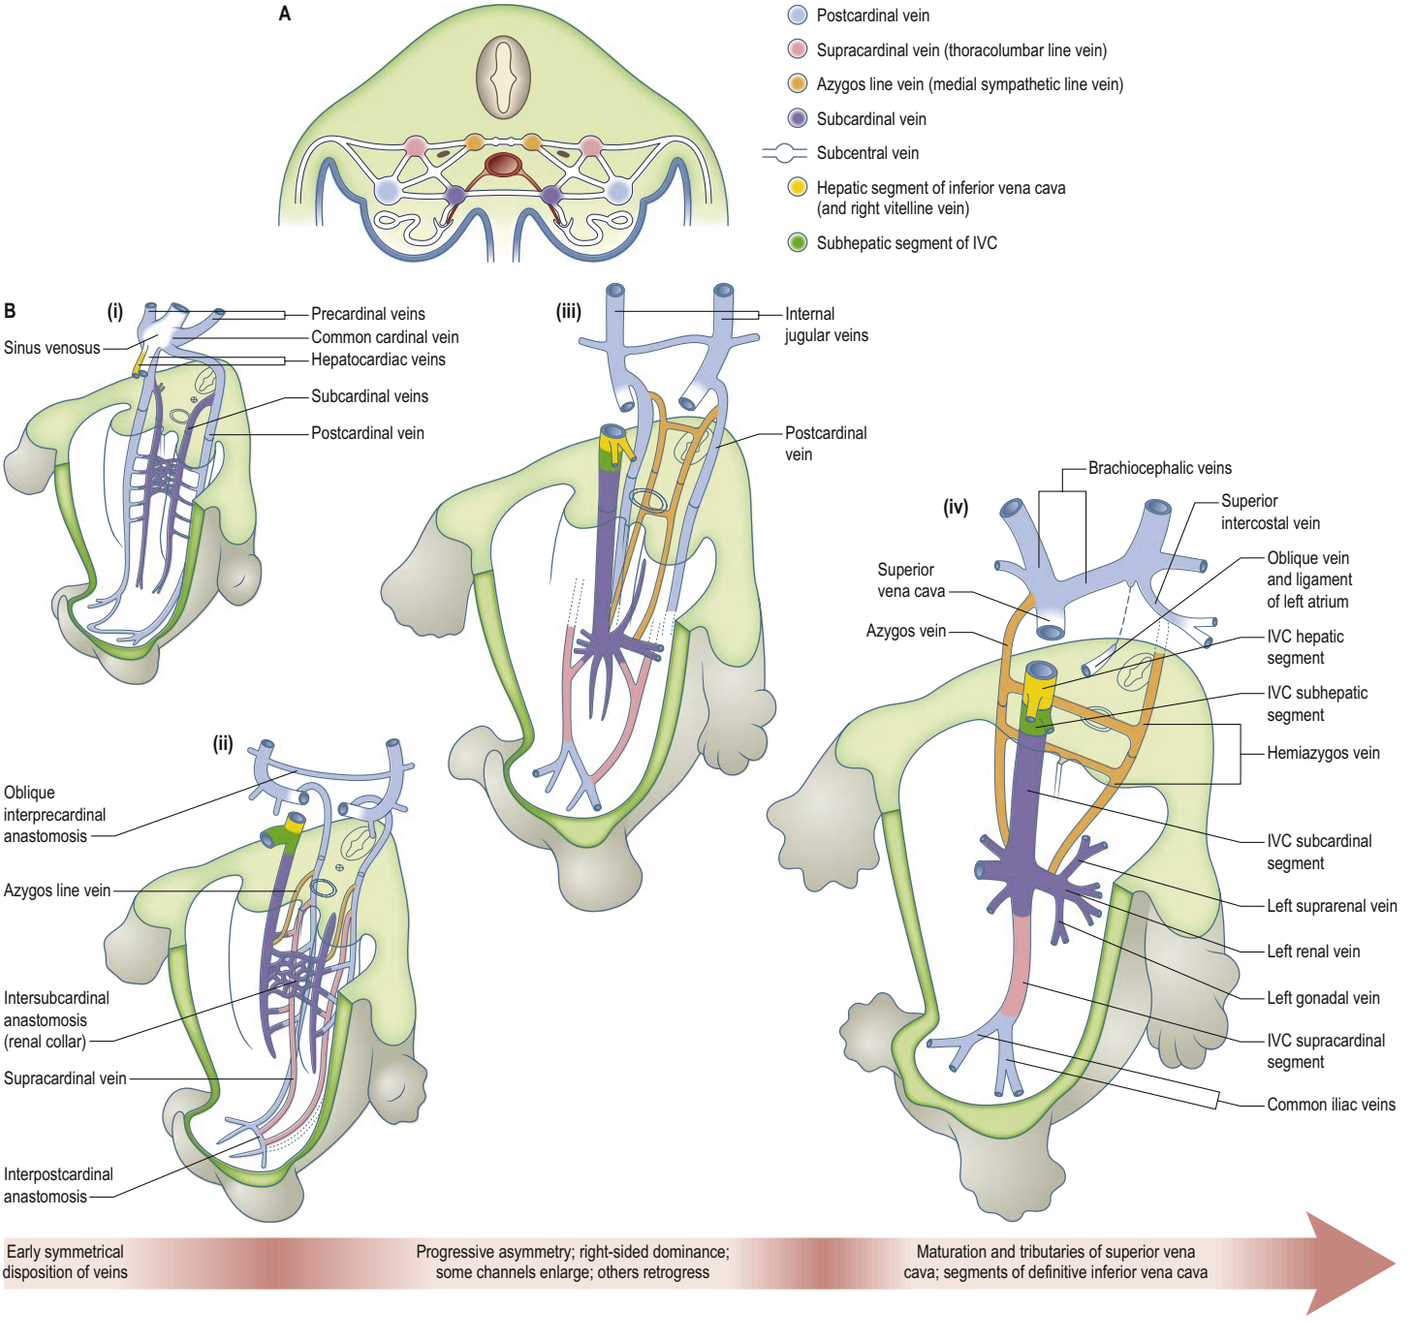

Fig. 13.19 Somatic venous development. **A**, A section through the embryonic trunk. Principal longitudinal veins are colour-coded. Interconnections and intersegmental veins are uncoloured. **B**, The development of the principal somatic veins, from the early symmetric state, through states of increasing asymmetry, to the definitive arrangement. Abbreviations: IVC, inferior vena cava.

Precostal or lumbocostal venous line

A precostal or lumbocostal venous line, anterior to the vertebrocostal element and posterior to the supracardinal, is recognized by some authorities. The ascending lumbar vein is a possible derivative.

Further development of the somatic veins

The final arrangement of the embryonic abdominal and thoracic longitudinal cardinal veins may be summarized as follows. The terminal part of the left postcardinal vein forms the distal part of the left superior intercostal vein. On the right side, its cranial end persists as the terminal part of the azygos vein. The caudal part of the subcardinal vein is, in part, incorporated in the testicular or ovarian vein and partly disappears. The cranial end of the right subcardinal vein is incorporated into the inferior vena cava and also forms the right suprarenal vein. The left subcardinal vein, cranial to the intersubcardinal anastomosis, is incorporated into the left suprarenal vein. The renal and testicular or ovarian veins on both sides join the supracardinal–subcardinal anastomosis. On the left side, this connects directly to the forming inferior vena cava via an intersubcardinal anastomosis; the right supracardinal vein forms much of the caudal (postrenal) segment of the inferior vena cava. The left supracardinal vein disappears entirely. The right azygos line persists in its thoracic part to form all but the terminal part of the azygos vein. Its lumbar part can usually be identified as a small vessel that leaves the azygos vein on the body of the twelfth thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins. The subcentral veins give rise to the retro-aortic parts of the left lumbar veins and of the hemiazygos veins (see Fig. 13.19B(iv)).

Inferior vena cava

The inferior vena cava (see Fig. 13.19B(iv)) is a composite vessel that develops on the posterior abdominal wall dorsal to the developing peritoneal cavity. It forms as a consequence of the temporal remodelling of the successive venous complexes described above. The precise mode of development of its postrenal segment (caudal to the renal vein) is still somewhat uncertain. Its function is initially carried out by the right and left postcardinal veins which receive the venous drainage of the

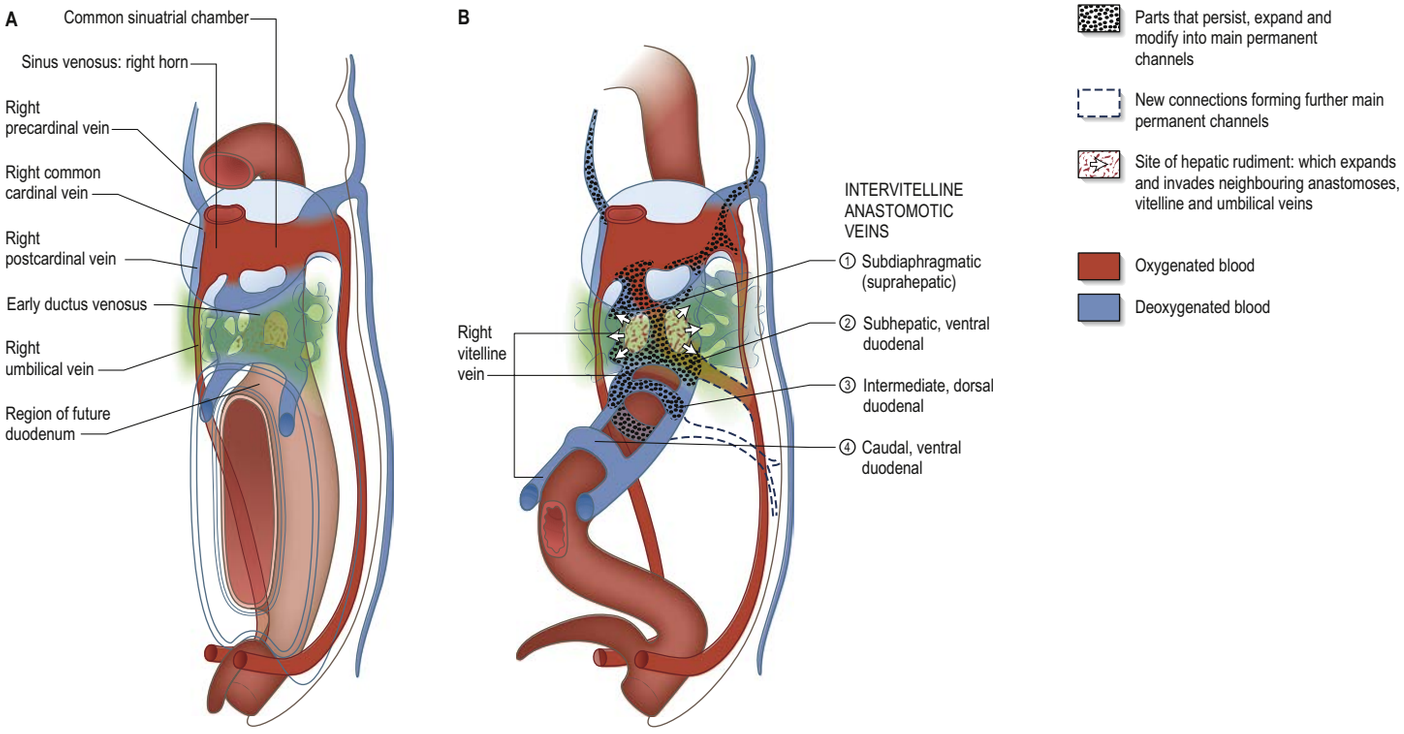

Fig. 13.20 Development of the vitelline, umbilical and terminal cardinal vein complexes: the early symmetric condition. **A**, The early symmetric arrangement of cardinal and umbilical veins entering the sinus venosus; blood from the yolk sac passes, via vitelline veins, through anastomoses forming in the septum transversum mesenchyme (green). **B**, The developing duodenum is surrounded by transverse duodenal intervitelline anastomoses. Changes in the developing gut and umbilical veins cause shifts in the routes taken by venous blood flowing to the sinus venosus.

lower limb buds and pelvis, and run in the dorsal part of the mesonephric ridges, receiving tributaries from the body wall (intersegmental veins) and from the derivatives of the mesonephroi. Many of the changes seen in the development of the infrahepatic caval and azygos systems in the human may result from lateral to medial movement of the vessels as a consequence of the growth of the abdominal viscera (Hikspoors et al 2015).

Descriptions of venous development are very largely based on studies on animals, where the dimensions and final disposition of visceral organs differ from those found in humans. In some animals, the right postcardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases, the right ureter, on leaving the kidney, passes medially, dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Rarely, a similar condition is found in humans, and indicates the persistence of the right postcardinal vein and failure of the right supracardinal to play its normal part in the development of the inferior vena cava.

Only the supracardinal part of the inferior vena cava receives intersegmental venous drainage. The postrenal (caudal) segment of the inferior vena cava is on a plane that lies dorsal to the plane of the prerenal (cranial) segment. Thus, the right phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, whereas the testicular or ovarian artery, which has a similar developmental origin, passes anterior to it.

In summary, the inferior vena cava is formed from below upwards by the confluence of: the common iliac veins, a short segment of the right postcardinal vein, the postcardinal–supracardinal anastomosis, part of the right supracardinal vein, the right supracardinal–subcardinal anastomosis, right subcardinal vein, a new anastomotic channel of double origin (the hepatic segment of the inferior vena cava) and the cardiac termination of the right vitelline hepatocardiac vein (common hepatic vein).

Visceral venous complexes, ductus venosus and the portal vein

Early vitelline veins

The early vitelline veins drain capillary plexuses that develop within the extraembryonic splanchnopleuric mesenchyme of the secondary yolk sac (see Fig. 9.10). With head, tail and lateral fold formation, elongation of the rostral endoderm forms the foregut, the allantois is brought within the body cavity with the hindgut dorsally, and the midgut remains confluent with the yolk sac (see Fig. 10.10). At stage 12, derivatives from all these levels possess a venous drainage that is originally vitelline and enters the sinus venosus as the most medial of the vessels contributing to the inflow tract of the heart (see Fig. 13.8). The intraembryonic confluence of both vitelline veins descends between stages 14 and 18 as the heart descends.

Early umbilical veins

The early umbilical veins form in the mesenchyme surrounding the allantois and in the mesenchymal connecting stalk confluent with the developing placenta (see Figs 9.2, 9.10, 13.1). The human endodermal allantois is very small, projecting only into the (proximal) embryonic end of the connecting stalk, which is therefore regarded as precociously formed allantoic mesenchyme. Peripheral venules drain the mesenchymal cores of the placental chorionic villous stems and terminal villi. They are the radicles of a single vessel, the vena umbilicalis impar, that traverses the mixed mesenchyme of the connecting stalk to reach the caudal rim of the developing umbilical cord where it divides into primitive right and left umbilical veins. Each curves rostrally in the somatopleuric lateral border of the umbilicus, i.e. where intraembryonic and extraembryonic or amniotic somatopleure are continuous, lying lateral to the communication between both the intraembryonic and the extraembryonic coeloms. Rostrolateral to the umbilicus, the two umbilical veins reach, enter and traverse the junctional mesenchyme of the septum transversum and connect with septal capillary plexuses (Fig. 13.20). They then continue, entering their corresponding horn of the sinus venosus lateral to the terminations of the vitelline veins.

Later vitelline veins

From stage 13 the vitelline veins passing to the embryo from the yolk sac wall enter an intervitelline anastomosis (hepatic plexus) in the caudal part of the septum transversum before reaching the sinus venosus. This network is ventral to the future subdiaphragmatic end of the oesophagus, primitive stomach, the superior (first) and descending (second) regions of the duodenum and the remainder of the duodenal tube. The channel is sometimes termed suprahepatic because of the position of the hepatic primordium; as the latter expands, it becomes partly intrahepatic. The terminations of the vitelline veins from this time are termed hepatocardiac channels.

Development of the portal circulation is initiated by changes in the disposition of the duodenum and related changes to the intervitelline anastomotic veins. The duodenum develops from the caudal part of the foregut (that part of the gut with dorsolateral pericardioperitoneal canals), and the cranial part of the midgut. All portions are surrounded

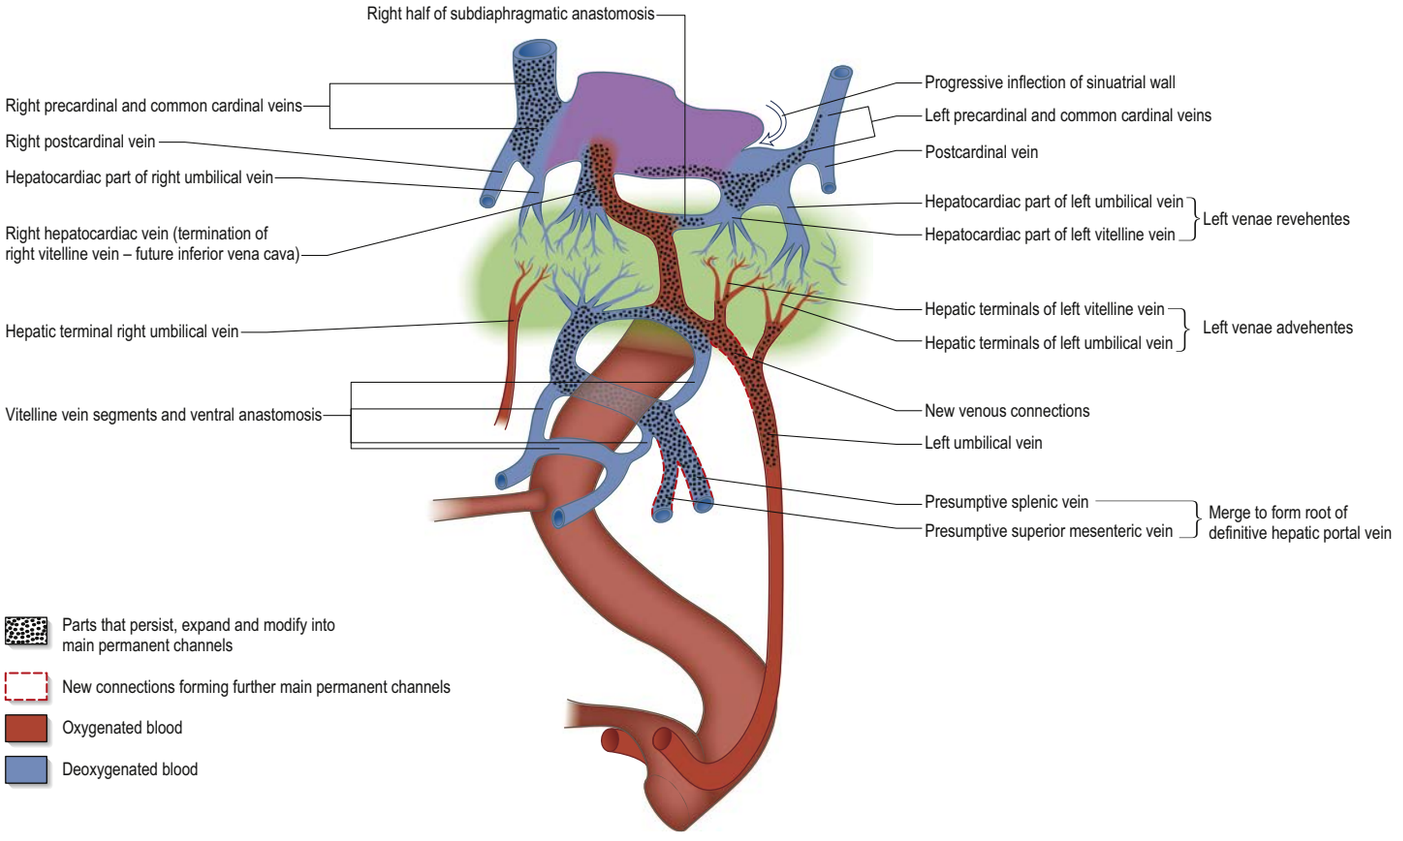

Fig. 13.21 Development of the vitelline, umbilical and terminal cardinal vein complexes: a mid-stage of asymmetry has been reached between the early symmetric condition (see Fig. 13.20) and the definitive late prenatal state. The extent of the liver within the septum transversum mesenchyme is shown in green.

by splanchnopleuric mesenchyme: the portal circulation develops from angiogenic lineages in this tissue. Ventrally only the caudal part of the foregut is continuous with the ventral mesogastrium, derived from the cranial part of the septum transversum mesenchyme; the cranial midgut ventral surface lies free in the future peritoneal cavity. Dorsally, the duodenum is attached by splanchnopleuric mesenchyme to a dorsal mesoduodenum cranially and the dorsal mesentery of the midgut caudally.

Proximally a subdiaphragmatic (suprahepatic) anastomosis lies close to the foregut portion of the duodenum. As the cranial midgut portion of the duodenum lengthens, three more transverse duodenal intervitelline anastomoses, subhepatic (ventral duodenal), intermediate (dorsal duodenal) and caudal (ventral duodenal), become visible (see Fig. 13.20B). As can be inferred from their names, their relation to the duodenum alternates and it has become customary to describe the blood flow through these paraduodenal vitelline veins and their associated anastomoses as forming a figure of eight.

Distally, when the connection of the yolk sac to the midgut narrows, forming the vitelline duct, the vitelline veins also lengthen and continue on each side of the duct (see Fig. 21.2B). They lengthen even further when the midgut loop extends into the extraembryonic coelom. The left vitelline vein lies within the dorsal mesentery between the proximal and distal parts of the midgut loop. In stage 14 embryos, the right vitelline vein is cranial to the proximal midgut loop within the mesenchyme surrounding the vitelline duct; from stage 16 onwards it appears disconnected from this mesenchyme and free within the abdominal cavity alongside the vitelline duct. Its course forms the central axis of the primary midgut loop and marks the apex of the loop until the return of the herniated small intestine to the abdominal cavity (Hikspoors et al 2015).

Later umbilical veins

The further development of the vitelline veins and their anastomoses is closely interlocked with the growth of hepatic sinusoids in the septum transversum and changes to the umbilical veins. Evagination of hepatic 'cords' of presumptive hepatocytes from the endodermal foregut into the septum transversum mesenchyme initiates the formation of early plexiform connections of the hepatic sinusoids. As these expand laterally and extend caudally, they merge with the terminal connections of the vitelline and umbilical veins and subsume them within a series of complex branching vessels conducting blood in and out of the hepatic sinusoids.

Both deoxygenated and oxygenated blood enter the developing hepatic sinusoids, in the same way as the adult liver sinusoids convey portal and systemic blood. However, in the embryo and fetus, both blood supplies travel within veins. Vitelline veins from the extraembryonic yolk sac and the intraembryonic developing gut carry deoxygenated blood, and umbilical veins carry oxygenated blood from the placenta. All of these vessels branch and enter the liver via afferent hepatic veins, the venae advehentes. Blood leaves the hepatic sinusoids through four efferent hepatic veins, the venae revehentes; these are the terminal ends of the right and left vitelline veins, and the right and left umbilical veins, now termed hepatocardiac veins, all of which enter the sinus venosus (**Fig. 13.21**).

Changes to the circulation that involve returning venous blood to the right side via modifications of the cardinal system of veins occur contemporaneously with changes to the terminal portions of the vitelline and umbilical veins. The right umbilical vein regresses and atrophies during stages 14–15 (see Fig. 13.21). The hepatic terminal of the left umbilical vein retains some vessels that discharge into the sinusoids, but blood flow preferentially enlarges connections with the left half of the subhepatic (ventral duodenal) intervitelline anastomosis. These connections form a channel, the ductus venosus, which courses to the right half of the subdiaphragmatic anastomosis to join the right hepatocardiac channel (the termination of the right vitelline vein) and empty into the inferior vena cava (see Fig. 13.21; **Fig. 13.22**). The portal vein is derived from presumptive superior mesenteric and splenic veins that pass via the intermediate (dorsal duodenal) intervitelline anastomosis into the liver sinusoids via a right vena advehente. Blood in the umbilical vein supplies the left lobe of the liver and ductus venosus; the right lobe of the liver receives blood from the portal circulation. This arrangement means that the left lobe of the liver receives the most oxygenated blood returning from the placenta: the remainder (proportions change during the third trimester) passes into the ductus venosus and, via haemodynamic streaming, to the inferior vena cava and right atrium, then through the foramen ovale to the left atrium, to supply heart muscle and brain.

EMBRYONIC LYMPHATIC VESSELS

Lymphatic endothelial cells in lymphatic capillaries display a discontinuous basal lamina and basement membrane. They are held by anchoring filaments to the surrounding extracellular matrix. In the mouse, their differentiation starts with expression of Sox-18 and Prox-1,

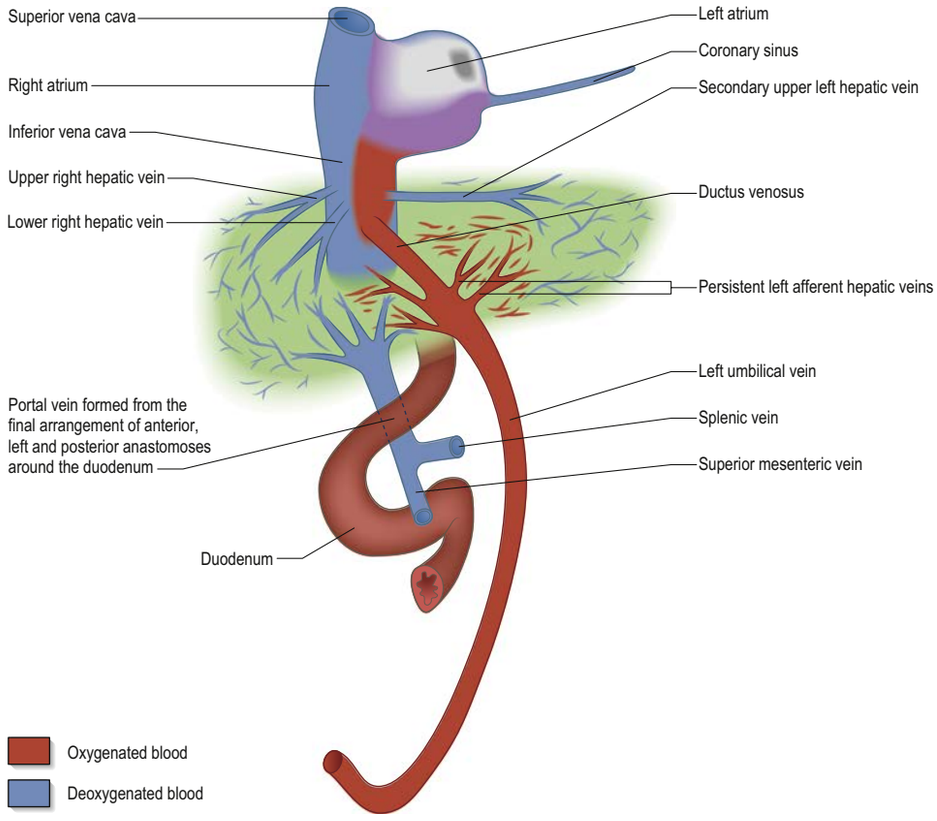

Fig. 13.22 The condition of some main upper abdominal and intrathoracic right atrial terminal veins in the later prenatal months. The rotation of the stomach and movement of the duodenum produce relative changes in the final arrangement of the duodenal intervitelline anastomoses that form the hepatic portal vein.

a Prospero homeobox transcription factor, in a subset of cardinal veins (Zhou et al 2010, Park et al 2011). Prox-1 is the most specific and functional lymphatic marker: its disruption leads to failure of lymphatic vessel development. Abnormal or absent lymphatic development is also seen with lack of vascular endothelial growth factor 3 (VEGFR3) and lack of angiopoietin 1, respectively (Yamashita 2007). Abnormalities of development and of remodelling of primary lymphatic vessels also occur if Akt, a serine/theonine protein kinase, is absent, possibly due to insufficient recruitment of smooth muscle cells to larger lymphatic vessels (Zhou et al 2010). An overview of the development of the mammalian lymphatic vasculature and genes involved, based on the mouse embryo, is given in Yang and Oliver (2014).

The earliest lymphatic vessels arise from budding of lymphatic endothelial cells from the cardinal veins to form lymph sacs (Eichmann et al 2005). Six early lymph sacs can be identified; two are paired (the jugular and the posterior lymph sacs) and two are unpaired (the retroperitoneal sac and the cisterna chyli). In lower mammals, an additional pair (subclavian) is present, but in the human embryo, these are merely extensions of the jugular sacs.

The jugular lymph sac is the first to appear, at the junction of the subclavian vein with the precardinal vein, with later prolongations along the internal and external jugular veins. The posterior lymph sac encircles the left common iliac vein, the retroperitoneal sac appears in the root of the mesentery near the suprarenal glands, and the cisterna chyli appears opposite the third and fourth lumbar vertebrae (**Fig. 13.23**). The lymph vessels bud out from the lymph sacs along lines that correspond more or less closely with the course of embryonic blood vessels (typically of the veins); many also arise *de novo* in the mesenchyme and establish connections with existing vessels (**Fig. 13.24**). The deeper plexuses are the first to be developed in the body wall and the wall of the intestine, and the vessels in the superficial layers are gradually formed by continued growth.

The thoracic duct is derived from left and right lymphatic trunks joined across the midline by anastomoses. The definitive duct consists of the lower portion of the right trunk, a transverse anastomosis and the upper portion of the left trunk. In contrast to the adult arrangement, the fetal thoracic duct is dilated at its origin from the cisterna chyli, and there is no associated lymphatic plexus draining the thoracic wall (Amore et al 2016). Perinatal and neonatal chylous visceral effusions are rare, but may be caused by hypoplastic or hyperplastic development of the lymphatic system. Chylothorax is the most common cause of pleural effusion in the neonate; primary chylous ascites is caused by anomalous development of the intra-abdominal lymphatic vessels (Bellini et al 2012).

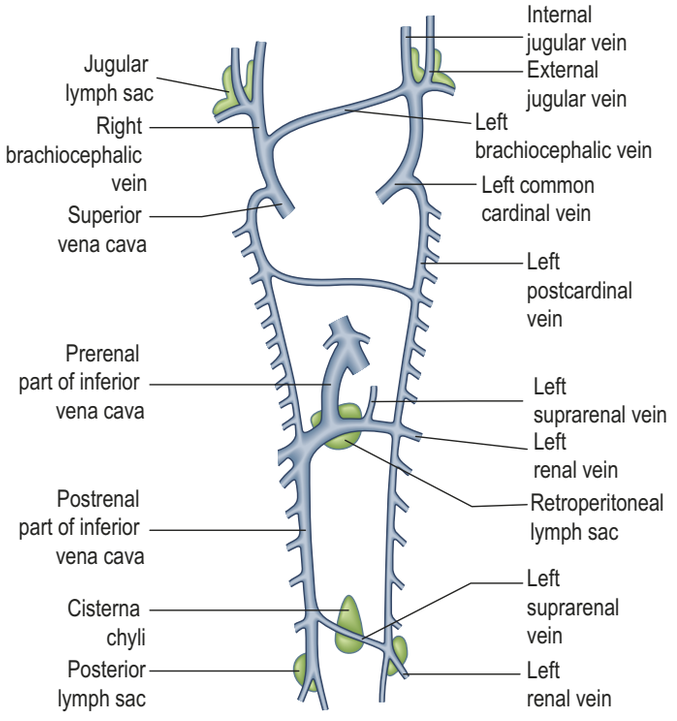

Fig. 13.23 Relative positions of the primary lymph sacs (as originally determined by Sabin (1912)).

Lymph nodes and lymphoid tissues

Lymph vessels can be seen in the embryo in the cervical region from stage 16. Lymph nodes provide regional proliferative foci for lymphocytes and have been identified from week 9. Early lymph sacs become infiltrated by lymphoid cells, and the outer portion of each sac becomes the subcapsular sinus of the lymph node. Morphological differentiation of medullary and cortical compartments has not been observed until the end of postfertilization week 10 (Tonar et al 2001). At the same time as these early lymph nodes are developing, the nasopharyngeal wall is infiltrated by lymphoid cells that are believed to herald the early development of the tubal and nasopharyngeal tonsils.

FETAL CIRCULATION

As the cardiovascular system develops, the embryonic circulation is modified into a fetal circulation that is able to establish a separate pulmonary circulation at birth. The dorsal aortae persist on the cranial side of the third aortic arches as the internal carotid arteries (see Fig. 17.9). The dorsal aorta between the third and fourth aortic arches, the carotid duct, diminishes and ultimately disappears. From the fourth arch to the origin of the seventh intersegmental artery, the right dorsal aorta becomes part of the right subclavian artery, and caudal to the seventh intersegmental artery, the right dorsal aorta disappears up to the site where the thoracic aortae fuse. The remnants of the left carotid duct are found in the descending part of the aortic arch. The fused right and left embryonic dorsal aortae persist as the definitive descending thoracic and abdominal aorta.

Concomitant changes also occur in the early venous system. The precardinal veins enlarge as the embryo develops. They are further augmented by the subclavian veins from the upper limb buds, which become the chief tributaries of the common cardinal veins, gradually assuming a craniocaudal orientation as the thorax enlarges around the heart (see Fig. 13.19). These parts of the original precardinal vein, rostral to the subclavian veins, are now the internal jugular veins, and their confluences are the brachiocephalic veins. The right and left common cardinal veins are originally of the same diameter but the development of a large oblique transverse connection means that the left brachiocephalic vein carries more blood across from the left to the right. The part of the original right precardinal vein between the junction of the two brachiocephalic veins and the azygos veins will give rise to the upper part of the superior vena cava. The caudal part of this vessel, below the entrance of the azygos vein, is formed by the right common cardinal vein. The left precardinal and left common cardinal veins caudal to the transverse branching of the left brachiocephalic vein will disappear; the precardinal vein constitutes the terminal part of the left superior intercostal vein, while the common cardinal vein is represented by the ligament of the left superior vena cava and the oblique vein of the left atrium (vein of Marshall). The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, on occasion, the fourth intercostal veins. The oblique vein of the left atrium passes downwards across the back of the left atrium to open into the coronary sinus, which represents the persistent left sinus horn.

Functioning fetal shunts

The adult circulation consists of higher pressure systemic and lower pressure pulmonary circulations, whereas the fetal circulation consists of systemic and placental circulations and a very limited high resistance pulmonary circulation (because the lung fields are not open). The ductus venosus, foramen ovale and ductus arteriosus are important conduits in the fetal circulation: the connection of a number of vascular ducts (shunts) and a valve between the atria enables the fetal circulation to change to the adult circuits within hours and days after delivery.

The placenta serves as the organ for fetal exchange of nutrients, gases and waste products of the blood, and in the second trimester receives 30% of the cardiac output (Kiserud and Haugen 2017). Fetal blood reaches the placenta via two umbilical arteries (carrying deoxygenated blood) and, in fetal life, returns by a single left umbilical vein (carrying oxygenated blood) because the right embryonic umbilical vein regresses. The left umbilical vein enters the abdomen at the umbilicus and angles upwards towards the liver in the caudal edge of the peritoneal layers of the original ventral mesentery, later termed the falciform ligament (see Fig. 21.6). The vein reaches the hepatic surface, joins the left branch of the comparatively small portal vein at the porta hepatis, and continues as the ductus venosus which ascends posterior to the liver to join the left hepatic vein near its termination in the inferior vena cava (**Fig. 13.25**; see Figs 13.20–13.22). In the second trimester about 70% of the blood in the umbilical vein passes into the liver and 30% passes into the ductus venosus (Kiserud and Haugen 2017).

The ductus venosus in the fetus does not appear to change size between postmenstrual weeks 13–17. During this time the portal sinus, which leads to the ductus venosus, has an average diameter of 2.6 mm and is lined by smooth endothelium. It ends at a thickening of subendothelial elastic fibres that form a protrusion into the ductal lumen, the shelf of the ductus venosus inlet. The ductus venosus is about 5.1 mm long (range 3.4–6.5) and has an average diameter of 1.4 mm at its inlet and outlet. It displays longitudinal endothelial corrugations supported by underlying elastin fibres and a single layer of longitudinally arranged smooth muscle cells that extends along the entire length of the ductus. Adrenergic nerve fibres have been identified in the wall of the ductus venosus at postmenstrual weeks 20–24; contraction in response to noradrenaline, acetylcholine and 5-HT has been demonstrated, as has dilation in response to NO, PGE1 and hypoxaemia (Kiserud and Haugen 2017). From the portal sinus to the subdiaphragmatic vestibulum, the ductus venosus progressively narrows and then dilates; the lumen is described as hourglass-shaped. It has been suggested that, unlike other veins, the ductus venosus acts as a high-pressure vessel: the narrowing of the inlet accelerates low-pressure, high-volume flow in the portal sinus, and the abundant elastic fibres in its wall propagate the wave by elastic recoil (Mavrides et al 2002). For details of the fetoplacental circulation see Kiserud and Haugen (2017).

Blood from the ductus venosus and hepatic veins joins the venous return from the lower limbs and abdominal wall in the inferior vena cava and enters the right atrium. The portocaval pressure gradient (blood pressure of the intra-abdominal umbilical vein) accelerates the blood in the ductus venosus to a velocity three times that of the umbilical vein and in the most favourable direction to open the foramen ovale

valve and enter the left atrium (Kiserud and Haugen 2017). On ultrasound examination the foramen ovale can be seen with the septum primum, a flap-like valve, pushed to the left (see Video 13.2). From the left atrium, blood enters the left ventricle and from there flows to the aorta and is probably distributed almost entirely to the heart, head and upper limbs. Blood returning from the head and upper limbs enters the right atrium via the superior vena cava, flows through the right atrioventricular orifice into the right ventricle, together with the small amount of blood that is returned via the inferior vena cava, and then passes into the pulmonary trunk. However, because the fetal lungs are largely inactive, only a small amount of blood, 13% at week 20 and 21% at week 38, will flow from the right ventricle through the right and left pulmonary arteries to return to the left atrium via the pulmonary veins. The greater part of the outflow through the pulmonary trunk is carried by the ductus arteriosus directly to the aorta, where it mixes with any remaining blood that comes from the left ventricle. During the second half of pregnancy, the fetus maintains a combined cardiac output of 400 mL/kg/min; approximately two-thirds of the total fetal cardiac output is ejected by the right ventricle and the remaining third by the left ventricle (Kiserud and Haugen 2017, Fineman and Maltepe 2018).

The ductus arteriosus, a remnant of the left sixth pharyngeal arch artery, allows blood from the right ventricle to reach the arch of the aorta and thus bypass the fetal lungs (see Fig. 13.25; **Fig. 13.26**). In the fetus, it arises as a direct continuation of the pulmonary trunk at the point where it divides into right and left pulmonary arteries. It is 8–12 mm long, and joins the aorta at an angle of 30–35° on the left side, anterolaterally, below the origin of the left subclavian artery. The opening of the ductus arteriosus into the aorta is greatly elongated. Its diameter at its origin from the pulmonary trunk, when distended with blood, is 4–5 mm, which is nearly equal to the diameter of the adjacent ascending aorta (5–6 mm). Both arteries taper to a smaller diameter as they pass inferiorly and the aorta remains slightly larger (4 mm) (**Fig. 13.27**).

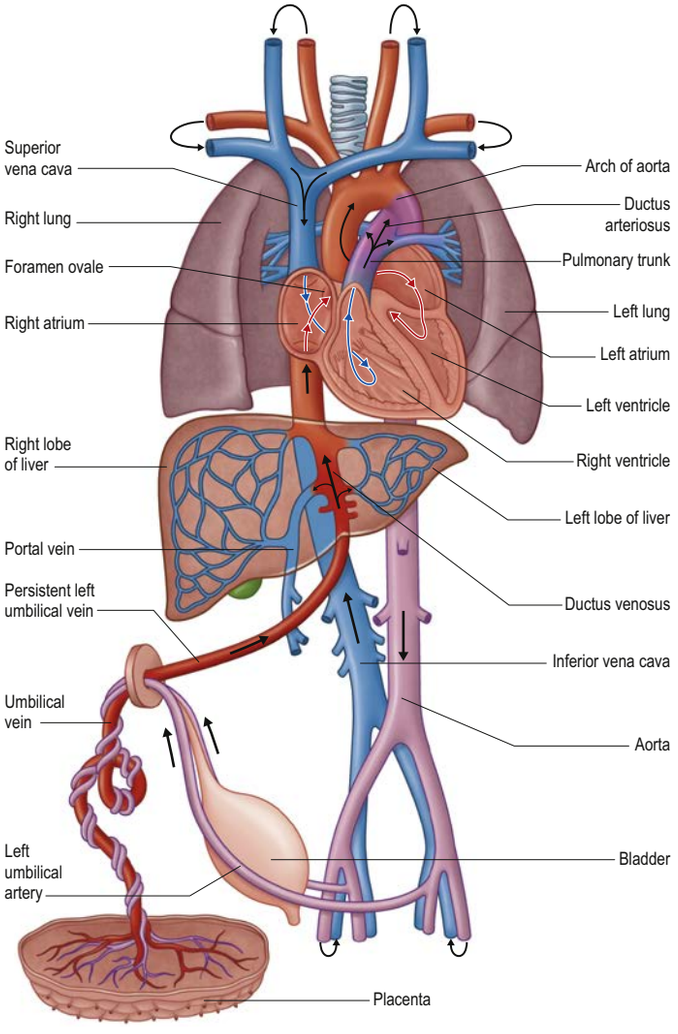

Fig. 13.25 A plan of the fetal cardiovascular circulation: the arrows indicate the direction of blood flow. The placenta is drawn to a greatly reduced scale.

The ductus arteriosus differs from the other great vessels that arise from the heart because its tunica media contains smooth muscle rather than layers of elastin. The intima of the ductus arteriosus starts to thicken by accumulation of glycosaminoglycans beneath the endothelium. The left recurrent laryngeal nerve (which, at stage 16, is very large in relation to the aortic arch system) passes inferior to the ductus arteriosus.

The ductus arteriosus remains patent during intrauterine life due to synergistic interaction of high circulating PGE2 (prostaglandin E2) and low oxygen tension (Hung et al 2018). Fetal and neonatal ductal tissue produce PGE_2 and to a lesser extent PGE_{12}. Treatment for conditions such as polyhydramnios, where indomethacin is given, may cause premature intrauterine closure of the ductus arteriosus and consequent associated problems.

Antenatal ultrasound imaging of the fetal heart and circulation

The first trimester ultrasound scan to confirm successful implantation and a live conceptus will identify an embryonic heartbeat from postmenstrual week 6 (stage 10 embryo). The embryonic heart rate is about 175 beats per minute at stage 23.

In the routine second trimester ultrasound scan at 18–20 postmenstrual weeks, the evaluation initially checks that the fetal heart and stomach are both on the left and that the liver is on the right. A specific series of sectional views of the heart are recorded. In a four-chamber view of the fetal heart (observed up to about postmenstrual week 28), the following are checked: the heart occupies about one-third of the thorax in the anterior left quadrant of the chest; the two atria are of equal size as are the two ventricles and there is an intact interventricular septum; and the apex of the heart points to the left anterior thorax. In moving images, the ventricles show equal contraction, the two atrioventricular canals open equally and the foramen ovale flap valve can be seen flickering in the left atrium (see Videos 13.2, 23.1). The function and rhythm of the heart is recorded. The heart rate is about 140 beats per minute throughout fetal life, despite the increase in heart size over this period: heart rate increase is a sign of fetal distress. The blood flow through the heart can be demonstrated with colour flow (**Fig. 13.28**). After postmenstrual week 28 the right ventricle may look dilated compared with the left. The origin of the great vessels from their respective ventricles is assessed in transverse section, and the aorta is assessed longitudinally (see Fig. 23.5); it normally arises in the centre of the thorax and the vessels to the head and neck can be seen arising from the curve of the aortic arch.

In a healthy near-term fetus the ductus venosus has an hourglass shape. Ultrasound studies have shown that 30% of umbilical venous flow enters the ductus venosus at about postmenstrual week 20 declining to 20% during the last trimester (Kiserud and Haugen 2017). Blood flow in this fetal shunt regulates inflow to the right atrium through a constricted aperture that admits umbilical venous blood via a narrow, high velocity flow directly to the foramen ovale. In healthy fetuses the ductus venosus regulates the distribution of placental nutrients and oxygen by restricting the centralization of blood flow, and it can actively dilate in hypoxaemia (Kaimal 2019). Anomalous flow in the first trimester has been reported in Down's syndrome and fetal growth restriction is associated with changes of flow through the ductus venosus. (For further details of ultrasound findings consult Coady and Bower (2015).)

Neonatal heart and circulatory changes at birth

At full term (notionally 40 postmenstrual weeks), the heart is situated midway between the crown of the head and the lower level of the buttocks and weighs about 20 g (see Fig. 23.14). Because the right ventricle has been working against the systemic pressure in the fetus, the pulmonary circulation not yet being active, the right ventricle is heavier at birth and continues to be so for up to 1–2 postnatal months. With the establishment of the pulmonary circulation, the work of the right side of the heart decreases, and the left side of the heart, particularly the ventricle, grows rapidly to meet the increased demand. The ventral surface of the heart is formed mainly by the right atrium and right ventricle, as in the adult. This surface is usually covered by the thymus, which may extend over the base of the right ventricle. Soon

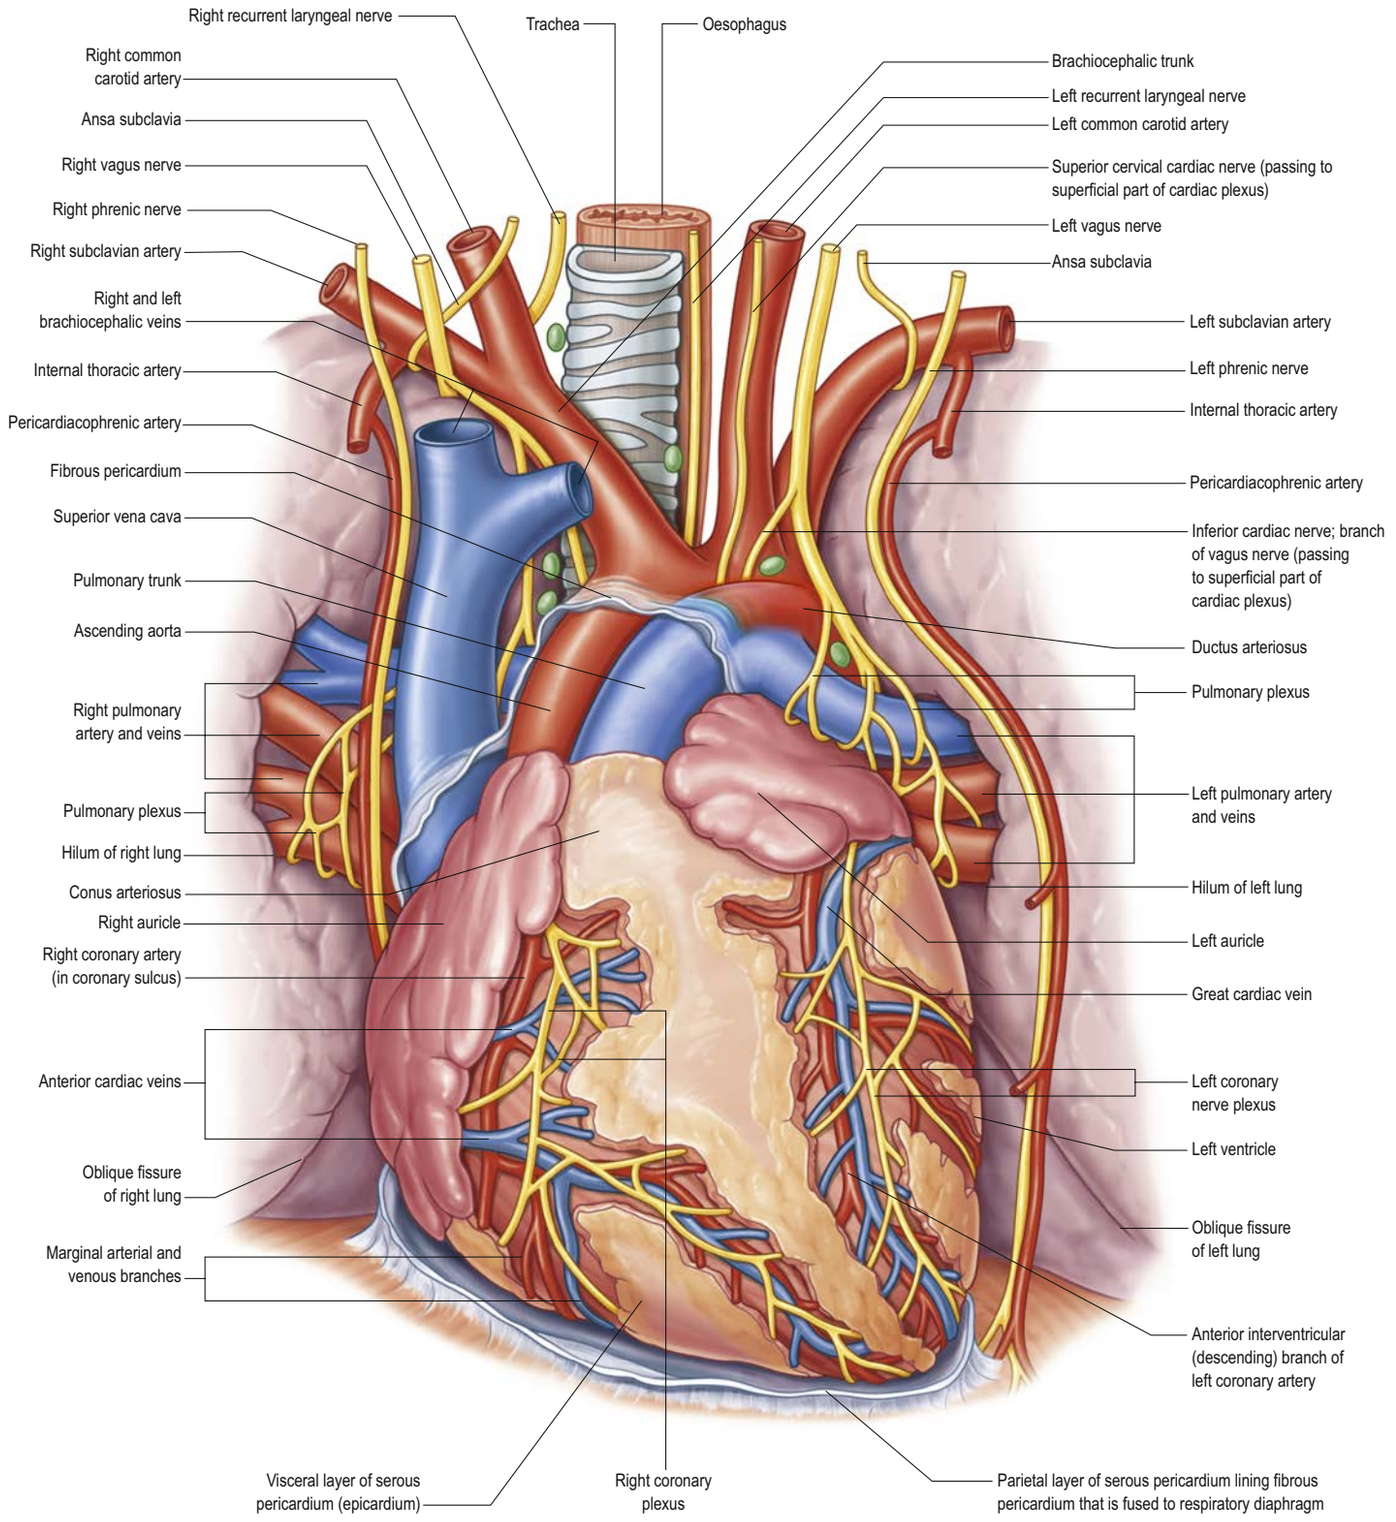

Fig. 13.26 An anterior view of the heart and great vessels in a neonate. The lungs have been displaced to expose the heart, and the pericardium and epicardium have been dissected off the heart and the roots of the great vessels. Note that, after birth, blood flow has reversed through the ductus arteriosus prior to its closure. (Adapted with permission from Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger.)

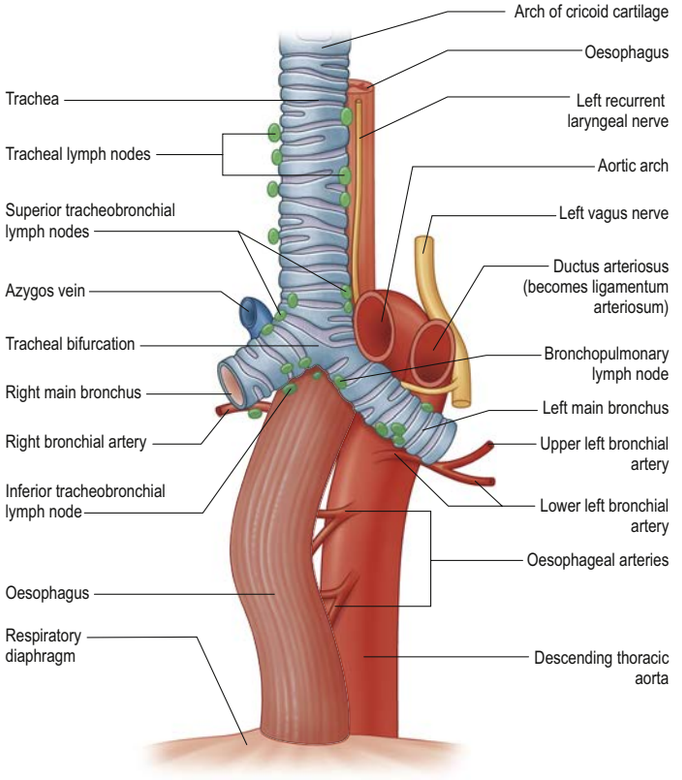

Fig. 13.27 A, An anterior view with the heart removed to show the relationship between the left primary bronchus, the aortic arch and the ductus arteriosus in a full-term fetus. (B, *continued online*)

after birth, the fetal shunts of the foramen ovale and the ductus arteriosus and ductus venosus will close. The umbilical vessels will also occlude as the circulation of the neonate becomes independent of maternal oxygen supply after detachment of the placenta from the uterine wall.

Congenital heart disease has an overall prevalence of 8/1000 births (Tarabit et al 2018). Neonates with congenital heart disease are at higher risk of fetal growth restriction and preterm birth; infant mortality rates are reported to be 20% for congenital heart disease and 65% for congenital heart disease and preterm delivery (Laas et al 2017). Assisted reproductive techniques have been shown to affect the incidence of preterm delivery and of congenital heart disease. The incidence of preterm birth in cases of congenital heart disease has been reported as about 13% in spontaneously conceived neonates, and about 40% in conception following infertility treatments (Tarabit et al 2018).

Closure of the umbilical vessels

Umbilical arteries

The fetal umbilical arteries are continuous with the internal iliac arteries. Their lumen is 2–3 mm in diameter at their origin, when distended. They narrow as they approach the umbilicus, where there is a reciprocal thickening of the tunica media, reflecting an increase in the number of longitudinal smooth muscle and elastic fibres. The umbilical vessels lack a nerve supply in their extra-abdominal course. Before birth, there is a proliferation of connective tissue within the vessel wall. Within minutes of delivery, blood flow within the umbilical cord vessels decreases and the vessels constrict in response to handling, stretching, cooling and altered tensions of oxygen and carbon dioxide. After the cord is severed, the umbilical arteries constrict, preventing significant blood loss; thrombi often form in the distal ends of the arteries. Full closure of the umbilical vessels is mediated by several factors including prostaglandins, endoperoxides and serotonin. As oxygen tension increases shortly after birth, bradykinin, one of the kinin polypeptide hormones that induce contraction or relaxation of smooth muscle, forms in the blood of the umbilical cord. It is also formed and released by granular leukocytes in the lungs of the neonate after exposure to adequate oxygen. Bradykinin is a potent constrictor of the umbilical arteries and veins, and of the ductus arteriosus, but is also a potent inhibitor of contraction of the pulmonary vessels. The umbilical arteries obliterate from their distal ends until, by the end of postnatal month 2–3, involution has occurred at the level of the superior vesical arteries: the proximal parts of the obliterated vessels remain as the medial umbilical ligaments (see Ch. 21).

Umbilical vein

The umbilical vein in the neonate is 2–3 cm long and 4–5 mm in diameter when distended. It passes from the umbilicus within the layers of the falciform ligament, superiorly and to the right, to the porta hepatis, where it gives off several large intrahepatic branches to the liver and then joins the left branch of the portal vein and the ductus venosus. The thin-walled umbilical vein possesses a definite internal lamina of elastic fibres at the umbilical ring but not in its intra-abdominal course. The tunica media contains smooth muscle fibres, collagen and elastic fibres.

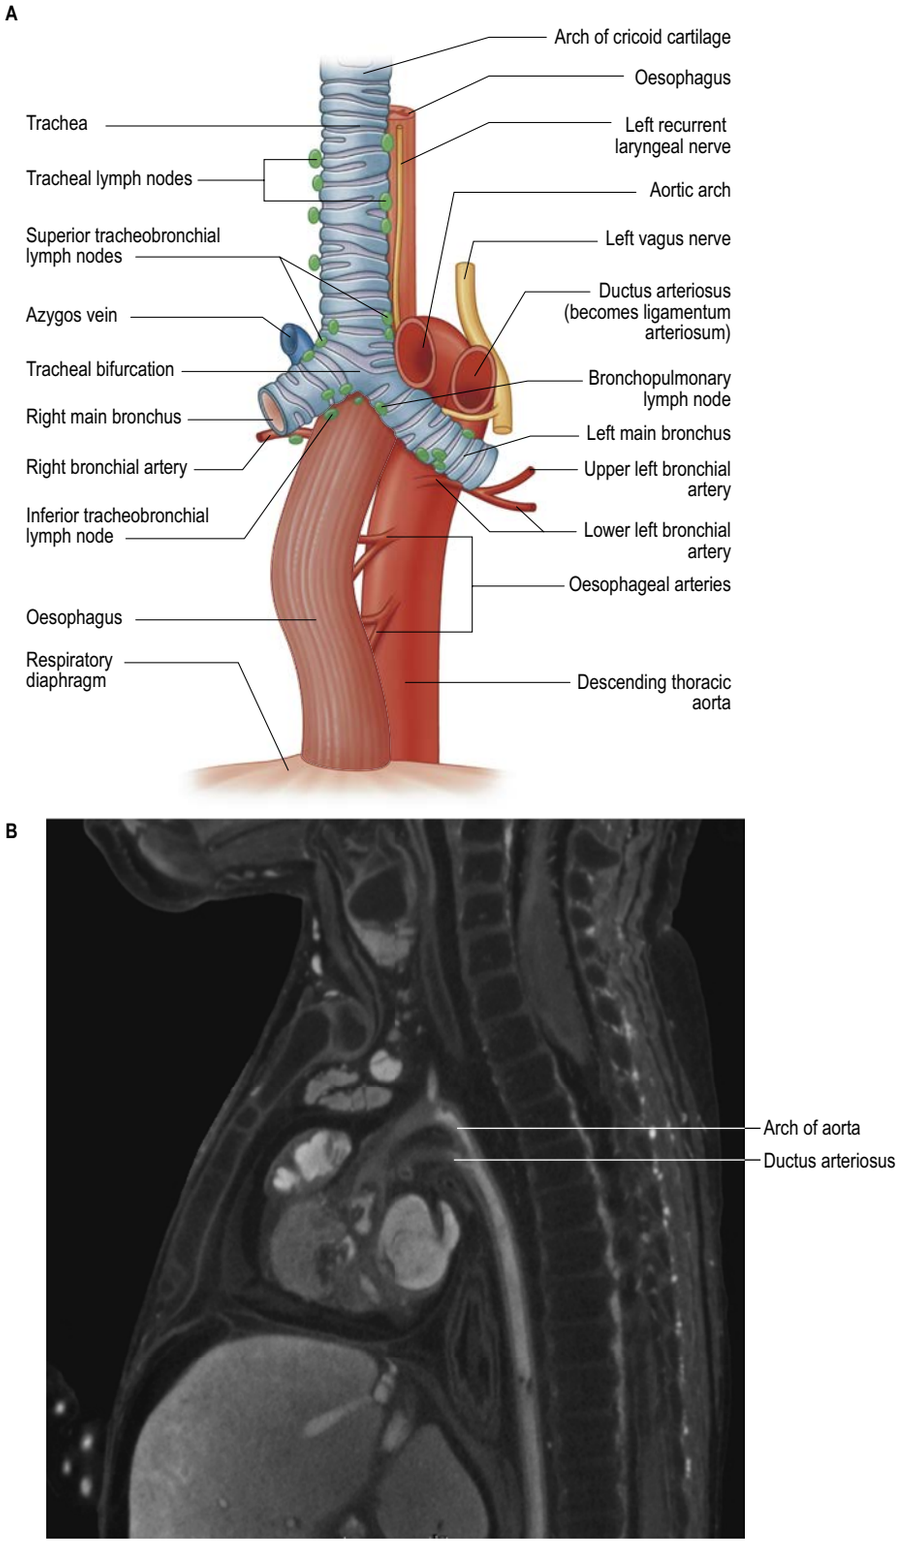
When the cord is severed, the umbilical vein constricts, but not as vigorously as the arteries. The rapid decrease in pressure in the umbilical vein after the cord is clamped means that the elastic tissue at the umbilical ring is sufficient to arrest any retrograde flow along the vessel. Before birth, there is a subintimal proliferation of connective tissue; after birth, the contraction of the collagen fibres in the tunica media and the increased subintimal connective tissue contribute to the transformation of the vessel into the ligamentum teres hepatis (round ligament of the liver). Obliteration occurs from the umbilical ring towards the hepatic end. No thrombi are formed in the obliteration process. For up to 48 hours after birth, the intra-abdominal portion of the umbilical vein can be easily dilated. In most adults, the original lumen of the vein persists through the ligamentum teres hepatis and can be dilated to 5–6 mm in diameter.

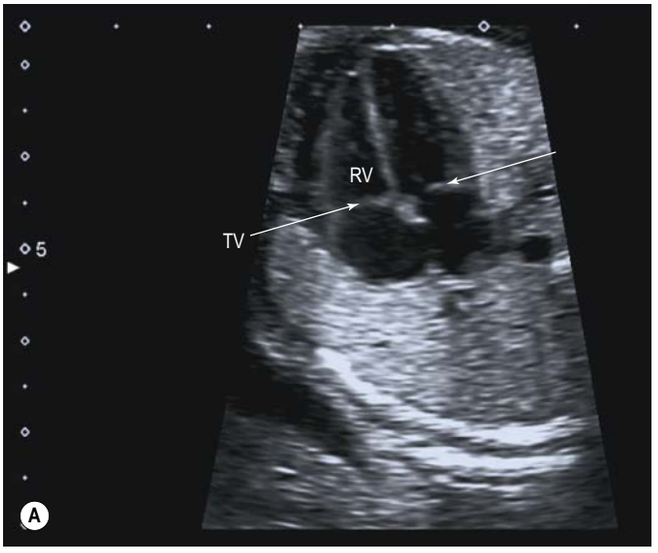
Closure of the ductus venosus

In the fetus, the ductus venosus is a direct continuation of the umbilical vein and arises from the left branch of the portal vein, directly opposite the termination of the umbilical vein. It passes for 2–3 cm within the layers of the lesser omentum, in a groove between the left lobe and caudate lobe of the liver, before terminating in either the inferior vena cava, or in the left hepatic vein immediately before it joins the inferior vena cava. In the area of transition into the portal sinus, the vessel wall contains circularly arranged smooth muscle fibres, collagen and abundant elastic fibres and its inner surface is ridged. After birth, with the loss of the umbilical blood flow, the blood pressure in the portal sinus drops, the width of the ductus venosus decreases and the inner edges are approximated. The remaining lumen becomes filled with cell-dense connective tissue that occludes the whole vessel. The ductus venosus is already closed in about one-third of neonates, for the remainder it closes between postnatal days 4 and 6, sooner in post-term and macrosomic neonates. Obliteration begins at the portal vein end in the second postnatal week, progresses to the vena cava and is complete by postnatal month 2–3. The fibrous remnant of the ductus venosus is the ligamentum venosum.

Closure of the foramen ovale

Within the heart, considered relative to the thoracic landmarks, the foramen ovale lies at the level of the third intercostal space (see Fig. 23.14). It is approximately 4–6 mm long and 3–4 mm wide and blood passes through it from the ventrally positioned right atrium dorsally and cranially to reach the left atrium. At birth, as pulmonary respiration begins, pulmonary blood flow increases dramatically and the left atrium now receives pulmonary venous blood under a relatively high pressure. A decrease in pressure occurs in the inferior vena cava as a result of the reduction of venous return concomitant with occlusion of the umbilical vein and ductus venosus, lowering the right atrial pressure. Left atrial pressure is now greater than that of the right atrium, and the foramen ovale is closed by apposition. Subsequent fusion of the primary septum to the rims of the secondary septum occurs, likely by fibrosis mediated by transition of the endocardium into mesenchyme. Although the foramen ovale closes functionally after pulmonary respiration is established, it does not become structurally closed until later: it is obliterated in fewer than 3% of infants 2 weeks after birth. In adults, fusion is sometimes incomplete, and the foramen remains probe-patent in up to one-third of all individuals. Almost invariably, this lack of fusion has no functional effect because the inequality of atrial pressures and the valve-like arrangement of the opening do not favour right to left shunting of blood.





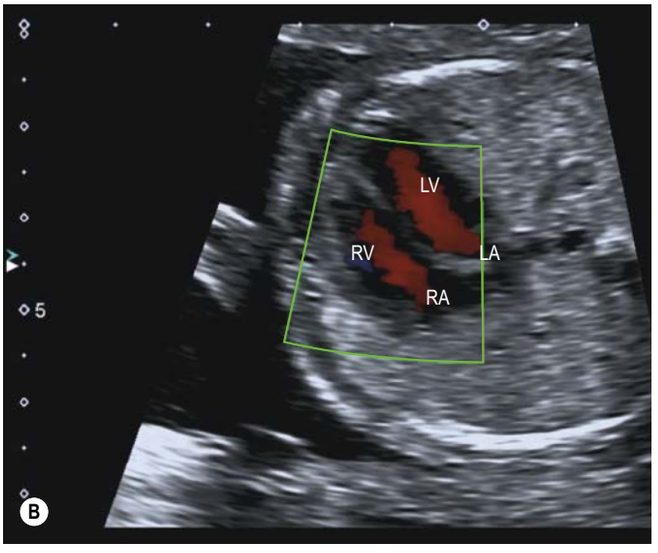


Fig. 13.27 A, An anterior view with the heart removed to show the relationship between the left primary bronchus, the aortic arch and the ductus arteriosus in a full-term fetus. **B**, MicroCT sagittal section of a fetus at 14 postmenstrual weeks. Note that the ductus arteriosus and arch of aorta have a similar calibre. (A, Adapted with permission from Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger. Closure of the ductus arteriosus

At birth when a neonate takes its first breaths the lungs expand and the pulmonary resistance decreases. Blood flow from the right ventricle now passes along the pulmonary trunk to the lungs and the flow along the ductus arteriosus reverses, flowing from the aorta to the pulmonary trunk. Animal studies have shown that reversal of flow occurs rapidly after ventilation begins. Blood flow from the left ventricle travels via the aorta: the ductus arteriosus contributes almost 50% of total pulmonary blood flow in the neonate. The initial process of ductal closure consists of contraction of the smooth muscle cells and development of sub-endothelial oedema. Initial constriction at birth has been attributed to increased oxygen tension and decrease in prostaglandin E_2 (Hung et al 2018). Other factors in the closure process include increased plasma catecholamine concentrations; suppression of prostaglandin I2 production; unresponsive prostaglandin E receptors; a synergistic role of prostaglandin F2a and oxygen concentrations; and a decrease in plasma adenosine concentration. The high oxygen tension of the reversed blood flow through the ductus is thought to initiate the synthesis of a hydroperoxy fatty acid that suppresses prostacyclin production, thus exposing the ductus to the contractile effects of prostaglandin endoperoxide. A neural factor may also be involved; the muscular wall has afferent and efferent nerve endings and responds to adrenaline (epinephrine) and noradrenaline (norepinephrine) within 10 minutes of the onset of ventilation; after 2 postnatal hours, the response to adrenaline falls to about 25%. The turbulence and increased shear stress of blood flow through the ductus apparently releases vasoconstrictive factors from the endothelium (Crossley et al 2009). For details of the molecular mechanisms regulating ductus closure see Hung et al (2018).

The first stage of ductal closure is completed within 10–15 hours, occurring in 50% of full-term neonates at 24 hours, in 90% by 48 hours and in 100% by 72 hours. Definitive closure usually takes 2–3 weeks, but can take up to 3 months before it is considered permanent. Several mechanisms have been implicated as mediators of permanent closure, including intimal cushion formation, proliferation and migration of smooth muscle cells, endothelial cell proliferation and production of extracellular matrix (Hung et al 2018). Following functional closure, the ductal smooth muscle cells undergo apoptosis, resulting in fibrosis and the formation of the ligamentum arteriosum that connects the left pulmonary artery (near its origin) to the aortic arch.

Patent ductus arteriosus

Patent ductus arteriosus can be defined as a failure of the ductus arteriosus to close within 72 hours after birth (Dice and Bhatia 2007). It affects 1 in 2000 live births in the United States and is seen most frequently in preterm neonates and in up to 70% of those born before postmenstrual week 28 (Clyman 2013, Gillam-Krakauer and Reese 2018). Persistent patency of the ductus arteriosus should be distinguished from delayed closure. The persistently patent ductus can be an obligatory part of the circulation when associated with transposition of the great arteries since it allows shunting: the patency may be ensured by appropriate medication. Developmentally, failure to close may be related to reduced intimal thickening, the presence of a thick elastic lamina, low levels of circulating prostaglandins and a low oxygen tension after birth. The condition affects 66% of infants with congenital heart disease born at high altitude (Chun et al 2019). Rubella infection and a genetic predisposition are associated with a patent ductus arteriosus. Patent ductus arteriosus is almost always found in Char syndrome, a mutation in *TFAP2B*, encoding a transcription factor in cardiac neural crest cells (Huang et al 2008).

Coarctation of the aorta

Smooth muscle cells extending to the aortic wall rather than remaining within the wall of the ductus arteriosus may be a cause of aortic narrowing in preductal or postductal positions. A constriction, the aortic isthmus, is sometimes present in the aorta between the site of origin of the left subclavian artery and the orifice of the ductus arteriosus that can persist as a coarctation of the aorta. This can be found as an isolated lesion, with a normally closed ductus arteriosus. When the ductus arteriosus remains open coarctation is more likely to be associated with additional lesions within the heart, often a bicuspid aortic valve (O'Brien and Marshall 2015). Coarctation of the aorta has an estimated incidence of 1 in 2500 live births, affecting males more than females, and is the fifth most common heart defect (Kenny and Hijazi 2011).

Catheterization of neonatal blood vessels

In the neonate, the blood vessels of the trunk and their associated visceral branches are relatively larger than the vessels in the limbs, an arrangement that favours central pooling of blood. Neonatal peripheral vessels are particularly small, with delicate walls that can be easily damaged, and consequently their cannulation poses much more of a challenge than is the case with their adult counterparts. Large vessels are in the same relative positions as in the adult but may correspond to different vertebral levels. Thus, although the bifurcation of the common carotid artery into internal and external carotid arteries typically occurs at the level of the upper border of the thyroid cartilage in both neonate and adult, the thyroid cartilage is relatively higher in the neonatal neck than it is in the adult. The renal arteries also arise at a higher vertebral level in the neonate, often that between the twelfth thoracic and first lumbar vertebrae, whereas they arise at the level of the inferior part of the body of the first lumbar vertebra/upper border of the body of the second lumbar vertebra in the adult. The abdominal aorta bifurcates into common iliac arteries at the upper border of the body of the fourth lumbar vertebra, rather than at the lower border of the body of the fourth lumbar vertebra, as typically occurs in the adult.

Umbilical arterial catheterization

Insertion of an umbilical catheter is undertaken to provide direct access to the arterial circulation. Arterial blood can be withdrawn repeatedly for measurement of oxygen and carbon dioxide partial pressures, pH, base excess and many other parameters of blood biochemistry and haematology. The indwelling catheter also enables the continuous measurement of arterial blood pressure. The catheter is inserted directly into either the cut end or the side of one of the two umbilical arteries in the umbilical cord stump that remains attached to the baby after transection of the umbilical cord at the time of delivery. The catheter tip is then advanced along the length of the umbilical artery, through the internal iliac artery, into the common iliac artery and, from there, into the aorta. In order to keep the catheter patent, a small volume of fluid is continuously infused through it. It is important for the tip of the catheter to be located well away from arteries branching from the aorta, to avoid potentially harmful perfusion of these arteries with the catheter fluid. Thus, umbilical arterial catheter tips are placed in the descending aorta either in a 'high' position, above the coeliac trunk but well below the ductus arteriosus, or in a 'low' position, below the renal and inferior mesenteric arteries but above the point where the aorta bifurcates into the two common iliac arteries. The length of catheter to be inserted can be estimated from charts relating the required catheter length to external body measurements, or from birth weight. Positioning of the catheter is assessed by means of radiographs of the abdomen or chest: a 'high' catheter tip should be located in the descending aorta somewhere between the levels of the sixth and ninth thoracic vertebrae, while a 'low' catheter tip should be at a level between the third and fourth lumbar vertebrae. Relevant anatomical reference points are given in **Table 13.2**.

Umbilical vein catheterization

The umbilical vein may be catheterized for initial central venous access in preterm babies and in term neonates to enable exchange and transfusion of blood, for central venous pressure measurement and for emergency vascular access. The catheter is inserted into the cut end of the umbilical vein and is advanced along the length of the vein, through the ductus venosus and into the inferior vena cava; the tip is placed between the ductus venosus and the right atrium. Positioning of the catheter tip is confirmed radiologically: it should be located just above the respiratory diaphragm at a point that is level with the ninth or tenth thoracic vertebrae. Estimation of the required catheter length can be determined from standard charts.

Central venous catheterization

Small-bore catheters can be fed into large central veins, superior or inferior venae cavae, just outside the right atrium, via needles or catheters inserted in the peripheral veins. Typically, the median cubital or basilic veins are used in the upper limb, the long saphenous vein at the medial malleolus in the lower limb, and the superficial temporal vein in the scalp. The tip of the catheter is sited at the entrance to the right atrium. The required catheter length is

TABLE 13.2 Key anatomical reference points for umbilical arterial catheterization

Structure	Vertebral level
Ductus arteriosus	T4–T5
Coeliac artery	T12
Superior mesenteric artery	L1
Renal artery	T12–L1
Inferior mesenteric artery	L3
Aortic bifurcation	L4–L5

assessed from direct measurement of the distance between the proximal surface entry point in the limb or scalp to the right atrium, estimated at mid-sternal level.

Peripheral arterial puncture

It is common practice to insert a small-bore cannula into a peripheral artery in neonates receiving intensive care when either the umbilical artery is not accessible or there are clinical reasons to avoid cannulation of the umbilical vessels, e.g. if the umbilical cord has dried or in older neonates. Trans-illumination can be used to provide an outline of the artery to be cannulated. The peripheral arteries that are most commonly used are the radial artery, just proximal to the radiocarpal join on the palmar (volar) surface of the wrist, or the posterior tibial artery, posterior to the medial malleolus. The proximity of the ulnar nerve to the ulnar artery increases the risk of iatrogenic nerve damage associated with cannulation of the ulnar artery, and there is a higher risk of ischaemia with cannulation of this vessel. The relatively poor collateral circulation associated with the dorsalis pedis artery means that this artery is used only as a last resort. The axillary artery is now used in infants with difficult peripheral access; the brachial artery at the antecubital fossa, which was used previously, is rarely used because it has poor collateral circulation and the median nerve is in close proximity.

Confirmation that an adequate collateral circulation is present when cannulating the radial artery can be obtained by performing Allen's test (Ch. 48). Alternatively, intact arterial flow can usually be confirmed, particularly in the preterm infant, by direct visualization of the arteries using trans-illumination. A cold light source is placed on the posterior aspect of the lower forearm and the shadow of the pulsating arteries can be seen on the anterior surface of the forearm.

CHAPTER 14

Development of the nervous system

The entire nervous system and the special sense organs originate from three sources, each derived from specific cell populations of the early epiblast termed neural ectoderm. The first source to be clearly delineated is the neural plate, which gives rise to the central nervous system (CNS), the somatic motor nerves and the preganglionic autonomic nerves. The second source is from cells at the perimeter of the neural plate, neural crest cells, which remove themselves by epithelial to mesenchymal transition from the plate and migrate away just prior to its fusion into a neural tube. These cells give rise to the majority of the neurones and glia of the peripheral nervous system (PNS), i.e. the somatic sensory nerves, the somatic and autonomic ganglia, postganglionic autonomic nerves and suprarenal and chromaffin cells, as well as significant mesenchymal populations in the head. The third source is from ectodermal placodes, focal thickenings of the ectoderm covering the embryonic head, that contribute cells to the cranial sensory neurones and form the olfactory epithelia, the epithelia of the inner ear and, by a non-neuronal contribution, the lens of the eye. Early establishment of a pial capillary network, derived from mesenchymal neural crest cells, provides cell lines for neuroepithelial:endothelial interactions throughout the developing nervous system.

NEURULATION

Primary neurulation

Primary neurulation begins at stage 9 and is completed during stage 12 (Figs 14.1–14.2) (embryonic stages 10–23 correlated to postfertilization days of development and postmenstrual weeks of pregnancy are shown in Fig. 23.3). The process is continuous spatially and temporally but has been envisaged as four stages. It begins with local elongation of the ectoderm cells in a midline zone of the embryonic disc and their reorganization into a pseudostratified epithelium, the neural plate. This is followed by reshaping and bending of the neural plate into a neural groove that subsequently closes to form a neural tube bidirectionally from its mid portion to its cranial and caudal ends. A continuous surface ectoderm forms dorsal to the tube. As neurulation proceeds, the neural tube elongates by convergent extension, a process where the apical surfaces of adjacent cells narrow (convergence) and there is rostrocaudal elongation (extension) (Bay and Caspary 2012, Nikolopoulou et al 2017).

Two sites of dorsal fusion of the neural tube appear in succession in the human embryo. The initial fusion site, termed α, or the dorsal lip of the rostral neuropore, is in the rhombencephalic region from which closure extends both rostrally and caudally. A second site, termed β, or the terminal lip of the rostral neuropore, forms in the prosencephalic region and extends caudally (O'Rahilly and Müller 2002). Closure of the rostral neuropore is completed in stage 11 when about 19–20 pairs of somites are present. Continued generation of the neural plate from the primitive node adds caudal regions to the elongating and closing neural tube and generation of mesenchyme from the primitive streak adds paraxial mesenchymal populations that form somites as the neural tube closes (Ch. 18). Primary neurulation ends and the caudal neuropore starts to close in stage 12 (30–32 days postfertilization, see Fig. 23.3), when approximately 29 somites are present: the final site of closure corresponds to the level of the future somite 31 (the level of the future second sacral vertebra) (O'Rahilly and Müller 2004).

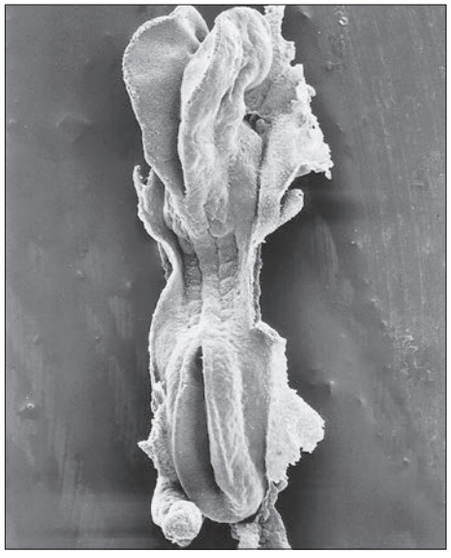

Fig. 14.1 A scanning electron micrograph of a neurulating rat embryo comparable to a stage 10 human embryo. The expanded brain region can be seen at the top of the image; somite formation occurs centrally as neurulation proceeds caudally. Caudally, the ridge of underlying neural crest cells can be seen medial to the unsegmented paraxial mesenchyme. (Photograph by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

Secondary neurulation

Secondary neurulation is the process by which the caudal portion of the neural tube is formed in the absence of a neural plate. It starts from the closure of the caudal neuropore at stage 12 and ends at about stage 17. At the time of caudal neuropore closure the caudal midline cells are generically termed the caudal eminence (O'Rahilly and Müller 2004). A specific population of mesenchymal cells, the caudoneural hinge or junction, shares the same molecular markers as the primitive node. These cells aggregate at the midline and undergo mesenchymal to epithelial transition, producing a cellular cylinder that is contiguous with the caudal end of the neural tube. Further elongation of the caudal neural tube involves cavitation of the neural cylinder. In a study of human embryos, the caudal end of the forming neural tube showed multiple outpouchings of the lumen at stage 18. The most caudal part was accompanied by a notochord. Immunohistochemical staining was negative for a range of neuronal antigens: N-CAM and NeuN labelling was seen after stage 16 and neurofilament-associated protein (3A10) labelled cells were seen from stages 16 and 18 in dorsal tissues. Apoptosis was noted in the very terminal end of the caudal eminence and the caudal portion of the neural tube showed regression at stage 19 (Yang et al 2014). Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction and the paraxial mesenchyme concurrently undergoes somitogenesis. The range of processes involved in secondary neurulation, the mechanisms of generation of caudal tissues, their further interactions within the developing cloacal region, and the formation of associated somatic and autonomic nerves, are all still as yet unknown. It may be that, as occurs in the head, where special populations of cells are required to form and provide neurological control of the oropharyngeal reflexes associated with the airway and proximal gut, a similar system occurs in the caudal region, where special cell populations provide tissues for the cloacal region and control the reflexes of the enteric, urinary and reproductive sphincters.

Failure of neurulation

Failure of neurulation produces the conditions of craniorachischisis totalis (where the entire neural tube is unfused in the dorsal midline), cranioschisis or anencephaly (where the neural tube is fused dorsally to form the spinal cord but is not fused dorsally in the brain), and spina bifida (where local regions of the spinal neural tube are unfused, or there is failure of formation of the vertebral neural arches) (Fig. 14.3; see Fig. 18.14). Anencephalic fetuses display severe disturbances in the shape, position and ossification of the basichondrocranium and in the course of the intracranial notochord, and so the condition is more complicated than 'simply' a failure of neural tube fusion. Spinal neural

Primary neurulation depends on cellular changes within the neural plate; and may also also involve movements of the paraxial mesenchyme in the trunk. Initial fusion of the surface ectoderm is followed by fusion of the neural ectoderm. The neural ectodermal cells become elongated and then wedge-shaped. The forces needed to shape the neural tube are intrinsic to the cells of the neurectoderm: human embryonic stem cells can self-organize into three-dimensional neural structures (Eiraku and Sasai 2012, Sasai et al 2012). Epithelial populations are established in the embryo with the formation of the epiblast. Three main control pathways that maintain epithelial apicobasal polarity have been described (Crumbs, Baz/PAR-3, Scribble) and Wnt/planar cell polarity gene expression is involved with epithelial cell movement. When the neural tube is closing, its walls consist of a pseudostratified layer of columnar neural epithelial cells (see below). The cells increase in length and develop numerous longitudinally disposed microtubules; their apical surfaces are joined by tight junctions supported by claudins and linked to the actin cytoskeleton that forms a dense paraluminal web of microfilaments. The nuclei assume basal positions and this, together with the contraction of apically arranged actin, imparts a slight wedge conformation along the midline of the neural plate, creating a median hinge point that is termed the floor plate. The apical location of Wnt and the planar polarity genes maintain the apicobasal polarity and contribute to the convergent extension movements (Baumholtz et al 2017). Movements of the cell populations on each side of the floor plate promote elevation of the layer and neural tube formation.

The position of hinge points within the neural plate confers different luminal characteristics within the formed neural tube. With a median hinge point the neural folds remain relatively straight and the tube in this position has a slit-shaped lumen, as can be seen from the initial region of fusion rostralwards. If dorsolateral hinge points are added the resulting neural tube lumen becomes rhombic, and if all neuroepithelial cells exhibit some apical narrowing then the tube has a circular lumen. Rostrally, the slit-shaped profile depends more on support from adjacent tissues than at the caudal end of the tube where secondary neurulation produces a neural tube with a circular lumen.

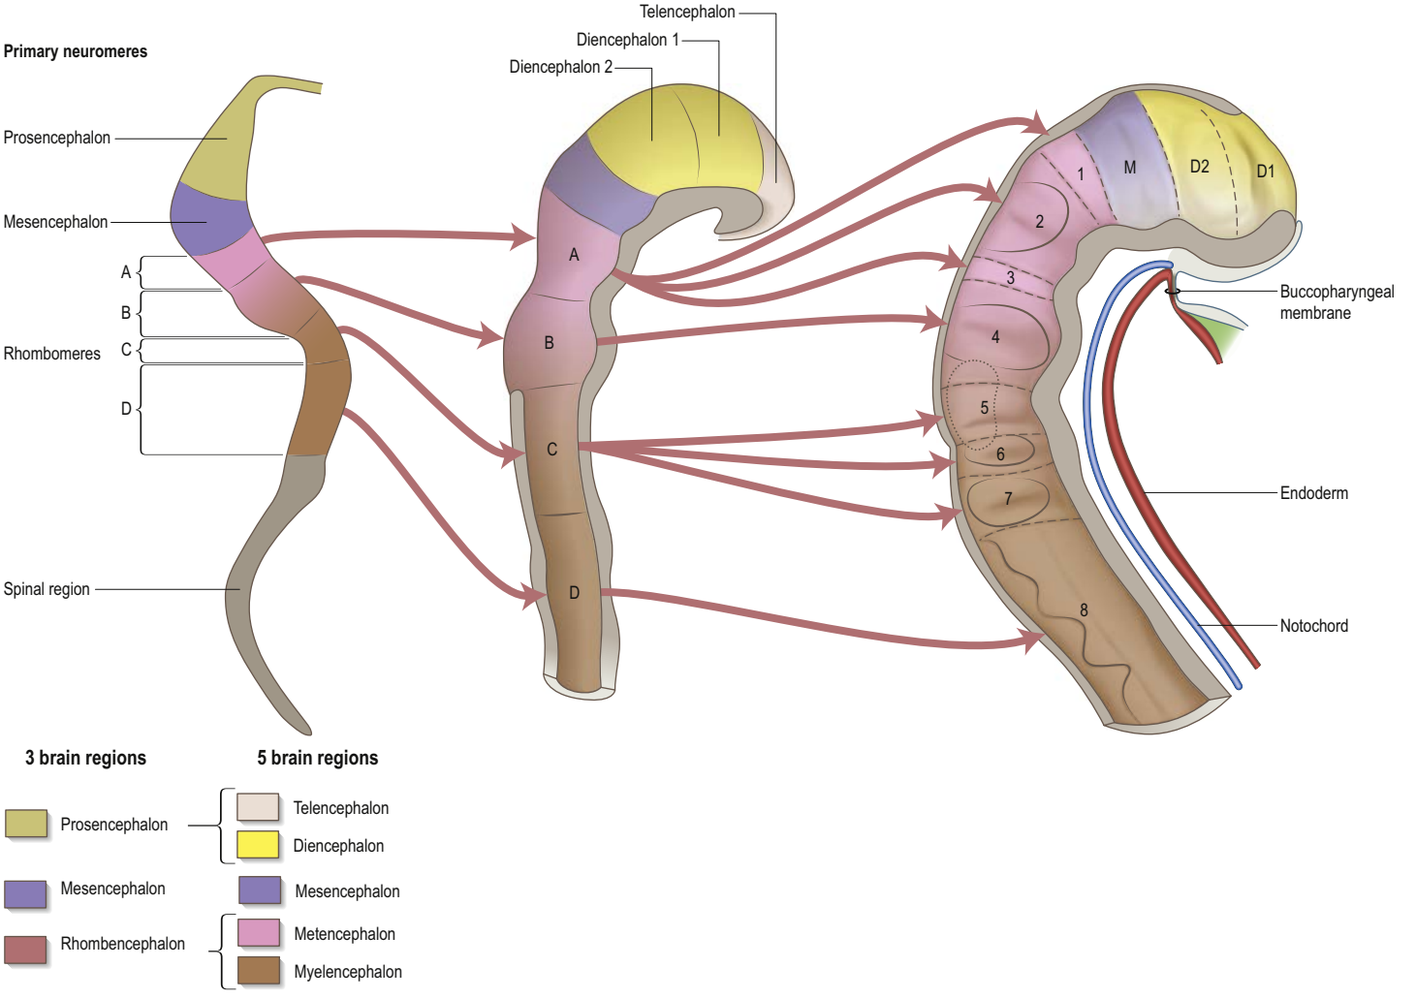

Fig. 14.2 The primary brain regions, neuromeres and their expansion during neurulation.

tube defects commonly correspond to the junctional region between primary and secondary neurulation processes (Dady et al 2014). Heterozygous mutations in the polarity gene signalling pathway have been identified in individuals with neural tube defects. Defects in the structure or function of the primary cilium (see below) are also associated with neural tube defects and with changes in cortical formation thought to underlie cognitive deficits and mental retardation in a range of recessive ciliopathies (Higginbotham et al 2013, Wheway et al 2018).

EARLY BRAIN REGIONS

Prior to the closure of the neural tube, the neural folds become considerably expanded in the head region. The first indication of a brain and its major divisions can be seen at stage 10 (see Fig. 14.2; **Fig. 14.4**). Regional expansions, the prosencephalon (forebrain), mesencephalon (midbrain) and rhombencephalon (hindbrain), have been called the three primary cerebral vesicles, although the term 'vesicle' in this context is probably inappropriate to describe localized accelerations of growth in the wall of the brain. As the neural tube closes, the neural wall appears to form a series of ridges and depressions perpendicular to its long axis. These transient repeating segments are termed primary neuromeres. Initially, six can be identified, namely, the prosencephalon, mesencephalon and four subdivisions of the rhombencephalon, rhombomeres A, B, C and D. The primary neuromeres themselves become subdivided during stages 10, 11 and 12, and a total of 16 secondary neuromeres have been identified. The prosencephalon gives rise to the telencephalon, diencephalon 1 (D1) and diencephalon 2 (D2), which has three subdivisions. The mesencephalon is subdivided into the mesencephalon 1 (M1) and mesencephalon 2 (M2). The rhombencephalon is subdivided into the isthmus rhombencephali and rhombomeres 1–8; the original rhombomere A gives rise to secondary rhombomeres 1, 2 and 3; rhombomere B gives rise to secondary rhombomere 4; rhombomere C gives rise to secondary rhombomeres 5, 6 and 7; and rhombomere D gives rise to secondary rhombomere 8 (O'Rahilly and Müller 1999). As the rhombencephalon grows, the rhombomeric boundaries become less distinct. With the early appearance of the cerebellum from the isthmus rhombencephali and rhombomere 1, the rhombencephalon is traditionally divided into the metencephalon, which extends to about rhombomere 3, and the myelencephalon, which extends to the spinomedullary junction. A summary of the derivatives of the cerebral regions is given in **Table 14.1**.

Before the closure of the neural tube the elongation of the brain occurs concurrently with the appearance of three flexures, two are concave ventrally and one is concave dorsally. During stages 13 and 14 the brain bends at the mesencephalon (mesencephalic flexure) so that the prosencephalon bends in a ventral direction around the cephalic end of the notochord and foregut until its floor lies almost parallel with that of the rhombencephalon (see Fig. 14.4). A bend (cervical flexure) also appears at the junction of the rhombencephalon and spinal cord, increasing in angulation over stages 14–20, by which time the rhombencephalon forms nearly a right-angle to the spinal cord. Extension of the head takes place after stage 20 and the cervical flexure diminishes and eventually disappears. The third bend, the pontine flexure, is directed ventrally between the metencephalon and myelencephalon and does not substantially affect the outline of the head. In this region, the roof plate thins until it is composed only of a single layer of cells and pia mater, the tela choroidea. The flexure of the neural tube at this point produces a rhombic shape in the roof that later forms the medullary velum.

NEURAL CREST

The neuronal populations of the early epiblast become arranged in the medial region of the embryonic disc as the neural plate (see Fig 10.5). Laterally, neural folds or crests indicate a transitional region between the neural and surface ectoderm. Cells in the crests undergo epithelial to mesenchymal transition and leave the epithelium just prior to its fusion with the contralateral fold in the rhombencephalic dorsal midline: their new mesenchymal phenotype means that they acquire migratory properties. Two distinct populations of neural crest cells are formed: a neuronal population produced throughout the brain and spinal cord that gives rise to sensory and autonomic neurones and associated glia, and a non-neuronal mesenchymal population that arises only from the brain (**Figs 14.5-14.6**). As development proceeds, sequential migration of these cells gives rise to four neural crest subpopulations: cranial, vagal, trunk and sacral.

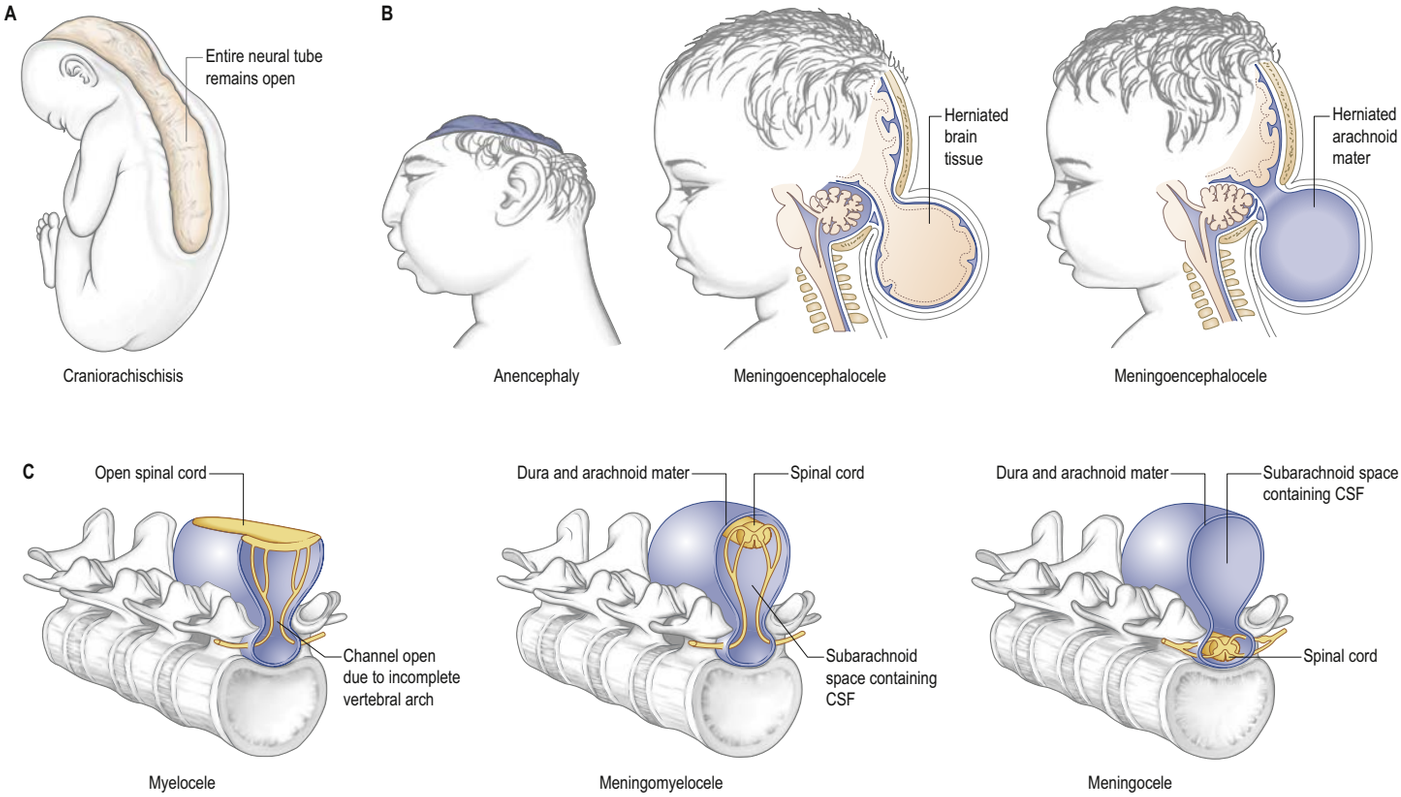

Fig. 14.3 Defects caused by failure of neural tube formation. **A**, Total failure of neurulation. **B**, Failure of rostral neurulation. **C**, Failure of caudal neurulation. Abbreviation: CSF, cerebrospinal fluid.

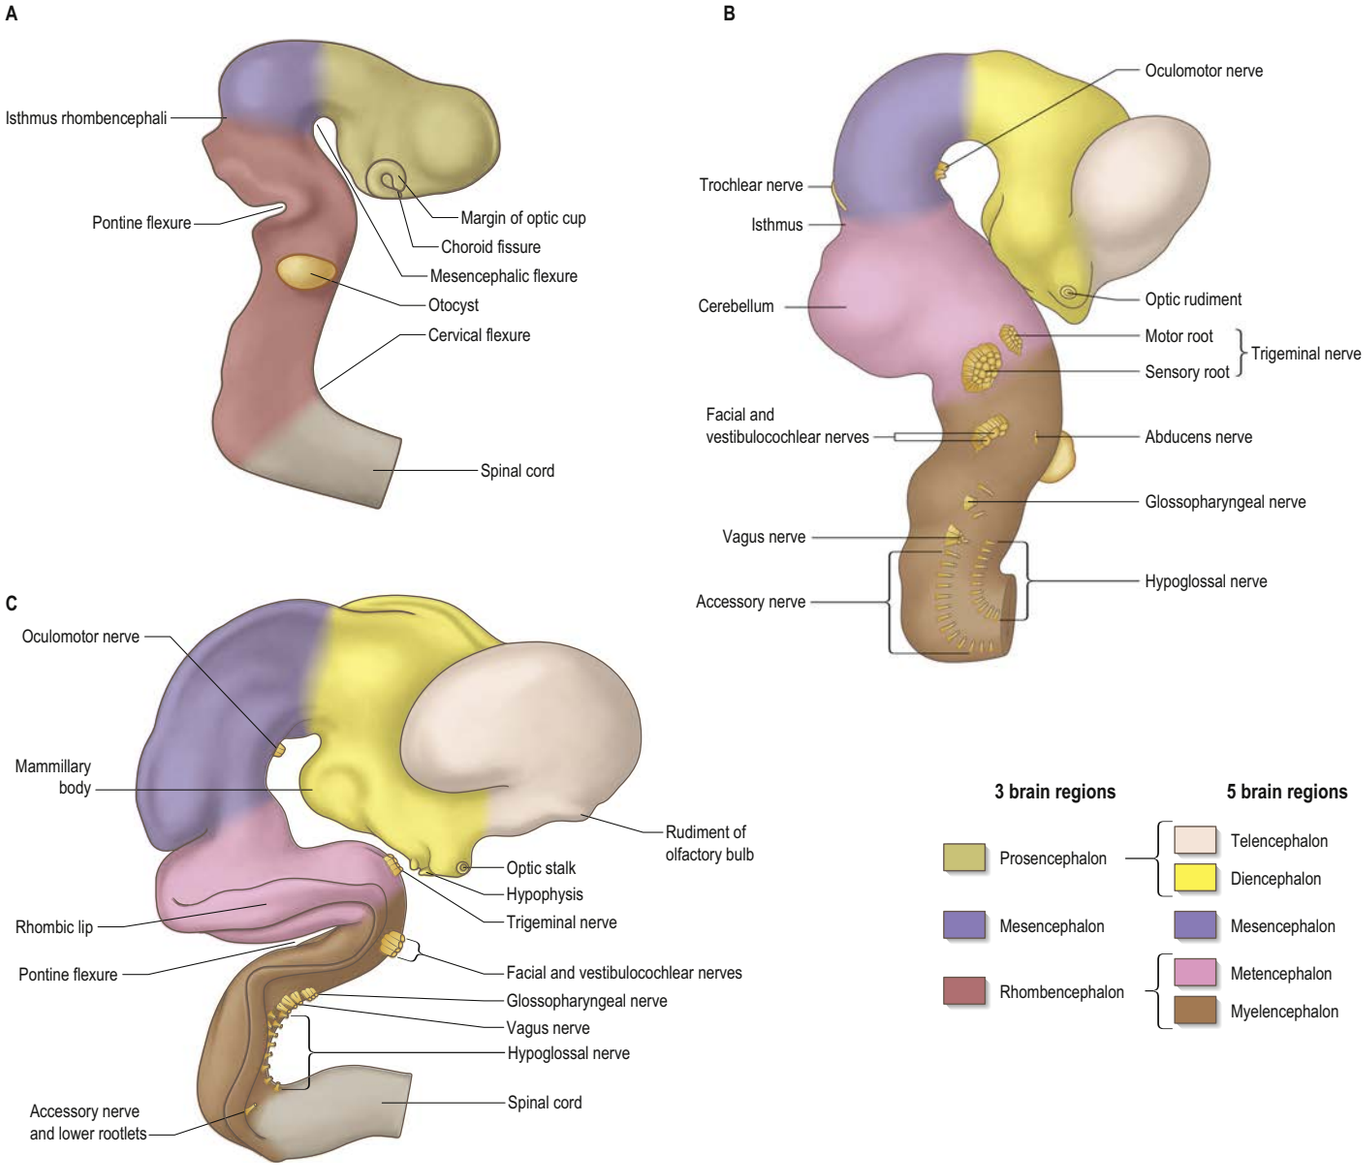

Fig. 14.4 Formation of the mesencephalic, cervical and pontine flexures; human embryos, lateral views. The roof of the rhombencephalon has been removed in each case. **A**, Stage 16. **B**, Stage 17. **C**, Stage 18.

TABLE 14.1 Derivatives of the cerebral regions from caudal to rostral

Cerebral region	Derivatives
Rhombencephalon (or hindbrain)	
1. Myelencephalon	Medulla oblongata Caudal part of the fourth ventricle Inferior cerebellar peduncles
2. Metencephalon	Pons Cerebellum Middle part of the fourth ventricle Middle cerebellar peduncles
3. Isthmus rhombencephali	Superior medullary velum Superior cerebellar peduncles
Mesencephalon (or midbrain)	Cerebral peduncles Tegmentum Tectum Aqueduct
Prosencephalon (or forebrain)	
1. Diencephalon	Thalamus Metathalamus Subthalamus Epithalamus Caudal part of the hypothalamus Caudal part of the third ventricle
2. Telencephalon	Rostral part of the hypothalamus Rostral part of the third ventricle Cerebral hemispheres Lateral ventricles Cortex (archicortex, paleocortex, neocortex) Corpus striatum

Cells within the rostral prosencephalic neural fold and smaller populations of cells in bilateral sites lateral to the early brain do not form migratory neural crest cells but remain within the surface epithelium as ectodermal placodes. Neural crest cells arising from the diencephalon up to the level of the future pineal gland (epiphysis) contribute mesenchymal populations to the frontonasal process. From stage 10 a number of transverse subdivisions perpendicular to the long axis of the brain can be seen within the rhombencephalon, dividing it into segments termed rhombomeres (Müller and O'Rahilly 1997). Eight main rhombomeres extend from the midbrain–hindbrain boundary rostrally to the developing spinal cord caudally (see Fig. 14.2). Both non-neuronal neural crest mesenchyme and neuronal somatic sensory and autonomic ganglia are formed from rhombencephalic crest cells (see Fig. 12.4). Rhombomeres 1 and 2 produce neural crest cells that invade the first pharyngeal arch; rhombomere 4 crest cells migrate into pharyngeal arch 2; rhombomere 6 crest cells migrate into pharyngeal arch 3; rhombomeres 7 and 8 derived neural crest cells migrate into pharyngeal arches 4 and 6. Rhombomeres 3 and 5 give rise to only a very small number of neural crest cells that migrate rostrally and caudally to enter the adjacent even-numbered rhombomeres. These rostral origins give rise to cranial and vagal neural crest. Vagal neural crest migration is extensive: the cells pass ventrally into the developing heart and appear to have a particular association with organs that arise from endoderm, e.g. the thymus gland, foregut-derived respiratory tubes and the gut, where they give rise to the enteric nervous system (Hutchins et al 2018).

Trunk neural crest cells are patterned by their migration through the somites. As the crest cells move laterally and ventrally they can pass between the somites and within the rostral sclerotomal half of each somite, but they cannot penetrate the caudal portion of the sclerotomal mesenchyme. The segmental distribution of the spinal and sympathetic ganglia

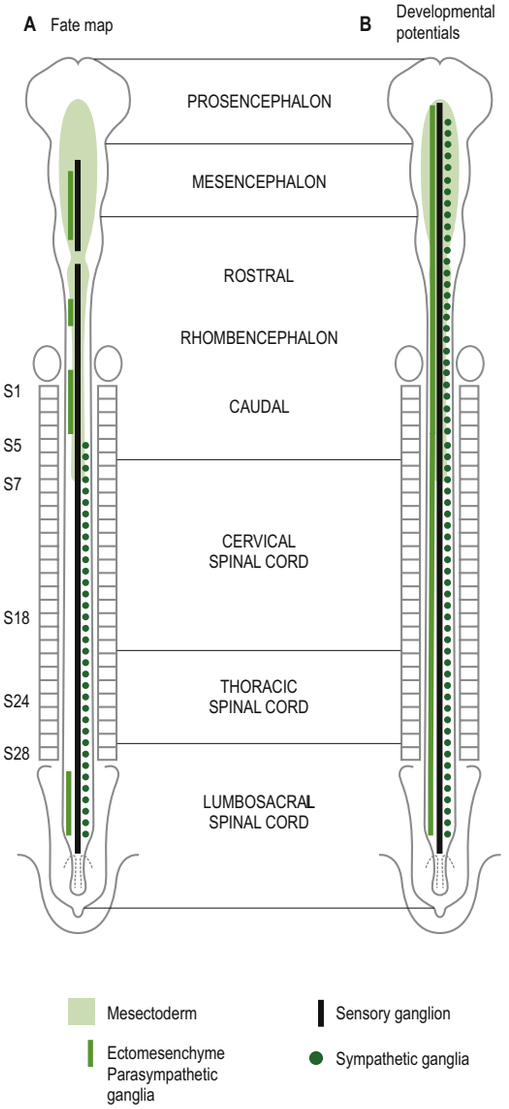

Fig. 14.5 A, A fate map along the neural crest of the presumptive territories that yield ectomesenchyme, sensory, parasympathetic and sympathetic ganglia, and neural crest-derived mesenchyme in normal development. **B**, Developmental potentials for the same cell types. If neural crest cells from any level of the neural axis are implanted into the appropriate sites of a host embryo, they can give rise to almost all of the cell types forming the various kinds of peripheral nervous system ganglia. This is not true for neural crest-derived mesenchyme, whose precursors are confined to the cephalic area of the crest down to the level of somite 5. Key: S, somite.

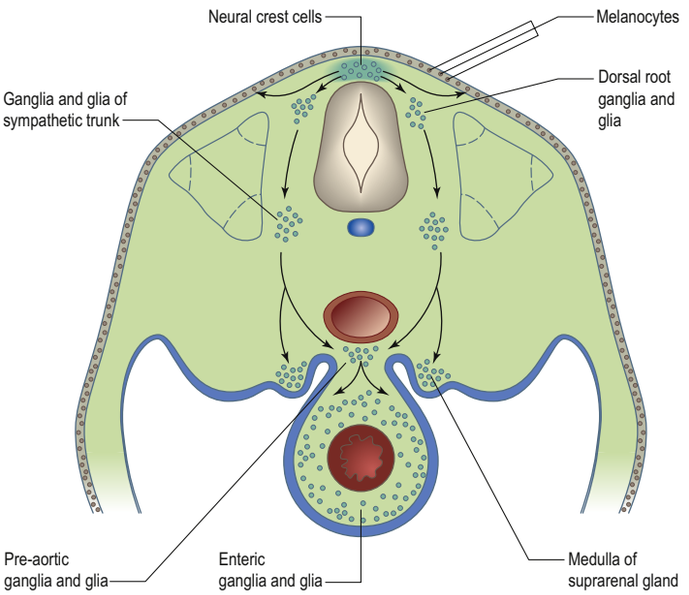

Fig. 14.6 A, Migration routes taken by trunk neural crest cells. (B, *continued online*)

is therefore imposed on trunk neural crest cells by a pre-pattern that exists within the somitic paraxial mesenchyme (see Fig. 14.6; see Ch. 18; Figs 18.4, 18.8). Caudally, from approximately somite 29 secondary neurulation processes produce the most caudal sacral neural crest.

Melanocytes develop from lateral migration of a subpopulation of neural crest cells derived from both the head and the trunk (see Fig. 14.6). They form one of the three pigment cell types (the others being retinal pigment epithelium and the pigment cells of the pineal organ, both of which originate from the diencephalon).

ECTODERMAL PLACODES

Before the neural tube closes, the elevating neural folds contain two distinctive neuronal populations. The larger population, of neural crest cells, migrates from the neural epithelium prior to neural tube fusion. The smaller population, of neuroepithelial cells, becomes incorporated into the surface ectoderm after neural tube closure. These areas of neuroepithelium within the surface ectoderm have been termed ectodermal placodes. Although the majority of the ectodermal placodes form nervous tissue, non-neurogenic placodes also occur (Begbie and Graham 2001). After an appropriate inductive stimulus, the placodes thicken and they either generate migratory neuronal cells that will contribute to the cranial sensory ganglia, or the whole placodal region invaginates to form a vesicle beneath the remaining surface ectoderm. Neurogenic placodes undergo both processes. Paired non-neurogenic placodes invaginate to form the lens vesicles under the inductive influence of the optic vesicles (Ch. 15).

The neural folds meet in the rostral midline adjacent to the buccopharyngeal membrane. The rostral neural fold does not generate neural crest but gives rise to the hypophysial placode, i.e. the future Rathke's pouch, which remains within the surface ectoderm directly rostral to the buccopharyngeal membrane. The rostral neural fold also gives rise to the olfactory placodes that remain as paired, laterally placed placodes, and to the epithelium of the nasal cavity (**Fig. 14.7**).

Further caudally, similar neurogenic placodes, the epibranchial, otic and trigeminal placodes, can be identified (**Fig. 14.8**). The epibranchial placodes appear in the surface ectoderm immediately dorsal to the area of pharyngeal (branchial) cleft formation. The first epibranchial placode is located at the level of the first pharyngeal groove and contributes cells to the distal (geniculate) ganglion of the facial nerve. The second and third epibranchial placodes contribute cells to the petrosal and nodose ganglia of the glossopharyngeal and vagus nerves, respectively. These placodes thicken and cells begin to detach from their epithelium soon after the pharyngeal pouches have contacted the overlying ectoderm. Concurrently, the neural crest cells reach and move beyond these lateral extensions of the pharynx. Neurones migrate from the epibranchial placodes internally to the sites of ganglion formation, where they show signs of early differentiation into neurones, including the formation of neurites.

The otic placodes, located lateral to the myelencephalon, invaginate to form otic vesicles from which the membranous labyrinth of the inner ear develops (Ch. 16). Neurones of the vestibulocochlear ganglia arise from neurones that bud off the ventromedial aspect of the otic cup, after which they can be distinguished in the acoustic and vestibular ganglia.

The profundal and maxillomandibular trigeminal placodes, which fuse in humans to form a single entity, lie rostral to the otic placodes, alongside the mesencephalic–rhombencephalic junction. Prospective neuroblasts migrate from foci dispersed throughout the surface ectoderm lateral and ventrolateral to the caudal mesencephalon and metencephalon to contribute to the distal portions of the trigeminal ganglia.

A small endodermal diverticulum, Seessel's pouch, projects towards the brain from the cranial end of the foregut, immediately caudal to the buccopharyngeal membrane. In some marsupials, this pouch forms a part of the hypophysis, but it is not well defined and disappears entirely in humans.

Pituitary gland (hypophysis cerebri)

The hypophysis cerebri consists of the adenohypophysis, derived from an ectodermal placode, and the neurohypophysis, derived from the neural plate. Prior to neurulation, these cell populations are adjacent within the rostral portion of the floor of the neural plate and the contiguous midline neural fold (see Fig. 14.7). During primary neurulation the neurohypophysial cells remain within the floor of the prosencephalon but the adenohypophysial cells are displaced into the ectoderm as a placode rostral to the buccopharyngeal membrane. Both components remain in contact: there is no growth or migration of one to meet the other during subsequent development.

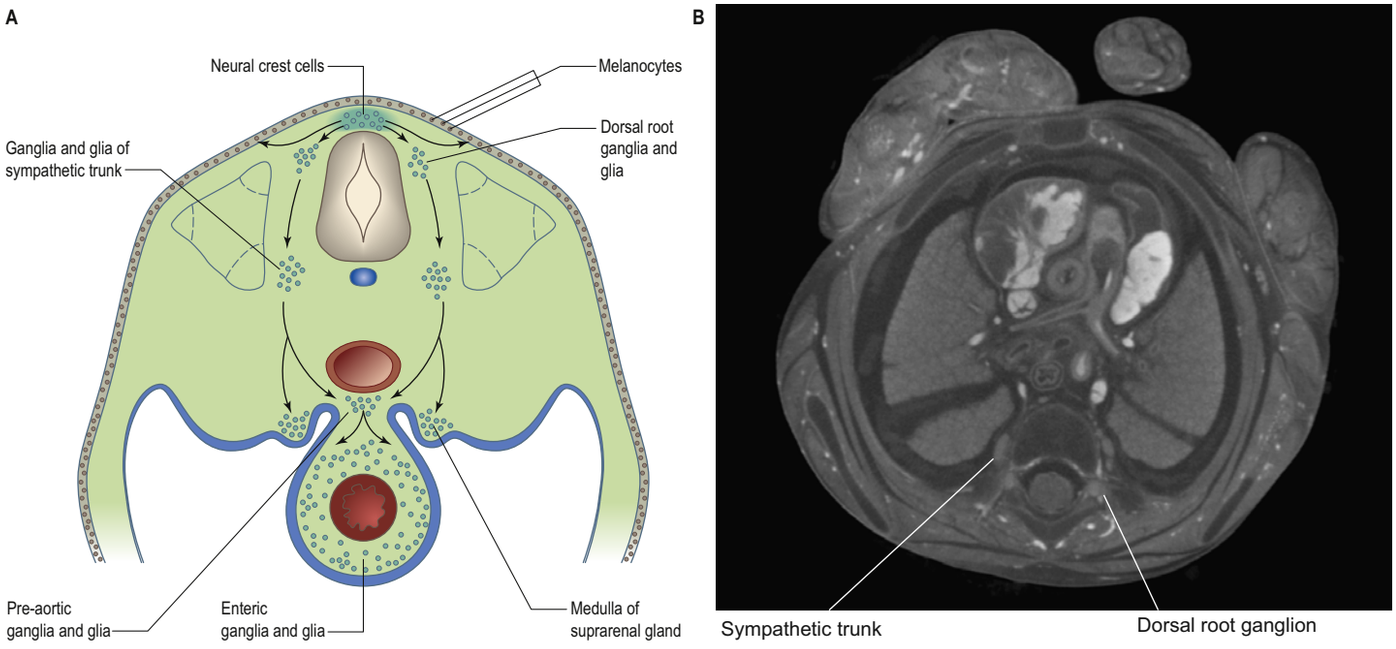

Fig. 14.6 A, Migration routes taken by trunk neural crest cells. **B**, MicroCT image of axial section at the level of the heart in a 14-postmenstrual-week fetus showing the neural crest cell derivatives, the bilateral dorsal root ganglia and sympathetic trunks. (B, Courtesy of Dr Owen Arthurs and Dr Susan Shelmerdine, Great Ormond Street Hospital, London.)

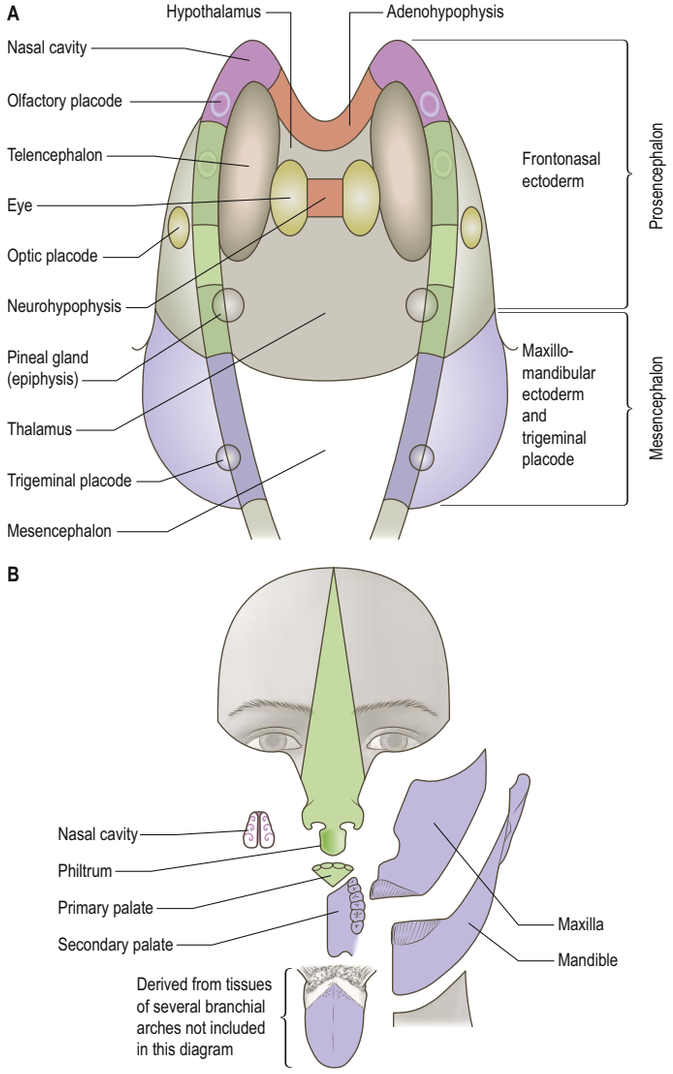

Fig. 14.7 A fate map of the rostral region of the neural primordium as established by the quail–chick chimera system. **A**, The various territories yielding rostral head are indicated on the neural plate and neural fold of a 1–3-somite embryo. **B**, The results obtained in the avian embryo have been extrapolated to the human head. For example, the neural fold area that is coloured green in **A** yields the epithelium of the nose, philtrum and primary palate.

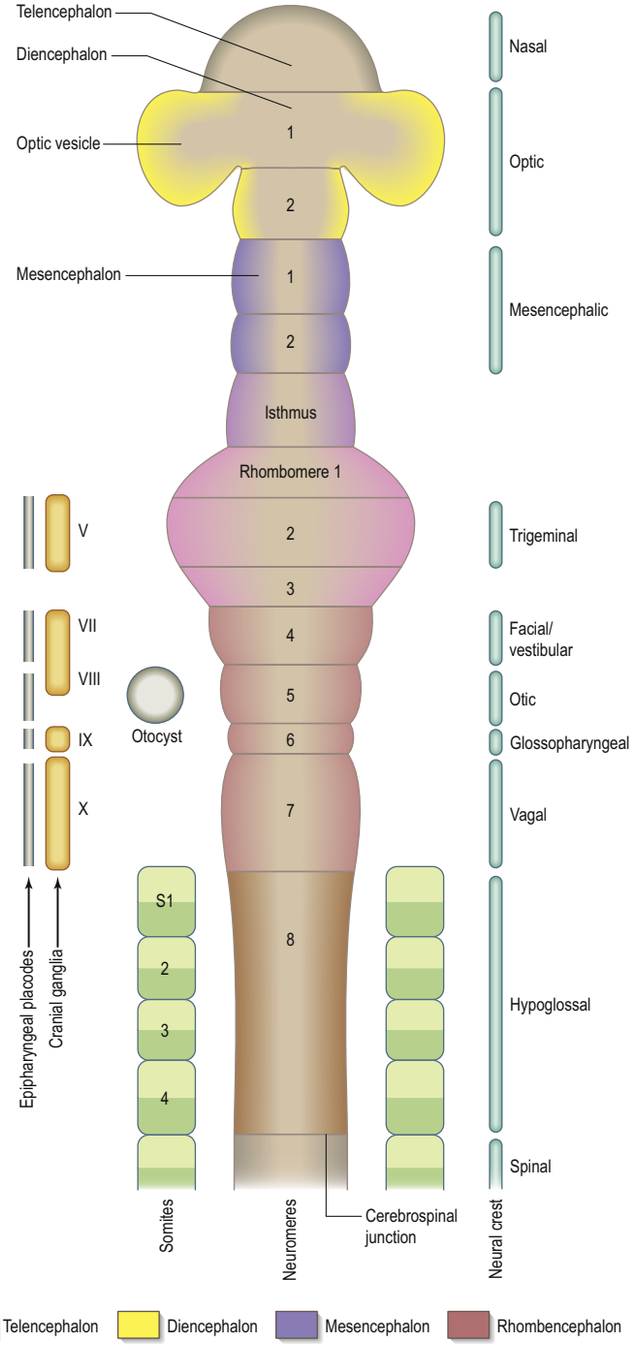

Fig. 14.8 A scheme of a human embryo at stage 13, rendered flat to eliminate the cerebral flexures. The cranial sensory ganglia and otocyst, derived from the epibranchial placodes, are shown on the left. The levels of origin of the neural crest that contribute to the cranial sensory ganglia and mesenchymal populations in the head are indicated on the right. This arrangement may vary in other species. (Courtesy of Professor R O'Rahilly and Dr F Müller.)

The buccopharyngeal membrane ruptures at about stage 12. By stage 13 the placodal thickening of the adenohypophysis can be seen just rostral to the edge of the now ruptured buccopharyngeal membrane and rostral to the tip of the subjacent notochord. The placode invaginates to form the roof and walls of a saccular depression, the adenohypophysial (Rathke's) pouch (Figs 14.9–14.10) that expands laterally to remain associated with the floor and sides of the overlying diencephalic wall. By stage 15 an infundibular recess in the floor of the diencephalon is present, and it evaginates to form the infundibular process and infundibular stem during stage 16. During stage 18 the adenohypophysis and neurohypophysis are closely apposed with no intervening mesenchyme: the wall of the neurohypophysis has characteristic folds. There is vascular mesenchyme between the adenohypophysis and the hypothalamic floor in stage 18 and between the adenohypophysis and neurohypophysis by stage 20. At this time, the adenohypophysial stem is solid and embedded in the chondrocranium.

The interactions between hypothalamic and oral ectoderm previously identified in cultured mouse embryos can be replicated in human embryonic stem cells grown in serum-free floating embryoid body-like aggregates. The tissues that form will generate hormone-producing cells and differentiated cell lines that respond to corticotrophic hormone and secrete ACTH, and respond to GHRH and secrete growth hormone (Ozone et al 2016). For an overview of the regulatory factors involved in pituitary embryogenesis and the conditions under which pituitary stem cells may be activated in postnatal life see Cox et al (2017).

At birth the hypophysis is about one-sixth of the weight of the adult gland. It increases in weight to become about one-half of the weight of the adult gland at 7 years, and attains adult weight at puberty. Throughout postnatal life, the gland appears larger in females, in both size and weight. Traces of the original invagination point of the adenohypophysial pouch may be present at the junction of the septum of the nose and palate. A craniopharyngeal canal is a defect of the midline of the body of the sphenoid bone that extends from the floor of the sella turcica to the roof of the nasopharynx: three types of craniopharyngeal canals have been identified based on CT and MR imaging (Abele et al 2014).

EARLY CELLULAR ARRANGEMENT AND HISTOGENESIS OF THE NEURAL TUBE

Formation of the neural tube floor plate is matched by ventral ingression of the notochord from the primitive node. Dorsoventral patterning of the neural tube is dependent on this close contact because the original floor plate and the dorsal site of fusion of the neural tube initially contain non-neural cells. Motor neurones usually develop ventrally,

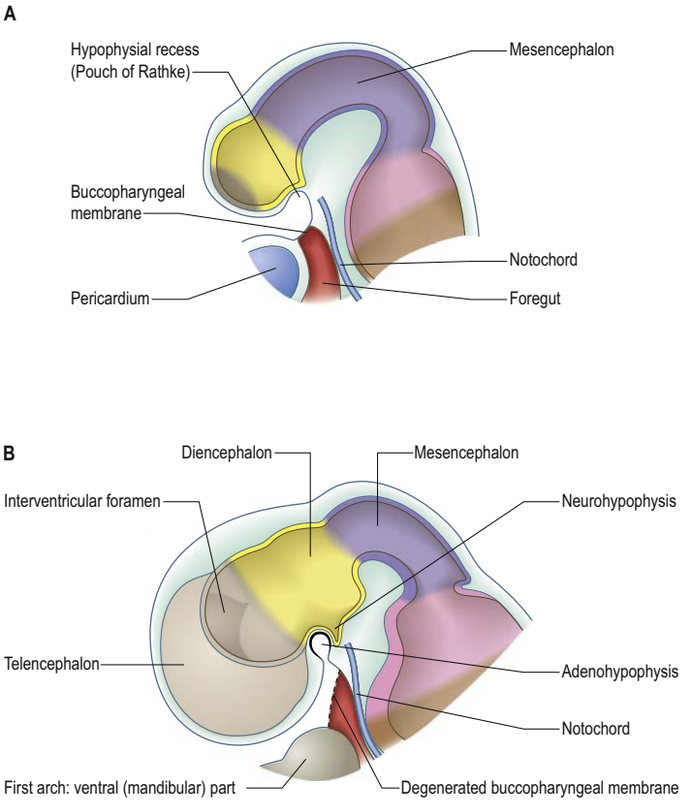

Fig. 14.10 A–B, Initial stages in the development of the hypophysis: sagittal sections of early embryo heads.

close to the notochord, and sensory neurones develop dorsally. Experimental removal of the notochord results in the elimination of the floor plate and motor neurones, and the differentiation of dorsal cell types in the ventral region of the cord (Dodd et al 1998). Experimental grafting of another notochord dorsally results in the induction of a floor plate and ectopic motor neurones close to the grafted notochord. Grafting an isolated neural floor plate dorsal to the neural tube also results in induction of ectopic motor neurones overlying the graft (**Fig. 14.11**). Elucidation of the specific transcription factors involved in the early patterning of the neural tube has enabled the *in vitro* culture of hPSCs and recapitulation of these early processes. Graded Shh signalling originating in the notochord and floor plate establishes discrete individual neuronal precursor domains that later give rise to specific classes of postmitotic motor neurones (Pantani 2016).

Three zones or regions can be identified within the wall of the early neural tube as the pseudostratified epithelium proliferates. Conventionally, these zones have been named ventricular, mantle and marginal, from deep to superficial (**Fig. 14.12**). The inner, ventricular zone (germinal, primitive ependymal or matrix layer) contains the apical, nucleated parts of the pseudostratified columnar neuroepithelial cells and rounded cells undergoing mitosis. As daughter cells migrate ventriculofugally (radially) from the ventricular zone, a middle, mantle layer (intermediate zone) is formed. Radial glial cells form early with processes extending from the ventricular surface (apical cell surface) to the pial surface (basal cell surface). The lateral connection of adjacent apical or basal surfaces give rise to layers termed the internal and external glia limitans (glial limiting membrane), respectively. The region containing the basal surfaces and cytoplasmic processes of the radial glia is termed the marginal zone; it will be invaded later by vascular endothelium, varieties of glial cells and axonal processes extending from neuroblasts.

The neural tube caudal to the developing brain is initially oval in transverse section and its lumen is narrow and slit-like (**Fig. 14.13**). Proliferation in the ventricular zone and migration of the resulting progeny means that the lateral walls thicken and the lumen, now the central canal, widens in its dorsal part. A longitudinal sulcus limitans develops on each side, dividing the ventricular and mantle (now also referred to as intermediate) zones in each lateral wall into a ventrolateral lamina or basal plate, and a dorsolateral lamina or alar plate, respectively. The widening central canal becomes somewhat rhombic on cross-section (**Fig. 14.14**).

The early spinal cord and much of the brainstem retain only the ventricular, intermediate and marginal zones. However, in the telencephalon, cellular proliferation extends deeper than the ventricular zone. A population of cells resulting from the asymmetric division of stem cells at the ventricular zone move to a subventricular zone, where they divide symmetrically. Cells from both layers continue to multiply to provide generations of neurones and glia that subsequently migrate into the intermediate and marginal zones. Those in the subventricular zone are termed intermediate neural progenitor cells or basal progenitors to emphasize the fact that they are no longer attached to the apical (ventricular) surface. They translocate their nuclei to an abventricular location for mitosis. Radially migrating cells from the ventricular zone in the developing cerebral hemispheres form a zone, the cortical plate, outside the intermediate zone. The most recently formed cells migrate to the outermost layers of the cortical plate, so that earlier derived and migrating cells become subjacent to those migrating at a later time. The subplate zone is a crucial additional transient stratum found deep to the early cortical plate in the forebrain (Molnar et al 2019).

In the cerebellar cortex, some mitotic subventricular stem cells migrate across the entire neural wall to form a subpial population and establish a new zone of cell division and differentiation. Many cells formed in this site remain subpial in position, but others migrate back towards the ventricle through the developing nervous tissue, and finish their migrations in various definitive sites where they differentiate into neurones or macroglial cells.

Segmentation in the neural tube

The early neural tube is visibly divided into segments by shallow transverse folds that extend perpendicular to its long axis. Primary neuromeres can be identified at stage 9, with 16 secondary neuromeres present at stage 14. Rhombomeres, the segments within the rhombencephalon, identified from stage 10, are crucial units of pattern formation (Tümpel et al 2009). Other brain regions are not segmented in quite the same way as the hindbrain. Morphological boundaries, domains of cell lineage restriction and of cell mixing, and regions of gene expression that abut sharp boundaries, are found in the diencephalon and telencephalon. Although these segmental units lose their morphological prominence with subsequent development, they represent the fundamental ground plan of the neuraxis, creating a series of semi-autonomous units, within which local variations in patterning can then develop. It is likely that compartmentation of cell groups with some, if not all, of the features of rhombomeres plays an important role in the formation of various brain regions.

Domains of expression of developmental control genes abut rhombomere boundaries. Single-cell labelling experiments have revealed that cells within rhombomeres form segregated non-mixing populations (**Fig. 14.16**). The neural crest also shows intrinsic segmentation in the rhombencephalon. It is segregated into streams at its point of origin in the dorsal neural tube, which may represent a mechanism whereby morphogenetic specification of the premigratory neural crest cells is conveyed to the pharyngeal arches (see Fig. 12.4). Developmental studies of rhombomeric fate, developmental gene expression, progeny analysis and fate mapping are calling into question the traditional

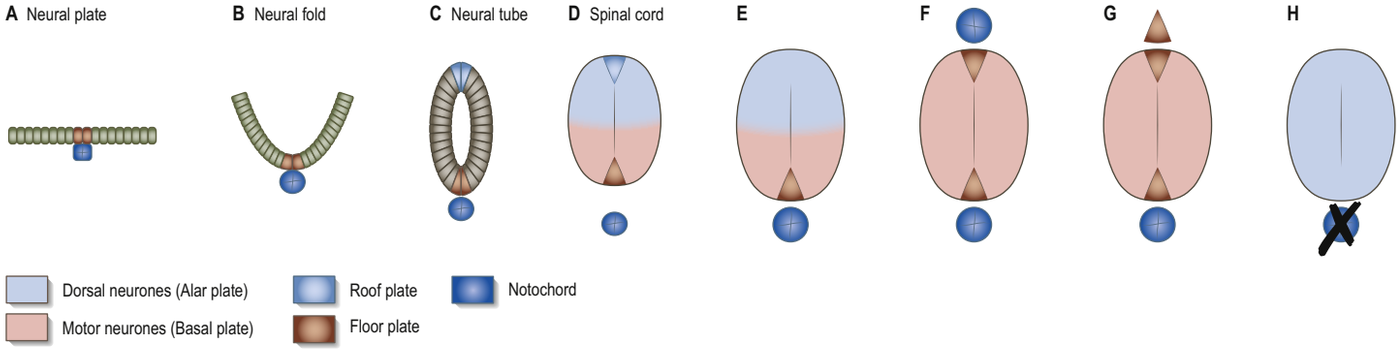

Fig. 14.11 A–D, Successive stages in the development of the neural tube and spinal cord. **A**, The neural plate consists of epithelial cells. Cells in the midline of the neural plate are contacted directly by the notochord. More lateral regions of the neural plate overlie the paraxial mesenchyme (not shown). **B**, During neurulation, the neural plate bends at its midline and this elevates the lateral edges of the plate as the neural folds. Contact between the midline of the neural plate and the notochord is maintained at this stage. **C**, The neural tube is formed when the dorsal tips of the neural folds fuse. Cells in the region of fusion form the roof plate, a specialized group of dorsal midline cells. **D**, Cells at the ventral midline of the neural tube retain proximity to the notochord and differentiate into the floor plate. After neural tube closure, neuroepithelial cells continue to proliferate and eventually differentiate into defined classes of neurones at different dorsoventral positions within the spinal cord. For example, sensory relay, commissural and other classes of dorsal neurones differentiate near to the roof plate, and motor neurones differentiate ventrally near the floor plate, which, by this time, is no longer in contact with the notochord. **E–H**, Summary of the results obtained from experiments in chick embryos in which either a notochord or floor plate is grafted to the dorsal midline of the neural tube, or the notochord is removed before neural tube closure. **E**, The normal condition: motor neurones are located ventrally and sensory relay neurones are located dorsally. **F**, Dorsal grafts of a notochord result in the induction of a floor plate in the dorsal midline and ectopic dorsal motor neurones. **G**, Dorsal grafts of a floor plate induce a new floor plate in the dorsal midline and ectopic dorsal motor neurones. **H**, Removal of the notochord results in the elimination of the floor plate and motor neurones, and the expression of dorsal cell types in the ventral region of the spinal cord. (Adapted with permission from Jessell TM, Dodd J 1992 Midline signals that control the dorso-ventral polarity of the neural tube. Semin Neurosci I4:317–325.)

Planar cell polarity genes are expressed by the neuroepithelium. Each cell displays an apical non-motile primary cilium (internal 9 + 0 configuration of microtubules), and a system of intraflagellar transport (Tissir and Goffinet 2010). The membrane of the primary cilium expresses receptors and ion channels and modulates signalling pathways for Shh, Wnt and PDGFα (Lee and Gleeson 2010).

Pseudostratified epithelial proliferation of neuroepithelial progenitor cells at the ventricular zone is recognized by interkinetic nuclear migration. The cells have a relatively small basal surface that generates a basal lamina, a similarly small apical surface (with a primary cilium) joined by an adherence junctional belt, and extensive lateral surfaces that span the neuroepithelial wall. Their nuclei migrate basally during G1 phase of the cell cycle; S-phase (DNA replication) occurs as the nuclei approach the basal lamina. During G2, the nuclei migrate apically (toward the neural tube lumen) where cell division occurs. The basal body of the primary cilium is anchored to the apical surface: the cilium persists through the cell cycle until the onset of mitosis when the basal body and associated second centriole form the centrosomes of the mitotic spindle (Taverna and Huttner 2010). The movement of the nuclei during proliferation is responsible for the pseudostratified appearance of the epithelium, because the nuclei move basally and then apically as they pass through a complete mitotic cycle (**Fig. 14.15**).

The first populations formed by symmetric division become radial glial cells: through their contact with both the neural tube lumen and the outer pial surface, they provide a scaffold on which future cell progeny can migrate. Radial glial cells express GFAP, distinguishing them from neuroepithelial progenitor cells (Silver et al 2019). The Golgi apparatus in radial glial cells remains apical to the nucleus and perpendicular to the apicobasal axis of the cell and appears to have only a minor role in synthesis of constituents for the basolateral plasma membrane (Taverna et al 2016). Arl13b, a cilia-specific small guanosine triphosphatase (GTPase), is essential for the formation of radial glia (Higginbotham et al 2013). Later, asymmetric divisions produce one neuroepithelial progenitor cell and another cell that migrates radially (ventriculofugally), so producing clones of neuroblasts and glioblasts. With development of the intermediate zone, the nuclei of cells undergoing asymmetric division show interkinetic nuclear migration only within the ventricular and subventricular zones (Taverna and Huttner 2010). The heterogeneity of the radial glial cell population, which can become detached from the basal and apical surfaces as development proceeds, has yet to be elucidated (Silver et al 2019). The stem cells in the ventricular zone finally produce two postmitotic daughter cells that differentiate into ependyma that lines the ventricular system. The ventricular epithelium differentiates into choroid plexus and specialized circumventricular organs in particular sites within the third and fourth ventricles.

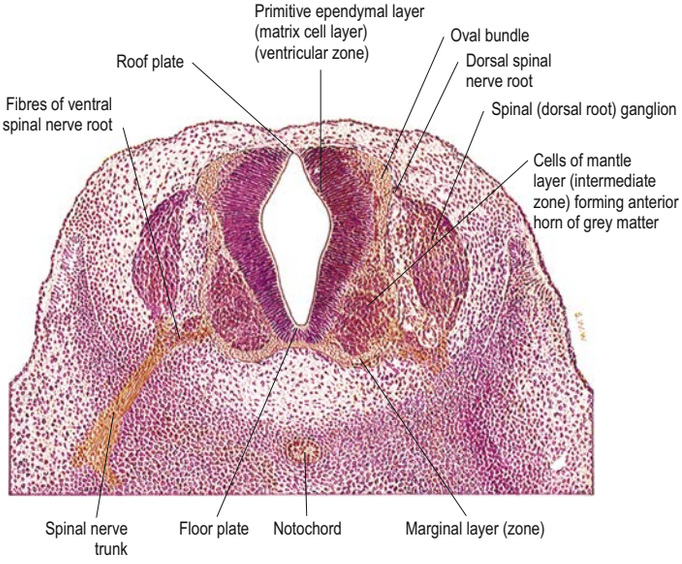

Fig. 14.14 Transverse section of the spinal cord in the cervical region of a human embryo about stage 16.

subdivisions of the brainstem into midbrain, pons and medulla oblongata that have been based on the external appearance of the human brainstem (Watson et al 2019). The brainstem boundaries identified by these new analyses are illustrated in **Fig. 14.17** and Figs 28.25, 28.26.

The significance of intrinsic segmentation in the hindbrain is underlined by the absence of overt segmentation of the adjacent paraxial mesenchyme. There is no firm evidence for intrinsic segmentation in the spinal cord. Instead, segmentation of the neural crest, motor axons and thus, eventually, the spinal nerves, is dependent on the segmentation of the neighbouring somites. Both neural crest cell migration and motor axon outgrowth occur through only the rostral and not the caudal sclerotome of each somite, so that dorsal root ganglia form only at intervals. The caudal sclerotome possesses inhibitory properties that deter neural crest cells and motor axons from entering.

Genes such as the *Hox* and *Pax* gene families, which encode transcription factor proteins, show intriguing expression patterns within the nervous system. Genes of the *Hox-b* cluster, for example, are expressed throughout the caudal neural tube, and up to discrete limits in the hindbrain that coincide with rhombomere boundaries. The ordering of these genes within a cluster on the chromosome (5′–3′) is the same as the caudal to rostral limits of expression of consecutive genes. This characteristic pattern is surprisingly similar in fish, frogs, birds and mammals. *Hox* genes play a role in patterning not only of the neural tube but also of much of the head region, consistent with their expression in neural crest cells, and within the pharyngeal arches. Disruption of *Hox a-3* gene in mice mimics DiGeorge's syndrome, a congenital human disorder characterized by the absence (or near absence) of the thymus, parathyroid and thyroid glands, hypotrophy of the walls of the arteries derived from the aortic arches, and subsequent conotruncal cardiac malformations. Some *Pax* genes are expressed in different dorsoventral domains within the neural tube. *Pax-3* is expressed in the alar lamina, including the neural crest, while *Pax-6* is expressed in the intermediate plate. The *Pax-3* gene has the same chromosomal localization as the mouse mutation Splotch and the affected locus in the human Waardenburg's syndrome, both of which are characterized by neural crest disturbances with pigmentation disorders and occasional neural tube defects. Both *Hox* and *Pax* genes have restricted expression patterns with respect to the rostrocaudal and the dorsoventral axes of the neural tube, consistent with roles in positional specification. The expression pattern of *Hox* and other genes expressed in rhombomeres, and the transcriptional analysis of individual rhombomeres illustrate the genome-wide complexity of mid- and hindbrain patterning in animal embryos (Krumlauf et al 1993, Chambers et al 2009, Wilson and Chambers 2014).

While craniocaudal positional values are probably conferred on the neuroepithelium at the neural plate or early neural tube stage, dorsoventral positional values may become fixed later. The development of the dorsoventral axis is heavily influenced by the presence of the underlying notochord. The notochord induces the floor plate in the ventral midline of the neural tube. This specialized region consists of a strip of non-neural cells with distinctive adhesive and functional properties. Notochord and floor plate together participate in inducing the differentiation of the motor columns. Motor neurone differentiation occurs early, giving some grounds for the idea of a ventral to dorsal wave of differentiation. The notochord/floor plate complex may also be responsible for allotting the values of more dorsal cell types within the tube (see Fig. 14.11). For example, the dorsal domain of expression of *Pax-3* extends more ventrally in chick embryos experimentally deprived of notochord and floor plate, while grafting an extra notochord adjacent to the dorsal neural tube leads to a repression of *Pax-3* expression.

Cell populations of the early brain and their growth

Cells in the nervous system are derived from three embryonic sources. The neural plate and tube give rise to CNS neurones, astrocytes and oligodendrocytes, and neuronal neural crest cells and ectodermal

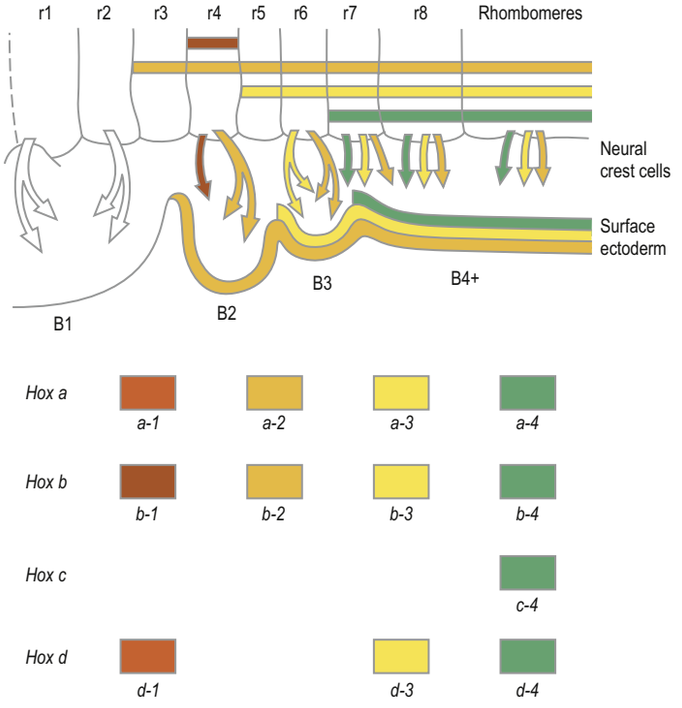

Fig. 14.16 *Hox* gene expression domains in the branchiorhombomeric area in the mouse embryo at E9.5. The arrows indicate neural crest cells migrating from the rhombencephalon and midbrain. Cells migrating from the rhombencephalon are shaded to indicate the *Hox* genes they express. The same combination of *Hox* genes is expressed in the rhombomeres and in the superficial ectoderm of the pharyngeal arches at the corresponding rostrocaudal levels. The four *Hox* clusters are represented below. (Adapted with permission from the Annual Review of Cell and Developmental Biology, Volume 8, 1992 by Annual Reviews.)

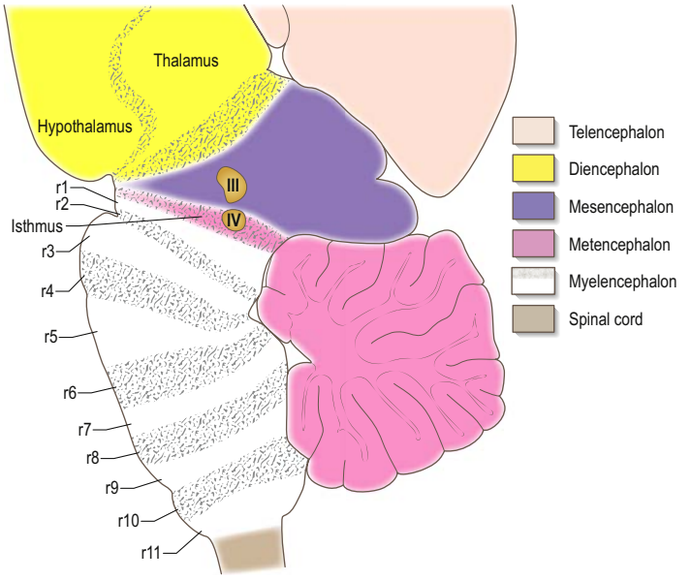

Fig 14.17 The extent of the rhombomeres in the brainstem (r1–r11). Traditionally, based on the ventral appearance of the brainstem, the mesencephalon has been described as extending from the thalamus to the rostral margin of the pons, and including the posterior commissure, the nuclei for cranial nerves III and IV, the interpeduncular nuclei and the isthmus. Studies of developmental gene expression, progeny analysis and fate mapping of the rhombomeres in the brainstem have shown that whereas the mesencephalon does include the oculomotor nerve nuclei (III), the posterior commissure is part of the diencephalon and the abducens nerve nuclei (VI) and the isthmus are part of the rhombencephalon (subdivided into metencephalon and myelencephalon). The isthmus, an important organizer of brainstem development, is now recognized as part of the rhombencephalon and designated rhombomere 0. (Adapted with permission from Watson C, Bartholomaeus C, Pueles L 2019 Time for radical changes in brain stem nomenclature – applying the lessons from developmental gene patterns. Front Neuroanat 13:10. doi.org/10.3389/fnana.2019.00010.)

placodes give rise to PNS ganglionic neurones, both somatic and autonomic, and associated astrocytes and Schwann cells. Neuronal neural crest cells also form all neurones and glia of the enteric nervous system and the chromaffin cells of the suprarenal (adrenal) cortex. Non-neuronal neural crest cells form angiogenic mesenchyme in the layers around the developing neural tube, and other haematogenic precursors give rise to microglial cells that subsequently enter the nervous system. Human neural development is now being investigated by *in vitro* studies of human pluripotent stem cells (hPSCs), 3D culture and the development of cerebral organoids from human tissue (Lee et al 2017). The latter have been used to identify cortical cell types infected by Zika virus and the screening of potential pharmacological treatments (Molnar et al 2019).

Proliferation of the ventricular zone of the early neural tube gives rise to neurones before glial cells. The timing of events differs in various parts of the CNS and between species. Most neurones are formed prenatally in mammals but postnatal neurogenesis occurs in the cerebral cortex, olfactory bulb and the small granular cells of the cerebellum. Gliogenesis continues after birth in periventricular and other sites.

Immature neurones are initially rotund or fusiform. Their cytoplasm contains a prominent Golgi apparatus, many lysosomes, glycogen and numerous unattached ribosomes. As maturation proceeds, cells send out fine cytoplasmic processes that contain neurofilaments, microtubules and other structures, often including centrioles at their bases where microtubules form. Internally, cisternae of the endoplasmic reticulum appear and attached ribosomes and mitochondria proliferate, while the glycogen content progressively diminishes.

Astrocytes differentiate into protoplasmic and fibrous phenotypes. Human cortical protoplasmic astrocytes first appear around postmenstrual week 20 and their density continues to increase into postnatal life. During early adulthood gliogenic progenitors from the subventricular zone can contribute to the generation of new astrocytes in response to injury (Krencik et al 2017).

Oligodendrocytes arise later in development and myelinate developing CNS axons over a protracted period. (For details of myelin formed by oligodendrocytes see Chapter 3.) Oligodendrocyte progenitor cells are prevalent initially in the brainstem at about postmenstrual week 22 and cortical myelination continues into postnatal life. The oligodendrocyte precursor cell population is heterogeneous; maturation appears to be both spatially and temporally controlled (Dimou and Simons 2017). Research in this area is frustrated by methodological difficulties (differentiated oligodendrocytes are very difficult to isolate): single cell transcriptome techniques have been used to study oligodendrocyte lineage (Van Bruggen et al 2017). Synapses between oligodendrocyte precusor cells and neurones have been observed. Vesicular neurotransmitter release and adenosine signalling via adenosine receptors regulate the migration of oligodendrocyte progenitor cells at the motor exit point transition zone in zebra fish embryos (Fontenas et al 2019; see p. 241).

Schwann cells are derived from neural crest cells of the head and trunk. They associate with most PNS axons and many produce myelin, responding to neuronal signals. Schwann cell precursors are multipotent embryonic progenitors that may migrate into the peripheral tissues and signpost nerve fibre migration routes; they also cling to extending axons and, in this way, spread throughout the body with the developing peripheral nervous system. Factors secreted by Schwann cell precursors may pattern the development of neurovascular bundles (Furlan and Adameyko 2018).

Microglial cells are derived from haemopoietic cells found in the yolk sac and precursor blood stem cells become seeded in various body regions (Tay et al 2017). Microglial cells enter the brain by two routes, initially via pial vessels and later also via the early cerebral circulation that supplies both the ventricular zone and the developing choroid plexuses in the lateral ventricle (Reemst et al 2016, Michell-Robinson et al 2017, Menassa and Gomez-Nicola 2018). Within the developing nervous system they have roles during late neurogenesis and gliogenesis. They remain within the CNS after the blood–brain barrier matures and are able to proliferate and respond to homeostatic disequilibrium throughout pre and postnatal life. For the time line of human microglial development see Menassa and Gomez-Nicola (2018).

Early neuronal growth

Early neuroblasts form one main process, the axon, and other processes that establish a dendritic tree. Studied in tissue culture, axons may grow as much as 1 mm per day, navigating with precision over complex courses and considerable distances to reach their targets. Eventually, axons make functional contact with their appropriate end organs (neuromuscular endings, secretomotor terminals, sensory corpuscles or synapses with other neurones). There are reciprocal interactions with the target tissues: reciprocal signalling occurs during development, postnatally and in adult life (Harris 2008, da Silva and Wang 2011).

Ramón y Cajal was the first to describe the expanded growing tips of axons, naming them growth cones. These tips are constantly active, changing shape and extending and withdrawing filopodia and lamellipodia, small protuberances that apparently 'explore' the local environment for a suitable surface over which to extend. This incessant palpatory activity depends on the organization and dynamics of actin filaments that fill the leading margin (peripheral (P–) domain) of the growth cone. It is regulated by actin-binding proteins that control all aspects of filament assembly, turnover, interactions with other filaments and cytoplasmic components, and the production of mechanical forces. Adhesive ligands and extrinsic guidance cues bind growth cone receptors to their substratum and trigger signalling activities involving Rho GTPases, kinases, phosphatases, cyclic nucleotides and Ca^{2+} fluxes. Adhesion to a substratum appears to be important for transient consolidation (stabilization) of the growth cone, elaboration of the axonal cytoskeleton in the direction of growth, and transduction of mechanical forces into traction in order to pull the axon towards its next target (Gomez and Letourneau 2014). After consolidation, the exploratory behaviour begins again, resembling the behaviour at the leading edge of migratory cells such as fibroblasts and neutrophils.

Axon extension occurs when growth cones encounter a permissive physical substrate containing short-range cues such as appropriate extracellular matrix components, transmembrane phosphatases and cadherins. Axonal repulsion requires negative cues that inhibit the progress of the growth cone. Long-range cues diffuse from distant targets down gradients of specific factors, inducing neurones to turn their axons either towards the source of an attractive signal or away from a repulsive signal. Topographic projections, such as the retinotectal pathway, are established as specific populations of growth cones follow spatial gradients of guidance cues (Kalil et al 2011).

Once growth cones have arrived in their appropriate target area, they form terminals and synapses. Extensive dendritic trees are generated and subsequently shaped by dendrite retraction and pruning. Signalling mechanisms underlying these processes are poorly understood: centrosomal CaMKIIβ signalling has been proposed as a mechanism restricting dendrite elaboration while promoting dendrite pruning (Puram et al 2011). The final shape of dendritic trees is influenced by patterns of afferent connections and their activity and is necessary for the accurate formation of neuronal circuitry. Dendritic spine density in childhood exceeds adult values by two- to three-fold and begins to decrease during puberty. However, the overproduction and later pruning of supernumerary synapses continues well into the third decade of life before stabilizing (Petanjek et al 2011, Kolb et al 2013). Successful neuronal connectivity is the product of a series of tightly regulated programmed events that include axon initiation, growth cone formation and navigation, and the formation and pruning of dendritic trees and synapses (Chiu et al 2013).

Axonal and dendritic outgrowth is initiated and supported by neurotrophins. Differential responses reflect the distribution of receptors or components of the relevant signal transduction pathways on neuronal, axonal and dendritic surfaces. Structurally and functionally related neurotrophic molecules include the nerve growth factor (NGF) superfamily and the GDNF family (Cirulli and Alleva 2009, Park and Poo 2013, West et al 2014). The NGF superfamily includes BDNF, NT-3 and NT-4/5, which exert their survival effects selectively on particular subsets of neurones. NGF is specific to sensory ganglion cells from the neural crest, sympathetic postganglionic neurones and basal forebrain cholinergic neurones. BDNF promotes the survival of retinal ganglion cells, motor neurones and some placode-derived neurones, such as those of the nodose ganglion, that are unresponsive to NGF. NT-3 has effects on motor neurones, limb proprioceptive neurones and both placode- and neural crest-derived sensory neurones. Other growth factors that influence the growth and survival of neural cells include the FGFs and ciliary neurotrophic factor (CNTF), which are unrelated in sequence to the NGF family. Members of the FGF family support the survival of embryonic neurones from many regions of the CNS. CNTF may control the proliferation and differentiation of sympathetic ganglion cells and astrocytes.

Each of the neurotrophins binds specifically to certain receptors on the cell surface. The receptor $p75^{NTR}$ binds all the neurotrophins with similar affinity, whereas members of the family of receptor tyrosine kinases (Trks) bind with higher affinity and display binding preferences for particular neurotrophins; the presence of a Trk receptor seems to be required for $p75^{NTR}$ function.

CNS/PNS zone patterning

Relatively little is known about tissue interactions at the CNS/PNS junctional zone between neural plate-derived motor neurones (with axons extending into the periphery) and neural crest-derived somatic sensory neurones (with processes entering the neuraxis from the periphery). Transition zones between the central and peripheral nervous systems show segregation of neurones and their axons and also of central and peripheral glia. Different processes appear to operate in the spinal cord at the basal plate motor exit points and alar plate dorsal root entry zones. The experimental evidence for these findings has come largely from zebrafish and mouse embryos, indicating some conservation of developmental processes.

Early in development peripheral nervous cells are apparently able to migrate in and out of the developing spinal cord before the radial glial end feet establish an external glia limitans (Smith et al 2016). Once a continuous glia limitans is in place, neural crest derivatives, termed boundary cap cells, migrate along the spinal cord and transiently cluster at transition zones that match the sites of axonal exit and entry points. In mouse embryos, where *Krox-20* is expressed early in rhombomeres 3 and 5, the expression persists in boundary cap cells and later in Schwann cells (Fontenas and Kucenas 2017). Loss of boundary cells adjacent to the basal plate results in the presence of ectopic cell bodies of motor neurones in the ventral rootlets; inactivation of *Krox-20* results in ectopic cell bodies of motor neurones within the motor ventral rootlets and ectopic oligodendrocytes, rather than Schwann cells, within the proximal parts of both motor and sensory nerve rootlets. Perineurial glia are *nkx2.2a*-expressing cells that originate from the basal plate of the spinal cord and migrate apparently exclusively into the motor exit rootlets along the motor axons, ensheathing them, forming tight junctions and differentiating into perineurium. In zebrafish, loss of *nkx2.2a* leads to motor axons exiting the CNS ectopically, cell bodies of motor neurones moving out of the spinal cord and an absence of perineurial ensheathment of motor axons peripherally (Kucenas 2015, Fontenas and Kucenas 2017). The origin of sensory perineurial glia has yet to be established.

At the alar plate a different mechanism is seen. Axons extending centrally from sensory neurones in the dorsal root ganglia form actin-rich filopodia that extend toward the dorsal root entry zone. Pioneer axons migrate along the radial glial end-feet, then cross the CNS/PNS radial glial boundary to form rostral and caudal projections within the CNS (Nichols and Smith 2019). The growth cones swell during entry and are thought to rearrange their actin filaments dynamically as they cross the glia limitans. Whether or not boundary cap cells are associated with sensory axon entry is still unclear; the temporal dynamics indicate entry of rostral growth cones before more caudal ones, and the later coalescence of peripheral glial populations (Fontenas and Kucenas 2017, Nichols and Smith 2019).

PERIPHERAL NERVOUS SYSTEM

Somatic nerves

Spinal nerves

Each spinal nerve is connected to the spinal cord by a ventral root and a dorsal root (**Fig. 14.18**). The fibres of the ventral rootlets grow out from cell bodies in the anterior and lateral parts of the intermediate zone and pass through the overlying marginal zone and external limiting membrane. Some enter the myotomes of the somites, and some penetrate the somites, reaching the adjacent somatopleure: in both sites, they ultimately form α-, β- or γ-efferents. At appropriate levels these axons are accompanied by the outgrowing axons of preganglionic sympathetic neuroblasts (segments T1–L2) or preganglionic parasympathetic neuroblasts (S2–S4).

The fibres of the dorsal rootlets extend from cell somata in dorsal root ganglia into the spinal cord and into the periphery. Neural crest cells are produced continuously along the length of the spinal cord, but gangliogenic cells migrate only into the rostral part of each somitic sclerotome, where they condense and proliferate to form a bilateral series of oval primordial spinal ganglia (dorsal root ganglia) (see Fig. 14.6; Ch. 18). Negative factors in the caudal sclerotome deter neural crest cells from entering. The rostral sclerotome has a mitogenic effect on the crest cells that settle within it. From the ventral region of each ganglion, a small part separates to form sympathochromaffin cells, while the remainder becomes a definitive spinal ganglion (dorsal root ganglion). The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the caudal region, are equal in number to the somites. The cells of the ganglia, like the cells of the intermediate zone of the early neural tube, are glial and neuronal precursors. The glial precursors develop into satellite cells (which become closely applied to the ganglionic nerve cell somata), Schwann cells and, possibly, other cells. The neuroblasts, at first round or oval, soon become fusiform, and their extremities gradually elongate into central and peripheral processes. The central processes grow into the neural tube as the fibres of the dorsal nerve roots, while the peripheral processes grow ventrolaterally to mingle with the fibres of the ventral root, thus forming a mixed spinal nerve. As development proceeds, the original bipolar form of the cells in the spinal ganglia changes:

Several families of signalling molecules are known to be instructive guidance cues. The original canonical group of netrins, semaphorins, slits and ephrins has now been amplified by members of three families of developmental morphogens (bone morphogenetic protein (BMP), Hedgehog and Wnt families), and a number of growth factors (hepatocyte growth factor (HGF), fibroblast growth factors (FGFs) and glial cell-derived neurotrophic factor (GDNF)) for subsets of motor axons, e.g. neurotrophins (brain-derived neurotrophic factor (BDNF) and neurotrophin 3 (NT3)) for sensory axons, neuregulins for thalamocortical axons, and vascular endothelial growth factor A (VEGFA) for commissural axons (Omotade et al 2017).

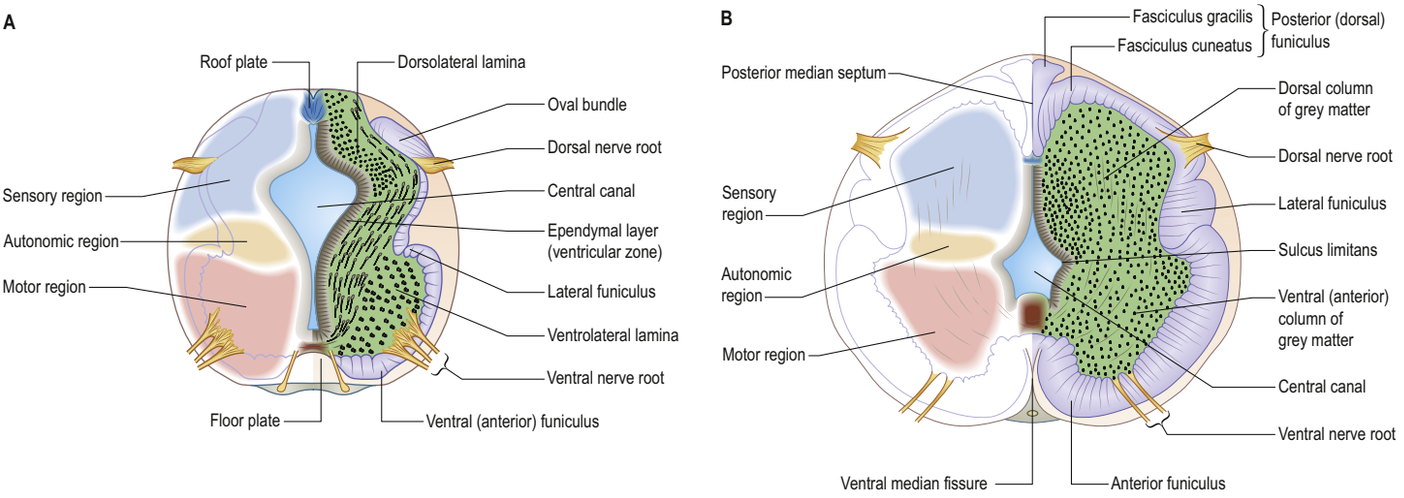

Fig. 14.18 The developing spinal cord, human embryos. Transverse sections. **A**, Approximately stage 17. **B**, Approximately postmenstrual week 12.

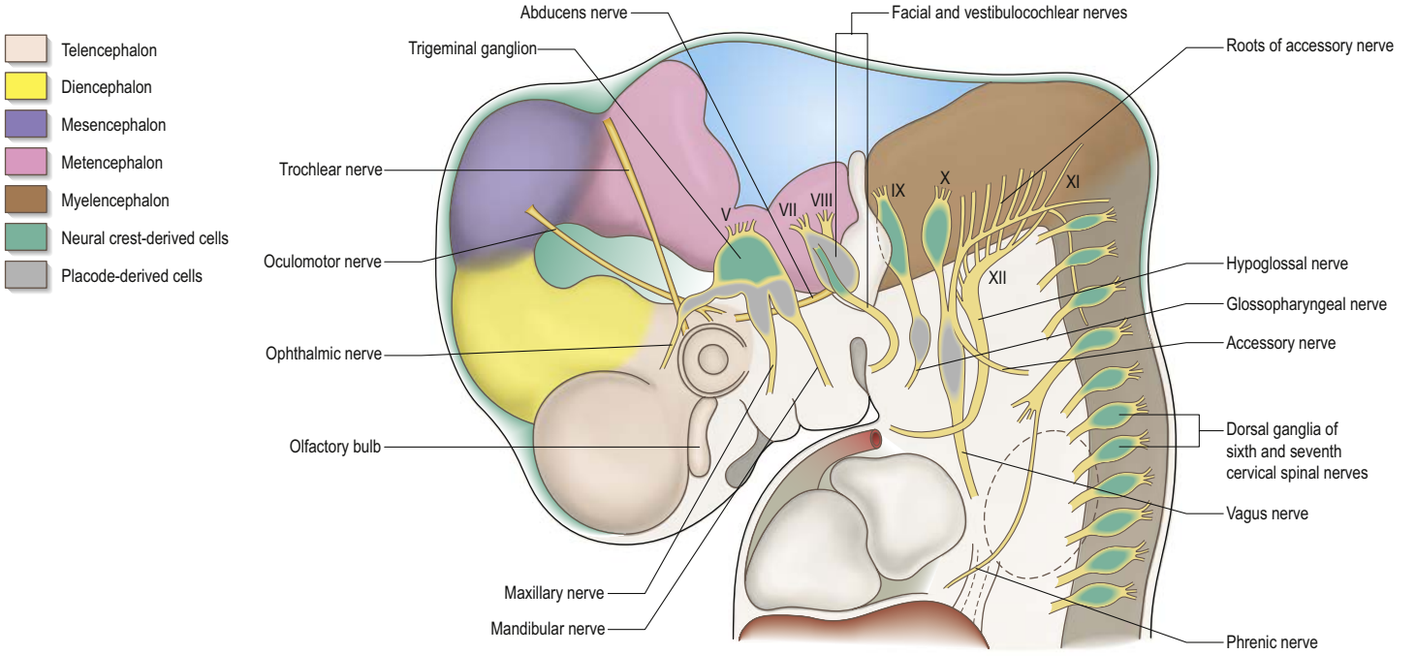

Fig. 14.19 Brain and cranial nerves, human embryo stage 16. Note the derivation of the ganglia associated with the trigeminal, facial, vestibulocochlear, glossopharyngeal, vagus and accessory nerves.

the two processes become closer and ultimately fuse to form a single stem, producing the characteristic morphology of a unipolar neurone. The bipolar form is retained in the ganglion of the vestibulocochlear nerve. For details of the timing of spinal nerve maturation, see Ashwell and Waite (2012).

Cranial nerves

Cranial nerves may contain motor or sensory fibres or both types of fibres. With the exception of the olfactory and optic nerves, cranial nerves develop in a manner that is similar, in some respects, to the development of the components of the spinal nerves. The somata of motor neuroblasts originate within the neuroepithelium, while those of sensory neuroblasts are derived from the neural crest, with the addition in the head of contributions from ectodermal placodes (Fig. 14.19).

The motor fibres of the cranial nerves that project to striated muscle are the axons of cells originating in the basal plate of the midbrain and hindbrain. The functional and morphological distinction between the neurones within these nerves is based on the types of muscle innervated. In the trunk, the motor roots of the spinal nerves all emerge from the spinal cord close to the ventral midline to supply the muscles derived from the somites.

In the head, the motor outflow is traditionally segregated into two pathways (see Figs 14.4B,C, 14.19). General somatic efferent neurones exit ventrally in a similar manner to those of the spinal cord. Thus, the oculomotor, trochlear, abducens and hypoglossal nerves parallel the organization of the somatic motor neurones in the spinal cord. The second motor component, special branchial efferent, consists of the motor components of the trigeminal, facial, glossopharyngeal and vagus nerves that supply the pharyngeal (branchial) arches, and the (spinal) accessory nerve. These nerves all have nerve exit points more dorsally placed than the somatic motor system.

The cranial nerves also contain general visceral efferent (parasympathetic preganglionic) neurones that travel in the oculomotor, facial, glossopharyngeal and vagus nerves and leave the hindbrain via the same exit points as the special branchial efferent fibres. All three categories of motor neurones probably originate from the same region of the basal plate, adjacent to the floor plate. The definitive arrangement of nuclei reflects the differential migration of neuronal somata. It is not known whether all these cell types share a common precursor within the rhombencephalon. In the spinal cord, somatic motor and preganglionic autonomic neurones are linearly related.

Motor neurone types are designated according to the types of muscles or structures they innervate. General somatic efferent nerves supply striated muscle derived from the cranial (occipital) somites and prechordal mesenchyme. Myogenic cells from the ventrolateral edge of the epithelial plate of occipital somites give rise to the intrinsic muscles of the tongue, while the prechordal mesenchyme gives rise to the extraocular muscles. Special branchial efferent nerves supply the

striated muscles developing within the pharyngeal (branchial) arches, which are derived from parachordal mesenchyme rostrocaudally between the occipital somites and the prechordal mesenchyme. All the voluntary muscles of the head originate from axial (prechordal) or paraxial mesenchyme, rendering the distinction between somatic efferent supply and branchial efferent supply somewhat artificial. However, the obviously special nature of the arch musculature, its patterning by the neural crest cells, its particularly rich innervation for both voluntary and reflex activity, and the different origins from the basal plate of the branchial efferent nerves compared to the somatic efferent nerves, make the retention of a distinction between the two of some value.

The cranial sensory ganglia are derived in part from the neural crest and in part from cells of the ectodermal placodes (see Figs 14.8, 14.18). Generally, neurones distal to the brain are derived from placodes while proximal ones are derived from the neural crest (see Fig. 12.4). Supporting cells of all sensory ganglia arise from the neural crest. The most rostral sensory ganglion, the trigeminal, contains both neural crest- and placode-derived neurones that mediate general somatic afferent functions. This is also the case for more caudal cranial nerves (the facial, glossopharyngeal and vagus), but the two cell populations form separate ganglia in the case of each nerve. The proximal series of ganglia is neural crest-derived (forming the proximal root of the facial nerve, the superior ganglion of the glossopharyngeal nerve, the jugular ganglion of the vagus nerve, and associated glial precursors) while the distal series is derived from placodal cells (forming the neurones of the geniculate ganglion of the facial nerve, the petrosal ganglion of the glossopharyngeal nerve and the nodose ganglion of the vagus nerve). These ganglia contain neurones that mediate special and general visceral afferent and somatic afferent functions. The vestibular ganglion contains both crest and placodal cells, and the cochlear ganglion contains only placodal neurones; the axons from these cells are special somatic afferents and they all travel in the vestibulocochlear nerve.

The neurones and supporting cells of the cranial autonomic ganglia in the head and the trunk originate from neural crest cells. Caudal to the vagal ganglion, the occipital region of the neural crest is concerned with the 'ganglia' of the accessory and hypoglossal nerves. Rudimentary ganglion cells may occur along the hypoglossal nerve in the human embryo but they subsequently regress. Ganglion cells are found on the developing intraspinal root of the accessory nerve and are believed to persist in the adult. The central processes of the cells of these various ganglia, where they persist, enter the alar lamina of the hindbrain. Their peripheral processes join the efferent components of the nerve to be distributed to the various tissues innervated. Some incoming fibres from the facial, glossopharyngeal and vagus nerves collect to form an oval bundle, the tractus solitarius, on the lateral aspect of the myelencephalon. This bundle is the homologue of the oval bundle (of His) of the spinal cord, but in the hindbrain it becomes more deeply placed by the overgrowth, folding and subsequent fusion of tissue derived from the rhombic lip on the external aspect of the bundle. For details of the development of sensory and cranial nerve nuclei see Ashwell and Mai (2012).

Myelination of spinal and cranial nerves

PNS myelination, by Schwann cells, occurs over a protracted period that starts during the second trimester. Motor roots start to myelinate before sensory roots in the PNS, whereas sensory nerves start to myelinate before motor nerves. The cranial nerves of the midbrain, pons and medulla oblongata begin to myelinate from about postmenstrual week 22. For reviews of the molecular mechanisms regulating myelination in the CNS and PNS (including precursor specification, proliferation, migration, differentiation and myelination of appropriate axons), see Elbaz and Popko (2017) and Herbert and Monk (2017), respectively.

Autonomic nervous system

Autonomic nerves, apart from the preganglionic motor axons that arise from the CNS, are formed by the neural crest. For the purposes of the following description, the autonomic nervous system encompasses sympathetic and parasympathetic neurones and their accompanying glia in the peripheral ganglia, the chromaffin cells in the suprarenal medulla and other sites, and the neurones and glia of the enteric nervous system. Within the head, the neural crest cells migrate prior to neural fusion, generating autonomic neurones and a vast mesenchymal population. During caudal neurulation in the trunk, neural crest cells migrate from the neural epithelium to lie transitorily on the fused neural tube, they subsequently migrate laterally and then ventrally to their respective destinations (see Fig. 14.6). Four major neural crest cell populations, cranial, vagal, trunk and lumbosacral, are destined to form autonomic nerves.

Parasympathetic ganglia

Parasympathetic preganglionic (general visceral efferent) neurones innervate the sphincter pupillae and ciliaris muscles, the exocrine glands of the head, and the thoracic and abdominal viscera. From rostral to caudal, three populations of neural crest (cranial neural crest, cardiac neural crest and vagal neural crest) give rise to parasympathetic postganglionic neurones.

Neural crest cells from the caudal third of the mesencephalon and the rostral metencephalon migrate along or close to the ophthalmic branch of the trigeminal nerve and give rise to the ciliary ganglion. Cells migrating from the nucleus of the oculomotor nerve may also contribute to the ganglion; a few scattered cells are often demonstrable in postnatal life along the course of this nerve. Preotic myelencephalic neural crest cells give rise to the pterygopalatine ganglion, which may also receive contributions from the ganglia of the trigeminal and facial nerves. The otic and submandibular ganglia are also derived from myelencephalic neural crest and may receive contributions from the glossopharyngeal and facial cranial nerves, respectively (see Fig. 12.4).

Neural crest from the region located between the otic placode and the caudal limit of somite 3 has been termed cardiac neural crest. Cells derived from these levels migrate through pharyngeal arches 3, 4 and 6, where they provide, *inter alia*, support for the embryonic aortic arch arteries, cells of the aorticopulmonary septum and truncus arteriosus. Some of these neural crest cells also differentiate into the neural anlage of the parasympathetic ganglia of the heart.

The origin and migration of the sacral neural crest from the caudal eminence and the formation of the caudal parasympathetic ganglia has recently been disputed, and it has been suggested that the sacral autonomic flow is entirely sympathetic and not parasympathetic (Espinosa-Medina et al 2016, Espinosa-Medina et al 2017, Horn 2018). The distinct vasodilator and vasoconstrictor mechanisms of blood vessels in the pelvic viscera, and the complexities of control of the lower urinary tract, lower enteric sphincters and the reproductive reflexes pathways, plus their central connections to circuits in the spinal cord, brainstem, hypothalamus and cortex, are significant. The precise coordination of activity in these pathways and the distinctive functional discharge patterns that define each type of autonomic pathway inform this continuing discussion (Jänig et al 2018). Sacral postganglionic parasympathetic neurones are generated later than sympathetic neurones from sacral glial progenitor-like cells associated with the extending nerves. The analysis of transcription factors expressed by cranial, thoracolumbar and sacral autonomic neurone precursors suggest that, whereas the developmental processes of thoracolumbar and sacral autonomic neurones are similar, both differ from processes seen in the development of cranial parasympathetic precursors (Ernsberger and Rohrer 2018).

Sympathetic ganglia

Neural crest cells migrate ventrally, penetrate the underlying somites and continue to the region of the future paravertebral and prevertebral plexuses, where they form the sympathetic trunks and the major ganglia around the anterior visceral branches of the abdominal aorta (see Figs 14.6, 14.20). Neural crest cells are induced to differentiate into sympathetic neurones by the dorsal aorta through the actions of the signalling molecules Bmp-4 and Bmp-7. The sympathetic trunk appears earlier in the lower cervical and thoracic regions than in the lumbosacral regions; outflow from the lumbosacral sympathetic trunk to the sciatic nerve has been reported about postmenstrual weeks 18–21 (Ashwell and Waite 2012). In mouse embryos, the superior cervical ganglion may arise from vagal neural crest cells (Hutchins et al 2018).

Chromaffin cells

Chromaffin cells are derived from the neural crest. They are found at numerous sites throughout the body, namely the classic chromaffin cells of the suprarenal medulla, bronchial neuroepithelial cells, dispersed epithelial endocrine cells of the gut (formerly known as argentaffin cells), carotid body cells and the paraganglia. The sympathetic ganglia, suprarenal medulla and chromaffin cells are all derived from the cells of the sympathosuprarenal lineage. In the suprarenal medulla, first seen in stage 14, these cells differentiate into small and intermediate-sized neuroblasts or sympathoblasts, and larger, initially rounded phaeochromocytoblasts. Large cells with pale nuclei, thought to be the progenitors of chromaffin cells, can be detected after stage 23, and clusters of small neurones are evident from postmenstrual week 14.

Sympathetic preganglionic neuronal axons leave the spinal cord with the somatic motor rootlets at motor exit points and travel only in the ventral rootlets: the process is presumably controlled by boundary cap cells. When a postganglionic neuroblast is in place it extends axons and dendrites, and synaptogenesis occurs. The earliest axonal outgrowths from the superior cervical ganglion occur at about stage 14. The local environment plays a major role in controlling the appropriate differentiation of the presumptive autonomic ganglion neurones: the factors responsible for subsequent development of an adrenergic, cholinergic or peptidergic phenotype have not been identified. Cholinergic characteristics are acquired relatively early and the appropriate phenotypic expression may be promoted by cholinergic differentiation factor and ciliary neurotrophic factor.
