CHD affecting the left side of the heart include bicuspid aortic valve, aortic stenosis and complex single ventricular hearts, with the most complex being hypoplastic left heart syndrome, which requires at least three major palliative surgeries and often results in a viable heart albeit with very abnormal anatomy and cardiac pathophysiology. CHD involving the great vessels, and systemic and pulmonary venous anomalies include coarctation of the aorta, various forms of interrupted aortic arch, vascular rings or slings, various forms of transposition of the great arteries, and double outlet right ventricle as well as total anomalous pulmonary venous return. The cardiac pathophysiology and symptoms resulting from these vary but can range from having a minor impact to causing complete alteration of the cardiac physiology. In-depth reading on these various congenital heart disease can be found in this reference (Martini et al., 2012).

Arrhythmias

Arrhythmias can occur as a result of congenital or acquired abnormalities in different ion channels, affecting membrane potential, or defects in the conduction system, such as defects in initiation by pacemaker cells or defects in signal propagation. Arrhythmias range from bradycardia or sinus tachycardia to various levels of heart block and abnormal tachycardia (supraventricular and ventricular tachycardia), and all cause abnormal or uncoordinated contraction.

Arrhythmias have been shown to be secondary to either focal or nonfocal mechanisms. Focal mechanisms include abnormal impulse initiation (normal or abnormal automaticity), triggering from either early or delayed after depolarizations and reflection, whereas the nonfocal mechanisms are various forms of reentry due to circus movement. Examples of automaticity mechanisms of arrhythmias include sinoatrial node dysfunction, enhanced automaticity, overdrive suppression of automaticity, and parasystolic or modulated presystolic activities. Whereas, examples of after depolarization and triggered activities include early after depolarizations and triggered activity, cellular origin of early after depolarizations, ionic mechanisms responsible for early after depolarizations, or delayed after depolarization-induced triggered activity (January et al., 1991; Patterson et al., 2006; Maruyama et al., 2011). The ultimate effect of arrhythmia is poor cardiac output and thus inadequate nutrient and oxygen delivery. Specific mechanisms of arrhythmias will be addressed in later chapters, and many fine comprehensive reviews of the basic mechanisms of cardiac arrhythmia are available (Antzelevitch and Burashnikov, 2011; Tse, 2016; Kanno and Saffitz, 2001; Baruscotti et al., 2005; Cranefield, 1977).

Coronary Heart Disease

The coronary artery system provides oxygen and nutrient-rich blood flow to the metabolically active myocardium and is highly autoregulated (intrinsic ability to maintain blood flow over a wide range of pressures). Coronary heart disease can arise from congenital anomalies, where it is typically diagnosed in childhood, or can be acquired, resulting in narrowing of the coronary arteries, coronary ischemia, and ultimately myocardial infarction. Kawasaki's disease (Newburger et al., 2004), an inflammatory condition thought to be triggered by an autoimmune response, is most commonly seen in children and, left untreated, can lead to coronary aneurysms. Most other acquired coronary heart disease is adult onset.

Although congenital and acquired coronary heart diseases are anatomically different, both result in inadequate blood flow delivered to the region of the myocardium that is affected by the abnormal coronary vasculature. This myocardial injury leads to ventricular dysfunction, arrhythmia, or valve regurgitation depending on the specific areas of the myocardium that is affect. Impaired ventricular function results in a decrease in the ability to generate cardiac output needed to supply nutrients and oxygen to peripheral organs (Mosher et al., 1964).

Congenital coronary anomalies (CCAs) can be isolated but are frequently associated with various forms of CHD. Anatomically and physiologically important CCAs include anomalous left coronary artery arising from the pulmonary artery, resulting in ischemia when the pulmonary vascular resistance drops, decreasing the coronary perfusion pressure. Other CCAs include anomalous origin of the right and left coronary artery from the opposite sinus and can run within the wall of the aorta (intramural) or between the aorta and pulmonary artery (interarterial), myocardial bridge, and, rarely, coronary ostial atresia with collateral flow from the opposite side of the coronary system. The major risk for this group of CCAs is inadequate blood flow delivery to the myocardium that can occur at rest, but worsens with exercise, leading to transient myocardial ischemia, myocardial infarction, or sudden cardiac death. Details of these CCAs, a comprehensive list of all CCAs, and causes and treatment of acquired coronary artery disease can be found in these review articles (Libby and Theroux, 2005; Nabel and Braunwald, 2012; Hauser, 2005; Taylor et al., 1992).

Cardiac Hypertrophy

Normal cardiac development produces an efficient pump that maintains optimal cardiac output and end organ perfusion with minimum wall stress (Grossman et al., 1975). Cardiac hypertrophy occurs as a fundamental process of adaptation to an increased workload due to hemodynamic stress. It can be genetically programmed, as in various forms of hypertrophic cardiomyopathy (Kawano et al., 2016), or it can occur in response to increased hemodynamic load and mechanical stress resulting from arterial hypertension, myocardial infarction, chronic ischemia, inflammation, or valvular disease (Burchfield et al., 2013; Souders et al., 2012; French and Kramer, 2007). The type of hypertrophic remodeling depends on the trigger and concomitant progression of contractile dysfunction. Concentric hypertrophy, in which ventricular walls thicken to reduce capacity, is a common response to increased afterload (such as occurring with valve stenosis or hypertensive heart disease), whereas eccentric hypertrophy, in which the internal diameter of the ventricular wall increases, is often observed in conditions of LV volume overload (such as occurring with valve regurgitation or shunt) (Pfeffer and Braunwald, 1990; Dorn et al., 2003; Kupari et al., 2005; Burchfield et al., 2013). In concentric hypertrophy, sarcomeres are added in parallel to increase wall thickness; in eccentric hypertrophy, sarcomeres are added in series to increase wall diameter. Though cardiac hypertrophy may initially be beneficial (compensatory to maintain cardiac output), as it augments the number of contractile units and reduces ventricular wall stress (Grossman et al., 1975), over time the increased metabolic demand ultimately leads to decompensation with resultant heart failure, associated arrhythmia, and risk of sudden cardiac death (Krishnamoorthy et al., 2011; Pellikka et al., 2005; Haider et al., 1998; Wassilew et al., 2016; Henderson and Anderson, 2009).

The increased mechanical stress in the heart caused by cardiac hypertrophy leads to alterations in cellular signaling and gene expression. In early cardiac hypertrophy, there is a rapid induction of protooncogenes (including c-fos, c-jun, and c-myc) and heat shock proteins (including hsp70) (Kee et al., 2008; Simpson, 1989; Brand et al., 1993). This is followed by both quantitative and qualitative modulation in gene expression and protein synthesis that induce hypertrophy (Komuro et al., 1988; Izumo et al., 1988). Hypertrophy-promoting hormonal factors that are either locally or systemically induced include angiotensin II, endothelin-1, and transforming growth factor-β (van Wamel et al., 2001). Intracellular signaling pathways in cardiomyocytes are activated by mechanical stress via activation of cell surface integrins and their associated cytoskeletal proteins, as well as by interaction with sarcolemmal proteins such as ion channels, ion exchangers, and phospholipases. Mechanical stress also decreases expression of key cardiomyocyte membrane proteins such as SERCA (Anger et al., 1998; Nagai et al., 1989). Subsequent increases in intracellular calcium concentration activate the calcium and calmodulin-dependent phosphatase calcineurin, which is a novel hypertrophic signaling pathway. Interestingly, expression of other key sarcomeric proteins is altered to more fetal, or dedifferentiated, forms, including a switch from cardiac α-actin to skeletal α-actin, and a switch from the α-form of myosin heavy chain to the β-form (Schwartz et al., 1986). It is important to note that many of the mechanisms of cardiac hypertrophy described earlier and in the literature have been observed in cell culture and/or animal models, and it remains uncertain if these same mechanisms lead to cardiac hypertrophy in humans (Maron et al., 2006; Elliott et al., 2008; Sedmera and McQuinn, 2008).

Heart Failure

All of the above-described cardiac pathophysiological states, if left untreated, will lead to heart failure (HF). Thus HF can result from increased hemodynamic overload, ischemia-related dysfunction, ventricular remodeling, excessive neurohormonal stimulation, abnormal myocyte calcium cycling, excessive or inadequate proliferation of the extracellular matrix, accelerated apoptosis, and/or genetic mutations (Dassanayaka and Jones, 2015; Efimov et al., 2010). HF is defined as the inability of the heart to meet the demands of the body due to insufficient force to pump enough blood (systolic heart failure), the inability fill with sufficient blood volume (diastolic heart failure), or a combination of both. Diastolic and systolic HF are highly complex diseases, and both are major contributors to morbidity and mortality. HF can also be classified as predominantly left ventricular, right ventricular, or biventricular and can be chronic or acute depending on the time of onset (Marti et al., 2013). The New York Heart Association's functional classification system, based on activity limitations, is often used by physicians in patient diagnosis and treatment (Guyatt, 1993; Kubo et al., 2004).

Systolic HF is further classified based on ejection fraction and is categorized as either heart failure with preserved ejection fraction (HFpEF) or heart failure with reduced ejection fraction (HFrEF) (Dassanayaka and Jones, 2015; Paulus and Tschope, 2013; Zamani et al., 2015; Maeder et al., 2010). Systolic HF can also be categorized based on cardiac output and is classified as either low-output failure (most common, with a resting cardiac index of 2.5 L/min/m (Moore et al., 2014) and elevated systemic vascular resistance) or high-output failure (resting cardiac index greater than 2.5 L/min/m (Moore et al., 2014) and lowered systemic vascular resistance). In low-output HF there is insufficient cardiac output to meet the body's demand, which worsens during times of increased metabolic demand. Common causes of high-output HF includes severe anemia, vascular shunting, hyperthyroidism, and vitamin B1 deficiency, and high output HF is frequently associated with ventricular dilation.

Diastolic HF, a common form of HFpEF, has increasing prevalence with age, and it has very complex mechanisms and heterogeneous pathophysiology (Basaraba and Barry, 2015; Andersson and Vasan, 2014; Yancy et al., 2013; Kitzman and Upadhya, 2014). Although the major pathology is diastolic dysfunction with impaired ventricular filling, other factors including abnormal ventricular–arterial coupling, systolic dysfunction, pulmonary hypertension, neuroendocrine dysfunction, and chronotropic incompetence contribute to diastolic HF. Diastolic failure is typically seen in patients with hypertensive or valvular heart disease, or with hypertrophic or restrictive cardiomyopathy, but it can also occur in a variety of clinical other disorders. Early recognition and appropriate therapy of diastolic dysfunction may prevent further progression to diastolic HF and death. Identification of diastolic HF requires evidence of signs or symptoms of HF, normal to slightly reduce left ventricular ejection fraction, and evidence of increased diastolic filling pressure. There are limited treatment options, the most important of which is treatment of the underlying disease (Kitzman and Upadhya, 2014).

Summary and Conclusions

The integration of the normal structure–function relationships in the heart is complex, and our understanding of these relationships is continuously evolving. New discoveries through research and clinical practice ultimately guide the best clinical management of these diseases of the heart. The chapters that follow will provide an in-depth glimpse into these new cutting-edge areas of cardiovascular research and medicine, and they will provide further understanding and fodder for debate on the best methods to study and manage cardiovascular diseases.

Introduction

The past ~20 years have been an exciting time for stem cell research and regenerative medicine. The heart long believed to be terminally differentiated organ was discovered to regenerate continuously throughout adult life, albeit at a slow pace (Beltrami et al., 2001; Bergmann et al., 2009, 2015). This paradigm shift led to the discovery and isolation of several populations of cells with stem- and progenitor-like properties, including self-renewal, clonogenicity, and multipotentiality in vitro and in vivo from the adult mammalian heart (Chong et al., 2014). Many of these cells, including KIT^+ cardiac stem cells (Beltrami et al., 2003), $SCA1^+$ cells, Islet-1^+ cells, stage-specific embryonic antigen (SSEA)-1^+, and epicardial progenitors, are identified based on the expression of unique cell surface markers and/or transcription factors, whereas others, such as resident cardiac mesenchymal stem cells (MSCs), side population cells, and cardiospheres, are identified on the basis of specific in-vitro physical properties, such as the ability to form spheres or colony-forming units (Bernal and Galvez, 2013; Faiella and Atoui, 2016; Bollini et al., 2011). Typically, stem cells reside in niches where they are structurally connected to the supporting cells by gap and adherens junctions. The niche constitutes the microenvironment within which stem cells retain their undifferentiated state and receive growth signals from the supporting cells.

Cardiac Stem Cells (CSCs)

KIT Cardiac stem cells (CSCs) have been described in multiple species ranging from rodents to large animals to humans and are likely heterogeneous in nature (Hatzistergos and Hare, 2016). As endogenous resident cells, CSCs are a promising target for additional therapy after cardiomyocyte loss in both the acute and chronic phases of ischemic cardiac disease. Considerable effort has been made to identify specific markers of those stem cells with cardiomyogenic potential. Among the various markers employed to identify resident CSCs, KIT (CD117) has played a prominent role (Torella et al., 2006). KIT (previously known as c-KIT) was first identified in the 1980s as a protooncogene in mammalian cells (Yarden et al., 1987). In 2003, a landmark study showed that KIT identifies rare cardiac-resident adult stem cells, thereby establishing adult cardiac stem cell biology as a field of investigation (Beltrami et al., 2003).

Heterogeneous KIT^+ cardiac cells, some positive for the cardiomyocyte progenitor markers Nkx2-5, GATA4, and Mef2c but negative for hematopoietic lineage markers (LIN^-), are clonogenic, self-renewing, and able to differentiate into cardiomyocytes, smooth muscle cells, and endothelial cells in vitro and are sufficient to stimulate myocardial regeneration following cardiac injury in rats and mice (Ellison et al., 2013). These findings provided the missing link between the identification of small dividing myocytes and the origin of these repopulating cells, laying the ground work for introducing KIT^+ CSCs for treatment of the failing heart. However, analyses of KIT expression during mouse development show that only a small proportion of cardiomyocytes are derived from KIT^+ cardiac progenitor cells (Hatzistergos et al., 2015; van Berlo et al., 2014). These cardiomyocytes form KIT^+ cardiac neural crest cells, an origin that may partly explain their limited prevalence and contribution to the myocardial lineage (Hatzistergos et al., 2015). In contrast, the more prevalent KIT^+ cardiac cells form vascular components and likely originate in the cardiogenic

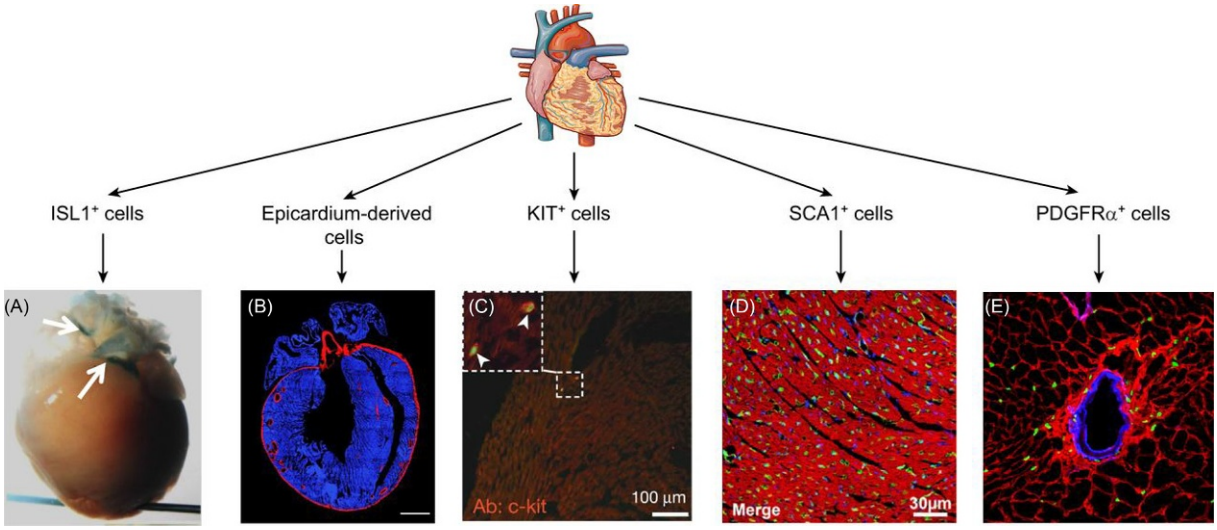

Fig. 1 Stem cell populations in the adult heart. Numerous stem cell populations have been described in the adult heart, many of which are depicted here. (A) A heart from a mouse with an *Isl1*-nuclear *lacZ* knock-in allele. β-Galactosidase stained (*blue*) ISL1$^+$ cells are rare and present in the adult heart only in the conduction system including the sinoatrial node (*arrows*). (B) The epicardium (red perimeter, Note: coronary vessels within the myocardium also stain red) gives rise to perivascular cells and stromal fibroblasts in development, and in the adult this potential is retained, and is activated after injury. Nuclei of cardiac cells are stained with DAPI (*blue*). Scale bar: 500 μm (C) KIT$^+$ cells in the adult mouse heart shown by expression of a *Kit*-Cre allele (*green*) and staining for the endogenous KIT protein (*red*). Inset: two mononuclear KIT-expressing cells (*arrowheads*) (D) SCA1$^+$ cells within the interstitium of the adult heart, marked by GFP (*green*), phalloidin (*red*) showing cardiomyocytes, and DAPI (*blue*) stains nuclei. (E) A heart from a mouse containing a Pdgfra knock-in allele. PDGFRα-expressing cells are present throughout the cardiomyocyte interstitium and within the adventitial zone of coronary arteries. collagen VI (*red*) and smooth muscle cells positive for α-smooth muscle actin (*blue*). Original figure reproduced with permission from Santini et al., 2016.

mesoderm (Hatzistergos and Hare, 2016; Hatzistergos et al., 2015, 2016; Sultana et al., 2015). Despite this skewed developmental origin transplantation of culture-expanded KIT$^+$ CSCs promotes their multilineage differentiation into cardiomyocytes, endothelial and smooth muscle cells in vivo, providing a potentially important cell-based therapeutic strategy for promoting heart regeneration in patients with heart disease (Anversa et al., 2013; Bearzi et al., 2007; Beltrami et al., 2003; Bolli et al., 2011).

These findings led to the SCIPIO trial, the first Phase I clinical trial of KIT$^+$ CSCs in patients with ischemic heart disease (www.clinicaltrials.gov, NCT00474461). In this trial 1 million autologous KIT$^+$ CSCs were administered via intracoronary infusion into patients with ischemic heart failure that were undergoing coronary artery bypass graft (CABG). The 1-year follow-up results from the SCIPIO trial showed that this therapy is safe and feasible and promotes significant improvements in global and regional LV function, decreases scar size, and induces regeneration of viable myocardium (Chugh et al., 2012). Despite their apparent therapeutic utility, there are caveats with respect to the KIT$^+$ cells; they are very rare within the resident myocardium, and their cardiomyocyte derivatives are relatively immature in terms of ultrastructure and Ca^{2+} handling (Bollini et al., 2011).

In addition to KIT$^+$ cells, SCA1$^+$ cells, Islet-1$^+$ cells, the specific side population (SP) cells, cardiospheres (CSs), and cardiosphere-derived cells (CDCs), stage-specific embryonic antigen-1 (SSEA-1$^+$) and epicardial progenitors have been isolated from the heart (**Fig. 1**) (Hierlihy et al., 2002; Messina et al., 2004; Leite et al., 2015; Bollini et al., 2011). This surprisingly high number of CSC subtypes stands in stark contrast with the properties of all other self-renewing organs, in which a single tissue-specific adult stem cell is normally seen (Santini et al., 2016). CSCs promise much in the way of regenerative potential; however, several questions remain unanswered relating to their origin, cell surface markers, degree of overlap of the various subpopulations, and the processes underlying in vivo homeostasis.

CSC Subtypes

SCA1

SCA1 (also known as LY6A) is a cell surface protein often used to identify or enrich for hematopoietic stem cells (Holmes and Stanford, 2007) and is upregulated in a variety of murine cancer stem cells. SCA1 is a convenient marker for stem cell studies because it is expressed in most stem/progenitor cells in a variety of tissues, including the mammary gland (Welm et al., 2002), prostate (Xin et al., 2005), dermis (Toma et al., 2005), skeletal muscle (Gussoni et al., 1999), heart (Rosenblatt-Velin et al., 2005), and liver (Wulf et al., 2003). However, in all cases, it is unclear if the SCA1$^+$ populations are tissue-specific precursor/stem cells or are the hematopoietic, mesenchymal, or endothelial precursor/stem cells associated with these tissues (Holmes and Stanford, 2007).

In the heart, SCA1$^+$ cells are highly heterogeneous and include microvascular endothelial cells, KIT$^+$ progenitor cells, PDGFRα$^+$ cardiac colony-forming units-fibroblast (cCFU-F) and stromal cells, as well other interstitial and perivascular cells. The SCA1$^+$

fraction expresses the cardiac transcription factors GATA4 and Mef2c but lacks other cardiomyocyte lineage markers including Nkx2-5 (Oh et al., 2003). In fact, SCA1$^+$ cells have cardiogenic and vascular differentiation potential (Matsuura et al., 2004; Hsueh et al., 2014) although the multilineage potential of their single-cell progeny is uncertain.

Isl1

The LIM-homeodomain transcription factor, Isl1, binds and controls cis-regulatory elements of the insulin gene (Karlsson et al., 1990). Isl1 is expressed in cardiac neural crest cells and mesodermal progenitors of the second heart field (SHF). Upon differentiation, Isl1 expression is downregulated, suggesting that this transcription factor defines a cardiogenic progenitor cell population (Peng et al., 2013; Prall et al., 2007; Cai et al., 2003). Isl1 cells isolated and expanded from embryonic and postnatal hearts, differentiate into cardiomyocytes, endothelial cells, and smooth muscle cells, among others (Bu et al., 2009; Domian et al., 2009; Moretti et al., 2006; Laugwitz et al., 2005). Hearts of mice lacking Isl1 display severe cardiac defects, including complete absence of the outflow tract and right ventricle and partial loss of the atria. Although Isl1$^+$ CSCs may represent a very attractive source of endogenous cardiac progenitors, their clinical applicability in the adult patient is limited, since the Isl1$^+$ progenitor population rapidly declines after birth. Therefore, the therapeutic potential of Isl1$^+$ cells may depend on the ability to isolate and expand them in vitro or to derive them from human embryonic stem (ES) or induced Pluripotent Stem (iPS) cells prior to cell transplantation.

Side population cells

Side population (SP) cells were first described by Hierlihy et al. and are characterized by their ability to promote the efflux of metabolic markers, such as Hoechst dye, via the Abcg2 protein on their cell surface (Hierlihy et al., 2002). The Abcg2 protein belongs to the family of transporters linked to the ATP cassette (ABC transporters), which early during cardiac development endows these cells with their characteristic phenotype (Di Felice et al., 2009). Under pathological conditions, human *Abcg2* mRNA levels increase, suggesting the possibility of the activation and proliferation of SP cells in response to cardiac disease in an attempt to promote repair (Smith et al., 2008). Increased numbers of Abcg2$^+$ cells have also been detected in the marginal zone of acute infarcted myocardium (Barile et al., 2007). Despite the apparent cardiovascular lineage potential of these populations, there is no definitive proof that cardiac SP cells represent a bona fide stem cell population as defined by clonogenic and self-renewal properties.

Cardiospheres

Cardiospheres (CSs) are outgrowth cells derived from cultured cardiac explants that grow as self-adherent clusters in vitro (Messina et al., 2004). To obtain sufficient numbers of CSs for therapeutic purpose, they can also be cultured and expanded as a monolayer of Cardiosphere-Derived Cells (CDCs) over many passages (Messina et al., 2004). CSs are clonogenic, express stem and endothelial progenitor cell markers, such as KIT, SCA1, CD31, CD34, Nanog, and SOX2, and spontaneously differentiate into cardiomyocytes and vascular cells (Messina et al., 2004; Li et al., 2010). Murine CSs injected into ischemic murine hearts can differentiate into vascular cells and cardiomyocytes (Messina et al., 2004), and CSs derived from the injured myocardium of mice can differentiate into cardiac cells in vivo (Ye et al., 2012). Porcine and human CDCs can also differentiate into endothelial cells and cardiomyocytes in vitro and in vivo (Smith et al., 2007). Together, CSs and CDCs could represent a useful source of CSCs, as they can be easily isolated from a small amount of starting material and can be greatly expanded, without losing differentiation potential. However, a recent report investigating stem cell surface markers showed that CDCs are CD105$^+$ stromal cells of intrinsic cardiac origin that include a variable fraction of CD90 (Thy-1)$^+$ cells and a small minority of KIT$^+$ cardiac progenitors (Cheng et al., 2014). Thus, the majority population is negative for both CD90 and KIT and positive for CD105, suggesting that they are mesenchymal stem cells (MSCs), but their active principle is, as yet, undefined. A clinical trial in which CDCs were transplanted into infarcted areas revealed that the KIT$^+$ cells in cardiospheres are not an important determinant of the therapeutic efficacy of CDCs, whereas their CD90$^+$ cells appear to undermine the overall benefit of CDC therapy (Cheng et al., 2014).

SSEA-1

An SSEA-1$^+$ (stage-specific embryonic antigen-1$^+$) cardiac stem cell population was recently isolated from neonatal and adult rat heart (Bollini et al., 2011). These cells resemble an immature pool of embryonic progenitors and give rise to both myocardial and endocardial cells during normal cardiac development. Pluripotent stem cell-derived SSEA-1$^+$ cells express mesodermal and cardiac lineage marker genes and freshly sorted SSEA-1$^+$ cells expressed brachyury and Flk1, two genes characteristic of early mesoderm (Blin et al., 2010). Furthermore, these cells expressed mesoderm posterior 1 (Mesp1) (Bondue et al., 2008); Tbx6, a mesodermal muscle gene upstream of Mesp1 (Christiaen et al., 2009); Tbx5, a ventricular marker; and Tbx18, a marker of both epicardium (Cai et al., 2008) and the left ventricle (Franco et al., 2006). SSEA-1$^+$ cells also express myocardin (MYOCD), GATA4, Mef2c, and Nkx2-5, key smooth muscle, and cardiac transcription factors of the FHF, as well as Isl1 and Tbx20, the latter more reminiscent of the SHF. A minority of SSEA-1$^+$ population also express Nestin (NES) or PAX3, 2 markers found in neural crest cells (Blin et al., 2010). Under controlled in vitro conditions, SSEA-1$^+$ cells demonstrate cardiomyogenic differentiation potential, forming beating colonies and, when transplanted into an infarcted rat heart, promoting SSEA-1$^+$ myocardial regeneration and functional improvement. It has been suggested that SSEA-1$^+$ CSCs represent a population of embryonic-like primitive cardiac stem cells that can give rise to more committed KIT$^+$, Sca-1$^+$, Abcg2$^+$ cells at later stages of differentiation (Bollini et al., 2011; Ott et al., 2007). These results suggest SSEA-1$^+$ progenitors as candidates for use in cardiac regenerative medicine.

Epicardial cells

Epicardium-derived cells (EPDCs) are a cell population with the potential to restore the myocardium and coronary vasculature. An archetypal example of the paradigm of recapitulating embryonic roles for therapeutic application, the epicardium, and its derivatives play an essential role in the formation of the coronary myocardium and vasculature during development and retain a regenerative potential in the adult (Bollini et al., 2014). The epicardium is derived from the outgrowth of cells from the proepicardial organ, a transient embryonic structure, to overlie the developing heart tube. EPDCs are marked by the transcription factors Wilms tumor 1 (Wt1) (Zhou et al., 2008) and/or Tbx18 (Cai et al., 2008) and can differentiate into smooth muscle, and endothelial cells in all four heart chambers. A rare population of KIT^{+} (Limana et al., 2007) stem cells that express a marker profile identical to those previously described in the myocardium can also be found in the adult human and mouse epicardium. Embryonic EPDCs possess extensive migratory capacities upon stimulation by paracrine factors from the underlying myocardium (Munoz-Chapuli et al., 2002). However, the adult epicardium lies quiescent and requires stimulation by those factors that promote coronary vasculogenesis during development. One such stimulatory factor, Thymosin β4 (Tβ4), restores the quiescent adult epicardium to its pluripotent embryonic state. Tβ4 treatment of infarcted hearts induces significant EPDC proliferation and the formation of a network of perfused, functional vessels that enhance blood flow to the ischemic myocardium. Moreover, Tβ4 facilitates an epicardial contribution of mature de novo cardiomyocytes, structurally and functionally coupled to resident myocardium, which may contribute to the functional improvement of Tβ4-treated hearts post-MI (Smart et al., 2013). Other factors with proven potency in stimulating adult EPDCs are emerging. Activation of the prokineticin receptor (PKR1) results in secretion of its ligand, PK2, by cardiomyocytes. In transgenic mice overexpressing PRK1, PK2 acts on EPDCs, augmenting their proliferation, which subsequently induces neovascularization (Urayama et al., 2008). High-molecular-weight hyaluronan stimulates migration and differentiation of epicardial cells in vitro (Craig et al., 2010). Whether either of these stimuli can be translated into the adult heart for activation of EPDCs remains to be investigated.

Conclusions

Considering these main cell populations, ongoing research is assessing which types of cells are the best candidates for cardiac cell therapy. It is also possible that combining two or more types of stem cells would have additive or synergistic benefits. Studies combining KIT+ CSCs with MSCs indicate that the combination of these two cell types produces greater therapeutic effects than a single cell type in swine models of ischemic cardiomyopathy (Karantalis et al., 2015; Natsumeda et al., 2016; Williams et al., 2013). Based on these combinatorial stem cell approaches, the "Combination of Mesenchymal and C-kit+Cardiac Stem Cells as Regenerative Therapy for Heart Failure" (CONCERT-HF, NCT02501811) trial was recently initiated. The goal of this clinical trial is to assess if administering a combination of autologous CSCs and MSCs improves cardiac structure and function in patients with chronic ischemic cardiomyopathy.

Currently, the extensive cardiac damage resulting from ischemic cardiomyopathy cannot be completely reversed by stem cell therapy, i.e., the regenerative potential of stem cells in damaged tissues is limited (Hatzistergos et al., 2010). Moreover, after a decade of intense research in the field of cardiac cell therapy, there seem to be more questions than answers. Future basic, translational, and clinical research is certainly needed to advance this field further and lead to the development of novel clinical treatments for patients with cardiac failure.

Pluripotent Stem Cells

Introduction

Pluripotent cells can give rise to all cell types, except extraembryonic cells (those that make up placental tissue and extra embryonic membranes) (Ameen et al., 2008; Smith, 2001). The bona fide pluripotent stem cell is the embryonic stem (ES) cell. ES cells are derived from mammalian blastocysts and have the ability to differentiate into cells of all three germ layers (ectoderm, endoderm, and mesoderm). ES cells exhibit robust and infinite growth (self-renewal) while maintaining their normal karyotype. Over the last ~10 years, the advent of induced pluripotent stem cell (iPSC) technology has revolutionized the fields of regenerative medicine, disease modeling, drug discovery/screening, and toxicological testing. In spite of these exciting innovations, there are still major challenges associated with the widespread use of iPSC technology including improving reprogramming efficiency, minimizing genetic and epigenetic instability, and reducing the high costs associated with iPSCs derivatives for high-throughput screening (HTS) applications. There are also problems shared by both ES and iPS cells, including reducing their propensity for tumor formation in vivo and driving maturity of ES- and iPS-derived cells to a more adult phenotype, e.g., iPSC-derived cells such as cardiomyocytes (iPSC-CMs), in terms of structure, calcium cycling, and electrophysiology. iPSCs have yet to enter the clinic for heart-related diseases.

Embryonic Stem Cells

ES cells were first established from mice in 1981 (Evans and Kaufman, 1981), and from humans in 1998 (Thomson et al., 1998). The successful derivation of human ES cell lines extended their great potential to the study of human diseases and allowed us to envisage the future prospect of regenerative medicine. However, there are ethical implications associated with these cells. They are

derived from the inner cell mass of in vitro-fertilized human embryos. Since these embryos could in theory develop into a person, the destruction of these embryos to obtain the cells is, for some, controversial and remains far from settled. Important developments have helped reduce much of the heated debate over ES cell research, in particular the advent of induced pluripotent stem cell (iPSC) technology—fibroblasts (or other somatic cells) genetically engineered to behave like ES cells (Shi et al., 2017).

Induced Pluripotent Stem Cells (iPSCs)

iPSCs hold great promise for cardiac cell therapy (Yoshida and Yamanaka, 2010). Recently, preclinical studies using a variety of cell preparations, including undifferentiated iPSCs, iPSC-derived cardiac progenitors, cardiomyocytes, smooth muscle cells, and endothelial cells, have shown evidence of cardiac repair (Ahmed et al., 2011; Dai et al., 2011; Kawamura et al., 2012; Xiong et al., 2013; Shinozawa et al., 2017; Menasche et al., 2015). The progress in the iPSC field has clearly demonstrated that cellular reprogramming to pluripotency is a fast-evolving technology with great promise for clinical application.

iPSCs are ES-like cells that have been reprogrammed from somatic cells (Mikkelsen et al., 2008; Chin et al., 2010; Guenther et al., 2010). Takahashi and Yamanaka, in 2006, devised an elegant screen for transcription regulator factors within a pool of 24 pluripotency-associated candidate genes that when coexpressed from retroviral vectors in mouse embryonic fibroblasts (MEFs) could activate *Fbxo15*-β-geo (a fusion of the β-galactosidase and neomycin resistance genes) and induce the formation of drug-resistant colonies with characteristic ES cell morphology. None of those factors alone supported cell survival in the presence of antibiotic; however, 22 colonies were formed in the wells that were transduced with all 24 genes. And all these colonies exhibited an ES cell morphology rather than that of the MEFs from which they originated. Next, the authors narrowed down the pool of 24 candidates to a set of reprogramming factors subsequently by identifying the minimally required core set of four genes, comprising octamer-binding protein 3/4 (OCT3/4), SRY-box containing gene 2 (SOX2), Krüppel-like factor 4 (KLF4) and c-MYC, collectively referred to as OSKM factors. The cells reprogrammed by OSKM factors exhibited ES cell-like properties. The resultant cells generated by selection for *Fbxo15* activation, expressed markers of pluripotent stem cells, such as SSEA-1 and Nanog, developed teratomas when injected subcutaneously into immune compromised mice, and contributed to different tissues of developing embryos upon blastocyst injection (Takahashi and Yamanaka, 2006), thereby fulfilling some of the criteria of pluripotency. iPSCs have since been derived from different species—including humans (Takahashi et al., 2007; Yu et al., 2007; Park et al., 2008), mouse (Okita et al., 2007), rats (Li et al., 2009), pig (Wu et al., 2009), and rhesus monkeys (Liu et al., 2008)—by expression of the OSKM factors, demonstrating that fundamental features of the transcriptional network governing pluripotency remain conserved during evolution. These studies opened a new field of stem cell research. The Nobel Prize committee awarded Shinya Yamanaka and Sir John Gurdon the Nobel prize in Physiology or Medicine in 2012 "for the discovery that mature cells can be reprogrammed to become pluripotent."

Advances in iPSC generation

Although successful reprogramming occurred, these "first-generation" iPSCs expressed lower levels of several key pluripotency genes compared with ES cells and appeared to be only partially reprogrammed. Therefore, several laboratories, including Yamanaka's (Okita et al., 2007), attempted to improve the efficiency and quality of iPSC generation. For example, by selecting for the reactivation of the essential pluripotency genes Nanog or Oct4 instead of *Fbxo15*, iPSCs were generated that more closely resemble ES cells molecularly and functionally (Okita et al., 2007; Maherali et al., 2007; Wernig et al., 2007). Furthermore, iPSCs were generated by using only three transcription factors (OCT3/4, KLF4, SOX2, without c-MYC) (Nakagawa et al., 2008). Other methods, including integrating and nonintegrating recombinant viruses (Kaji et al., 2009; Stadtfeld et al., 2008; Zhou and Freed, 2009; Schlaeger et al., 2015), DNA expression vectors (Okita et al., 2008), episomal vectors (Okita et al., 2011), mini-circle vectors (Jia et al., 2010), and liposomal magnetofection (Park et al., 2012) have facilitated the generation of iPSCs. Non-DNA methods involving proteins (Zhou et al., 2009), mRNA molecules (Warren et al., 2010), and various chemical agents (Hou et al., 2013) have also been tested, and a chemical method that produces iPSCs appears to be promising (Hou et al., 2013). iPSCs can be generated in the presence of small molecules (e.g., ascorbic acid and CHIR-99021 and PD-0325901), which may improve reprogramming efficiency (Lin and Wu 2015). A recent report showed that efficiency in iPSC reprogramming can be significantly improved in a microfluidic environment where microliter-volume confinement resulted in a 50-fold increase in efficiency over traditional reprogramming by delivery of synthetic mRNAs encoding transcription factors (TFs) (Luni et al., 2016). High quality and pure human (h)iPSCs were obtained in 2 weeks from initial reprogramming and subsequently differentiated into functional hepatocyte- and cardiomyocyte-like cells in the same platform without additional expansion (Luni et al., 2016). Thus, the microfluidic platform promotes a highly efficient and fast iPSC reprogramming while consistently reducing the required culture media and reagents, ultimately significantly lowering the overall costs. Thus, this technology can provide the opportunity for the affordable generation of high numbers of hiPSCs from a large cohort of patients in an accelerated time frame. More comprehensive knowledge of the reprogramming process is therefore crucial for future clinical applications of iPSCs.

iPSC-derived cardiomyocytes

During gastrulation, cardiomyocytes emerge from the mesodermal layer, in particular from the anterior region of the primitive streak. The balance between inductive signals, mainly fibroblast growth factors (FGFs) and bone morphogenetic proteins (BMPs), members of the transforming growth factor (TGF)β superfamily, and repressive signals, mostly Wingless/INT proteins (WNTs) and ß-catenin, induce the development of cardiac progenitors (Brade et al., 2013; Abu-Issa and Kirby, 2007). Following the

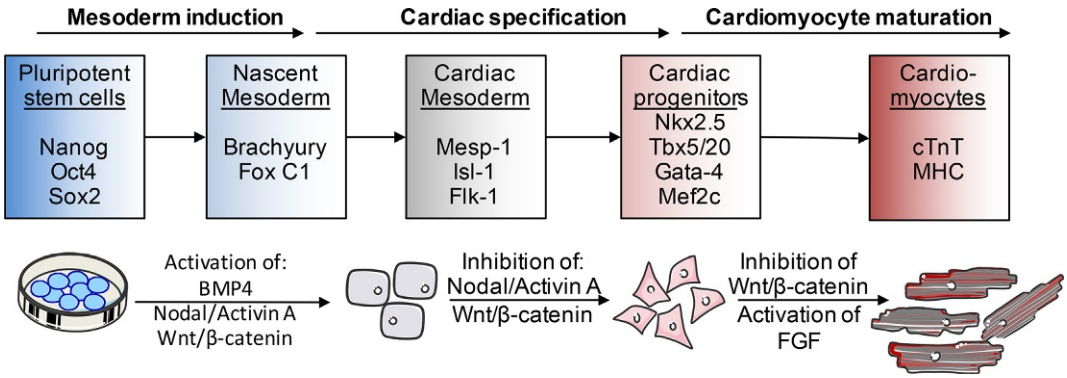

Fig. 2 Sequential stages to obtain cardiomyocytes from pluripotent stem cells. Pluripotent stem cells, differentiate into early mesoderm and subsequently into cardiac mesoderm, committed cardiac progenitors and ultimately into functional beating cardiomyocytes. Transcription factors present at each step are indicated and can be used to monitor the progression of differentiation. The activation or inhibition of biomolecules (growth factors and small molecules) play important regulatory roles in pluripotent stem cell expansion and their differentiation into cardiomyocytes. The figure was composed of original images and images obtained from the Servier Medical Art image bank (www.servier.com/Powerpoint-image-bank).

migration of these cells to the cardiac crescent, the primitive beating heart tube is formed, composed of synchronously beating small myocytes. The contractile impulse begins within the primary pacemaker area in the primitive atrium that will later evolve into the sino-atrial node, where the fast-beating pacemaker myocytes will reside. As development proceeds, CMs in different anatomical regions of the hearts, comprising atria and ventricles, will be generated and linked by the conduction system that includes the sinus node, the internodal pathways, the atrioventricular (AV) node, the AV bundles, and Purkinje fibers (Brade et al., 2013; Barbuti et al., 2016).

Recapitulating natural physiological signaling pathways under in vitro differentiation into cardiac cells is the main concept behind the generation of iPSC-CMs, including the activation or inhibition of signaling pathways. This procedure is dependent on the use of WNT, FGF, and acitvin A, as described earlier. The cardiomyocytes derived from ES/iPS cells consist of several subtypes of cardiomyocytes, including atrial, sinus nodal, and ventricular cardiomyocytes. Under laboratory conditions, the differentiation iPSC-CMs is mostly triggered by the formation of embryoid bodies using the in vitro hanging drop method, monolayer cultures, and inductive cocultures with endoderm-like cells (END2) (Pekkanen-Mattila et al., 2011). Stage-specific markers that mimic developmental processes in embryos have been identified, including mesoderm cells (brachyury), cardiac mesoderm (Mesp1, Flk1, and Isl-1), cardiac progenitors (Nkx2-5, GATA4), and cardiomyocytes (myosin heavy chains). The differentiation of cardiomyocytes with growth factors such as Activin A/Nodal, Bmp4, Cerberus, Wnt3a, and Wnt11 is under investigation (Skalova et al., 2015) (Fig. 2). Although the progress with differentiation protocols has been striking, a closer examination of the resulting cell populations reveals that significant cellular heterogeneity (ventricular-like, atrial-like, and nodal-like cardiomyocytes) and nondifferentiated cells remain, which could adversely affect clinical outcomes. Other hurdles remain in realizing iPSC applications in human heart regeneration, including (a) large-scale cultivation systems required to obtain the billions of required differentiated cells, (b) minimizing residual undifferentiated stem cells and non-CM differentiated cell populations, (c) functional and electrophysiological characterization of purified cardiomyocytes, (d) improved survival of iPSC-CM following transplantation, and e) confirmation of safety and efficacy in large animal models prior to clinical application.

Modeling of genetic diseases of the heart

Human iPSC-CMs offer a unique platform by which human cardiac diseases can be modeled in vitro. Patient-specific iPSCs represent a novel technology that holds great promise for analyzing the molecular basis of heart disease and the outcomes of regenerative medicine (Fig. 3). While the utility of iPSC-based in vitro models will depend upon the nature of the disease, this approach is well suited if a genetic mutation is the causative or contributing factor. iPSC-CMs derived from patient-specific iPSC may reflect the dysfunctional characteristics found in cardiomyocytes in vivo and provides a platform for testing treatments. A few examples of the power of this approach are presented later.

The first disease-specific iPSCs for a pathology affecting the heart were derived from patients with LEOPARD syndrome (LS) (Carvajal-Vergara et al., 2010), an autosomal-dominant developmental disorder with pleomorphic effects on several tissues and organ systems, with hypertrophic cardiomyopathy often being the cause of mortality. Approximately 90% of LS cases are caused by point mutations in the PTPN11 gene that encodes the protein tyrosine phosphatase SHP2. Most cases of LS are due to a single base substitution, either A-to-G at position 386 changing amino acid 279 from Tyrosine to Cysteine (Y279C) or C-to-T at position 1403 (T468M). A minority of cases due to other point mutations (Y279S, A461T, G464A, R498W/L, Q506P, and Q510E/G) were documented subsequently (Conti et al., 2003; Yoshida et al., 2004). Cells were obtained from two patients heterozygous for a T468M substitution mutation in PTPN11, and iPSC lines and subsequently LS-iPSC-CMs were derived (Carvajal-Vergara et al., 2010). These LS-iPSC-CMs had significantly larger surface areas, increased sarcomere assembly, and preferential localization of NFATc4 in the nucleus compared to cardiomyocytes derived from human embryonic stem cells or iPSC-CMs derived from a healthy

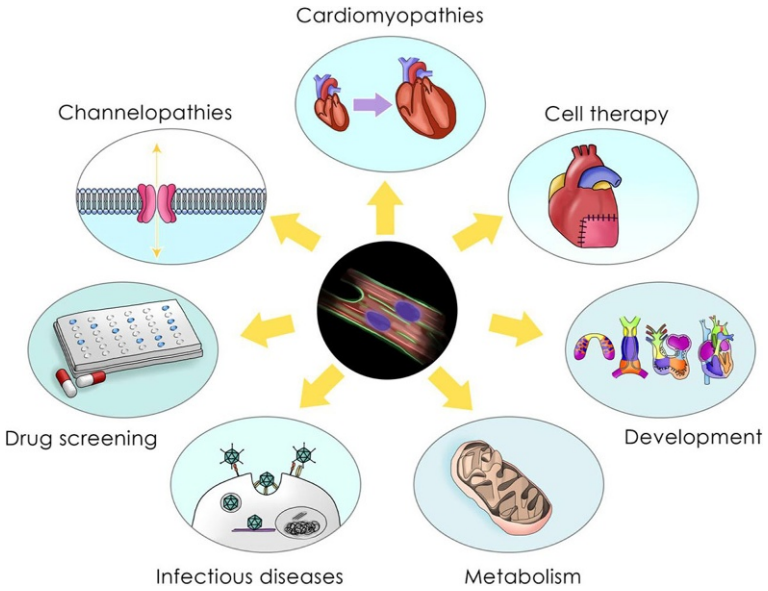

Fig. 3 Current applications of patient-specific induced pluripotent stem cell-derived cardiomyocyte (iPSC-CM) technology. iPSC-CMs have been used for disease modeling of inherited cardiomyopathies and channelopathies, regenerative therapies, drug discovery, and cardiotoxicity testing, as well as for studying metabolicabnormalities and cardiac development. Adapted from Karakikes et al., 2015. Used with permission.

brother of one of the LS patients. This LS model demonstrated for the first time that signal transduction (RAS-MAPK) is perturbed in LS, and this effect was seen as early as the pluripotent stem cell stage.

Dilated cardiomyopathy (DCM) is the most prevalent form of cardiomyopathy and is characterized by ventricular dilatation, systolic dysfunction, and progressive heart failure (Harvey and Leinwand, 2011). DCM-iPSC-CMs were generated from a family carrying a point mutation (R173W) in the gene encoding the sarcomeric protein, cardiac troponin T. Compared to control, healthy individuals in the same family cohort, DCM-iPSC-CMs exhibited altered regulation of Ca^{2+}, decreased contractility, and abnormal distribution of sarcomeric α-actinin. When stimulated with a β-adrenergic agonist, DCM iPSC-CMs showed characteristics of cellular stress such as reduced beating rates, compromised contraction, and a greater number of cells with abnormal sarcomeric α-actinin distribution. However, treatment with β-adrenergic blockers or overexpression of the channel protein, Serca2a, improved the function of DCM iPSC-CMs group (Sun et al., 2012). Thus, DCM iPSC-CMs recapitulate in part the morphological and functional phenotypes of DCM.

Familial hypertrophic cardiomyopathy (HCM) is a primary disorder of cardiac muscle and is characterized by a thickened ventricular wall and ventricular septum, increased myocardial fibrosis, disorganized myofibers, and an arrhythmic heart beat (Maron, 2002). Patient-derived HCM-iPSCs carrying a single missense mutation (R442G) in the MYH7 gene were studied. As expected, HCM-iPSC-CMs were larger and had disorganized sarcomere structures and arrhythmic beatings. Additionally, HCM iPSC-CMs exhibited irregular Ca^{2+} handling and ion-channel functions. A large number of genes responsible for "cell proliferation" were increased in HCM-iPSC-CMs compared with control iPSC-CMs. Together these findings suggest a molecular mechanism underlying HCM (Han et al., 2014).

Using a similar approach, additional studies generating patient-specific iPSC-CMs have been applied to model a large number of genetically based arrhythmias, such as long QT syndrome (Moretti et al., 2010), catecholaminergic polymorphic ventricular tachycardia (CPVT) (Itzhaki et al., 2012), arrhythmogenic right ventricular cardiomyopathy (ARVD) (Ma et al., 2013), overlap syndrome (Davis et al., 2012), and others. Furthermore, transplantation of iPSC-CM sheets over the left ventricular surface improves cardiac function in murine and porcine models of chronic myocardial infarction (Kawamura et al., 2012; Higuchi et al., 2015).

While the therapeutic use of human iPSC-CMs is feasible, an autologous approach would be time-consuming, laborious, and cost prohibitive. The use of allogeneic iPSC-CMs might address these issues (**Fig. 4**); however, transplantation of allogeneic iPSC-CMs might induce an immune response and graft rejection. A proof of concept study was recently carried out by Shiba et al. They initially administered $4x10^8$ MHC-mismatched allogeneic iPSC-CMs into immunosuppressed cynomolgus monkeys 2-weeks following infarction, but the cells were rejected within 4 weeks. However, when an equal number of MHC-matched allogeneic iPSC-CMs were similarly injected, the cells survived for 12 weeks with no evidence of immune rejection and the animals exhibited improved cardiac contractile function compared to placebo injected animals. Cell-treated animals did, however, have a significantly higher incidence of ventricular tachycardia (Shiba et al., 2016). This study suggests that allogeneic iPSC-CMs can provide therapeutic efficacy, but that many issues still need to be addressed.

The generation of disease-specific iPSC-CMs represents an important step forward in cardiovascular research and can serve as a useful platform for exploring disease mechanisms and drug screening. This technology can reproduce most peculiarities of a pathological phenotype, including electrophysiological abnormalities, disorganized cellular structure, sensitivity to drugs, and

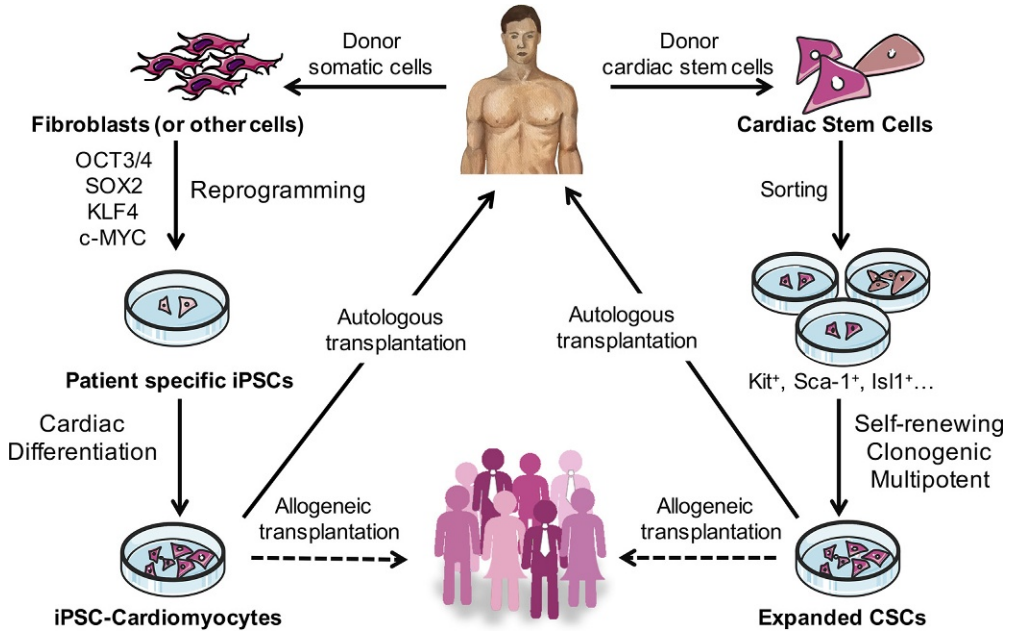

Fig. 4 Cardiac cell therapy strategies using cardiac stem cells (CSC) and induced pluripotent stem cells (iPSCs). CSCs have the potential to proliferate and differentiate into cardiac lineages. CSC subtypes can be sorted by different markers (e.g., Kit, sca-1, and others) each of which may provide characteristic tissue regeneration and repair. iPSCs can be obtained by transducing patient somatic cells (e.g., fibroblasts) with a set of exogenous genes (e.g., Yamanaka factors: OCT3/4, SOX2, KLF4, and c-MYC) or other methodologies. The donor-specific iPSCs can be induced to become iPSC-cardiomyocytes. After expansion, both stem cell populations may be used for autologous transplantation or allogeneic transplantation. The figure was composed of original images and images from the Servier Medical Art image bank (www.servier.com/Powerpoint-image-bank).

other factors. Additionally, the models can be successfully applied to study new methods of genome engineering, such as TALENs and CRISPR/Cas9. However, despite all the excitement associated with iPSCs, there are still several issues that must be solved before this promising technology can be used for clinical purposes.

Conclusions

iPSCs represent an exciting alternative to ES cells, avoiding the ethical issues and providing the opportunity to produce more accurate models for studying human diseases and subsequently more effective therapies. This field is relatively new and substantial progress has already been made, but further intensive investigations into the properties of iPSCs are needed both to increase our understanding of the basic biology of pluripotency and cellular differentiation and to address issues associated with the therapeutic applications of iPSCs. Improvement of the current technologies has been rapid and is ongoing, and the goal of producing clinical-grade human iPSCs and iPSC-derived cells that provide safe and effective therapies appears to be in reach.

Introduction

A variety of brady- and tachy-arrhythmias can coexist with heart failure (HF) and complicate the care of HF patients. Moreover, an arrhythmia itself may cause or exacerbate HF (e.g., arrhythmia-induced cardiomyopathy (AIC)) and control of these arrhythmias can reverse the cardiomyopathy. The presence of bradyarrhythmias may not only directly increase morbidity in HF patients, but also interfere with titration of atrioventricular (AV) nodal blockers such as beta-blockers and calcium channel blockers used to treat tachyarrhythmias.

This article reviews the diagnosis and management of arrhythmias in patients with HF.

Evaluation of Arrhythmias for Patients With HF

Persistent or frequent cardiac arrhythmias can be readily diagnosed with 12-lead electrocardiogram (ECG). Most arrhythmias, however, are paroxysmal and occur intermittently, requiring further diagnostic testing such as ambulatory monitoring or invasive electrophysiologic study (EPS). The Holter monitor is a 24-h monitor system that is particularly useful in evaluating patients with relatively frequent arrhythmias. It is an indispensable monitoring modality to assess frequency of premature ventricular complex (PVC) and adequacy of rate control in patients with atrial fibrillation (AF). Various types of continuous event recorders are commercially available to provide diagnostic information, usually up to 1 month, for patients with less frequent symptoms suggestive of arrhythmias such as palpitation, dizziness, and syncope. Modern event recorders allow recording of patient-activated events as well as auto-triggered brady- and tachycardiac events and provide timely feedback for physicians and patients (Rosero et al., 2013). Implantable loop recorders (ILRs) are subcutaneously implanted devices that allow for long-term (>3 years) arrhythmia monitoring. The ILRs have been increasingly implanted for the evaluation of unexplained syncope and detection of subclinical AF for patients with cryptogenic stroke (Mittal, 2014; Afzal et al., 2015).

Invasive cardiac electrophysiology study may be indicated in patients with HF to provide the definitive diagnosis of an arrhythmia, establish the etiology of syncope, and assess risk of sudden arrhythmic death. In case of documented tachyarrhythmias, EPS defines accurate underlying mechanism of a specific arrhythmia and localizes cardiac structure responsible for the arrhythmia, which then allows targeted pharmacologic and/or nonpharmacologic (catheter ablation and device) therapies.

Cardiac imaging is an integral part of comprehensive assessment for patients with HF and arrhythmia. In addition to standard imaging modalities such as echocardiography, radionuclide myocardial perfusion imaging, and cardiac CT, cardiovascular magnetic resonance imaging (MRI) has been increasingly utilized in care of patients with HF and arrhythmias. Cardiac MRI provides high spatial resolution and excellent tissue characterization. Increased risk of ventricular arrhythmia and sudden death has been revealed in patients with both ischemic and nonischemic cardiomyopathies who demonstrate more extensive myocardial fibrosis detected

 https://doi.org/10.1016/B978-0-12-809657-4.99644-3

by late-gadolinium enhancement (LGE) technique (Stirrat and White, 2013; Kallianos et al., 2015). Cardiac MRI is an essential tool in the diagnosis and potential arrhythmic risk assessment of hypertrophic cardiomyopathy (HCM). The extent of LGE-detected myocardial fibrosis has been associated with higher sudden cardiac death (SCD) risk in patients with HCM (Maron, 2015; Weng et al., 2016). The diagnosis of cardiac sarcoidosis frequently relies on CMR, which may demonstrate myocardial inflammation, edema, and fibrosis due to cardiac involvement of the disease (Birnie et al., 2016).

Supraventricular Arrhythmias

Sinus Tachycardia

Sinus tachycardia is common in patients with systolic HF and often correlates with the disease severity. Heart rate reduction can be a therapeutic target in this population. Ivabradine is an inhibitor of the sinoatrial "funny" current (I_f current). In a large randomized control trial, ivabradine has been shown to decrease the composite endpoint of cardiovascular mortality and hospital admission in patients with left ventricular ejection fraction (LVEF) $\leq$35% and heart rate $\geq$ 70 bpm (Swedberg et al., 2010). The use of ivabradine in this population is considered reasonable; however, the guidelines emphasize the initial effort at up-titrating a beta-blocker to a maximum tolerated dose (Yancy et al., 2016).

Atrial Fibrillation

AF is the most common sustained arrhythmia in HF patients (**Fig. 1**). Presence of HF is a risk factor for AF regardless of LVEF, and the diagnosis of AF confers higher mortality in patients with HF (Maisel and Stevenson, 2003; Tsang et al., 2002; Wang et al., 2003). Although clinicians often attempt to restore and maintain sinus rhythm in patients with HF and AF, studies have demonstrated no significant difference in morality between strategies of rate control versus rhythm control in patients with and without HF (Wyse et al., 2002; Roy et al., 2008). Pharmacologic options other than beta-blockers used for rhythm control in systolic HF are generally limited to class III antiarrhythmic drugs (AADs): sotalol, dofetilide, and amiodarone (**Table 1**). Sotalol and dofetilide are contraindicated in patients with prolonged QT interval and/or renal dysfunction. The U.S. Food and Drug Administration mandates a minimum 72-h in-hospital ECG monitoring for the initiation of dofetilide due to the significant risk of QT prolongation and torsades de pointes (TdP). Dronedarone, another class III agent, is contraindicated in patients with symptomatic HF with recent decompensation requiring hospitalization or NYHA class IV failure, and is rarely used in HF population (Kober et al., 2008). Class Ic agents (flecainide and propafenone) are contraindicated in patients with coronary artery disease and/or structural heart disease, limiting its use in HF population in general. Beta-blockers are the mainstay of pharmacotherapy for rate control. Calcium channel blockers should be avoided in patients with impaired LV function due to their negative inotropic effect. AV nodal ablation combined with an

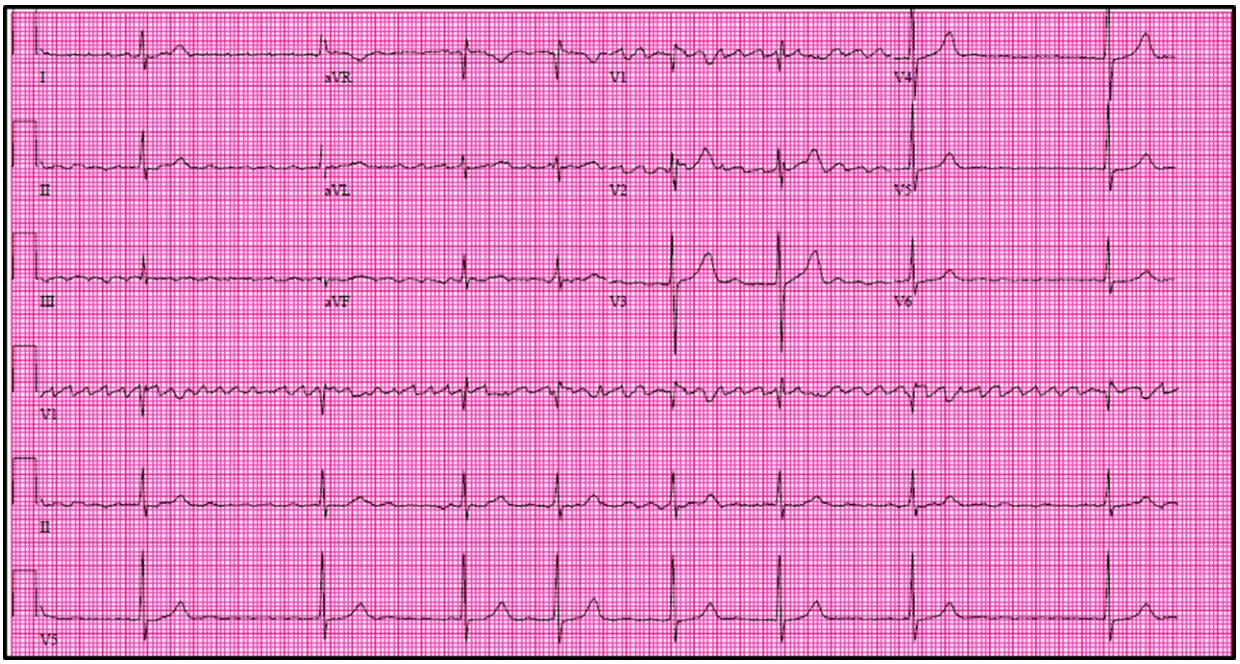

Fig. 1 The 12-lead electrocardiogram shows atrial fibrillation with controlled ventricular response. Fibrillatory waves without discrete P waves and variable intervals between QRS complexes are characteristic.

Table 1 Frequently used antiarrhythmic drugs

Vaughan-Williams classification	*Medication*	*Common use*	*Dose*	*Side effects*	*Comments*
Ia	Procainamide	Preexcited AF (AF associated with WPW), VT	IV: 17 mg/kg at 20–50 mg/min	Hypotension, GI, blood dyscrasias, lupus-like symptoms, TdP	Active metabolite (NAPA) may accumulate if ↓renal function
	Quinidine	VT	PO: Quinidine sulfate 300 mg q8-q12 h Quinidine gluconate 324 mg q8-q12h	GI, TdP, tinnitus, blood dyscrasias	Not commonly used
	Disopyramide	AF, particularly vagally mediated subtype, AF with HCM	PO: 150 mg q6h	Blurry vision, closed-angle glaucoma, urinary retention (anticholinergic effects)	Contraindicated in low EF due to its negative inotropic effect
Ib	Lidocaine	VT	IV: 1 mg/kg bolus; followed by 1–3 mg/min	CNS side effects including seizure and coma	Check blood level to monitor toxicity (therapeutic: 1.5–5 mcg/mL, toxic >9 mg/mL)
	Mexiletine	PVC, VT	PO:150–300 mg q8 h	GI, confusion, tremor, ataxia	Commonly combined with class III drug
Ic	Flecainide	AF, SVT, PVC	PO: 50–150 mg q12h	Proarrhythmic effect	Contraindicated in CAD, significant LVH and low EF. Concomitant AV-nodal blocking agent necessary
	Propafenone	AF, SVT, PVC	PO: 150–300 mg q8h		
II	Metoprolol	AF, SVT, PVC, VT	IV: 5–15 mg q6-8 h PO: Immediate release (tartrate) 25–200 mg q12h Extended (succinate) 25–200 mg daily	Bradycardia, hypotension, bronchospasm, depression	Cardio-selective Metoprolol succinate (extended release) preferred for HF
	Carvedilol		PO: 3.125–25 mg q12h		+ alpha-blockade
	Atenolol		PO: 25–100 mg daily		Cardio-selective
	Esmolol	AF	IV: 0.5–1 mg/kg bolus, followed by 0.05–0.3 mg/kg/min		Cardio-selective
III	Amiodarone	AF, PVC, VT	IV: 150–300 mg bolus, 1 mg/min × 6 h, then 0.5 mg/min × 18 h PO: Loading dose 200–400 mg q8-12 h for 1–2 weeks. Maintenance 200–400 mg daily	Eye, skin discoloration, GI, thyroid (hypo- and hyperthyroid), liver, lung, CNS, neuropathy, tremor, bradycardia, hypotension	Slow onset of effect (days to weeks), and slow elimination (weeks to months)
	Sotalol	AF, PVC, VT	PO: 80–160 mg q12h	TdP, bradycardia, hypotension, HF exacerbation	Mandatory QT monitoring. Avoid hypokalemia and other QT prolonging drugs
	Dofetilide	AF, PVC, VT	PO: 125–500 mcg q 12 h	TdP, AV block	
	Dronedarone	AF	PO: 400 mg q 12 h	HF exacerbation, liver toxicity	Contraindicated in class IV HF, recent decompensated HF, and permanent AF
IV	Verapamil	AF, idiopathic PVC&VT	IV: 2.5–5 mg PO: 120–360 mg daily	Bradycardia, hypotension, constipation	Contraindicated in low EF due to its negative inotropic effect
	Diltiazem	AF, PVC	IV: 0.25 mg/kg bolus; followed by 5–15 mg/h PO: 120–360 mg daily		

AF, atrial fibrillation; *WPW*, Wolff–Parkinson–White syndrome; *VT*, ventricular tachycardia; *TdP*, torsades de pointes; *NAPA*, *N*-acetyl-procainamide; *HCM*, hypertrophic cardiomyopathy; *GI*, gastrointestinal side effect; *PVC*, premature ventricular complex; *CAD*, coronary artery disease; *LVH*, left ventricular hypertrophy; *EF*, ejection fraction; *CNS*, central nervous system; *HF*, heart failure; *SVT*, supraventricular tachycardia.

appropriate device therapy (single-chamber pacemaker, dual-chamber pacemaker, or biventricular pacing system) may be necessary when pharmacologic therapy fails to attain optimal rate control or is poorly tolerated by patients (Kay et al., 1998). Since the AV nodal ablation obligates 100% right ventricular (RV) pacing which can promote further decline in LV function in systolic HF, biventricular pacing system (RV and LV pacing leads) is recommended in patients with LVEF <35%, and should be strongly considered even for patients with less severe LV dysfunction (Epstein et al., 2013a; Leon et al., 2002; Curtis et al., 2013).

Catheter ablation of symptomatic AF is an established treatment option. The efficacy of AF catheter ablation in patients with systolic HF has been evaluated (Anselmino et al., 2016). The long-term success with single ablation procedure is only 40%–50%, and is lower compared to the outcome in general population without HF. The important subset of AF patients in which catheter ablation seems most beneficial is likely those with AIC related to persistent AF (Choi et al., 2010). Significant improvement in LV systolic function is expected after successful ablation and may allow discontinuation of long-term AAD.

Systemic anticoagulation either with warfarin or novel oral anticoagulant is critical for stroke prevention regardless of whether a rhythm or rate control strategy is used.

Atrial Flutter

Atria flutter (AFL) is an organized macroreentrant atrial arrhythmia. Typical AFL involves the cavotricuspid isthmus (the area between the inferior vena cava and the tricuspid annulus), and rotates along the tricuspid valve annulus in a counter-clock direction when seen in the left anterior oblique projection. Twelve-lead ECG of typical AFL is characterized by negative flutter waves in the inferior leads and positive flutter waves in lead V1 (**Fig. 2**). Catheter ablation of the cavotricuspid isthmus is a safe and effective treatment. AF and AFL often coexist in patients with HF in whom only AFL was diagnosed prior to the AFL ablation and the decision to discontinue oral anticoagulant after successful AFL ablation needs to be carefully made after extended ambulatory monitoring and weighed against the risk of thromboembolic complications due to previously undiagnosed AF. Increased left atrial size and AF inducibility with various pacing protocols during AFL ablation have been implicated as risk factors for incidence of AF post-AFL ablation (Ellis et al., 2007; Romero et al., 2017).

Atrial Tachycardia

Atrial tachycardia (AT) is relatively common in patients with HF, and incessant AT may cause or exacerbate systolic HF. With the widespread use of 3D electroanatomic mapping systems, catheter ablation of AT has become highly successful. The P wave morphology of the AT on the 12-lead ECG can assist in localization of the AT origin, and help prepare for the procedure (e.g., need for trans-septal left atrial catheterization and counseling on procedural risk) (Teh et al., 2009). A positive P wave in lead V1 and negative P waves in lateral leads (Leads I and aVL) suggest left atrial origin. Crista terminalis and pulmonary vein ostia are common sites for focal AT in right atrium and left atrium, respectively (Teh et al., 2009).

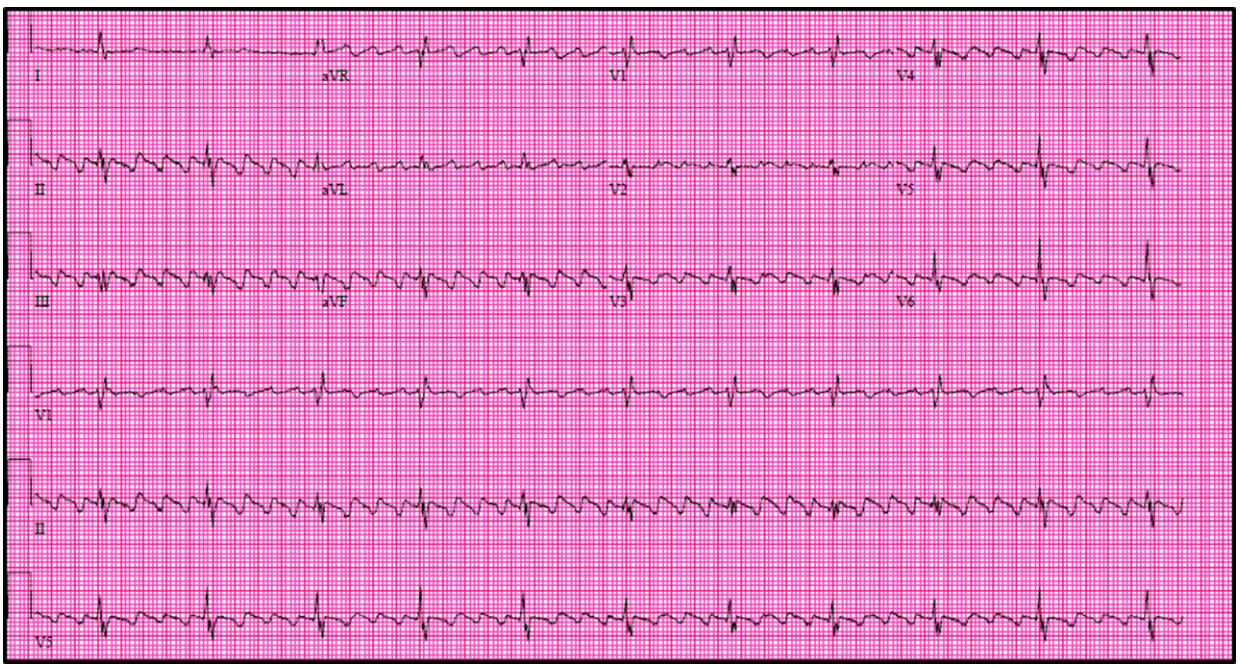

Fig. 2 The 12-lead electrocardiogram shows typical atrial flutter with 4:1 atrioventricular block. Negative flutter waves in the inferior leads (leads II, III, and aVF) and positive flutter waves in the lead V1 are noted.

Other Supraventricular Tachycardias

Catheter ablation is a reasonable first-line therapy for AV nodal reentrant tachycardia (AVNRT) and AV reentrant tachycardia (AVRT) due to its high success rates and low complication risk (**Fig. 3**). Target ablation sites for AVNRT and AVRT are slow pathway and AV accessory pathway, respectively. Although verapamil and diltiazem are reasonable pharmacologic agents for the management of SVT in the general population, the presence of reduced LVEF precludes the use of calcium channel blockers due to their negative inotropic effect. Aggressive treatment of SVT, including catheter ablation, is particularly crucial in patients with implantable cardioverter defibrillator (ICD) to avoid inappropriate shocks for supraventricular tachyarrhythmias (Cardoso et al., 2015).

Ventricular Arrhythmias

Ventricular Tachycardia and Ventricular Fibrillation

Ventricular arrhythmias including PVC, nonsustained VT (NSVT), and sustained VT/VF are more common in patients with structural heart disease, particularly in patients with severely reduced LVEF (**Fig. 4**). SCD is the leading cause of death in industrialized countries and the estimated annual incidence is 300,000–350,000 in the United States (Myerburg et al., 1993; Zheng et al., 2001). Sustained ventricular tachyarrhythmias (VTA) are the most common arrhythmias leading to SCD, and underlying coronary artery disease accounts for a large proportion of SCD in older patients whereas young SCD victims frequently suffer from inherited channelopathies, HCM, dilated cardiomyopathy, and myocarditis (European Heart Rhythm A et al., 2006; Priori et al., 2015). In this section, we discuss the role of pharmacologic and nonpharmacologic therapies in the management of VTA in patients with systolic HF either due to ischemic or nonischemic etiology (Pedersen et al., 2014).

Beta-blockers (bisoprolol, metoprolol XL, carvedilol) are the cornerstone therapy in patients who are at increased risk for VTA and it reduces all-cause mortality and SCD in patients with systolic HF (Anon, 1999a,b). Although there are other available AADs used for patients with frequent VTA to minimize ICD therapy, AAD therapy has not been shown to improve mortality. Ironically, some AADs have been associated with increased mortality. Most notable includes the Vaughan-Williams Class IC drugs, which were studied to suppress PVCs in postmyocardial infarction (MI) patients with LVEF $\leq$40%. The CAST-I and II (Cardiac Arrhythmia Suppression Trials) demonstrated increased mortality associated with flecainide, encainide, and moricizine despite effective PVC suppression (The Cardiac Arrhythmia Suppression Trial (CAST), 1989; Feld et al., 1992).

Other commonly used oral AADs to suppress PVCs, NSVTs, and VTAs include mexiletine, amiodarone, sotalol, and dofetilide (Rose-Jones et al., 2014; Schleifer et al., 2015; **Table 1**). Mexiletine is a Vaughan-Williams Class IB agent and has similar electrophysiological properties to lidocaine. Mexiletine has been used alone and more commonly in conjunction with class III drug such as amiodarone and sotalol (Manolis et al., 1990; Gao et al., 2013). Mexiletine is generally well tolerated and safe; however, it is associated with neurologic (tremor, dizziness) and gastrointestinal (nausea, anorexia) side effects.

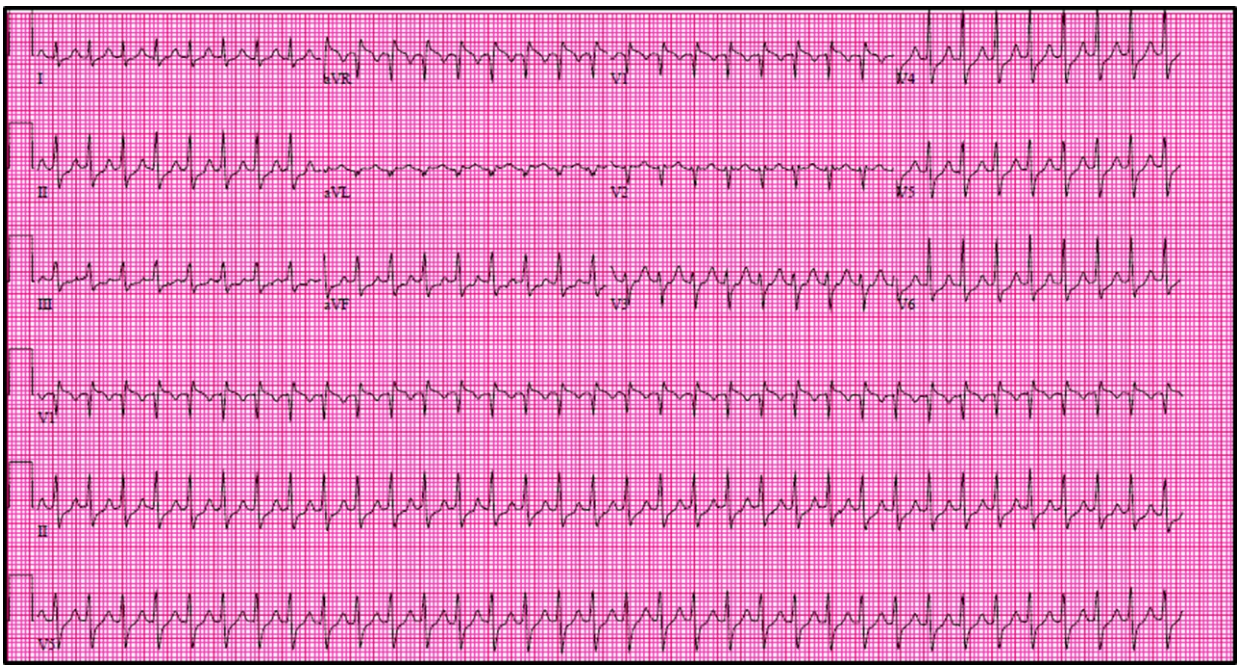

Fig. 3 The 12-lead electrocardiogram shows a narrow complex tachycardia with heart rate of 202 beats per minute. This patient underwent an invasive electrophysiology study, which confirmed the mechanism of the tachycardia to be typical atrioventricular reentrant tachycardia (AVNRT).

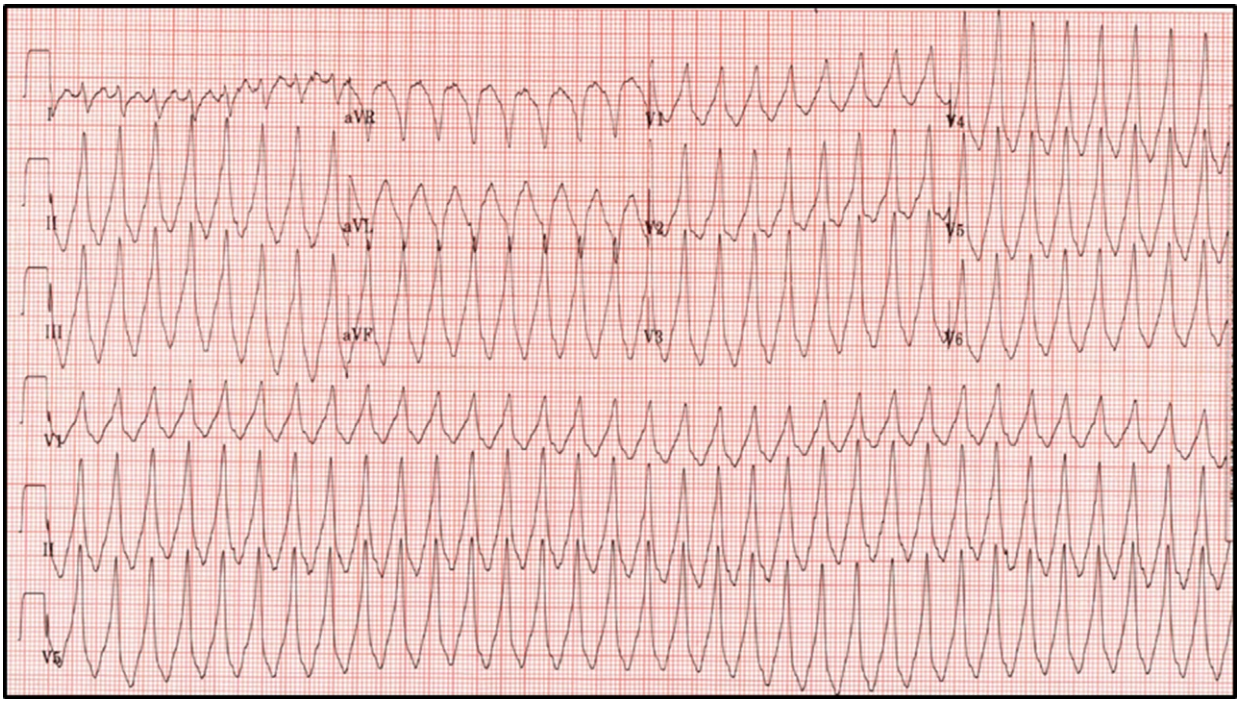

Fig. 4 The 12-lead electrocardiogram of a patient with idiopathic ventricular tachycardia (VT).

Amiodarone is one of the most commonly used AADs for acute therapy of VTAs as well as for chronic suppressive therapy. Although it is classified as a class III AAD, it exhibits various pharmacologic properties including beta-blockade, sodium channel blockade, and potassium channel blockade. Before the routine use of ICDs for SCD prevention, amiodarone was once believed to decrease morality, but the contemporary large-scale clinical trial (SCD-HeFT) showed no survival benefit of amiodarone in patients with NYHA class II–III HF (EF $\leq$35%) as compared with placebo (Bardy et al., 2005). Potential side effects of amiodarone affect thyroid, lung, liver, gastrointestinal tract, skin and eye, and chronic use of the drug calls for close monitoring for organ toxicities including liver function test, thyroid function test, and lung function testing. In the comparative study (OPTIC), amiodarone plus beta-blocker was more effective in reducing the risk of ICD shocks when compared with beta-blocker or sotalol alone, but amiodarone plus beta-blocker was associated with increased risk of drug-related adverse effects (Connolly et al., 2006).

Sotalol is a nonselective beta-blocker that also exhibits class III antiarrhythmic properties. Sotalol (160–320 mg/day) was evaluated as an adjunct therapy to suppress VTA in patients with ICD, and the study showed that sotalol was associated with a lower risk of all-cause mortality or ICD shocks compared to placebo (Pacifico et al., 1999). Sotalol is associated with the risk of TdP and HF exacerbation. Inpatient loading and close monitoring of QT interval is highly recommended. Dofetilide is a class III drug currently approved for the treatment of AF in the United States. Dofetilide appears to be safe in patients with recent MI and systolic HF, as demonstrated in the DIAMOND study. In this trial, 1510 post-MI patients and a low LVEF $\leq$35% were randomized to dofetilide versus placebo. There was no difference in all-cause mortality, but TdP was observed in 7 out of 749 patients in the dofetilide group (Køber et al., 2000). Dofetilide has been evaluated for VTA suppression and has been shown to be as effective as sotalol and may be better tolerated than amiodarone and sotalol. Due to the life-threatening proarrhythmic risk, dofetilide is contraindicated when baseline QTc interval is greater than 440 ms (>500 ms with conduction system abnormalities) and inpatient loading with 3-day ECG monitoring is mandatory for drug initiation. Risk factors for TdP associated with dofetilide include female gender, hypokalemia, and concomitant diuretic use (Shenasa and Shenasa, 2016).

Catheter ablation is an effective adjunctive treatment strategy in patients with systolic HF and sustained monomorphic VT (Yamada and Kay, 2012; Raymond et al., 2009). The survival benefit of the ICD has been well established; however, both appropriate and inappropriate shocks are associated with increased mortality in addition to psychological burden on the ICD recipients (Proietti et al., 2015). Ventricular tachycardia ablation may be the only treatment option in setting of drug-refractory VT storm ($\geq$3 ICD therapies within 24 h) and multiple ICD interventions.

The most common mechanism of VT in patients with systolic HF is a reentrant circuit associated with abnormal myocardial substrate due to previous MI, nonischemic cardiomyopathy, arrhythmogenic RV dysplasia/cardiomyopathy, or other infiltrative myocardial diseases. In post-MI VT, the VT circuit is generally found on the ventricular endocardial surface, and ablation strategies typically target the critical components of the VT circuit identified by mapping procedures during spontaneous or induced VT. This approach requires sustained and hemodynamically stable VT, but it is not always attainable due to VT noninducibility or hemodynamic instability during VT. An alternative approach to VT ablation is to identify abnormal myocardial substrates likely responsible for clinical VT during sinus rhythm or ventricular pacing (substrate mapping), and target them for ablation (Santangeli

and Marchlinski, 2016). Both approaches appear equally effective; however the latter approach generally requires more extensive radiofrequency lesions to achieve the procedural endpoint of VT noninducibility (Kumar et al., 2016). The VT circuit may harbor critical arrhythmogenic substrates in the epicardial myocardium only accessible from the pericardial space, particularly in patients with nonischemic cardiomyopathy. These patients may require epicardial mapping and ablation for controlling VT (Tedrow and Stevenson, 2009; Della Bella et al., 2011). Potential risks of epicardial mapping and ablation include coronary artery damage, pericardial bleeding and cardiac tamponade, phrenic nerve injury, and extra-cardiac organ damage (lung, liver, gastrointestinal tract).

Presently, VT ablation is generally reserved for patients with recurrent VT episodes on at least one AAD or for those intolerant to AADs. The safety and efficacy of "prophylactic" catheter ablation has been evaluated in prospective studies for post-MI patients with spontaneous VTA on no AAD. The SMASH-VT enrolled 128 patients with spontaneous VT and VF (VF = 18%) and showed fewer ICD shocks when compared to a control group (Reddy et al., 2007). The VTACH study is another randomized trial which enrolled 110 patients with VT and LVEF $\leq$50% and demonstrated a higher VTA free survival rate in the ablation group, compared to the control group (no ablation group) (Kuck et al., 2010). In the VANISH trial which recruited patients with recurrent VT despite the use of an AAD, catheter ablation has been shown to be superior to escalation of AAD therapy (increased dose of amiodarone or addition of another AAD) with respect to the composite outcome of death, VT storm, or appropriate shocks. The greatest benefit of catheter ablation was observed in a subgroup of patients who were already receiving amiodarone. There was, however, no mortality difference during a mean follow-up duration of 28 months (Sapp et al., 2016). Recently published long-term analysis of nonrandomized VT ablation trial in patients with ischemic cardiomyopathy showed decreased amiodarone requirement and hospitalization over the 3-year follow-up duration (TERMOCOOL VT trial) (Marchlinski et al., 2016). Whether VT ablation should be performed as a first-line therapy before the trial of AAD in patients with ischemic cardiomyopathy and ICD shocks remains unknown. In contrast to ischemic cardiomyopathy, there have been no prospective randomized studies evaluating the role of VT ablation in patients with nonischemic cardiomyopathy, and long-term outcome of VT ablation in this population has been less well defined. A largest single-center ablation experience in patients with nonischemic cardiomyopathy, including a high rate of adjuvant epicardial ablation (32%), reported a VT-free survival rate of 69% at 60-month follow-up (Muser et al., 2016). Ventricular tachycardia ablation in patients with structural heart disease is rapidly evolving and it is hoped that emerging imaging techniques (cardiac MR, real-time image integration technique), new mapping tools (high-density mapping), and ablation technologies (force sensing catheter, intramural needle ablation) will enhance procedural safety and efficacy (Sapp et al., 2016; Wissner et al., 2012; Yamashita et al., 2016; Viswanathan et al., 2017).

Patients presenting with HF and polymorphic VT or VF warrant thorough evaluation of the underlying etiology, particularly the presence of myocardial ischemia. Polymorphic VT is a ventricular tachycardia with clearly defined QRS complexes that change continuously from beat to beat. TdP is a form of polymorphic VT that occurs in setting of a prolonged QT interval, and is characterized by appearance of QRS complexes twisting around the isoelectric line of the recording (twisting of the points) (Fig. 5). TdP is frequently associated with electrolyte abnormalities (hypokalemia and hypomagnesemia) and the use of QT prolonging drugs (AADs, antibiotics, and psychotropic drugs). Acute treatment of TdP includes external defibrillation, intravenous magnesium sulfate, lidocaine (Class Ib AAD shortens the QT interval), isoproterenol infusion, and temporary overdrive pacing. Overdrive pacing allows shortening of the QT interval by increasing the heart rate >100 bpm. Ventricular fibrillation is a chaotic tachycardia without consistently identifiable QRS complexes and calls for immediate defibrillation (Pedersen et al., 2014).

Premature Ventricular Complex

The presence of frequent PVCs may cause and exacerbate cardiomyopathy and HF (Fig. 6). It may also prevent delivering effective cardiac resynchronization therapy (CRT). PVC-induced cardiomyopathy is an arrhythmia-induced, potentially reversible condition. Postulated mechanisms of PVC-induced cardiomyopathy include ventricular dyssynchrony akin to bundle branch block, abnormal

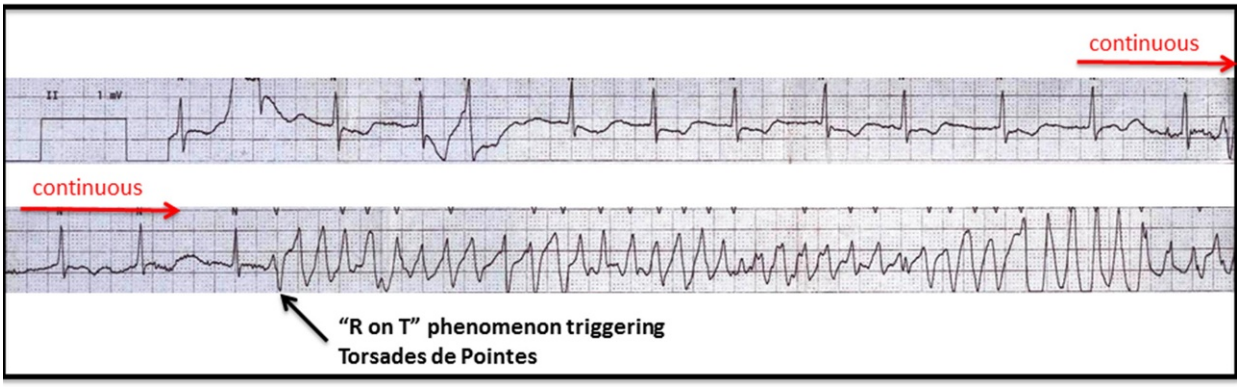

Fig. 5 An example of torsades de pointes (TdP) rhythm. Note prolonged baseline QT interval and initiation of TdP with a premature ventricular complex occurring during the T wave ("R on T" phenomenon). Courtesy of Behzad Pavri MD, Thomas Jefferson University, Philadelphia, PA, USA.

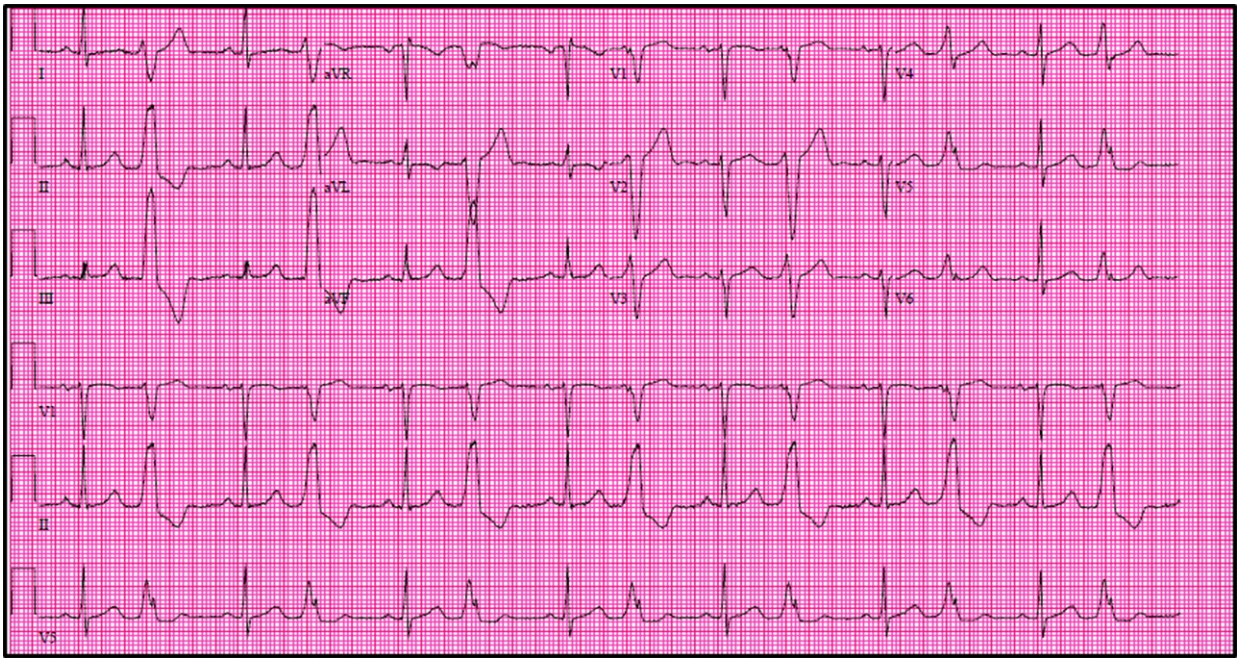

Fig. 6 The 12-lead electrocardiogram shows frequent premature ventricular complexes (PVC). This PVC was successfully ablated in the right ventricular outflow tract.

Ca^{2+} handling, and abnormal ventricular filling from post-PVC pause (Gopinathannair et al., 2015). Although a higher PVC burden (particularly >24%) correlates with the incidence of cardiomyopathy, not every patient with frequent PVC burden develops cardiomyopathy, and PVC-induced cardiomyopathy is rare when a PVC burden is less than 10% (Baman et al., 2010). A beta-blocker is a safe first-line pharmacologic therapy for frequent PVCs in the setting of cardiomyopathy; however, its efficacy for PVC suppression is only modest. Catheter ablation is a reasonable first-line therapy for PVC-induced cardiomyopathy due to frequent monomorphic (unifocal) PVCs. AADs such as mexiletine, sotalol, and amiodarone may be necessary if PVC focus is not amenable to catheter ablation, or multifocal PVCs are encountered. Class Ic AADs such as flecainide and propafenone should be avoided in patients with a reduced LVEF to their proarrhythmic effects. Right and left ventricular outflow tracts are the most common sites for idiopathic PVC. These outflow PVCs are generally associated with benign prognosis, however, rarely cause PVC-induced polymorphic VT and sudden cardiac arrest (Noda et al., 2005).

Device Therapy for SCD Prevention

Rationale for ICD

Today, ICD has an established role in the primary and secondary SCD prevention. Historically, due to the considerable morbidity and mortality associated with surgical implantation (via thoracotomy) of the early generation ICD device, only those who survived cardiac arrest due to VTA qualified for the device implantation in 1980s. Transvenous insertion of the ICD lead and subsequent miniaturization of the pulse generator implanted in the pectoral region eventually led to the widespread use of the ICDs. Survival benefits of secondary prevention ICD placement over chronic AAD therapy were later demonstrated in landmark prospective trials (AVID, CIDS, CASH) (The Antiarrhythmics versus Implantable Defibrillators (AVID) Investigators, 1997; Connolly et al., 2000a; Kuck et al., 2000). A meta-analysis (ICD: $n = 934$ vs. amiodarone: $n = 932$) showed significant reductions in all-cause mortality and in arrhythmic death in patients implanted with ICDs when compared with chronic amiodarone therapy alone (Connolly et al., 2000b).

The proven success of ICD therapy in SCD survivors set the stage for prospective trials for primary prevention ICD therapy for patients at risk for SCD. Specifically, MI survivors with impaired LV systolic function and HF were consistently recognized as conferring the highest risk of cardiac morality, particularly due to sudden arrhythmic death, and targeted for primary prevention trials. A substantial body of clinical evidence emerged from early studies including patients with coronary artery disease and an impaired LVEF (<30–40%), and showed survival benefit in this population (MUSTT, MADIT I, MADIT II) (Buxton et al., 1999; Moss et al., 1996; Moss et al., 2002). In the MUSTT trial, post-MI patients with NSVT and LVEF ≤40% were risk-stratified using invasive electrophysiology study (EPS). Patients with inducible, sustained VTA were randomly assigned to either the EPS-guided therapy group or no AAD therapy. In the EPS-guided therapy group, ICD placement was recommended when VTA was induced on at least one AAD. The primary endpoint of cardiac arrest or arrhythmic death occurred less in the EPS-guided therapy group, and the

benefit was largely driven by the presence of ICD. It should be noted that within the EPS-guided therapy group, assignment to ICD placement (46% in the EPS group) versus AAD therapy was not randomized, and patients were required to fail at least one AAD to receive ICD (Buxton et al., 1999). The findings of MUSTT have been incorporated in the guidelines for primary prevention ICD implantation (Epstein et al., 2013a).

Notably, studies evaluating primary prevention ICD implantation early after MI (30–40 days) did not show mortality benefit (DINAMIT, IRIS). Current device guidelines do not recommend primary prevention ICD placement within 40 days of MI (Epstein et al., 2013a). Likewise, routine ICD placement at the time of coronary artery bypass grafting showed increased infection risk without any survival benefit (CABG-PATCH) (Bigger, 1997). Therefore, it is recommended that LVEF should be reassessed and primary prevention ICD placement should be deferred for at least 3 months after surgical or percutaneous coronary revascularization. A wearable cardioverter defibrillator may be considered for patients perceived to be high risk for SCD during the waiting period (Epstein et al., 2013b; Reek et al., 2016) (**Fig. 7**).

In contrast to the robust evidence of the ICD benefit in patients with ischemic cardiomyopathy, evidence for primary prevention ICD placement in nonischemic cardiomyopathy is not as conclusive. Three prospective studies (AMIOVIRT, CAT, and DEFINITE) failed to demonstrate the benefit of primary prevention ICD in this population (Strickberger et al., 2003; Bansch, 2002; Kadish et al., 2004). The current guideline recommendations regarding the role of primary prevention ICD placement in nonischemic cardiomyopathy derive largely from SCD-HeFT, the largest primary prevention ICD trial to date including 2521 patients with both ischemic and nonischemic patients (Ischemic: 52% vs. nonischemic cardiomyopathy: 48%), NYHA class II/III HF, and LVEF $\leq$35% (Bardy et al., 2005). Patients were randomized to placebo, amiodarone, and ICD arms. The primary prevention ICD therapy was associated with 23% reduction in all-cause mortality, as compared with placebo. Amiodarone showed no survival benefit in this study.

Recently, the utility of primary prevention ICD therapy in nonischemic cardiomyopathy was questioned in a multicenter prospective study in Denmark, in which patients with nonischemic cardiomyopathy and LVEF $\leq$35% were randomly assigned to ICD therapy versus no ICD (DANISH trial) (Kober et al., 2016). Contemporary background pharmacotherapy (beta-blocker, angiotensin-converting enzyme (ACE) inhibitor, or angiotensin receptor blocker (ARB)) was used in >90% of participants, and 58% of patients in both groups received CRT based on the current CRT guidelines. After a median follow-up of 68 months, all-cause mortality was similar in both groups. The DANISH study, however, suggested a mortality benefit of the ICD in younger patients (<68 years of age) while the benefit of ICD to reduce SCD was likely offset by a high nonarrhythmic death rate in older patients with severe cardiomyopathy. Although the study was "neutral" in the total population, it strongly suggests the importance of patient selection for primary prevention ICD for patients with HF due to nonischemic cardiomyopathy. In essence, primary prevention ICD therapy should not be universally withheld for patients with severe nonischemic cardiomyopathy who qualify for the ICD implantation based on the current device guidelines (Epstein et al., 2013a).

Primary prevention ICD trials are summarized in **Table 2**. A complete list of primary and secondary prevention ICD indications (and contraindications) is found elsewhere (Epstein et al., 2013a).

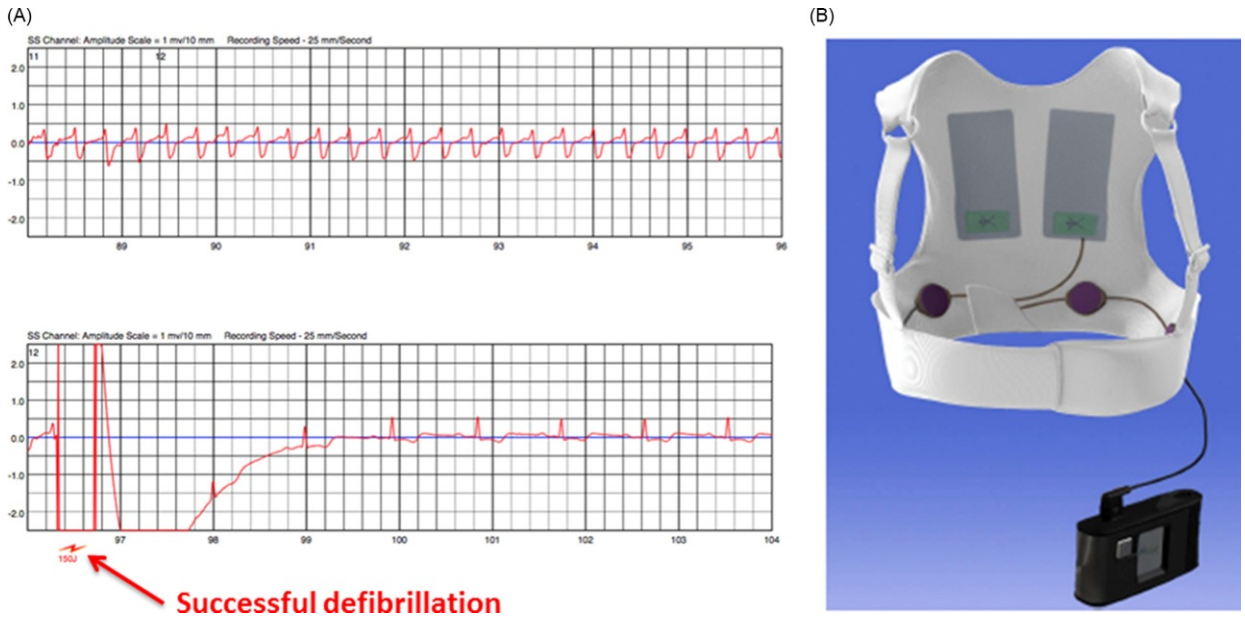

Fig. 7 (A) This is a rhythm strip of a 61-year-old man with recent ST-elevation myocardial infarction and severely depressed left ventricular systolic function (ejection fraction = 25%) who was discharged on a wearable defibrillator. He was found unresponsive due to pulseless VT and successfully resuscitated by the wearable defibrillator (150 J shock) with immediate restoration of sinus rhythm. He subsequently received a secondary prevention implantable defibrillator. (B) A commercially available wearable defibrillator. Image courtesy of ZOLL Medical Corporation, Pittsburgh, PA, USA.

Table 2 Primary prevention ICD trials

ICM versus NICM	*Trial published year*	*EF cutoff*	*Inclusion criteria*	*Study arms*	*Number of patients in ICD arm/control arm*	*Endpoints*	*Results*	*Comments*
ICM	MUSTT 1999	0.4	NSVT. 4 or more days post-MI	EP-guided Rx (AAD or ICD if AAD failed) vs. No Rx	$n=704$, EP-guided Rx:351 (ICD:161), No Rx:353	Primary: cardiac arrest or arrhythmic death Secondary: overall mortality, cardiac death, spontaneous sustained VT	Median f/u 39 mo. Cardiac arrest or arrhythmic death at 5 yrs in EPG:25%, in No Rx:32% (RR 0.73, $P=0.04$), overall mortality at 5 yrs in EPG:42%, in No Rx:48% (RR 1.80, $P=0.06$)	In EPG group, 5-yr rate of cardiac arrest or arrhythmic death was 9% in ICD group and 37% in AAD group ($P=0.001$)
	MADIT I 1996	0.35	MI 3 weeks or more before entry, CHF NYHA I to III, NSVT and inducible and refractory VT/VF, age 25–80	ICD (98 transthoracic and 98 transvenous implants) vs. control	$n=196$, ICD:95, Control:101	Overall mortality	Mean f/u 27 mo, death in ICD:15, in control:39 (HR 0.46, $P=0.009$)	
	MADIT II 2002	0.3	Age >21 (no upper age limit), more than 1 month post-MI	ICD (single chamber or dual chamber) vs. control	$n=1232$, ICD:742, Control:490	Overall mortality	Mean f/u 20 mo, death in ICD:14.2%, in control:19.8% (HR 0.69, $P=0.016$)	Statistically nonsignificant increase in new or worsened HF in ICD group
	CABG-PATCH 1997	0.36	Elective CABG, abnormal SAECG, age <80	Epicardial ICD vs. control	$n=900$, ICD:446, Control:454	Overall mortality	Mean f/u 32 mo, death in ICD:101, in control:95 (HR 1.07, $P=0.64$)	More postoperative infections in ICD group
Implant early after MI	DINAMIT 2004	0.35	6–40 days post-MI, low HRV or elevated HR on Holter monitoring at least 3 days post-MI, age 18–80	Single-chamber ICD vs. control	$n=674$, ICD:332, Control:342	Overall mortality	Mean f/u 30 mo, death in ICD:62, in control:58 (HR 1.08, $P=0.66$)	Statistically significant increase in nonarrhythmic death in ICD group (HR 1.75, $P=0.02$)
	IRIS 2009	0.4	5–31 days post-MI, heart rate >90 bpm on first ECG or NSVT >150 bpm on Holter, age 18–80	ICD (81% single chamber) vs. control	$n=898$, ICD:445, Control:453	Overall mortality	Mean f/u 37 mo, death in ICD:116, in control:117 (HR 1.04, $P=0.78$)	Statistically significant increase in non-SCD (HR 1.92, $P=0.001$). NYHA IV CHF excluded
NICM	AMIOVIRT2003	0.35	Asymptomatic NSVT lasting <30 s, NYHA I–III CHF, age >18	ICD vs. amiodarone	$n=103$, ICD:51, Amiodarone:52	Overall morality	Mean f/u 24 mo, no difference in survival at 1 yr and 3 yrs ($P=0.8$)	
	CAT 2002	0.3	Recent onset NICM <9 mo, NYHA II or III CHF, age 18–70	ICD vs. control	$n=104$, ICD:50, Control:54	Overall mortality	Mean f/u 5.5 yrs, at 4 yrs, cumulative survival in ICD:80% in control:86% ($P=0.554$)

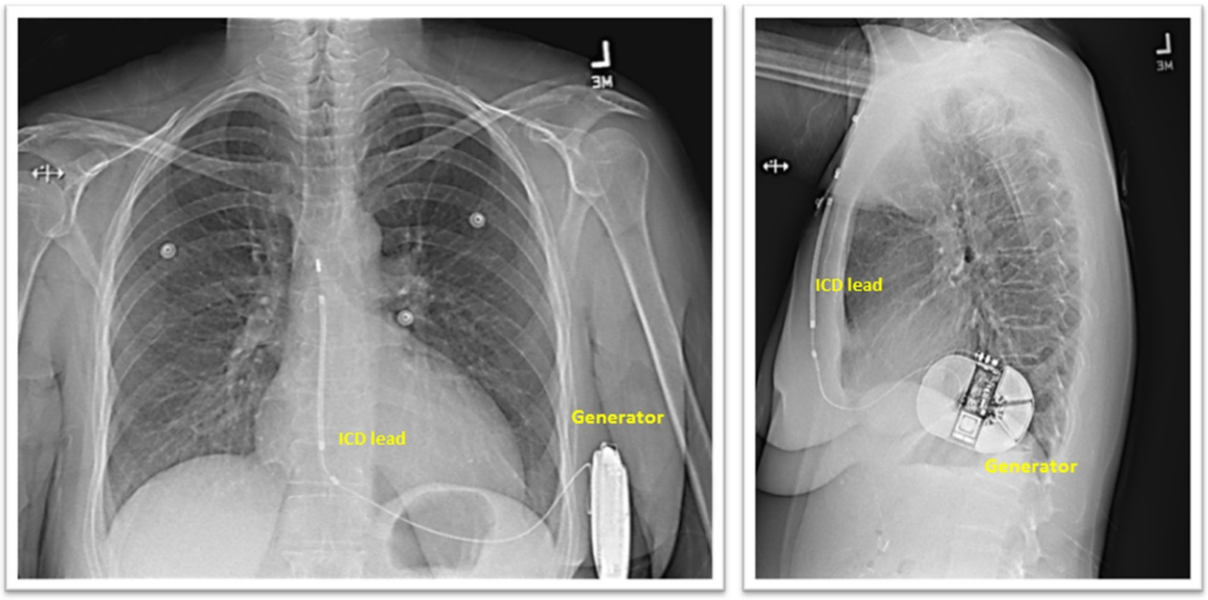

Fig. 8 Posteroanterior (left) and lateral (right) chest X-ray images of subcutaneous defibrillator.

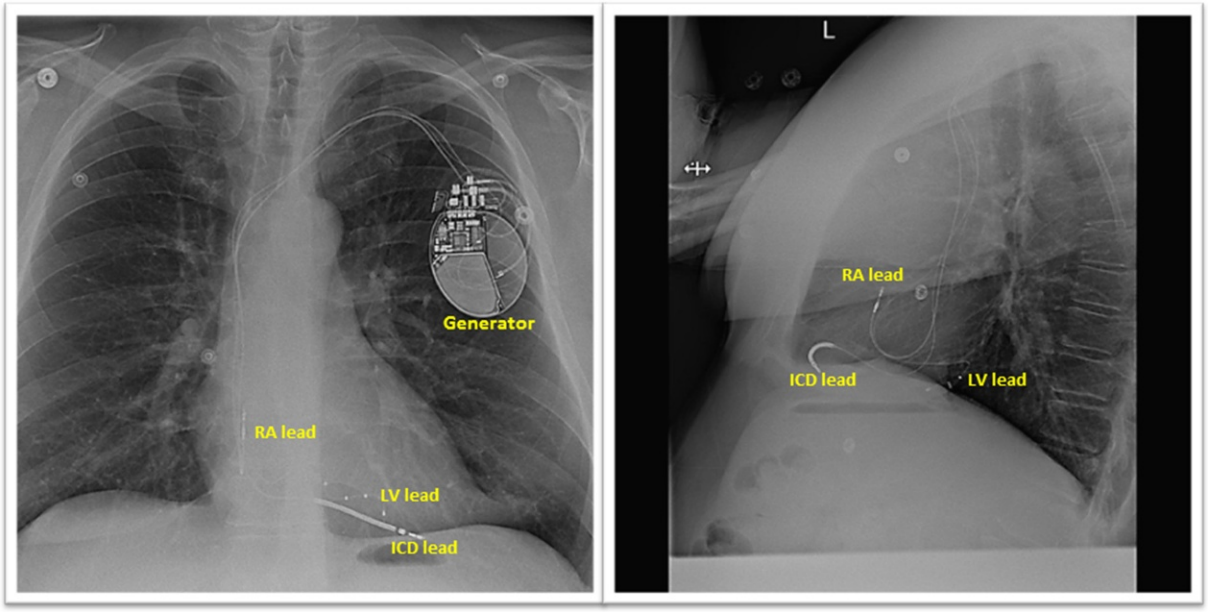

Fig. 9 Posteroanterior (left) and lateral (right) chest X-ray images of biventricular-ICD system. The ICD lead is placed in the right ventricular apex and the LV lead is placed in the posterolateral branch of the coronary vein. *RA*, right atrium; *LV*, left ventricle; *ICD*, implantable cardioverter defibrillator.

Subcutaneous ICD

Contemporary transvenous ICD system consists of a transvenous defibrillation lead and a pectoral pulse generator. Transvenous lead placement is associated with short-term (pneumothorax, hemothorax, cardiac perforation, and tamponade) and long-term complications (tricuspid regurgitation, endocarditis, lead failure, inappropriate shock) (Udo et al., 2012). The totally subcutaneous ICD (SICD) system has been developed to circumvent most of the transvenous lead-associated complications (Lewis and Gold, 2016). The system consists of a pulse generator implanted in the lateral chest wall and a single sensing and defibrillation lead tunneled in the subcutaneous tissue in the anterior chest wall (Fig. 8). Unlike conventional transvenous defibrillation leads, the SICD lead has no central lumen and is believed to be more durable. There is virtually no risk of lead-associated endocarditis or bacteremia owing to the lack of an endovascular component. The SICD is particularly suitable for young patients, patients with limited or no vascular access (congenital heart disease, dialysis, upper body venous occlusion), and patients with previous history of device-related infection or at increased risk for infection. Several limitations of the current SICD system should be noted. First,

patients need to go through preimplant ECG screening to avoid T wave oversensing which can lead to inappropriate ICD shocks. At present, the SICD is not equipped with pacing (other than postdefibrillation temporary demand pacing) or antitachycardia pacing (ATP) capability, and is not suitable for patients with pacing indications (bradycardia and CRT) and with monomorphic VT amenable to ATP. Lastly, although the SICD appears more attractive in certain patient populations as compared with the transvenous ICD system, no head-to-head comparative data is available at present with regard to mortality, efficacy, and complications (Weiss et al., 2013; Lambiase et al., 2014; Burke et al., 2015; Olde Nordkamp et al., 2012).

Risk Stratification

Impaired LV systolic function and the presence of HF are the most powerful predictors of SCD, but the low LVEF alone is neither sensitive nor specific for this purpose. As a result, a substantial number of patients with ICD do not receive appropriate ICD therapy while they are subjected to a myriad of long-term device-related complications including infection, lead malfunction, and inappropriate shocks. Post hoc analysis of MADIT II demonstrated feasibility of simple clinical score to assess relative benefit of the primary prevention ICD in an individual patient. The scoring system consists of five readily available clinical factors, including NYHA class, age >70 years old, blood urea nitrogen >26 mg/dL, QRS duration >120 ms, and the presence of AF, and each factor is assigned 1 point. In this analysis, patients with low (risk = 0) and intermediate risk (risk = 1 or 2) derived the most benefit while patients with a high-risk score (risk ≥ 3) and those with severe renal dysfunction (serum creatinine ≥ 2.5 mg/dL) did not benefit from primary prevention ICD (Goldenberg et al., 2008; Barsheshet et al., 2012).

Likewise, patients with HF with a preserved or mildly depressed LVEF who may be at risk for SCD are automatically excluded from receiving the potentially life-saving device based on the current LVEF-based recommendations for primary prevention ICD (Epstein et al., 2013a; Al-Khatib et al., 2007). There are numerous noninvasive risk markers for SCD including QRS duration, QT interval, QT dispersion, signal-averaged ECG, heart rate variability, and T-wave alternans; however, clinical utility of these markers to guide appropriate patient selection for primary prevention ICD therapy has not been established (Goldberger et al., 2008).

Bundle Branch Block and CRT

Prolonged QRS duration >120 ms is seen in 30%–40% of patients with systolic HF and is associated with increased mortality (Braunschweig et al., 2017). Particularly, left bundle branch block (LBBB) has been associated with higher cardiac event rates in HF patients and is also a risk factor for developing future HF in asymptomatic patients (Baldasseroni et al., 2002; Dhingra et al., 2006). CRT aims to restore interventricular and intraventricular conduction delay by providing nearly simultaneous right and left ventricular pacing. Historically, left ventricular pacing was first provided via epicardial LV lead, but subsequently transvenous LV lead placement via coronary vein cannulation was developed in late 1990s and became the standard implanting technique (Daubert et al., 1998; **Fig. 9**). Survival benefit of CRT was confirmed in two landmark trials (COMPANION, CARE-HF) as well as in a meta-analysis (Bristow et al., 2004; Cleland et al., 2005; Bradley et al., 2003). The COMPANION trial randomized 1520 patients with sinus rhythm, NYHA class III/IV HF, LVEF ≤35%, QRS ≥120 m to optimal medical therapy, CRT pacemaker (CRT-P), or CRT defibrillator (CRT-D). The primary endpoint of death or hospitalization was significantly reduced in both CRT-P and CRT-D groups compared to the optimal medical therapy alone. In this trial, a statistically significant reduction in all-cause mortality was observed only in the CRT-D group, but not in the CRT-P group (Bristow et al., 2004). The mortality benefit of CRT-P device was later demonstrated in the CARE-HF trial, in which 813 patients were randomized to optimal medical therapy alone versus optimal medical therapy and CRT-P (Cleland et al., 2005). These encouraging CRT benefits eventually paved the way for CRT trials for less symptomatic HF patients (REVERSE, MADIT-CRT, RAFT) (Linde et al., 2008; Moss et al., 2009; Tang et al., 2010). The MADIT-CRT enrolled 1820 patients with NYHA class I/II HF, LVEF ≤30%, and QRS ≥130 m and demonstrated decreased primary endpoint of death or HF events in patients with CRT-D, as compared with patients with ICD (Moss et al., 2009).

Although these landmark trials included patients with QRS ≥120 m, subsequent analyses showed that the greatest benefit of CRT device was observed among patients with QRS >150 ms (Sipahi et al., 2011; Stavrakis et al., 2012). Furthermore, CRT benefit was only observed in patients with LBBB morphology, but not in those with non-LBBB QRS morphologies (RBBB, IVCD) (Bilchick et al., 2010; Nery et al., 2011). Currently, U.S. device therapy guidelines provide class I CRT indication to those with sinus rhythm, NYHA class II/III/ambulatory IV HF, LVEF ≤35%, and LBBB QRS ≥150 m. A complete list of CRT indications is found elsewhere (Epstein et al., 2013a).

Presently, U.S. device guidelines do not recommend CRT in patients with QRS <120 ms under any circumstance despite the fact that some HF patients with narrow QRS exhibit mechanical dyssynchrony by imaging assessment (Epstein et al., 2013a; Bleeker et al., 2004; Ghio et al., 2004). In order to evaluate the potential utility of CRT for patients with systolic HF, narrow QRS interval, and mechanical dyssynchrony, the EchoCRT recruited patients with NYHA class III/IV HF, and LVEF ≤35%, QRS <130 m and an echocardiographic evidence of LV dyssynchrony and randomized them to CRT-D versus standard ICD therapy. The study was terminated prematurely for futility after randomizing 809 patients. The primary outcome of death or HF hospitalization was similar in both groups, but more deaths were observed in the CRT-D group (Ruschitzka et al., 2013). Meta-analysis of studies evaluating the benefit of CRT in patients with systolic HF and QRS ≤130 ms suggested increased all-cause mortality compared to nonresynchronized ICD (Shah et al., 2015).

AV Block

When relatively young patients present with AV block, infectious and noninfectious causes need to be thoroughly evaluated. Some disease processes are reversible including myocarditis (e.g., Lyme disease) and myocardial ischemia. Two important noninfectious causes deserve special mention due to the significant risk of ventricular arrhythmias and SCD. Sarcoidosis is a noncaseating, granulomatous disorder of unknown etiology that can affect myocardium and the conduction system of the heart. Presentations of cardiac sarcoidosis include conduction system disease, cardiomyopathy, atrial and VTA, and SCD. Specialized imaging techniques such as cardiac MRI, 18F-Fluorodeoxyglucose PET, and radionuclide imaging are frequently required for the diagnosis when endomyocardial biopsy is either unavailable or nondiagnostic. Implantation of an ICD system should be considered when the patient presents with a clear pacing indication or if impaired LV function is present (LVEF <50%) (Birnie et al., 2016). Patients with familial dilated cardiomyopathy caused by mutations in LMNA gene (lamin A and lamin C) have high risk of progressive AV block, ventricular arrhythmias, and SCD. Prophylactic ICD placement is generally considered appropriate in patients with LMNA-associated cardiomyopathy and a pacing indication even when LVEF is >35% (Hasselberg et al., 2014; van Rijsingen et al., 2012).

Cardiomyopathy Due to Arrhythmia

AIC is a potentially reversible condition due to frequent atrial or ventricular arrhythmias (Gopinathannair et al., 2015). Cardiomyopathy can be partially or completely reversible once arrhythmias are effectively suppressed. Common arrhythmias associated with AIC include AF, AFL, AT, and PVCs. Exact pathophysiology responsible for AIC is incompletely understood, but it likely shares the same underlying mechanisms with cardiomyopathy due to chronic RV pacing, including ventricular dyssynchrony (due to frequent PVC), LV remodeling, neurohormonal activation, and abnormal Ca^{2+} handling. When suspected, AIC should be treated with evidence-based HF regimen (ACE inhibitor/ARB and beta-blocker) and aggressive arrhythmic suppression with either pharmacologic therapy or catheter ablation. It is unknown whether pharmacologic HF regimen should be continued after complete recovery of cardiomyopathy.

Arrhythmias Post Orthotropic Heart Transplantation

Orthotropic heart transplantation (OHT) is an established treatment for patients with end-stage HF. A variety of supraventricular and VTA and successful catheter ablation of these arrhythmias have been reported in the literature. Predisposing factors for these arrhythmias include myocardial ischemia, inflammation, conduction block caused by biatrial anastomosis, parasympathetic denervation, cardiac allograft vasculopathy, and rejection (Thajudeen et al., 2012; Hamon et al., 2014).

Atrial tachyarrhythmias are the most common entities and biatrial anastomosis appears to be associated with higher risk of atrial arrhythmias due to inherent conduction block or slow conduction across the anastomosis lines. Presently, most transplant centers use bicaval donor-to-recipient anastomosis.

Generally, resting heart rate is elevated after OHT due to parasympathetic denervation. However, bradyarrhythmias may be observed after OHT, and usually results from sinus node dysfunction. Biatrial anastomosis is associated with an increased risk of sinus node dysfunction compared to bicaval technique. Sinus bradycardia in the immediate postoperative period may require temporary pacing, but sympathomimetics such as terbutaline and isoproterenol can achieve the target heart rate of 90 bpm. Rejection should be suspected and promptly excluded in case of sustained or late onset bradyarrhythmias. Asystole and pulseless electrical activity are far more frequent than VF as a cause of SCD in OHT recipients, and cardiac allograft vasculopathy (transplant coronary artery disease) is a recognized underlying mechanism for SCD (Vaseghi et al., 2009). A role of primary prevention ICD in OHT recipients who do not meet the conventional criteria is unknown (Tsai et al., 2009).

Normal Cardiac Physiology

Three fundamental mechanisms are involved to properly circulate oxygenated blood in conjunction with the pulmonary system (Katz, 1988). These mechanisms are based on mechanics, cell physiology, and molecular biology. The mechanical mechanisms are based on length dependence to change preload and afterload and are theoretically rooted in the sliding-filament theory and the Frank–Starling relationship. The cell physiologic mechanisms involve the cardiac contractile proteins responding to calcium fluxes to mediate excitation–contraction coupling and relaxation. The molecular biological mechanisms revolve around individual protein expression and their sequences, which influences the structure and function of sarcomeres and metabolic processes within individual cells. To understand contractile function and dysfunction of the heart, a description of the organ, cell, and myofilaments is necessary.

Heart Structure and Function

The heart is a biologic pump and serves to circulate blood through the body (Katz, 2010). The heart is composed of myocytes and nonmyocytes. The nonmyocytes include connective tissue, vascular smooth muscle cells, and endothelial cells, among the heterogeneous population of cells, and account for nearly 70% of the heart's cellular population with the remaining 30% as the cardiomyocyte population (Colucci, 2004). The cardiomyocytes are enmeshed in a collagen network and separated longitudinally by intercalated discs, which are specialized cell–cell junctions (Forbes and Sperelakis, 1985). The intercalated discs provide strong mechanical connections between adjacent cells. The normal structure of the heart allows for a sufficient amount of oxygen and nutrients to circulate throughout an organism's entire body.

In humans, the heart is a four-chamber system with two atria (left and right) and two ventricles (left and right). The shape of the human heart is described as an upside-down pear where the atria form the curved top of the heart and the ventricles form a pointed base. The left ventricle contracts with the most force to overcome a blood flow resistance over distance and eject oxygen-enriched blood from the heart into the body compared to the right ventricle that pumps oxygen-depleted blood into the lungs. The left atrium receives oxygenated blood from the lungs, whereas the right atrium receives deoxygenated blood from the body. The left and right side of the mammalian heart is separated by a septum. A valve connects each atrium to the ventricle below it (mitral valve for the left and tricuspid valve for the right). The top of the heart connects to the aorta artery, the pulmonary artery, superior vena cava, and inferior vena cava, which connect to the pulmonary system.

The heart mechanically pumps blood by contracting myofilaments in each cardiomyocyte, which is triggered by electrical stimulation and calcium release, among other elements. The electrical signal cascade begins in the sinoatrial node (SA node), located in the right atrium, with a second cascade triggered in the atrioventricular node (AV node), and located between the atria and ventricles in Koch's triangle. Under normal conditions, electrical activity is spontaneously generated by the SA node, which then travels to the AV node.

The trigger for electrical activity is based in depolarization of the cardiomyocyte in the cardio action potential. The action potential travels to all regions of the cell through the t-tubules that causes opening of voltage-gated calcium channels, influx of calcium into the cytosol, and calcium-induced calcium release from the sarcoplasmic reticulum (SR). When calcium is released from the SR and binds to troponin C, the tropomyosin repositions to reveal the cross-bridge binding site on the actin and the myosin head binds to the actin. The myosin head then binds to the actin and slides the myosin past the actin (Huxley, 1969) with the splitting of adenosine triphosphate (ATP), resulting in a contraction.

The myosin movement across the actin filament is known as a power-stroke cycle (Spudich, 2001). This power-stroke cycle occurs through the hydrolysis of ATP and release of energy (Hill, 1974). Briefly, ATP binds to the myosin head and is broken down into adenosine diphosphate (ADP) and phosphate (P). When the binding site for myosin is revealed on actin, the myosin will weakly bind to actin. The P is then released and empowers the power-stroke of the myosin (Goody, 2003). The myosin disconnects from actin and binds to new ATP, which also creates a reversion to the start of a new cross-bridge cycle and contraction. After a delay, the potassium channels then reopen and cause repolarization to the cardiomyocyte. The sarcomere, and ultimately the heart, will then relax as calcium is pumped back into the SR.

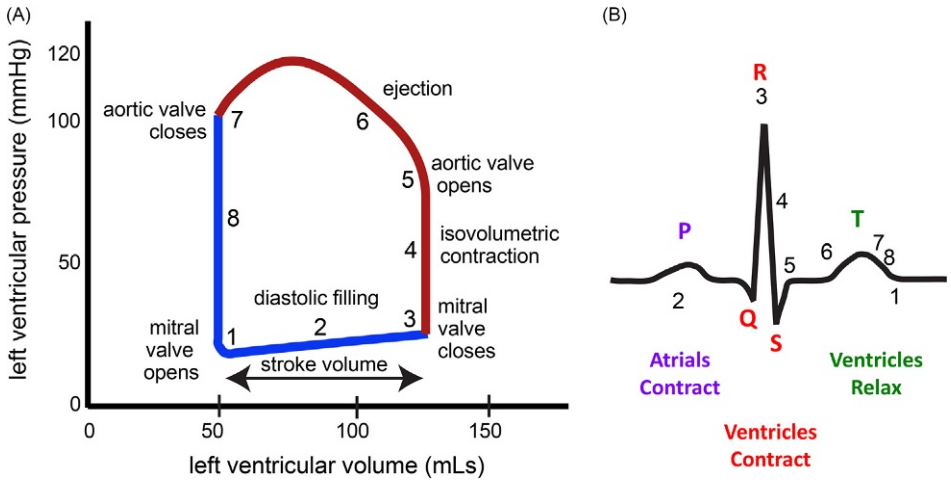

Fig. 1 Pressure–volume relationship of the human heart. (A) The pressure–volume relationship of the left ventricle creates a loop as the heart fills (1–3) and ejects (5–7) blood during a contractile cycle. Systolic pressure (*red*), measured in arteries, increases with inotropy (contractility) of the left ventricle as oxygenated blood is ejected from the heart; diastolic pressure (*blue*), also measured in arteries, occurs between contractility as the left ventricle is empty and filling with blood. Stroke volume is the amount of blood pumped from the left ventricle during a beat. Normal human left ventricular pressure and volume are shown. (B) An electrocardiograph (ECG) trace displays the electrical activity of the heart over a contraction. The numbers correspond to the left ventricle pressure–volume, while the letters represent the normal cardiac electrical deflections toward or away from electromagnetics measuring the electrical activity within the heart, which induces the contraction.

Measuring changes in the left ventricular (LV) volume and the cardiac output (CO) is based on the stroke volume (SV) and heart rate (HR), which is related by:

$$CO = HR^{*}SV$$

The ability of the heart to eject blood, through the SV, at a given afterload and preload describes heart contractility (Katz, 1939). The afterload relates to arterial pressure and affects the end-systolic volume (ESV), and extent of cellular shortening, whereas the preload relates to an end-diastolic volume (EDV). The pressure/volume relationship is described in terms of pressure–volume loop analysis (Fig. 1). The CO is also related to volume as:

$$CO = HR(EDV - ESV)$$

The CO is therefore dependent on the contractility properties of the individual, and aggregate, of the cardiomyocytes. The strength of the systolic contraction is directly proportional to its diastolic expansion as first described by Ernest Starling, stating:

> *The greater the length of the fibre, and therefore the greater amount of surface of its longitudinal contractile elements at the moment when it begins to contract, the greater will be the energy in the form of contractile stress set up in its contraction, and the more extensive will be the chemical changes involved. This relation between the length of the heart fibre and its power of contraction I have called 'the law of the heart'* (Starling, 1920).

Starling essentially stated that the SV of the heart increases in response to an increase in heart's end-diastolic length, which subsequently will increase EDV in a normal heart caused by increase in the blood volume while filling the heart when other factors remain constant. Otto Frank investigated isometric and isotonic contractility of the heart, which was a precursor and contributed to Starling's work.

The Frank–Starling law of the heart is typically graphed with EDV along the X-axis and CO along the Y-axis (Fig. 2). During the filling of the heart with blood, the ventricular walls stretch that leads to a more powerful ejection fraction (EF). The EF is defined as the EDV that is ejected out of the ventricle during a contraction and is mathematically defined as:

$$EF = SV/EDV$$

An increase of blood volume increases the EDV and SV. This length–tension relationship between the fiber length and force produced is typically studied in the laboratory with isolated cardiac cells or myofibrils and can be clinically examined in a number of ways including echocardiogram, magnetic resonance imaging, and computerized tomography.

The amount of active tension developed in cardiac muscle is known to be a function of preload. Active tension is influenced by the number of cross-bridges reacting with actin, which depends on sarcomere length. Changes in preload and sarcomere length also affect active tension by altering sensitivity of troponin C to calcium. The magnitude and rate of active tension is therefore influenced by the preload, which affects inotropy. The changes in inotropy alter the rate of force and pressure development by the ventricle and influence the ejection velocity. The effects of inotropy are described in terms of a force–velocity relationship. The force–velocity relationship describes the relationship between external work and shortening velocity (Katz, 1939; Brutsaert and Sonnenblick,

1969). Essentially, the greater the external load applied on the muscle, the slower the rate of shortening. And likewise, an increase in velocity at any given preload results from increased inotropy and increases force generation by the actin and myosin cross-bridge binding state and turnover.

In review of the structure–function relationship of the heart, it is very evident that the individual cardiomyocytes and myofilaments are the critical components necessary in normal function of the heart.

Cardiomyocyte Structure and Function

Cardiomyocytes are specialized muscle cells with the function of contracting, thus causing the heart to pump blood through the body. Approximately 70% of the proteins within a cardiomyocyte are composed of three types of myofilaments: thick, thin, and elastic (Katz, 2010). The myofilaments are neatly organized within sarcomeres. Sarcomeres are systematically organized in series to form a myofibril and bundles of myofibrils in parallel to create the myocyte. The sarcomere structure is described in terms of lines and bands. The Z-lines (Z-disc) are a dense transverse network that serves as the anchorage site for the thin filaments, as well as the elastic protein titin. Titin extends from the Z-disc, binding to the thick filaments, myosin, to the M-line (middle line). The M-band cross-links myosins and titin. Between the Z-disc and the M-band, and closest to the Z-disc, is the I-band. The I-band (isotropic band) is the zone of thin filaments not interdigitated with thick filaments. The A-band (anisotropic band) is composed of closely packed myosin. Within the A-band is the H-zone, the region where thick filaments are not superimposed by thin filaments. Within the H-zone is the M-line. The thin and thick filament overlap, and their interaction allows for a contraction. During a contraction, the A-bands remain at approximately 1.65 μm in length, and the sarcomere (Z-disc to Z-disc) shortens from approximately 2.2 to 1.7 μm in a beating heart (Katz, 2010) (**Fig. 3**).

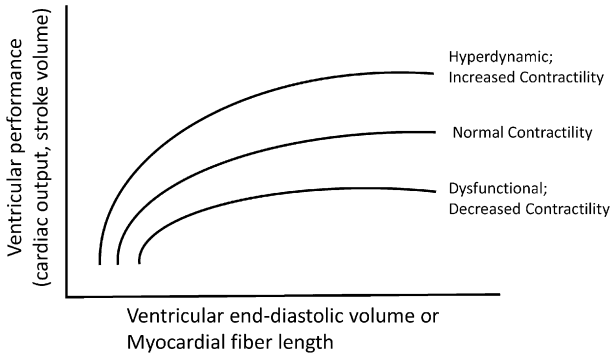

Fig. 2 Frank–Starling law of the heart summarized in graphical representation. As the heart fills with blood and increases the end-diastolic volume, the myofibrils within the cardiomyocyte lengthen and cause a more powerful contraction and ejection fraction.

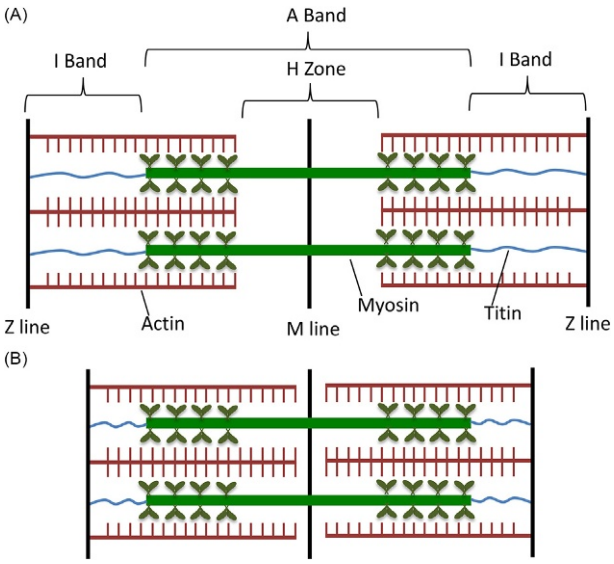

Fig. 3 Schematic of sarcomere in relaxed and contracted state. (A) The sarcomere is relaxed when calcium is not bound to Troponin C in the thin filament. (B) When calcium is bound to Troponin C, the tropomyosin reconfigures along the F-actin allowing for the myosin head in the thick filament to attach to the thin filament and form a cross-bridge. The myosin performs a power stroke and, in the aggregate, creates a contraction within the sarcomere.

The thin filaments in the heart are comprised of F-actin, nebulette, tropomyosin, and the troponin complex. Tropomyosin is positioned in a groove along and between the two actin strands (Solaro, 2011). The troponin complex consists of troponin C, troponin I, and troponin T and is clustered at approximately 400 Å intervals to each other, connecting the ends of the tropomyosin.

The thick filament is an aggregate of individual myosin molecules. Myosin is composed of two heavy chains and two light chains and discussed in terms of a tail and pair of heads. The tail is a coiled coil where the two myosin heavy chains are wound around each other. The heads consist of the globular region of one myosin heavy chain along with the two myosin light chains. The binding affinity between the troponin complex, tropomyosin, and actin is dependent on whether calcium is bound to troponin C. A contraction can proceed when calcium binds to troponin C.

For calcium to bind to troponin C, the depolarization of the cell membrane occurs, triggering an action potential with a less negative value inside the cell membrane compared to the outside. The change in action potential along the cellular membrane is typically modeled with five phases (Carmeliet and Vereecke, 2002). The voltage-gated calcium channels are typically triggered by an influx of sodium, with a potassium equilibrium potential precursory to the sodium influx. The calcium that enters the cardiomyocyte induces calcium release from stored calcium within the SR. Ultimately, calcium then binds to troponin C triggering a contraction.

For a contraction to occur, energy is also necessary. The mitochondria are primarily responsible for providing the energy for cells to function, governed through the synthesis of ATP via the Krebs cycle. Muscle cells, cardiac in particular, require a very large amount and constant supply of ATP. Therefore, cardiomyocytes require a high content of mitochondria, which has been measured as 30% of normal adult cardiac cell volume (Eisenberg, 1983; Piquereau et al., 2013). The constant supply of energy allows for sarcomeres within the cardiomyocyte to contract.

The force generated during the contraction within the cell is transmitted externally via the mechanical linkages from cell-to-cell ends at the intercalated discs. Additionally, force is transmitted laterally by the costameres at the Z-disc located at the peripheral cell membrane (Samarel, 2005). The focal adhesion complex plays an important role in attaching a cell to the extracellular matrix (ECM) (LaNasa and Bryant, 2009; Samarel, 2005). The complex additionally connects myofibrils to the membrane and serves as a mediating site for relaying external and internal forces and intracellular signaling (Kaprielian et al., 2000). The focal adhesion complex is built upon signaling from a focal adhesion kinase (FAK) where phosphorylation initiates a cascade of protein signaling (Samarel, 2005); it is also through FAK that cellular motility is controlled (Mitra et al., 2005). When the complex is mature, the focal adhesion serves as a strong anchorage site and hub for force absorption and transmission within the cardiomyocyte.

To understand cellular mechanics, structural engineering is applicable. Basic structural mechanics relies on three primary aspects to describe a body: the static equilibrium, the stiffness, and the compatibility conditions (Heyman, 2008). The static equilibrium is based on a body's internal structure equilibrium, from forces and moments, with respect to the external load acting on the system. The stiffness is based on the body's elastic deformation properties, such as internal tension and compression, defined by Young's Modulus (stress over strain). This leads to the compatibility conditions, which are the balance between a body's static equilibrium with an external load and its internal stiffness properties, described by surface stress and surface tension. These structural engineering principles apply to all cells but are demonstrated here in cardiomyocytes.

Using advanced imaging and analysis techniques, the cellular mechanics are subdomain regulated (Curtis et al., 2013; Broughton and Russell, 2015), and cardiomyocyte contractility has variation down to the individual sarcomere within the myofibril (Jacot et al., 2008; Chapin et al., 2014). The myofibrils are anchored to the substrate through the combination of focal adhesions, costameres, and ECM ligands (Samarel, 2005; Petit and Thiery, 2000). The substrate represents a static load, and therefore external force, acting against a deformable elastic body, the myocyte. The myocyte will then internally respond to counterbalance this load and stabilize through its own deformation properties within the mechanotransduction proteins, such as the focal adhesion protein paxillin. To explain this concept mathematically, one should first turn to Maxwell's reciprocal theorem that states:

$$\nabla_{ij} = \nabla_{ji}$$

This theorem provides that when an elastic structure is subjected to a force applied in a specific direction at location i, an elastic deflection occurs a distance ji. Similarly, an elastic deflection ij results from a force applied at location j (Yang, 2005; Heyman, 2008). This essentially provides that force symmetry occurs at the matrix of elastic flexibility coefficients. However, as evidenced from line scan and traction force analyses, the contractility properties are unique at each individual point within the cell to balance the internal forces to the external static load. This principle, therefore, leads to the recognition that the myocyte and its contractility are mechanically anisotropic.

Anisotropic elasticity is based on the basic concept that properties are not similar throughout an entire object (Patnaik et al., 1999). In the theory of linear elasticity, stress is a measurement of the intensity of force and measured in force per unit area. Cardiomyocyte function is found to be directionally dependent, and therefore, plane stress is defined in tensor notation, such that:

$$\sigma_{ij} = \begin{bmatrix} \sigma_{xx} & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & \sigma_{yy} & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & \sigma_{zz} \end{bmatrix}$$

The static equilibrium described using tensor notation to define normal and shear stress is evident within cardiomyocytes configured in 2D, with a flat substrate, or 3D, with a microtopography substrate, surface; the static equilibrium is further regulated

by the stiffness of the substrate, which influences the external load. This leads to the discussion of cellular stiffness based on elastic deformation.

The stiffness of the cell is described in terms of the elastic deformation properties and may be described in terms of tension. The active tension in the cell is generated by the interaction between actin and myosin, which is a dynamic system that continually changes during each individual contraction (Granzier and Irving, 1995). Active tension behaves under an oscillating frequency with each cellular contraction and undergoes both a tensile force at the focal adhesion sites and a compressive force in the myofibril centroid during shortening in each contraction. If adjacent myofibrils do not synchronously contract, these asynchronized myofibrils will also experience a shear force during the cycle. This active tension cycle is based on a strain since it is a length change along the myofibril. To mathematically explain this principle, strain is also defined in tensor notation, such that:

$$\varepsilon_{ij} = \begin{bmatrix} \varepsilon_{xx} & \gamma_{yx} & \gamma_{zx} \\ \gamma_{xy} & \varepsilon_{yy} & \gamma_{zy} \\ \gamma_{xz} & \gamma_{yz} & \varepsilon_{zz} \end{bmatrix}$$

Each strain displacement of any point within the system is related by the differential subparts of the normal and shear components of the plane, denoted by:

$$\varepsilon_x = \frac{\partial u}{\partial x},\ \varepsilon_y = \frac{\partial v}{\partial y},\ \varepsilon_z = \frac{\partial w}{\partial z}$$

$$\gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x},\ \gamma_{xz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x},\ \gamma_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}$$

Whereas u, v, and w are the displacement components of the body, or cell, as described in this model. The use of tensor notation to describe the strain within the cell is also applicable in summation with the passive or resting tension to describe cellular stiffness as total tension (Granzier and Irving, 1995).

Passive or resting tension is a steady-state system that may increase overtime to counterbalance the load acting upon the cell. This passive tension is related by the shortening velocity and the stress development within the cardiomyocyte (Katz, 1939; Granzier and Irving, 1995). This static load in combination with the dynamic load caused from contractility leads to the total tension and force generation with the cell. It is from the balance of forces generated within the cell to respond to the accumulation of internal and external loads that the conditions of compatibility must be satisfied.

In structural mechanics, the balance of external and internal forces of a body is related by three equilibrium equations and three compatibility conditions (Yang, 2005). This balancing of external and internal forces is evident in all cell types including, but not limited to, neurons, adipose, bone, and muscle cells, as cells respond to the forces caused by the stiffness of the surrounding microenvironment (Discher et al., 2005; Hazeltine et al., 2012; Hersch et al., 2013). This balancing and internal response to external cues is so critical that stem cell differentiation can be directed down certain lineages just by modification to the stiffness of the external microenvironment (Engler et al., 2006). The compatibility conditions to describe the balance of forces within a body are exceptionally complex; and Saint-Venant mathematically determined how to solve for the compatibility conditions by relating such conditions to tractions along the boundary of the body (Yang, 2005; Patnaik et al., 1999).

Saint-Venant's principle essentially states that when a localized stress distribution occurs in response to the immediate region of the load, an essentially equivalent stress will occur at a distance from this localized stress to counterbalance the forces (Yang, 2005; Heyman, 2008). It was from the manipulation of complex equations representing conditions of compatibility into easier, solvable terms using tractions along the boundary of a body that this third element of structural mechanics is solved for real-world problems. These tractions define boundary conditions of a three-dimensional body consist of surface stress and surface tension that stabilize the body (Patnaik et al., 1999). Applying boundary conditions to an elastic body, such as a cell, the results are experimentally found using traction force microscopy techniques. Although some labs have referenced a bead displacement as a readout of sarcomere shortening within the cell (Hazeltine et al., 2012; Broughton and Russell, 2015), the line scan is a direct measurement of sarcomere shortening. The bead displacement is better applied to solve for boundary conditions of the cell and defines such balancing of subdomain forces between the cell and the substrate surface.

Surface stress of a solid is defined as the amount of reversible work per unit area to elastically deform a surface (Gurtin and Ian Murdoch, 1978). It is from this balance of force described in terms of surface stress why previous research, correctly, indicated cells demonstrate a stress response to increased substrate stiffness (Discher et al., 2005; Patnaik et al., 1999; Hazeltine et al., 2012; Hersch et al., 2013). To complete the discussion of boundary conditions, the surface tension is complementary to surface stress.

Surface tension of solids is not well understood or scientifically described in comparison to the surface tension of fluids (Style et al., 2013). Surface tension is a measurement of force per unit length or energy per unit area. Historically, surface tensions of solids were not studied in depth because the force generated by surface tension of a solid was considered negligible. However, recent research is demonstrating the importance of surface tension for soft elastomer solids (Style et al., 2013). It is from this combined analysis of the surface stress, forces per unit area, and surface tension, force per distance, that demonstrate the overall cellular compatibility conditions demonstrating a balance of the extrinsic to intrinsic loads imposed upon and within the local microenvironment of the cell.

The intricate details of each protein structure and its function within the cardiomyocyte are critical to the proper functioning of individual contractions within each sarcomere along the myofibrils of each cardiomyocyte and, in the aggregate, the heart. It is when

a primary mechanism—mechanical, chemical, or genetic—strays from the normal state in which a cellular dysfunction occurs, resulting in a cardiac myopathy.

Cardiac Dysfunction

Cardiomyopathies and Heart Failure

Environmental stress, disease, genetics, and age that lead to pathophysiology of heart failure are common in human populations. Some common cardiovascular conditions such as myocardial infarction (MI), valvular heart disease, and systemic hypertension may lead to secondary changes, collectively known as "remodeling," in response to abnormal mechanical forces working against otherwise normal cardiomyocytes. In the aggregate, cardiomyocyte remodeling may lead to alterations in the interstitial matrix, chamber enlargement, abnormalities of systolic and diastolic pump function and myocyte concentric or eccentric hypertrophy, arrhythmia and necrosis (Pfeffer et al., 1991).

Congestive heart failure is most likely caused by ischemia, with earlier reports stating 20% of all failures (Manolio et al., 1992) to more recent reports of 60% (He et al., 2001). Additionally, systemic diseases, such as metabolic derangements, toxin exposures, and genetic disorders, may additionally affect cardiac function resulting in a cardiomyopathy (Felker et al., 2000). These causes leading up to heart failure, particularly in the left ventricle, have myocyte hypertrophy, fibrosis deposition, and LV chamber enlargement. Abnormalities to the systole, diastole, or both functions contribute to the dysfunction leading to such heart failure. These failures can be based on single point mutations within the myofilament proteins (Tartiff, 2005).

When the heart responds to a MI, chamber remodeling occurs. The left ventricle is particularly prone to experience the brunt of remodeling and can undergo immediate contour changes as a result of thinning and elongation of the region affected by the regional ischemia inducing myocardial necrosis. During the critical initial minutes of a MI, when acute ischemia progresses to necrosis, regional systolic dysfunction sets in. Once cell death occurs, particularly if the MI and cell death involved the ventricular apex region, there is likelihood for infarct expansion (Colan et al., 1992). As a whole, infarct expansion causes regional stretching and thinning of the ventricle wall until the connective tissue within the infarcted region provides sufficient resistance to oppose further deformation (Colan et al., 1992). At the individual cardiomyocyte level, the cardiomyocyte will remodel with an increase of sarcomeres in series along the myofibrils to create elongated myocytes due to the stretching of the ventricle wall (Pangonytė et al., 2008).

During ventricle remodeling and expansion as a result of infarction or lack of sarcomeric contractractility, the apex radius increases causing increased wall stress and wall tension on the remaining myocardium, leading to the likelihood of further cavity enlargement and shape distortion (Jugdutt and Michorowski, 1987). This phenomenon, known as dilated cardiomyopathy, can be mathematically described using the Law of Laplace. Using this theory, the wall stress and wall tension increases proportionately to the increased apex radius. The changes in wall thickness of the heart that lead to a myopathy may be hypertrophic, evident by an increase in absolute wall thickness, or dilated, evident by an increase in radius with no change or thinning in wall thickness (**Fig. 4**). As a result there is an increased volume of blood pumped into the left ventricle, causing an increased pressure/volume relationship.

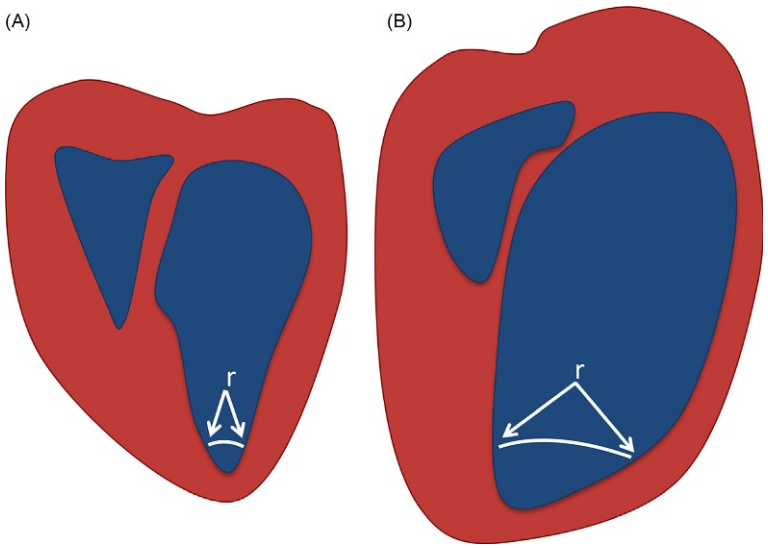

Fig. 4 Interpretive drawing of normal and dilated left ventricle. (A) A normal heart with smaller apex. (B) Infarct expansion due to remodeling affecting the apex region of the left ventricle, resulting in increased apex radius, increased wall stress and wall tension on remaining myocardium and likelihood of further cavity enlargement and shape distortion. Mathematically, using the Law of Laplace, the wall stress and wall tension increases proportionately to this increased radius. Interpretation based on Pfeffer et al. (1991).

It is in the weeks to months after the infarction that the extent of damage caused by the MI can be assessed regarding regional remodeling and months to years to assess the damage of the infarct expansion and the global heart enlargement (Pfeffer et al., 1991; Gaudron et al., 1993).

When a cardiomyopathy is present, the blood supply does not meet the oxygen demand. This failure to eject blood against the load acting upon it relates to the ventricular wall stress (σ) and aortic pressure, or afterload, and therefore cardiomyocyte shortening. The Law of LaPlace essentially states that wall tension (surface tension) is proportionate to the pressure multiplied by radius for thin-walled spheres or cylinders. Transcribing this law in application of the heart, this relationship is known as:

$$T \propto \frac{P \cdot r}{2}$$

where T = ventricular wall tension, P = ventricular pressure, r = ventricular radius. Wall stress is wall tension divided by wall thickness and the geometric shape of the ventricle affects the wall stress, thus wall stress is defined as:

$$\sigma \propto \frac{P \cdot r}{2h} = \frac{T}{h}$$

where σ = ventricular wall tension and h = ventricular wall thickness. Under the assumption of constant pressure, in cases of a thickened wall, or hypertrophied ventricle, the wall stress and afterload are reduced, whereas in the cases of an increased ventricular radius, or dilated ventricle, the wall stress and afterload increase. The increase of aortic pressure, and therefore increase in afterload, causes an ESV increase that leads to a decrease in SV and eventual heart failure and can again be described in terms of pressure volume loops (**Fig. 5**). This tension relationship describes both the hypertrophic and dilated cardiomyopathy heart condition, and cardiac function can be predicted at the cellular level (Davis et al., 2016). Using human-induced pluripotent stem cells derived into cardiomyocytes (hIPS-CMs), researchers can predict if experimental pharmacological treatment serves as a potential therapeutic intervention to treat patients with hypertrophic and dilated cardiomyopathy caused by protein mutations (Matsa et al., 2011; Zhang et al., 2014; Broughton et al., 2016). The mechanics of cardiac function and dysfunction at the organ, cellular, and molecular levels are extremely complex and continue to hold exceptional importance in one of the most relevant human diseases in the 21st century.

Heart Failure Clinical Relevance

In the United States, about 5.1 million people suffer from congestive heart failure, and such failure is a contributing cause of death for one in nine people (Go et al., 2014). The cost of congestive heart failure is an estimated $32 billion every year, which includes the cost of health care services, medications to treat heart failure, and missed days of work (Heidenreich et al., 2011). However, the direct and indirect costs of heart disease per year in the United States total $207.3 billion dollars in 2011–12 and remain the leading cause of death (Mozaffarian et al., 2015). Globally, heart disease is the number one cause of deaths per year, and the trend is expected to continue (Mozaffarian et al., 2015). There is, therefore, a strong need to better understand, prevent, and treat heart disease and heart failure.

The survival after clinical diagnosis of congestive heart failure in the Framingham Heart Study was found to be 3.2 years for men and 5.4 years for women (Ho et al., 1993). For clinicians to classify the severity of the congestive heart failure and better treat the patient, the degree of functional impairment conferred by the abnormality may be utilized as defined by the New York Heart Association (NYHA) Functional Classification system (Fleg et al., 2000). Using the NYHA Functional Classification System, studies have shown that individuals with class IV congestive heart failure, compared to those without any congestive heart failure diagnosis,

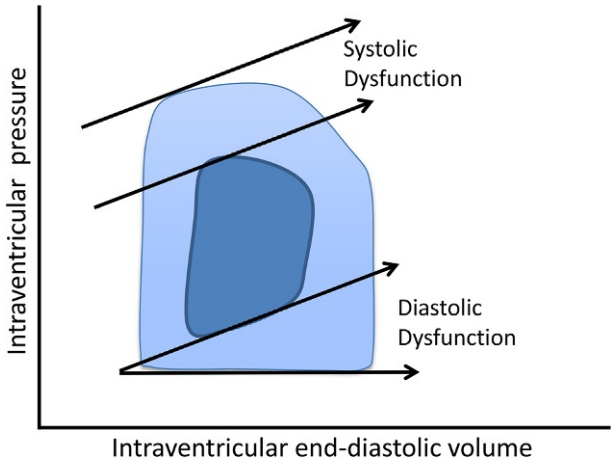

Fig. 5 Pressure–volume relationship of the failing heart. The pressure–volume relationship of the heart is compromised after dilated cardiomyopathy. Inotropy decreases as the pressure volume shifts to the right. Systolic dysfunction occurs when the left ventricle cannot properly contract to eject blood. Diastolic dysfunction occurs when the ventricles do not properly relax, eventually causing stiffness and incapability to fill with blood.

have a 27% survival rate within 3 years of class IV diagnosis (Califf et al., 1982). These example statistics demonstrate the overwhelming burden and need for researchers to study mechanisms leading to systolic and diastolic dysfunction of the heart. It is in further understanding the molecular and cellular form–function relationships that a better appreciation of cardiac mechanics is achieved. With recognizing these small but powerful genetic and environmental influences on the function of the heart, more impactful therapeutic interventions to prevent, diagnose, and treat heart disease will integrate into the healthcare of people.

Glossary

Collagen volume fraction Quantification of the area occupied by collagen as percent of total area, commonly determined in tissue sections by staining for fibrillar collagen.
Endomysium Layer of connective tissue surrounding each muscle fiber.
Epicardial-derived cells Cells arising from the embryonic epicardium that include cardiac fibroblasts, vascular smooth muscle cells, and pericytes.
Epicardium Mesothelial covering of the heart that during development contains cardiac fibroblast and coronary vascular smooth muscle cell progenitors.
Fibrocyte Cell that expresses both leukocyte and mesenchymal cell markers.
Fibrosis Excess deposition of extracellular matrix resulting in scarring and thickening of tissue.
Hypertrophy Increase in either heart size or cardiomyocyte size in the absence of proliferation.
Matricellular proteins Secreted proteins that interact with ECM to regulate cell function without directly contributing to the organization of ECM.
MicroRNA A small and highly conserved noncoding RNA that regulates gene expression.
Myofibroblast A fibroblast that expresses contractile actin filaments most commonly identified by smooth muscle actin alpha (αSMA) expression.
Perimysium Layer of connective tissue surrounding each muscle fascicle.
Pressure overload Experimentally, constriction of the transverse aorta to impose hypertrophy and fibrosis in the left ventricle and pathological condition where heart must contract in the presence of excessive afterload.
Reactive fibrosis Deposition of extracellular matrix without significant cardiomyocyte loss.
Remodeling Modification, deposition, and degradation of ECM.
Replacement fibrosis Deposition of extracellular matrix to compensate for the loss of cardiomyocytes most commonly after myocardial infarction.

Introduction

Fibroblasts are mesenchymal cells that secrete extracellular matrix (ECM) macromolecules. Within the heart ventricles, atria, and septum, the cardiac fibroblast is the cell responsible for ECM production. Under normal physiological conditions, cardiac fibroblasts are thought to regulate ECM homeostasis by producing, degrading, and organizing collagen, processes that are essential for proper heart function. In addition to controlling ECM, fibroblasts secrete cytokines, growth factors, and proteases. Under pathological conditions and during aging, cardiac fibroblasts proliferate, become activated, and produce components of the ECM including collagens and proteoglycans. Collectively, these events are termed cardiac fibrosis. When ECM-producing fibroblasts persist, fibrosis expands and leads to cardiac dysfunction. Cardiac fibrosis occurs in most forms of heart disease and is an important determinant for progression to heart failure (Querejeta et al., 2004; Berk et al., 2007; Hutchinson et al., 2010). Fibrosis remains a major concern of heart disease, and the importance of the fibroblast in cardiac pathology is apparent as we learn more about the functions of this cell. In this article, we summarize current concepts regarding the cardiac fibroblast including their origins and roles in normal heart function and fibrosis. We will also discuss potential therapeutic strategies for reducing fibrosis that target cellular pathways associated with fibroblast activation and ECM remodeling.

Characteristics of the Cardiac Fibroblast

The heart is composed of many different cell types including cardiomyocytes, fibroblasts, smooth muscle cells, pericytes, and endothelial cells (Nag, 1980; Camelliti et al., 2005a). Although much of our current knowledge of the cardiac fibroblast is from in vitro systems and animal models of heart stress and injury, in this section, we focus on the identification and function of the fibroblast in the uninjured heart.

Cardiac Fibroblast Identity

Resident fibroblasts

At the center of many of the uncertainties regarding cardiac fibroblasts is the relative difficulty in clearly distinguishing them from other cell types, such as pericytes and macrophages. Traditionally, cardiac fibroblasts have been defined as cells that are derived from embryonic mesoderm and embedded within the fibrillar collagen matrix of the heart (Kanekar et al., 1998; Chang et al., 2002; Goldsmith et al., 2004). Fibroblasts have a flat spindle-shaped morphology, a highly developed rough endoplasmic reticulum, the abundant cytoplasmic granules, and a heterochromatic, oval nucleus (Nag, 1980; Camelliti et al., 2005a). At the ultra structural level, the main distinction between a fibroblast and a pericyte is that the pericyte resides next to a capillary (Nag, 1980). While characterizing a fibroblast by electron microscopy can be informative, more practical approaches have been adopted for routine identification.

A variety of markers has been used to identify the cardiac fibroblast by immunohistochemistry, in situ hybridization, and flow cytometry, although few of these markers are specific to the cardiac fibroblast (**Table 1**). Identification of the fibroblast can be accomplished by detection of proteins that are enriched in fibroblasts combined with specific markers that permit the exclusion of other cell types. As one of the defining features of a fibroblast, production of collagen types I and III can be used to distinguish fibroblasts from other cells (Weber, 1989; Eghbali et al., 1989a). But because these are secreted proteins, detection is limited to

Table 1 Markers of cardiac fibroblasts

Cardiac fibroblast markers	*Human gene(s)*	*Function*	*Location*
Collagen type I	*COL1A1*, *COL1A2*	Matrix protein	Extracellular
Collagen type III	*COL3A1*	Matrix protein	Extracellular
Discoidin domain receptor tyrosine kinase 2	*DDR2*	Receptor tyrosine kinase for collagen	Surface (low)
Lysyl oxidase, lysyl oxidase homolog 2	*LOX*, *LOXL2*	Collagen cross-linking enzyme	Extracellular
Vimentin	*VIM*	Intermediate filament protein	Intracellular
Platelet-derived growth factor receptor alpha	*PDGFRA*	Receptor tyrosine kinase for PDGF	Surface
Prolyl 4-hydroxylase	*P4HA1*, *P4HB*	Collagen-modifying enzyme	Intracellular
Tcf21	*TCF21*	Transcription factor	Intracellular
Activated cardiac fibroblast/myofibroblast markers	*Human gene*	*Function*	*Location*
Fibronectin ED-A	*FN1*	Matrix protein, alternative splice variant of fibronectin 1	Extracellular
Smooth muscle alpha-actin	*ACTA2*	Actin molecule in contractile cells	Intracellular
Periostin	*POSTN*	Matrix protein	Extracellular

Listed are proteins used to identify fibroblasts. Many are expressed by other cells, such as lymphocytes, smooth muscle cells, and endothelial cells. Detection and specificity may vary from species to species.

either in situ hybridization (Bing et al., 1997; Smith et al., 2011), staining for intracellular collagen pro-proteins (Zhou et al., 2010), or single-cell RNA expression analysis (Kanisicak et al., 2016). Expression of other proteins involved in collagen production and assembly, such as prolyl 4-hydroxylase or lysyl oxidase, not only is used less often but also may identify fibroblast populations (Gonzalez-Santamaria et al., 2016; Yang et al., 2016).

There are several other commonly used fibroblast markers. Vimentin is an intermediate filament protein that can be used for cardiac fibroblast identification (Camelliti et al., 2004b, 2005a,b; Kanisicak et al., 2016). Platelet-derived growth factor receptor α (PDGFRα) is a receptor tyrosine kinase that is expressed by cardiac fibroblasts during development and in the adult heart (Smith et al., 2011; Moore-Morris et al., 2016; Kanisicak et al., 2016; Ieronimakis et al., 2013). Discoidin domain receptor 2 (DDR2), a transmembrane receptor involved in collagen maturation, has also been used to detect cardiac fibroblasts (Goldsmith et al., 2004; Camelliti et al., 2005a; Vogel et al., 1997) but is also expressed by leukocytes (Goldsmith et al., 2004). Other markers that have been used to identify cardiac fibroblasts include surface antigens recognized by MEFSK4 (Pinto et al., 2016), Thy1 (CD90) (Ali et al., 2014), Sca1 (Ieronimakis et al., 2013), and Fsp1 (Zeisberg et al., 2007). These markers not only may identify a subset of cardiac fibroblasts but also are expressed by immune and/or endothelial cells (Pinto et al., 2016; Holmes and Stanford, 2007; Raff, 1971; Jurisic et al., 2010; Kong et al., 2013).

Activated fibroblasts and myofibroblasts

Smooth muscle alpha-actin (αSMA) is the definitive marker for the activated cardiac fibroblast population known as the myofibroblast (Frangogiannis et al., 2000), but this actin isoform is also abundant in vascular smooth muscle cells (Skalli et al., 1989). Upon activation, fibroblasts switch fibronectin isoform usage to the extra domain A isoform, and there are antibodies that can bind specifically to this isoform (Santiago et al., 2010; Serini et al., 1998). More recently, periostin expression has been demonstrated to be uniquely upregulated in fibroblasts responding to heart injury (Kanisicak et al., 2016; Kaur et al., 2016).

In the mouse, genetic tools have been developed to follow fibroblasts (reviewed in Swonger et al., 2016). Genetically engineered mice using cis-regulatory elements for collagen 1a1 (Yata et al., 2003), 1a2 (Zheng et al., 2002), PDGFRα (Hamilton et al., 2003), Tcf21 (Acharya et al., 2012), and periostin (Kanisicak et al., 2016; Kaur et al., 2016; Takeda et al., 2010) provide means for identifying and tracing the cardiac fibroblast lineage in vivo (see **Fig. 1**), but use of these mouse lines requires additional breeding and can be time-consuming.

As characterization of the cardiac fibroblast improves, identification of additional fibroblast-specific genes is likely to occur. Until then, the use of multiple markers is advised to distinguish fibroblasts from other cellular populations in the heart.

Cardiac Fibroblast Number

Early studies using transmission and scanning electron microscopy determined that nonmyocytes constitute 70% of the cells in adult rat heart (Nag, 1980; Zak, 1974). These studies used location and morphology to classify the cell types and did not report the relative number of fibroblasts. Later studies using flow cytometry and histology comparing fibroblast content in mouse and rat hearts found that the relative numbers of cardiomyocytes and nonmyocytes differ depending on the species, age, gender, and fibroblast markers used (Banerjee et al., 2007; Moore-Morris et al., 2016; Camelliti et al., 2004a). Recently, studies in the mouse and

human have refined our understanding of the relative numbers of fibroblasts in the heart. Using a combination of flow cytometry, histology, and reporter mouse lines to identify resident fibroblast populations, the number of fibroblasts within the mouse heart was found to be 10%–12% (Pinto et al., 2016), a number that is substantially lower than previous estimates (Banerjee et al., 2007). Similar analyses in the human heart, using immunohistochemistry and flow cytometry to identify cardiomyocytes and endothelial cells, estimated that the percent of mesenchymal cells ranges from 20% to 58% depending on the identification method (Pinto et al., 2016; Bergmann et al., 2015).

Cardiac Fibroblast Distribution

Despite the proposed role for fibroblasts in maintaining the ECM of the heart, details are lacking regarding the location and dynamics of the fibroblast population. Most studies have investigated regional fibroblast density after heart injury, but few studies have examined fibroblast location in the healthy heart, possibly due to inability to clearly distinguish fibroblasts from other cell populations. In the heart, fibroblast density varies depending on the region. The highest concentrations of fibroblasts can be found in the valves, annulus fibrosus (Opthof et al., 1987), and adventitia of the coronary arteries. Typically, the fibroblast population within the valves is referred to as valve interstitial cells or valvular fibroblasts. Due to their anatomical location, these cells are unlikely to play a role in ventricular fibrosis. However, some heart dissociation protocols for isolation and culture of cardiac fibroblasts may include contamination by this cell population. The densely organized fibroblasts found around the sinoatrial node (Shiraishi et al., 1992; Keith and Flack, 1907) and in the annulus fibrosus are essential for insulating the electric impulses of the conduction system (Kolditz et al., 2008). In coronary vessels, fibroblasts comprise the majority of the cells in the collagen-rich adventitia, but several other cell populations also reside in this space (reviewed in ATVB Majesky, 2015).

Little is known about the relative density and distribution of interstitial cardiac fibroblasts. Located between muscle fibers, these solitary cells are spindle shaped with long filopodia (Goldsmith et al., 2004) that contain no stress fibers (Tomasek et al., 2002). Connexin-40 positive gap junctions can be observed between cardiac fibroblasts (Camelliti et al., 2004b). One report showed fibroblasts in close apposition to the heart capillary network (Bowers et al., 2010), but a distinction between fibroblast and pericyte was not made. A population of fibroblasts has also been described that is tightly associated with cardiomyocyte fibers (Nag, 1980), and occasionally, connexin-45 positive gap junctions have been observed between fibroblasts and cardiomyocytes (Camelliti et al., 2004b).

Cardiac Fibroblast Developmental Origins

Resident cardiac fibroblasts arise from two developmental sources, the epicardium and the endocardial cushions. Classic studies in the avian system used fate mapping to show that many fibroblasts originate from the proepicardial organ. These progenitor cells migrate over the heart tube forming the embryonic epicardium. Between embryonic days 12 and 14, a subset of these cells invades the atrial and ventricular myocardium after undergoing an epithelial-to-mesenchymal transition (EMT). Epicardial-derived cells differentiate into vascular smooth muscle cells and fibroblasts that are interspersed throughout the myocardium and also surround the coronary vessels (Perez-Pomares et al., 2002; Snider et al., 2009; Gittenberger-de Groot et al., 1998; Mikawa and Gourdie, 1996; Dettman et al., 1998). More recently, several groups have identified a population of fibroblasts arising from the endocardial cushions. These endocardial-derived fibroblasts constitute a portion of fibroblasts that reside in the ventricular septum and right ventricle (Moore-Morris et al., 2014; Ali et al., 2014). Despite distinct developmental origins, these two fibroblast populations have similar gene expression patterns and proliferation rates after pressure overload (Moore-Morris et al., 2014; Ali et al., 2014).

While many genes play crucial roles in epicardial formation and EMT (Krainock et al., 2016; von Gise and Pu, 2012), only two genes have been identified that are required specifically for ventricular fibroblast formation. When PDGFRα expression is disrupted in epicardial cells during embryonic development, ventricular fibroblasts fail to develop (Smith et al., 2011; Rudat et al., 2013; Acharya et al., 2012). Similarly, hearts lacking the bHLH transcription factor, Tcf21, have a deficiency in cardiac fibroblasts (Acharya et al., 2012). The importance of these two genes was observed in the epicardial-derived cardiac fibroblasts, but it remains to be determined if the endocardial-derived fibroblast population is also disrupted in the absence of these genes.

Additional Putative Sources of Fibroblasts

In addition to the two resident fibroblast populations, several other cell types have been identified that contribute to the fibrotic process after injury. These sources include pericytes (Kramann et al., 2015; Henderson et al., 2013), epicardial cells (Zhou and Pu, 2011; Duan et al., 2012; van Wijk et al., 2012), endothelial cells (Zeisberg et al., 2007; Widyantoro et al., 2010), and fibrocytes or circulating hematopoietic cells (van Amerongen et al., 2008a; Haudek et al., 2006, 2010; Bucala et al., 1994; Sopel et al., 2012; Lei et al., 2013; Mollmann et al., 2006). The estimated participation of each of these cell populations varies from 3% to 10% depending on the fibroblast source, injury type, and method of quantification (Zeisberg et al., 2007; Haudek et al., 2006; Crawford et al., 2012). Although it is definite that cells other than resident fibroblasts play important roles in the fibrotic process, it is less clear if all of these sources of fibroblasts have a significant role in ECM production after injury. Several recent studies using parabiosis, bone marrow chimeras, lineage tracing, and single-cell RNA sequencing have suggested that resident cardiac fibroblasts account for the majority of ECM production in the heart after injury (Ali et al., 2014; Moore-Morris et al., 2014; Ruiz-Villalba et al., 2015; Banerjee et al., 2007; Guimaraes-Camboa et al., 2017; Kanisicak et al., 2016).

Cardiac Fibroblast Function

Function During Homeostasis

The heart, unlike other organs, is in a constant state of relaxation and contraction, and the ECM provides structural integrity and scaffolding for cardiomyocytes, ensuring appropriate distribution of mechanical forces throughout the cardiac tissue. As cardiac fibroblasts are the major source of ECM components, it has been postulated that they monitor and regulate ECM by balancing ECM synthesis and degradation (Butt et al., 1995; Atance et al., 2004; Kandalam et al., 2011; Spinale, 2007; Petrov et al., 2002). Collagens (I, III, IV, V, and VI) constitute the majority of proteins in the space between the myofibers, with types I and III comprising 90% of the ECM content (Bashey et al., 1992b; Medugorac and Jacob, 1983; Weber, 1989). In the healthy heart, fibroblasts maintain a relatively slow turnover of fibrillar collagen (Bonnin et al., 1981; Laurent et al., 1978). Collagen fibers form by cross-linking facilitated by lysyl oxidases (LOXs) (Reiser et al., 1992; Robins, 2007). In addition to collagens, fibroblasts make a great number of other proteins required for ECM organization and cardiac signaling including fibronectin, elastin, laminins, fibrillins, glycoproteins, and proteoglycans (Speiser et al., 1992).

Fibroblasts reportedly control other essential processes such as angiogenesis, vascular homeostasis, and cardiomyocyte proliferation (Ieda et al., 2009; Zhao and Eghbali-Webb, 2001; Ubil et al., 2014). One way that fibroblasts communicate with cardiomyocytes, endothelial cells, and immune cells is by secretion of growth factors and cytokines. Fibroblast secretion of the proangiogenic factors fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) stimulates blood vessel formation upon injury (Murakami and Simons, 2008; Lavine et al., 2006). Matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) produced by fibroblasts also modulate neutrophil–endothelial cell adhesion and angiogenesis (Fernandez-Patron et al., 2001; Qi et al., 2003; Nikolova et al., 2012). Fibroblast-derived transforming growth factor-beta (TGF-β) and interleukin-6 (IL-6) signaling have been implicated in the regulation of myocardial function in both healthy and diseased hearts (Dobaczewski et al., 2011; Fredj et al., 2005). During development, fibroblasts secrete matrix molecules that activate beta-1 integrin on cardiomyocytes and regulate their proliferation (Ieda et al., 2009). As identification and classification of fibroblasts become more precise, so will our understanding of the basal functions of the resident cardiac fibroblast.

Function After Injury

While relatively few studies focus on the homeostatic role of the cardiac fibroblast, there is a significant amount of information regarding cardiac fibroblast behavior after injury. In general, fibrosis is divided into two categories, replacement or reparative fibrosis and reactive fibrosis. The former describes the process where ECM is deposited by cardiac fibroblasts to compensate for cardiomyocyte loss. Reactive fibrosis, on the other hand, is located in both the interstitium and adventitia and is generally not associated with immediate cardiomyocyte death. Fibroblasts undergo a phenotypic transition from a resting state to an activated state, predominantly characterized by increased ECM production. This activated fibroblast is often referred to as a myofibroblast, but recent data have suggested that identification of the myofibroblast using αSMA may underestimate the number of fibroblasts participating in the remodeling process (Moore-Morris et al., 2014). Other studies also suggest that cardiac fibroblasts can acquire additional distinct phenotypes described as proinflammatory and matrix-degrading phenotypes during the early inflammatory phase. In vitro studies suggest that interleukin-1 (IL-1), tumor necrosis factor-alpha (TNF-α), and oncostatin M may regulate the acquisition of distinct fibroblast phenotypes (Turner et al., 2009; Lafontant et al., 2006; Siwik et al., 2000).

Fibrotic remodeling permits the heart to adapt to mechanical, metabolic, and inflammatory stress, and the activated cardiac fibroblast has three main tasks: proliferation, secretion of growth factors and cytokines, and ECM deposition and remodeling. The location and duration of these activities depend on the underlying cause of fibrosis. Growth factors and cytokines (e.g., TNF-α, IL1-β, TGF-β, and platelet-derived growth factor (PDGF)), as well as mechanical stretch, have a demonstrated capacity to activate cardiac fibroblasts (Awad et al., 2010; Tyagi et al., 1998; Atance et al., 2004; Dobaczewski et al., 2011; Smith et al., 2011; Zhao et al., 2011; Ponten et al., 2005). Secreted factors, including profibrotic factors (TGF-β, angiotensin II, and endothelin-1 (ET-1)) (Leask, 2010; Yamamoto et al., 2000; Kulasekaran et al., 2009), mast cell-specific proteases (tryptase and chymase) (Zhao et al., 2008; Lu et al., 2012; Somasundaram et al., 2005), and PDGFs (Zymek et al., 2006), are also associated with regulation of fibroblast activation.

Fibroblast proliferation

Signaling pathways that direct fibroblast proliferation have been identified using both in vitro and in vivo methods. Some of the best understood cardiac fibroblast mitogenic signals occur after activation of G protein-coupled receptors, including β-adrenergic and angiotensin type I (AT1) receptors (McEwan et al., 1998; Turner et al., 2003; Schorb et al., 1993; Samuel et al., 2004). Receptor tyrosine kinase activation by PDGFs, insulin-like growth factor, and FGFs also regulates fibroblast proliferation (Ponten et al., 2005; Zhao et al., 2013; Yi et al., 2014; Samuel et al., 2004; Virag et al., 2007; Gallini et al., 2016; Olson and Soriano, 2009). Inflammatory cytokines have variable effects on fibroblast proliferation. For example, the proinflammatory cytokine IL-1β reduces cardiac fibroblast proliferation in vitro (Palmer et al., 1995). The role of IL-6 on fibroblast proliferation is less clear. Perinatal fibroblasts in IL-6 null hearts exhibit increased proliferation (Banerjee et al., 2009), while inhibition of IL-6 in vitro leads to decreased cardiac fibroblast numbers (Fredj et al., 2005). Interestingly, fibroblast proliferation is regulated not only by secreted factors but also by altered hormone production, such as relaxin and aldosterone (Samuel et al., 2004; Rombouts et al., 2001).

Inflammation

A delicate interplay exists between cardiac fibroblasts and immune/inflammatory cells. Regardless of the event initiating fibrosis, there are some common attributes of the fibroblast's role in inflammation (reviewed by Frieler and Mortensen, 2015; Epelman et al., 2015; Van Linthout et al., 2014). While it is assumed that fibroblasts secrete some proinflammatory cytokines after injury, often, the cellular source of cytokine production is not clearly delineated. The paucity of information regarding fibroblast mediation of inflammation is due to the lack of reliable means for identifying the fibroblast from other cell types in vivo. Nonetheless, there is some information regarding the role of the fibroblast during the inflammatory stage of heart injury. Studies using ischemia/reperfusion and myocardial infarction (MI) models of injury have shown that inflammasome activation in fibroblasts is essential for the initial inflammatory response (Kawaguchi et al., 2011; Sandanger et al., 2013). Cardiac fibroblasts activated in vitro express neutrophil-recruiting chemokines (CXCL1, CXCL2, and CXCL5) and other proinflammatory cytokines (IL1β, IL6, and TNFα) (Lafontant et al., 2006; Turner et al., 2009). In addition to having direct effects on inflammatory cells, some fibroblast activities occur indirectly by their influence on other cell populations (Fernandez-Patron et al., 2001). The field is still in its infancy regarding our understanding of cardiac fibroblast communication with inflammatory cells, and future studies are likely to reveal important insights into this topic.

Matrix remodeling

ECM components play a pivotal role in the remodeling process. One of the hallmarks of an activated fibroblast is the abundant secretion of collagens, resulting in scar formation or fibrosis. In the case of acute MI, the collagen network is essential for replacing lost cardiomyocytes and preventing ventricular rupture (Davis et al., 2015; van Amerongen et al., 2007; Schellings et al., 2009). During cardiac remodeling, resting or quiescent fibroblasts become activated by multiple factors produced in response to cardiomyocyte injury and inflammation (Siwik et al., 2000; Awad et al., 2010; Kulasekaran et al., 2009; Kanisicak et al., 2016). Not only cardiac fibroblasts produce the majority of collagen following injury (Petrov et al., 2002; Bashey et al., 1992a; Brilla et al., 1994), but also they modify ECM architecture by catalyzing collagen cross-linking through the action of LOX and lysyl oxidase-like 2 (LOXL-2) proteins (Yang et al., 2016). Fibroblast-produced MMPs and TIMPs also balance degradation of ECM permitting movement of cardiac fibroblasts and immune cells into the site of injury (Turner et al., 2010; Chiao et al., 2012; Spinale, 2007; Cleutjens et al., 1995; Kandalam et al., 2010). It is important to note that while cardiac fibroblasts do upregulate expression of MMPs after activation, many other cell types also produce these proteases (Saxena et al., 2013).

Matricellular proteins are components of the ECM that act as biological mediators of cell function. One matricellular protein that regulates cardiac fibrosis is periostin. Periostin expression in fibroblasts is increased in the infarct area after MI (Liu et al., 2012), and periostin-deficient mice showed reduced fibrosis after acute MI due to reduction of the recruitment of activated fibroblasts (Shimazaki et al., 2008; Oka et al., 2007). It has been suggested that one action of periostin is to promote cardiac repair via integrin-mediated induction of cardiomyocyte proliferation (Shimazaki et al., 2008). These results suggest that periostin contributes to cardiac repair, but the role of periostin during chronic remodeling is less clear.

TGF-β is one of the key mediators of the fibrogenic response. TGF-β leads to cardiac fibroblast activation potentially mediated by integrins αvβ5 and αvβ3 or PDGF-D as shown in vitro (Zhao et al., 2013; Sarrazy et al., 2014). In vivo work also suggests a pivotal role for TGF-β in regulation of fibrosis. TGF-β1 secretion is increased quickly in response to heart injury. TGF-β1-overexpressing mice exhibited significant cardiac hypertrophy and interstitial fibrosis (Rosenkranz et al., 2002). Moreover, the loss of Smad3, a downstream effector of TGF-β, resulted in reduced interstitial fibrosis in the remote myocardium in hearts but had no defect in resolution of inflammation in healing infarcts compared with their wild-type counterparts (Bujak et al., 2007).

Causes of Fibrosis

In the heart, there are multiple pathological processes that result in fibrosis. In most cases, fibrosis is not the primary disease, but a secondary response to tissue stress and inflammation. Later, we describe the heart pathologies that can culminate in fibrosis and focus on the actions of the fibroblast in fibrotic progression.

Myocardial infarction

MI is a frequent cause of cardiac injury. Following MI, a large number of myocardial cells die due to ischemia. Because there is negligible regenerative capacity in the adult heart, the loss of cardiomyocytes triggers a reparative response in which the dying cells are replaced with a fibrotic scar (Frangogiannis, 2006; van den Borne et al., 2010). This scar formation is driven by deposition of fibrin, which acts as a provisional matrix, providing a foundation for invading inflammatory cells and cardiac fibroblasts that are involved in repair of damaged tissue (Greiling and Clark, 1997). These fibrin scaffolds are eventually degraded and ultimately a scar is formed that covers up to 80% of the infarct area (reviewed by Turner and Porter, 2013; Dobaczewski et al., 2006; Sun and Weber, 2000).

Following MI, a number of secreted factors influence cardiac fibroblast and inflammatory cell responses (Briaud et al., 2001; Frangogiannis, 2012; Arslan et al., 2011; Timmers et al., 2012). Proinflammatory cytokines (TNF-α, TGF-β, and IL-6) and vasoactive peptides (ET-1 and natriuretic peptides) are increased in the myocardium (Ma et al., 2012). The recruited immune cells clear damaged and dying cells, while cardiac fibroblasts produce MMPs that degrade ECM and permit migration of cells into the infarct area (Dobaczewski et al., 2006; Li et al., 2002).

Increased production of TNF-α, IL-6, and VEGF after MI also promotes fibroblast activation and collagen synthesis (Saini et al., 2005; Taimeh et al., 2013; Wang et al., 2016a). The injury area expands, and over time, the infarct zone begins to thin. This replacement fibrosis prevents cardiac rupture after the ischemic insult but may become maladaptive. Sustained collagen deposition combined with increased cross-linking disturbs tissue architecture leading to ventricular wall stiffening, hypertrophy of the remaining cardiomyocytes, and potentially resulting in heart failure.

Experimentally, molecular mechanisms of cardiac remodeling after MI have been studied in mouse and rat injury models focused on the left ventricle through cryoablation (van den Bos et al., 2005; van Amerongen et al., 2008b), ligation of the left anterior descending artery (Eberli et al., 1998; Johns and Olson, 1954), and ischemia–reperfusion (Nossuli et al., 2000).

Pressure overload/hypertension

Pressure overload results in hypertrophy of the left ventricular wall with little or no change in chamber size (Norton et al., 2002; Weber et al., 1988). It can be caused by hypertension, aortic stenosis, or coarctation of the aorta. Chronic pressure overload causes excessive collagen synthesis and myocardial thickening (Thiedemann et al., 1983; Jalil et al., 1988) through the activation of profibrotic growth factors (TGF-β, angiotensin II (Ang II), ET-1, and aldosterone) (Hutchinson et al., 2010; Creemers and Pinto, 2011; Koitabashi et al., 2011; Senbonmatsu et al., 2000; Yorikane et al., 1993).

Hypertensive heart disease represents two key pathological processes, cardiomyocyte hypertrophy and accumulation of fibrotic tissue within the cardiac interstitium (Fagard, 1992; Berk et al., 2007; Querejeta et al., 2004). Hypertensive patients have increased collagen volume fraction of the myocardium compared with their normotensive counterparts (Querejeta et al., 2004; Kasner et al., 2011). The severity of fibrosis in hypertension disease may vary. With mild hypertension, increased collagen deposition in the endomysium and perimysium and cardiomyocyte hypertrophy are observed, although ECM structure is preserved. However, severe hypertension leads to cardiomyocyte cell death and replacement fibrosis resulting in expanded focal areas of disorganized ECM (Olivetti et al., 1994; Rossi, 1998).

Experimentally, thoracic banding achieves pressure overload. Infusion of Ang II/phenylephrine, isoproterenol, or aldosterone can also initiate hypertension-mediated cardiac fibrosis in rodent models (Hasenfuss, 1998). Both hemodynamic (pressure overload) and nonhemodynamic factors (TGF-β, Ang II, ET-1, and aldosterone) induce fibrosis in hypertensive disease (Berk et al., 2007; Kahan, 1998; Ganau et al., 1990). Experimental models have shown that recruitment and activation of macrophages through T-cell responses act as critical modulators for hypertension and reparative fibrosis (Ma et al., 2014; Laroumanie et al., 2014).

Aging

In the absence of MI and pressure overload, the aged heart exhibits alterations in collagen and ECM deposition (Eghbali et al., 1989b; Capasso et al., 1990). Aging is associated with left ventricular hypertrophy and fibrosis, ultimately leading to heart failure. The state of normal systolic function combined with diastolic dysfunction has been termed heart failure with preserved ejection fraction (HFpEF), and aging is considered one factor in the HFpEF epidemic (Aronow et al., 1998; Bryg et al., 1987; Loffredo et al., 2014). Common features of aging-associated heart failure are the loss of cardiomyocytes and increased fibroblast-mediated ECM remodeling (Olivetti et al., 1991; Horn et al., 2012) resulting in reduced pump function and ventricular wall stiffening (Melissari et al., 1991; Horn and Trafford, 2016). One mechanism to explain this fibrosis is that cardiomyocytes become more susceptible to mitochondrial permeability transition pore (mPTP)-triggered cell death leading to replacement fibrosis (Di Lisa et al., 2001; Morita et al., 2009). Also, increased oxidative stress from dysfunctional mitochondria leads to reactive oxygen species and fibrosis (Dai et al., 2011). Analyses of human hearts have suggested that reactive fibrosis is common in the aged heart (Jellis et al., 2010; Liu et al., 2013). Studies have suggested that in the aging heart, ECM disorganization and matricellular protein changes contribute more to the disease state rather than overall increases in collagen levels (Annoni et al., 1998; Thomas et al., 2000; McCurdy et al., 2010; Bradshaw et al., 2010; de Castro Bras et al., 2014; Horn, 2015; Chiao et al., 2012).

Diabetes mellitus

Cardiac fibrosis has been documented in both type I and II diabetes mellitus (Turkbey et al., 2011; Shimizu et al., 1993; Sutherland et al., 1989). Histological analysis has demonstrated that cardiac fibrosis in diabetic patients occurs independent of coronary atherosclerosis or hypertension and is accompanied by cardiomyocyte hypertrophy and microvascular abnormalities (Rubler et al., 1972; Gherasim et al., 1985). Fibrosis in diabetes is characterized by excessive accumulation of collagen types I and III in both left and right ventricles (Shimizu et al., 1993).

Type I diabetes models have shown interstitial myocardial fibrosis with cardiomyocyte hypertrophy, induction of profibrotic factors, and microvascular rarefaction (Ares-Carrasco et al., 2009; Black et al., 2010; Shiomi et al., 2003). Also, type II diabetes models have shown fibrosis with cardiomyocyte hypertrophy and diastolic dysfunction (Daniels et al., 2012; Huynh et al., 2012). Hyperglycemia leads to accumulation of advanced glycation end products that cross-link ECM proteins in both the intracellular and extracellular space (Cooper, 2004; Liu et al., 2003; Brownlee et al., 1986). In addition, hyperglycemia stimulates cardiac fibroblast proliferation and activation in vitro (Shamhart et al., 2014; Aguilar et al., 2014; Fowlkes et al., 2013), but the roles of hyperglycemia in fibrotic remodeling in vivo remain elusive. Angiotensin signaling is associated with diabetes-mediated fibrosis, which is accompanied by increased TGF-β-Smad signaling, accentuated TGF-β responses and generation of ROS to induce fibroblast activation (Brown et al., 1997; Zaman et al., 2001; Vazquez-Medina et al., 2013). Also, increased systemic levels of proinflammatory cytokines and chemokines, such as TNF-α and IL-1β, contribute to accelerate fibrosis development in diabetes (Suzuki et al., 2015; Westermann et al., 2007).

Therapeutic Targets

Because there are few therapies directed specifically at fibroblasts and their activities, there is a broad opportunity for the development of new clinical interventions targeting the fibroblast. Later, we describe a few examples of potential treatments that may reduce fibrosis.

Growth Factors

TGF-β

The role of TGF-β signaling in fibroblast proliferation and matrix production is an intensely studied topic. Many studies indicate a crucial role of TGF-β in the pathogenesis of cardiac fibrosis and hypertrophic remodeling (Dobaczewski et al., 2011; Bujak and Frangogiannis, 2007; Koitabashi et al., 2011). In vitro studies have demonstrated that TGF-β stimulation induces fibroblast conversion to myofibroblasts and enhances ECM protein synthesis and deposition (Petrov et al., 2002; Desmouliere et al., 1993). Treatment of soluble TGF-β receptor in vivo has either protective or detrimental effects in MI depending on the time point of TGF-β signaling blockage after MI (Okada et al., 2005; Ikeuchi et al., 2004). Moreover, a small molecule inhibitor of ALK5 (a TGF-β type I receptor) attenuated cardiac fibrosis after pressure overload and MI (Tan et al., 2010; Engebretsen et al., 2014).

Angiotensin II

Studies have demonstrated that Ang II promotes cardiomyocyte hypertrophy (Gray et al., 1998; Schultz Jel et al., 2002) and enhances ECM protein synthesis (Lijnen et al., 2000; Brilla et al., 1994, 1997). Ang II upregulates TGF-β expression through the AT1 receptor in cardiomyocytes and fibroblasts, indicating that TGF-β acts downstream of Ang II (Gao et al., 2009). Administration of angiotensin receptor blockers, such as losartan, results in reduced fibrosis both in cardiac experimental injury models and in patients (Shibasaki et al., 2005; Diez et al., 2002; Lim et al., 2001). Although manipulation of renin–angiotensin signaling may have direct influences on fibroblast behavior, this pathway functions in many cell type; and identification of more specific means for targeting this pathway in fibroblasts would be a significant advance.

MicroRNAs

It has become clear that cardiac microRNAs (miR) actively participate in different aspects of cardiac remodeling, such as cell proliferation, apoptosis, and fibrosis, and miR has become attractive targets for therapeutic interventions (van Rooij and Olson, 2012). Evidence is accumulating that multiple miRs function in cardiac fibrosis, and studies have demonstrated that manipulation of these miRs can impact fibroblast behavior during cardiac fibrosis. Due to their ability to regulate several proteins and pathways at once, manipulation of miR activity by injecting either stable miR analogs or miR inhibitors called antagomirs or antimiRs has become an active area of drug discovery.

Connective tissue growth factor (CTGF) has emerged as an important modulator of fibrotic responses in tissues and acts as a downstream mediator that enhances the fibrogenic action of TGF-β in fibroblasts (Ahmed et al., 2004; Chen et al., 2000; Chujo et al., 2005). It has been reported that cardiac miR, miR-30, (cardiomyocytes and cardiac fibroblasts), and miR-133 (cardiomyocytes) regulate CTGF, and expression level of these miR is negatively correlated with CTGF levels, collagen production, and fibrosis. These results suggest that these two miRs may act as negative regulators of fibrosis and could therefore be useful in broadly altering fibrotic responses (Duisters et al., 2009). miR-21 is upregulated in cardiac fibroblasts after injury (van Rooij et al., 2008), and in vivo silencing of miR-21 in a pressure overload model attenuates fibrosis and heart failure via suppression of ERK–MAPK signaling (Thum et al., 2008). Recent findings also show that overexpression of miR-9 attenuates cardiac fibrosis via PDGFR-β-mediated cardiac fibroblast proliferation and collagen synthesis (Wang et al., 2016b; Zhang et al., 2011). miR-101a can modulate TGF-β signaling, suggesting another potential avenue for fibrosis regulation (Zhao et al., 2015; Pan et al., 2012). miR-24 expression is correlated with fibrosis in hypertrophic hearts, and intramyocardial injection of miR-24 improves heart function and attenuates fibrosis after MI (Wang et al., 2012). miR-1 attenuates pathological remodeling and cardiac hypertrophy in pressure overload model (Karakikes et al., 2013). Taken together, these findings point to the manipulation of miRNAs as novel therapeutic targets during cardiac fibrosis.

Lysyl oxidase

Tissue stiffness is dependent not only on the abundance of collagen but also on the amount of collagen cross-linking (Herrmann et al., 2003; Capasso et al., 1989; Iimoto et al., 1988; Lopez et al., 2010). Thus, strategies for modulation of matrix stiffness are being considered as a therapeutic target for cardiac fibrosis. LOX activity is associated with fibrosis in multiple organs, and increased levels of LOX have been reported in patients with hypertensive and chronic heart disease. Higher LOX expression is observed in areas of interstitial and perivascular fibrosis (Maki, 2009; Lopez et al., 2010). It has been shown that treatment with a LOX inhibitor, β-aminopropionitrile, reduced collagen cross-linking and myocardial stiffness in healthy pig hearts (Kato et al., 1995), age-related myocardial fibrosis (Rosin et al., 2015), and MI (Gonzalez-Santamaria et al., 2016). A recent study has shown that LOXL2 secretion is increased in the serum of patients with heart failure, and LOXL2 correlates with collagen cross-linking and diastolic abnormalities. Specifically, inhibition of LOXL2 activity using a neutralizing antibody after transverse aortic constriction reduces interstitial fibrosis and improves heart function (Yang et al., 2016), suggesting that it could also be used as a biomarker. Therefore, regulation of LOX activity has become an attractive therapeutic target for cardiac fibrosis.

Summary

Cardiac fibroblasts are essential for regulating ECM homeostasis and remodeling in heart, but an accurate understanding of the multifaceted role of the fibroblast has been constrained due to limitations in studying these cells. As our knowledge of fibroblast composition and behavior in normal and pathological heart conditions improves, so will our ability to modulate these cells during disease processes.

Introduction

Heart failure is a clinical manifestation of cardiovascular disease, a leading cause of death worldwide. In the United States, nearly 800,000 patients die of cardiovascular disease each year (Mozaffarian et al., 2016). Almost all etiologies of heart failure involve pathological cardiac hypertrophy and remodeling.

Hypertrophic growth is the primary mechanism by which the heart responds to stimuli that increase intraventricular wall stress and demand enhanced cardiac performance. In accordance with Laplace's law, which states that ventricular wall stress is proportional to both ventricular pressure and cavity radius and inversely proportional to ventricular wall thickness, cardiac hypertrophy is an adaptive response to reduce wall stress and hence is beneficial for heart function (Burch et al., 1952). Cardiac hypertrophy is classified as physiological when associated with physiological stimuli or as pathological when associated with hemodynamic stress. Physiological hypertrophy occurs during normal postnatal growth from birth to adulthood, pregnancy, or in response to sustained exercise training. In this case, the wall thickness increases proportionally to the chamber size and normal cardiac structure and function are maintained. In contrast, pathological hypertrophy develops in response to chronic increase in the hemodynamic load caused by hypertension, aortic stenosis, aortic coarctation, mitral regurgitation, or myocardial infarction, among others. In these conditions, hemodynamic stress increases intraventricular pressure or volume and promotes an adaptive compensatory hypertrophic response, which progresses into maladaptive remodeling with prolongation increase in wall stress. Pathological hypertrophy is often associated with impaired myocardial vascularization, fibrosis, cell death, inflammation, and chamber dilation, which ultimately lead to cardiac dysfunction and heart failure (Shimizu and Minamino, 2016; Diwan and Dorn, 2007; Dorn, 2007).

Heart failure is broadly classified into two types: heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF). HFrEF is mainly due to cardiomyocyte death or reduced cardiac function, fibrosis, and adverse remodeling caused by myocardial infarction, hypertension, and cardiomyopathy. The common pathophysiology responsible for HFpEF is associated with concentric myocardial hypertrophy and diastolic left ventricular (LV) dysfunction caused by a variety of risk factors including hypertension, metabolic syndrome, and aging. The molecular mechanisms underlying HFpEF involve myocyte hypertrophy, endothelial dysfunction, inflammation, fibrosis, and oxidative stress (Heinzel et al., 2015; Jumean and Konstam, 2015).

The human heart contains an estimated 2–3 billion cardiac muscle cells, accounting for only a third of the total number of cells. Other non-myocyte cells include fibroblasts, vascular cells (smooth muscle and endothelial cells of the coronary vasculature and endocardium), and immune cells. Unlike other cell types, cardiomyocytes become terminally differentiated shortly after birth and lose the ability to proliferate, although a very low renewal rate occurs throughout life (Bergmann et al., 2009; Porrello et al., 2011). Thus, "the sine qua non" of myocardial hypertrophy is the increase in size of individual cardiomyocytes through new sarcomere addition and organization, rather than cell proliferation. Postnatal growth, from birth to adulthood, is an example of cardiomyocyte hypertrophy increasing heart mass to keep pace with increase in body weight (Hew and Keller, 2003). Physiological and pathological stimuli promote a dynamic range of growth response. Pregnancy causes a reversible "physiological" LV hypertrophy characterized by an increase of up to 34% of LV mass which returns to the original mass after delivery (Schannwell et al., 2002). In athletes, depending on athletic conditioning, cardiac mass has been reported between 9% and 90% greater, as compared with

 https://doi.org/10.1016/B978-0-12-809657-4.99834-X

nonathletes (Pluim et al., 2000). By contrast, surgical constriction of the aorta induces an increase of cardiac mass by 40% within 1 week (Rockman et al., 1991).

In addition to changes in myocyte morphology (size and shape), electrophysiology, and metabolism, intercellular signaling and communication between different cell types are critical in the pathophysiology of ventricular hypertrophy and transition to heart failure (Tirziu et al., 2010). This article highlights the molecular basis of hypertrophic signaling and the contribution of cellular communication to myocardial hypertrophy and heart failure.

Cardiomyocyte Hypertrophy

Phenotypic Features

Consistent efforts have been made to uncover phenotypic differences in cardiomyocyte hypertrophy under physiological versus pathological conditions. A hallmark feature of pathological hypertrophy is the induction of the "hypertrophic program of fetal genes," absent in physiological hypertrophy. The well-known markers of pathological hypertrophy include: atrial natriuretic peptide, B-type natriuretic peptide, and the fetal isoform of contractile proteins including skeletal α-actin and the β-isoform of myosin heavy chain (β-MHC) (Dorn et al., 2003). However, it should be noted that in adult human heart the reduction in α-MHC expression is associated with pathological hypertrophy and heart failure (Dorn et al., 2003). In addition, altered expression of the calcium cycling protein, sarco(endo)plasmic reticulum Ca^{2+}ATPase 2a (SERCA2a), instrumental in calcium handling and cardiomyocyte contractility, is often associated with contractile dysfunction and progression to heart failure (Shareef et al., 2014).

One long-lasting theory was that the duration of hemodynamic stress, intermittent versus constant, determines whether the hypertrophy is physiological or pathological. Physiological overloads such as exercise are considered intermittent, whereas pathological overloads such as hypertension are constant. However, intermittent pathological pressure overload in mouse hearts provides convincing evidence that the nature of pathological stress is the molecular trigger of cardiac dysfunction, rather than its duration (intermittent vs. constant) or hypertrophic growth per se (Perrino et al., 2006).

At the cellular level, cardiomyocytes enlarge by enhancing protein synthesis and increasing the number of the sarcomere units. The alignment of additional sarcomeres either in parallel or series determines whether the myocytes are thicker or elongated (Lorell and Carabello, 2000). Based on these alignments, two different hypertrophic phenotypes could be identified: concentric and eccentric (Grossman et al., 1975). Concentric hypertrophy, induced by LV pressure overload in aortic stenosis and hypertension, is associated with thicker cardiomyocytes, increased LV wall thickness, and no changes in LV chamber size. In contrast, eccentric hypertrophy induced by volume overload in aortic and mitral insufficiency is associated with elongated cardiomyocytes and increases of both wall thickness and LV chamber size. In both cases, hypertrophy helps to normalize systolic stress, but not diastolic wall stress (Grossman et al., 1975). A proportional increase in myocyte length and width is typically observed in exercise-induced physiological hypertrophy. In heart failure, cardiomyocytes are disproportionately elongated relative to their width.

Morphological changes in size and shape ultimately affect cardiomyocyte to cardiomyocyte communication. This is particularly important as adverse remodeling impairs myocyte electrical coupling. The electrical impulse is propagated among adjacent cardiomyocytes through gap junctions. In the heart, gap junctions are composed of three major connexins, connexin (Cx)43 (α_1 connexin), Cx45 (α_6 connexin), and Cx40 (α_5 connexin) and each exhibits different channel properties and regional expression pattern (Lo, 2000; Teunissen et al., 2004). Gap junction remodeling, a set of molecular and functional changes that occur during pathological progression, alters the expression and phosphorylation of connexins and induces the lateralization of the gap junction from the intercalated disk (Severs et al., 2008; Kieken et al., 2009). Gap junction remodeling ultimately increases the risk for fatal ventricular arrhythmias. It has been suggested that Cx43, the major connexin expressed in working ventricular myocardium, is upregulated during the compensatory phase of hypertrophy and downregulated and heterogeneously redistributed to the lateral sides of cardiomyocytes with the progression to heart failure (Fontes et al., 2012). However, it is worth mentioning that electrical uncoupling and arrhythmogenicity in pathological hypertrophy and heart failure are most likely a synergistic effect between reduced Cx43 expression and increased fibrosis and collagen deposition (de Jong et al., 2011).

Research over the past few decades has identified numerous factors and signaling pathways involved in cardiomyocyte hypertrophy. In physiological hypertrophic response to growth factors, the activation of the phosphatidylinositol 3-kinase (PI3K) α/serine–threonine protein kinase v-akt murine thymoma viral oncogene homolog (Akt) 1 pathway is a typical mechanism. In response to hemodynamic stress and neurohumoral factors, the activation of calcium–calmodulin–calcineurin/nuclear factor of activated T-cells (NFAT) pathway through the G-protein-coupled receptors (GPCRs) is a potent inducer of hypertrophy. However, the propagation of hypertrophic stimulation extends to a more complex network of signaling events and pathways concurrently integrated within cellular crosstalk that ultimately may determine the outcome: either physiological or compensatory or pathological hypertrophy.

Signaling Mechanisms of Physiological Hypertrophic Response

Growth factors and signaling

The growth factors involved in physiological hypertrophic response are well-characterized and include thyroid hormone (TH), insulin, growth hormone, and insulin-like growth factor 1 (IGF-1) (Maillet et al., 2013). The role of TH in postnatal growth in children is well-recognized and its beneficial effects in preventing pathological heart remodeling have started to emerge (Pantos and

Mourouzis, 2015). A mounting body of evidence demonstrates the benefit of TH replacement therapy in animal models of heart failure, often associated with reduced TH levels (Gerdes and Iervasi, 2010). For instance, TH optimized LV chamber geometry and attenuated adverse remodeling after myocardial infarct (Pantos et al., 2007, 2008). Likewise, in a rat model of LV pressure overload, treatment with TH restored cardiomyocyte calcium sensitivity and contractility by upregulating SERCA2a and α-MHC expression (Chang et al., 1997). Also, atrial fibrillation post-myocardial infarction was attenuated by TH treatment (Zhang et al., 2014). TH induces physiological hypertrophy most likely through activation of p38 mitogen-activated protein kinase (MAPK) and PI3K/Akt/mammalian target of rapamycin complex 1 (mTORC1) signaling (Kenessey and Ojamaa, 2006; Kinugawa et al., 2005). TH effects are not limited to cardiomyocytes. TH activates the Akt pathway and platelet-derived growth factor (PDGF) signaling in endothelial cells and promotes angiogenesis and increased capillary density, which has the potential to increase the delivery of blood supply and nutrients in hypertrophied myocardium (Chen et al., 2012; Makino et al., 2009). However, although therapeutic activity in animal models is promising, large clinical trials are still awaited to test the efficacy of TH treatment in patients with heart failure (Pantos and Mourouzis, 2015).

In the heart, insulin signaling regulates glucose and lipid metabolism, cell growth and differentiation, protein synthesis, and fatty acid oxidation (Saltiel and Kahn, 2001). Insulin binding to the insulin receptor (IR) leads to recruitment and phosphorylation of insulin receptor substrate (IRS)-1 and -2, which activate the PI3K-Akt signaling pathway. Insulin signaling is critical for normal heart development. Gene deletion of IRS-1, IRS-2, and IR resulted in smaller hearts and worsened response to hypertrophic stimuli (Hu et al., 2003; Boudina et al., 2009; Belke et al., 2002; Araki et al., 1994).

IGF-1 signaling is the best known contributor to physiological hypertrophy in response to endurance exercise (**Fig. 1**). IGF-1 regulates cell proliferation, differentiation, metabolism, and survival and is critical for normal development and postnatal growth. In athletes, increase in cardiac IGF-1 has been associated with eccentric hypertrophy (Neri Serneri et al., 2001). IGF-1 binds to its tyrosine kinase receptor IGF1-R, which activates the PI3K/Akt pathway through IRS-1 and IRS-2 (Troncoso et al., 2014). The role of Akt1 as downstream effector of IGF-1 signaling was demonstrated in Akt1-deficient mice, where physiological hypertrophy in

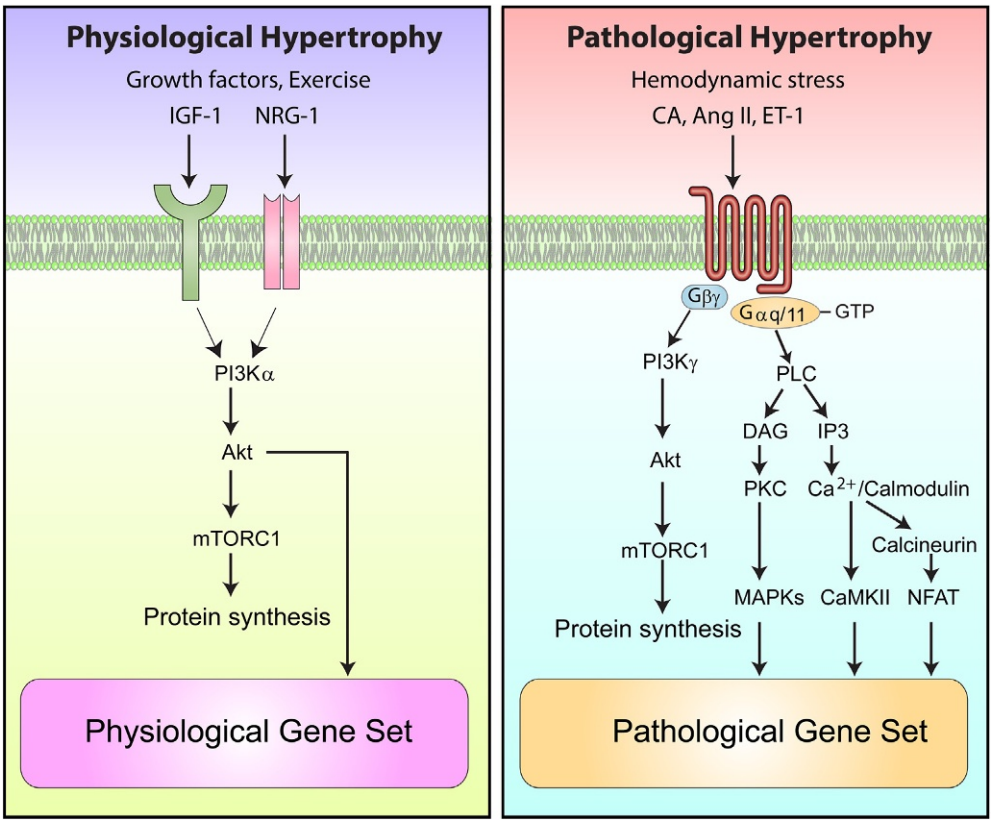

Fig. 1 Key signaling pathways involved in physiological and pathological cardiac hypertrophy. In physiological hypertrophic response to growth factors or exercise, the activation of the PI3Kα/Akt pathway is a typical mechanism to induce protein synthesis and the hypertrophic program of gene expression. In response to hemodynamic stress and neurohumoral factors, the activation of the Gαq/11-PLC pathway through G-protein-coupled receptors is a major mechanism of cardiomyocyte hypertrophy. Downstream, the pathological hypertrophic gene set is induced through several pathways including calcineurin/NFAT, PKC, MAPKs, and CaMKII. In addition, Gβγ-induced activation of the PI3Kγ-dependent Akt/mTOC1 pathway contributes to protein synthesis. *IGF-1*, insulin-like growth factor 1; *NRG-1*, neuregulin-1; *PI3K*, phosphoinositide kinase 3; *Akt*, v-akt murine thymoma viral oncogene homolog 1; *mTORC1*, mammalian target of rapamycin complex 1; *CA*, catecholamine; *Ang II*, angiotensin II; *ET-1*, endothelin 1; *PLC*, phospholipase C; *DAG*, diacylglycerol; *IP3*, inositol trisphosphate; *PKC*, protein kinase C; *NFAT*, nuclear factor of activated T-cells; *CaMKII*, Ca^{2+}/calmodulin-dependent protein kinase II; *MAPKs*, mitogen-activated protein kinases.

response to swimming was completely abolished (DeBosch et al., 2006). Akt1 activation in response to exercise training and transgenic expression of PI3K, IGF-1, and IGF1-R varies from two- to sixfold increase (McMullen et al., 2003, 2004; Shioi et al., 2000). Cardiomyocyte-specific overexpression of IGF1-R promotes a specific physiologic hypertrophy response in a PI3K(p110α)-dependent manner with no pathological features (McMullen et al., 2004). The expression of a dominant active PI3K(p110α) mutant promotes physiological hypertrophy and preserves contractile function, while a dominant negative PI3K(p110α) mutant prevents exercise-induced hypertrophy and exacerbates cardiac dysfunction under hemodynamic stress (McMullen et al., 2003, 2007; Lin et al., 2010). Akt1 promotes myocardial hypertrophy in response to exercise by downregulating the transcription factor CCAAT/enhancer-binding protein β (C/EBPβ). C/EBPβ interacts with serum response factor and contributes to the regulation of the so-called "physiological gene set" involved in cardiomyocyte hypertrophy and differentiation: GATA-binding protein 4 (GATA4), T-box 5 (Tbx5), and NK2 homeobox 5 (Nkx2.5) (Bostrom et al., 2010; Lerchenmüller and Rosenzweig, 2014). Mice with reduced cardiac expression of C/EBPβ have a physiological hypertrophic phenotype and are protected against adverse remodeling (Bostrom et al., 2010). Reduction in C/EBPβ is linked to increased expression of Creb-binding protein/p300-interacting transactivator with ED-rich carboxy-terminal domain-4 (CITED4). Cardiac-specific transgenic CITED4 expression in adult mice was sufficient to promote cardiomyocyte hypertrophy and normal cardiac function, comparable with that induced by exercise training (Bezzerides et al., 2016). CITED4 activates mTORC1, most likely accounting for protein synthesis and cardiomyocyte growth (Bezzerides et al., 2016; Kemi et al., 2008; Ma and Blenis, 2009).

Traditionally, endurance exercise has been regarded as a well-balanced physiological growth, where cardiomyocyte hypertrophy is accompanied by appropriate increase in coronary microvasculature and blood flow (Lerchenmüller and Rosenzweig, 2014). The molecular mechanism most likely involves the vascular endothelial growth factor A (VEGFA) signaling and endothelial nitric oxide synthase (eNOS) activation through the Akt pathway (Iemitsu et al., 2006). In this context, it is worth mentioning that IGF-1 was found to promote angiogenesis in vitro and ex vivo experiments (Su et al., 2003).

miRNAs and physiological hypertrophic response

Several miRNAs are involved in the regulation of physiological hypertrophic response (Fernandes et al., 2015). Cardiac-specific miR-1 and miR-133, downregulated in pathological hypertrophy, are also reduced in physiological hypertrophy induced by cardiac-specific Akt1 transgenic overexpression and exercise training, suggesting their contribution to a wide-spectrum of hypertrophic responses (Care et al., 2007; Ellison et al., 2012). MiR-1 negatively regulates cardiac mass by modulating the IGF pathway and calcium signaling (Ikeda et al., 2009; Elia et al., 2009), while miR-133 is a negative modulator of calcineurin/NFAT signaling (Care et al., 2007; Li et al., 2010).

Cardiac miR-222 is an important modulator of exercise-induced cardiac growth and is protective against adverse remodeling and cardiac dysfunction (Liu et al., 2015). Interestingly, exercise training increased miR-222 expression in both healthy volunteers and heart failure patients (Baggish et al., 2011; Liu et al., 2015). Both gain- and loss-of-function studies showed that miR-222 targets cyclin-dependent kinase inhibitor 1B (p27), homeobox containing 1 (HMBOX1), and homeodomain-interacting protein kinase 1/2 (HIPK1/2) to regulate myocardial hypertrophy (Liu et al., 2015). Most likely, the reduction of p27 and HIPK1/2 has a proliferative effect, while the reduction of HMBOX1 stimulates cardiomyocyte hypertrophy.

An endothelial-specific miRNA, miR-126, is also upregulated by exercise. MiR-126 promotes angiogenesis and increases capillary density by repressing two negative regulators of the VEGF pathway: sprouty-related protein 1 (Spred-1), a suppressor of the Ras/MAPK pathway, and PI3K regulatory subunit 2, a negative regulator of the PI3K/Akt/eNOS pathway (Silva et al., 2012). Exercise training in pathological conditions, such as hypertension, could prevent microvascular rarefaction by inducing miR-126 expression (Fernandes et al., 2012).

Another interesting miRNA induced by exercise is miR-29c, a negative modulator of extracellular matrix (ECM) components collagen I and III. High performance training in rats is well-tolerated and ventricular compliance improved due to an inhibitory effect of miR-29c on ECM deposition and cardiac fibrosis (Soci et al., 2011). In exercise-trained myocardial-infarcted rats, the increase of miR-29 prevents excessive fibrosis and is therefore beneficial for heart function (Melo et al., 2014).

Hyperplasia and physiological hypertrophic response

Although controversial, recent studies support the idea that physiological adaptation to endurance exercise is a combination of cardiac hypertrophy and hyperplasia, involving cardiomyocytes and endothelial cells (Bostrom et al., 2010; Waring et al., 2014). Cardiomyogenesis has been recently reported in a rat model of endurance exercise where a significant number of newly myocytes arose from endogenous c-kit$^+$ cardiac stem cells (CSCs) (Waring et al., 2014). Consistent with this idea, growth factors such as IGF-1 and neuregulin 1 (NRG-1) have been previously reported to induce cardiomyocyte proliferation in vitro and in vivo (Bersell et al., 2009; Bostrom et al., 2010). Furthermore, in exercise-trained rats with myocardia infarct, the increased production of NRG-1 promoted cardiac repair and the recruitment of c-kit$^+$ CSCs by binding to receptor tyrosine kinase ErbB2/ErbB4 followed by downstream activation of the PI3K/Akt signaling (Cai et al., 2016). The recognition of the exercise-induced regenerative capacity in the adult heart may lead to future therapeutic avenues for patients with heart failure.

Signaling Mechanisms of Pathological Hypertrophic Response

Major triggers of pathological hypertrophy include biomechanical stress and neurohumoral factors (Hill and Olson, 2008). The mechanisms by which biomechanical stress is transduced within cardiomyocytes are uncertain, but suggest the involvement of

stretch-activated cation channels, ECM, integrins, and cellular cytoskeleton among others (Sadoshima and Izumo, 1997; Sharif-Naeini et al., 2010; Lyon et al., 2015). The adrenergic and renin-angiotensin systems have been extensively studied as neurohumoral mechanisms of pathological hypertrophy in chronic heart failure. Beta-adrenergic receptor blockers (β-blockers), angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARB), and a recent combination of an ARB with an inhibitor of neprilysin (ARNI) are first-line therapies for the heart failure (Yancy et al., 2016). The key signaling pathways involved in the pathological hypertrophic response are briefly summarized.

Signal transduction through myocardial GPCRs, including adrenergic, angiotensin, and endothelin receptors, is critically involved in the cardiac response to hemodynamic stress and the development of cardiac hypertrophy, fibrosis, heart failure, and arrhythmia. GPCRs transduce agonist-induced signals to intracellular effectors through the activation of three principal classes of heterotrimeric G protein complexes composed by one GTP-binding Gα subunit (Gαs, Gαq/$G\alpha_{11}$, or Gαs) tightly associated in the GDP-bound transition state with an obligate Gβγ subunit.

Adrenergic receptors (ARs) bind catecholamines, such as noradrenaline and adrenaline, and mediate chronotropic and inotropic effects, as part of the acute fight-or-flight response, in both physiological and pathological conditions. In patients with heart failure, elevated levels of catecholamines and chronic activation of the adrenergic system result in a poor clinical outcome and shortened life expectancy (Cohn, 1995). There are two main ARs in the heart: β-ARs, roughly 90%, and α_1-ARs, likely 10% of the total ARs. Increased β-adrenergic activity causes the heart to beat fast, while increased α-adrenergic activity constricts the arterioles and increases the blood pressure.

β-ARs signaling and cardiomyocyte hypertrophy

Cardiomyocytes mainly expresses β1 and β2 ARs. The β1-AR subtype is the most predominant (80%–90% of total β-ARs) and is mainly responsible for the positive chronotropic and inotropic effects of catecholamines (Brodde et al., 2006; Fu et al., 2012; Lohse et al., 2003). Both, β1- and β2-ARs couple to the heterotrimeric Gs protein complex and activate adenylyl cyclase (AC) to generate cAMP. Then, cAMP activates protein kinase A (PKA), which regulates key Ca^{2+}-handling proteins involved in cardiac contractility: L-type channels, phospholamban (PLN), troponin I, ryanodine receptors (RyR), myosin-binding protein-C, and protein phosphatase inhibitor-1 (Lohse et al., 2003). Although acute activation of β1-AR is initially adaptive, chronic activation leads to cardiac dysfunction and heart failure associated with β1-AR downregulation and desensitization (Bristow et al., 1982; Ungerer et al., 1994; Dorn, 2009).

Despite strong indication of cardiomyocyte hypertrophy in mice with cardiac β1-ARs transgenic overexpression or upon stimulation with isoproterenol (ISO, a non-selective β-AR agonist), or dobutamine (a β1-AR selective agonist) the mechanism of the hypertrophic response is not fully understood (Osadchii, 2007; Engelhardt et al., 1999). One scenario plays out the possibility that the cAMP/PKA pathway increases the transcriptional activity of cAMP response element (CRE) on CRE-responsive genes in a manner dependent on cAMP-response element modulator (CREM). The loss- and gain-of-function studies showed that CREM is required for β1-AR-induced hypertrophy (Lewin et al., 2009). Likewise, inhibition of CRE-mediated transcription by the over-expression of inducible cAMP early repressor was also shown to prevent ISO-induced hypertrophic response (Tomita et al., 2003). Another scenario supports the idea that the activation of Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), whether dependent or independent of PKA activity, modulates the β-AR-induced hypertrophic response (Grimm and Brown, 2010). This is also supported by the cardiac-specific overexpression of a peptide AC3-I, a CaMKII inhibitor, which significantly prevented myocardial hypertrophy and pathological remodeling in response to β-agonist stimulation (Zhang et al., 2005). Although the precise mechanism by which the β-AR/CaMKII axis contributes to the hypertrophic response is still elusive, recent studies have suggested that CaMKII is rather involved in mitochondrial dysfunction, cardiac fibrosis, and adverse cardiac remodeling (Grimm et al., 2015; Xu et al., 2016).

Beta-AR desensitization, probably the most detrimental effect induced by chronic receptor stimulation, is regulated by the GPCR kinases GRK2 and GRK5. Intriguingly, the inhibition of β-AR desensitization substantially prevented the progression of pathological hypertrophy and restored cardiac function in several animal models of heart failure (Hullmann et al., 2016). The inhibition of GRK2 with a C-terminal peptide known as βARKct showed that preventing GRK2 binding to Gβγ improved cardiac contractility (Koch et al., 1995; Shah et al., 2001; White et al., 2000). Furthermore, the recent interest in non-canonical signaling induced by GRK2 and GRK5 has led to discovery of unexpected roles of GRK2 in cardiac metabolism and survival and GRK5 in pathological hypertrophy (Woodall et al., 2014; Traynham et al., 2015, 2016).

There is also support for the idea that sustained β-AR activation promotes cardiomyocyte hypertrophy via neurohumoral factors such as angiotensin II (Ang II), interleukin 6 (IL-6), and endothelin 1 (ET-1) (Ferreira et al., 2008; Yin et al., 2003; Morimoto et al., 2001).

α-ARs, Ang II and ET-1 receptor signaling, and cardiomyocyte hypertrophy

Cardiac α1-ARs, angiotensin II type 1 receptor (AT1), and endothelin receptor (ET_A) couple to the Gq/11 (Gαq)-phospholipase C pathway, which is considered a major mechanism involved in the cardiomyocyte hypertrophic response (**Fig. 1**). The canonical effectors of activated GTP-bound family Gαq subunits are β-isoforms of phospholipase C (PLC-β). Activation of PLC-β cleaves phosphatidylinositol, increasing inositol trisphosphate (IP3) and diacylglycerol (DAG). IP3 binds to the IP3-receptor to release calcium and DAG activates protein kinase C (PKC). Downstream, hypertrophic signaling is propagated through several pathways: calcineurin/NFAT, MAPKs, and CAMKII, among others (Hubbard and Hepler, 2006; Sugden and Clerk, 1997; van Berlo et al., 2013). In addition, Gβγ subunit activates the PI3K p110γ-dependent Akt/mTORC1 pathway of cardiomyocyte hypertrophy (Dupre

et al., 2009; Kerchner et al., 2004; Naga Prasad et al., 2000; Ma and Blenis, 2009). The key role of Gαq was demonstrated in mouse models, where cardiac-specific Gαq transgenic overexpression exacerbated pathological hypertrophy and failure, whereas Gαq conditional deletion prevented the hypertrophic response to chronic pressure overload (D'Angelo et al., 1997; Mende et al., 1998; Wettschureck et al., 2001).

Calcineurin, a Ca^{2+}/calmodulin-activated serine/threonine phosphatase, dephosphorylates and induces the translocation of cytoplasmic NFAT to the nucleus. Subsequently, NFAT forms complexes with the cofactors GATA4 and myocyte enhancer factor-2 (MEF-2) to activate transcription of the hypertrophic program of gene expression (Heineke and Molkentin, 2006). Although the role of the calcineurin /NFAT pathway in pathological hypertrophy is well-recognized, smaller hearts in calcineurin-deficient mice suggest potential contribution of the calcineurin/NFAT signaling to normal heart development (Wilkins et al., 2004).

CaMKII is also regulated by the Gαq-induced Ca^{2+}/calmodulin activity and, like PKA and PKC, modulates acute cellular Ca handling (Maier and Bers, 2002). It has been shown that myocardial transgenic overexpression of the predominant cardiac CaMKIIδc isoform, like overexpression of Gαq, was sufficient to induce cardiac hypertrophy and transition to heart failure (Zhang et al., 2003). Conversely, CaMKIIδ gene deletion attenuated cardiac dysfunction and pathological remodeling in response to chronic pressure overload (Backs et al., 2009; Ling et al., 2009). However, a recent study employing a compound mouse model with cardiac-specific Gαq transgenic overexpression and CaMKIIδ deletion concluded that CaMKIIδ induces mitochondrial gene reprogramming responsible for the transition to heart failure and has no effect on hypertrophy (Westenbrink et al., 2015). Interestingly, similar changes in mitochondrial gene expression have also been observed in pressure overload-induced pathological hypertrophy (Westenbrink et al., 2015). It is worth noting that CaMKII activation in response to β-agonist led to mitochondrial dysfunction as well.

MAPK signaling cascades consist in successively acting protein kinases that ultimately result in the activation of three main pathways: extracellular signal-regulated kinases (ERKs), c-Jun amino-terminal kinase (JNK), and p38. The role of ERK1/2 in cardiomyocyte hypertrophy is very complex, often complicated by their potential contribution to both physiological and pathological growth mechanisms. Cardiac-restricted expression of activated MEK1 (upstream of ERK1/2) in mice induced compensated hypertrophy with no cardiac dysfunction or fibrosis (Bueno et al., 2000). Genetic inhibition of cardiac ERK1/2 had no effect on hypertrophy, but exacerbated heart failure in response to chronic pressure overload (Purcell et al., 2007). Recent evidence has further suggested that autophosphorylation of ERK1/2 at Thr188 via Gβγ is critical for ERK1/2-induced hypertrophy associated with pathological stimuli (Lorenz et al., 2009). Subsequently, employing an ERK2(T188A) mutant that interferes with ERK1/2^{Thr188} phosphorylation, the pathological hypertrophic response to pressure overload was significantly attenuated, while physiological hypertrophy in response to exercise was unchanged (Ruppert et al., 2013). JNK and p38 are stress-activated kinases and their roles in cardiomyocyte hypertrophy are still controversial (Shimizu and Minamino, 2016). On the other hand, it has been asserted that JNK and p38 promote cardiomyocyte apoptosis, adverse remodeling, and heart failure (Baines and Molkentin, 2005).

miRNAs and pathological hypertrophic response

During the past decade, several miRNAs have been associated with myocardial hypertrophy (Sayed et al., 2007; van Rooij et al., 2008). The first discovered miRNA, miR-208, has been shown to play a key role in the upregulation of β-MHC (a fetal slow contracting ATP isoform of MHC) and cardiac dysfunction in response to hemodynamic stress (van Rooij et al., 2007). Other early reports found the expression of miR-1 and miR-133, which belong to the same transcriptional unit, inversely correlated with cardiac hypertrophy in response to pressure overload, Akt1 transgenic expression, and exercise (Care et al., 2007). Interestingly, knocking down miR-133 in mice with an infusion of antisense RNA oligonucleotide appeared to be sufficient to induce cardiac hypertrophy and activation of the fetal program of gene expression (Care et al., 2007). Consistent with the role in pathological hypertrophy, gain- and loss-of-function studies showed that miR-133 negatively regulates NFATc4 and components of the β1-AR/cAMP/PKA pathway (Castaldi et al., 2014; Li et al., 2010). MiR-1, although not as potent as miR-133, can prevent cardiomyocyte hypertrophy by targeting calmodulin, GATA4, and MEF-2 (Ikeda et al., 2009).

Other miRNAs are consistently upregulated in cardiomyocytes in the settings of pathological pressure overload in vivo and upon treatment with neurohumoral factors in vitro. Interesting examples are calcineurin/NFAT-responsive miRNAs: miR-199b and miR-23a. MiR-199b enhances calcineurin/NFAT-mediated pathological cardiac hypertrophy by targeting the nuclear NFAT kinase dual-specificity tyrosine-(Y)-phosphorylation-regulated kinase 1a (Dyrk1a) in an apparent pathogenic feed forward mechanism (da Costa Martins et al., 2010). MiR-23a conveys the hypertrophic signal by suppressing two anti-hypertrophic effectors: muscle ring finger protein-1 (MuRF1) and forkhead box O3 (FOXO3) (Lin et al., 2009; Wang et al., 2012). FOXO3, a regulator of the atrophy-related gene program and suppressor of calcinurin/NFAT signaling, is also targeted by miR-212/132 (Ucar et al., 2012). Both miR-212 and miR-132 are upregulated by cardiac stress and are necessary and sufficient to induce pathological hypertrophy in vitro and in vivo. In addition, pharmacological inhibition of miR-132 with antagomir prevented cardiac hypertrophy and heart failure induced by chronic LV pressure overload (Ucar et al., 2012).

Cardiomyocyte Hypertrophy and Endothelial Cells/Cardiac Angiogenesis

Cardiomyocytes secrete a large variety of factors that affect the coronary vasculature during development and stress response. Among these are VEGFA, fibroblast growth factor 2 (FGF2), PDGF, transforming growth factor β (TGF-β), ET-1, urocortin, adenosine, angiopoietins, and myokines. For instance, cardiomyocyte-specific deletion of VEGFA in mice during development

resulted in hearts with fewer coronary microvessels, thinned ventricular walls, and abnormal response to β-adrenergic stimulation. This demonstrates a critical role for cardiomyocyte-derived VEGFA for cardiac angiogenesis and normal myocardium development (Giordano et al., 2001).

A balanced hypertrophic growth implies that myocardial requirements for oxygen and nutrients are met by a commensurate growth of the coronary microvasculature and increase in blood flow. Failure of the vasculature to match cardiomyocyte growth can lead to cardiac dysfunction and ultimately failure. Compelling evidence for the importance of myocyte-vascular balance was provided in mice with cardiac hypertrophy induced by overexpression of Akt1. Akt1 modulates postnatal physiological hypertrophy in response to insulin signaling and nutritional status (Shiojima et al., 2002). However, transgenic overexpression of activated Akt1 in the mouse heart led to a large variety of phenotypes from cardiac hypertrophy with preserved systolic function, to cardiac dilatation and failure (Matsui et al., 2002). Initial activation of the Akt pathway promoted hypertrophy while preserving cardiac function (Condorelli et al., 2002; Kim et al., 2003; Shioi et al., 2002), whereas long-term activation led to pathological hypertrophy and cardiac dysfunction (Shiojima et al., 2005). The progression to pathological hypertrophy was thought to be caused by inadequate expansion of coronary angiogenesis to support the increase in cardiac mass with matching blood supply and nutrients. To directly demonstrate this, a tetracycline-inducible system of the cardiac Akt1 transgene was used. Short-term (2 weeks) Akt1 induction in cardiomyocytes promoted a physiological hypertrophic response accompanied by an increase in capillary density. Angiogenesis was induced at least in part by increased secretion of cardiomyocyte-derived VEGFA and angiopoientin-2 (Shiojima et al., 2005). However, activation of Akt1 for longer than 2 weeks resulted in a disproportional increase in cardiac mass relative to the extent of angiogenesis. This demonstrates the importance of coordination of cardiac muscle and the coronary vasculature in order to maintain cardiac function and suggests that angiogenic adaptation might be limited and imbalanced relative to the extent of hypertrophy (Walsh and Shiojima, 2007). Whether this limitation is due to a diminution in myocyte production of angiogenic growth factors, or increased production of antiangiogenic factors, or perhaps incapacitated endothelial response to angiogenic factors remains uncertain.

The importance of vascular balance during the hypertrophic response is further emphasized in peripartum cardiomyopathy (PPCM), a life-threatening condition characterized by sudden onset of heart failure in previously healthy women. Though PPCM etiology remains unknown, the current paradigm suggests that late-gestational secretion of antiangiogenic factors superimposed with reduced production of angiogenic factors in the heart causes vascular rarefaction that fails to provide sufficient amount of blood supply and nutrients to support the heart adaptation to increased hemodynamic and metabolic challenges (Bello and Arany, 2015; Patten et al., 2012). Ultimately, this mismatch leads to the development of systolic heart failure. Although approximately half of the affected women recover cardiac function postpartum, a large number develops chronic heart failure (Fett and Markham, 2015). There are two potential antiangiogenic factors contributing to this vascular imbalance (Bello and Arany, 2015). The first factor is a soluble version of the VEGF receptor 1 or soluble Fms-like tyrosine kinase 1 (sFLT1) secreted by the placenta in late gestation. sFLT1 binds and traps circulating VEGFA. The second factor is a 16 kDa fragment produced by proteolytic cleavage of the nursing hormone prolactin (PRL), secreted by the pituitary gland. The 16 kDa PRL fragment induces endothelial cell apoptosis and release of endothelial miR-146a into exosomes. Taken up by cardiomyocytes, miR-146a impairs metabolic activity and cardiac function by suppressing ErbB4, a NRG-1 receptor and an important modulator of physiological hypertrophic response during pregnancy (Halkein et al., 2013; Hilfiker-Kleiner et al., 2007). Additionally, superimposed reduction in cardiomyocyte-derived VEGFA exacerbates the angiogenic imbalance in the maternal heart (Patten et al., 2012). No specific therapy is available for PPCM other than standard treatment for heart failure. An ongoing randomized, controlled clinical trial is being performed in Germany to evaluate the efficacy and safety of bromocriptine (an inhibitor of PRL production) for improvement of LV function in PPCM patients. Although bromocriptine can lower PRL, it does not address the causes leading to PPCM (Hilfiker-Kleiner et al., 2012). Overall, there is a scientific consensus for a better understating of the PPCM mechanism of disease and more efficient therapeutic options.

Myocardial infarction is another clinical setting that provides evidence of the importance of cardiac myocyte-derived factors influencing the vasculature. In fact, there is strong evidence that VEGFA is substantially increased in the ischemic myocardium (Li et al., 1996) and the vasculature in ischemic heart exhibits greater sensitivity to VEGF- and other growth factor-induced vasodilation (Sellke et al., 1996). Transcriptional regulation of the ischemic response is broadly mediated by hypoxia-inducible factor 1 (HIF-1). HIF-1 levels increase in response to hypoxia and alter the expression of factors involved in angiogenesis and vasomotor reactivity including all the glycolytic enzymes, the Glut1 glucose transporter, VEGFA, PDGF-B, hepatic growth factor, TGF-β1, iNOS, ET-1, heme oxygenase, connective tissue growth factor (CTGF), and many others (Giordano, 2005; Semenza, 2001). Although HIF potentially could play an important role in vascular adaptation during myocardial hypertrophy, accumulation of p53 inhibits HIF-1 activity and angiogenesis in response to chronic LV pressure overload (Sano et al., 2007). Conversely, inducing angiogenesis with angiogenic factors or inhibiting p53 accumulation enhanced hypertrophic response and restored cardiac function under chronic pressure overload. Interestingly, the recently discovered angiogenic factor Canopy 2 (CNPY2), a HIF-1α regulated gene, prevents the antiangiogenic effect of p53 and vascular rarefaction in chronic pressure overload. Moreover, cardiac-specific CNPY2 transgenic overexpression attenuated the transition from compensatory hypertrophic response to ventricular dysfunction (Guo et al., 2015).

Transcription factors can also alter the expression of paracrine factors produced by cardiomyocytes to adjust angiogenic response. An interesting example is GATA4, which modulates cardiomyocyte differentiation and adaptive hypertrophic response in the adult heart. Cardiomyocyte-specific transgenic expression of GATA4 promoted myocardial angiogenesis, increased coronary flow, and perfusion-dependent cardiac contractility (Heineke et al., 2007). GATA4-induced angiogenesis in this model was

independent of the hypertrophic response and was mediated through direct regulation of VEGFA promoter activity (Heineke et al., 2007).

Recently, PDGF receptor β (PDGFR-β) has been shown to be required for cardiomyocyte-induced angiogenesis. The role of PDGFR-β in heart was initially noticed in cancer patients who developed heart failure following treatment with PDGFR-β inhibitors. Mice with cardiomyocyte-specific PDGFR-β gene deletion develop heart failure in response to pressure overload associated with impairment in cardiac angiogenesis (Chintalgattu et al., 2010). However, the mechanism by which PDGFR-β controls the paracrine angiogenic potential of cardiomyocytes is not clear. Also, the identity of the paracrine factors responsible for PDGFR-β-dependent angiogenic capacity of cardiomyocytes remains to be determined (Chintalgattu et al., 2010).

Myokines, cardioprotective factors secreted by cardiomyocytes, can act in a paracrine manner to induce angiogenesis. For instance, follistatin-like 1 (Fstl1), which is highly expressed by cardiomyocytes in response to pressure overload and myocardial infarction, activates the Akt pathway to promote survival in cardiomyocytes and angiogenesis in endothelial cells (Oshima et al., 2008; Ouchi et al., 2008). Different than other members of the follistatin family that function as extracellular-binding partners of the TGF-β superfamily, Fstll binds disco-interacting protein 2 homolog A, a cell-surface receptor, present on both cardiomyocytes and endothelial cells (Ouchi et al., 2010).

Endothelial Cells/Cardiac Angiogenesis and Cardiomyocyte Hypertrophy

The vasomotor control of coronary arteries plays a critical role in maintaining sufficient supply of oxygen and nutrients to the myocardium in response to exercise training, hemodynamic stress, and neurohumoral factors. A recent report has proposed that endothelial cells account for more than 60% of non-myocyte cell population and most likely their role in cardiac physiopathology is greater than previously anticipated (Pinto et al., 2016). Endothelium contributes to cardiovascular homeostasis by regulating vascular permeability, vascular resistance, and myocardial stiffness. Endothelium releases vasodilator and vasoconstrictor factors (nitric oxide (NO), ET-1), prostaglandins, pro- and anticoagulant factors, and growth factors (FGF, VEGFA, PDGF). In addition, the luminal surface of the endothelium harbors a number of enzymes, including ACE, capable of affecting myocardial and vascular function under hemodynamic stress.

Myocardial angiogenesis and increase in capillary density are critical for the development of cardiac hypertrophy. For instance, trapping VEGFA with a soluble VEGF receptor 2 decoy during pressure overload accelerates the progression of heart failure due to inhibition of the compensatory growth response, or possibly due to a reduction in size of the existing vasculature (Izumiya et al., 2006). Furthermore, myocardial hibernation and cardiac function appear to be regulated by the endothelial cell mass. A reduction in cardiac VEGFA levels induced by a cardiac-specific expression of a sFLT1 decoy reduced vascular density and promoted hypoperfusion and myocardial hibernation (May et al., 2008). The effect was reversible, since normal coronary vessel density and recovered heart function occurred once expression of the VEGF trap was discontinued.

The endothelium secretes factors, such as NRG-1 and apelin, which support the compensatory hypertrophic response to hemodynamic stress. In the heart, NRG-1 expression is restricted to the endocardial and microvascular endothelium, whereas its tyrosine kinase receptors ErbB2 and ErbB4 are expressed on cardiomyocytes (Lemmens et al., 2006). Disruption of NRG-1/ErB2 with trastuzumab (Herseptin), an inhibitory antibody against ErbB2, used in the treatment of mammary carcinomas, was discovered to induce cardiomyopathy in treated patients (Lemmens et al., 2007). NRG/ErbB signaling is indispensable during cardiac and neuronal development (Meyer and Birchmeier, 1995; Gassmann et al., 1995) and regulates the cardiac subtype specification nodal vs. ventricular myocytes in differentiating human embryonic stem cells (Zhu et al., 2010). Furthermore, increased NRG-1/ ErbB4 signaling by NRG-1 injection or ErbB4 overexpression promoted cardiomyocyte proliferation and myocardial regeneration after myocardial infarction (Bersell et al., 2009). In response to pressure overload, NRG-1/ErbB signaling increases during the compensatory phase of concentric growth and then decreases as the heart begins to fail (Lemmens et al., 2006, 2007). Interestingly, activation of NRG-1 signaling improves cardiac function in pressure overload-induced heart failure by inhibiting the abnormal sympathetic hyperactivity (Matsukawa et al., 2014). Mechanistically, the activation of NRG-1/ErbB signaling promotes cardiomyocyte hypertrophy via ERK1/2 and PI3K/Akt pathways (Baliga et al., 1999).

Apelin acts via its GPCR receptor APJ and likely plays an important role in cardiovascular pathophysiology by opposing actions to the rennin-angiotensin system (Ashley et al., 2006). While Ang II increases vascular tone and raises blood pressure, apelin promotes vasodilation via a NO-dependent mechanism. In the heart, apelin is primarily expressed by the endothelium, while APJ is expressed on cardiomyocytes, smooth muscle cells, and endothelial cells, suggesting a paracrine mode of action (Chen et al., 2003; Kleinz and Davenport, 2004; Kleinz et al., 2005; Rosenkranz, 2004). Apelin expression is induced in response to hypoxia in the ischemic heart (Chun et al., 2008; Sheikh et al., 2008) and promotes cardiac neovascularization after myocardial infarction by recruiting stem cells (Tempel et al., 2012). Several reports associate apelin deficiency with myocardial decompensation and human heart failure (Chen et al., 2003; Foldes et al., 2003; Chong et al., 2006; Charo et al., 2009). In hypertensive rats, the levels of apelin and APJ are maintained during the compensatory LV hypertrophic response and decline as heart failure sets in (Iwanaga et al., 2006). This may be due to an inhibitory effect of Ang II, because an AT1 receptor blocker, telmisartan, restores apelin/APJ expression. Apelin also improves cardiac contractility through a mechanism dependent on the activation of the PKC epsilon and ERK1/2 signaling (Perjes et al., 2014). However, whether apelin is beneficial for cardiac hypertrophy is still controversial, considering its effect to promote myocardial hypertrophy and cardiac dysfunction in the absence of pathological stimulation (Lu et al., 2016).

It has become evident that the endothelium has a role in the regulation of the heart size. The endothelium controls the size of adipose tissue, the prostate gland, and the liver (Tirziu and Simons, 2009). In the heart, early studies provide evidence of an angiogenesis-induced myocardial hypertrophy mechanism under stimulation with TH in rats. Although TH initially induced an increase in capillary density, this event was followed by the development of physiological hypertrophy and enhancement of ventricular function (Tomanek and Busch, 1998). The TH-induced angiogenic response required in part an early upregulation of FGF2 expression (Tomanek et al., 1998).

A more direct approach in analyzing the role of endothelium in determining heart size was addressed in conditional mouse models by cardiac-specific overexpression of angiogenic factor PR39 or placental growth factor (PlGF) (Tirziu et al., 2007; Jaba et al., 2013). PR39 or PlGF transgene expression for short-term (3 weeks) in the adult mouse heart led to a significant increase in endothelial cell mass and capillary/myocyte ratio with no changes in heart size. However, longer induction (6 weeks) promoted cardiomyocyte hypertrophy and increase in heart size. In both models, the hypertrophy was physiological, preserved contractile function, and was not accompanied by fibrosis or induction of markers associated with pathological hypertrophy. Mechanistically, higher baseline NO production due to increased vascular density promotes cardiomyocyte hypertrophy by targeting regulator of G protein signaling type 4 (RGS4) and relieving the repression of Gβγ-dependent PI3Kγ activation of the Akt/mTORC1 pathway (Jaba et al., 2013). In this sequence of events, NO is important for its role in proteosomal degradation of RGS4 through the Arg/N-end rule pathway of protein degradation (Hu et al., 2005). Consequently, a conditional RGS4-gain-of-function mouse, eNOS inhibitors, and angiogenic stimulation in eNOS knockout mice prevented myocardial hypertrophy. Furthermore, miR-182 was shown to be targeted by the endothelium to cardiomyocyte communication (Li et al., 2016). Although the mechanism by which endothelial NO induces miR182 in cardiomyocytes is not clear, miR-182 contributes to the cardiomyocyte hypertrophic response. MiR-182 fine-tuned the activation of the Akt/mTORC1 pathway in cardiomyocytes by reducing the expression of branched chain aminotransferase 2, responsible for branched chain amino acids (BCAAs) catabolism and FOXO3 (Li et al., 2016). Although cardiomyocyte-derived angiogenic growth factors cannot be excluded, the paracrine action of endothelium-derived NO appears to be an important hypertrophic mechanism in the context of superfluous supply of nutrients, in the absence of external stimuli. In another report, cardiomyocyte transgenic PlGF expression did not induce angiogenesis at the baseline. However, in this model PlGF induced greater hypertrophy in response to pressure overload through a paracrine signaling generated from the endothelium-fibroblast crosstalk (Accornero et al., 2011).

Another member of the VEGF family, VEGFB, promoted cardiac hypertrophy (Karpanen et al., 2008; Bry et al., 2010; Kivela et al., 2014). However, opposed to the PlGF model (Jaba et al., 2013), transgenic overexpression of VEGFB in the heart induces an increase in vessel diameter rather than an increase in vessel density and hypertrophy is independent of NO (Kivela et al., 2014). This apparent mechanistic difference between PlGF and VEGFB, both binding to VEGFR1, may reflect the capability of PlGF to induce angiogenesis and activate endothelial eNOS through VEGFR1 phosphorylation at Tyr794 (Ahmad et al., 2006; Roncal et al., 2008). In contrast, the VEGFB gain- and loss-of-function models provide evidence of a VEGFB-induced metabolic reprogramming mechanism in cardiomyocytes which favors glucose oxidation and protein synthesis, without increasing fatty acid uptake (Kivela et al., 2014). In the light of recent evidence that a BCAA metabolite released by cardiomyocytes instructs endothelium to facilitate fatty acid import into muscle (Jang et al., 2016), it is highly probable that VEGFB-induced metabolic changes mediate cardiomyocyte-endothelial cell crosstalk.

Cardiomyocyte Hypertrophy and Fibroblasts/Cardiac Fibrosis

Cardiac fibrosis, or excessive deposition of the ECM proteins, is a hallmark of pathological hypertrophy and heart failure. In response to increased wall stress, cardiac fibroblasts proliferate and produce the majority of ECM proteins (fibronectin, laminin, proteoglycan, collagen I and III) deposited in the interstitium (around cardiomyocytes) and perivascular region (in the adventitia of coronary arteries) (Piek et al., 2016). Fibroblasts sense and respond to biomechanical stress (MacKenna et al., 2000) and humoral factors including Ang II, ET-1, TGF-β, FGF2, and IGF-1 (Manabe et al., 2002; Bujak and Frangogiannis, 2007; Bouzegrhane and Thibault, 2002). Once activated, fibroblasts transdifferentiate into myofibroblasts, cells that express smooth muscle type contractile proteins and exhibit increased proliferative and secretory properties (Tomasek et al., 2002). While fibrosis may initially preserve cardiac function, a sustained fibrotic response promotes myocardial stiffness and atrial fibrillation and deprives the stressed myocardium of vascular supply. On the other hand, in myocardial infarction, α-smooth muscle actin (α-SMA) expressing myofibroblasts prevent wall rupture and adverse remodeling by facilitating scar formation and contraction (Shinde et al., 2017). In addition, fibroblasts can interact directly with cardiomyocytes via hetero-cellular gap junction coupling, which ultimately alters impulse generation and conduction (Tanaka et al., 2017).

Fibroblasts previously were thought to be an abundant non-myocyte cell population in the heart. However, advanced tracing techniques have recently estimated that the resident fibroblast makes up less than 20% of all non-myocyte cells (Pinto et al., 2016). Under pathological conditions, fibroblasts exhibit significant heterogeneity and plasticity, but the lack of reliable and specific markers has hampered efforts to understand their origin and biology. Not long ago, it was reported that up to 70% of cardiac fibroblasts in chronic pressure overload was derived from pathologically induced endothelial-to-mesenchymal

transition (EndoMT) (Zeisberg et al., 2007). This process was mediated by TGF-β1 and inhibited by bone morphogenic protein 7, a TGF-β superfamily member known to antagonize TGF-β signaling (Potenta et al., 2008; Zeisberg et al., 2007). Many other cell types have been suggested as a source of activated fibroblasts. For instance, pericytes were reported to be a major source of myofibroblasts containing α-SMA (Kramann et al., 2015). Cells of hematopoietic origin and infiltrating immune cells have been described to transdifferentiate into cardiac fibroblasts in the diseased heart (Crawford et al., 2012; van Amerongen et al., 2008). However, recent studies employing genetic lineage tracing revealed that fibroblast heterogeneity observed in pressure overload results from activated resident fibroblasts, derived from developmentally lineages of epicardial and endocardial/endothelial origin (Ali et al., 2014; Moore-Morris et al., 2014, 2016). Besides, endothelial-lineage tracing (Moore-Morris et al., 2014) and bone marrow transplant (Ali et al., 2014) argue against contribution of EndoMT and infiltrating hematopoietically derived fibroblasts to the pool of activated fibroblasts and cardiac fibrosis under hemodynamic stress. Similarly, another study employing periostin-lineage tracing provided evidence of myofibroblasts arising from the tissue-resident fibroblasts (Kanisicak et al., 2016).

Several signaling pathways have been implicated in fibroblast activation (Travers et al., 2016). In addition, bidirectional fibroblast-cardiomyocyte crosstalk plays an important role in myocardial hypertrophy and fibrosis. For instance, TGF-β, a potent mediator of fibroblast activation and cardiac fibrosis, is induced in fibroblasts and cardiomyocytes by Ang II via AT1 receptor (Campbell and Katwa, 1997; Schultz Jel et al., 2002). In fibroblasts, TGF-β activates the expression of profibrotic genes by binding to the type I TGF-β receptor and phosphorylation of Smad2/3, which subsequently bind Smad 4 and translocate to the nucleus. In cardiomyocytes, TGF-β binds to the type II TGF-β receptor and promotes cardiac hypertrophy by the activation of TGF-β-activated kinase-1 (TAK1) and induction of hypertrophic responsiveness to β-adrenergic stimulation (Rosenkranz, 2004). In addition, chronic stimulation of β2-ARs can induce fibroblast proliferation and ECM deposition (Turner et al., 2003). Interestingly, ET-1 is thought to interact with Ang II signaling. Deletion of ET-1 in endothelium prevented the development of cardiac fibrosis and hypertrophic response to Ang II stimulation (Adiarto et al., 2012).

It has become evident that miRNAs are involved in the fibroblast-cardiomyocyte crosstalk. For instance, CTGF, a TGF-β-activated factor, is directly regulated by miR-133 and miR-30 (Duisters et al., 2009). While miR-133 is specifically expressed in cardiomyocytes, miR-30 is expressed in both cardiac fibroblasts and myocytes. The decrease of these two miRNAs in pathological hypertrophy allows CTGF levels to increase. This suggests that cardiomyocyte-released CTGF contributes in a paracrine manner to augment cardiac fibrosis and collagen deposition (Duisters et al., 2009; Care et al., 2007; van Rooij and Olson, 2009). Furthermore, miRNA-enriched exosomes secreted by cardiac fibroblasts are taken up by cardiomyocytes and promote hypertrophy (Bang et al., 2014). MiR-21*, one of passenger strand miRNAs which normally undergo intracellular degradation, was identified as a paracrine signaling mediator of cardiomyocyte hypertrophy.

Recently, cardiac fibroblasts have been appreciated for their cardioprotective potential. For example, IGF-1 produced and secreted by fibroblasts is required for the adaptive response to pressure overload and cardiomyocyte hypertrophy. The transcription factor Krüppel-like factor 5 (Klf5) regulates IGF-1 expression and its haploinsufficiency in fibroblasts attenuates cardiomyocyte hypertrophy and fibrosis, whereas cardiomyocyte-specific Klf5 deletion has no effect on cardiomyocyte hypertrophy (Takeda et al., 2010). Interestingly, the conversion of fibroblasts to functional cardiomyocytes could be enhanced by Akt1. The addition of Akt1 to a pre-established reprograming cocktail boosted the generation of cardiomyocytes and cardiomyocyte hypertrophy potentially through the IGF-1/PI3K/Akt/mTORC1 pathway (Zhou et al., 2015). Furthermore, cardiac repair could be enhanced by cardiac fibroblasts undergoing mesenchymal-endothelial transition to generate de novo endothelial cells. This switch in fibroblast fate appears to be regulated by the transcription factor p53 (Ubil et al., 2014).

It is worth noting that cardiac fibroblasts in the adult heart promote myocyte hypertrophy, whereas during embryonic development they promote myocyte proliferation. The latter is mediated in part by secretion of fibronectin, collagen, and heparin-binding EGF-like growth factors that collaboratively interact and promote cardiomyocyte proliferation via β1-integrin signaling (Ieda et al., 2009). Therefore, a shift in the fibroblast genetic program changes the way fibroblasts communicate with cardiomyocytes in postnatal life versus embryonic development.

Cardiomyocyte Hypertrophy and Immune Cells/Cardiac Inflammation

There is increasing evidence that inflammatory signaling and resident and recruited immune cells contribute to the regulation of cardiomyocyte hypertrophy (Frieler and Mortensen, 2015; Kamo et al., 2015). Cardiomyocytes and non-cardiomyocyte cells in the heart secrete and respond to numerous pro-inflammatory cytokines, but responses are complex, depending on the cell type and pathophysiological circumstances: hypertrophic remodeling, cardiac injury, or heart failure. For instance, in patients with heart failure, the circulating levels of pro-inflammatory cytokines TNF-α, IL-6, and IL-1β correlated with the severity of disease (Testa et al., 1996). Cardiac TNF-α is induced by chronic pressure overload and appears to be involved in cardiac hypertrophy, myocyte apoptosis, inflammatory response, and cardiac dysfunction (Sun et al., 2007). Mice with cardiac-specific TNF-α transgenic overexpression recapitulate some of the features of pathological hypertrophy including cardiac hypertrophy and fibrosis, but they die suddenly of congestive heart failure (Kubota et al., 1997). On the other hand, clinical trials with TNF-α inhibitors, entanercept

(a recombinant human TNF receptor that binds to circulating TNF-α) and infliximab (a chimeric monoclonal antibody against TNF-α), failed to provide any benefit in patients with chronic heart failure (Chung et al., 2003; Mann et al., 2004). In the case of IL-6, various pleiotropic effects confound the understanding of the signaling mechanism (Fontes et al., 2015). For instance, IL-6 infusion alone, in the absence of hypertension, resulted in cardiomyocyte hypertrophy, increased fibrosis, and diastolic dysfunction, whereas IL-6 genetic deletion was protective in Ang II-induced cardiac fibrosis, by interfering with macrophage-stimulated fibroblast production of TGFβ-1 (Ma et al., 2012; Melendez et al., 2010). Furthermore, loss of gp130, a component of the IL-6 receptor complex, impaired the compensatory hypertrophic response and accelerated the onset of dilated cardiomyopathy and cardiomyocyte death during pressure overload (Hirota et al., 1999). IL-1β signaling has been associated with myocardial hypertrophy, cardiomyocyte apoptosis, and cardiac dysfunction and is the most promising therapeutic target to reduce the adverse remodeling in patients with heart failure (Bujak and Frangogiannis, 2009). Interestingly, low levels of IL-1β generated in response to pressure overload caused fibroblast-derived IGF-1 release to activate the Akt pathway and maintain the hypertrophic response in cardiomyocytes during early adaptation to hemodynamic stress (Honsho et al., 2009).

Macrophages also play an important role in the hypertrophic response. In the adult mouse heart, there are 4 distinct macrophage subsets that have different functions and origins (Epelman et al., 2014). During Ang II infusion, expansion of macrophage populations occurs through both local proliferation and monocyte recruitment as early as 2 days, before hypertrophy and fibrosis set in (Epelman et al., 2014). Importantly, Ang II infusion induced a CCR2+, $CD11c^{hi}$ macrophage subset, predominantly derived from circulating monocytes, enriched in genes regulating the inflammasome activity and IL-1β production. In response to pressure overload, $Ly6c^{lo}$ macrophages were specifically increased, while the number of $Ly6c^{hi}$ macrophages remained apparently unchanged (Weisheit et al., 2014). In addition, the depletion of macrophages by intravenous administration of liposomal clodronate in hypertensive Ren-2 rats had no effect on cardiac hypertrophy, but exacerbated cardiac dysfunction, indicating a potential role of macrophages in preserving the cardiac function (Zandbergen et al., 2009). Furthermore, recent evidence shows the contribution of macrophage miR-155 to cardiomyocyte hypertrophy. The gain- and loss-of-function studies showed that macrophage miR-155, not cardiomyocyte miR-155, promotes cardiomyocyte hypertrophy, cardiac inflammation, and dysfunction in response to pressure overload (Heymans et al., 2013). MiR-155-induced downregulation of suppressor of cytokine signaling 1 (Socs1) in macrophages was responsible for the paracrine-induced growth response in cardiomyocytes (Heymans et al., 2013). However, the precise identity of the paracrine signaling remains to be determined.

Recent studies have implicated mast cells in myocardial hypertrophy and cardiac fibrosis. Mast cells reside in the heart and their number is increased in response to pressure overload (Levick et al., 2011). Interestingly, pressure overload increased mast cell infiltration and fibrosis in the atrium, causing atrial fibrillation (Liao et al., 2010). This apparent communication between mast cells and fibroblasts led to the upregulation of PDGFA expression, responsible for fibroblast proliferation and collagen deposition. In contrast, treatment with the mast cell stabilizer cromolyn or bone reconstitution from mast cell-deficient mice prevented the upregulation of atrial PDGFA expression and atrial fibrosis (Liao et al., 2010) Furthermore, mast cell-deficient mice showed significant reduction in chronic pressure overload-induced cardiac hypertrophy and fibrosis and protection against adverse cardiac remodeling and failure (Hara et al., 2002). The effect of mast cells on fibroblast proliferation and ECM synthesis is at least in part mediated by the secretion of chymase and tryptase. Chymase increases TGF-β1 expression and signaling, while tryptase activates protease-activated receptor 2 and MAPK signaling in fibroblasts (McLarty et al., 2011; Zhao et al., 2008).

Conclusions

While cardiac hypertrophy is thought to be an adaptive response to hemodynamic stress, the complexity of molecular signaling congruently and inadvertently may irreversibly cause cardiac dysfunction with chronic exposure to stress. Once it has been said: "no cell is an island entire of itself" and "The constitutional endowment and the environment of a cell are both vital to its performance. An organism cannot be broken down into its component parts and rebuilt step by step as a house may be" (Smithers, 1969). There are no better words to describe the complex paradigm of cardiac hypertrophy. Although physiological and pathological hypertrophies have molecular and functional differences, an important question is whether mechanisms responsible for physiological response can be exploited to the benefit of patients with pathological hypertrophy and heart failure. Exercise training reduces cardiac risk factors and improves the quality of life in a variety of cardiovascular diseases (Johnson et al., 2015). However, it remains to be determined whether exercise can leverage the protective features of physiological response against pathological remodeling in patients with heart failure.

There are intricate conversations among multiple cell types within the cardiac microenvironment. The implications of these interactions are various and affect critical processes of the hypertrophic response: cardiomyocyte hypertrophy, angiogenesis, and cardiac fibrosis (**Fig. 2**). Elucidation of the molecular mechanisms mediating this cellular communication may lead to the discovery of novel therapeutic targets or biomarkers. It is also possible that paracrine factors mediating cellular crosstalk will show the benefit of inducing protective pathways in several cell types and generate a balanced growth response with preserved cardiac function. Despite the fact that there have been major breakthroughs, it is clear that a deeper understanding of cardiac hypertrophy will be critical to achieve exciting advancements in the treatment of cardiac hypertrophy and heart failure.

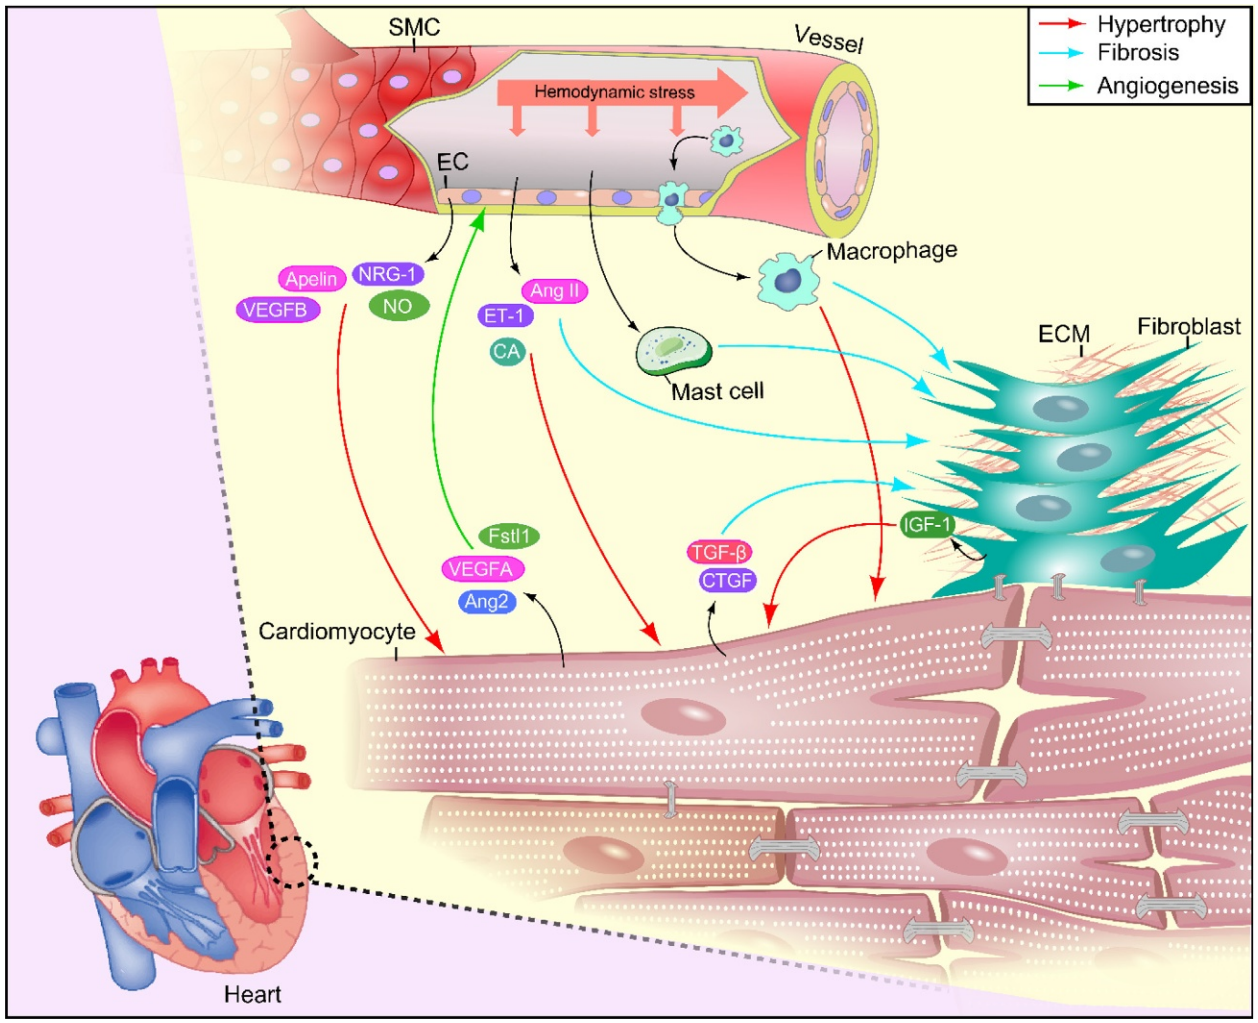

Fig. 2 Cardiac hypertrophy cellular crosstalk paradigm. The propagation of the hypertrophic response to hemodynamic stress extends beyond cardiomyocytes, the major players, to a complex network of signaling events concurrently integrated within cellular crosstalk. Several paracrine factors, known and unknown, drive cellular communications: cardiomyocytes to endothelium, endothelium to cardiomyocytes, cardiomyocytes to fibroblasts, fibroblasts to cardiomyocytes, immune cells to fibroblasts, immune cells to cardiomyocytes. In addition, direct cell–cell contacts via gap junctions may occur between cardiomyocytes and fibroblasts. Overall, this cellular crosstalk contributes to the key processes of cardiomyocyte hypertrophy, angiogenesis, and fibrosis. In particular, angiogenesis is important in meeting demands in blood supplies, oxygen and nutrients of the growing heart, as an imbalance in the extent of hypertrophic and angiogenic responses leads to a progressive deterioration of heart function. Hypertrophic signaling from endothelium and even fibroblasts may provide support for the compensatory hypertrophic response to cardiac stress. However, perturbations in the balance of this network during sustained hemodynamic stress can lead to a variety of pathological events including heart failure as a result of inadequate vascular compensation for myocyte hypertrophy, cardiac fibrosis, and adverse remodeling. *SMC*, smooth muscle cell; *EC*, endothelial cell; *ECM*, extracellular matrix.

Introduction

Cardiomyopathy, and the heart failure associated with it, is a leading cause of cardiovascular and overall morbidity and mortality in the United States and throughout the world (McMurray et al., 1998; Mozaffarian et al., 2016). Determining the etiology of heart failure is a crucial step in choosing the appropriate management strategy to achieve the best patient outcomes. Advances in cardiac magnetic resonance (CMR) have led to a detailed and comprehensive evaluation of the cardiovascular system. CMR is a valuable tool in diagnosis and management of cardiomyopathy and allows for patient-centered and personalized cardiovascular care.

The comprehensive nature of CMR not only provides detailed evaluation of structure and function but more recently tissue characterization. CMR is the gold standard for quantification of cardiac volumes and function. Valvular heart disease can be evaluated in detail with phase contrast imaging yielding quantification of flow and velocity. CMR is the optimal imaging modality in the assessment and management of congenital heart disease. Angiographic imaging, with its recent advances in flow dynamics, can provide an all-inclusive evaluation of aortopathies and vasculopathies. However, the most striking and revolutionary capability of CMR has been tissue characterization. Late gadolinium enhancement identifies focal ischemic and nonischemic scar. T1 mapping allows for quantification of diffuse myocardial fibrosis by measuring the extent of interstitial expansion via extracellular volume fraction. T2 mapping is able to identify areas of edema and inflammation, while T2 star mapping quantifies myocardial iron content. Cutting edge sequences are now evaluating myocardial fibrosis without the use of gadolinium contrast. Together, these CMR techniques provide highly diagnostic and prognostic information, especially in the evaluation of cardiomyopathy. This information is acquired without the use of ionizing radiation, and while some limitations exist in the use of CMR in patients with implanted metallic devices and contrast in those with renal dysfunction, CMR remains a rapidly evolving and cutting edge tool for clinicians in the evaluation of heart failure. This chapter highlights the utility of CMR in diagnosis and management of patients with commonly encountered cardiomyopathies.

Ischemic Cardiomyopathy

Ischemic heart disease is one of the most common causes of heart disease (Mozaffarian et al., 2016). Multiple imaging techniques exist to evaluate ischemic cardiomyopathy; however, CMR is one of the more comprehensive diagnostic strategies. CMR has the capability to identify ischemic myocardium with stress testing, myocardium at risk in the acute setting, localize infarct scar to provide information about viability, as well as identify the presence of thrombus—all in one exam.

The hallmark of ischemic cardiomyopathy is a typical pattern of subendocardial to transmural scar as noted with late gadolinium enhancement imaging (LGE) (Choi et al., 2001). During an acute myocardial infarction, damaged myocytes allow gadolinium to diffuse into the intracellular space, resulting in increased tissue concentration of gadolinium compared with normal myocardium. While in chronic infarction, as necrotic tissue is replaced by collagenous scar, the interstitial space expands, which leads to increased gadolinium tissue concentration. Higher tissue concentrations of gadolinium shorten the T1 relaxation time and thus appear bright, or "hyperenhanced," while viable regions appear black, or "nulled"(Rehwald et al., 2002). The transmural extent of infarction is a key predictor of improvement in contractile function, with 51%–75% transmural extent associated with limited viability and 76%–100% associated with virtually no viability (Choi et al., 2001; Kim et al., 2000). CMR is the only modality that can accurately determine the transmural extent of infarct scar given its high spatial resolution. This is an important distinction as it has been repeatedly shown that revascularization of patients with viable myocardium leads to significant improvement in clinical outcome (Kim et al., 2000). **Fig. 1** demonstrates a transmural myocardial infarction in the mid inferolateral wall consistent with nonviable

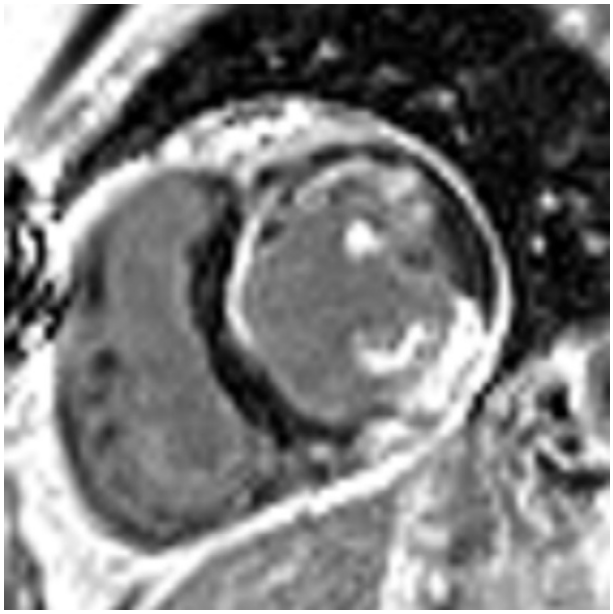

Fig. 1 Subendocardial and transmural myocardial infarction on late gadolinium enhancement short-axis image.

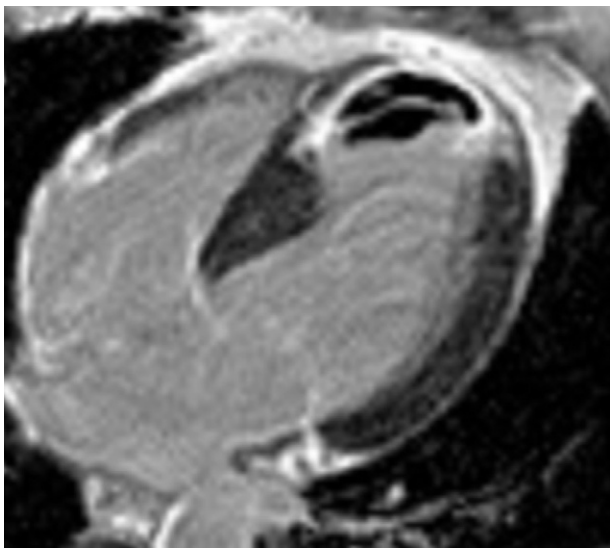

Fig. 2 Horizontal long-axis late gadolinium enhancement image demonstrates myocardial infarction (*white*) and a large apical thrombus (*black*).

myocardium, while the anterior, anteroseptal, and anterolateral walls exhibit a subendocardial infarction involving 50% of myocardial wall thickness suggesting partial viability.

Additional evaluation of the ischemic myocardium can be accomplished with stress CMR (adenosine, dobutamine, or treadmill stress). Multiple studies have shown the superior diagnostic performance of stress CMR as compared with standard imaging (Schwitter et al., 2008; Hamon et al., 2010; Flotats et al., 2012). Stress CMR can demonstrate ischemia with stress-induced wall motion and perfusion abnormalities, which together with LGE viability data paint a thorough picture of the myocardium. CMR also plays a role in the acute setting of a myocardial infarction by identifying the myocardium at risk with T2-based edema imaging. The additional information of the salvageable myocardium can impact the need and timing of revascularization (Klocke, 2010).

An important component of the CMR exam in patients with ischemic cardiomyopathy is the identification of ventricular thrombi. The presence of a ventricular thrombus is associated with larger infarct size, lower ejection fraction, and ultimately major adverse cardiac events (Pöss et al., 2015). LGE imaging has high sensitivity in identifying even small thrombi which appear as a low signal intensity mass surrounded by high intensity structures including the ventricular cavity and surrounding myocardium. Fig. 2 demonstrates significant infarct scar with a large apical thrombus.

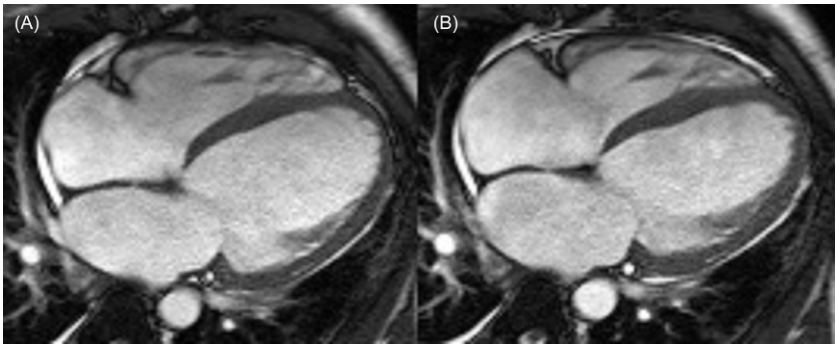

Fig. 3 Horizontal long-axis cine images at end-diastole and end-systole in a patient with dilated cardiomyopathy.

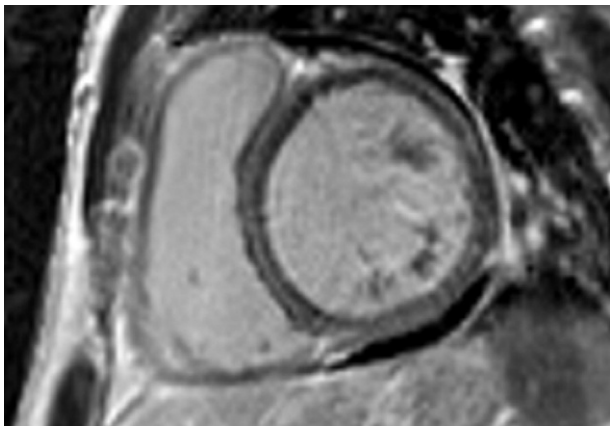

Fig. 4 Short-axis late gadolinium enhancement images with linear midmyocardial septal fibrosis in a patient with dilated cardiomyopathy.

Comprehensive CMR imaging in ischemic cardiomyopathy permits clinicians to confidently make key decisions about the need and timing of revascularization, use of systemic anticoagulation, and tailoring medical and device-based therapy.

Dilated Cardiomyopathy

Dilated cardiomyopathy comprises a large number of etiologies and a broad genetic basis (Haas et al., 2015). The evaluation of nonischemic dilated cardiomyopathy often involves CMR which not only identifies the structure, degree of ventricular dysfunction, but provides important prognostic information about myocardial tissue. The diagnosis is established with a typical LGE pattern of linear midwall fibrosis, particularly present in the septum (Mahrholdt et al., 2005; Almehmadi et al., 2014). **Fig. 3** demonstrates end-diastolic and end-systolic cine frames of a patient with severe biventricular dilation and dysfunction. LGE imaging reveals prominent midwall fibrosis in the septum in the same patient (**Fig. 4**). The presence of midwall fibrosis has high prognostic value and is strongly associated with ventricular arrhythmias, heart failure, and sudden cardiac death (Gulati et al., 2013; Di Marco et al., 2017). These findings are independent of ejection fraction thus raising important questions about appropriate patient selection for implantable cardioverter-defibrillator (ICD) placement (currently only based on ejection fraction). LGE presence could guide selection of ideal candidates for ICD implantation irrespective of the severity of systolic dysfunction.

Additional diagnostic and prognostic information can be obtained from evaluation of diffuse myocardial fibrosis. While LGE can accurately identify focal myocardial replacement fibrosis, it cannot assess diffuse interstitial fibrosis as image contrast relies on the different signal intensities between fibrotic and "normal" myocardium (Mewton et al., 2011). In diffuse nonischemic processes, these differences may not exist. However, T1 mapping can quantify diffuse fibrosis by measurement of the extracellular volume fraction (ECV). An elevated ECV has been shown to be associated with worse outcomes in multiple disease states, including the nonischemic cardiomyopathy population (Zareba et al., 2013).

Hypertrophic Cardiomyopathy

CMR is a powerful diagnostic and prognostic tool in hypertrophic cardiomyopathy (HCM). Assessment of the location and extent of myocardial wall thickness, the presence of myocardial crypts, and visualization of abnormal mitral apparatus can all be

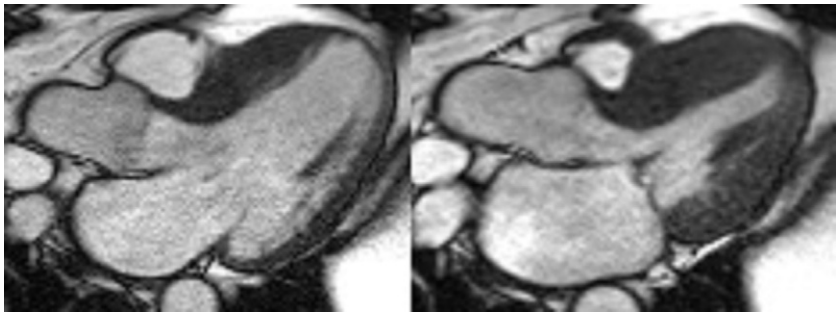

Fig. 5 Three-chamber cine images at end-diastole and end-systole in a patient with hypertrophic cardiomyopathy.

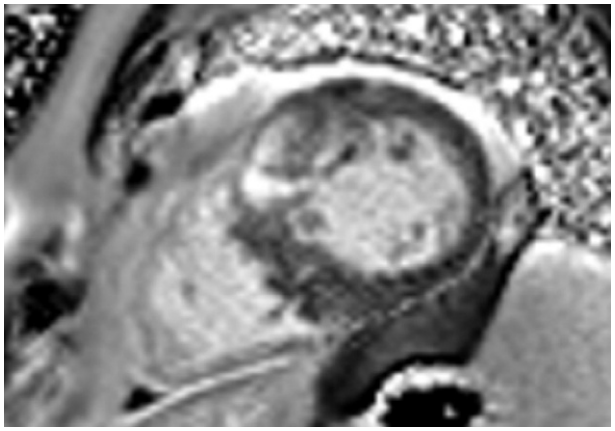

Fig. 6 Short-axis late gadolinium enhancement images demonstrating prominent patchy midmyocardial fibrosis in a patient with hypertrophic cardiomyopathy.

accomplished with cine imaging. Phase contrast imaging can identify the degree of left ventricular outflow tract obstruction secondary to the hypertrophic process. The presence and amount of myocardial fibrosis can be measured by LGE. **Fig. 5** shows prominent asymmetric septal hypertrophy with a maximum wall thickness of 2.5 cm in a patient with genetically confirmed HCM. Short-axis LGE images demonstrate extensive midmyocardial septal fibrosis—a poor prognostic indicator (**Fig. 6**).

The presence of LGE is an independent predictor of adverse outcomes in HCM patients. Studies have demonstrated a significant relationship between LGE and cardiac as well as all-cause mortality in this patient population (Green et al., 2012; Chan et al., 2014). Quantification of LGE can also aid in risk stratifications—an important study demonstrated that LGE $\geq$ 15% of LV mass is linked to a twofold increase in the risk of sudden cardiac death in otherwise lower risk patients. CMR allows for earlier diagnosis and identification of high-risk HCM patients. HCM thought leaders advocate for including CMR fibrosis assessment in the overall risk stratification of HCM patients when deciding on primary prevention ICD placement (Maron and Maron, 2016).

Cardiac Sarcoidosis

The evaluation of cardiac sarcoidosis with CMR has added significant value to the diagnosis and management of a disease process whose patchy cardiac involvement can be difficult to confirm with myocardial biopsy. Cardiac sarcoidosis can lead to conduction abnormalities, arrhythmias, heart failure, and sudden cardiac death. Left ventricular ejection fraction has traditionally been the major predictor of mortality in patient with cardiac sarcoid (Hulten et al., 2016).

CMR can evaluate both the reversible inflamed and irreversible scarred myocardium in patients with cardiac sarcoidosis. T2 mapping allows identification of active inflammation which has been shown to correspond to electrocardiographic and arrhythmic abnormalities (Crouser et al., 2014). **Fig. 7** demonstrates abnormal signal in the inferior wall on T2 mapping, indicating inflammation in a patient with cardiac sarcoid; while **Fig. 8** reveals normalization of T2 signal after immunosuppressive therapy with prednisone and methotrexate in the same patient.

The typical LGE pattern in cardiac sarcoidosis involves patchy midmyocardial fibrosis, particularly in the inferolateral wall and septum; however, other patterns can be seen (Hulten et al., 2016). The presence of LGE has been shown to be associated with ventricular arrhythmias and mortality in patients with cardiac sarcoidosis despite a normal ejection fraction (Murtagh et al., 2016). Recent consensus statements advocate for including myocardial inflammation and fibrosis data in appropriate ICD selection in sarcoidosis patients with cardiac involvement (Birnie et al., 2014).

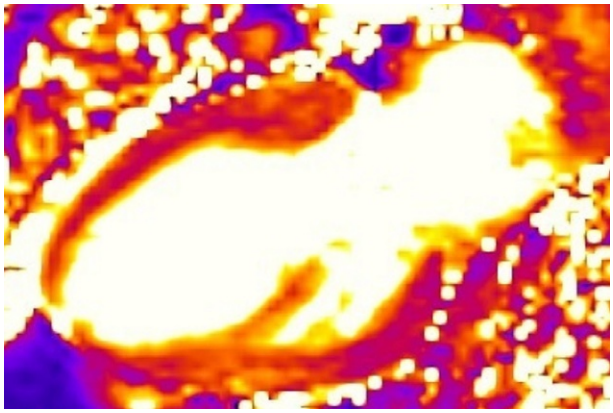

Fig. 7 Vertical long-axis T2 maps demonstrating abnormal T2 signal in the inferior wall consistent with myocardial inflammation in a patient with active cardiac sarcoidosis.

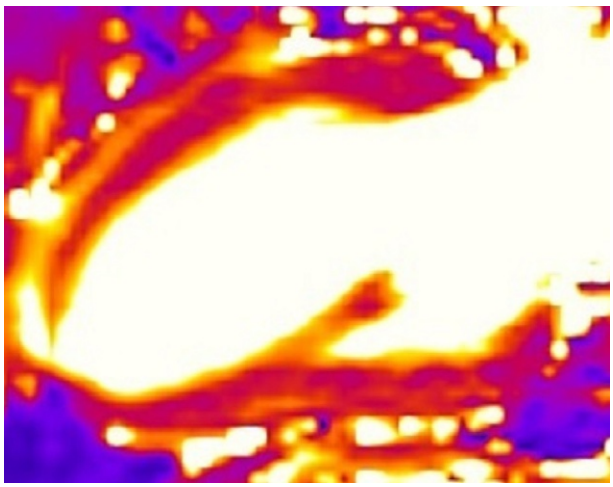

Fig. 8 Vertical long-axis T2 maps demonstrating normalization of T2 signal after immunosuppressive therapy in a patient with cardiac sarcoid.

Chemotherapy-Induced Cardiomyopathy

Chemotherapy-induced cardiomyopathy is a well-described form of left ventricular dysfunction that occurs as a result of myocardial toxicity related to chemotherapy. Various cardiotoxic chemotherapeutic agents have been implicated; however, anthracycline-induced cardiotoxicity is the most well studied. CMR can accurately and reliably assess left ventricular function with cine imaging without the need for gadolinium-based contrast (Armstrong et al., 2012). MR is also ideally suited for the serial nature of cardiotoxicity assessment given the lack of radiation needed to image.

Late gadolinium enhancement in chemotherapy-induced cardiomyopathy can demonstrate midwall fibrosis of nonischemic etiology. However, earlier detection of cardiotoxic myocardial tissue changes provides an opportunity for prompt therapeutic intervention. Studies have shown that patients treated with anthracyclines have abnormal T1 mapping, particularly higher native T1 times and elevated ECVs, in the absence of left ventricular dysfunction (Jordan et al., 2014; Neilan et al., 2013). Furthermore, these elevations were shown to be independent of underlying cancer or cardiovascular comorbidities, but rather related to the cardiotoxic cancer treatment regimen (Jordan et al., 2016). As CMR continues to become part of routine clinical practice, further studies will determine how myocardial tissue changes can be modified.

Cardiac Amyloidosis

Cardiac infiltration in amyloidosis results in a restrictive cardiomyopathy leading to heart failure, ventricular arrhythmias, and death. While the genetics of amyloidosis are fairly well-understood (Gertz et al., 2015), the diagnosis of cardiac involvement had in the past relied on clinical suspicion and biopsy. The prognosis varies based on the type of cardiac amyloidosis with life expectancy ranges of 5 months to 5 years (Kyle et al., 1996; Pinney et al., 2013). Current therapeutics, including targeted chemotherapy along

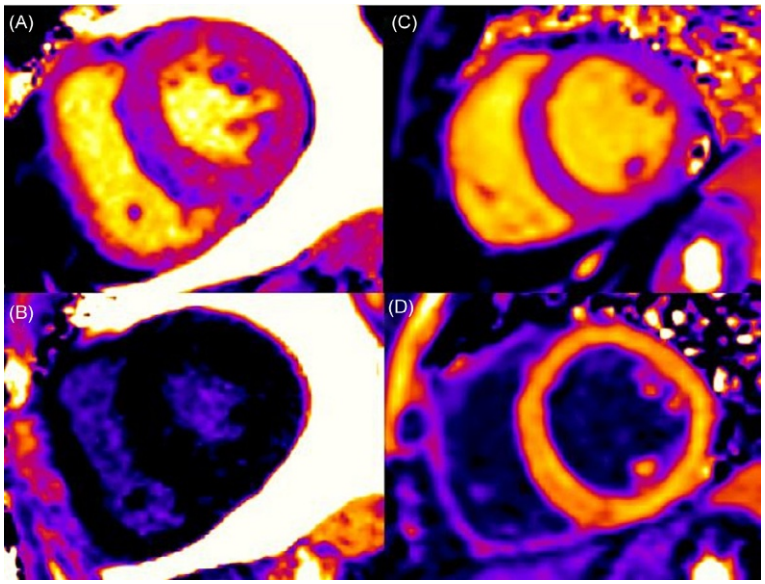

Fig. 9 Pre- and postcontrast T1 maps (MOLLI sequence) in a patient with cardiac amyloidosis (panels A and B) and a healthy individual (panels C and D).

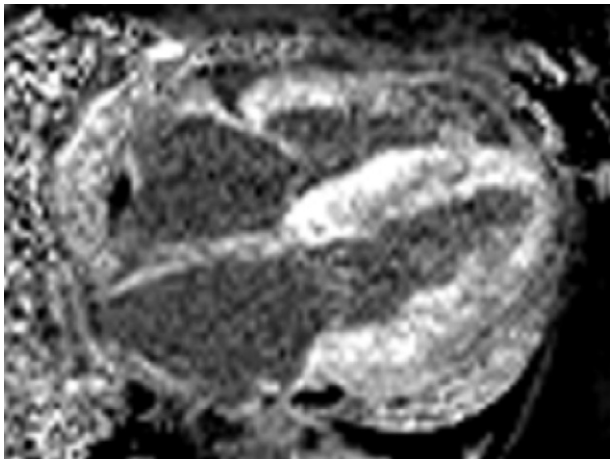

Fig. 10 Diffuse myocardial hyperenhancement and characteristic dark blood pool in a horizontal long-axis late gadolinium enhancement image classic for cardiac amyloidosis.

with heart failure medications, provide variable response rates; however, earlier detection is thought to improve outcomes. The amyloid protein deposits in the myocardial interstitium, thereby expanding the extracellular matrix. CMR is uniquely suited for the diagnosis of cardiac amyloid given the ability to quantify the extracellular space via the measurement of extracellular volume fraction with T1 mapping (Moon et al., 2013). ECV is significantly elevated in cardiac amyloid and also highly prognostic (Banypersad et al., 2013, 2015). **Fig. 9** demonstrates the striking difference between pre- and postcontrast T1 maps in a patient with cardiac amyloid (panels A and B) and a healthy individual (panels C and D).

A distinct LGE pattern is seen with cardiac amyloid with prominent and often diffuse myocardial hyperenhancement which can be circumferential, transmural, or subendocardial (Syed et al., 2010). Different subtypes of amyloid can also present with different LGE patterns (Dungu et al., 2014). **Fig. 10** demonstrates diffuse hyperenhancement (biventricular and biatrial) in a patient with cardiac amyloidosis.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is caused by an autosomal dominant genetic mutation in desmosomal proteins, resulting in fibrofatty replacement of the myocardium leading to wall thinning and aneurysm formation (Basso et al., 2009). This abnormal myocardial structure leads to ventricular dysfunction and potentially fatal arrhythmias. While ARVC was historically felt to be isolated to the right ventricle, more evidence suggests possible left ventricular involvement. CMR is the imaging

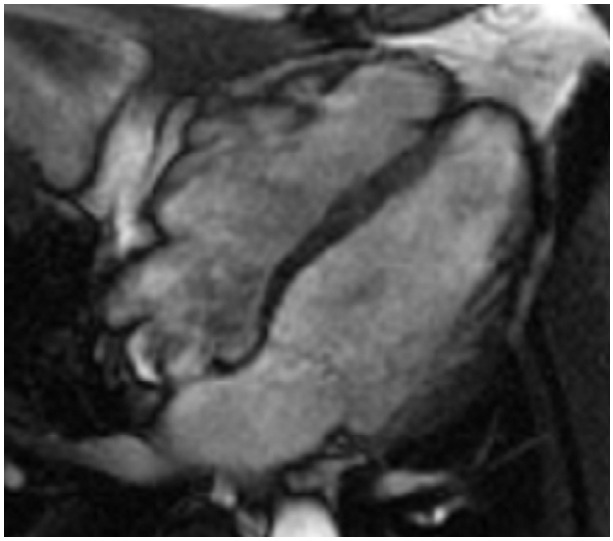

Fig. 11 Horizontal long-axis cine image at end-diastole in a patient with ARVC showing RV dilatation and multiple irregularities and aneurysms of the RV free wall.

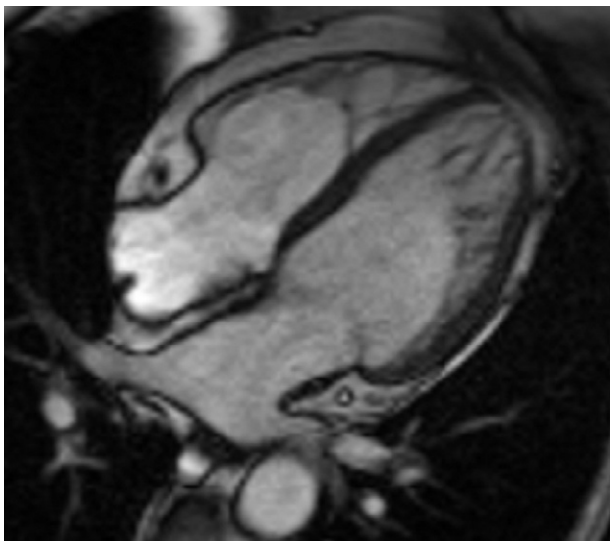

Fig. 12 Horizontal long-axis cine image at end-diastole showing prominent biventricular trabeculae in a patient with noncompaction cardiomyopathy.

modality of choice in ARVC and has been incorporated into the revised Task Force Criteria (Marcus et al., 2010). Cine imaging allows for assessment of right ventricular wall motion, presence of aneurysms, myocardial fat deposition, and precise quantification of right ventricular function (Tandri et al., 2008). **Fig. 11** is an end-diastolic cine frame of a patient with ARVC demonstrating RV dilation and aneurysm formation in the RV free wall.

Left Ventricular Noncompaction

Left ventricular noncompaction cardiomyopathy is characterized by abnormal trabeculae in the left ventricular apex and lateral wall. The disease results from cessation of the normal compaction process of the myocardium during cardiac development, and can result in a variety of patterns of cardiomyopathy, including arrhythmogenic, hypertrophic, dilated, and restrictive cardiomyopathy (Towbin et al., 2015). Patients affected by left ventricular noncompaction cardiomyopathy are at risk for heart failure, ventricular arrhythmias, and sudden death. There is also elevated risk of thrombus formation within the trabeculae due to decreased flow, whether from systolic dysfunction or the morphology of the LV cavity between trabeculae.

CMR provides high-resolution images of noncompacted myocardium and studies have shown that a noncompacted to compacted layer ratio greater than 2.3 has high diagnostic accuracy for distinguishing pathologic noncompaction (Petersen et al., 2005). Numerous LGE patterns have been described including trabecular, midwall, subendocardial, and transmural, which correlate with disease severity (Nucifora et al., 2011). LGE imaging can also identify ventricular thrombi in patients with noncompaction cardiomyopathy. **Fig. 12** is an end-diastolic cine frame demonstrating prominent biventricular trabeculae.

Myocarditis

Myocarditis is an inflammatory disease of the myocardium with an often heterogeneous clinical presentation and etiology. Although infectious etiologies (direct viral infections or postviral immune mediate response) account for the majority of cases, myocardial inflammation can be triggered by any immunologic reaction (Friedrich et al., 2009). Patients often present with a viral syndrome, chest pain, ST segment abnormalities on EKG, and troponin elevation.

CMR plays an important role in diagnosing myocarditis as it can demonstrate the extent of inflammation along with differentiate between ischemic and nonischemic injury. T2 mapping allows for quantitative assessment of myocardial T2 signal which reflects water content. Elevated T2 signal identifies myocardial tissue inflammation and/or edema and has been shown to reliably detect myocardial involvement in patients with myocarditis (Giri et al., 2009; Thavendiranathan et al., 2012). The typical LGE pattern in myocarditis involves midmyocardial to epicardial enhancement. LGE also has significant prognostic value in myocarditis (Grun et al., 2012), with patients exhibiting extensive LGE having poorer outcomes than those with no or minimal LGE. CMR images provide additional insight in myocarditis, including ventricular function, presence of pericardial effusion, and evidence of pericardial thickening and enhancement if concomitant pericarditis is present. **Fig. 13** is a short-axis T2 map demonstrating elevated T2 values in the anterior and lateral walls. LGE images reveal striking enhancement predominantly in the lateral wall (**Fig. 14**).

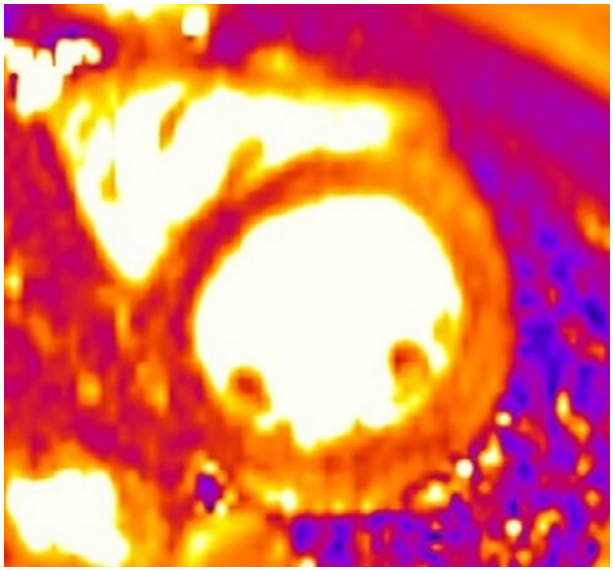

Fig. 13 Short-axis T2 map demonstrating elevated T2 signal in the anterior and lateral walls in a patient with myocarditis.

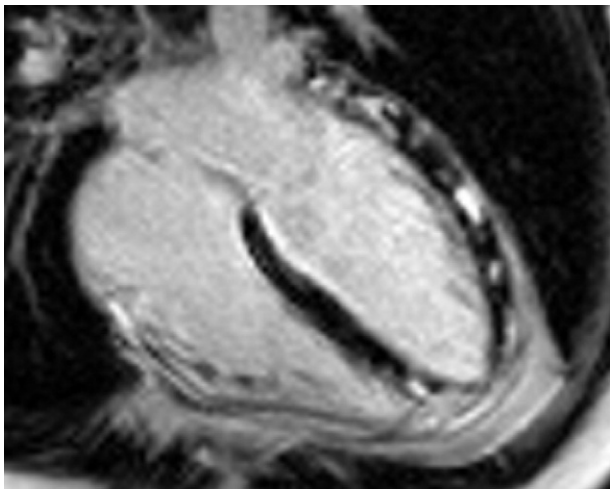

Fig. 14 Horizontal long-axis late gadolinium enhancement imaging demonstrating striking lateral enhancement in a patient with myocarditis.

Takotsubo Cardiomyopathy

Takotsubo, or stress-induced cardiomyopathy, typically presents with signs and symptoms concerning for acute coronary syndrome despite lack of obstructive coronary artery disease. It often follows emotional or physical stress and is possibly thought to be related to an excess of catecholamines leading to myocardial stunning as well as microcirculatory dysfunction (Kohan et al., 2014).

CMR is particularly useful in Takotsubo cardiomyopathy due its tissue characterization capabilities. Cine images demonstrate wall motion abnormalities typically in the mid an apical segments with basal sparing, often in a noncoronary distribution. **Fig. 15** demonstrates this wall motion pattern in end-diastolic and end-systolic images. T2 imaging reveals myocardial edema/inflammation in the affected segments, often without significant LGE burden (Thavendiranathan et al., 2012; Eitel et al., 2011). **Fig. 16** reveals elevated T2 signal in the mid and apical segments. Diagnosis of Takotsubo cardiomyopathy usually portends favorable survival and prognosis; however, the presence of LGE has been associated with more profound heart failure and delayed recovery in this patient population (Naruse et al., 2011).

Cardiac Iron Overload

Chronic iron overload states seen in hemochromatosis or chronic transfusion syndrome can result in iron deposition into the myocardium leading to overt cardiomyopathy. Early disease is characterized by diastolic dysfunction, leading to ventricular dilation with eventual systolic dysfunction, atrial and ventricular arrhythmias (Gujja et al., 2010; Kirk et al., 2009). Myocardial iron uptake

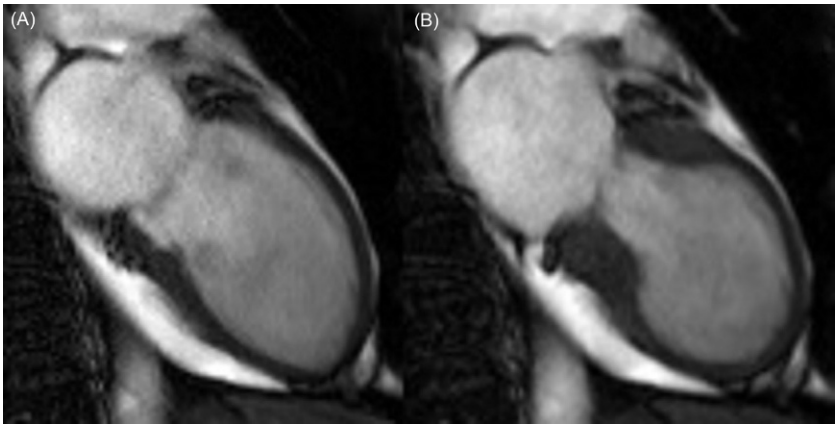

Fig. 15 Vertical long-axis cine images at end-diastole and end-systole in a patient with takotsubo cardiomyopathy.

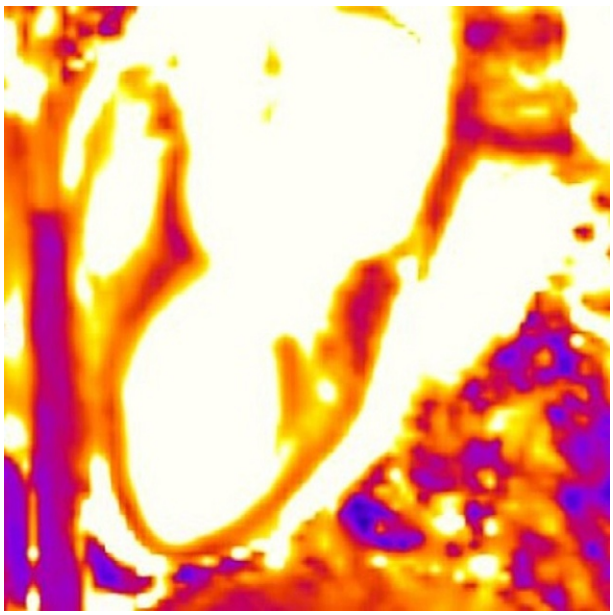

Fig. 16 T2 map in a patient with takotsubo cardiomyopathy demonstrating diffusely abnormal T2 signal in mid and apical segments.

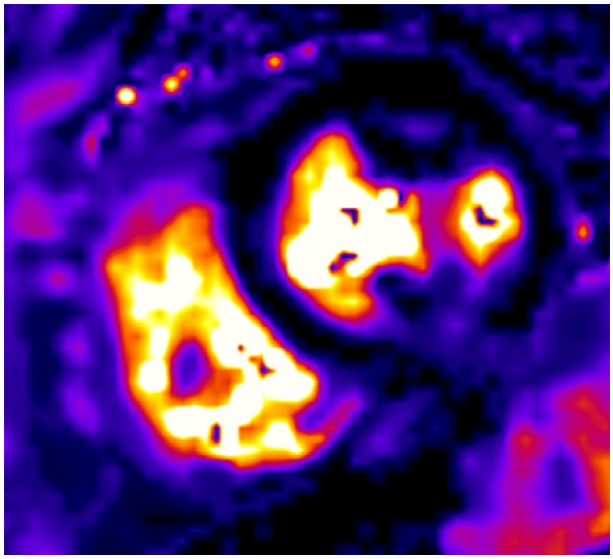

Fig. 17 Short-axis T2* map in a patient with hereditary hemochromatosis demonstrating severe myocardial iron overload.

often lags behind the iron deposition rate in other organs, particularly the liver (Kremastinos and Farmakis, 2011); however, once heart failure ensues prognosis is significantly worsened. Strategies aimed at early diagnosis to institute prompt therapy have had a significant impact on survival.

CMR is especially well suited for early detection and quantification of cardiac and hepatic iron overload as well as for monitoring response to therapy. CMR T2* relaxometry imaging is more reliable than serum ferritin or liver iron measurements in determining the degree of iron overload in the myocardial tissue (Kirk et al., 2009). T2* values <20 ms inversely correlate with ejection fraction, and severe iron overload with T2* values of <10 ms is associated with the development of heart failure and arrhythmias (Gujja et al., 2010; Kirk et al., 2009). **Fig. 17** is a short-axis T2* map demonstrating severe myocardial iron overload with a T2* value of 1.8 ms.

Introduction

Cardiac pacing has evolved dramatically over the past half century from simple externalized devices that treated life threatening bradycardias to sophisticated, highly programmable platforms to treat cardiomyopathies and heart failure. Electrical stimulation to create cardiac activity was first pioneered in the early 1930s by a prominent cardiologist Albert Hyman who developed the "Hyman Otor" a device with a manual crank generator that created an electrical current conducted through a long needle placed intercostally to stimulate myocardial tissue (Beck et al., 2010). Large externalized pacing devices with myocardial wires were later developed and perfected by C. Walton Lillehei, a prominent cardiac surgeon at the University of Minnesota, and used for postoperative cardiac pacing. It was not until a power outage in 1957 that Lillehei along with an equipment engineer, Earl Bakken, developed the first portable transistorized battery powered pacemaker. On October 8th, 1960, the first self-contained battery powered internalized pacemaker was inserted into Anne Larsson, a patient with complete AV block and Stokes Adams attack (Aquilina, 2006; Beck et al., 2010).

For the past 60 years, despite remarkable breakthroughs in pacing technologies, device size, battery longevity, remote monitoring and lead performance, the overall configuration of the cardiac pacemaker has not changed; one or more leads placed transvenously in contact with myocardial tissue and attached to a pulse generator placed subcutaneously. Nonetheless, innovations in catheter based techniques, energy sources, and miniaturized electronic platforms has brought in a new era in cardiac pacing; the leadless cardiac pacemakers (LCP) comprising of either a multicomponent leadless pacemaker system or a self-contained electrode and generator in a single device (El-Chami et al., 2017). The remarkable evolution of cardiac pacing has been paralleled with an unprecedented development in cardiac rhythm diagnostic tools that went from portable Holter monitors to miniaturized fully implantable loop recorders. In this review we will summarize the basics in cardiac pacing and pacing physiology and moreover highlight advances in pacing modalities (cardiac resynchronization therapy, multipoint pacing, His bundle pacing) and novel pacing technologies (leadless pacing and battery-less devices) in addition to a brief overview on advances in cardiac rhythm monitoring.

Basics of Cardiac Pacing

Pulse Generator and Leads

The pacemaker system comprises two main components; the leads that are placed transvenously in contact with myocardial tissue and the pulse generator or "can" that is connected to the leads and placed subcutaneously typically in the pectoral region. A pacemaker generates an electrical pulse capable of depolarizing the underlying myocardial tissue in addition to sensing any intrinsic cardiac electrical activity. The leads consist of conductor cables and electrodes separated by insulation material (silicone or polyurethane). A side-by-side relationship of the conductor cables denotes a coradial design; whereas, a conductor coil within a conductor coil implies a coaxial design. The electrodes are typically located at the lead tip and more proximally along the lead (ring electrode). The lead tips are attached to the myocardium by a screw in penetrating helix (active fixation mechanism) or via tines projecting from the lead tip that attach to trabeculae (passive fixation mechanism). Newer generation leads consist of steroid eluting

collars, which minimize inflammation and fibrosis at the lead tips that lead to elevated capture thresholds and failure to pace. Whereas pacemakers generate a stable voltage, the leads are typically designed to feature higher resistances (400–1200 ohms) to minimize current drain and battery depletion. The pulse generator in turn is comprised of the electrical circuitry and lithium iodide batteries that became the battery of choice for modern pacemakers owing to the smaller size, production cost, and highly predictable voltage decay and battery life (Mulpuru et al., 2017).

Pacemaker Function

As eluded to earlier, pacemakers not only generate an electrical current to depolarize the underlying myocardium but also sense myocardial electrical activity. The minimum amount of energy needed to depolarize the myocardium is termed capture threshold. A pacemaker stimulus is characterized by its amplitude (volts) and pulse width (milliseconds), the duration over which the stimulus is delivered. Optimizing both these parameters is integral in maintaining battery longevity while minimizing capture of nearby structures. The electrical current delivered is either bipolar or unipolar. With bipolar pacing, the current delivered is between the tip electrode (cathode) and the ring electrode (anode). With unipolar pacing, energy delivered is between the lead tip and the can (anode). Bipolar pacing is generally more desirable because of minimal extracardiac stimulation making bipolar leads the standard in endocardial pacing (Mulpuru et al., 2017; Beck et al., 2010). Sensing, on the other hand is a feature by which the pacemaker depicts myocardial depolarization in proximity to the lead tip. For optimal function a pacemaker must sense 'near-field' (contact) signals and reject 'far-field' (noncontact signals) and repolarization signals. The advent of bipolar sensing, between closely spaced tip and ring electrodes has minimized myopotential oversensing, far-field signals, and electromagnetic interference (EMI), which were present with unipolar sensing (tip to can). In conclusion, the safety and reliability of pacemaker leads exhibit 97%–99% 5-year survival.

Pacemaker Modes

The pacing mode is reported as a 4-letter code, in which the first position identifies the chamber paced (A for atrium, V for ventricle, D for both chambers), the second position denotes the sensed chamber, the third position denotes the device's response to any sensed events; whereby the device will inhibit pacing (I) trigger pacing output (T) or both (D). The fourth letter code indicates whether rate response is on. The rate responsive feature provides chronotropic response. Devices use different sensors to determine rate responsiveness to physiological demands.

The most commonly utilized pacing modes are DDD, DDI, VVI, and AAI. DDD mode, the standard dual-chamber pacing mode, is used when the sinus mode is intact, but AV conduction impaired. Sinus activity is sensed and will trigger ventricular pacing following a programmed AV delay. Rate response (DDDR) is sometimes used when sinus function is impaired. Ventricular-only pacing, VVI(R), is used in patients with chronic atrial fibrillation, or infrequent pauses or bradycardias. The potential for tracking fast atrial rhythms is excluded. Rate response provides chronotropic support when needed. AAI(R) or atrial only pacing, on the other hand, is reserved for isolated sinus node dysfunction with intact AV nodal conduction. DDI mode is utilized in individuals with paroxysmal atrial tachyarrhythmias to prevent tracking of fast atrial rhythms. Asynchronous modes (DOO/VOO) are programmed to avoid recognition of electrical activity, most commonly electrocautery, MRI signals, or other EMI. These modes prevent sensing of extrinsic electrical activity that can otherwise inhibit pacing.

Basic Pacemaker Programming

Right ventricular pacing activates the interventricular septum before the left ventricular lateral wall, which is manifested as a left bundle branch block pattern on the surface electrocardiogram (ECG). This results in LV dyssynchrony, with deleterious effects on left ventricular function and adverse clinical outcomes, including heart failure and increase in mortality (Wilkoff et al., 2002). Pacing-induced cardiomyopathy is a well-recognized consequence of chronic right ventricular pacing, even among patients with preserved baseline ejection fraction (EF) and occurs in as much as 20% of individuals with chronic right ventricular pacing (Khurshid et al., 2014). It is reported that a pacing burden of 20% is associated with pacing-induced cardiomyopathy (Khurshid et al., 2014). Basic programming features of pacemakers are centered on minimizing ventricular pacing. Different features were developed in dual chamber devices that utilize atrial-only pacing with automatic switching to dual chamber pacing with failed AV conduction or algorithms that automatically prolong AV intervals with shortening of these intervals with no intrinsic AV conduction. These various programming algorithms have decreased significantly the rates of right ventricular pacing in patients without complete AV block (Stockburger et al., 2015; Sweeney et al., 2007).

Rate response or rate-adaptive pacing is a feature in modern pacemakers to increase the pacing rate in response to physical or emotional exertion. Rate-adaptive pacing improves exercise capacity in patients with chronotropic incompetence. Accelerometers are the most commonly used in rate adaptive pacing and increase pacing heart rate in response to upper extremity movements. Other physiological sensors utilized in some devices rely on minute ventilation, cardiac contractility, and blood temperature to increasing pacing rate.

Cardiac Resynchronization Therapy

Overview

Cardiac pacing has evolved over the years from treating life-threatening bradyarrhythmias to standard of care in the management of cardiomyopathies and heart failure. Cardiac resynchronization therapy was introduced as a concept to treat heart failure by improving dyssynchrony, where the lateral segment of the left ventricle is both electrically and mechanically delayed than the earlier activated interventricular septum. Dyssynchrony which is manifest with a left bundle branch block on ECG is either interventricular (between the right and left ventricle) or intraventricular (between the septum and lateral LV wall).

Early animal studies in the late 1980s demonstrated the presence of ventricular dyssynchrony with widening of the QRS complex (Burkhoff et al., 1986). Later studies suggested that simultaneously pacing the LV along with the RV, resulted in a more synchronous ventricular activation manifested with a reduction in QRS complex (Foster et al., 1995). Over the years, numerous randomized studies have shown benefit for CRT by improvement of stroke volume, LV contractility, EF, cardiac output, improvement in heart failure symptoms (Bristow et al., 2004; Cleland et al., 2005; Moss et al., 2009; Tang et al., 2010; Abraham et al., 2002; Cazeau et al., 2001), and overall reduction in mortality (Bristow et al., 2004; Cleland et al., 2005; Moss et al., 2009; Tang et al., 2010).

CRT unfortunately has not been shown to be effective in as many as one third of patients, who are nonresponders; therefore, careful patient selection, optimal lead placement, and device programming are integral in managing patients referred for resynchronization therapy (Jaffe and Morin, 2014; Madhavan et al., 2017). Electrocardiographic criteria and severity of heart failure play a central role in patient selection. In many studies, the presence of LBBB was the most powerful predictor for CRT response (Bristow et al., 2004; Tang et al., 2010; Moss et al., 2009; Cleland et al., 2005; Cazeau et al., 2001; Abraham et al., 2002). In addition a wide QRS (>150 ms) predicted the likelihood of response where the wider the QRS was, the greater the likelihood of response. This is reflected in current guidelines for CRT placement, where the presence of a LBBB with a QRS duration of >150 ms is a class I recommendation for resynchronization therapy in patients with clinical heart failure.

Left ventricular lead placement, which is placed transvenously within a coronary sinus tributary, is an important factor for achieving optimal resynchronization. In general, the farther the right and left ventricular electrodes are, the more favorable the CRT response, where posterolateral and lateral positions are preferred to a more apically placed lead that has been associated at times with adverse outcomes. As for device programming, CRT devices are programmed in a fashion to maximize biventricular (BiV) pacing. Heart failure outcomes and mortality correlate with the percentage of BiV pacing where >98.4% BiV pacing has been associated with favorable outcomes (Bleeker et al., 2006). In modern CRT devices, right ventricular sensed events result in triggered pacing of the left ventricle with less favorable hemodynamic effects than "true" BiV pacing. PVCs and rapidly conducted atrial fibrillation frequently result in trigger pacing, and treatment of PVCs and rate control of atrial fibrillation (Ganesan et al., 2012) are two critical strategies to achieve optimal resynchronization therapy.

Multisite and Multipoint Pacing in CRT

Multisite pacing using two LV leads positioned in various branches of the coronary sinus was developed as a means to treat dyssynchrony with early promising results involving improvement of EF, LV dimensions, and symptoms in small nonrandomized studies. This approach was soon abandoned due to the complexity of the procedure, the need for multiple adapters, rapid battery depletion, and the advent of the quadripolar lead. The quadripolar lead is comprised of widely spaced electrodes along the LV lead offering different bi-pole options for pacing from different points along the left ventricle with best capture threshold and optimal delays. The quadripolar lead also laid the foundation for multipoint pacing, which is near-simultaneous pacing from widely spaced electrodes along the multipolar LV lead in a fashion to capture a large area of myocardium. Multipoint pacing has been shown to improve hemodynamic parameters like stroke volume, stroke work, EF, and various diastolic parameters when compared with conventional BiV pacing (Pappone et al., 2014).

Endocardial LV Pacing

Endocardial LV pacing has been proposed as a means for resynchronization therapy to overcome obstacles encountered with traditional epicardial pacing from a coronary sinus branch, including difficult anatomy, lead dislodgement, and phrenic nerve capture. Moreover, LV endocardial pacing allows a choice for optimal lead placement in nonscarred myocardium and a favorable endocardial to epicardial pacing activation resulting in a narrower QRS and improved hemodynamics (Garrigue et al., 2001). Some small studies have demonstrated the feasibility of LV endocardial pacing through leads placed transapically, or through the interatrial or interventricular septum (Betts et al., 2014; Garrigue et al., 2001). This approach to CRT has nonetheless resulted in an increased number of thromboembolic events and mitral regurgitation.

His Bundle Pacing

The nonphysiological effects RV pacing are well recognized notably with an increase in heart failure and atrial fibrillation (Sweeney et al., 2003; Wilkoff et al., 2002). Cardiac resynchronization therapy has limited benefits in a number of patients including those with non-LBBB and mild heart failure. His bundle pacing has evolved as an attractive pacing modality, as the most physiological means for

pacing. Capture of the His bundle at high pacing outputs recruits the right and left ventricular conduction system resulting in a narrow paced QRS complex. His bundle pacing is typically performed with a small caliber active fixation lead through a specialized delivery sheath delivered to the membranous septum proximal to the tricuspid valve. His bundle pacing has been successfully performed with or without concomitant mapping of the His bundle location or placing a backup RV pacing lead (Sharma et al., 2015). Procedural success has been as high as 80%–90% with the use of newer tools (Sharma et al., 2017) and the lead dislodgement rate has been comparable with conventional pacing leads (Zanon et al., 2011). His bundle pacing has also been proposed as an alternative therapy for cardiac resynchronization therapy in individuals with cardiomyopathy and LBBB (Lustgarten et al., 2015).

Leadless Cardiac Pacing

Despite breakthroughs in pacemaker and lead designs along with increasing complexity of pacing algorithms, the overall paradigm of the permanent pacemaker remains to be transvenous lead(s) attached to a generator implanted typically in the pectoral region. Lead related complications including lead failure, venous occlusion and thrombosis, valvular trauma, myocardial perforation, and infection are well recognized. In theory, the advent of a complete intracardiac device would mitigate many of these lead related complications something that was recognized over 20 years ago. To date, there are two distinct strategies to leadless pacing; the single-component platform and the multicomponent platform.

The single component pacemaker system comprises of the pulse generator, electrodes, and sensors in one compact capsule delivered via a catheter system through a transfemoral venous approach into the right ventricle. The only FDA approved device is the Micra (Medtronic Inc., Minneapolis MN) Transcatheter Pacing System (TPS) that has been widely studied. The TPS, which weighs approximately 2 g with a volume of 0.8 cc, is functionally similar to a conventional pacemaker with a rate adaptive accelerometer and battery longevity of 12 years. The device is delivered on a catheter system through a 23F femoral venous introducer and navigated into the right ventricle with a steerable mechanism. The TPS is then fixed into the right ventricle using four electrically inert nitinol tines. The tether is thereafter cut and the delivery system is removed. The device has been compared to a cohort of conventional transvenous pacemakers with favorable short and intermediate complication rates with an overall efficacy rate of low and stable capture thresholds of >90% (Reynolds et al., 2016). Another single component leadless system that has also been studied is the Nanostim (St. Jude medical, St. Paul MN) LCP with early promising results (Reddy et al., 2015), though this system awaits FDA approval.

The experience with the multicomponent pacemaker system is largely from the WiSE CRT platform (Auricchio et al., 2014). It consists of a subcutaneous pulse generator coupled with a receiver electrode implanted in the LV endocardium. Candidates for the WiSE CRT system have an existing conventional RV pacing device. The pulse generator detects a right ventricular pacing pulse from the existing device (pacemaker or defibrillator) and delivers ultrasonic energy to the LV electrode, which converts ultrasound energy emitted from the pulse generator into pacing pulses. The WiSE CRT trial was terminated early due to safety concerns (Auricchio et al., 2014) yet design modifications to the device and the delivery system have addressed the procedural complication rate; nonetheless, the overall efficacy of the device is yet to be determined (Miller et al., 2015). Another multicomponent system utilizing electromagnetic energy (induction energy) from a transmitter located subcutaneously to a receiver electrode has been studied in animal models, yet no human data is available to date (Wieneke et al., 2009).

Cardiac Rhythm Monitoring

Cardiac rhythm monitoring has long played a central role in diagnosis of cardiac related syncope, monitoring of certain arrhythmias and symptomatic events correlating with cardiac rhythm disturbances. Lately, the role of cardiac monitoring has expanded to monitoring suspected atrial fibrillation in individuals with cryptogenic stroke.

Ambulatory Holter monitors (24 or 48 h) provide continuous ECG monitoring through three leads attached to a patient's chest. The two main advantages to Holter monitors are continuous ECG monitoring and quantification of arrhythmia burden. The brief duration of monitoring and the lack of real time transmissions are among the main drawbacks to Holter monitoring (Zimetbaum and Goldman, 2010). The ZioPatch monitor is a water resistant adhesive patch that provides extended continuous ambulatory electrocardiographic monitoring for 14 days. Similar to Holter monitoring, the ZioPatch lacks real time transmission although symptoms could be accurately logged by recording on the device.

Loop recorders, with “loop memory”, on the other hand continuously analyze the rhythm and store data a few minutes before arrhythmia onset or once activated by the patient. They can reliably correlate symptoms with arrhythmia as well as exclude an arrhythmia as the cause of symptoms. External loop recorders (ELR) are attached to a patient's chest and monitor the rhythm for a maximum of 30 days. Internal loop recorders (ILR) are small devices that are implanted subcutaneously in the left parasternal region by a minimally invasive procedure (Giada et al., 2012). Newer ILRs have been miniaturized to the size of a paperclip with a battery life of 3 years, yet allow registration along one ECG lead making arrhythmia interpretation difficult in some cases. Data is transmitted remotely through a monitor that wirelessly connects with the ILR. ILRs are commonly used in clinical practice in the management of patients with syncope and early detection of atrial fibrillation in patients with cryptogenic stroke. The ISSUE-2 trial showed that therapy guided by ILR findings led to a significant reduction in the number of syncopal events per year (92% relative risk reduction) (Brignole et al., 2006). Likewise, the CRTSTAL AF trial showed that ILRs were superior to conventional 24-h monitoring in detection of atrial fibrillation in patients with cryptogenic stroke (Sanna et al., 2014).

Mobile Cardiac Outpatient Telemetry (MCOT) is an external ambulatory monitor that monitors patients for 30 days providing continuous analysis of the ECG and real-time transmission of every event. Despite the fact that recent ELRs have auto-triggered and symptom-triggered features, episodes are stored in devices until transmitted or downloaded. ELRs also do not have the capability to record and store all 30 days of ECG information making real-time MCOTs advantageous to other forms of outpatient cardiac monitoring (Rothman et al., 2007).

In conclusion, cardiac pacing has come a long way since the early days of treating life threatening bradycardias and has evolved over the years as a treatment strategy in individuals with heart failure. Leadless pacing has catapulted the field into a new era. The future of cardiac pacing lies with miniaturizing the technology and the lead that once stood as the cornerstone for pacing will soon become obsolete.

Introduction to Heart Regeneration and Stem Cells

Promoting heart repair and regeneration after injury is a long sought-after target among clinical and basic scientists; some consider this the "holy grail" for heart failure research. Researchers in the field of regenerative medicine have utilized unique model systems in lower vertebrates such as zebrafish and amphibians to study heart regeneration. These have been helpful in investigating the regenerative capabilities of the heart but the difficulty arises when similar research is attempted in mammals. In mammalian species, heart regeneration after injury has been found to occur primarily in early stages of life. After the adult heart has completed development, the heart appears to be incapable of regenerating large areas of damage such as that caused by a heart attack. This has led to considerable effort and attention on the hypothesis that adult progenitor or stem cells can be manipulated to achieve the ultimate goals of restoring damaged myocardium and improving cardiac function in patients with heart injury and heart failure. There has been considerable success using stem cells as therapy in other clinical applications, which has helped to accelerate this line of investigation.

Stem cells by definition have two major roles, the capability of self-renewal and their capacity to differentiate into a variety of cell lineages. Many types of stem cells have been utilized as therapies to treat a variety of diseases and disorders. The most widely known use of stem cells clinically is bone marrow or stem cell transplantation for hematological disorders and cancers such as aplastic anemia and leukemia, respectively. The first successful stem cell transplant in humans was performed in the 1950s by Dr. E. Donnall Thomas to treat leukemia in a patient who had a perfect donor match from his/her identical twin. In the 1950s this was considered radical, but decades later stem cell therapy has become quite common in certain clinical situations. The field of cardiovascular medicine has the opportunity to learn from the work performed in these other disciplines.

Stem cell therapy introduces either allogeneic or autologous stem cells to the body to repair the damaged tissue, regenerating and rejuvenating the organ in need of repair. Allogeneic stem cell transplantation uses stem cells from either a matched relative or unrelated donor while autologous transplantation utilizes stem cells harvested from the patient receiving the stem cell therapy. Currently, clinical trials of stem cell therapy for heart regeneration more commonly use autologous stem cell transplantations over allogeneic transplants. Both sources of stem cells have their own combination of advantages and disadvantages. Autologous stem cell transplants can limit side effects and complications that come with allogeneic transplantations such as graft versus host disease, a disease where the donor stem cells (graft) target the patient's (host's) normal tissues as foreign to the body. A limitation of autologous stem cell transplantation is patient age and wellness. For example, clinical comorbidities such as diabetes as well as age can negatively impact the likelihood that harvested cells will engraft. Thus allogeneic cell transplantation brings forth the benefit of receiving cells donated by a young and healthy donor. This observation has obvious implications for use of autologous stem cell for treatment of cardiovascular diseases. Here we will discuss multiple facets of stem cell therapy including the types of stem cells used, how the stem cells work in heart rejuvenation, and the direction the field is going for clinical trials.

How Stem Cell Therapy Works

Types of Stem Cells Studied in Heart Disease

A variety of stem cells have been studied in preclinical and clinical platforms as cardiovascular disease therapy. Stem cells in heart regeneration studies include bone marrow-derived mesenchymal stem cells, hematopoietic stem cells, endothelial progenitor cells,

 https://doi.org/10.1016/B978-0-12-809657-4.65740-X

and cardiac progenitor cells. Stem cells by definition have the capability to self-renew, as well as the ability to differentiate into mature cardiac cell types such as cardiac myocytes, fibroblasts, endothelial cells, and smooth muscle cells. Introducing stem cells to a weakened heart muscle might allow these cells to differentiate into mature cardiac myocytes that improves muscle strength. Differentiation to endothelial cells can help promote neovascularization of the damaged myocardium and improve cardiac function. A more detailed assessment of these different stem cell types will be discussed below (Table 1).

Bone marrow-derived mesenchymal stem cells

Bone marrow-derived mesenchymal stem cells are adult nonhematopoietic stromal stem cells discovered in the 1970s by A.J. Friedenstein. They are one of the most studied types of cells for therapy of cardiovascular diseases and are thought to be one of the most promising types of cells for treatment. Their multipotent ability to differentiate into multiple mature cardiac cell lineages such as cardiac myocytes, endothelial cells, smooth muscle cells, and cardiac fibroblasts makes them an attractive stem cell for therapy. Extensive studies on bone marrow-derived mesenchymal stem cells support this impression. In addition to these cells having the potential to differentiate into mature cardiac lineages, many studies have focused on their immune modulating functions such as the secreted factors (secretome) these cells produce that work in both paracrine and autocrine mechanisms to regulate cardiac response to injury. The secretome of stem cells will be discussed in more detail below. The immune modulating functions of these specific stem cells include suppression of neutrophil and T cell proliferation, in part by suppressing expression of proinflammatory cytokines as well as increasing production of anti-inflammatory cytokines. A clear benefit of bone marrow-derived mesenchymal stem cells is the ability to harvest these cells from a bone marrow biopsy. This makes these cells fairly easy to obtain. Since these cells are collected through a bone marrow biopsy, if a donor match was available, allogeneic stem cell transplantation could be utilized or the patient could undergo a biopsy and receive an autologous transplant pending his/her wellness status.

Hematopoietic stem cells

Hematopoietic stem cells are the cells which maintain the populations of blood and immune cells. Hematopoietic stem cells can be isolated from blood, bone marrow, and umbilical cord blood. Though these cells naturally reside in the body to repopulate the mature hematopoietic cells of lymphoid and myeloid lineage, studies have investigated their efficacy to repair damaged myocardium. These cells were mostly tested due to the ease of obtaining them. As with bone marrow-derived mesenchymal stem cells, hematopoietic stem cells can be utilized for both autologous and allogeneic cell transplantation due to the relatively noninvasive nature of collecting these cells. Whether hematopoietic stem cells can directly contribute to heart regeneration is controversial. Some studies report the ability of these stem cells to transdifferentiate into cardiomyocytes, but this has not been reproduced by all investigators working in this field. Nevertheless, these cells continue to be investigated and have even moved into clinical trials.

Endothelial progenitor cells

Endothelial progenitor cells are described as a class of circulating cells that can be identified by cell markers similar to those of endothelial cell and hematopoietic stem cell markers. While these cells are very similar to hematopoietic stem cells, they are distinguished by their ability to respond to endothelial cell stimuli such as vascular endothelial growth factor (VEGF), differentiate to mature endothelial cells, and incorporate into as well as form vascular structures. In vivo, these cells have been reported to home to sites of ischemia and injury, where they promote vascular repair through new vessel formation. It is due to this and given that they can be found in the circulation that endothelial progenitor cells are an attractive choice as therapy.

Cardiac progenitor cells

Cardiac progenitor cells (also referred to as cardiac-derived mesenchymal stem cells) are mesenchymal-like multipotent cells isolated from atrial or ventricular myocardial tissue. These cells are highly proliferative, and are capable of differentiating into multiple mesenchymal-derived cell lineages including mature cardiac cells. A major advantage of these cells is that they are derived and isolated from the myocardium; thus they are presumably adapted to the cardiac microenvironment. A major problem with cell

Table 1 Major stem cell types used in stem cell therapy for heart disease

Stem cell type	*Cell surface markers*
Bone marrow-derived mesenchymal stem cell	CD105+CD73+CD90+CD44+CD34-CD45-
Hematopoietic stem cell	CD34+CD90+cKit+Lin-CD38-CD31-
Endothelial progenitor cell[a]	CD34+CD31+CD133+VEGFR2+
Cardiac progenitor cell[b]	CD105+CD31-CD45-

Stem cells are characterized by specific combinations of cell surface markers. Endothelial progenitor cells and cardiac progenitor cells are classified with additional characterization as noted in the footnotes.

[a]It should be noted that in addition to these markers these cells are characterized by their ability to grow ex vivo, especially in response to endothelial stimuli such as VEGF.

[b]These cells also require further analysis such as identification of transcription factors GATA4 and Nkx2.5. The markers listed are the three major markers; others reported in the literature require further analysis and confirmation.

therapies that use cells from noncardiac tissue is that those cells are taken from their stem cell niche and introduced into damaged and stressed cardiac tissue where the signals necessary to stimulate the desired cell responses may or may not exist. Given that cardiac progenitor cells reside locally, harvesting these cells to expand the population ex vivo prior to returning to their host environment theoretically makes these an attractive stem cell choice for therapy. The challenge with these cells is to safely obtain them from a patient, which requires an invasive biopsy from an endovascular or open surgical approach. A subpopulation of these cells is highly proliferative; therefore, cells can be expanded ex vivo prior to reimplantation via another invasive procedure. Thus use of cardiac progenitor cells as therapy is essentially more invasive than using cells that can be harvested from the blood or even bone marrow.

Mixed stem cell therapies

Another area of interest for heart regeneration with stem cell therapy is the use of multiple types of stem cells as a stem cell hybrid. The idea behind this approach is to combine complimentary stem cell types to improve their efficacy and functionality. One such combination involves cotreatment with bone marrow-derived mesenchymal stem cells and cardiac progenitor cells as a way to combine their unique properties. The benefit of the cardiac progenitor cells, as discussed previously, is their familiarity with the microenvironment, whereas the benefit of the bone marrow-derived mesenchymal stem cells is perhaps the secreted factors these cells provide to the local myocardial microenvironment. Another mixed stem cell population have been termed CardioChimeras and CardioClusters (Quijada et al., 2015). These cells are a mix of cardiac progenitor cells and mesenchymal stem cells engineered ex vivo. Though this method uses the same cells others have investigated in combination stem cell therapies, this method has the benefit of allowing for direct cell–cell interactions prior to introduction to the heart. The CardioClusters are a 3D mixture of mesenchymal stem cells, cardiac progenitor cells, endothelial progenitor cells, and fibroblasts that are meant to create their own microenvironment that might improve survival of the implanted cells. Whole bone marrow or bone marrow mononuclear cells are another mixed cell population that has been tested. Whole bone marrow includes a variety of cell types; at least two of the cell types discussed previously (hematopoietic stem cells and bone marrow-derived mesenchymal stem cells) would contribute to the cell combination.

Delivery

One of the challenges of stem cell therapy for heart disease is development of methods to deliver these cells in a way that allows them to incorporate into and survive at the site of injury. In stem cell therapy for blood disorders and cancers, the hematopoietic stem cells are delivered intravenously as the cells are inherently able to move from the blood stream to the bone marrow where they engraft. The two major strategies for delivery of stem cells to the heart are intravenous infusion versus local delivery of stem cells by intracoronary delivery and direct intramyocardial injection of cells. Local delivery by intramyocardial injection can occur via an endocardial catheter or injection into the epicardium with direct visualization of the heart.

Systemic delivery of stem cells with intravenous infusion is much like the methodology of delivering current stem cell therapies to support treatment of malignancies. This delivery method is minimally invasive making it an attractive approach to treat patients. The challenge of this method is to ensure the cells are capable of engrafting in the area of therapeutic interest. Since these cells are delivered intravenously, these cells will passage through the heart, though the first capillary bed they encounter will be pulmonary. In preclinical trials using systemic intravenous delivery, the majority of cells do in fact accumulate in the lungs. There are signals created by damaged tissues that might improve homing. For example stromal-derived factor 1 (SDF1) is induced by tissue injury and appears to activate stem cells within the vicinity to migrate to and repair the damaged tissue. Understanding and manipulating stem cells to respond to local cardiac signals may allow for intravenous delivery of stem cells to succeed.

Local delivery of stem cells to the heart can be performed by two different methods. Studies with intramyocardial injection take the approach of delivering the cells directly to the site of damage. This requires visualization of the myocardium, as in direct access during open heart surgery with direct epicardial injection of cells at or near the site of damage. This method is obviously more invasive and adds a level of risk. Nevertheless, injection of stem cells directly to the cardiac muscle is attractive because of the certainty that one has placed the cells at the site of injury. A similar, though somewhat less invasive, method is to use a catheter-based approach for endocardial injections. This method requires the placement of an intravascular catheter that reaches the left ventricular endocardial space through the aortic valve.

Additionally, through bioengineering methodologies, the use of a hydrogel via patch, sheet, or injectable is another methodology for local delivery of the stem cells (Sepantafar et al., 2016). This method requires seeding the cells within the hydrogel to be placed onto the myocardium during an open heart surgery. The hydrogel can also be engineered to release essential nutrients or factors such as basic fibroblast growth factor (bFGF) which aid in the self-renewal and antiapoptotic capabilities of the stem cells. The hydrogel provides an environment where the cells are able to build a network with the adjoining tissue due to the less toxic environment it has in the damaged myocardium. This method is primarily tested in preclinical trials but is progressing to some Phase I/II clinical trials (Fig. 1).

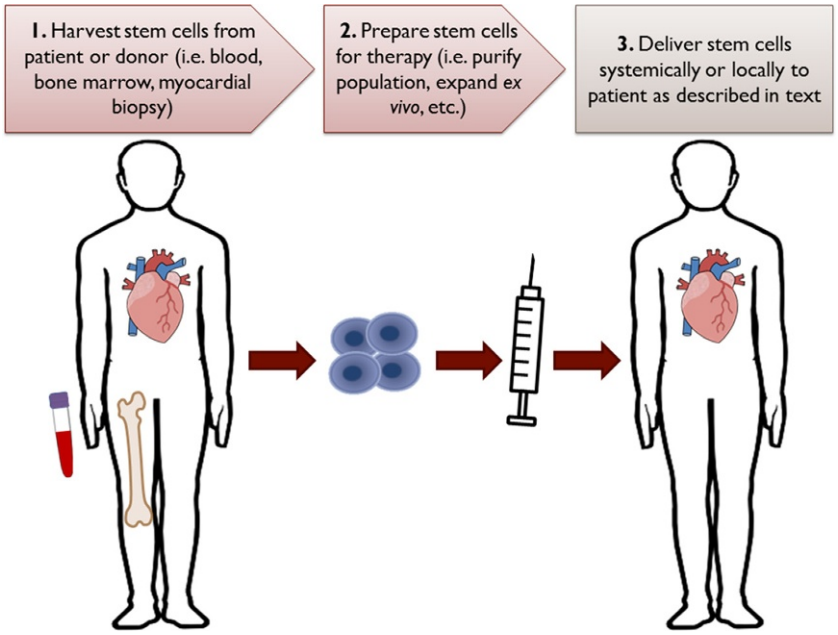

Fig. 1 Stem cell therapy for heart regeneration. Different types of stem cells isolated from bone marrow, blood, and cardiac tissue are currently being tested in clinical trials as treatments for heart disease and heart failure. Stem cells can be harvested from the patient directly or from a matched donor to be injected locally or systemically to the patient who requires stem cell therapy intervention.

Stem Cell Functions: Homing, Engraftment, Survival, Self-Renewal, Proliferation, and Differentiation

The success of stem cells as therapy depends upon the cell's ability to home to the appropriate site for engraftment as well as survive in the new environment (Chavakis et al., 2008). With the exception of cardiac progenitor cells, the stem cells are taken from noncardiac tissues. There are many steps involved in cellular homing including migration and adhesion. Stem cells such as bone marrow-derived mesenchymal stem cells are known to have high expression of integrins on their cells' surface. One of the major functions of the family of integrin proteins is their ability to promote both migration and adhesion. Integrins are commonly activated by the extracellular matrix and couple the matrix to intracellular signaling. The extracellular matrix composition can act via integrins to determine what function the cells take. For example, fibronectin is known to activate integrin alpha 5 beta 1 in mesenchymal stem cells to promote migration via the phosphorylation of platelet-derived growth factor receptor (PDGFR)-β (Veevers-Lowe et al., 2011).

The goal of stem cell therapy is for the stem cells to engraft into the myocardium and contribute to tissue repair. Ideally cells maintain their stemness and proliferative properties and are able to provide the cells necessary for tissue repair over a long time course. It appears that stem cells have autocrine and paracrine mechanisms that are important determinants of their proliferation as well as differentiation. This is regulated in part by the microenvironment these cells reside in. Under normal conditions, a healthy tissue appears to maintain a microenvironment that is optimal for local stem cells involved in tissue maintenance. A diseased heart requiring consideration for stem cell therapy is most likely a toxic microenvironment for stem cells. Thus the success of stem cell therapies requires considerable understanding of and strategies to help stem cells overcome the microenvironmental conditions. Garnering a better understanding of stem cell's needs as well as the challenges cells face within the damaged myocardium is needed for cell therapies to reach their potential (Fig. 2).

Secretome

It is clear that some benefits of stem cell therapy arise from the stem cell's secreted factors which are known to regulate tissue morphogenesis and repair. Stem cells are known to have autocrine and paracrine factors that make up their secretome. The autocrine effects of the secretome promote proliferation of these stem cells driving their self-renewal capabilities. These factors appear essential for the maintenance of stem cell stemness, and regulate their self-renewal such that cells are available for tissue renewal. One such factor is secreted frizzled related protein (SFRP-2) which is reported to promote self-renewal and survival of mesenchymal stem cells but also aid in myocardial repair (Gallina et al., 2015). The paracrine effects of the secretome regulate the other cells within the environment of the stem cells. The secretome of the stem cells regulates the generation of chemokines, cytokines,

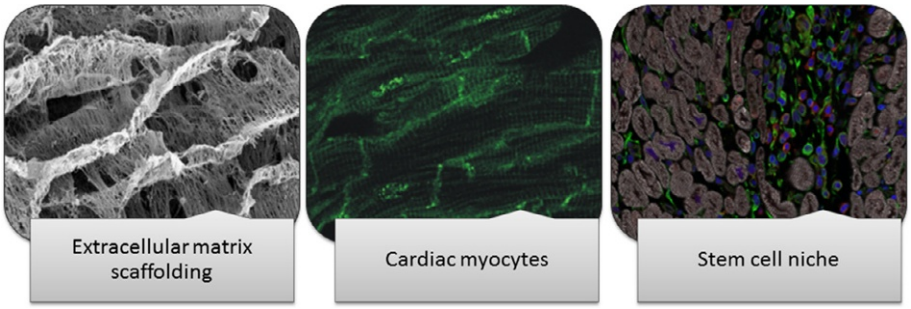

Fig. 2 Stem cell niche in the heart. The heart has many contributors to the structure and microenvironment for stem cells within the tissue. The extracellular matrix (image on *left*) provides the scaffolding between cells to maintain tissue structure while also lending cellular signals. Cardiac myocytes (*middle* image) aid in the contractility of the cardiac tissue while the stem cell niche (image on *right*) in the heart can be a combination of cardiac myocytes with other cell types such as endothelial cells and fibroblasts. The niche for stem cells with the heart can be made of a combination of extracellular matrix, cardiac myocytes, endothelial cells, fibroblasts, and other cells within the cardiac tissue. Disruption of this environment can alter the stem cell function which is common in heart disease.

exosomes and other secreted factors that will promote myocardial regeneration and repair (Gnecchi et al., 2008; Ranganath et al., 2012; Gallina et al., 2015). It should be noted that the stem cells themselves are not the only cells to produce a secretome. The cells within the damaged and surrounding healthy myocardium also produce their own secretome. These factors in combination with the factors produced from the stem cells play a part in the success of this therapeutic approach.

One of the most studied factors within the secretome is stromal-derived factor 1 (SDF1, also known as CXCL12). SDF1 is a chemokine that is important for angiogenesis and cell trafficking. After injury, SDF1 is secreted from cells located within the damaged tissue. SDF1 has been demonstrated to promote migration and homing of stem cells to the injured tissue (Chavakis et al., 2008). SDF1 promotes the recruitment and homing capabilities of stem cells through its receptor CXCR4 which is commonly expressed on stem cells (Zaruba and Franz, 2010). This has led to the concept that SDF1 might be useful as an adjunct to stem cell therapies. SDF1 is one of many factors that have been shown to have beneficial roles in aiding the repair of the damaged tissue. There are many other growth and survival factors in the secretome, such as insulin growth factor for activating nearby cardiac stem cells and having antiapoptotic roles, VEGF contributes to cardiomyocyte and endothelial cell survival, and cysteine-rich angiogenic inducer (Cyr61) promotes angiogenesis (Gallina et al., 2015).

Proinflammatory and anti-inflammatory factors also contribute to the secretome and influence how these cells function. The innate immune system is activated in damaged myocardium, leading to proinflammatory cytokine expression that can alter the function of the stem cells. In response, stem cells themselves are reported to counteract with production of anti-inflammatory cytokines. This is perhaps a mechanism to promote a microenvironment that is required for stem cell survival (Bernardo and Fibbe, 2013). A related article on this topic, *Immune Mechanisms in Cardiac Physiology*, covers more broadly the inflammatory response and which pro- and anti-inflammatory cytokines contribute to the condition of the myocardium following injury.

Overview of Recent Stem Cell Clinical Trials for Heart Disease

Stem cell therapy for heart disease has yet to reach regulatory approval, and is still in development. The first clinical trial to use stem cell therapy for heart failure was reported in 2002 (Vrtovec et al., 2013). Preclinical models and the current stem cell therapies used in the clinic for other noncardiac-related diseases have set the groundwork for stem cell therapy as a method to regenerate the damaged heart. As described earlier, there are many factors that need to be determined in order to find the most successful approach in this therapeutic area. The combination of the type of stem cells, source of the stem cells (allogeneic vs. autologous), mode of delivery, and the clinical problem which needs to be treated all need to be weighed carefully. In **Table 2** a few of the ongoing and recently completed clinical trials are listed, and in **Table 3** select clinical trials are organized to demonstrate the variety of clinical conditions being treated with stem cell therapy as well as the different stem cell therapy approaches in delivery, cell type, and source of cells.

Conclusions

The work before us in both developmental biology research and stem cell transplantation in other areas of clinical medicine are the key to developing successful stem cell therapies for cardiovascular disease and heart failure. Developmental biology researchers have spent decades uncovering the mechanisms to how a functional heart is created through an organized program starting with pluripotent stem cells. Clinical medicine such as the development of bone marrow transplantation techniques for treatment of hematological malignancies lends insight into the importance of proper isolation, HLA typing (if allogeneic transplantation), and

Table 2 Background on select clinical trials utilizing stem cell therapy to treat heart disease

Trial name	*Clinicaltrials.gov ID*[d]	*Trial status*	*Trial phase*	*Type of cells used*	*Allogeneic or autologous*	*Study results*
Prospective randomized study of mesenchymal stem cell therapy in patients Undergoing cardiac surgery (PROMETHEUS)	NCT00587990	Completed	Phase I/II	Mesenchymal stem cells	Autologous	Intramyocardial injection of the stem cells improved overall left ventricular function. Findings should be confirmed with the required placebo group[a]
Allogeneic stem cell therapy in heart failure (CSCC_ASCII)	NCT03092284	Recruiting	Phase II	Adipose-derived stromal stem cells	Allogeneic	Study ongoing
CSCC_ASC therapy in patients with severe heart failure	NCT02387723	Completed	Phase I	Adipose-derived stromal stem cells	Allogeneic	Results not yet reported but has moved on to Phase II (CSCC_ASCII)
Stem cells therapy in advanced heart failure	NCT02871466	Completed	Phase IV	Stem cells, type undisclosed	Autologous	Results not yet reported
Stem cell therapy in patients with severe heart failure and undergoing left ventricular assist device placement (ASSURANCE)	NCT00869024	Completed	Phase I/II	Bone marrow-derived mononuclear cells	Autologous	Results not yet reported
Repetitive Intramyocardial CD34+ cell therapy in dilated cardiomyopathy (REMEDIUM)	NCT02248532	Recruiting	Phase II/III	CD34+ stem cells isolated from peripheral blood (hematopoietic stem cells)	Autologous	Study ongoing. estimated completion January 2018
AutoLogous human CArdiac-derived stem cell to treat ischemic cArdiomyopathy (ALCADIA)	NCT00981006	Completed	Phase I	Cardiac-derived stem cells	Autologous	Early results presented at conference confirm safety and efficacy of this method[b]
The Transendocardial Autologous Cells (hMSC or hBMC) in Ischemic Heart Failure Trial (TAC-HFT)	NCT00768066	Completed	Phase I/II	Mesenchymal stem cells or bone marrow cells	Autologous	Results indicated the transendocardial delivery of both cell types was safe; no definitive results on efficacy but enough evidence to proceed to a larger trial[c]

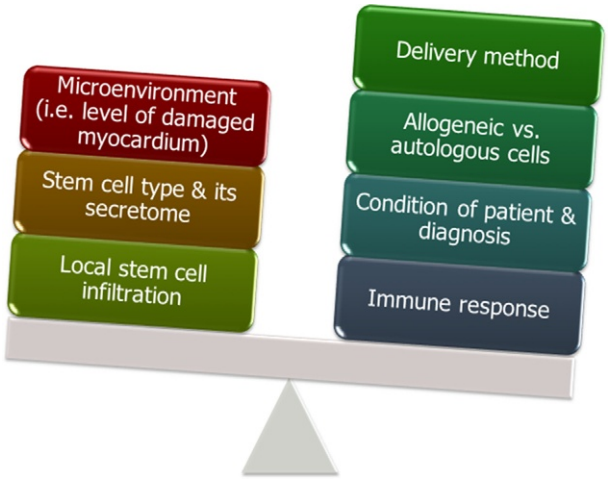

Fig. 3 Balancing barriers to stem cell therapy success. Stem cell therapy success relies on a balance of many contributing factors. The combination such as type of stem cell, delivery method, and clinical diagnosis of the patient all factor into the success of the stem cell therapy. Finding the appropriate combination to balance the pros and the cons is still being determined in basic and clinical research.

delivery of cells to ensure a successful therapeutic. The investigations into utilizing various stem cell types as a therapy for cardiovascular medicine are still in their infancy stages but the value in this therapeutic approach is clear. Cardiovascular medicine needs to identify the proper combination of stem cell type, source of stem cells, and delivery method required for the most successful stem cell therapy to treat the patient's specific clinical diagnosis. Further collaboration between basic and clinical researchers in this field is required to expand our knowledge and fine-tune what is needed for a successful transition from the bench to the bedside (Fig. 3).

Introduction

The prevalence of heart failure is approximately 2% in the population of the western world and despite pharmacological and nonpharmacological therapy it is still associated with severe morbidity and high mortality rates (Ponikowski et al., 2016). Widening of the QRS complex on the surface ECG is found in around 30% of patients with heart failure with reduced ejection fraction (HFrEF) and may indicate the presence of a dyssynchronous activation and contraction pattern (Baldasseroni et al., 2002). It became clear in the 1990s that ventricular dyssynchrony could be reversed by cardiac resynchronization therapy (CRT) and during the past 15 years several randomized controlled trials showed that CRT significantly decreases morbidity and mortality in patients with HFrEF and dyssynchrony. QRS prolongation in HFrEF is mainly caused by left bundle branch block (LBBB), nonspecific QRS prolongation, right bundle branch block (RBBB), and right ventricular pacing (RVP). In the case of LBBB, the interventricular septum is initially activated followed by a further rapid activation of the right bundle branch and finally a delayed activation of the left ventricle (LV) posterolateral wall (**Fig. 1**). During implantation of a CRT device, an additional ventricular pacing lead is positioned in a side branch of the coronary sinus to stimulate LV regions simultaneously with the right ventricle resulting in a homogeneous LV activation and contraction pattern (**Video 1–6**).

Randomized Controlled Trials Establishing the Role of CRT in HFrEF

The first randomized controlled clinical trials investigated CRT efficacy in patients with HFrEF (EF $\leq$ 35%), moderate-to-severe symptoms, evident as New York Heart Association (NYHA) functional class III-IV and electrical dyssynchrony (QRS duration $\geq$ 120 ms). The MUSTIC trial included 67 patients (Cazeau et al., 2001) and significant improvement of some functional endpoints was observed after CRT implantation (**Table 1**.). Two larger randomized controlled trials also showed beneficial CRT effects on morbidity and mortality in similar patients. In the COMPANION trial, 1520 patients were randomized in three arms: optimal medical therapy, CRT with a defibrillator (CRT-D), or CRT without a defibrillator (CRT-P). After a 12-month follow-up CRT-D or CRT-P significantly reduced combined death or hospitalization for any cause (Bristow et al., 2004). The CARE-HF study (Cleland et al., 2005) randomized 813 patients and showed for the first time that during a 30-month follow-up CRT-P was associated with a significant reduction in all-cause mortality as compared to optimal medical therapy. In addition, these large clinical trials reported improvement of LV size and function, peak oxygen consumption, 6-minute walking distance, quality of life scores, and mitral regurgitation severity. Long-term follow-up of the MUSTIC and CARE-HF studies showed lasting beneficial effects of CRT on reverse remodeling (Linde et al., 2002) and further trials investigated whether CRT was able to reduce clinical events in patients with less severe HFrEF (i.e., NYHA class I-II symptoms) and QRS prolongation. In the REVERSE study (Linde et al., 2008), CRT-P or CRT-D was implanted in 610 patients and CRT was turned on in two thirds of them. In the CRT ON group, CRT was associated with reverse remodeling and significantly increased time to first hospitalization but it did not significantly improve symptoms or exercise capacity in these patients with little functional impairment at baseline. The MADIT-CRT trial (Moss et al., 2009) compared CRT-D with ICD alone in 1820 patients with NYHA class I and II symptoms, LVEF $\leq$ 30%, and QRS interval $\geq$ 130 ms. CRT-D implantation resulted in a significant reduction of combined all-cause death or heart failure events during a follow-up of 2.4 years as compared to ICD alone (17.2% vs. 25.3%, $p = 0.001$). This was mainly driven by a reduction in heart

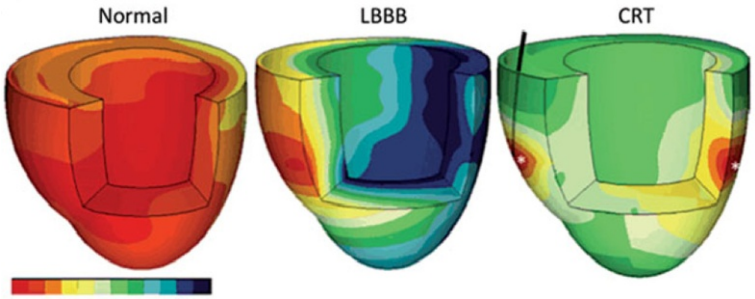

Fig. 1 Homogenous electrical activation pattern in the heart with normal intrinsic conduction (left panel). During LBBB activation (middle panel), septum is activated early followed by a late activation of the LV lateral wall. However, these regional differences in electrical activation are ameliorated by performing biventricular pacing after CRT implantation (right panel) (Gorcsan and Prinzen, 2012). Table 1 Clinical studies of CRT in patients with HFrEF

Study (reference)	*Inclusion criteria*	*Patient number*	*Study design*	*Follow-up (M)*	*Results*
MUSTIC SR (Cazeau et al., 2001)	EF ≤ 35%, QRS ≥ 150 ms	67	1:1 CRT ON/OFF	3/12	Improved 6MWT, pVO_2, reduced HF hospitalization
MUSTIC AF (Linde et al., 2002)	EF ≤ 35%, QRS ≥ 150 ms	37	1:1 CRT ON/OFF	3/12	Improved 6MWT, pVO_2, reduced HF hospitalization
MIRACLE (Abraham et al., 2002)	EF ≤ 35%, QRS ≥ 130 ms	453	1:1 CRT ON/OFF	6	Improved 6MWT, pVO_2
MIRACLE-ICD (Young et al., 2003)	EF ≤ 35%, QRS ≥ 130 ms	555	1:1 CRT ON/OFF	6	Improved NYHA, VE/CO_2, LV volumes
PATH-CHF (Auricchio et al., 2003)	EF ≤ 35%, QRS ≥ 120 ms	41	CRT/RV pacing/ epicardial LV pacing	12	Improved 6MWT and pVO_2
CONTAK CD (Higgins et al., 2003)	EF ≤ 35%, QRS ≥ 120 ms	290	1:1 CRT ON/OFF	6	Improved NYHA, VE/CO_2, LV volumes
COMPANION (Bristow et al., 2004)	EF ≤ 35%, QRS ≥ 120 ms	1520	1:2:2 OMT/CRTP/CRTD	15	Reduced mortality or hospitalization
CARE-HF (Cleland et al., 2005)	EF ≤ 35%, QRS ≥ 120 ms	813	1:1 OMT/CRTP	30	Reduced mortality and hospitalization
REVERSE (Linde et al., 2008)	EF ≤ 40%, QRS ≥ 120 ms	610	2:1 CRT ON/OFF	12–24	Reverse remodeling and longer time to first hospitalization
MADIT-CRT (Moss et al., 2009)	EF ≤ 30%, QRS ≥ 130 ms	1820	3:2 CRT-D/ICD	28.8	Reduced combined mortality and hospitalization
RAFT (Tang et al., 2010)	EF ≤ 30%, QRS ≥ 120 ms	1798	1:1 CRT-D/ICD	40	Reduced mortality and hospitalization
MADIT-CRT extended (Goldenberg et al., 2014)	EF ≤ 30%, QRS ≥ 130 ms	854	3:2 CRT-D/ICD	84	Reduced mortality

EF, ejection fraction; *M*, months; *ms*, milliseconds; *NYHA*, New York Heart Association Functional Class; *OMT*, optimal medical therapy; *pVO_2*, peak oxygen consumption; *6MWT*, distance covered during a 6-minute walk test.

failure events and all-cause mortality was not reduced. A 7-year follow-up of the study showed, however, that CRT was associated with a reduction in all-cause mortality in patients with LBBB (38% relative risk reduction, $p = 0.003$) (Goldenberg et al., 2014). The RAFT trial (Tang et al., 2010) also showed a mortality benefit from CRT in patients with less symptomatic heart failure. After a follow-up of 40 months, in 1798 patients, the primary outcome—death or hospitalizations for heart failure—was significantly reduced among recipients of CRT-D compared with those with an ICD alone (33.2% vs. 40.3%; $p < 0.001$), as were the secondary outcomes of death from any cause and hospitalizations for heart failure. The RAFT trial included also patients with atrial fibrillation (AF) and patients with HFrEF and RVP for bradycardia indication.

Improving CRT Therapy

Patient Selection

QRS width and morphology

RBBB and nonspecific QRS prolongation

These large randomized trials established the pivotal role of CRT in the management of patients with HFrEF and prolonged QRS. Nevertheless, around 30% of patients do not show echocardiographic signs of reverse remodeling and/or improved symptoms after CRT implantation and they are considered nonresponders. 2/3 of the patients randomized in the clinical trials had widened QRS with LBBB morphology, which means that the major evidence is within this subgroup. The effects of CRT in patients with HFrEF and RBBB are, however, much less known as only 5%–10% of the patients had RBBB in the randomized and controlled studies (Linde et al., 2008). Posttrial subgroup analyses of the large trials and studies on medical registries have highlighted that CRT is more

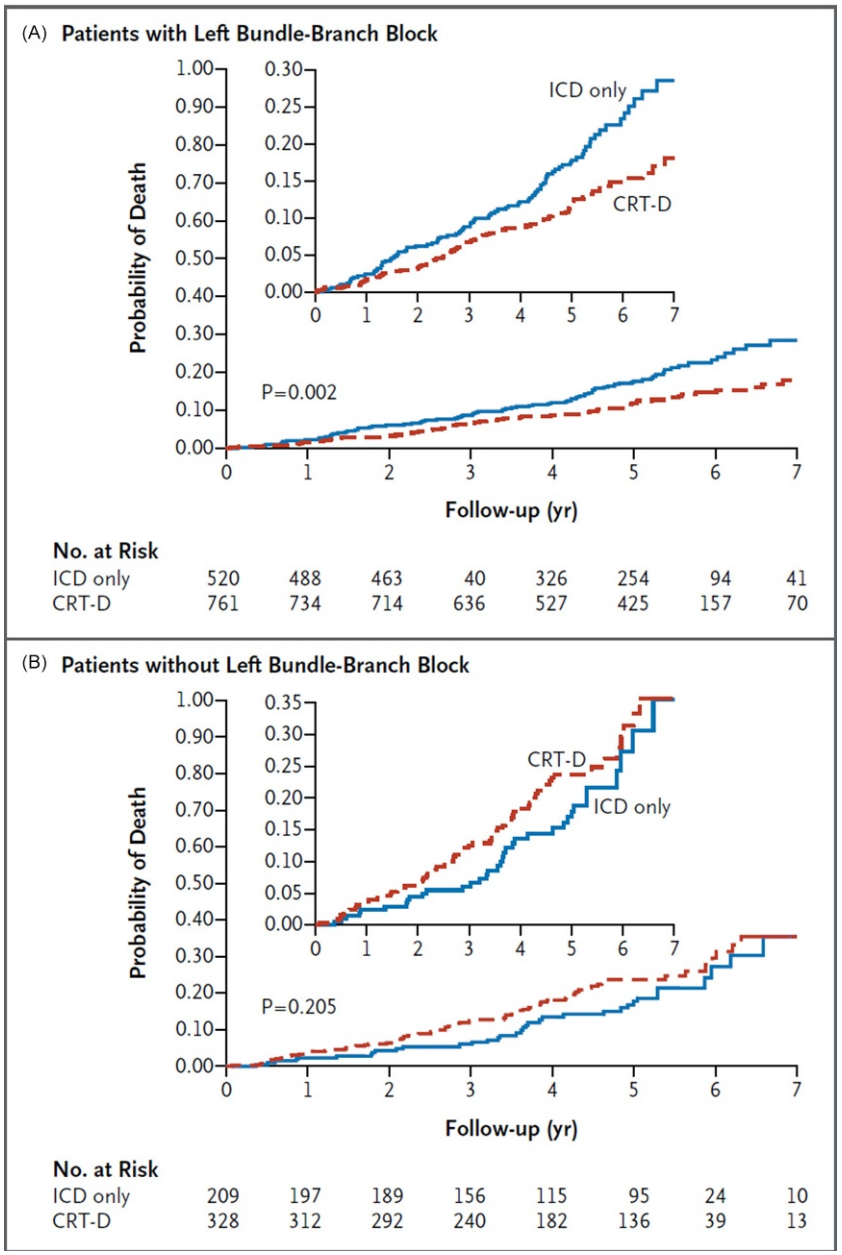

Fig. 2 Long-term analysis of the MADIT-CRT study shows lower cumulative probability of death from any cause in patients with LBBB (A) but not in patients without LBBB (B) (Goldenberg et al., 2014). Reprinted with permission from the Massachusetts Medical Society.

effective in patients with LBBB compared to RBBB (Bilchick et al., 2010; Tang et al., 2010; Peterson et al., 2013; Goldenberg et al., 2014, **Fig. 2**). In contrast, another large case-based meta-analysis (Cleland et al., 2013) found only prolonged QRS duration to be strongly predictive of the response to CRT even in patients with RBBB or nonspecific QRS prolongation. It may be speculated that some patients with RBBB may potentially benefit from biventricular pacing. Especially in ischemic cardiomyopathy, the electrical activation wave fronts in RBBB are heterogeneous and a proportion of patients with RBBB and concomitant LV intraventricular conduction defect have significant LV delay (Fantoni et al., 2005). In one of the early studies CRT had beneficial effects in a proportion of RBBB subjects showing echocardiographic signs of concomitant LV intraventricular dyssynchrony (Garrigue et al., 2001a). Similarly, the presence of left anterior hemiblock among patients with RBBB was associated with greater response to CRT in another study (Chandra et al., 2010). Left ventricular (LV) activation delay was found to correlate well with QRS duration in both LBBB and RBBB (Varma, 2009) and, furthermore, patients with non-LBBB and longer LV activation delay had a lower heart failure hospitalization rate after CRT implantation (Kandala et al., 2013, **Fig. 3**). In a secondary analysis of the MADIT-CRT trial, patients with non-LBBB and prolonged PR interval had a significantly better outcome as compared to non-LBBB patients with normal PR (Kutyifa et al., 2014). Similarly, in a post-hoc analysis of the COMPANION trial prolonged PR interval resulted in a better outcome

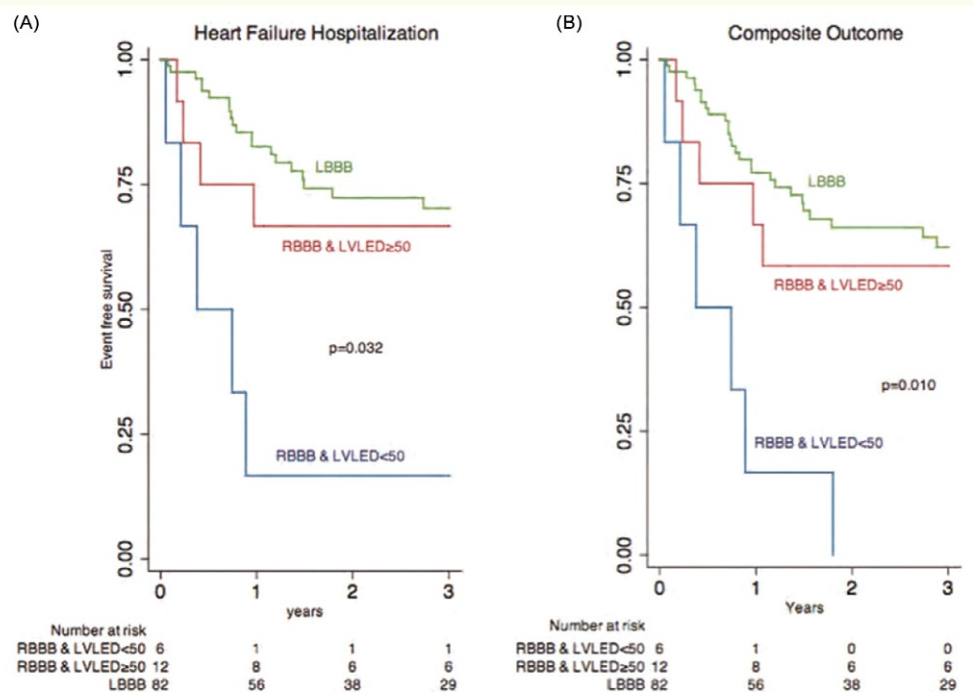

Fig. 3 Event-free survival for heart failure hospitalization (A) and the composite outcome at 3 years (B) comparing LV lead electrical delay <50% versus LV lead electrical delay ≥50% within LBBB and non-LBBB (Kandala et al., 2013). Reprinted with permission from the European Society of Cardiology.

after CRT implantation in both LBBB and non-LBBB patients (Lin et al., 2017). Identification of patients with RBBB or intraventricular conduction defect who may benefit from CRT is being evaluated in a prospective study with individualized targeting of the LV lead in patients with a non-LBBB morphology (ENHANCE CRT; ClinicalTrials.gov NCT01983293).

Definition of LBBB

As LBBB was recognized as the primary target for CRT, there was growing interest how to exactly characterize LBBB morphology. The conventional and widely used criteria (Linde et al., 2008; Moss et al., 2009) of complete LBBB are a QRS duration ≥120 ms, with a QS complex in the V1 lead, and the absence of Q waves in the lateral leads. Some studies have, however, suggested that 1/3 of patients diagnosed with LBBB by conventional electrocardiographic criteria may likely have a combination of LV hypertrophy and left anterior fascicular block (Grant and Dodge, 1956; Vassallo et al., 1984; Auricchio et al., 2004) and not true LBBB. On the basis of computer simulations, stricter criteria for complete LBBB were suggested that include a QRS duration ≥140 ms for men and ≥130 ms for women, along with mid-QRS notching or slurring in two or more contiguous leads of V1, V2, V5, V6, I, and aVL (Strauss et al., 2011, **Fig. 4**). The presence of mid-QRS notching was shown to distinguish true complete LBBB from LV hypertrophy, LV dilatation, and incomplete LBBB in a simulation study (Galeotti et al., 2013). Additionally, a mechanical LBBB pattern in 2D longitudinal strain echocardiography is frequently associated with the presence of notching on electrocardiography (Risum et al., 2013). Refinement of the definition of LBBB morphology with notching and slurring significantly improved prediction of CRT response and clinical outcome compared to the conventional definition (Mascioli et al., 2012; Tian et al., 2013). The inclusion of QRS notching or slurring in the lateral leads might improve patient selection but further studies are necessary to evaluate which electrocardiographic criterion for LBBB correlates best with CRT response.

Narrow QRS

Conversely, later studies consequently showed that CRT is not indicated in patients with narrow QRS. In the ECHO-CRT trial, patients with HFrEF, QRS < 130 ms, and echocardiographic signs of mechanic dyssynchrony by tissue Doppler imaging or speckle tracking were randomized (Ruschitzka et al., 2013). The study was stopped for futility as there was a significantly increased mortality in the CRT ON arm. Patients with a QRS duration of <130 ms may thus even be harmed by CRT regardless of LV dyssynchrony on echocardiography. This applies not only to those with a QRS duration of <120 ms but also to those with QRS 120–130 ms (Steffel et al., 2015).

Ischemic heart disease

Ischemic heart disease (IHD) and hypertension are common underlying causes of HFrEF and approximately 50%–60% of CRT recipients have underlying IHD with or without a previous myocardial infarction. In these patients, the overall outcome is worse and the LV reverse remodeling is less prominent than in nonischemic patients (Linde et al., 2010). Nevertheless, subgroup analyses

Fig. 4 Two ECGs with a complete left bundle branch block according to the classical criteria (A, Linde et al., 2008) and the stricter criteria from Strauss (B, Strauss et al., 2011).

of large randomized clinical trials indicate that patients with underlying IHD have similar outcome benefits as compared to those with nonischemic etiology. In the CARE-HF trial, patients with ischemic etiology had a significant reduction in total mortality after CRT implantation and it was similar as for those with nonischemic cardiomyopathy (Wikstrom et al., 2009). Similar observations were made in the REVERSE trial of patients with milder HFrEF (Linde et al., 2010, **Fig. 5**).

Atrial fibrillation

HFrEF is associated with AF in a substantial proportion of patients ranging from 10% in NYHA I to 50% in NYHA IV (Maisel and Stevenson, 2003). The large randomized clinical trials, however, have almost exclusively included patients with sinus rhythm at baseline. The only exception was an early small, randomized trial (Linde et al., 2002) and a small population of the RAFT trial (Tang et al., 2010). Therefore, the efficacy of CRT is less known in patients with symptomatic HFrEF, wide QRS, and AF. CRT may be less effective in AF as compared to sinus rhythm because it is not able to improve ventricular filling by optimizing atrioventricular coupling. Suboptimal ventricular filling due to delayed atrioventricular timing is frequently present in HFrEF and sinus rhythm. In addition, it may be more difficult to achieve sufficiently high percentage of biventricular pacing in patients with AF due to short RR intervals and fusion beats. Even a small decrease (<5%–10%) in the percentage of biventricular pacing is associated with worse outcome in CRT recipients (Koplan et al., 2009). Some meta-analyses compared the effect of CRT in patients with AF and sinus rhythm. The results from these meta-analyses are not consistent since some indicate that CRT is less effective in AF (Wilton et al., 2011) while others show no difference between CRT efficacy in sinus rhythm versus AF (Upadhyay et al., 2008). Patients with HFrEF and AF can be suitable CRT candidates in two clinical situations. First, patients may have QRS prolongation and heart failure symptoms similarly to patients in sinus rhythm. Second, patients may have AF where pharmacological rate control is difficult and atrioventricular junction ablation is considered. In a smaller clinical trial, CRT implantation after atrioventricular junction ablation was associated with improved LV function and reduction of adverse clinical events as compared to RVP (Brignole et al., 2011). Large-scale clinical studies are necessary in the future to further investigate the evidence of CRT efficacy in patients with AF.

Continuous RVP

Conventional ventricular pacing for bradycardia is delivered by RVP. In a proportion of patients RVP is similar to LBBB in terms of electrical activation and contraction pattern and may compromise systolic function (Prinzen and Peschar, 2002). Most patients without structural heart disease tolerate chronic RVP well. In patients with EF ≤ 40%, however, frequent RVP (>40%) was associated

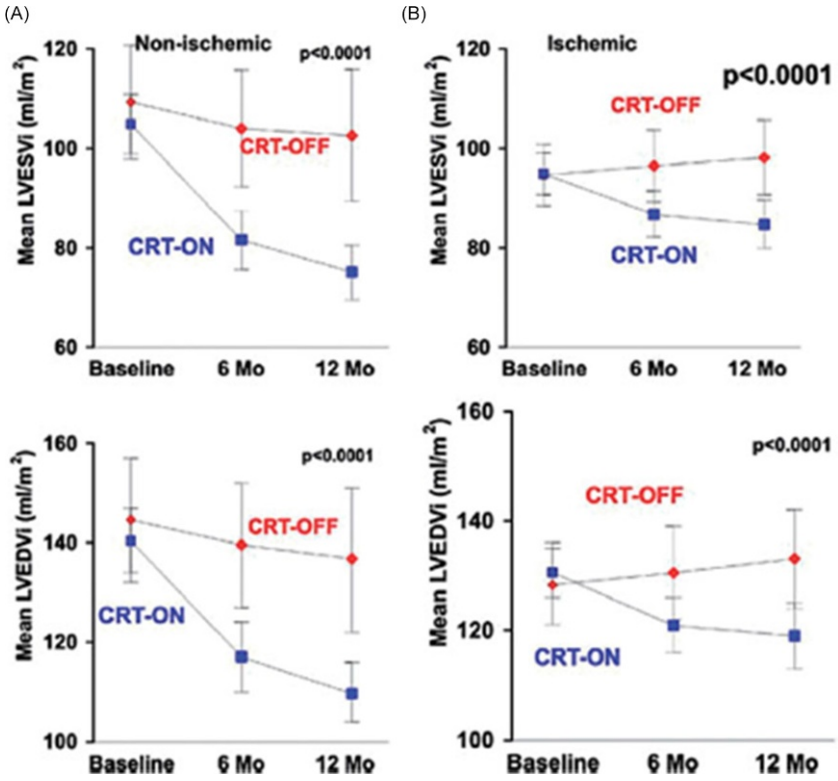

Fig. 5 CRT has a smaller but significant effect on reverse remodeling in ischemic (B) versus nonischemic cardiomyopathy (A) (Linde et al., 2010). Reprinted with permission from Elsevier.

with further deterioration of cardiac function and increased clinical events (Wilkoff et al., 2002). In a clinical context, there are two scenarios where this may be important. First, patients may develop LV dysfunction during antibradycardia pacing using RVP and may need an additional LV lead. There are some studies suggesting that upgrading a conventional RVP device to a CRT in the case of HFrEF and high percentage RVP may be beneficial. The RAFT trial was the only large randomized clinical CRT trial that included a small subgroup of these patients (Tang et al., 2010) but the subgroup was too small to draw firm conclusions on. However, several smaller clinical studies have investigated the effect of CRT versus RVP in patients with EF $\leq$ 40% and symptoms of heart failure. These studies have generally shown that CRT results in an echocardiographic reverse remodeling and amelioration of heart failure symptoms (Hoijer et al., 2006). In addition, data from both observational studies and registries support the upgrade of RVP devices to CRT in patients with HFrEF. In the second scenario, patients with preexisting LV dysfunction may develop an indication for chronic antibradycardia pacing. De novo implantation of CRT was compared to a conventional RVP device in patients with a bradycardia indication for RVP (mostly high degree AV block) and moderate-to-serve systolic dysfunction in several randomized controlled clinical trials. The HOBIPACE (Kindermann et al., 2006), COMBAT (Martinelli Filho et al., 2010), and BLOCK HF (Curtis et al., 2013) trials included approximately 880 patients and consistently showed improved outcome of de novo CRT compared to RVP device implantation in terms of improved cardiac structure and function, improved quality of life, and reduction in clinical events. The PACE trial (Yu et al., 2009) randomized patients with preserved EF and a bradycardia indication for ventricular pacing to receive either CRT or RVP. This study showed that CRT could prevent the deterioration of cardiac function and progression of remodeling. The efficacy of CRT on clinical endpoints in the case of preserved EF remains largely unknown as no sufficiently powered clinical trials have been conducted.

Lead Positioning

The LV region, which is activated latest during LBBB, RVP, or other conduction abnormalities, should be theoretically the optimal site for lead placement and subsequent stimulation in order to obtain maximal resynchronization. During the conventional approach, the LV lead is placed transvenously in a lateral or posterolateral second- or third-order branch of the coronary sinus vein. This strategy is based on the expected pattern of delayed electrical and mechanical activation of the lateral and posterolateral wall in patients with LBBB. Placement of the LV lead can be challenging due to heterogeneity of coronary sinus venous anatomy (Blendea et al., 2007). The response to CRT is often variable even when the LV lead is placed in this optimal anatomical position (Derval et al., 2010) reflecting the heterogeneity of ventricular activation even within similar QRS duration or bundle branch morphology (Rodriguez et al., 2003; Fung et al., 2004) as was also found in canine models of LBBB (Ploux et al., 2014).

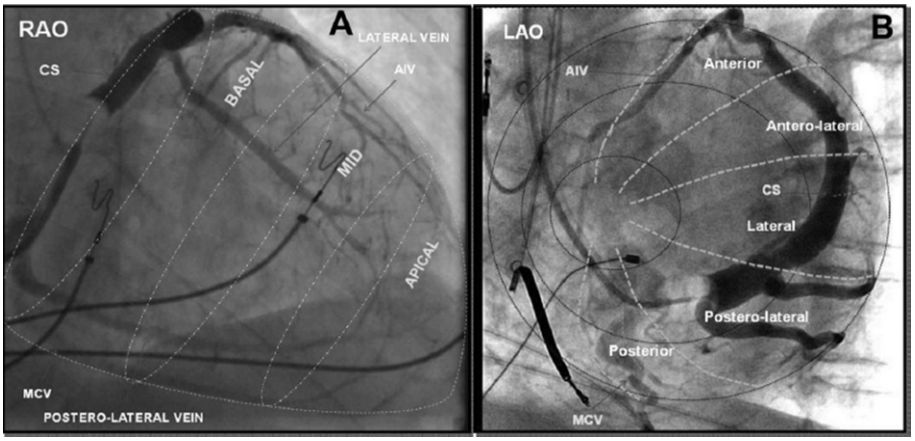

Fig. 6 Angiographic classification of LV lead position (Singh et al., 2011). Right anterior oblique (RAO) view (A) is used to divide the LV wall along the long axis of the heart into basal, midventricular (MID), and apical segments. The segmentation of the LV wall along the short axis of the heart is performed using the left anterior oblique (LAO) view (B). LV wall is divided then into anterior, anterolateral, lateral, posterolateral, and posterior segments. AIV indicates anterior interventricular vein; *CS*, coronary sinus; *MCV*, middle cardiac vein. Anatomically, placement of the LV lead can be organized along the long and short axes (Singh et al., 2011, **Fig. 6**). Subgroup analyses of the large, randomized CRT trials are not consistent regarding the superiority of positioning the LV lead in a specific anatomical region during implantation. In the COMPANION trial, no difference was observed in the CRT effect between anterior, lateral, or posterior LV lead positions. On the other hand, posttrial analyses of the REVERSE and MADIT-CRT studies indicated that a lateral lead position should be preferred and that a basal or mid ventricular LV region is more optimal as compared to an apical position (Singh et al., 2011). However, there is no clear evidence that a supreme anatomical area should routinely be targeted during CRT implantation. Considering the heterogeneous activation of the LV it is tempting to establish more individualized approaches to find an optimal LV lead position. Theoretically, it may be achieved by targeting regions of maximal electrical delay (Singh et al., 2006; Gold et al., 2013), maximal mechanical delay (Bilchick et al., 2008; Saba et al., 2013), or lead positions that maximize hemodynamic improvement (Duckett et al., 2011). Since CRT is a form of electrical therapy for patients with abnormalities of electrical conduction, an optimal CRT response may be achieved by targeting the site of latest electrical activation. It can most practically be identified by measuring the time between the beginning of the surface QRS and the sensed intracardiac signal of the LV lead (QLV) (Ellenbogen et al., 2010). The QLV delay can subsequently be corrected for baseline QRS duration to determine the LV lead electrical delay (Singh et al., 2006). Implantation of LV lead at sites of longer QLV was associated with a significantly greater LV reverse remodeling and improvement in patient symptoms. The site of latest electrical activation can also be detected by electroanatomical mapping catheters (Ryu et al., 2010). Although mechanical dyssynchrony has failed to predict CRT response or identify patients with narrow QRS who may benefit from CRT, newer methods to assess mechanical dyssynchrony (e.g., speckle tracking and cardiac MRI) (Bilchick et al., 2008; Khan et al., 2012; Saba et al., 2013) were studied. In the largest randomized trials it was shown that speckle tracking guided lead placement to the areas with the latest activation but without scar resulted in significantly reduced adverse clinical events (Saba et al., 2013, **Fig. 7**) and higher response rates (Khan et al., 2012). Importantly, exact concordance was only achieved in 30% of patients demonstrating the limitations of coronary venous anatomy (Saba et al., 2013). In a recent study, LV lead placement guided by the combined use of MRI and longitudinal myocardial strain was associated with a significantly better echocardiographic response after CRT implantation (Bertini et al., 2016). Pacing in myocardial scar might lead to inadequate resynchronization. LV lead implantation at sites of scar (even in optimal anatomical location) has been associated with poor response to CRT in large single-center studies (Adelstein and Saba, 2007; Leyva et al., 2011; Khan et al., 2012).

Multisite Pacing

A beneficial clinical response to CRT is based on an optimized LV electrical stimulation resulting in synchronous myocardial contraction. The LV is conventionally stimulated by one pacing vector but multisite pacing (MSP) also emerged as a strategy to enhance clinical response to CRT. More pacing locations in the LV may increase the chance to capture an LV region ideal for resynchronization. MSP can be achieved by introducing two LV electrodes in different side branches of the coronary sinus (**Fig. 8**) or by multipolar LV leads (**Video 1–6**).

Multiple LV leads

It was demonstrated in animal models that addition of further LV pacing electrodes resulted in an acute hemodynamic improvement as compared to single-lead LV pacing (Ploux et al., 2014). Human studies also showed significantly better CRT responses by implanting multiple LV leads (Rogers et al., 2012). It was hypothesized that stimulation by more LV leads may have induced a rapid and potentially more physiological LV activation (Ramanathan et al., 2004). The beneficial effects of MSP may be different in

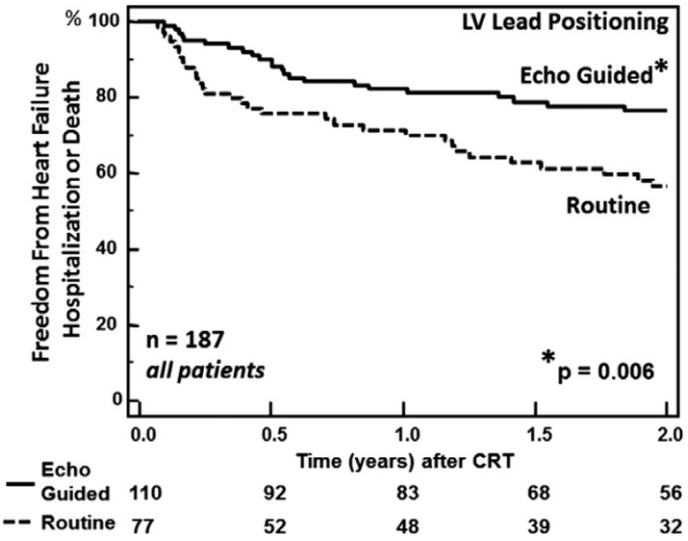

Fig. 7 Kaplan–Meier plots of the results of freedom from heart failure hospitalization or death after CRT. Patients randomized to echocardiography-guided LV lead positioning strategy had a significantly more favorable clinical outcome in comparison to routinely treated patients (Saba et al., 2013). Fig. 8 Multisite pacing achieved by two electrodes in different side branches of the coronary sinus (Lenarczyk et al., 2007). The electrode in an anterolateral branch is marked with a black arrow and the lead in a posterolateral branch is marked with a white arrow. Reprinted with permission from Elsevier.

patients with HFrEF of ischemic or nonischemic etiology. Patients with nonischemic cardiomyopathy responded adequately to conventional CRT while MSP resulted in a significantly higher acute hemodynamic response in patients with myocardial scarring and ischemic HFrEF may be a more appropriate target group for MSP (Ginks et al., 2012a,b). Additional studies have also shown an improvement in the acute LV hemodynamic response (LVdP/dtmax) (Pappone et al., 2000), LV ejection fraction (Lenarczyk et al., 2007), and LV end-systolic volume (Leclercq et al., 2008). As regards clinical endpoints, the results are not consistent as some studies reported improvement in the NYHA functional status (Lenarczyk et al., 2009) and exercise tolerance (Rogers et al., 2012) while others have not shown such clinical benefit (Leclercq et al., 2008).

Multipolar LV leads

Multipolar LV leads can induce electrical activation usually at four stimulation sites, and therefore, MSP can be achieved by a single quadripolar LV lead. High implant success rates, satisfactory pacing parameters, and stable positioning were reported (Tomassoni et al., 2013). Multipolar LV leads offer a considerably large number of available pacing configurations and, therefore, problems such as high capture thresholds and diaphragmatic stimulation can easily be solved. A few preliminary studies were performed to investigate the effects of MSP delivered via multipolar LV leads. Some studies showed increase of the LV acute systolic function (Thibault et al., 2013; Pappone et al., 2014), which was consistently observed regardless of QRS duration or LV lead position (Zanon et al., 2015). Interestingly, acute hemodynamic response to MSP via multipolar LV leads was not significantly different as compared to MSP via multiple LV leads (Shetty et al., 2014). Other studies reported improvement of radial strain (Rinaldi et al.,

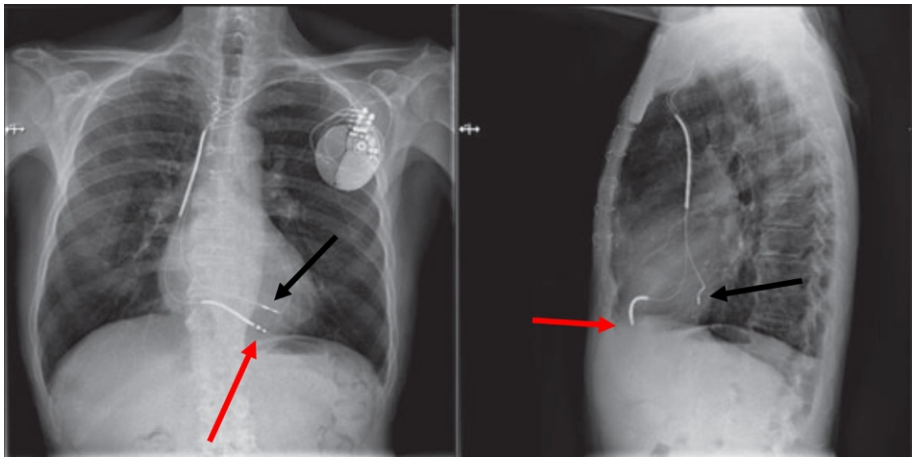

Fig. 9 Position of an endocardial LV lead after a transseptal implantation. Anteroposterior and lateral X-ray images show the final position of an endocardial LV lead (*black arrow*) and a RV lead (*red arrow*) (Calvo et al., 2014). 2014) and mechanical dyssynchrony (Rinaldi et al., 2013; Osca et al., 2016) during multipolar pacing as compared to conventional CRT. Subsequently, a small clinical study was conducted to investigate the clinical effects of multipolar leads. After a 12-month follow-up improved echocardiographic and clinical response was observed in the group with multipolar pacing (Pappone et al., 2015). Similarly to MSP by two LV leads, bioengineering simulations have suggested that MSP by multipolar LV leads may be more beneficial in subjects with ischemic cardiomyopathy and heterogeneous LV activation (Niederer et al., 2012). Randomized, prospective, multicenter studies investigating the safety and efficacy of MSP via a single multipolar LV lead are ongoing. The MOre REsponse on Cardiac Resynchronization Therapy With MultiPoint Pacing (MORE-CRT MPP) aims to recruit patients with class I or IIa indications for CRT therapy. After a 6-month period of conventional LV pacing nonresponders (<15% reduction in LV end-systolic volume) are randomized to standard pacing or MSP via a quadripolar lead. The primary endpoint is >15% reduction in LV end-systolic volume after further 6 months.

Endocardial LV Pacing

Endocardial LV pacing (Calvo et al., 2014, **Fig. 9**) has a couple of theoretical benefits as compared to epicardial pacing: positioning of the lead is not limited by the anatomy of the coronary sinus branches; it likely requires lower pacing energy outputs, and there is no phrenic nerve stimulation; furthermore, it is probably more physiological and possibly less pro-arrhythmic by reduced dispersion of ventricular repolarization. The importance of a good lead position was observed in animal studies, in which endocardial pacing resulted in larger acute hemodynamic effects and better resynchronization of ventricular activation than with epicardial pacing (Bordachar et al., 2012; Strik et al., 2012). The possible reason of the more efficient electrical resynchronization is a faster impulse conduction and a shorter activation path length in the endocardial than in the epicardial layers. The results of some small observational clinical studies (Derval et al., 2010; Spragg et al., 2010; Ginks et al., 2012a) of endocardial CRT are consistent with the findings of the animal experiments. In these studies, acute hemodynamic responses at the best endocardial LV pacing site were significantly greater than those achieved via epicardial LV pacing (Spragg et al., 2010; Ginks et al., 2012a) and a small clinical study showed even long-term benefits (Garrigue et al., 2001b). However, endocardial LV lead placement might increase the risk of systemic thromboembolism, mitral insufficiency, and endocarditis (Rademakers et al., 2014). The recently published prospective, multicenter Alsync trial (Morgan et al., 2016) evaluated the feasibility and safety of LV endocardial pacing. The success rate of the implantation was 89% but 23% of the patients had periprocedural or mid-term complications during a 6-month follow-up. Clearly, better and easier techniques, such as wireless pacing, are required for endocardial CRT, after which randomized studies can be performed to investigate the benefits compared to epicardial CRT. Recently, a system for leadless RVP has been developed (Reddy et al., 2015, **Fig. 10**). This technique does not require a pacemaker pocket or lead and during the implantation the pacemaker, the size of which is a small coin, is introduced transvenously and screwed directly in the endocardium of the heart. It may be speculated that leadless LV endocardial pacing may be potentially beneficial for resynchronization without the major complications caused by endocardial LV leads. However, leadless pacing has not yet been tested as an alternative to conventional LV pacing and its place in a CRT context is therefore unknown.

Patient Care After CRT Implantation

In addition to routine follow-up of a patient with heart failure, care of the patient following implantation of CRT includes control of proper functioning of the device and the leads, optimization of device programming, and early recognition of patients at risk for nonresponse. A standard 12-lead ECG is very useful to detect LV noncapture, fusion beats (**Video 7–9**), and

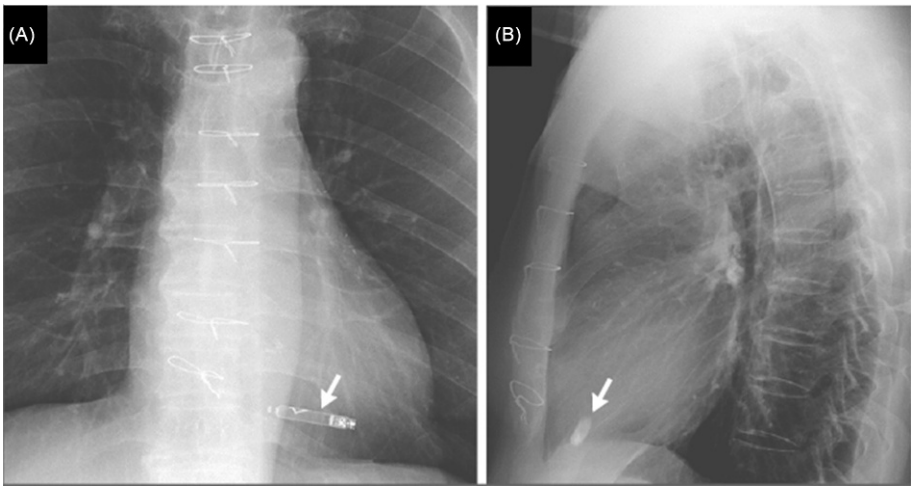

Fig. 10 Leadless cardiac pacemaker. Frontal (A) and lateral (B) chest radiographs of a patient after implantation of a Nanostim leadless cardiac pacemaker. The arrows indicate the location of the device in the region of the distal right ventricular septum and right ventricular apex (Reddy et al., 2015). Reprinted with permission from the Massachusetts Medical Society.

tachyarrhythmias. A chest X-ray can be used to determine LV lead position and in case of nonresponse repositioning of the LV lead may be considered (**Video 10–12**). As regards optimization of device programming, the delay between atrial sensing or stimulation and ventricular stimulation (AV-delay) and the timing interval between stimulation of each ventricle (VV-delay) are programmable parameters and their optimization may affect resynchronization and thereby improve clinical outcome. Optimizing the AV delay in patients with CRT resulted in an optimal atrioventricular coupling, improved hemodynamics, and cardiac function (Auricchio et al., 1999; Gras et al., 2009). Optimization can be performed by device algorithms based on intrinsic AV intervals, interventricular timing, and LV lead location (Ellenbogen et al., 2010; Kamdar et al., 2010; Singh et al., 2013) or by echocardiography guided assessment of mitral inflow patterns (Barold et al., 2008). AV optimization was shown to be beneficial to patients demonstrating nonresponse after CRT implantation (Mullens et al., 2009). In most studies, however, intrinsic device based on routine echocardiographic optimization of AV intervals did not significantly improve clinical outcome (Ellenbogen et al., 2010; Kamdar et al., 2010; Singh et al., 2013). In addition to AV optimization, optimization of VV delay was also demonstrated to improve hemodynamic parameters (Leon et al., 2005; Boriani et al., 2009). Similar to AV optimization, VV optimization can be performed by using intrinsic device algorithms or guided by echocardiography. Routine optimization of VV delay, however, did not result in a significantly better clinical outcome (Gras et al., 2009; Singh et al., 2013; Boriani et al., 2009). VV optimization may be of more importance to patients with ischemic cardiomyopathy and consequently heterogeneous activation patterns as compared to nonischemic cardiomyopathy (Marsan et al., 2009). Recently, a dynamic LV only pacing algorithm has been developed (AdaptivCRT; Medtronic, Minneapolis, MN) (Martin et al., 2012), which creates an effective fusion of LV pacing and native RV conduction. It was hypothesized that the physiologic activation of the RV and avoidance of RVP-induced dyssynchrony may be beneficial during resynchronization. Patients randomized to the AdaptivCRT algorithm experienced a 44% reduction in RVP compared to those undergoing standard echocardiography-guided optimization (Martin et al., 2012). Increased percentage of LV only pacing in all patients, as well as the use of the AdaptivCRT algorithm in patients with normal PR interval, were associated with a clinical benefit (Singh et al., 2013; Birnie et al., 2013). There may be a particular benefit of LV only pacing algorithms in patients demonstrating nonresponse to CRT as recently suggested (Thibault et al., 2011). Another optimization algorithm uses the Peak Endocardial Acceleration (PEA) signal system implanted in the RV lead (SonR sensor; Sorin Group, Milan, Italy) (Ritter et al., 2012; Delnoy et al., 2013). The CLEAR (Clinical Evaluation on Advanced Resynchronization) study aimed to assess the effects of CRT with automatically optimized AV and VV delays, based on this accelerometer-based technology (Ritter et al., 2012). After a short-term follow-up, the accelerometer-based algorithm was associated with an improved NYHA class as compared to standard echocardiographic optimization (Ritter et al., 2012) and a post hoc analysis suggested a possible mortality benefit in patients undergoing frequent, systematic optimization compared with standard care (Delnoy et al., 2013). The recently published RESPOND CRT study, a randomized controlled clinical trial, showed noninferiority but not superiority of the contractility sensor-guided optimization as compared to standard care in terms of clinical and echocardiographic CRT response (Brugada et al., 2017). Contemporary CRT devices offer a large number of monitoring parameters that are relevant for the longitudinal care of patients with heart failure (Singh et al., 2009). Information regarding heart rate, atrial and ventricular ectopic burden autonomic activity, transthoracic impedance, and patient activity are available in current CRT devices and may help to recognize worsening heart failure status earlier and, thus, prevent poor clinical outcome and heart failure hospitalizations (Auricchio et al., 2014; Vegh et al., 2014). Biventricular pacing percentage has been reported as an important determinant of clinical outcomes following CRT. A recent report from the LATITUDE investigators (Boston Scientific, Marlborough, MA) of nearly 37,000 patients suggested biventricular pacing percentages greater than 98% were associated with improved survival as compared to lower pacing percentages (Hayes et al., 2011). Device data including

biventricular pacing percentage, atrial, or ventricular ectopic burden or tachyarrhythmias may facilitate early intervention and improve clinical outcomes (Lakkireddy et al., 2012).

Conclusions

CRT, with or without ICD, has been well established in multiple large trials to improve reverse remodeling, symptoms, hospitalizations, and mortality in well-selected patients with heart failure when used in addition to optimal medical therapy. Consensus guidelines have identified the patients most likely to benefit from CRT as those with symptomatic (NYHA II-III) heart failure, LVEF $\leq$ 35%, and wide QRS duration. Subsequent analysis showed that patients with wide QRS and LBBB pattern benefit most from CRT whereas the positive effects of CRT in RBBB or nonspecific QRS prolongation are less clear and require further investigation by randomized controlled trials. CRT was subsequently shown to have beneficial effects in patients with HFrEF and wide QRS duration in case of ischemic cardiomyopathy, AF or continuous RVP. The proportion of nonresponders may be reduced by better patient selection and more optimal lead positioning individually targeting areas with the latest activation but without scar. MSP by multiple and multipolar LV leads may result in a more synchronous myocardial contraction in selected patients. Randomized controlled trials are ongoing to evaluate the clinical efficacy of MSP in larger patient populations. Endocardial LV pacing is an alternative therapeutic option but its widespread clinical use has been questioned by safety considerations. Leadless LV endocardial pacing may be a future technique potentially beneficial for resynchronization and without the major complications caused by endocardial LV leads.

Introduction

Advanced therapy with mechanical support and cardiac transplantation for refractory chronic heart failure have emerged as standard treatment for those considered end-stage despite advances in both pharmacologic and device treatment in the past decades. The survival benefit of defibrillators, cardiac resynchronization devices, and medical therapy has been well established, but morbidity and mortality associated with advanced heart failure remains disproportionate, reaching nearly 50% for 5-year mortality and greater than 50% 1-year mortality for end-stage patients. Cardiac transplantation has a median survival range from 10 to 13 years based upon a patient surviving the first year; 1 year survival has improved in the most recent era with an unadjusted rate of 86% in 2009–13 compared with 84% in the 2002–08 era (Lund et al., 2015). Although

replacement of the heart is standard treatment for select patients with refractory symptoms, mechanical support has emerged as an acceptable alternative for those who are either not candidates or require more urgent definitive therapy. In fact, around 42% patients were transplanted from left ventricular assist devices (LVAD) in 2013. Although the first successful human heart transplant was performed in 1967 in South Africa and followed by the first United States case the following year, cardiac transplantation faced many challenges that limited survival ranging from medical management to surgical techniques. Improvement in immunosuppression was a key factor with the development of calcineurin inhibitors (i.e., cyclosporine) in the 1980s (Reitz et al., 1981) and continues to improve with refinements in surgical technique, recipient and donor selection, donor management, immunosuppression, and treatment of comorbidities. Estimated annual transplant rates are >4000 cases with the limiting factor being shortage of available donors (**Fig. 1**).

Evaluating the Transplant Candidate

Indications

Cardiac transplantation is reserved for advanced heart failure, refractory angina, and intractable ventricular arrhythmias (Macdonald, 2008) (**Table 1**). Candidates for cardiac transplantation have New York Heart Association (NYHA) Class III–IV symptoms despite optimal medical and device therapy, including resynchronization therapy and often surgical treatment of ischemic and/or valvular heart disease. Etiology of heart failure most commonly involves coronary artery disease or nonischemic cardiomyopathy and less often restrictive cardiomyopathy, valvular heart disease, and congenital heart disease (**Fig. 2**). Trends in the most recent era of 2009 to June 2014 include an increase in dilated cardiomyopathy from 52.1% in the previous era (2004–08) to 55.6% currently and a decline in coronary artery disease from 38.8% to 35.1% in the current era (Lund et al., 2015). Other less commonly transplanted indications involve (1) repeated ventricular arrhythmias despite pharmacologic and ablative treatment due to the risk of sudden death and hemodynamic intolerance with the arrhythmias, and (2) chronic angina unresponsive to medical therapy which is not amenable to further revascularization. These indications are the result of end-stage disease failing maximal therapy and reducing quality of life and survival.

Cardiopulmonary Exercise Testing as a Guide to Candidacy

Cardiopulmonary exercise testing assesses peak oxygen consumption (VO_2) and provides an objective measure in addition to NYHA class, ejection fraction, and clinical status (blood pressure, heart rate, readmissions, tolerance of medical therapy). A VO_2 result between 10 and 14 mL/kg/min is associated with a reduced survival; evaluation for transplantation is recommended.

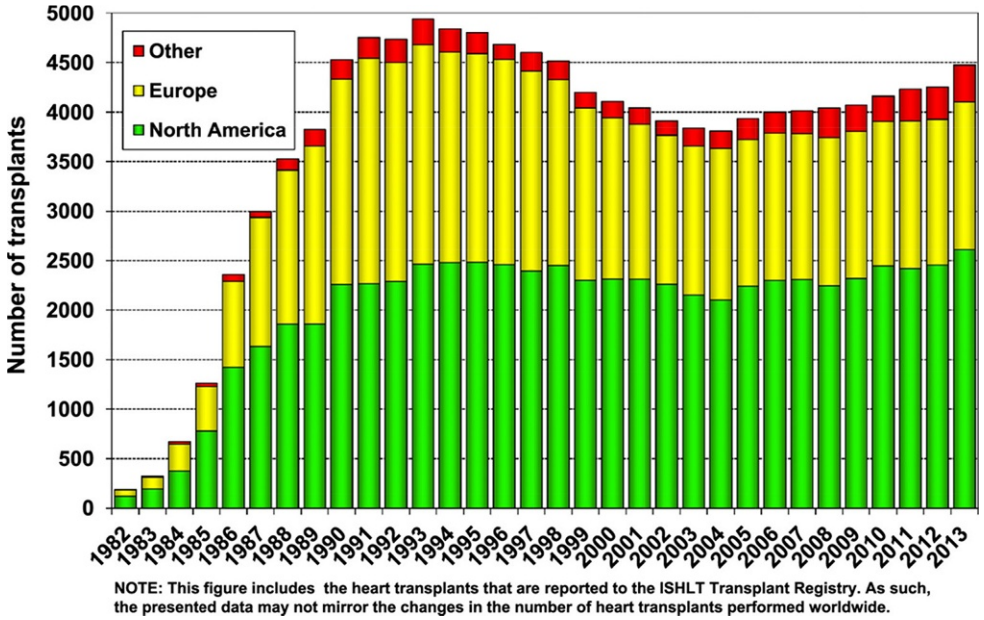

Fig. 1 Heart transplant volume as reported to the ISHLT Transplant Registry. Reprinted from Lund, L. H., Edwards, L. B., Kucheryavaya, A. Y. et al. (2015). Table 1 Indications for heart transplantation

Advanced systolic heart failure
- NYHA class III–IV symptoms
- Low cardiac output
- Cardiopulmonary exercise testing with peak VO_2 max <12–14 mL/kg/min or <50% predicted in select patients

Acute heart failure not expected to recover
- Acute myocardial infarction
- Acute myocarditis

Refractory angina in ischemic disease
- Not amenable to percutaneous or surgical revascularization
- Unresponsive to maximal medical therapy

Intractable ventricular arrhythmias
- Maximal antiarrhythmic therapy and ablative therapy

Advanced diastolic heart failure symptoms in restrictive or hypertrophic cardiomyopathy
Congenital heart disease with refractory symptoms

NYHA, New York Heart Association; *Vo_2*, maximal oxygen uptake.

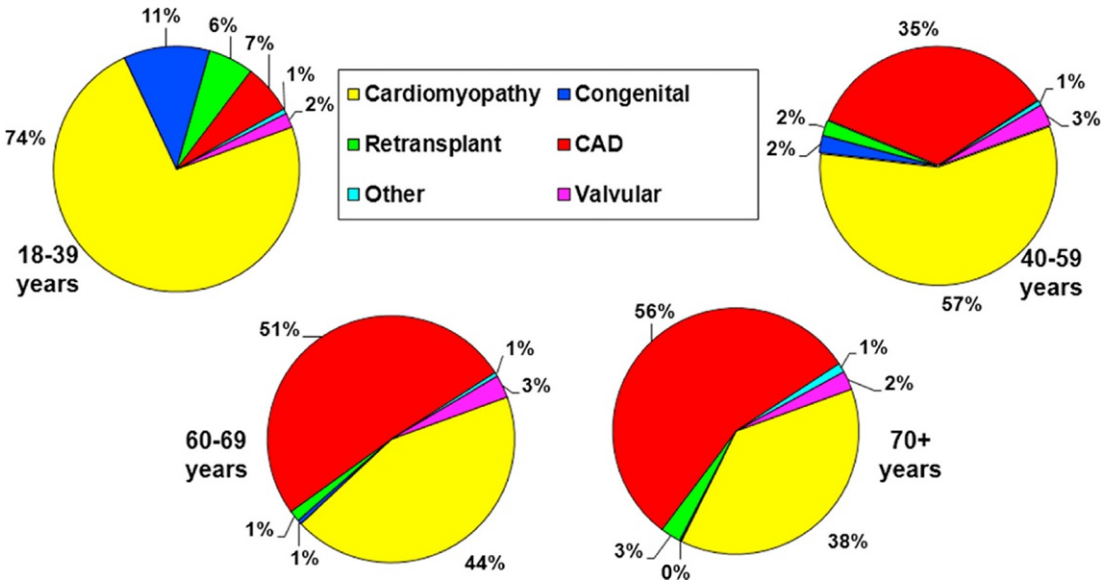

Fig. 2 Etiology of adult heart transplantation indication from January 2009 to June 2014. Reprinted from Lund, L. H., Edwards, L. B., Kucheryavaya, A. Y. et al. (2015). The registry of the International Society for Heart and Lung Transplantation: Thirty-second official adult heart transplantation report—2015; focus theme: Early graft failure. *The Journal of Heart and Lung Transplantation* **34** (10), 1244–1254. Although listing criteria detail peak $VO_2 \leq 12$ mL/kg/min in those taking a beta-blocker and ≤ 14 mL/kg/min if intolerant of a beta-blocker, it is acceptable to evaluate alternate parameters from peak exercise in younger patients <50 years of age and women (Mehra et al., 2006, 2016). In these patients due to variations in peak VO_2 based on gender and age, a peak $VO_2 < 50\%$ predicted can also guide candidacy.

Patients should reach anaerobic threshold, which is defined as a respiratory exchange ratio (RER) >1.05 and represents carbon dioxide production exceeding oxygen consumption during exercise. If patients have a submaximal test, perhaps due to deconditioning, parameters such as the ventilatory response to exercise, or the ventilation to carbon dioxide slope (VE/VCO_2), can be measured throughout the duration of exercise. A higher slope, $VE/VCO_2 > 35$, signifies worse prognosis and is noted in patients with low cardiac output, pulmonary hypertension, and a higher dead space volume.

Current guidelines recommend using heart failure prognosis scores adjunctively to cardiopulmonary exercise testing, but not using the prognostic scores independently of this data or other objective data as some data suggests risk is underestimated with the prognostic scores alone (Mehra et al., 2016; Alba et al., 2013). If the estimated 1-year survival in the Seattle Heart Failure Model (SHFM) is <80% or Heart Failure Survival Score (HFSS) is medium/high risk, it is reasonable to use this score to assist VO_2 data when determining listing candidates for transplantation (Table 2).

Table 2 Heart failure survival score: variables

Ischemic etiology
Interventricular Conduction delay
Left ventricular ejection fraction
Heart rate
Serum sodium
Mean arterial pressure
Peak VO_2 or maximal oxygen uptake

Contraindications

The majority of contraindications to transplant are relative contraindications as opposed to absolute and are weighed according to the patient's comorbidities and clinical status. These contraindications may vary among transplant centers as to absolute or relative in terms of patient candidacy (**Table 3**).

Age

Cardiac transplant recipient age has increased over the last several decades until 2010 and has remained stable around age 54 over the past few years (Lund et al., 2015). Historically, candidates who were 65 years or older were considered higher risk with lower expected survival, but current guidelines recommend considering patients ≤70 years of age based on improved survival in older patients and select patients >70 years of age (Mehra et al., 2006, 2016). Long-term follow-up of patients >65 years after cardiac transplant revealed similar 10-year survival and causes of death when compared with younger patients (groups included recipients <60, 60–64, and >65 years); there was no difference in freedom from severe infection, cancer, or severe graft vasculopathy (Zuckermann et al., 2003). Moreover, older patients displayed immunosenescence, or a gradual decline in the immune system with age, leading to fewer rejection episodes and a larger percentage of patients who were not on maintenance steroid therapy. Review of the UNOS database ($n = 50{,}432$) for transplanted patients from 1987 to 2014 confirmed similar outcomes for recipients in their 70s compared with recipients in their 60s despite being more likely to receive organs from donors with a history of tobacco, alcohol, or cocaine use or donors considered high risk for transmission of disease (Cooper et al., 2016). Contrary evidence has endorsed reduced survival in older recipients (Tjang et al., 2008; Marielli et al., 2008), therefore leading to current guideline recommendations to carefully select older patients based on comorbidities, such as renal function, with specific donor and recipient criteria in place at the transplanting center (Mehra et al., 2016). Upper age limit remains center-specific criteria with each individual center determining if they will have an absolute cutoff for candidacy based upon chronologic age.

Obesity

Obesity in cardiac surgery is associated with complications of infections, poor wound healing, pulmonary status, and thromboembolic events. Risk associated with transplantation involves higher risk of rejection, vasculopathy, and mortality (Lietz et al., 2001). Weight gain is a likelihood posttransplant due to cardiac cachexia with end-stage heart failure, and is often related to age and gender (Williams et al., 2006); progression of preexisting comorbidities is a reality for this reason in addition to immunosuppression regimens that can affect weight gain and blood sugar. Therefore, recipient weight is an essential parameter for candidacy, measured as body mass index (BMI, weight in kilograms per height in meters squared) or percent ideal body weight (PIBW) for a given height and gender. Both measurements take into account height as opposed to considering weight only. The International Society for Heart and Lung Transplantation (ISHLT) guidelines recommend a pretransplant BMI <35 kg/m^2 or PIBW <140%, and state it is "reasonable" to recommend weight loss in candidates who do not meet this criteria due to the association with poor outcomes (Mehra et al., 2006). This criteria has been amended from previous recommendation of 30 kg/m^2 in the most recent guidelines based upon data suggesting that BMI <35 kg/m^2 is not clearly associated with higher mortality although patients above this cutoff have longer wait times and lower likelihood of suitable donors (Russo et al., 2010a; Weiss et al., 2009a). Given the prevalence of obesity, many centers accept a higher BMI or PIBW in recipients and the upper limit is usually center specific.

Pulmonary hypertension assessment

Due to the risk of right heart failure posttransplantation, irreversible pulmonary hypertension is an absolute contraindication to candidacy and right heart catheterization is required in all candidates (Mehra et al., 2006). In advanced heart failure, secondary or venous pulmonary hypertension develops as a result of elevated filling pressures. Although it is usually considered reversible with a low pulmonary vascular resistance (PVR), an irreversible or fixed component may develop due to persistent elevation of filling pressures as a result of chronic intimal changes and medial hypertrophy in the pulmonary vasculature. A donor heart cannot withstand the high afterload of an elevated PVR, which results in failure of the right ventricle and adverse outcomes including acute cardiogenic shock and mortality (Butler et al., 2005). Therefore, routine evaluation of candidates includes invasive assessment of pulmonary pressures, filling pressures, cardiac output, and PVR. When the PVR >3 Woods units, pulmonary artery systolic pressure (PASP) >50 mmHg, PVR index >6, or a transpulmonary gradient >15 mmHg (difference of the mean PA and wedge pressure), transplant candidacy is usually not considered unless provocative testing with a vasodilator reduces the pressures and PVR to an acceptable level while maintaining a systemic blood pressure >85 mmHg

Table 3 Contraindications in cardiac transplantation (Mehra et al., 2016)

Advanced age (select patients >70 years)
Obesity
● BMI >35 kg/m^2 or PIBW >140%
Fixed pulmonary hypertensiont
● PVR >5 Woods units
● TPG >15 mmHg
● PA systolic pressure >50–60 mmHg or >50% systemic pressure in conjunction with the above parameters
● Inability to reduce PVR <2.5 Woods units with vasodilator or inotrope with systemic BP >85 mmHg
Diabetes mellitus complications
● Persistent poorly controlled (Hgb A_{1c} >7.5 mg/dL)
● End-organ complications other than nonproliferative retinopathy
Irreversible renal, hepatic, or pulmonary disease unless undergoing dual organ transplantation
● Irreversible renal dysfunction with eGFR <30 mL/min/1.73 m^2 is a relative contraindication to heart transplant only
Active infection or malignancy
● Recent malignancy
● Risk of recurrence
Clinically severe peripheral or cerebral vascular disease not amenable to revascularization or that limits rehabilitation
Psychosocial factors hindering compliance and/or comprehension of management
● Active or recent substance abuse (alcohol, illicit drugs, tobacco)
● Poor compliance with medical regimen or follow-up
● Insufficient social support system
● Psychiatric illness that is not well controlled on therapy

BMI, body mass index; *PIBW*, percent ideal body weight; *PVR*, pulmonary vascular resistance; *TPG*, transpulmonary gradient; *PA*, pulmonary artery; *BP*, blood pressure; *Hgb*, hemoglobin; *eGFR*, estimated glomerular filtration rate; *Hgb A1c*, glycosylated hemoglobin.

(Mehra et al., 2006). If the PVR is reduced to <2.5 Woods units in the setting of a BP <85 mmHg, the patient remains high risk for right heart failure and mortality after transplantation. If patients fail acute vasodilator testing, further hemodynamic monitoring with more aggressive intervention, for example, inotropes and diuretics, is usually undertaken to determine reversibility of pulmonary hypertension. Mechanical devices such as intraaortic balloon pump or left ventricular assist devices (LVAD) are reasonable therapies to effectively unload these patients; reevaluation of hemodynamics is usually performed 3–6 months after LVAD to allow time for reversal and successful bridge to transplantation (Kutty et al., 2013). Patients who remain irreversible with fixed, elevated PVR may also have underlying lung disease, concurrent obstructive sleep apnea, or chronic thromboembolic pulmonary hypertension, which should be excluded.

Diabetes mellitus

Diabetes with end-organ damage (proliferative retinopathy, nephropathy, and neuropathy) or poorly controlled blood sugars (glycosylated hemoglobin, HbA_{1c}, >7.5 mg/dL) is considered a relative contraindication. In a review of >20,000 recipients in the United Network for Organ Sharing (UNOS) database, Russo et al. (2006) found that uncomplicated diabetic patients have improved survival when compared to those with complicated diabetes, defined as the collective number of diabetic-related complications such as severe obesity, peripheral vascular disease, cerebrovascular accident, and history of renal failure; 10-year survival was negatively impacted by the presence of diabetes in another review of predictive factors (Kilic et al., 2012a). Further evidence is lacking to further delineate what degree of end-organ involvement is acceptable, but guidelines recommend considering only those with nonproliferative retinopathy (Mehra et al., 2006). Dual organ candidacy with a combined heart–kidney transplantation should be evaluated in select cases of nephropathy. Consultation with an endocrinologist should be part of the evaluation process to reach HbA_{1c} <7.5 mg/dL.

Renal dysfunction

Estimated glomerular filtration rate (eGFR) or creatinine clearance should be used to assess renal function, and evaluation includes workup of intrinsic renal disease, which would be considered irreversible or unlikely to correct after improving cardiac function. This assessment of chronic kidney disease (CKD) includes imaging, quantifying proteinuria, and evaluating for renal arterial disease. Transplant programs are faced with the effect of renal dysfunction on outcomes. In a review of 1732 patients from 1996 to 2007 in the United Kingdom, patients with CKD stage IV, V, or on dialysis had an increased risk of mortality with the highest risk associated with CKD stage V not receiving dialysis. Initiating dialysis reduced this risk but not to that of the CKD stage IV patients. Those with impaired renal function at the time of listing were more likely to develop CKD with function often deteriorating within the first year after transplantation, progressing from 50% with CKD stage III or higher immediately before transplantation to 77% during the first

year (Thomas et al., 2012). Risk factors for developing CKD included recipient age, female gender, diabetes, and temporary dialysis or hemofiltration perioperatively (Thomas et al., 2012; Hamour et al., 2009). ISHLT listing criteria state that it is reasonable not to consider irreversible renal dysfunction with eGFR <30 mL/min/1.73 m^2 for heart transplantation alone; dual organ candidacy should be considered in appropriate cases (Mehra et al., 2006).

Active infection and malignancy

Both active infection and malignancy, with the exception of nonmelanoma skin cancers, are absolute contraindications to transplantation due to the risk of progression with immunosuppression. The duration to wait after remission for malignancy is arbitrary and dependent on the type of cancer, response to treatment, and risk of recurrence (Mehra et al., 2006). Malignancy that is in remission and has a low risk of recurrence will usually be considered after oncology consultation, especially when considering the urgency of the patient clinical presentation. For example, a patient with end-stage heart failure and prostate cancer within the past few years would be a reasonable candidate based on the success rate of treatment and slow-growing nature of this cancer as opposed to a patient who presents with chemotherapy-induced cardiomyopathy closer to treatment for breast cancer. Pretransplant evaluation includes routine screening for malignancy.

Active infection must be resolved before considering transplantation with documentation of negative cultures and resolving signs of infection. Chronic infections such as hepatitis B or C and human immunodeficiency virus (HIV) present a more complex circumstance for listing; in the past, such patients would not have been considered. With growing experience, patients with these chronic infections have been successfully transplanted if they do not have extensive organ involvement with the disease; however, experience is limited and many centers still consider such infections a contraindication. Hepatitis C positive heart transplant recipients have a worse survival in two database reviews: (a) UNOS from 1991 to 2014, higher mortality at 5 and 10 years with late renal and liver dysfunction occurring more frequently despite similar baseline pretransplant liver function when compared with hepatitis C negative recipients and (b) Scientific Registry of Transplant Recipients from 1995 to 2013, HCV+ was independently associated with a higher mortality posttransplant (Kumar et al., 2016; Stepanova et al., 2016). However, the success of current antiviral agents may significantly impact survival in these patients, leading to consideration of listing based upon HCV genotype and liver biopsy (Mehra et al., 2006).

Select HIV-positive patients without active or opportunistic infections who are stable on combined antiretroviral therapy with an undetectable viral load and CD4 count >200 μL have been successfully transplanted (Uriel et al., 2009; Agüero et al., 2016. Current ISHLT guidelines support consideration in the appropriate patient with chronic infections, but close collaboration with transplant infectious disease specialists should be undertaken in these situations given the challenges of managing antiretroviral therapy and immunosuppression.

Peripheral vascular disease

Symptomatic cerebral or peripheral vascular disease is considered a contraindication to candidacy if clinically severe or not amenable to revascularization when rehabilitation posttransplant would be limited. Asymptomatic disease will likely be considered, but it is an individual center decision. Retrospective data suggested progression of peripheral vascular disease posttransplantation; another registry found patients with symptomatic cerebrovascular disease pretransplant were at a higher risk of stroke and functional decline posttransplantation but not a higher mortality rate (Patlolla et al., 2011). Cardiac rehabilitation capability is critical in any candidate with vascular disease.

Psychosocial factors

A detailed psychosocial assessment of all transplant candidates is a fundamental step in the evaluation. This includes compliance with medical therapy and clinical follow-up, psychiatric history, substance abuse history, and social support network. Initial assessment is usually performed by dedicated social workers in transplant programs in which caregivers and patients usually meet with the social worker. If the patients have concerning psychiatric history or active illness, many are often referred to a psychiatrist or psychologist for further evaluation or neurocognitive testing based on concerns with cognitive function. Substance abuse (alcohol, illicit drugs, or tobacco) are all contraindications to listing and programs require 6–12 months of abstinence documented with negative toxicology screens; current alcohol abuse or illicit drug use are absolute contraindications in transplant programs. Various interventions are recommended including rehabilitation or substance abuse programs, counseling, and sponsorship. Active tobacco use is a relative contraindication due to the association with poor outcomes. Medical marijuana poses a new controversial issue without a clear answer regarding candidacy; it should likely be treated similar to alcohol, which is legal, but abuse, inability to quit, or cognitive impairment are barriers to transplant candidacy. Many patients are denied candidacy based on their psychosocial situation as this has been critical to long-term success (Rivard et al., 2005). Patients who have demonstrated poor medication compliance are not considered candidates, and severe cognitive-behavioral disabilities and dementia are considered contraindications since a benefit has not been established and there is potential for harm (Mehra et al., 2006). Comprehensive screening tools are now incorporated into the psychosocial assessment in many transplant programs for standardization and predicting psychosocial outcome (Maldonado et al., 2012). Success of heart transplantation is dependent upon the recipient's compliance with therapy and follow-up in addition to coping with the challenges of receiving such a scarce resource which includes an emotional and financial burden to patients and caregivers.

Ventricular assist devices as bridge to transplantation

Patients with comorbidities that limit current candidacy have been bridged to transplantation (BTT) with ventricular assist devices (VAD). This has been successful when pulmonary hypertension is present as reversal has been documented over time with mechanical support (Etz et al., 2010). Other treatable comorbidities, such as obesity, renal failure, tobacco use, and cancer, are also reasonable as BTT indications for VAD support. Renal failure should be evaluated for the degree of intrinsic renal disease related to other comorbidities, such as diabetes, that would likely not improve with improved cardiac function. Weight loss surgeries have been performed successfully in morbidly obese VAD patients to improve BMI to an acceptable range for transplant candidacy (Chaudhry et al., 2015). Patients with restrictive cardiomyopathy represent a complicated patient population that is not typically bridged with VAD support due to the restrictive physiology of the heart that does not respond similarly to the dilated ventricle with systolic dysfunction.

Amyloidosis

Treatment of amyloidosis with heart transplantation depends on the subtype and extent of cardiac and/or systemic involvement. Due to the higher mortality and progression of disease, only select patients with primary or AL amyloidosis may be considered for heart transplant and autologous stem cell transplant in centers with collaborative heart transplant and hematology programs, but is considered a contraindication for heart transplant alone (Mehra et al., 2006). Patients with transthyretin-related (TTR) amyloidosis may be considered for combined heart–liver transplantation since the protein is synthesized in the liver, and liver transplantation is the definitive treatment in familial amyloidosis. In a single-center review, combined transplantation in this situation has a survival similar to heart only patients (Raichlin et al., 2009). Older patients with TTR amyloid and only cardiac manisfestation may be considered for heart transplant alone, but younger patients would be combined heart–liver candidates to prevent systemic progression including cardiac involvement posttransplantation.

Waitlist Management

Listing candidates

Patients are waitlisted for heart transplant after decision by a multidisciplinary selection committee consisting of the various team members involved in the evaluation process: cardiac surgeons, heart failure cardiologists, coordinators, pharmacists, social workers, and subspecialty consultants such as pulmonology, nephrology, and infectious disease. Current listing status in 2016 comprises three levels, 1A, 1B, and 2 from the most urgent status to the least urgent. See **Table 4** for details on the current listing status (OPTN Policy, 2017). Patients accrue time on the waitlist regardless of status and are matched to available organs based on size, blood type,

Table 4 United network for organ sharing waitlist status criteria (as of 2016) (OPTN Policy, 2017)

Status 1A: recertified every 14 days from initial listing as status 1A

- Mechanical circulatory support
  - LVAD and/or RVAD if clinically stable can be listed as 1A at any point after implantation for 30 days without a complication
  - LVAD or RVAD with significant device-related complication: thromboembolism, infection, device failure, ventricular arrhythmias
  - IABP, TAH, or ECMO
- Mechanical ventilation
- Inotrope support
  - Continuous hemodynamic monitoring plus multiple inotropes or high dose of single inotrope

Status 1AE (by exception): recertified every 14 days from initial listing as status 1AE

- Urgent clinical status but patient does not meet above criteria (i.e., ventricular tachyarrhythmias preventing inotrope use or hemodynamic monitoring)
- Approved by appropriate Regional Review Board

Status 1B

- LVAD and/or RVAD beyond 30 days without a complication
- Continuous infusion of single inotrope without hemodynamic monitoring

Status 1B (by exception): Does not meet status 1B criteria, similar requirements as status 1AE

Status 2

- Candidates not meeting status 1A or 1B criteria

Status 7

- Temporarily unsuitable for transplantation

LVAD, left ventricular assist device; *RVAD*, right ventricular assist device; *IABP*, intraaortic balloon pump; *TAH*, total artificial heart; *ECMO*, extracorporeal membrane oxygenation.

and medical urgency or waitlist status. The goal of organ allocation is to transplant those who are the most critical and have the shortest survival. Average wait times on the list will vary by region. Patients who are large and blood type O will typically wait longer than those who are nonblood type O and smaller. For this reason, VADs are implanted in those who are less likely to survive while waiting for an available organ and are termed "bridge to transplantation." Some transplant programs have an alternate list for higher risk recipients (age >70 years, renal dysfunction, retransplantation) and donors (high risk behavior, older donors, or presence of coronary artery disease). The United Network for Organ Sharing currently is in the process of updating thoracic organ allocation, which will risk stratify recipients into more categories based on the extent of support to reflect our utilization of mechanical circulatory support devices and address geographic disparities in donor access. Patients who are grouped into status 1A in our current scheme will be further categorized based on the type of support, such as the highest status given to temporary or nondischargeable mechanical support, and certain VAD complications while the stable VAD patient is considered similar to the chronic inotrope patient without hemodynamic monitoring.

Right heart catheterization

Routine right heart catheterization (RHC) is performed as part of the transplant evaluation and periodically as part of waitlist management, which is center specific based upon the individual patient and usually varies in the 3- to 6-month range (Mehra et al., 2006). A vasodilator challenge is indicated when PASP >50 mmHg and TPG >15 mmHg or PVR >3 Woods units while maintaining systolic blood pressure >85 mmHg; commonly utilized agents are nitroprusside or nitroglycerin as an acute vasodilator and milrinone or dobutamine for inotrope support. If the patient becomes hypotensive with SBP <85 mmHg despite an appropriate decline in PVR with a vasodilator challenge, poor outcomes have been associated due to a high risk of right heart failure and mortality in this scenario (Mehra et al., 2006). If this challenge is unsuccessful, unloading of the LV will be attempted using diuretics for decongestion, continuous inotrope infusion, or in cases refractory to medical therapy, some type of mechanical support with temporary intraaortic balloon pump (IABP) or long-term with VAD. VAD in secondary PH has successfully reduced severe pulmonary hypertension to normal with PVR declining from 5 WU pre-VAD to 2.1 WU ($P < 0.05$) after VAD with similar 1-year posttransplant survival when compared with those receiving primary heart transplant (Kutty et al., 2013); other studies have found similar reversal in this population (John et al., 2010; Krishnamurthy et al., 2016). Reevaluation of hemodynamics after VAD is usually performed after 3–6 months of support to allow time for PH reversal. Patients with a fixed component of PH or elevated PVR should be evaluated for intrinsic pulmonary disease, chronic thromboembolic disease, and sleep apnea. Right heart catheterizations are regularly performed on waitlisted patients; our center's protocol requires RHC every 3 months if a vasodilator study was required to reverse PH or the patient is on a chronic inotrope infusion and every 6 months for the rest of the patients. Accurate assessment of hemodynamics and reversibility of PH is crucial for the success of heart transplantation due to the mortality associated with right heart failure in the setting of PH. Fixed PH or pulmonary arterial hypertension are considered contraindications to transplantation due to elevated and nonreversible PVR, but even reversible PH carries risk with a significantly higher risk of mortality posttransplant (Butler et al., 2005) and a nonsignificant trend to increased mortality in another study (Mogollón et al., 2008) emphasizing careful monitoring of these patients pre- and posttransplant.

Perioperative Transplant Management and Surgical Considerations

Donor Evaluation and Selection

Assessing the donor organ focuses on avoiding use of an inferior organ in critically ill patients waiting for transplantation. Organ procurement organizations (OPO) take on the responsibility of increasing the number of registered donors and coordinating the donation process. Procurement coordinators with a local OPO will evaluate potential donors; this process involves a comprehensive medical and social history, laboratory studies including blood type, infectious serologies (human immunodeficiency virus, hepatitis B and C, and cytomegalovirus), size including height and weight, and evaluation of cardiac function with an echocardiogram. Further cardiac studies, that is, coronary catheterization or right heart catheterization, are recommended based upon donor cause of death or risk factors, especially age. Substantial left ventricular hypertrophy (LVH), obstructive coronary disease, excessive inotrope use, ventricular arrhythmias, or reduced ejection fraction <40% are cardiac abnormalities that in general are not accepted for use in transplantation (Costanzo et al., 2010). Donors with chest trauma should be carefully assessed for any damage to the heart. Donor comorbidites may influence decisions on organ utilization. Data is limited regarding donor risk factors on transplant outcomes since these hearts are typically not transplanted.

Management of the donor by the OPO optimizes organ function through support of blood pressure, volume resuscitation, oxygenation, correction of electrolyte, and metabolic abnormalities including hormonal imbalances noted in brain death (insulin, corticosteroids, arginine vasopressin, tri-iodothyronine). The ischemic time may be referred to as the "cold" or "warm" ischemic time, but the total ischemic time is the total time from organ procurement in the donor to reperfusion in the recipient, also termed the "cold" ischemic time. "Warm" ischemic time refers to the duration of implantation or removal of the organ from ice until reperfusion. When evaluating a potential donor, the total ischemic time is considered, and guidelines recommend an ischemic time between 4 and 6 h with preference ≤4 h for older donor organs (Costanzo et al., 2010). ABO incompatibility is a well-established contraindication in adults due to hyperacute rejection. Size matching is usually within 20%–30% of recipient body size, although an average size male donor of 70 kg should typically be an appropriate size match for any recipient. Gender mismatching holds a mortality risk and poor outcomes due to the smaller female heart that is less likely to match the demands of a larger male recipient

or higher PVR (Kittleson et al., 2011; Weiss et al., 2009b). With an endpoint of 10-year survival, Kittleson et al. found a reduced survival in both types of gender mismatch when compared with gender-matched groups; in this single-center study of 857 patients from 1994 to 2008, findings suggest that an immunologic effect could also have a role in outcomes for mismatched recipients (Kittleson et al., 2011). Conversely, in a large UNOS database review of 18,240 transplants between 1999 and 2007, 5-year survival was the highest for matched male patients (male donor to male recipient) at 74.5%, while female donor to male recipients had a 15% increase in the risk of adjusted cumulative mortality (hazard ratio, 1.15; [1.02–1.30], $P=0.02$) (Weiss et al., 2009b). Female recipients of gender-matched or -mismatched organs showed no survival difference.

Utilization of donor hearts has decreased in the past decade and is around 40% in recent data (Khush et al., 2013). Predictors of donor nonuse were reviewed by Khush et al. within the California Transplant Donor Network from 2001 to 2008 with turndown of 1872 donors. Potential donors that were not accepted had the following: >50 years, female sex, cerebrovascular accident (CVA) as the cause of death, hypertension, diabetes, positive troponin, LV dysfunction with regional wall motion abnormalities, and LVH (Khush et al., 2013). Only CVA as the donor cause of death minimally predicted prolonged recipient posttransplant hospitalization (odds ratio, 1.41 [1.00–2.00]), while diabetes mellitus was the only donor predictor of reduced recipient 1-year survival (odds ratio 3.58, [1.18–10.84]). Experts have suggested that our current criteria for donor selection have resulted in discarding potentially useful organs leading to our present-day shortage of donors, and it seems likely that donor characteristics have a small contribution to posttransplant adverse events based on available data (Wittwer and Wahlers, 2008). Efforts to expand donor selection by liberalizing acceptance criteria and developing innovative organ perfusion techniques are ongoing as heart transplantation continues to remain limited by donor availability.

Organ Allocation

Organs are allocated according to the region, status on the waitlist, and matching by size and blood type. The allocation policy changed on June 12, 2006, to concentric 500 mile zones with the goal of prioritizing higher risk recipients, status 1A and 1B, and increasing the availability of a donor; prior to this updated policy, organs were offered to all status patients within a UNOS region before they were available to bordering regions (**Fig. 3**). Since this last revision, there has been an overall decline in the national waitlist mortality rate up to 180 days from 13.3% to 7.9% ($P<0.001$) and in the 2-year mortality rate from 17.3% to 14.6% ($P<0.001$). However, waitlist time has increased across the nation for status 1A and 1B candidates—maybe partly related to the rise in LVAD bridging, which was variable based upon the region with a range of <20%–40% (Schulze et al., 2014). Currently, LVAD patients have 30 days of 1A time regardless of a complication after which they are listed as 1B, but discussion is ongoing about the low waitlist mortality of continuous flow LVAD patients, which is similar to status 2 patients but lower than status 1A and 1B in a review of the UNOS database between 1999 and 2011 (Wever-Pinzon et al., 2013). However, patients with biventricular or temporary support or an LVAD complication were found to have a higher mortality. For this reason, the current allocation policy is under revision to create further tiers for the most urgent status based on type of support (temporary, biventricular support, temporary support) versus the stable LVAD patient or those with complications. Additional goals of the revision are to reduce the number of exception requests and increase organ sharing for the more urgent status candidates rather than the current scheme, which favors less urgent candidates in the local donor service area over more urgent candidates outside of the local donor area (https://optn.transplant.hrsa.gov/governance/public-comment/adult-heart-allocation-changes-2016/).

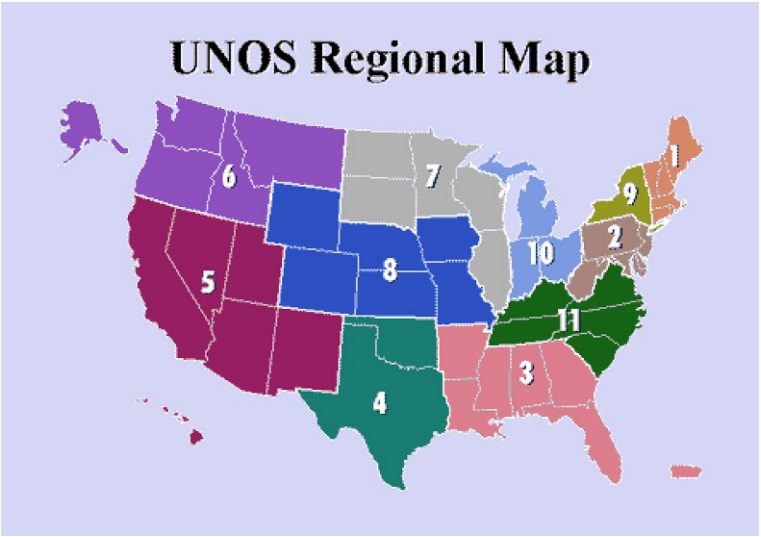

Fig. 3 The United Network for Organ Sharing (UNOS) manages organ allocation in the United States based upon these 10 geographic regions.

The Transplant Surgery

Donor procurement focuses on organ preservation and minimizing organ injury; both procuring and transplanting teams are involved in this process in order to limit the ischemic time. The organ is placed in a cold cardioplegia solution and transported to the transplanting center. Fig. 4 shows a comparison of the difference in size between the donor heart and recipient's dilated heart from heart failure. Experimental animal models have shown promise in using novel techniques to help reduce ischemia and reperfusion injury: targeted complement inhibition in recipients (Atkinson et al., 2013), cardioplegia solution supplemented with erythropoietin (Watson et al., 2013), a hypothermic hydrogen-rich water bath (Noda et al., 2013), and ex vivo heart perfusion after cardiocirculatory death (White et al., 2013; Tolboom et al., 2016). These methods require further investigation before incorporating into standard procedure.

Orthotopic heart transplantation was founded by Norman Shumway, Richard Lower, Adrian Kantrowitz, and Christiaan Barnard with Lower and Shumway first describing biatrial anastomosis in 1960 (Lower and Shumway, 1960). Biatrial anastomosis involves midatrial transection of both donor and recipient hearts along with transection of the great vessels just above the semilunar valves; the atrial septum is first reanastomosed followed by the great vessels. This method keeps the pulmonary venous connection to the left atrium intact in the recipient and includes the donor sinoatrial node in the right atrium. This method has evolved into the bicaval technique, first reported in 1991 by Dreyfus et al., in which the atria are not resected and anastomosis occurs at the inferior and superior vena cavae and pulmonary veins keeping the donor atria intact (Dreyfus et al., 1991). One benefit with the biatrial method is fewer connections with only two in the atria versus six atrial connections in the bicaval manner (two to the vena cavae and four to the pulmonary veins), possibly reducing ischemic time (Davies et al., 2010). The drawbacks to the biatrial technique are the large geometry of the atria and its possible effect on hemodynamics and arrhythmia risk along with the chance of damaging the sinoatrial node. Revising the implantation scheme was meant to reduce atrial size, atrial arrhythmias, tricuspid valve regurgitation, and bradycardia requiring a pacemaker which were considered to occur with more frequency in the biatrial method. Davies et al. reviewed almost 21,000 transplants from 1997 to 2007 with 59.3% biatrial and 38.1% bicaval anastomoses performed; they found bicaval anastomosis less often required postoperative pacemaker implantation and had a significant yet small survival advantage at 30 days and 1, 5, and 10 years (Davies et al., 2010). Despite the increasing use of the bicaval anastomosis, tricuspid regurgitation persists after transplantation in part due to repeated endomyocardial biopsies.

Physiology of the Transplanted Heart

When transplanted, the new heart is surgically "denervated" without afferent and efferent nerve supply (Pham et al., 2011). The recipient will often have a higher resting heart rate up to 100 beats per minute due to the loss of the efferent nerve supply from the central nervous system to the heart; due to this loss of vagal tone, they also will not respond to drugs dependent on the autonomic nervous system, such as atropine. The afferent supply, or that from the heart to the central nervous system, is responsible for angina and is not generally present in transplant patients due to denervation. Without angina, patients who are ischemic tend to present with heart failure symptoms or arrhythmias instead. Exercise intolerance or a blunted response to exercise is a trademark feature after transplantation related to efferent denervation since the recipient is now reliant upon circulating catecholamines for chronotropic effect. The heart is slow to increase the heart rate in response to exercise and also slow to recover postexercise as these levels decline. The baroreceptor reflex is not intact in these patients either due to sympathetic and parasympathetic denervation, which leads to a more sensitive orthostatic response and absent effect of carotid sinus massage. Reinnervation is a phenomenon that tends to arise with time as is evident by a lower resting heart rate and the presence of angina in some patients, but it is not a predictable event as to who, when, or how much (Pham et al., 2011).

Post-transplant Management and Challenges

Immunosuppression

The immunosuppression regimen consists of multiple drugs with many pharmacologic interactions and side effects, but this regimen lays the groundwork for successful outcomes and prevention of rejection in transplant recipients. The early regimen tends to have the highest intensity since rejection risk is the greatest in the early posttransplant period, and maintenance therapy tends to require lower doses as this risk declines with time in the majority of patients. An appropriate regimen will vary for the individual patient based upon the crossmatch, extent of sensitization (or pre- and posttransplant antibodies), and comorbidities in order to balance preventing rejection with avoiding complications associated with chronic overimmunosuppression such as infection and malignancy.

Induction

Approximately half of transplant centers use induction therapy as an adjuvant treatment in the postoperative management of a transplant recipient due to the risk of early rejection (Lund et al., 2015); immunologic mechanisms in this early stage include the concern that donor antigen expression is triggered by donor brain death, ischemia and reperfusion, and the trauma of surgery (Lindenfeld et al., 2004a). Induction allows delay of calcineurin antagonists in the setting of acute or worsening chronic kidney disease during the early postoperative period. Induction therapy includes T cell cytolytic agents such as polyclonal antithymocyte antibodies derived from rabbits (thymoglobulin) or horses (ATGAM) and the monoclonal antibody OKT3 derived from mice; these agents result in marked depletion of T lymphocytes. Interleukin-2 (IL-2) antagonists, such as basiliximab and daclizumab, inhibit proliferation and differentiation of T cells activated through the IL-2 pathway. The decision to induce any patient must take into consideration the infectious/malignancy risk versus rejection risk of these agents leading many centers to treat patients based upon the individual risk profile rather than inducing all transplant patients. Studies have shown varying results in terms of infectious risk with the choice of induction agent but similar efficacy in preventing rejection that requires treatment in small comparison studies of ATG and daclizumab (Carlsen et al., 2005; Mullen et al., 2014).

Maintenance regimen

Maintenance regimens usually consist of triple therapy in the early transplantation period (calcineurin inhibitor, antimetabolite, and corticosteroids), and usually reduce to two drugs if possible as corticosteroids are gradually withdrawn. The transplant physician must be familiar with the numerous drug interactions and toxicities of an immunosuppressive regimen. The multiple targets of the various agents in a combination drug regimen are detailed in **Fig. 5**.

Corticosteroids

Corticosteroids inhibit cytokine production and lymphocyte proliferation (T and B cells, monocytes, granulocytes, and macrophages), and are part of the maintenance immunosuppression regimen during the first year of transplantation when rejection risk tends to be the highest. Steroids are also used for the treatment of acute and/or chronic cellular and humoral rejection (Lindenfeld et al., 2004b). Doses tend to be high initially and are tapered during the early posttransplant period with discontinuation in approximately 50% of patients during the first year based on their rejection history. Chronic use is avoided as much as possible due to the considerable side effect profile of corticosteroids, which includes poor wound healing, tremors, hypertension, depression/anxiety, skin fragility, weight gain, osteoporosis, cataracts, peptic ulcer disease, infectious risk, and myopathy. Adverse metabolic effects include hyperglycemia, fluid retention, salt retention, osteopenia, and hyperlipidemia. Adrenal insufficiency will develop in some patients on chronic steroid treatment.

Calcineurin inhibitors

Calcineurin inhibitors (CNI), cyclosporine and tacrolimus, inhibit calcineurin activation by binding this protein, and therefore hinder transcription of IL-2 and several cytokines. These drugs represent the foundation of immunosuppressive therapy since the beginning of cyclosporine use in the 1980s due to a significant increase in survival. Comparison studies of both drugs have provided some evidence that although survival is similar with both CNI, less rejection is associated with tacrolimus, which has led to its greater utilization in maintenance regimens (Kobashigawa et al., 2006a; Grimm et al., 2006; Ye et al., 2009), Kobashigawa et al. found a significantly lower occurrence of grade 3A or higher rejection in both groups treated with tacrolimus and an improved side effect profile with lower median serum triglycerides and creatinine in the tacrolimus/mycophenolate mofetil group (groups were tacrolimus plus mycophenolate or sirolimus and cyclosporine plus mycophenolate) (Kobashigawa et al., 2006a). Likewise, in a meta-analysis of seven randomized controlled trials ($n = 885$), similar survival and less rejection for tacrolimus versus cyclosporine microemulsion was confirmed along with a different side effect profile; a lesser extent of hypertension and dyslipidemia was found with tacrolimus but a higher rate of new onset diabetes (Ye et al., 2009). Nephrotoxicity is associated with both drugs.

Antimetabolite agents

Mycophenolate mofetil (MMF) has replaced azathioprine as the favored antimetabolite agent in the maintenance of immunosuppression regimens. Both drugs inhibit T and B lymphocyte proliferation by inhibiting DNA replication. The primary difference is that MMF is more selective in its action on de novo purine synthesis and, consequently, does not have the degree of bone marrow suppression noted with azathioprine. The latter acts upon both de novo and salvage pathways targeting all cell lines as opposed to

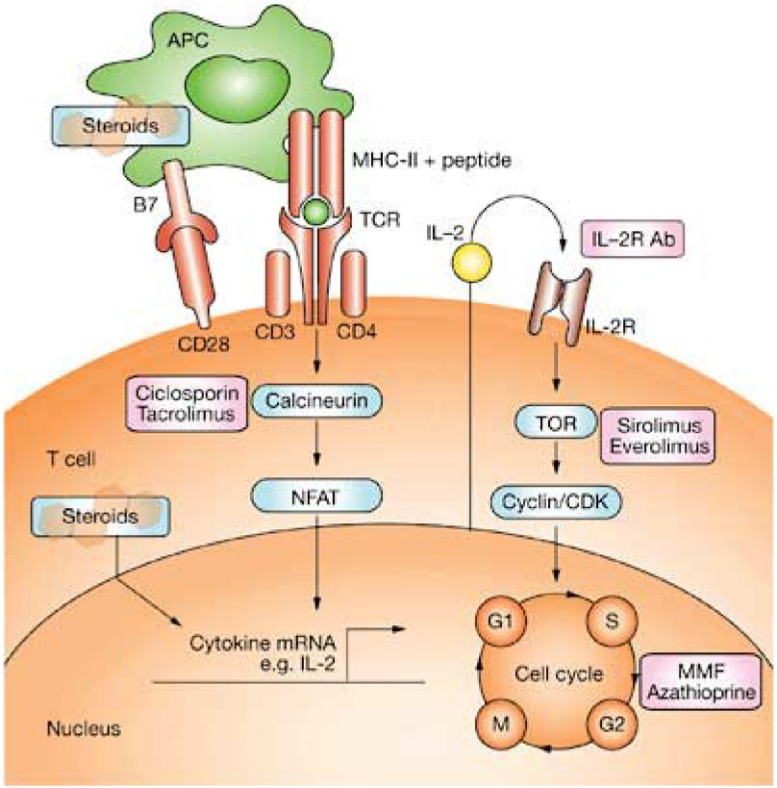

Fig. 5 Sites of action of immunosuppressive drugs. Presentation of donor antigen to antigen-presenting cells results in immunologic response, T-cell proliferation. This mechanism results in activation of calcineurin, which leads to production of interleukin-2 and subsequent cell proliferation. Immunosuppressive drugs *(in pink boxes)* exert their effects at a number of different targets to prevent T-cell proliferation. G1 (first growth phase), S (synthesis of DNA), G2 (second growth phase), and M (cell division) represent the phases of the cell cycle (Adapted with permission from reference Grimm, M., Rinaldi, M., Yonan, N. A. et al. (2006). Superior prevention of acute rejection by tacrolimus vs. cyclosporine in heart transplant recipients—A large European trial. *American Journal of Transplantation* **6**, 1387–1397. © (2001) American Society of Transplantation). *APC*, antigen-presenting cell; *CDK*, cyclin-dependent kinase; *IL-2*, interleukin-2; *IL-2R*, interleukin-2 receptor; *IL-2R Ab*, interleukin-2-receptor antibody; *MHC*, major histocompatibility complex; *MMF*, mycophenolate mofetil; *mRNA*, messenger RNA; *NFAT*, nuclear factor of activated T cells; *TCR*, T-cell receptor; *TOR*, target of rapamycin protein (Reprinted from Kobashigawa, J. lymphocytes only (Lindenfeld et al., 2004b). Comparison of MMF to azathioprine in cardiac transplant patients revealed an improved late survival using an MMF regimen in a randomized trial and ISHLT/UNOS registry data (Eisen et al., 2005; Hosenpud and Bennett, 2001). Adverse effects of MMF are primarily gastrointestinal with nausea, vomiting, diarrhea, and tend to be dose responsive; mycophenolate sodium (MPS) is an enteric-coated, delayed release formulation with less gastrointestinal upset and therefore fewer dose reductions along with a similar efficacy in maintenance regimens (Lehmkuhl et al., 2008; Kobashigawa et al., 2006b. Fewer dose reductions with MPS were associated with a higher average daily dose of MPS (88.4% MPS vs. 79.0% MMF of the recommended dose, $P = 0.016$) and a significantly lower rate of biopsy proven and treated rejection grade $\geq$3A (23.4% MPS vs. 44.0% MMF, $P = 0.032$) (Segovia et al., 2008).

Proliferation signal inhibitors

The mammalian target of rapamycin (mTOR) inhibitors, sirolimus and everolimus, has been gaining in use after cardiac transplantation and several clinical trials have demonstrated their efficacy. These drugs prevent T and B lymphocyte proliferation in addition to smooth muscle and endothelial cell proliferation in response to growth factors (Lindenfeld et al., 2004b). The latter clarifies advantages of these drugs in potentially preventing transplant coronary allograft vasculopathy (CAV) and possibly tumor regression. Both drugs have been associated with a lower incidence of CAV and rejection when compared with azathioprine (Keogh et al., 2004; Eisen et al., 2003). Combination therapy with CNI can aggravate CNI-related nephrotoxicity, but evidence suggests that reduced CNI levels plus earlier initiation of mTOR inhibitors preserve renal function without the loss of immunosuppressive protection (Gonzalez-Vilchez et al., 2014). Major side effects include hypertriglyceridemia, bone marrow suppression, diarrhea, capillary leak, poor wound healing, pneumonitis, and aphthous ulcers; the side effect profile of these agents often limit tolerance and result in withdrawal of treatment.

Rejection

Management of immunosuppression has shifted through the years with initial introduction of calcineurin inhibitors followed by mycophenolate mofetil replacing azathioprine and now tacrolimus as the leading CNI. Acute rejection is more common early after transplant with the risk subsequently declining over time. Hyperacute rejection occurs within hours of transplantation, but is unusual since it is related to ABO incompatibility. Cellular- and antibody-mediated rejection presents as acute or chronic occurring alone or in a mixed scenario. Acute cellular rejection (ACR) is T cell mediated and the most common form of rejection occurring within the first year posttransplant. Diffuse inflammation, myocyte injury, hemorrhage, and/or necrosis are graded according to the ISHLT grading scale (**Table 5**) (Stewart et al., 2005). Acute antibody-mediated rejection (AMR) is B cell related with immunopathologic findings of antibody deposition in the vasculature (arteriolar vasculitis) and complement activation, histopathologic findings of endothelial swelling and interstitial edema, and clinical features of hemodynamic compromise and allograft dysfunction (**Table 6**).

Symptoms

Symptoms of rejection are nonspecific or even clinically silent in earlier stages, often not apparent until rejection has progressed to an advanced stage. Patients present with heart failure signs, symptoms, or hypotension; exam findings could include volume overload or S_3 gallop. They may have vague symptoms of fatigue, cough, or a low-grade fever. Atrial arrhythmias or new pericardial effusions have also been a presenting sign.

Diagnosis

Given the absence of symptoms in early rejection, surveillance endomyocardial biopsies and right heart catheterization are performed in the routine management of heart transplant recipients in order to diagnose rejection before it has reached more advanced stages. **Tables 5** and **6** review the grading system for diagnosis of ACR and AMR, and **Figs. 6** and **7** are examples of biopsies with moderate to severe rejection. Endomyocardial biopsies (EMB) are performed preferentially through the right internal jugular vein followed by the femoral vein via inserting a bioptome into the right ventricle to obtain a few samples of endomyocardium. Centers perform EMB with echocardiography or fluoroscopy to identify the appropriate location and avoid complications of sampling the tricuspid valve apparatus or the free wall. A less invasive test using a blood sample is now in use, Allomap, which detects cellular rejection based on gene expression in peripheral blood mononuclear cells in the stable patient at low risk of rejection (Pham et al., 2010). Benefits included significantly fewer biopsies reducing the risk of biopsy-related complications such as tricuspid regurgitation, arrhythmias, and perforation. More recent data suggests that score variability may be used to predict probability that an event will occur (Crespo-Leiro et al., 2015). Routine surveillance with EMB in stable patients without a clear indication of heart failure symptoms or allograft dysfunction has been shown to have a low yield beyond 6 months posttransplant with the majority of episodes being mild and not requiring treatment (Orrego et al., 2012); therefore, noninvasive testing represents an advancement in this discipline. A novel 13-point risk score was developed and validated from the UNOS database between 1998 and 2008 ($n = 14{,}265$). The primary outcome was drug-treated rejection within 1 year of transplantation; four variables were associated with a strong correlation between observed and predicted rejection rates in the validation cohort ($r^2 = 0.96$, $P < 0.001$): younger age, female sex, race (Asian < white, black, Hispanic, and other), and degree of human leukocyte antigen (HLA) mismatching (4–6 antigen mismatches) (Kilic et al., 2012b).

Table 5 International Society for Heart and Lung Transplantation grading system for acute cellular rejection

2004 revised		*1990*	
Grade 0R	No rejection	Grade 0	No rejection
Grade 1R, mild	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage	Grade 1, mild	Focal perivascular and/or interstitial infiltrate without myocyte damage
		A—focal	
		B—diffuse	Diffuse infiltrate without myocyte damage
Grade 2R, moderate	2 or more foci of infiltrate with associated myocyte damage	Grade 2, moderate (Focal)	One focus of infiltrate with associated myocyte damage
		Grade 3, moderate	
		A—focal	Multifocal infiltrate with myocyte damage
Grade 3R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ±hemorrhage ± vasculitis	B—diffuse	Diffuse infiltrate with myocyte damage
		Grade 4, severe	Diffuse, polymorphous infiltrate with extensive myocyte damage ± edema, ±hemorrhage + vasculitis

Table 6 International Society for Heart and Lung Transplantation Grading System for Pathologic Diagnosis of Acute Antibody Mediated Rejection (AMR).

- pAMR 0—negative for pathologic AMR: histopathologic and immunopathologic studies are both negative.
- pAMR 1 (H+)—histopathologic AMR alone: histopathologic findings present and immunopathologic findings negative.
- pAMR 1 (I+)—immunopathologic AMR alone: histopathologic findings negative and immunopathologic findings positive (CD68+ and/or C4d+ for immunohistochemical staining and C4d+ with or without C3d+ for immunofluorescence staining).
- pAMR 2—pathologic AMR: histopathologic and immunopathologic findings are both present.
- pAMR 3—severe pathologic AMR: interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, findings of dying cells (pyknosis, karyorrhexis), marked edema, and immunopathologic findings are present.

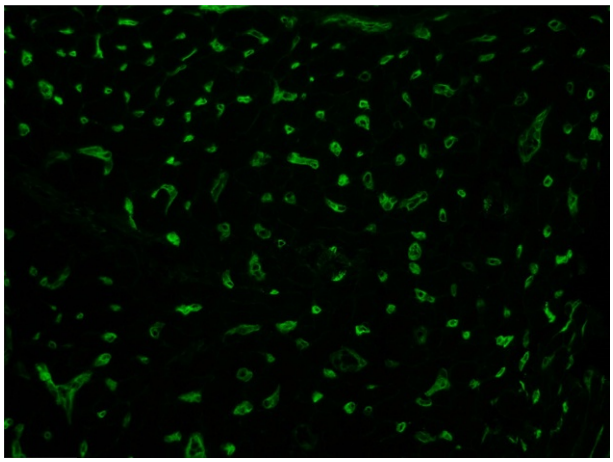

Fig. 7 Antibody-mediated rejection in a heart transplant recipient. Risk factors were younger age, female gender, and noncompliance with medication regimen. The patient was treated multiple times for rejection with subsequent graft dysfunction and chronic AMR despite aggressive therapy. Diffusely positive C4d staining in the capillaries appears as a "donut" appearance on this immunofluorescence sample. Courtesy of Ohio State University Wexner Medical Center.

Treatment

Therapy is based on clinical presentation, hemodynamic compromise on RHC and/or imaging, and histologic grade of the biopsy. Low-grade rejection in an asymptomatic patient is typically not treated. In scenarios of graft dysfunction or hemodynamic deterioration, treatment of ACR includes pulse and oral steroids, augmentation of oral immunosuppression (CNI, MMF, mTOR inhibitor), changing cyclosporine to tacrolimus, and the addition of antithymocyte antibody or cytolytic antibody.

AMR has historically been more challenging to treat than ACR and can lead to allograft dysfunction and cardiac vasculopathy (Nair et al., 2011). For this reason, treatment protocols are not standardized and will vary for transplant centers. Therapy focuses on the following four targets: suppression of T lymphocytes (ATG, CNI, MMF), inhibition of circulating antibodies (intravenous immunoglobulin or IVIG), elimination of circulating antibodies (apheresis), and suppression of B lymphocytes (rituximab) (Nair et al., 2011). Promising treatment includes proteasome inhibitors to deplete plasma cells, but limited data is available in cardiac transplantation. Although more difficult to treat than ACR and escalating immunosuppression does not always result in resolution, a combined approach seems best along with routine follow-up of anti-HLA antibodies. Chronic or refractory rejection, both cellular and humoral, can be further treated with total lymphoid radiation, or extracorporeal photopheresis, which requires central access. Other considerations include infection, such as cytomegalovirus, that can lead to rejection, and obtaining a detailed history to define the etiology of rejection since psychosocial factors, noncompliance, and changes in the patient's drug regimen resulting in lower drug levels could also play a role.

Complications

Primary graft dysfunction

A consensus statement from the ISHLT released in 2014 defined primary graft dysfunction within 24 h of completion of transplant surgery and involving the left and/or right ventricular function (Kobashigawa et al., 2014). It is not related to hyperacute rejection, pulmonary hypertension, or surgical complications, which would lead to secondary graft dysfunction; outcomes are usually death or retransplant associated with graft failure within the first 30 days after transplant. Recipient and donor risk factors contribute to primary graft dysfunction. Donor risk factors include cause of brain death, donor age, and female gender, while recipient risk factors include age, pulmonary hypertension (even within transplant acceptable criteria), and the more critically ill recipient (mechanical support, ventilation, inotrope) (Lund et al., 2015; Kobashigawa et al., 2014; Russo et al., 2010b). Surgical considerations are ischemic time, donor–recipient weight mismatch, and center volume with lower center volume associated with a higher rate of primary graft dysfunction. If graft function does not improve with supportive measures, retransplantation is an option although less likely due to multiorgan failure that may develop. In a UNOS database review from 1999 to 2007, Russo et al. found that 414 heart transplants were complicated by primary graft failure; of these, 85.5% died and 14.5% were retransplanted (Russo et al., 2010b).

Right ventricular dysfunction

Right ventricular (RV) dysfunction is common after cardiac transplantation, in as much as half of recipients, but acute, severe RV failure is high risk for early mortality (Bozbas et al., 2013). Pretransplant pulmonary hypertension increases the risk of peri- and postoperative RV dysfunction, explaining why high or fixed PVR is a contraindication to transplantation. When present, RV dysfunction is treated with inhaled vasodilators, such as nitric oxide or epoprostenol, and pulmonary afterload reduction with milrinone. Inotrope support of the RV with dobutamine or milrinone and volume control (diuretics, dialysis, ultrafiltration) are key management steps in this setting. Maintaining a higher heart rate also supports the RV. If RV dysfunction does not improve, worsening renal failure ensues contributing to a higher volume load on the transplanted heart.

Bradycardia

Posttransplantation, patients have a higher resting heart rate, usually around 110 bpm, which is related to denervation of the transplanted heart. A lower heart rate is considered “relative” bradycardia, which may be related to sinus node dysfunction, pretransplant negative chronotropic agents such as amiodarone, and possibly the type of anastomosis (Davies et al., 2010). Patients are dependent upon chronotropic response to maintain exercise tolerance, and in cases of chronotropic incompetence (or heart rates of 70 bpm), beta-agonists such as terbutaline could increase heart rate or, when persistent and symptomatic, a permanent pacemaker would be indicated.

Infection

Infection risk is greatest during the first year after transplantation due to the higher intensity immunosuppression regimen (Fishman, 2009, 2014). Risk assessment for a higher infectious risk involves critical illness entering transplantation, induction therapy, high dose corticosteroids, prior colonization with antimicrobial-resistant infections, graft dysfunction, early graft rejection, and technical complications such as prolonged intubation, surgical or urinary catheters, and wound infection. Early posttransplant infections tend to involve donor or recipient derived infection or are associated with surgical complications; therefore, they generally occur within the first month. These include nosocomial bacterial infections related to indwelling lines/catheters, pneumonia and wound infection with organisms such as *Staphylococcus*, *Pseudomonas*, *Proteus*, *Klebsiella*, *Escherichia coli*, and *Clostridium difficile* colitis (**Fig. 8**). Opportunistic infections usually occur later in the 1–6-month period after transplant arising from various sources: viral (cytomegalovirus, CMV), fungal (aspergillus, candida), and parasites (toxoplasmosis, pneumocystis). After 6 months, community-acquired infections are more common since immunosuppression tends to be less intense than initial regimens. Antiviral (CMV, herpes simplex virus) and pneumocystis carini prophylaxis are standard protocol in transplant centers; antifungal prophylaxis is not standardized and varies per center.

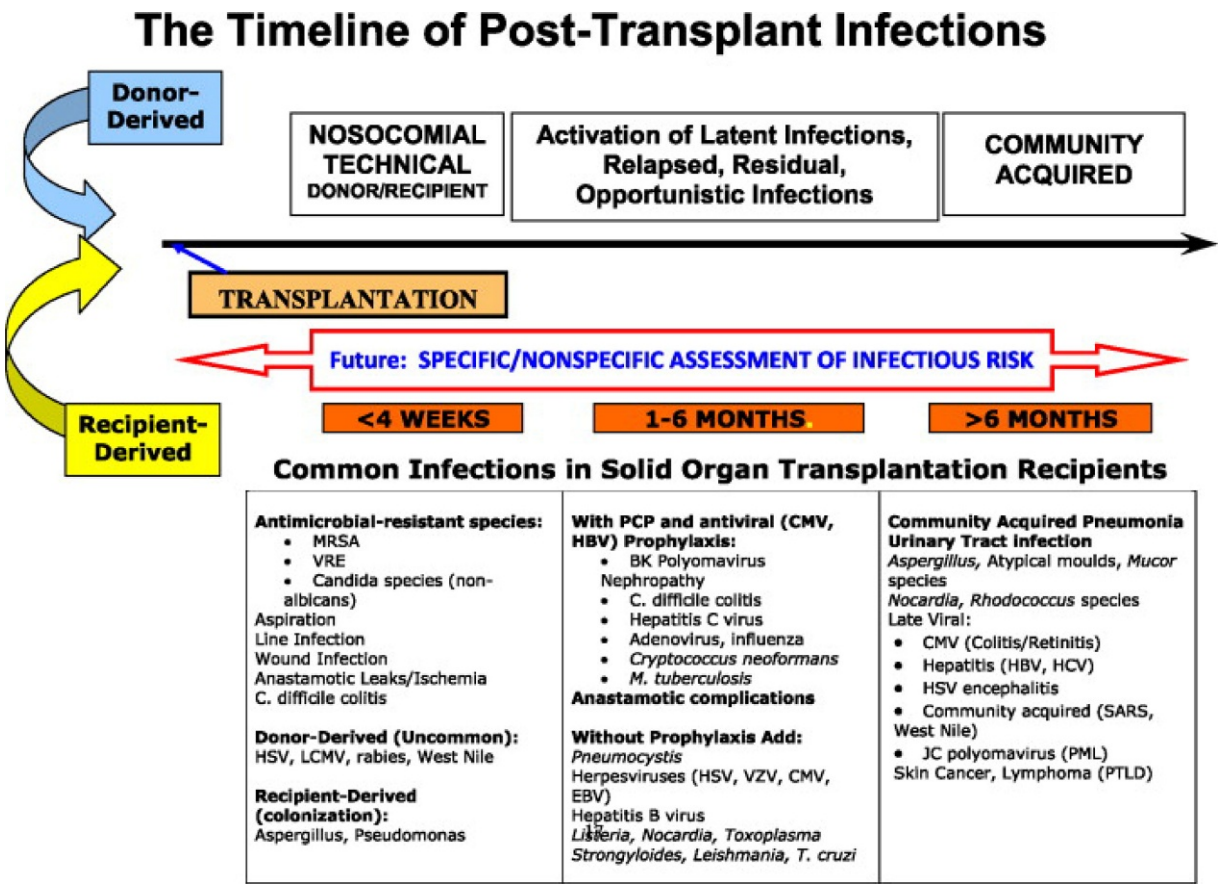

Fig. 8 Common infections in solid organ transplant recipients. Reprinted from Fishman, J. A. (2014). From the classic concepts to modern practice. *Clinical Microbiology and Infection***20**, 4–9. Copyright 2014, with permission from John Wiley and Sons

Malignancy

Malignancy is a common cause of late death ranging from 20% to 24% for patients beyond 3–10 years posttransplantation (**Fig. 9**) (Lund et al., 2015). Risk is related to the intensity and duration of chronic immunosuppression leading to decreased immune surveillance for cancer and activation of oncogenic viruses such as Epstein-Barr virus (EBV in posttransplant lymphoproliferative disorder, PTLD), human herpes virus 8 (HHV-8 in Kaposi's sarcoma), and human papilloma virus (HPV in anogenital cancer). The most common de novo posttransplant malignancy is skin cancer followed by lymphoproliferative disorders, PTLD. Squamous and basal cell cancers occur at a much higher rate in the solid organ transplant population and in younger patients, at many sites, and are also more aggressive than in the general population (Ajithkumar et al., 2007). Melanoma risk is greater but not as excessive as other skin cancers; the risk of Kaposi's sarcoma is increased tremendously. PTLD is the most common noncutaneous malignancy and most cases are related to EBV reactivation or primary infection. Breast, lung, prostate, bladder, and colon cancers also occur in transplant recipients, although evidence varies in terms of additional incidence in these patients, but may present more aggressively due to immunosuppression.

Multiple factors contribute to the development of malignancy in these patients including disruption of DNA repair mechanisms related to the immunosuppressive regimen and upregulation of angiogenic growth factors (**Fig. 10**) (Nair et al., 2014). Nair et al. suggest an algorithm that involves risk factor modification, cancer surveillance, modification of immunosuppression doses after diagnosis of malignancy, and nonimmune therapies (Nair et al., 2014). Prevention is key which follows current recommendations for cancer screening with mammograms, papanicolaou testing and gynecologic examinations, colonoscopy, dermatology examination, and prostate-specific antigen. Emphasis is placed on minimizing and protecting against sun exposure, smoking cessation, and antiviral prophylaxis in the early posttransplant period. If malignancy develops, immunosuppression is reduced, especially in the case of PTLD, with the goal of maintaining a balance of adequate immunosupression; MMF or CNI might be replaced with sirolimus which may have antiproliferative properties. The pleiotropic benefits of statins could play a role in reducing cancer-free survival posttransplant, but needs further clinical trial evaluation (Fro¨hlich et al., 2012). Additionally, future research could focus on malignancy prevention strategies such as biomarkers for tolerance prediction, memory B cell reduction, and naive B cell repopulation.

Comorbidities

Hypertension

Hypertension is prevalent in transplant patients and for the most part related to CNI therapy, with tacrolimus resulting in less hypertension than cyclosporine in a meta-analysis by Yu et al. of seven randomized controlled trials (Ye et al., 2009) Yu. The majority of patients will be hypertensive requiring multiple drugs in an antihypertensive regimen for control. Transplant patients have higher ambulatory BP including clinic, mean 24-h, mean daytime, and mean nighttime systolic/diastolic BP along with increased 24-h heart rate and decreased heart rate variability (Kotsis et al., 2005). There is also a reduced decline in nocturnal BP noted posttransplantation. Hypertension is a risk factor for other posttransplant complications such as renal failure and coronary vasculopathy. Beta-blockers are usually avoided in the early posttransplant course due to the recipient's denervation and dependence on circulating catecholamines for chronotropic response; symptoms of fatigue may be more pronounced if taking beta-blockers. Commonly used drug regimens for treatment include angiotensin-converting enzyme inhibitors or angiotensin receptor blockers based on renal dysfunction or hyperkalemia, calcium channel blockers such as amlodipine or diltiazem (which will increase CNI levels), thiazide diuretics, hydralazine, and nitrates.

Hyperlipidemia

Dyslipidemia is largely related to drug-induced side effects after transplantation, particularly from corticosteroids, CNI, and proliferation signal inhibitors. Development of hyperlipidemia contributes to CAV, peripheral vascular disease, and cerebrovascular disease. Statins, or HMG-CoA reductase inhibitors, are effective in reducing the lipid profile and have pleiotropic effects that extend the benefit beyond cholesterol lowering. These include promotion of apoptosis, inhibition of angiogenesis, downregulation of circulating cytokines, plaque stabilization, inhibition of smooth muscle cell proliferation, and improved endothelial function (Luo et al., 2014; Vallakati et al., 2016). Rhabdomyolysis is a risk of use in patients due to a drug interaction with CNI therapy, although it is likely lower with pravastatin since it is not metabolized by cytochrome enzymes like the other statins. Risk of rhabdomyolysis increases with higher statin doses or addition of other agents such as fibrates or niacin. There is also a potential immunomodulator role of statins due to an association with lower rejection in heart transplant recipients, and have been associated with a better long-term survival compared with patients who were not on statins (Luo et al., 2014; Vallakati et al., 2016; Som et al., 2014). A review of seven randomized controlled trials of statins in cardiac transplants ($n = 353$) confirmed a modest survival benefit of statins, low incidence of adverse effects but no difference in rejection episodes (Marchetti, 2004). In a larger meta-analysis of 2295 patients, pooled data also suggested improved survival with statin use but also decreased fatal rejection episodes, terminal cancer, and the incidence of coronary vasculopathy (Vallakati et al., 2016).

Diabetes mellitus

Diabetes is very common posttransplantation with approximately one-third of patients affected by 5 years (Marchetti, 2004). Many factors contribute to the development of diabetes: age, obesity, pretransplant diabetes, ethnicity, family history, and drug-induced side effects from corticosteroids and CNI drugs (tacrolimus more than cyclosporine). Diabetes has a negative impact on survival, renal function, and CAV risk, been associated with reduced long-term survival, and is associated with comorbidities such as CAV and renal dysfunction. A guideline consensus statement was developed for renal, liver, and heart transplantation to reduce individuals' risk of developing new onset diabetes and improve long-term associated complications from diabetes; guidelines include recommendations on screening, managing risk factors, and adjusting contributing immunosuppressive drugs (Wilkinson et al., 2005).

Renal failure

Renal dysfunction is a common posttransplantation complication and is associated with poor outcomes (Thomas et al., 2012). Risk factors for development include older recipient age, female gender, diabetes, temporary dialysis or hemofiltration perioperatively, and impaired renal function pretransplant or early posttransplant. The risk of death is higher for recipients with CKD stage 4, CKD stage 5, or those on dialysis when compared with CKD stage 3 or lower. In a series of renal biopsies performed in renal failure postcardiac transplantation, a diverse range of histopathologic findings were noted with multiple patient-specific factors contributing to CKD: acute kidney injury from hypotension, vasoconstrictor use and cardiopulmonary bypass, hypertensive and diabetic nephropathy, ischemic disease, and nephrotoxic medications, including CNI with vasoconstrictor effects (Pinney et al., 2012). In addition, CNI-induce vasoconstriction appears to worsen renal function when these underlying factors or intrinsic renal disease are present, rather than CNI being the sole etiology. Prevention involves managing comorbidities such as hypertension and diabetes along with nephrology involvement early. Renal sparing immunosuppression regimens are also initiated in these patients and include reducing CNI dose or converting from CNI to sirolimus/everolimus maintenance therapy alone or in combination with lower dose CNI (Arora et al., 2012; Zuckerman et al., 2012; Potena et al., 2012). Success of this conversion to proliferation signal inhibitors is earlier utilization since the presence of proteinuria seems to limit any benefit from this change in maintenance regimens (Pinney et al., 2012; Potena et al., 2012). Sirolimus is associated with a higher discontinuation rate due to the side effect profile and more episodes of acute rejection (Zuckerman et al., 2012). Other preventive measures include close surveillance of renal function and risk factors posttransplantation and minimizing nephrotoxic insults as much as possible.

Coronary vasculopathy

Coronary allograft vasculopathy is present in one-third of transplant recipients at 5 years posttransplantation and remains a major comorbidity limiting long-term survival after transplantation (**Fig. 9**) (Lund et al., 2015). Similar to surveillance biopsies, surveillance coronary angiography is performed routinely to detect development since patients do not present with typical angina symptoms due to denervation status. Symptoms might develop in some individuals over time if reinnervation is present, but most will have acute heart failure symptoms, arrhythmias, myocardial infarction, or sudden death (Pham et al., 2011).

Vasculopathy does not resemble native coronary artery disease (CAD) and has unique features that contribute to a difficult diagnosis with angiography. Involved areas are diffuse rather than focal and have less lipid and calcium deposition in the plaque when compared with CAD in nontransplant patients. CAV is a proliferative process consisting of diffuse intimal hyperplasia of the entire of length of the vessel, which can include the epicardial vessels and their branches and the microvasculature with intramyocardial arteries, arterioles, and capillaries (Vecchiati et al., 2014). "Distal pruning" is noted in the distal, smaller caliber epicardial vessels but intervention is not an option due to the size (**Fig. 11**). The concentric nature of involvement along the entire vessel often leads to underestimation of luminal narrowing and disease burden.

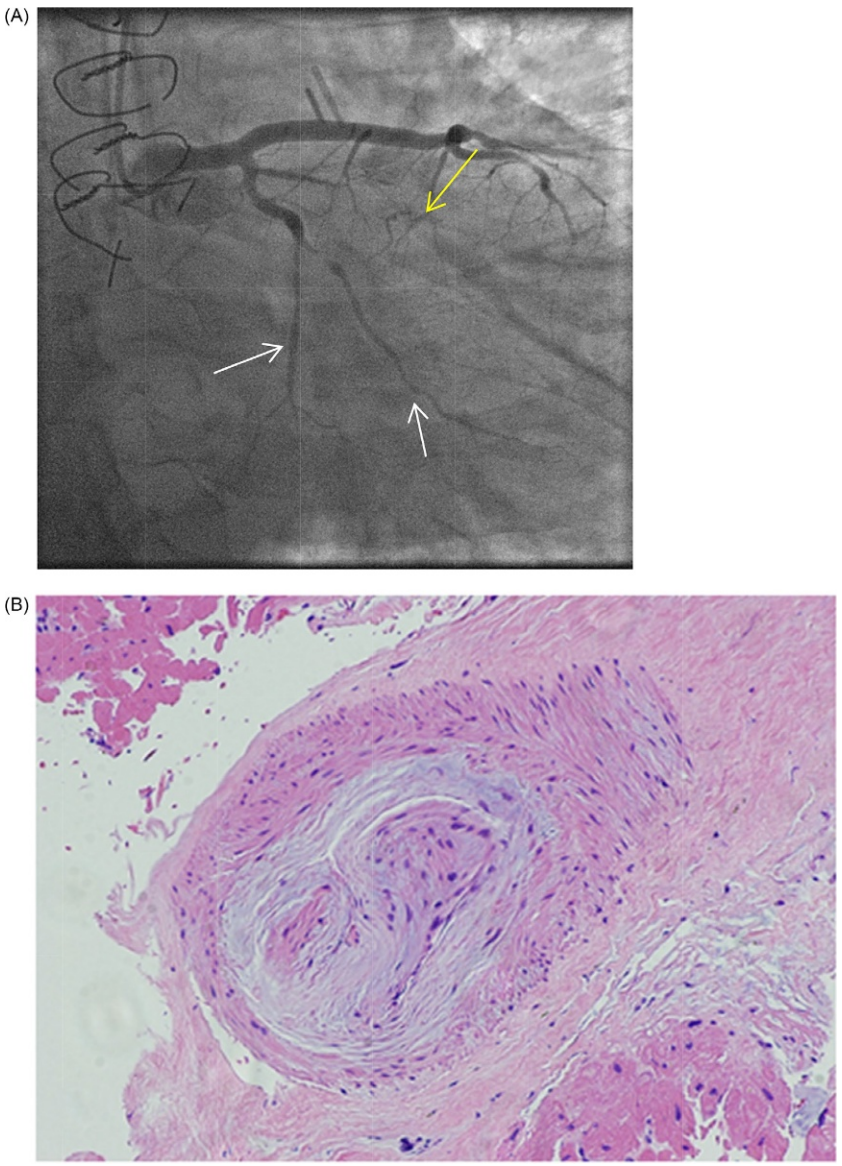

Fig. 11 Extensive coronary allograft vasculopathy (A) in large and distal vessels in a patient with recurrent cellular rejection and history of CMV. Arrows (*yellow*): total obliteration of the mid and distal left anterior descending artery. Arrows (*white*): severe transplant vasculopathy in the left circumflex and obtuse marginal branches. Pathology sample of coronary artery vasculopathy (B) demonstrating diffuse concentric intimal thickening. Courtesy of Ohio State University Wexner Medical Center.

Endothelial dysfunction is an early marker of CAV; evidence suggests both immunologic and nonimmunologic mechanisms contribute to endothelial damage and the subsequent inflammatory response (Vecchiati et al., 2014; Lim et al., 2016). The following immunologic mechanisms lead to a chronic immune response: (a) alloimmune injury from the degree of HLA antigen compatibility, (b) non-HLA allo- and auto-antibodies (or alloreactive T and humoral cells), and (c) dysregulation of the nitric oxide pathway leading to endothelial vasodilator dysfunction. The ensuing inflammatory response activates proliferation of smooth muscle cells and mononuclear infiltrate. Nonimmunologic factors are older donor age, longer ischemia–reperfusion time, CMV infection, and traditional risk factors such as hyperlipidemia and diabetes. In a single-center study, postoperative renal replacement therapy was also associated with CAV (Lim et al., 2016). Arteriosclerosis in CAV can result in de novo lesions but also remodeling of preexisting lesions in the donor heart. An important feature of CAV is intraplaque hemorrhages as a result of endothelial damage that may cause rapid increase of stenosis and generate a substrate for plaque destabilization (Angelini et al., 2014). Histopathology of CAV divides lesions into different phenotypes (inflammatory, smooth muscle, and fibrotic) that could be related to time after transplantation, age at transplantation, infection history, and the amount of atherosclerotic disease (Hulbers et al., 2014).

Routine angiography is an important screening tool for the detection of CAV, but other imaging modalities have added detailed assessment due to the challenging nature of CAV identification as mentioned earlier. Modalities include invasive, intracoronary imaging such as intravascular ultrasound (IVUS) and optical coherence tomography (OCT), and noninvasive imaging, such as dobutamine stress echocardiogram and coronary-computed tomography (Kobashigawa et al., 2005; Khandar et al., 2013; Sade et al., 2008; Wever-Pinzon et al., 2014). IVUS has been the gold standard and measures coronary intimal thickening, which has been associated with poor outcomes. Patients with intimal thickening on IVUS within the first year after transplantation had a higher incidence of death, graft loss, nonfatal major cardiac events, and angiographic CAV after 5 years (**Fig. 12**) (Kobashigawa et al., 2005). IVUS is limited due to low spatial resolution and cannot detect more subtle changes in intimal thickness. A newer intravascular imaging technology with higher spatial resolution has emerged with OCT, which allows for a more detailed evaluation of intimal thickness and characterization of atherosclerotic plaque having been shown to be very accurate when compared with histology (Khandar et al., 2013). Long-term outcome data correlating findings with cardiac events is limited since it is a newer technique. Noninvasive alternatives to coronary angiography utilize dobutamine stress echocardiography with a moderate sensitivity and specificity and a favorable meta-analysis of coronary-computed tomography angiography (Sade et al., 2008; Wever-Pinzon et al., 2014).

Prevention of CAV is key; management should focus on surgical factors such as reducing ischemic time and recipient factors to prevent recurrent rejection and infection, and modify traditional risk factors (hypertension, diabetes, smoking, and hyperlipidemia). Pharmacologic management utilizes traditional treatment with aspirin prophylaxis and statins, but also focuses on the immunosuppression regimen and inflammatory response. Early conversion to a PSI regimen may be more effective in preventing CAV progression as noted in three trials: a sirolimus-based regimen within the first 2 years and everolimus within the first year posttransplant (Matsuo et al., 2013; Masetti et al., 2013; Kobashigawa et al., 2013). Conversely, a recent prospective trial compared long-term outcomes in 126 patients receiving sirolimus + low-dose tacrolimus versus full-dose tacrolimus + MMF and found no significant difference between the two strategies in terms of survival, renal function, and CAV over the 8-year follow-up (Guethoff et al., 2015). In addition to lipid lowering, the pleiotropic benefits of high dose statins (antiinflammatory properties, inhibition of

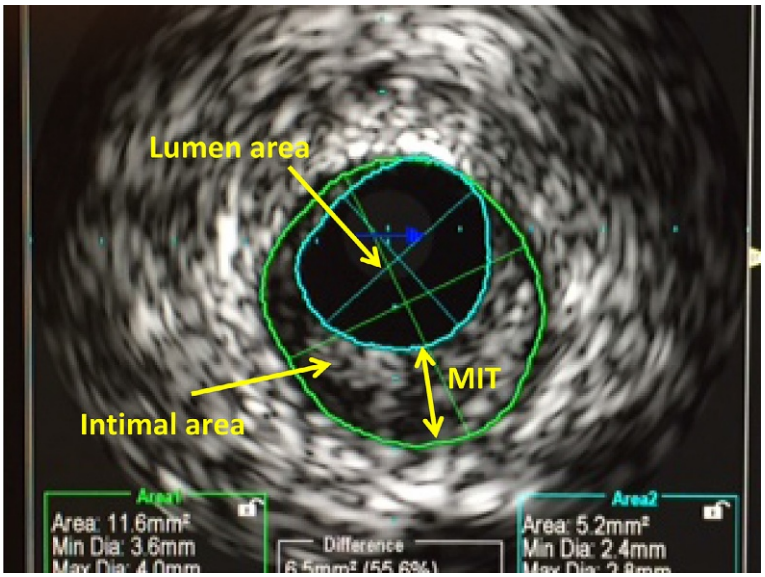

Fig. 12 Example of IVUS of mid LAD posttransplantation in a patient who present with anterior ST elevation. Example of intimal thickening on intravascular imaging with MIT. Courtesy of Ohio State University Wexner Medical Center.

smooth muscle cell proliferation, and improved endothelial function) have been associated with reduced early and late CAV progression (Masetti et al., 2013).

The ISHLT established the following classification system for defining the extent of CAV: (a) CAV_0, no detectable angiographic lesion, (b) CAV_1, mild, (c) CAV_2, moderate, (d) and CAV_3, severe, which are based on the degree of stenosis, number of vessels, and which vessels are involved (left main, primary vessel or branch vessel) (Mehra et al., 2010). This grading system was shown to have prognostic significance in a retrospective study assessing CAV at 1-year posttransplant and predicted major adverse cardiac events (death, acute coronary syndrome, coronary revascularization, heart failure admission unrelated to an acute rejection episode, and cardiac retransplantation) (Prada-Delgado et al., 2012).

Revascularization poses many challenges starting with lack of symptoms for many patients and whether to attempt revascularization. Limited outcome data exists and an appropriate choice of treatment is still questionable. Coronary artery bypass grafting in CAV has been associated with poor outcomes, which is not unexpected due to the nature of CAV with less proximal and mid-vessel stenosis and suboptimal distal anastomotic targets (Halle et al., 1995). In-stent restenosis with percutaneous coronary intervention is higher when compared with nontransplant patients (Bader et al., 2006). Database review of drug-eluting stents in six studies of CAV found a reduction in in-stent restenosis at 12 months when compared with bare metal stents, but there was no significant difference in mortality or major adverse cardiac events (Dasari et al., 2011). Further clinical trial data is needed to assess an outcome benefit of drug-eluting stents beyond the reduction in in-stent restenosis. Therefore, with the limited evidence on revascularization in this patient population, retransplantation is the definitive answer for severe CAV; candidacy is often restricted by comorbidities.

Osteoporosis

Osteoporosis and fragility fractures are a serious complication usually occurring in the first year after solid organ transplantation. Exposure to high doses of corticosteroids and CNI may contribute to rapid bone loss (Kulak et al., 2014). Other contributing factors to bone loss are immobilization and pretransplant risk factors including chronic disease. Bone density assessment is part of the pretransplant evaluation. Prevention should include combination therapy with calcium supplementation, vitamin D, and bisphosphonates in addition to weight-baring exercises.

Psychosocial factors

Psychosocial and behavioral factors have been shown to predict long-term survival after heart transplantation and are an important criteria for patient selection. In a quality of life assessment of more than 500 patients, Farmer et al. found that higher levels of social and economic satisfaction and education level predicted improved survival while poor compliance and higher NYHA class were associated with a worse survival (Farmer et al., 2013). Education level and socioeconomic status have a role in posttransplantation outcomes. In a large modern cohort of heart transplant recipients, patients with Medicare and Medicaid had a reduced long-term survival when compared to those with private insurance or self-pay; the survival difference was evident at 1-year and increased with time (Allen et al., 2012). In multivariable analysis, Medicare and Medicaid increased mortality risk by 18% and 33%, respectively ($P \leq 0.001$). Similar results were noted for college education with an 11% reduction in mortality risk and an absolute increase of 7% for 10-year survival. Older patients (≥ 60 years) have also reported more satisfaction with quality of life, social support, psychosocial adjustment, and adherence when compared with younger (<45 years) and middle-aged patients (between 45 and 59 years), suggesting they are better adjusted after cardiac transplantation (Shamaskin et al., 2012). Psychosocial factors have a major impact on transplant survival due to the required frequent follow-up by specialized health care professionals and management of a complicated medication regimen and comorbidities.

Survival

In the 32nd ISHLT adult and pediatric heart transplant report, 1- and 5-year survival are 82% and 69%, respectively, with a median survival of 11 years for all and 13 years for those surviving the first year (Lund et al., 2015). Survival has improved with successive eras, but the most recent cohort of 2009–13 shows improvement in the 1-year unadjusted survival at 86% in this most recent era as compared with 84% in the 2002–08 era ($p < 0.05$) (**Fig. 13**). Leading causes of death are related to graft failure, infection, and multiorgan failure. Cause of death varies with the duration after transplant. Earlier death tends to result from graft failure and infection while long-term mortality is more commonly from malignancy, cardiac allograft vasculopathy, and renal failure. The most common posttransplant morbidities are diabetes, hypertension, hyperlipidemia, and renal dysfunction. Functional status returns to normal activity levels in 90% but the percentage of patients returning work remains less than 50% at 1- and 3-year follow-up. In multivariable analysis, the most important continuous risk factors for 1-year mortality are donor age, recipient age, and recipient pretransplant creatinine. The number of older recipients >60 years is increasing, and age is a risk factor for mortality at all follow-up points according to the most recent ISHLT report with a focus theme on age (Lund et al., 2015).

Factors associated with long-term survival are age younger than 55 years, annual center volume of 9 or more transplants, younger donor age, and shorter ischemic time; each 1 h reduction in ischemic time improved the odds of 10-year survival by 11% ($p < 0.001$) (Kilic et al., 2012c). Similar improvement in survival was associated with each decade decrease in donor age. Mechanical ventilation and diabetes decreased the probability of long-term survival. A risk stratification tool, IMPACT (Index for Mortality Prediction After Cardiac Transplantation) using UNOS data, has been introduced and validated as a predictor of short-term and long-term mortality, and has potential as a prognostic aid in appropriate patient selection for transplant (Kilic et al., 2013). The score assigns points to

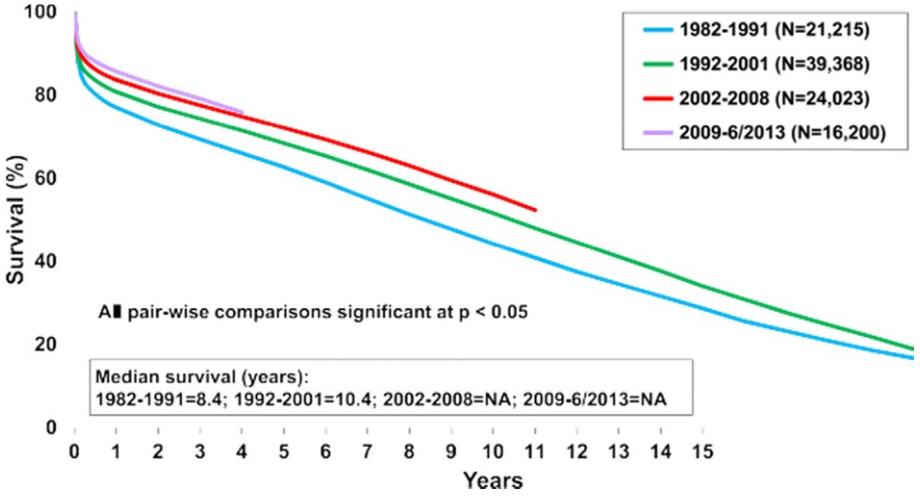

Fig. 13 Improvement in long-term survival in adult heart transplant recipients as documented by era. Reprinted from Lund, L. H., Edwards, L. B., Kucheryavaya, A. Y. et al. (2015). The registry of the International Society for Heart and Lung Transplantation: Thirty-second official adult heart transplantation report—2015; focus theme: Early graft failure. *The Journal of Heart and Lung Transplantation* **34** (10), 1244–1254. various pretransplant clinical features, such as age >60 years, bilirubin, creatinine clearance, dialysis before transplant, recent infection, female gender, type of ventricular assist device, and race.

Despite the overall improvement in posttransplant survival in the current area, racial outcome differences still persist. Racial differences in several studies have shown a persistently elevated mortality among black recipients and attribute the documented higher rate of graft loss in this patient population to a higher risk profile, immune-related mechanisms, differential drug absorption, and systemic complications of therapy (Liu et al., 2011; Singh et al., 2011). Racial differences also exist among waitlist outcomes in the United States; both black and Hispanic patients were more likely to be listed as an urgent status (1A/1B) when compared with white patients (Singh et al., 2012). Listed Hispanic patients are at a higher risk of dying on the waitlist or becoming too ill for a transplant in comparison with white patients while black patients have a similar waitlist mortality but a higher early posttransplant mortality. Further research is necessary to identify mechanisms for outcome differences among minorities and improve these disparities.

Retransplantation

Survival after retransplantation is overall very poor; the best results are associated with CAV as the indication. Other indications are associated with poor survival with acute rejection associated with the lowest survival (32% and 8% at 1 and 5 years, respectively) followed by early graft failure (50% and 39% at 1 and 5 years, respectively) (Radovancevic et al., 2003). Nevertheless, retransplantation is limited by patient comorbidities and graft failure.

Risk factors associated with a high risk of 1-year graft failure rates in patients who underwent retransplantation are older recipient age, increasing serum creatinine, and mechanical ventilation. The effect of multiple risk factors is cumulative as patients with all three factors had a 32% higher risk of graft failure within 5 years as compared with patients with no risk factors. Each decade increase in recipient age was associated with a 20% increase in 1-year graft failure and each 1-mg/dL increase in serum creatinine increased the risk of graft failure by 58% (Kilic et al., 2012d).

Conclusion

In summary, cardiac transplantation is the preferred treatment for end-stage heart failure in select patients with improved survival and quality of life in the current era due to multiple advances in the field. Bridging patients with mechanical support continues to increase and has improved outcomes, including reduced waitlist mortality if patients do not have a VAD-related complication. Enhancement of immunosuppression regimens has reduced acute allograft rejection episodes, and donor procurement and surgical techniques have contributed to improved donor function. Posttransplant care continues to utilize complex medical regimens with multiple drug interactions. Pre- and posttransplant comorbidities affect quality of life and survival with medical survival of 10 and 13 years for those surviving the first year. Early complications of graft failure and infection affect survival while later development of malignancy, renal failure, vasculopathy, and rejection reduce long-term survival. Investigative focus has been in the direction of risk-stratifying patient selection, expanding the donor pool, and further optimizing immunosuppression to prevent posttransplant complications. Continued advances in cardiac transplantation will lead to enhancement of patient management, long-term outcomes, and racial disparities.

Introduction

The liver is the largest gland in the body constituting 2% of total body weight. It is a highly vascular organ that receives 25% of the cardiac output with a dual blood flow system via the hepatic artery (~20%) and hepatic portal vein (~80%) (Bacon, 2012). It is responsible for multiple critical functions, including blood filtration, metabolism of carbohydrates, proteins, fats, hormones and foreign chemicals, biliary formation, storage of vitamins and iron, protein synthesis, and formation of coagulation factors.

The Centers for Disease Control and Prevention list chronic liver disease as the twelfth leading cause of mortality in 2014 in the United States with a mortality rate that has increased from 9.4% to 12% over the past decade (Kowalski and Abelmann, 1953). Chronic liver failure can result in cirrhosis, which is characterized by late-stage progressive hepatic fibrosis, architectural distortion, and formation of regenerative nodules (Bacon, 2012). The most common causes of cirrhosis are alcohol-related liver disease, chronic hepatitis C virus, chronic hepatitis B virus, and nonalcoholic fatty liver disease. Due to its diversity in function, it is not surprising that the complications of cirrhosis can adversely multiple organ systems, including neurological (e.g., hepatic encephalopathy), gastrointestinal (e.g., portal hypertension and varices), hematologic abnormalities (e.g., portal vein thrombosis), and cardiovascular (e.g., cirrhotic cardiomyopathy).

The physiologies of the heart and liver are closely intertwined. Liver dysfunction can result in cardiovascular pathology. Cardiac dysfunction can lead to hepatopathy. And there are diseases that simultaneously affect both heart and liver. The goal of this review is to help the reader better understand the challenges of diagnosing and managing this diverse group of patients.

Clinical Effects of Liver Dysfunction on the Cardiovascular System

Numerous studies over the last half century have documented the detrimental effect of liver dysfunction on the cardiovascular system due to a hyperdynamic circulatory state (Kowalski and Abelmann, 1953). "Cirrhotic cardiomyopathy" was a term coined back in 1980s to describe chronic cardiac dysfunction with normal to increased cardiac output and contractility at rest but a suboptimal response to pharmacological or physiological stress (Baik et al., 2007; Moller and Henriksen, 2010; Zardi et al., 2010). Cardiovascular imaging usually demonstrates normal or hyperdynamic left ventricular (LV) ejection fraction at rest, LV dilatation, reduced peak systolic velocity, and diastolic dysfunction (Kowalsky and Abelmann, 2003). Diastolic dysfunction affects approximately 50% of the patients (Alexopoulou et al., 2012). Echocardiography demonstrates impaired ventricular relaxation (reduction in early (E) and late (A) phases of trans-mitral ventricular filling) (Bernardi et al., 1998). Underlying mechanisms include myocardial hypertrophy, interstitial fibrosis, and subendothelial edema through activation of the renin–angiotensin–aldosterone system (Patel and Mehta, 2012). It has been hypothesized that other mechanical factors, such as poor intrathoracic compliance and the physical pressure of hepatomegaly, can cause diaphragmatic displacement and worsen underlying diastolic dysfunction.

Contributing to the phenotype of cirrhotic cardiomyopathy are a multitude of electrophysiologic abnormalities including chronotropic incompetence and prolonged QT interval. Chronotropic incompetence, defined as the lack of heart rate response to stress, is seen in 50%–80% of patients with cirrhosis and limits exercise capacity. The inability to reach target heart rate during physiologic or pharmacologic stress makes it difficult to assess for ischemia. Severity of cirrhosis and degree of portal hypertension are proportionally associated with chronotropic incompetence (Bernardi et al., 2012). Underlying mechanisms will be discussed in the next section of this review.

QT prolongation is seen on the electrocardiograms of more than 50% of patients with cirrhosis (Bernardi et al., 2012; Lazzeri et al., 1997). The exact mechanism behind QT prolongation in liver cirrhosis is not well understood; however, studies have implicated increased sympathetic tone along with cardiotoxins such as endotoxins and cytokines to be major contributing factors (Mohamed et al., 1996; Carey and Douglas, 2005). Trevisaniet al. demonstrated increased QT prolongation after transjugular intrahepatic portosystemic shunt procedure in cirrhotic patients suggesting increased venous return after portosystemic shunt as a putative mechanical mechanism (Chaudhry et al., 1999). The clinical significance of QT prolongation in cirrhotic patients remains indeterminate and controversial (Baik et al., 2007; Day et al., 1993; Bernardi et al., 1998). Studies of cirrhotic patients using an adjusted Child–Turcotte–Pugh score demonstrated that while the QTc interval prolongation was common in cirrhotic patients, its presence had no independent effect on mortality or risk of SCD. However other studies showed lower survival rate in cirrhotic patients with QT prolongation that was not attributable to sudden cardiac death or torsade de pointes which occur rarely in this population (Kim et al., 2017). Several studies show that prolonged QTc significantly improves in most patients after liver transplantation (Adigun et al., 2005; Mohamed et al., 1996; Carey and Douglas, 2005) and that improvement in the QT interval may be associated with improved survival after transplant (Mohamed et al., 1996).

Autonomic dysfunction appears to be present in approximately 50% of cirrhotic patients regardless of etiology (Chaudhry et al., 1999). Although it is usually asymptomatic, its presence correlates with increased mortality and morbidity before, during, and after liver transplantation due to hemodynamic instability in the setting of any stressful event. These patients have depressed heart rate variation with predominantly parasympathetic dysfunction and seemingly intact sympathetic function (Chaudhry et al., 1999; Milovanovic et al., 2009). Prevalence and severity of autonomic dysfunction are related to severity of liver dysfunction (Chaudhry et al., 1999; Milovanovic et al., 2009). One study has shown that autonomic dysfunction manifesting as parasympathetic impairment and sympathetic predominance is associated with risk for sudden cardiac death and ventricular arrhythmias (Milovanovic et al., 2009). Autonomic dysfunction regresses after liver transplantation in 63%–70% of patients. The improvement seen after liver transplantation suggests that the neuropathy is metabolically, neurohormonally, and/or hemodynamically mediated as opposed to structural damage of the parasympathetic system (Carey et al., 2008).

Liver dysfunction has direct effects on cardiovascular hemodynamics which in turn affect multiple organ systems making cirrhotic cardiomyopathy a challenging syndrome to treat and manage. Guidelines for the management of cirrhotic cardiomyopathy are similar to noncirrhotic patients with heart failure and include normalizing the preload and restoring the effective circulating volume using sodium restriction and diuretics, use of supplemental oxygen, afterload reduction, and noncardio-selective beta-blockers (Starr and Raines, 2011; Runyon and Committee, 2009). Due to the significant regenerative capacity of the liver, efforts to treat the underlying cause of liver dysfunction, for example alcohol abstinence, result in improvement in liver function (Pares et al., 1986; Veldt et al., 2002). Further highlighting the causality and reversibility of these disease states are reports of cirrhotic cardiomyopathy fully resolving after orthotopic liver transplantation (Milani et al., 2007; Cosardereliogluet al., 2016; Huffman et al., 2010).

Cardiovascular Molecular Mechanisms Affected by Chronic Liver Disease

The dysregulation of several molecular mechanisms, including adrenergic receptors, channelopathies, nitric oxide, carbon monoxide, endocannabinoids, and retinoids, has been described in cirrhotic cardiomyopathy. Both detrimental and beneficial effects on cardiac function through these mechanisms have been described in the literature.

The dynamic interaction between stimulatory β-adrenergic receptors and inhibitory muscarinic receptors plays an important role in the normal maintenance of heart rate and cardiac contractility. Cirrhotic patients have a blunted chronotropic and inotropic response in part due to decreased β-adrenergic receptor density (Battarbee et al., 1990; Ma et al., 1994; Gerbes et al., 1986; Lee et al., 1990), and in part attributed to receptor dysfunction. Impaired biliary clearance is known to be directly involved in decreased plasma membrane fluidity. The cardiomyocyte membranes of bile duct ligated rats with liver cirrhosis had increased cholesterol-to-phospholipid ratio causing decreased membrane fluidity, reduced cyclic adenosine monophosphate (cAMP) production, and suboptimal response to β-adrenergic stimulation (**Fig. 1**) (Ma et al., 1994; Gazawi et al., 2000). The role of various muscarinic acetylcholine receptor subtypes in cirrhotic cardiomyopathy has yet to be clearly defined. Of the five known muscarinic acetylcholine receptors, M2 and M3 are expressed in cardiac myocytes with greater density in the atria compared to ventricles (**Fig. 1**). Rodent models of cirrhosis have demonstrated blunted muscarinic responsiveness via a postreceptor effect (Jaue et al., 1997).

Nitric oxide is a vasodilator synthesized by vascular endothelium and cardiac myocytes. There are three different isoforms of nitric oxide namely, neuronal nitric oxide synthase (nNOS), endothelial nitric oxide synthase (eNOS), and inducible nitric oxide synthase (iNOS). iNOS has a cardiotoxic effect via negative chronotropic effect and induction of apoptosis, while the former two are cardioprotective (Zardi et al., 2010; Kim et al., 1999). Animal models have shown elevated iNOS mRNA expression in cirrhotic patients likely due to transient bacteremia and ongoing inflammatory process (Liu et al., 2000). Blocking nonspecific nitric oxide

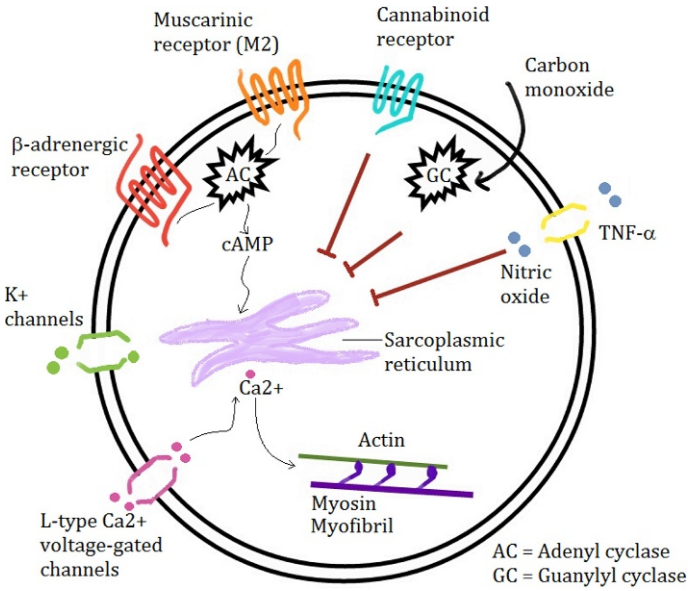

Fig. 1 Diagram of the various molecular mechanisms known to be involved in the pathophysiology of cardiovascular disease due to liver disease.

synthase improves cardiac contractility further supporting roles for nitric oxide synthases in cirrhotic cardiomyopathy (Herring et al., 2002; Han et al., 1995).

Carbon monoxide is produced via enzymatic action of heme oxygenase and primarily acts as a physiological vasodilator in splanchnic circulation. Bile duct ligated cirrhotic rats have increased carbon monoxide activity secondary to increased transcriptional activity. Carbon monoxide may result in negative inotropic effect via activation of cyclic guanosine monophosphate (Liu et al., 2001).

Animal models have implicated increased endocannabinoids activity in cirrhotic rats as a cause of decreased ventricular contractility. Studies have demonstrated that endocannabinoids, including anandamide and 2-arachidonoylglycerol, may result in decreased myocyte contractility via G-protein-coupled receptor pathway involving cannabinoid receptor type 1. Activation of this pathway causes inhibition of adenylate cyclase activity and reduction in intracellular calcium concentration (**Fig. 1**). Endocannabinoids also induce splanchnic vasodilatation. Cardiac contractility in the cirrhotic rats is restored with introduction of endocannabinoid/CB1 receptor blockade (Batkai et al., 2007).

Retinoids play an important role in cellular physiologic processes including cellular proliferation, differentiation, and apoptosis. Studies have shown that approximately 66%–75% of dietary retinoid is stored as retinyl esters in the liver (Li et al., 2014; Harrison, 2012). Liver retinoid levels vary among individuals in alcoholic liver disease (Bell et al., 1989). Murine models have demonstrated that cirrhotic mice with depleted hepatic retinoid stores while maintaining effective circulating Vitamin A levels are protected from cardiac injury and have increased ventricular gene expression and progenitor cells. The authors speculated that subclinical liver disease with depleted hepatic retinoid stores might have a cardioprotective benefit (Asson-Batres et al., 2016).

The numerous functions of the liver that are absolutely necessary for daily life make its study challenging. Treatment for the cardiovascular complications of cirrhosis remains limited by our incomplete knowledge about the underlying mechanisms. That disease reversal or regression is seen after liver transplantation suggests the possibility that a better understanding of these mechanisms may result in the development treatment options other than liver transplantation.

Clinical Effects of the Cardiovascular System on the Liver

Acute Cardiogenic Liver Injury

Acute cardiogenic liver injury, also known as hypoxic or ischemic hepatitis, is a condition where diminished cardiac output fails to meet the metabolic demands of hepatic cells in patients with underlying diagnosis of heart failure. The clinical features of ischemic hepatitis include right-upper quadrant abdominal pain, hepatomegaly, elevated serum bilirubin, significant transaminitis (ranging up to 10 × the upper limit of normal), and elevated lactate dehydrogenase levels (up to 10–20 × the upper limit of normal) (Seeto et al., 2000; Waseem and Chen, 2016). Early and rapid increase in LDH with ratio of alanine aminotransferase (ALT) to LDH < 1.5 is characteristic of cardiogenic cause of liver injury (Samsky et al., 2013).

The liver is a highly vascular organ, which can compensate for decrease in cardiac output by releasing adenosine which causes dilation of the hepatic vasculature and increased blood flow. The hepatic sinusoids are highly permeable permitting increased oxygen diffusion to the hepatocytes with oxygen extraction levels reaching close to 90%. However, this process is impaired in patients with venous congestion from heart failure. When these patients experience acute hemodynamic instability, it results in

impaired perfusion with hepatic insult (Waseem and Chen, 2016; Birrer et al., 2007; Henrion et al., 1994). Studies have demonstrated that profound hypotension by itself is not enough to precipitate ischemic hepatitis and suggest that the presence of hepatic congestion is a major contributing factor (Seeto et al., 2000).

Recommended treatments are directed toward optimizing circulation with the use of inotropes. Some studies have demonstrated benefit with the use of dopamine in patients with normotensive cardiogenic shock and acute kidney injury, and use of dobutamine in patients with reduced cardiac index (Kram et al., 1988; Naschitz and Yeshurun, 1987). Decongestion and maintenance of euvolemia may be preventative, though that is purely conjectural and not yet studied. The prognosis of ischemic hepatitis remains poor with in-hospital mortality rate exceeding greater than 50% (Waseem and Chen, 2016).

Congestive hepatopathy

Congestive hepatopathy is a chronic form of ischemia characterized by passive hepatic congestion due to congestive heart failure. Patients with congestive hepatopathy are often asymptomatic. Physical exam findings early in the course of hepatic congestion include peripheral edema, hepatomegaly with hepatojugular reflux, and pulsatile liver. Late in the course of congestive hepatopathy, physical exam findings are essentially those of end-stage liver disease such as ascites and jaundice. Chronic passive hepatic congestion can cause hepatic sinusoidal dilation, sinusoidal hypertension, and eventually lead to progressive hepatocyte atrophy and centrilobular fibrosis with development of portal hypertension and cirrhosis. Laboratory findings are notable for cholestatic pattern of injury with mild to moderate increase in serum γ-glutamyl transferase (GGT), alkaline phosphatase, and bilirubin levels. Elevations in GGT and alkaline phosphatase independently portend a poor prognostic outcome (Poelzl et al., 2012). The degree of injury is proportional to the severity of heart failure and valvular dysfunction such as tricuspid regurgitation.

As mentioned above, congestive hepatopathy can lead to cirrhosis if left untreated. Prevention and management of congestive hepatopathy is geared toward both treatment of the underlying cause of the heart failure and normalization of intracardiac filling pressures with diuresis. It has been observed that successful decongestion can result in significant liver recovery, which also supports the possibility that maintaining euvolemia may prevent the development of congestive hepatopathy. Patients with congestive hepatopathy (but not cirrhosis) who are status post cardiac transplantation demonstrate sustained improvement in biochemical liver function tests and 10-year long-term survival as shown by standard model for end-stage liver disease (MELD) scores (Dichtl et al., 2005; Chokshi et al., 2012).

Fontan liver disease

The Fontan operation is a palliative procedure for congenital heart disease patients who are born with either functional or anatomic single ventricle physiology. The procedure involves connecting central venous return (superior vena cava and inferior vena cava) directly to the pulmonary arteries and creating a functionally single pump system. Postoperative 15–20-year survival rate after Fontan procedure ranges from 60% to 85% with patients frequently requiring revision surgery or consideration of heart transplantation. The physiologic changes in the circulatory system post-Fontan include chronically reduced cardiac output (i.e. heart failure) and elevated hepatic venous pressure in the setting of high central venous pressure (Rychik and Gui-Yang, 2002; Kiesewetter et al., 2007). Hence, post-Fontan patients are a classic example of chronic congestive hepatopathy with liver cirrhosis, developing in the majority of patients by about eleven to fifteen years post-Fontan (Baek et al., 2010).

Patients post-Fontan are usually clinically asymptomatic during the first five years but demonstrate abnormalities during laboratory screening or radiological study (Baek et al., 2010). Consistent with the natural history of congestive hepatopathy, studies demonstrate a recurring pattern of hepatic injury with chronic congestion and tissue hypoxia. CT scan is notable for zonal or reticular enhancement, i.e., peripheral diffuse patchy enhancement. Reticular enhancement signifies extensive hepatic fibrosis. Liver biopsies are notable for sinusoidal dilation with variable and nonuniform fibrosis (Ford et al., 2015).

A growing number of patient status post Fontan are reaching adulthood and developing both failing Fontan and liver cirrhosis. These patients are difficult to assess because use of morbidity and mortality predictor scores such as the MELD score and Child–Turcotte–Pugh is confounded by cardiac ascites, use of diuretics, presence of cardiorenal syndrome, unreliable INR interpretation in the setting of vitamin K antagonist use, and impaired albumin assessment due to malnutrition and protein losing enteropathy (Carey and Douglas, 2005). Often the only treatment option is combined heart and liver transplantation, which is both high risk and limited as an option due to availability of organs (Ford et al., 2015).

Diseases that Affect Both the Liver and the Heart

Infections

Hepatitis C

While the most common manifestation of hepatitis C Virus (HCV) infection is in the form of a chronic hepatitis, HCV infection also has direct and indirect effects on the cardiovascular system. PCR studies have demonstrated that HCV can infect cardiomyocytes resulting in an acute myocarditis which can then progress to a chronic cardiomyopathy (Matsumori et al., 1998; Frustaci et al., 2002; Okabe et al., 1997). Both dilated and hypertrophic cardiomyopathies have been described in patients with HCV infection (Matsumori et al., 1995; Teragaki et al., 2003). There is strong evidence for genetic susceptibility to development of cardiomyopathy

in the presence of HCV infection. Specific HLA alleles are more prevalent in HCV-infected patients who develop dilated cardiomyopathy while other HLA alleles are more prevalent in those who develop hypertrophic cardiomyopathy (Matsumori, 2005; Naruse and Inoko, 2000). Myocyte damage is believed to be caused by several mechanisms. HCV infection is known to induce the expression of the cytokine TNF-α which is well described in the literature as a key mediator in the development and progression of myocarditis by causing myocyte depression, impaired β-adrenergic response (Matsumori, 2005; Sanchez and Bergasa, 2008). The HCV core protein can directly damage the myocardium (Omura et al., 2005). Transgenic mice for the HCV-core gene develop cardiomyopathies with significant histopathological findings (Omura et al., 2005). Another hypothesized mechanism is the activation of the immune response by anti-HCV antibodies causing myocyte injury. Supporting this hypothesis is a report that treatment with immunosuppressives of patients found to have HCV myocarditis with B cell infiltrates and anti-HCV antibodies resulted in normalization of cardiac chamber size and function (Frustaci et al., 2002).

Various studies have demonstrated that HCV infection is associated with a higher prevalence of insulin resistance and diabetes (Younossi et al., 2016; Macaluso et al., 2013; Petta et al., 2013; Chang, 2016; Lonardo et al., 2014). Studies show a causal effect—that the virus is able to alter lipid metabolism and insulin signaling and eradication of the virus reverses these metabolic abnormalities (Younossi et al., 2016; Macaluso et al., 2013; Pavone et al., 2016). Multiple studies also show a correlation between active HCV infection and the presence and severity of atherosclerosis in the carotids and coronary arteries (Ishizaka et al., 2003; Targher et al., 2007; Alyan et al., 2008; Yelken et al., 2009; Butt et al., 2009). Although there are other reports that found no association, meta-analyses performed for each of these conditions suggest that the presence of active HCV infection conveys significantly higher risk for cerebrovascular events and myocardial infarction even after adjusting for risk factors such as smoking and diabetes (Petta et al., 2016). How much of an effect the metabolic abnormalities invoked by HCV infection (visceral obesity, insulin resistance, diabetes mellitus) has on promoting atherosclerosis versus direct effects of the virus itself is unknown as there is evidence for both possibilities (Ishizaka et al., 2003).

Whether treatment of HCV infection is beneficial in reversing or halting its associated cardiovascular disease states remains unknown, but there is accumulating evidence that viral eradication may be beneficial. Case reports suggest that treatment resulting in viral clearance may result in myocardial recovery in patients with HCV-related myocarditis or cardiomyopathy (Matsumori et al., 1998; Okabe et al., 1997). One small study demonstrated improvement of myocardial perfusion defects in HCV-infected patients with myocarditis after treatment with interferon therapy (Matsumori et al., 1995). A recent retrospective study of interferon-free-based anti-HCV treatment regimen provides evidence that treatment may reverse HCV-related cardiomyopathy (Yelken et al., 2009). A community-based study of HCV subjects reported increased mortality due to cardiovascular disease in subjects with active HCV infection compared with uninfected subjects, but no increased risk in those subjects who were HCV-cleared (Lee et al., 2012). An observational study reported risk of lethal cerebrovascular events to be directly proportional to viral load (Lee et al., 2010). Cohort studies looking at treatment with interferon demonstrated significant reduction in acute coronary syndrome, cerebrovascular events, and end-stage renal disease (Hsu et al., 2013, 2014). Historically treatment of HCV has been limited in patients with cardiovascular disease as the physiological stress reaction induced by interferon treatment was reported to result in cardiomyopathy (Zhao et al., 2014; Martin et al., 2014). In recent years the development of interferon-free, anti-HCV viral regimens with minimal adverse events that are highly effective in viral eradication may offer new treatment opportunities for this group of patients.

Human immunodeficiency virus

Human immunodeficiency virus (HIV) is a type of retroviral infection that affects and compromises the immune system of the affected patient. Chronic HIV infection can result in acquired immunodeficiency syndrome (AIDS) which is defined as having a CD4 cell count less than 200 cells/uL. HIV/AIDS affects and effects both hepatic and cardiac diseases.

That HIV/AIDS patients are at substantially higher risk (1.5–2.0-fold) of developing coronary artery disease has been known for many years. HIV/AIDS patients can also develop both myocarditis and a nonischemic cardiomyopathy. The reported prevalence of cardiomyopathy ranges from 15% to 38% in HIV/AIDS patients (De Castro et al., 1992; Longo-Mbenza et al., 1998; Sliwa et al., 2012). Other cardiac diseases for which HIV/AIDS patients are at higher risk of developing include aortitis from occlusion of the vasa vasorum, inflammation-related wall weakness and autoimmune mechanisms, pericardial effusion with or without pericarditis, pulmonary arterial hypertension, major conduction defects, prolongation of the QT interval, and atrial fibrillation (Manga et al., 2017).

The mechanisms by which HIV/AIDS affect the heart are controversial. The HIV population is known to have at baseline a higher prevalence of traditional coronary artery disease risk factors such as smoking, diabetes, dyslipidemia, central obesity, and hypertension (Vachiat et al., 2017). The immune dysfunction of HIV is associated with ongoing inflammation, which is another known risk factor for the development of coronary artery disease. Treatment with combination antiretrovirals may not be effective because protease inhibitors are known to exacerbate dyslipidemia, endothelial dysfunction, and hypertension. It is thought that in HIV/AIDS-related myocarditis/cardiomyopathy direct HIV infection of the cardiomyocyte is the mechanism of disease. This is supported by studies demonstrating the presence of HIV virus intracellularly (Grody et al., 1990). This hypothesis is challenged by the lack of CD4 receptors in cardiomyocytes leading to the question of how the HIV virus could enter a cardiomyocyte. Other studies suggest that the immunocompromised state by HIV/AIDS results in a susceptibility and nonclearance of other viruses that are cardiotoxic (Shaboodien et al., 2013). The converse has also been suggested that HIV/AIDS infection renders cardiomyocytes more susceptible to the entry of cardiotropic viruses such as Epstein-Barr virus (Goldblum et al., 1990). Patients with HIV infection have increased levels of TNF-α and endothelin cytokines levels, resulting in indirect cardiotoxic effect. As already described above with HCV infection, elevated TNF-α levels cause myocyte depression, impaired β-adrenergic response. In HIV infection elevated TNF-alpha levels in conjunction with high endothelin levels result in enhanced catecholamine response, and LV hypertrophy

(Bloomfield and Leung, 2017; Lumsden and Bloomfield, 2016; Barbaro, 2005). The prevalence of myocarditis, nonischemic cardiomyopathy, and pericardial disease has decreased since the introduction of combination antiretroviral therapy (Bloomfield et al., 2015; Remick et al., 2014; Lind et al., 2011), suggesting viral and presence and load may play important mechanistic roles.

The liver can be both directly and indirectly affected by HIV/AIDS. Patients are often concomitantly infected with hepatitis B and hepatitis C and combined infection has been shown to increase their risk for developing cirrhosis and some of the cardiovascular diseases described above (Osibogun et al., 2017; Foca et al., 2016). Before the development of combination antiretroviral therapy, the most common cause of liver pathology was infection (Sonderup and Wainwright, 2017). Studies reported significant findings by biopsies of opportunistic infections such as mycobacterium avium complex which can precipitate hepatobiliary disease, tuberculosis, cytomegalovirus, schistosomiasis, histoplasmosis, and cryptococcosis (Sonderup and Wainwright, 2017).

Combined antiretroviral therapy has led to a decrease in opportunistic infections and, as a consequence, marked improvement in life expectancy for HIV infected patients. However as discussed above the treatments can exacerbate cardiac disease. They also significantly affect the liver with as many as 42% of patients showing evidence of drug-induced liver injury in one study (Sonderup and Wainwright, 2017). Antiretroviral agents can cause drug-induced liver injury via several mechanisms, including direct drug toxicity, hypersensitivity, mitochondrial toxicity, and immune related (Sonderup and Wainwright, 2017). Antiretroviral agents can also potentiate the hepatotoxic potential of other drugs, especially cardiac drugs. One common example of this are statins, which are the mainstay treatment regimen for hyperlipidemia treatment and frequently prescribed in this patient population due to the increased risk for coronary artery disease. Most of the statin medications are metabolized by cytochrome P450 3A4 (CYP 3A4). Antiretroviral medication class such as protease inhibitors downregulate the activity of CYP3A4 and can cause statin toxicity which can cause liver dysfunction and rhabdomyolysis (Dube et al., 2003).

Tropical diseases

Malaria, Q-Fever, and dengue are some of the tropical diseases known to cause cardiac and liver dysfunction via cytokine-mediated pathway (Herr et al., 2011; Malavige et al., 2004; Elgouhari and Huntington, 2016). Detailed discussion about these disease processes is beyond the scope of this chapter.

Infiltrative Diseases

Amyloidosis

Amyloidosis is a general term to describe a group of disorders with multiorgan system involvement because of extracellular tissue deposition of insoluble fibrillary proteins also called amyloid fibrils (Bejar et al., 2015). There are three different types of amyloidosis—AL, ATTR, and wild-type TTR. We will briefly review AL amyloidosis and discuss ATTR amyloidosis. Wild-type TTR amyloidosis will not be discussed as it is not known to significantly affect the liver.

AL amyloidosis is an aggressive form of amyloidosis caused by deposition of light-chain immunoglobulins in various tissues including kidney, soft tissue, liver, and heart due to an underlying plasma cell dyscrasia (Bejar et al., 2015). Clinical features of AL amyloidosis are variable and can include fatigue, weight loss, peripheral neuropathy, restrictive cardiomyopathy, hepatomegaly with elevated liver enzymes, macroglossia, purpura, and bleeding diathesis. Cardiac involvement is common in patients with AL amyloidosis and portends a poor prognosis. Amyloid deposition in the myocardium and microvasculature results in restrictive cardiomyopathy, cardiac arrhythmias, and heart failure (Falk et al., 2016). There are successful chemotherapeutic options for treatment of plasma cell dyscrasia, including melphalan with autologous hematopoietic stem cell transplantation or bortezomib-based chemotherapy (Zumbo et al., 2017). However, there are patients in whom cardiac involvement is so significant that they require heart transplantation prior to treatment for the plasma cell dyscrasia. In select patients at select centers this can be done with acceptable outcomes (Grogan et al., 2016).

ATTR amyloidosis is an autosomal dominant condition that is caused by the genetic mutation in the transthyretin (TTR) gene resulting in unstable TTR protein. Clinical manifestations of TTR amyloidosis depend on the protein mutation. For example, Val122Ile mutation is characterized by late amyloid cardiomyopathy characterized by progressive severe heart failure, Val30Met mutation results in lower extremity sensorimotor peripheral neuropathy. These patients typically present in 4th–6th decades of their life (Bejar et al., 2015; Galant et al., 2017). Orthotopic liver transplant can halt the disease in ATTR amyloidosis patients and can be performed with minimal risk and improve survival (Popescu and Dima, 2012). Unique to this group of patients is the domino liver transplant, a strategy where the explanted ATTR liver can be used as a living donor liver for other patients on the liver transplant waiting list, consequently not affecting the number of livers available as they are able to donate their own livers at the time of transplant (Bejar et al., 2015). Combined heart and liver transplantation is considered in select patients with severe heart disease. While additional data and registry information are essential to predict long-term success rate, an Italian study demonstrated promising results with 5-year survival rate of 82% among 14 patients who underwent combined orthotopic heart and liver transplantation (Careddu et al., 2015).

Hemochromatosis

Hemochromatosis is a syndrome characterized by excess of iron deposition leading to multiorgan disease including liver cirrhosis, diabetes, and cardiomyopathy. Primary or hereditary hemochromatosis is an autosomal recessive disorder with variable penetrance associated with *HFE* gene mutations on chromosome 6 encoding for human hemochromatosis protein. Mouse models have

demonstrated that human hemochromatosis protein is involved in iron homeostasis. Mutations in *HFE* gene result in increased gastrointestinal iron absorption, elevated plasma iron and transferrin saturation level, and iron overload in hepatocytes. Secondary hemochromatosis is a complication of another condition that results in chronic exposure to high levels of iron, such as chronic blood transfusions, long-term hemodialysis, or chronic liver disease. Cardiac iron deposition causes infiltrative cardiomyopathy, biventricular heart failure, and conduction abnormalities. Patients with hemochromatosis have a 14-fold increase in mortality due to heart disease (Bejar et al., 2015; Ripoll et al., 2011; Moller and Bernardi, 2013).

Wilson's Disease

Wilson's disease is an autosomal recessive disorder of copper metabolism characterized by excessive copper deposition in the liver, brain, heart, and other tissues. Cardiac manifestation of Wilson's disease includes arrhythmias, hypertrophic cardiomyopathy, and autonomic dysfunction (Factor et al., 1982; Kuan, 1987).

Autoimmune Diseases

Systemic Lupus Erythematosus

Systemic lupus erythematous (SLE) is an inflammatory disease with multiple immunologic abnormalities affecting multiple organs. Significant liver disease in patients with SLE is rare but reported hepatic manifestations include liver enzyme elevations and hepatomegaly. Hepatic complications as a result of antiphospholipid antibody syndrome include Budd–Chiari syndrome or veno-occlusive disease. Cardiac findings in patients with SLE include nonseptic pericarditis with or without effusion, verrucous (Libman–Sacks) endocarditis, coronary artery disease, and rare cases of myocarditis (Miner and Kim, 2014; Grover et al., 2014).

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder due to unclear etiology that is histopathologically characterized by noncaseating granulomas in the involved organs. While sarcoidosis typically affects young adults and pulmonary system, it can also involve other organ systems including liver (~15%) and heart (~2%–5%) (Baughman et al., 2001; Yigla et al., 2002). Most patients with hepatic sarcoidosis are asymptomatic with minimal laboratory abnormalities including elevated alkaline phosphatase and gamma glutamyltranspeptidase levels. However, there are case reports of sarcoidosis patients suffering from cholestatic liver disease, biliary strictures, obstructive jaundice, hepatic vein thrombosis and developing cirrhosis (Devaney et al., 1993; Efe et al., 2012). Clinical manifestations of cardiac sarcoidosis range from heart block to valvular dysfunction to life-threatening arrhythmias and cardiomyopathy.

Conclusion

The hepatic and cardiovascular organ systems are intimately linked. Liver disease can cause profoundly abnormal cardiovascular physiology resulting in cirrhotic cardiomyopathy, HPS, and hepatorenal syndrome. Chronic congestion from heart failure can result in hepatopathy, cirrhosis, and lower the threshold for the development of acute ischemic liver disease. That liver transplantation and decongestion reverse the aforementioned syndromes, respectively, warrants further investigation to better understand the pathophysiology behind cardiohepatic disease. Improved understanding of the underlying molecular mechanisms may help with the development of targeted therapies to improve clinical outcomes for patients with heart and liver dysfunction.

Introduction

Heart failure (HF) is a major and growing public health problem in the United States. Approximately 5 million patients in this country have HF and over 550,000 patients are diagnosed with HF for the first time each year (Mancini et al., 2009; Ansari and Massie, 2003). The number of HF deaths has increased steadily despite advances in treatment, in part, because of increasing numbers of patients with HF and better treatment of acute myocardial infarctions. Patients with HF commonly present with exercise intolerance, clinically manifested as shortness of breath and fatigue. The ability to perform individual tasks, particularly activities of daily living, is the leading determinant of prognosis. The New York Heart Association (NYHA) functional class is a subjective estimate of a patient's exercise ability and includes a subjective assessment, such as: "How many flights of stairs can you climb or how many blocks can you walk?" However, patients vary in their reporting and may inaccurately estimate their true functional capacity.

Cardiopulmonary exercise testing is a noninvasive test that grades the severity of exercise intolerance (American Thoracic Society and American College of Chest Physicians, 2003; Balady et al., 2010; Malhotra et al., 2016; Arena et al., 2007a). Studies have demonstrated that familiarization and fluctuations in motivation do not influence the results of the test. During CPX, oxygen consumption (VO_2), carbon dioxide elimination (VCO_2), and minute ventilation (Ve) are measured directly using a tight-fitting mask or nose clip, mouthpiece, and a metabolic cart. Performance of CPX follows the same absolute and relative contraindications to exercise testing established by the American College of Cardiology and American Heart Association (Fletcher et al., 2013). Unstable angina and ventricular arrhythmias and severe aortic stenosis are unequivocal reasons why an exercise test should not be performed until the patient is clinically stable. Generally, patients should abstain from ingesting caffeine for at least 12 h and/or eating for 3 h prior to CPX and should be dressed suited for exercise with comfortable clothes.

Peak VO_2

A peak VO_2 (maximal oxygen consumption) over 20 mL/kg/min is considered in the normal range in the average adult and suggests there is no serious cardiac, pulmonary, or neuromuscular pathology. There is a great deal of variability in test results depending on age and conditioning, and a trained athlete can reach a peak VO_2 as high as 80 mL/kg/min.

Peak VO_2 has proven to be a powerful prognosticator of survival in patients with HF (Mancini et al., 1991; Lund et al., 2005; Sue and Hansen, 1984), which is generally thought to represent a surrogate for maximal cardiac output and is used to identify high risk patients who would benefit from high priority listing and early transplantation. The American Heart Association/American College of Cardiology (AHA/ACC) guidelines on exercise testing recommend the CPX to distinguish between cardiac and pulmonary causes of unexplained exercise intolerance (Class I), evaluation of exercise capacity when a standard stress test is unreliable (IIa) and determination of intensity level for cardiac rehabilitation (IIb) (Sue and Hansen, 1984). The AHA/ACC (Mancini et al., 2009; Fletcher et al., 2013), European Society of Cardiology (ESC) (Swedberg et al., 2005), and the International Society for Heart and Lung Transplantation (ISHLT) guidelines (Mehra et al., 2006) recommend the use of peak VO_2 for heart transplant selection.

While there is no single parameter that qualifies a patient for transplant, those patients with peak VO_2 >14 mL/kg/min had a 1-year survival of 94% on optimal HF therapy, which was comparable to survival after transplant (Mancini et al., 1991). For such patients, listing for transplant is not indicated. Patients who were found to have a peak VO_2 of <14 mL/kg/min, however, had significantly lower survival rates, making listing for transplant appropriate. Based on these data, clinical use of CPX with a cutoff value for peak VO_2 of 14 mL/kg/min emerged as a key component of the transplant selection algorithm. Notably hemodynamic responses to exercise are greatly affected by gender, and a threshold value of 14 mL/kg/min may be quite inappropriate for women. In women, it is reasonable to consider using alternate standards in conjunction with peak VO_2 to guide listing, including percent of predicted (≤50%) peak VO_2 (Sue and Hansen, 1984; Swedberg et al., 2005; Mehra et al., 2006). Furthermore, most of the studies evaluating the relationship between peak VO_2 and HF prognosis were performed before the beta-blocker era, and recent studies have reassessed the value of peak VO_2 since this a major shift in therapy (Lund et al., 2003). The ISHLT (Mehra et al., 2006) currently

recommends a peak VO_2 <12 mL/kg/min as the value below which transplant should be considered for those treated with beta-blockers.

Peak VO_2 is the goal standard measurement of a patient's functional capacity as well as long-term prognosis; however, the interpretation of the test should take into consideration other parameters as well to obtain appropriate prognostic information.

Ventilatory Threshold

This physiologic event marks the exercise level at which the Ve increases exponentially (no longer in a linear fashion) relative to the increase in VO_2, where anaerobic metabolism increases in exercising muscles to sustain the work, as aerobic metabolic capacity can no longer meet the physiologic demands, and the body shifts to anaerobic metabolism as a source of energy (Balady et al., 2010; Forman et al., 2010). The key utility of ventilatory threshold (VT) is considered an index of submaximal exercise and independent of motivation. Often, it is a more practical performance index for those patients who are too anxious or debilitated to exercise to maximal exercise.

Anaerobic, ventilatory, and lactate threshold are used interchangeably; however, they are different but related events. VT usually occurs at 45%–65% of measured peak VO_2 in healthy untrained subjects. It occurs at a higher percentage of maximal effort in endurance-trained subjects. Exercise training has been shown to increase VO_2 at the VT, typically 10%–25% for previously sedentary individuals.

Several methods have been proposed for determination of VT; however, no universal agreement exists regarding which is best. The most common definitions of VT are the following: (1) The departure of VO_2 from a line of identity drawn through a plot of VCO_2 versus VO_2, often called the V-slope method; (2) the point at which a systematic increase in the ventilatory equivalent for oxygen (VE/VO_2) occurs without an increase in the ventilatory equivalent for carbon dioxide (VE/VCO_2); and (3) the point at which a systematic rise in end-tidal oxygen pressure ($PETO_2$) occurs without a decrease in the end-tidal carbon dioxide pressure ($PETCO_2$) (Balady et al., 2010). The assessment of all three of the aforementioned VT detection techniques in combination may result in an improved approximation of anaerobic threshold by blood lactate. The determination of the appropriate VT is fundamental for the interpretation of CPX given that important parameters like ventilatory efficiency (VE/VCO_2 slope) are determinates at VT.

Respiratory Exchange Ratio

The respiratory exchange ratio (RER) is the ratio between VCO_2 and VO_2 and an indicator of validity of the patient's effort during CPX (Balady et al., 2010; Forman et al., 2010). Achievement of at least 85% of age-predicted maximal heart rate is a well-recognized indicator of good effort by a patient during stress testing. However, the widespread use of beta-blocker in the HF population limits the use of this maximal heart rate to evaluate the quality of effort provided by a patient and determine if results are applicable. Peak RER is the most accurate measurement of a subject's effort. A peak RER $\geq$ 1.1 is considered an indication of excellent effort, however, not an indication to stop the test (similar to peak heart rate of 85% of predicted). A peak RER <1.0 in a CPX that is terminated by subject request, absent any electrocardiographic or hemodynamic abnormalities, generally reflects submaximal cardiovascular effort and the peak VO_2 should be interpreted with caution (Balady et al., 2010; Mezzani et al., 2003).

Assessment of peak RER is also important in clinical trials to demonstrate comparable participant effort among serial exercise tests (Balady et al., 2010; Brawner et al., 2008; Arena et al., 2007a). Reproducibility among tests could be difficult particularly if testing is performed by different personnel or in multi-institutional laboratories. If not adequately controlled, such variables can be expected to affect peak VO_2 which is an endpoint in most clinical trials in HF. Defining an acceptable magnitude of difference in functional capacity between serial tests, particularly at baseline, is valuable. Although there are no universal criteria for test reproducibility, peak/maximal VO_2 is generally considered reproducible if values vary by <10% on separate days. The ability of determine peak RER is an important reason that the incorporation of CPX should be strongly considered for interventional trials with a functional endpoint. Further, VT can occasionally be detected in subjects who achieve a RER <1.0, given that VT is detected somewhere in the RER range of 0.8–0.99 (Balady et al., 2010).

Ventilatory Efficiency

The most widely studied index of ventilatory efficiency is the Ve/VCO_2 slope (Balady et al., 2010; Forman et al., 2010). The relationship between Ve and VCO_2 during exercise is tightly coupled, because the former is modulated by the metabolic and anaerobic production of the latter. A Ve/VCO_2 slope <30 is considered normal without modification for age and sex (Balady et al., 2010; Sun et al., 2002). Abnormalities in ventilatory efficiency during exercise (VE/VCO_2 slope $\geq$ 34) portend a worse prognosis in patients with systolic HF and should lead to intensification of therapy in HF patients (Robbins et al., 1999; Arena et al., 2007b,c; Tsurungaya et al., 2006; Guazzi et al., 2008; Mancini and LeJemtel, 2007). Further, in patients with relatively preserved functional capacity (peak VO_2), a Ve/VCO_2 slope >34 still demonstrated a significantly higher cardiac event rate than other patients (35.0% vs. 13.3%, $P < 0.01$) (Tsurungaya et al., 2006), and some have proposed that it predicts cardiovascular risk irrespective of aerobic capacity (Arena et al., 2007c; Guazzi et al., 2008; Mancini and LeJemtel, 2007).

In patients with cardiopulmonary problems, there can be significant ventilation-perfusion mismatching and up-regulated ergo- and chemoreceptors leading to an elevated VE/VCO_2 slope. Further, there is an important relationship between ventilatory efficiency and right ventricular performance during exercise. A significant correlation was demonstrated between VE/VCO_2 slope and pulmonary vascular tone as assessed by exercise pulmonary vascular resistance and a negative correlation was shown between VE/VCO_2 slope and exercise right ventricular ejection fraction (Lewis et al., 2008). In fact, a patient with pulmonary hypertension can far exceed the normal threshold, some having Ve/VCO_2 slopes >60 if they have severe disease (Holverda et al., 2008).

CPX Advantages

Cardiopulmonary exercise testing is a well-established method for evaluation of cardiopulmonary diseases, provides an objective assessment of maximal aerobic capacity, estimates prognosis, and allows the physician to discriminate among many subtle and often overlapping etiologies. In general, when the anaerobic threshold is <40% of the predicted peak VO_2, circulatory insufficiency is suggested. A breathing reserve <20% would indicate ventilatory impairment, especially when accompanied by oxygen desaturation with exercise. If the patient has a reduction in both anaerobic threshold and breathing reserve, the more dominant finding may indicate the primary cause of the patient's functional limitation (Balady et al., 2010; Malhotra et al., 2016; Palange et al., 2007).

Further, the test allows for other cardiovascular diagnostic evaluations such as heart rate reserve, blood pressure response to exercise and coronary ischemia as well as the detection of oxygen desaturation during exercise. Some cardiopulmonary diseases have a distinct pattern during exercise. Patients with HF have a reduced peak VO_2 and anaerobic threshold and a shallower profile (or even flattening) of the oxygen-pulse increase with increasing VO_2. A steep increase in Ve/VCO_2 slope is observed and occasional periodic breathing at rest and during the early phase of exercise has been noted (Balady et al., 2010; Malhotra et al., 2016; Palange et al., 2007).

CPX Limitations

The test requires sophisticated expensive equipment, specially trained personnel and is labor- and cost-intensive, therefore usually limited to specialized centers. Interpretation of the CPX also demands specialized expertise, which is of vital importance. Quality assurance protocols have been described to help ensure the gas exchange data is physiologically reasonable and reproducible (Brawner et al., 2008). Even centers conducting a high volume of CPXs, clinically or for research, do not always pass quality assurance protocols, the most common reasons being: use of treadmill handrails by the patient for support, talking during the test, air leak around the mask, mouthpiece, or nose clip, inaccurate calibration procedures, errant pneumotach or flow sensor, error of gas analyzer or software that was not identified through calibration. Holding onto the treadmill handrails usually decreases the metabolic cost and should be discouraged (Balady et al., 2010; Forman et al., 2010). A valid test interpretation is crucially dependent on the calibration of airflow and gases (O_2 and CO_2) that are performed immediately prior to testing.

An area of current discussion is the optimal exercise modality (cycle ergometer vs. treadmill) has not been established (Balady et al., 2010; Forman et al., 2010; Maeder et al., 2008). Treadmill exercise testing has several advantages over cycle ergometer (**Table 1**) and for most subjects, treadmill walking is a more familiar activity than cycling; however, it tends to be criticized as patients tend to rely on handrails, which confounds assessments of work capacity. Walking on the treadmill involves a larger muscle mass and more work against gravity. Consequently, treadmill peak VO_2 is on average 5%–10% higher compared to exercise on a cycle ergometer. A cycle ergometer is less prone to noise artifact and allows for better quantification of the metabolic cost. Generally, it is less expensive and requires less space than a treadmill and the preferred method for patients with gait, balance instability, or orthopedic problems.

An adequate set of normal reference values has not been established (American Thoracic Society and American College of Chest Physicians, 2003; Forman et al., 2010; Miles et al., 1980; Wasserman et al., 2005). The selection of peak VO_2 predicted values (both

Table 1 Comparison of cycle ergometer and treadmill CPET

Variable	*Cycle*	*Treadmill*
Peak VO_2	Lower	Higher
Work rate measurement	Yes	No
Blood gas collection	Easier	More difficult
Noise and artifacts	Less	More
Safety (fewer musculoskeletal injuries)	Safer	Less safe (?)
Weight bearing in obese subjects	Less	More
Degree of leg muscle training	Less	More
Usefulness in supine position	Yes	No
Familiarity of exercise	Less	More
More appropriate for	Patients	Active normal subjects

mean and at the 95% confidence level) is a challenging problem, especially because body sizes and activity levels of a specific clinical population may differ from those of reference populations. Peak VO_2 during exercise varies with age, gender, body size, lean body mass, level of ordinary activity, and type of exercise. Peak VO_2 is generally expressed as mL/kg/min; however, the selection of an appropriate predicted peak VO_2 in overweight patients is difficult. Overweight individuals are more likely to have predominantly an increase in adipose tissue rather than an increase in potential exercising muscle mass. Thus, a direct correlation between increasing peak VO_2 and body weight cannot be implied. The current recommendations are to increase the predicted peak VO_2 by 6 mL/min for each kilogram of weight above normal (Wasserman et al., 2005) or to normalize the peak VO_2 by ideal body weight (instead of actual weight) estimated from the patient's height (Cicoira et al., 2004). Normalizing peak VO_2 for gender and age (using the percent predicted VO_2) in terms of listing criteria for heart transplantation has been recommended by the ISHLT guidelines (Mehra et al., 2006), particularly for young patients and women, for whom a threshold of 14 mL/kg/min may be inappropriate.

Introduction

Sarcoidosis is a disease known for invading many organ systems in a diverse group of patients, both by age and by ethnicity (Valeyre et al., 2014; Culver and Valeyre, 2016; Birnie et al., 2016a). Inflammatory involvement of these organs by noncaseating granulomas is a key diagnostic criterion. While pulmonary disease is the most common cause of death in this population, cardiac causes including arrhythmia and decompensated heart failure are the second most common, despite only 5% clinically diagnosed cardiac disease involvement (ATS, ERS, WASOG, 1999). This issue has been helped somewhat by advanced imaging, which has informed us that subclinical cardiac disease may be present in 25% of patients, and has led to earlier treatment with steroids and other immunomodulators, as well as antiarrhythmic procedures (Bussinguer et al., 2012). Prognosis is worse with cardiac involvement and depends on cardiac function at the time of treatment (Sadek et al., 2013).

Background

Sarcoidosis is a systemic inflammatory disorder characterized histologically by noncaseating granulomatous formation with potential for multisystem tissue involvement. The disease process disrupts physiologic architecture and function, often complicated by resultant scar formation. The cause of sarcoidosis remains poorly understood and the case-to-case diagnosis is often difficult, especially as it manifests in quite diverse and often nebulous ways (Valeyre et al., 2014; Culver and Valeyre, 2016; Yee, 2016). Modern diagnostic modalities have detected involvement in essentially every organ system, including pulmonary, cardiac, neural, hepatic, splenic, glandular, ocular, dermal, and bone tissues (Yee, 2016; Saidha et al., 2012; Birnie et al., 2015). The most recent joint consensus statements by the American Thoracic Society, the European Respiratory Society, and the World Association for Sarcoidosis and Other Granulomatous Disorders (WASOG) requires evidence of disease involvement of two organ systems for the diagnosis of sarcoidosis, although organ diagnosis itself is a subject of varying and evolving practice (Sperry et al., 2016).

Pathogenesis and Organ Involvement of Sarcoidosis

While the pathogenesis of sarcoidosis is incompletely known, the contemporary understanding is that there is an antigen-specific immune response to a likely infectious trigger, with interplay between both innate and adaptive immunity, ultimately contributing to noncaseating granulomatous inflammation (Culver and Valeyre, 2016). There is no clear evidence that sarcoidosis is a primary infectious disease. Yet, it is hypothesized that dead or partly degraded mycobacteria and propionibacteria, along with potentially other substances, may linger in macrophages due to their acid-fast nature, and thus chronically supply antigens that could be responsible for an immune response (Ishige et al., 1999; Chen and Moller, 2008). Granulomas that form then are thought to trap remnants of these agents that cannot be degraded further and continue to influence inflammation (Zissel et al., 2010).

The pathologic result varies widely by organ involvement, with poorly understood regional geographic prevalence (Cozier, 2016). Organ systems commonly involved include the skin, peripheral lymph nodes, eyes, liver, spleen, heart, and nervous system. Less commonly involved systems include the kidneys, parotid glands, larynx, bones, skeletal muscles, and gastrointestinal tract.

Epidemiology

Sarcoidosis has a worldwide prevalence estimated between 5 and 64 in 100,000, with the highest worldwide incidence reported in northern Europeans and in African Americans, particularly in women (Birnie et al., 2016a; ATS, ERS, WASOG, 1999). In Europe, Scandinavians seem to have the highest annual incidence, with an estimated 50–60 per 100,000 (Te et al., 2016). Meanwhile, in the United States, the annual incidence is estimated at 10.9 per 100,000 in Caucasians versus a markedly higher incidence of 35.5 per 100,000 in African Americans (Te et al., 2016). Worldwide, there is an age distribution pattern showing that 70% of cases occur between the ages 25 and 45, and only sparse incident cases exist for the pediatric population and for people older than age 70 (Birnie et al., 2016a). In Europe and Japan, there appears to be a bimodal distribution, with a later peak occurring in women older than age 50 (Te et al., 2016). For cardiac sarcoidosis, there is an unclear gender bias, with Japanese studies suggesting a higher prevalence in woman, and American studies suggesting a higher prevalence in men (ATS, ERS, WASOG, 1999; Sperry et al., 2016; Martusewicz-Boros et al., 2016; Yoshida et al., 1997; Sekiguchi et al., 1985).

Cardiac Sarcoidosis: Epidemiology, Prognosis, Morbidity, and Mortality

While sarcoidosis involves the lungs in more than 90% of patients, an estimated 5% of cases have clinically apparent cardiac involvement (Birnie et al., 2016a). In addition to this 5%, though, an estimated 20%–30% of patients with extracardiac sarcoidosis and no diagnosis of cardiac involvement are thought to have subclinical or simply undiagnosed cardiac sarcoidosis, as based on autopsy findings (Birnie et al., 2016a; Bussinguer et al., 2012; Birnie et al., 2016b). Imaging studies have shown similar percentages of asymptomatic cardiac involvement via the use of cardiac MRI and FDG-PET (Mehta et al., 2008; Nagai et al., 2014; Patel et al., 2009; Pizarro et al., 2016). Among all organ involvement, cardiac involvement is the second leading cause of death, behind pulmonary involvement (ATS, ERS, WASOG, 1999; Yee, 2016; Kandolin et al., 2015). In clinically diagnosed cases of cardiac sarcoidosis, the five-year mortality rate ranges from 10% to 85%, a number that varies geographically (Kandolin et al., 2011; Akashi et al., 2012). While this mortality rate is closer to 10%–40% in the United States, the rate attributed to cardiac involvement is estimated to be as much as 85% in Japan, where cardiac sarcoidosis seems to be the most common (Te et al., 2016; Yoshida et al., 1997; Sekiguchi et al., 1985).

Mortality due to cardiac sarcoidosis occurs from either sudden cardiac death (ventricular arrhythmia) or refractory decompensated heart failure (Birnie et al., 2016a). The degree of left ventricular systolic dysfunction appears to be the most important predictor of survival among patients with cardiac sarcoidosis (Birnie et al., 2016a; Chiu et al., 2005). The ten-year survival of patients with left ventricular ejection fraction (LVEF) of less than 30% has been found to be as low as 19%, compared to 100% ten-year survival in patients with preserved LVEF, according to a Japanese single-center retrospective study in 2005 (Chiu et al., 2005). While survivorship among those with cardiac sarcoidosis and LVEF less than 30% is likely somewhat higher with the now wider use of prophylactic implantable cardiac defibrillators (ICDs), low systolic function in the setting of cardiac sarcoidosis remains a high risk for sudden cardiac death due to the unpredictable substrate resulting from granuloma and scar formation. The data from clinical studies remain insufficient, though, to adequately risk-stratify for sudden cardiac death specifically due to sarcoidosis (Epstein et al., 2013). The data is also quite divergent about the prognosis of clinically silent cardiac sarcoidosis, with studies showing either quite good survival or a significant decline in survival (Mehta et al., 2008; Nagai et al., 2014; Patel et al., 2009; Greulich et al., 2013; Murtagh et al., 2016; Smedema et al., 2005a).

Manifestations of Sarcoidosis in the Heart

Granulomatous inflammation of the myocardium and the conduction system produces a broad range of sequelae, from sudden cardiac death to the insidious onset of heart failure (Yee, 2016). As cardiac sarcoidosis often is not diagnosed until the patient presents with arrhythmia, the Heart Rhythm Society recommends that workup for cardiac sarcoidosis be done in any patient with known extracardiac sarcoidosis who has an abnormal electrocardiogram (ECG), abnormal echocardiogram, or symptoms to suggest cardiomyopathy or arrhythmia (Birnie et al., 2014). The types of cardiac involvement can be most simply divided into three main categories: conduction abnormalities, ventricular arrhythmias, and heart failure (Birnie et al., 2016a; Birnie et al., 2016b; Kusano and Satomi, 2016; Cohen Aubart et al., 2016).

Sarcoid-induced conduction abnormalities include primarily atrioventricular block (up to 62% of cases) and bundle branch block (up to 61% of cases) (Birnie et al., 2016c; Nery et al., 2012). Interestingly, up to 33% of patients younger than age 60 presenting with clinically apparent high-grade conduction system disease are found in retrospect to have cardiac sarcoidosis as the primary etiology (Birnie et al., 2016c). High-grade atrioventricular conduction block occurs due to granulomatous involvement of the basal septum, thus directly damaging the conduction system. In association with this basal involvement, mitral or tricuspid insufficiency is often seen due to granulomatous encroachment producing direct valvular damage. Notably, inflammation at the same basal septal territory which results in conduction abnormalities can produce septal edema that can mimic the structural appearance of hypertrophic cardiomyopathy, but sarcoid involvement can be distinguished by new bundle branch block (Uchida et al., 2012).

Cardiac sarcoidosis also manifests in arrhythmias frequently. Up to 42% of cases present with ventricular tachyarrhythmias, while an additional 15% of cases present with supraventricular arrhythmias (Houston et al., 2016). Ventricular tachyarrhythmias, usually due to macro-reentrant arrhythmias around areas of scar, are especially worrisome, as they are presumably associated with sudden cardiac death. Consensus statements suggest that data from randomized defibrillator trials is applicable in this patient population (Birnie et al., 2014). Unfortunately, sarcoidosis of the heart presents clinically as sudden cardiac death in an estimated 60% of cases (Te et al., 2016; Houston et al., 2016). Predicting risk for sudden cardiac death is particularly problematic because distribution of the pathologic substrate is often variable and dynamic, much more so than other cardiomyopathies (Zipse and Tzou, 2016).

Heart failure in cardiac sarcoidosis occurs from two different processes, both which can lead to nonischemic systolic and/or diastolic dysfunction. The first is replacement of normal myocardium with fibroblastic scar tissue in response to granulomatous inflammation, thereby producing stiff and dysfunctional myocardium (Sperry et al., 2016; Epstein et al., 2013; Yufu et al., 2017). The other process is through insidious myocardial remodeling from chronic arrhythmia due to the underlying granulomatous involvement of the conduction system.

Outside of the above typical presentations of conduction disease, ventricular arrhythmias, and heart failure, cardiac sarcoidosis has also been demonstrated to produce coronary artery disease via granulomatous arterial infiltration (Smedema et al., 2005b). This process seems to create vasculitis and coronary spasm, manifesting as angina and what is essentially simulated myocardial infarction without significant epicardial coronary involvement (Roberts et al., 2014). In addition, there is an indeterminate prevalence of clinically silent cardiac sarcoidosis, with at least 25% of cases being either asymptomatic or undiagnosed due to diagnostic challenges (Birnie et al., 2016c). Postmortem diagnosis of cardiac sarcoidosis accounts for an estimated 20%–30% of cases in otherwise assumed extracardiac sarcoidosis, compared to the approximately 5% of cases diagnosed with clinically apparent cardiac involvement (Bussinguer et al., 2012; Birnie et al., 2016b).

Diagnostics

While it may appear that the incidence of cardiac sarcoidosis is increasing, this is likely more a reflection of improving diagnostic techniques to detect occult cases, rather than truly increased pathologic incidence (Birnie et al., 2016a). There is currently no formal consensus on screening for cardiac sarcoidosis as an etiology for nonischemic cardiomyopathy in patients without a known diagnosis of extracardiac sarcoidosis, but its patterns of presentation should influence suspicion and prompt diagnostic workup (Kandolin et al., 2011). In general, screening for cardiac sarcoidosis should be considered for patients younger than 55 years with unexplained high-grade atrioventricular block, patients younger than 55 years with new onset ECG abnormalities in the absence of known obstructive coronary artery disease, patients with sustained monomorphic ventricular tachycardia, and patients with a histologic diagnosis of extracardiac sarcoidosis, regardless of cardiac symptoms (Bussinguer et al., 2012; Blankstein and Waller, 2016; Natarajan et al., 2016).

Both echocardiogram and ECG are recommended for initial screening in suspected or known cardiac sarcoidosis (Birnie et al., 2014). Suspicious echocardiographic findings are LV dilatation (EDD $>$ 55 mm in women, $>$60 mm in men), septal thinning, local wall thinning or thickening, and impaired left ventricular (LV) longitudinal strain (Kusano and Satomi, 2016; Blankstein and Waller, 2016). Granulomatous involvement and scar tissue will tend to appear hyperechogenic on echocardiogram. Common ECG findings include new right or left bundle branch block, ventricular tachycardia, frequent PVCs, and abnormal Q waves (Nery et al., 2012; Sobue et al., 2015; Tanaka et al., 2016). Despite the ECG findings being quite nonspecific, rarely does a patient with cardiac sarcoidosis present with a normal ECG. In fact, a single center retrospective study in the United States demonstrated abnormal ECGs in all patients with cardiac sarcoidosis (Sperry et al., 2016). If there remains suspicion for cardiac sarcoidosis in a patient with a normal ECG, 24-h ambulatory Holter monitoring looking for these typical arrhythmias is recommended (Kashiwabara et al., 1999; Suzuki et al., 1994).

Advanced imaging modalities have become routine in the workup for cardiac sarcoidosis, increasing the diagnostic sensitivity and specificity (Blankstein and Waller, 2016; Youssef et al., 2011; Perez et al., 2016). Either magnetic resonance imaging (MRI) or ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) is recommended following abnormal echocardiogram or ECG findings, to confirm diagnosis and to determine myocardial involvement.

MRI is the current imaging modality of choice in cardiac sarcoidosis workup, due mostly to its more common accessibility over PET and high diagnostic sensitivity (Natarajan et al., 2016; Greulich et al., 2016; Bateman, 2016). Acute inflammation of the myocardium is best seen on T2-weighted imaging and with early gadolinium enhancement. Meanwhile, more chronic changes, such as wall thinning, hypertrophy, and fibrosis, are best demonstrated on T1-weighted imaging and with late gadolinium enhancement. The most common patterns of MRI enhancement in cardiac sarcoidosis are mid-myocardial and sub-epicardial, usually not in a vascular distribution (**Fig. 1**). In addition to its diagnostic utility, MRI is of particular use in predicting mortality from cardiac involvement, with late gadolinium enhancement findings being the most telling (Greulich et al., 2013; Greulich et al., 2016).

While FDG-PET may not be as widely utilized as MRI, it appears to be even more sensitive in detecting active disease. It also notably can attain higher image resolution (Bateman, 2016; Lee et al., 2016; Ishida et al., 2014). The cellular uptake of 18-Fluorodeoxyglucose (^{18}FDG), a glucose analog used in this study, in cardiac sarcoidosis is related to high macrophage activity

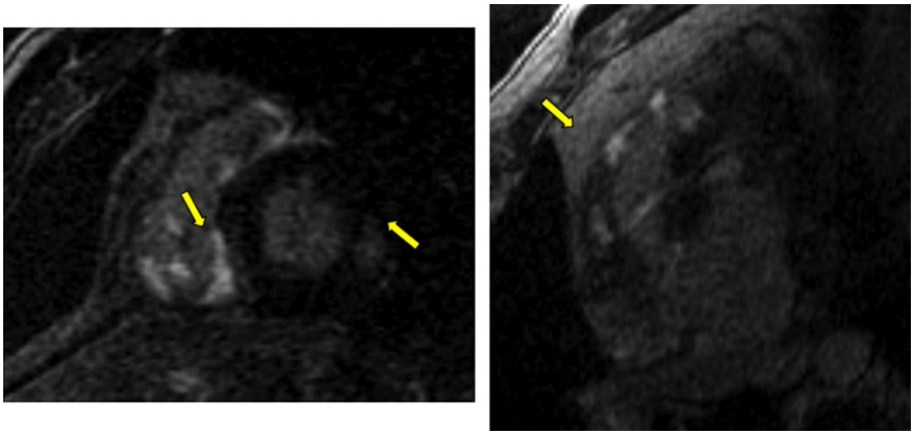

Fig. 1 Cardiac MRI imaging of cardiac sarcoidosis. The image shows patchy late gadolinium enhancement of the right ventricular outflow tract and mid-inferolateral wall (A, arrows) and the right ventricular free wall (B, arrow).

Fig. 2 FDG-PET imaging of cardiac sarcoidosis. The image included shows increased FDG uptake involving the septum and apex (arrow).

in the inflammatory milieu of active disease (Ishida et al., 2014). Accordingly, FDG PET is especially useful in detecting the inflammatory distribution in known disease and in gauging response to antiinflammatory treatment (**Fig. 2**). Generally, patterns of involvement can be seen just in focal areas or on a background of diffuse uptake. One challenge to this study is that imaging is entirely dependent on suppression of glucose utilization in normal, nonaffected myocardium, which requires significant dietary and behavioral rules for 24 h prior to the procedure (Bhambhvani, 2017). Another challenge is that ^{18}FDG activity is not specific to cardiac sarcoid. It can also be seen in hibernating myocardium, myocarditis, or even systemic rheumatologic conditions. Of note, fusion imaging, a composite of both FDG PET and MRI, is beginning to gain momentum in its ability to detect both high-resolution acute inflammation and more of the chronic changes that are seen better on MRI late gadolinium enhancement (Ferreira and Piechnik, 2016).

Endomyocardial biopsy, while diagnostic, is unfortunately quite limited by its low sensitivity (Kandolin et al., 2011; Kusano and Satomi, 2016). This shortcoming is attributed to the patchy myocardial distribution, which limits the likelihood of obtaining a successful diagnostic biopsy (Yee, 2016; Sperry et al., 2016; Kandolin et al., 2011; Kusano and Satomi, 2016). A diagnostic biopsy contains the histology that defines the disease: noncaseating granulomas and multinucleated giant cells, characteristically without myocardial necrosis (**Fig. 3**). In practice, though, biopsies are diagnostic of cardiac sarcoidosis in less than a quarter of patients who are later proven to indeed have cardiac sarcoidosis (Birnie et al., 2016c).

The most recent worldwide joint consensus statement on diagnosis of cardiac sarcoidosis, as prepared by the Heart Rhythm Society, European Heart Rhythm Association, World Association for Sarcoidosis and other Granulomatous Disorders (WASOG), American College of Chest Physicians, American Heart Association the American College of Cardiology and the Asia Pacific Heart Rhythm Society, aims to assist in diagnosis especially when faced with patients with inconclusive clinical data (Birnie et al., 2016c). As this consensus is a class C statement, it is intended as guidance rather than as criteria for diagnosis (**Table 1**).

Table 1 The first international expert consensus on the diagnosis and management of cardiac sarcoidosis

Options for diagnosis of cardiac sarcoidosis
1. Histological diagnosis from endomyocardial biopsy
– Noncaseating granuloma of myocardial tissue with no other causeidentified, including infectious staining
2. Clinical diagnosis
Diagnosis is probable (adequate for diagnosis) if the following are present
(A) Histological proof of extracardiac sarcoid and
(B) At least one of the following
(i) Steroid (with or without immunosuppressant) responsive heart block or cardiomyopathy
(ii) Ejection fraction $<$40% without other explanation
(iii) Sustained ventricular tachycardia
(iv) High-grade heart block
(v) FDG-PET (cardiac) shows sarcoid-consistent patchy tracer uptake
(vi) Cardiac MRI shows late Gadolinium enhancement in a sarcoid-consistent pattern
(vii) Positive gallium uptake in a sarcoid-consistent pattern and
(C) Other causes of these findings have been excluded

Modified from Ref. (Birnie et al., 2016c).

Prior to the aforementioned worldwide consensus statement, the Japanese Ministry of Health and Welfare has created diagnostic guidelines, first in 1993 and revised in 2006 (Soejima and Yada, 2009) (**Table 2**). These guidelines have often been applied to aid in diagnosis of cardiac sarcoidosis outside of Japan, despite this not being the primary intention. The flaw in these criteria, arguably, is their basis on the Japanese population, which does not necessarily represent other patient populations.

Management

Management of cardiac sarcoidosis is twofold: treatment aimed at limiting the inflammation, and interventions aimed at preventing arrhythmia from the disease.

Despite limited observational data, glucocorticoids are the standard antiinflammatory pharmacotherapy for limiting the inflammation and progression to fibrosis that occurs in cardiac sarcoidosis (Armstrong et al., 2015). Response to glucocorticoids

Table 2 Revised guidelines for diagnosing cardiac sarcoidosis 2006 (Japan Society of Sarcoidosis and other Granulomatous Disorders) (Soejima and Yada, 2009)

1. Histologic diagnosis group:
   Cardiac sarcoidosis is confirmed when myocardial biopsy specimens demonstrate noncaseating epithelioid cell granuloma with histological or clinical diagnosis of extracardiac sarcoidosis.
2. Clinical diagnosis group:
   Although myocardial biopsy specimens do not demonstrate noncaseating epithelioid cell granuloma, extracardiac sarcoidosis is diagnosed histologically or clinically and satisfies the following conditions and more than one in six basic diagnostic criteria.
   (1) More than 2 of 4 major criteria are satisfied.
   (2) One in 4 major criteria and more than 2 in 5 minor criteria are satisfied.

   Major criteria
   - Advanced AV block.
   - Basal thinning of the interventricular septum.
   - Positive cardiac 67Ga uptake.
   - Depressed ejection fraction of the left ventricle (LVEF $< 50\%$).

   Minor criteria
   - Abnormal ECG findings: Ventricular arrhythmias (VT, multifocal, or frequent PVCs), CRBBB, axis deviation, or abnormal Q-wave.
   - Abnormal echocardiography: Regional abnormal wall motion or morphological abnormality (ventricular aneurysm, wall thickening).
   - Nuclear medicine: Perfusion defect detected by 201Tl myocardial scintigraphy or 99Tc myocardial scintigraphy.
   - Gd-enhanced MRI: Delayed enhancement of myocardium.
   - Endomyocardial biopsy: Interstitial fibrosis or monocyte infiltration over moderate grade.

depends heavily on whether the cardiac dysfunction is attributed more to active inflammation or to fibrosis that is already present (Zipse and Tzou, 2016). In theory, the immunosuppressive effect of glucocorticoids will be of much less benefit in cases where there is already extensive fibrosis. It follows that early initiation of steroids is recommended to prevent fibrotic progression of disease.

There is no proven science to the steroid dosing, but 0.5 mg/kg of daily prednisone is typically the starting dose (Kusano and Satomi, 2016; Houston et al., 2016). We generally recommend repeating a PET scan 3 months after treatment initiation, which, if negative, can allow a 3-month steroid taper to 0.2 mg/kg daily, which would continue for another 9 months. We would then repeat a PET scan 3 months post treatment end, and if negative, would follow a patient with echocardiogram and EKG every 6-12 months. If at any point a PET scan is positive for relapse or continued inflammation, combination therapy with Methotrexate should be considered. The efficacy of other immunosuppressive therapy as an alternative to glucocorticoids is less known, but can be considered in cases of contraindication or intolerance to glucocorticoids.

Similar to the role in primary and secondary prevention of arrhythmia in other types of cardiomyopathies, options in cardiac sarcoidosis include ablation, permanent pacemaker, and ICD. Radiofrequency catheter ablation is an option for limiting tachyarrhythmia burden in the majority of cardiac sarcoidosis patients, although results are mixed (Muser et al., 2016; Birnie et al., 2016c; Nery et al., 2012). There is variable efficacy, likely due to the complex and dynamic substrate changes in sarcoidosis. Permanent pacemaker implantation is recommended for high grade or complete atrioventricular conduction block in the setting of cardiac sarcoidosis, even if the block appears to transiently resolve, as there is a very high probability for disease progression and risk for conduction block recurrence (Epstein et al., 2013).

As in patients with cardiomyopathy in general, ICD implantation is a class I indication for primary prevention in those with NYHA class II to III symptoms and an LVEF of 35% or less, as well as for secondary prevention in those with structural heart disease with sustained ventricular tachyarrhythmias (Epstein et al., 2013). Cardiac sarcoidosis is included in potentially both categories, and the Heart Rhythm Society has provided consensus recommendations for the use of devices (Epstein et al., 2013; Birnie et al., 2016c; Nery et al., 2012). ICDs have a IIa recommendation in patients with an indication for pacemaker and/or syncope or near-syncope felt to be arrhythmic. They also have a IIa recommendation for ventricular arrhythmias including over 30 s of ventricular tachycardia, or any relevant episodes of polymorphic ventricular tachycardia or fibrillation. There is a IIb recommendation in patients with LVEF 36%–49% or right ventricular EF $<40\%$ despite optimal medical therapy and immunosuppression for a period of time, with potential help with risk stratification from MRI or FDG-PET. Finally, if none of these categories are achieved, the patient may undergo an MRI, and if there is significant scar, an electrophysiology study can be performed, which, if positive, would give a IIa indication for ICD implantation (Epstein et al., 2013).

Notably, cardiac resynchronization therapy (CRT) guidelines fail to encompass a specific role in cardiac sarcoidosis, as there is currently a paucity of outcome data for this population (Zipse and Tzou, 2016). One pertinent question that could guide future research is whether CRT might be beneficial earlier in the course of cardiac sarcoidosis in the setting of LBBB or AV block, potentially limiting the progression to severe heart failure.

In cases of advanced heart failure attributed to cardiac sarcoidosis, left ventricular assist device (LVAD) implantation or heart transplant can be considered. The criteria for heart transplant include New York Heart Association class III-IV symptoms despite appropriate therapy and cardiogenic shock, which may occur in cardiac sarcoidosis. Importantly these criteria also include refractory ventricular arrhythmias despite appropriate defibrillation and ablation therapies.(Colvin et al., 2017) Criteria for LVAD implantation include poor cardiac output in the setting of heart failure, but also notably include systolic dysfunction with intractable

arrhythmias.(Kirklin et al., 2015) Therefore for patients with significant physical compromise or life-threatening arrhythmias, advanced therapies are an option. Notably, there is controversy regarding potential recurrence in the transplanted heart. In 14 patients with cardiac sarcoidosis as primary reason for heart transplant out of 825 patients undergoing heart transplant at a single center, 2 out of the 14 patients had confirmed sarcoidosis recurrence in the transplanted heart, and there was a trend toward higher 1 and 5 year mortality in all cardiac sarcoid patients who received transplants (Akashi et al., 2012).

Future Directions

Sarcoidosis has proven difficult to understand, with difficulty even accurately characterizing disease frequency within various populations and regions (Cozier, 2016). Multiple trials are seeking to better understand the genetic and regional markers for sarcoidosis activity. Medication trials, such as using atorvastatin or pentoxifylline for treatment, are awaiting results after recruitment, and therapies as advanced as hematopoietic stem cell transplant have haltingly been tried in recent studies (Clinicaltrials.gov). Much of the other thrust of current or recent research is in better understanding the utility of imaging for diagnostic and therapeutic purposes. It is our hope that existing treatment dosing strategies can be compared for efficacy in a systematic way, in order to allow for growth of our understanding of how best to help our patient survive and thrive with cardiac sarcoidosis.

Conclusion

Sarcoidosis is a diverse disease that in a minority of patients has severe effects on the heart. The diagnosis is difficult to make, but once made, treatment strategies including immunomodulatory therapies and electrophysiology procedures are often quite successful. It is our hope that this project helps to spread the knowledge of this uncommon presentation and facilitates the treatment of patients in the future.

Guidelines of World Health Organization (WHO) entitled "Prevention of Cardiovascular Disease" (World Health Organization, 2007) aims to prevent cardiovascular disease (CDV) in a number of WHO member states and contains abundant data in each region. For example, predicted 10-year risk of CDV for each sex in each region is summarized in risk prediction charts. With these risk prediction charts, it is possible to easily predict the absolute risk of CDV and establish a therapeutic target.

Risk prediction charts have also been prepared for regions where cholesterol cannot be measured, and are applicable in a wide range of countries including those of low- and high-income levels. From the viewpoint of CVD prevention, it particularly emphasizes the importance of life habits, including dietary habits, and control of risk factors in the therapeutic aspect.

The total risk concerning onset of CVD is judged by the combined effects of CVD risk factors, which coexist in many cases and act in a synergistic manner. Thus, a person who has several low-level risk factors is possible to have a higher total risk of CVD than a person having only one risk factor of a similar level. The risk prediction charts of WHO proposed that this time is also applicable to persons having metabolic syndrome.

Total risk thresholds vary depending on the financial resources level. The 10-year CVD risk thresholds that require intensive intervention are as follows:

High financial resources level: 20%
Intermediate financial resources level: 30%
Low financial resources level: 40%

Low thresholds for intervention increase the number of beneficiaries but also increase the total costs for chemotherapy and the number of adverse events.

Characteristics of the Risk Prediction Charts

The majority of risk prediction methods for predicting total CVD risk employ prediction formula obtained from diverse information sources. The most widely used information source is Framingham Heart Study (Wilson et al., 1998; British Heart Foundation, n.d.; McCormack et al., 1997; Jackson, 2000; Wood et al., 1998; D'Agostino et al., 2001; Marrugat et al., 2003). In risk charts and tables prepared, diverse age categories, risk evaluation periods, and risk factor profiles are deployed (**Figs. 1** and **2**) (World Health Organization, 2007). The current New Zealand CVD risk charts (Jackson, 2000) and the charts of Joint British Societies (Williams et al., 2004; British Heart Foundation, n.d.) have similar conception.

Risk scores prepared by using the Framingham equation have been widely examined in populations of European Americans and Europeans (Ferrario et al., 2005; D'Agostino et al., 2001; Marrugat et al., 2003; Brindle et al., 2003) as well as in Chinese population (Liu et al., 2004). The European guidelines on CVD prevention uses a new model for estimating the total risk based on the Systematic Coronary Risk Evaluation (SCORE) system (Conroy et al., 2003). Risk is estimated based on sex, age, smoking status, systolic blood pressure, and total cholesterol (TC) or the ratio of TC to high-density lipoprotein cholesterol (HDL-C). Unlike risk scoring based on the Framingham equation, SCORE predicts only the possibility of a fatal CVD event. Risk of fatal CVD of 5% or higher is defined as the threshold for high risk, instead of composite endpoints (including fatal and nonfatal coronary artery disease) of 20%.

Risk factors included in the current SCORE system are the same as those used in the Framingham score, but inclusion of new risk factors is being discussed including C-reactive protein, fibrinogen, and waist–hip ratio (Asia Pacific Cohort Studies Collaboration, 2006). It is likely necessary to continue investigating indices to include so as to respond to changing times.

Position for Measuring Waist Circumference

There is no international standard about the position for measuring waist circumference. We thus investigated the most effective position for measuring waist circumference to be used for diagnosis of metabolic syndrome.

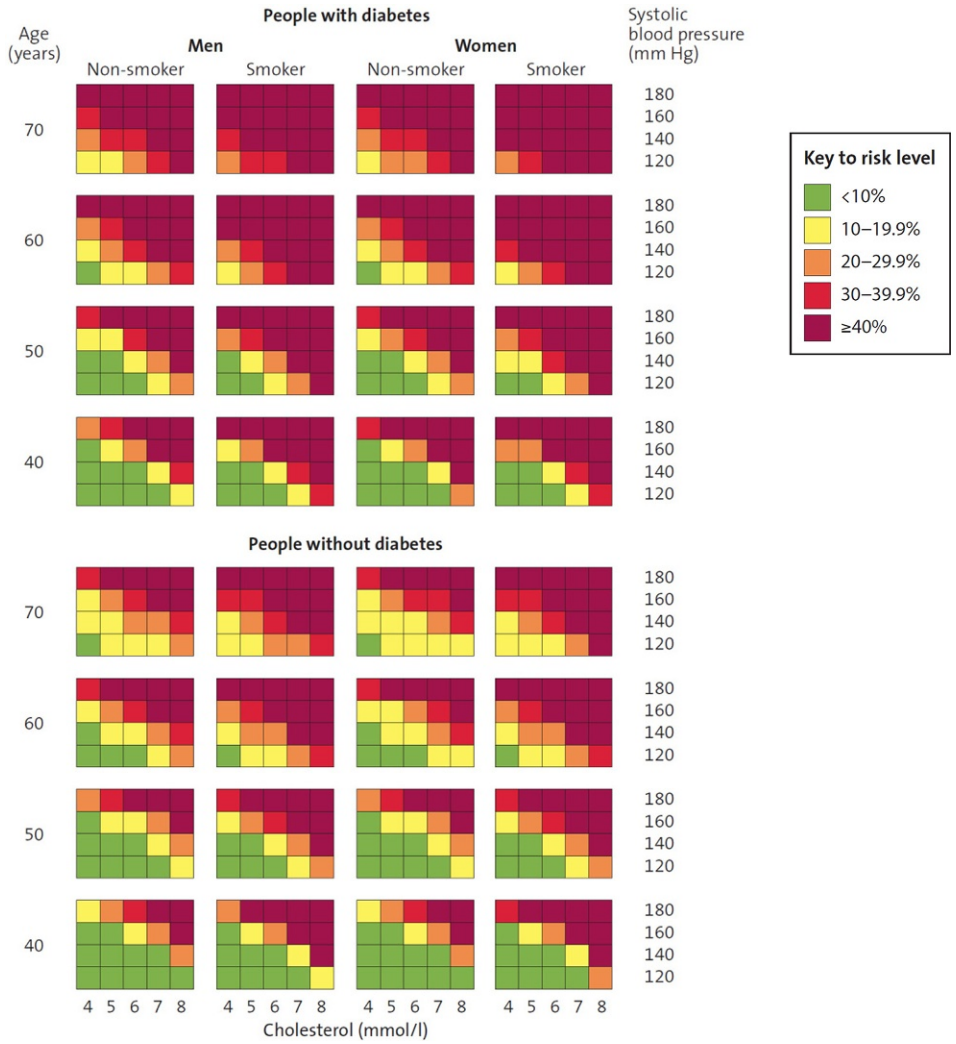

Fig. 1 Sample WHO/ISH risk prediction chart, for use where measurement of cholesterol level is possible (World Health Organization, 2007). The chart below indicates total 10-year risk of a fatal or non-fatal cardiovascular event (myocardial infarction or stroke), according to age, sex, blood pressure, presence or absence of diabetes, smoking status, and cholesterol level, for the WHO Region of South-East Asia.

Waist circumference of 1140 persons (including males and females) was measured at four typical body positions used to measure waist circumference in the world, that is, (1) the narrowest part, (2) the middle point between the lower edge of the costal arch and the upper line of the crista iliaca, (3) umbilical position, and (4) the upper line of the crista iliaca. The optimum position for predicting multiple risk factors of metabolic syndrome was investigated by drawing receiver operating characteristic curves. The mean difference between the largest and smallest waist circumference values was 3.9 cm in males and 12.6 cm in females, showing a large difference by measuring position in females. It was also found that there is no significant difference in the capability of predicting metabolic syndrome between positions measured (Fig. 3). This study revealed that waist circumference measured at any position was useful for diagnosis of metabolic syndrome in both males and females. It was suggested important to correctly measure waist circumference at the position specified by each diagnosis standard. However, it is desirable to internationally standardize the position for measuring waist circumference in order to facilitate comparing prevalence of metabolic syndrome among regions of the world. Conversion expressions among the measuring positions are also stated (Matsushita et al., 2010a).

Effects of Visceral Fat Area on Development of Multiple Risk Factors of Metabolic Syndrome

The effects of visceral fat area on development of multiple risk factors of metabolic syndrome were investigated by comparing with other physique indices.

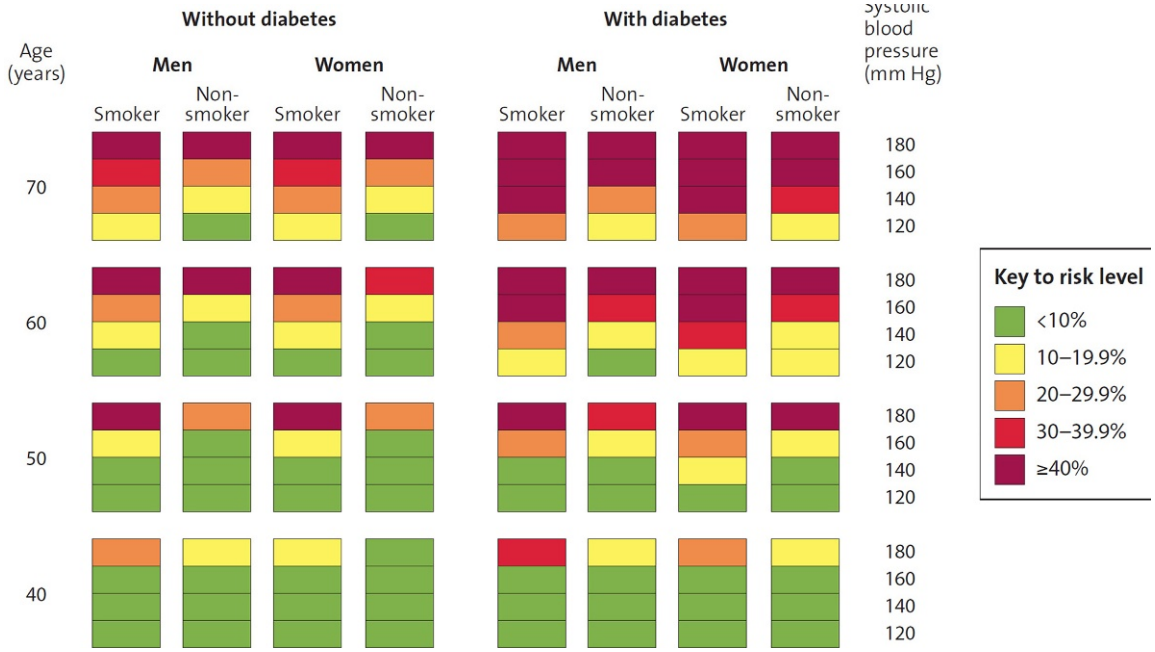

Fig. 2 Sample WHO/ISH risk prediction chart for use where measurement of cholesterol level is not possible (World Health Organization, 2007). The chart below indicates total 10-year risk of a fatal or non-fatal cardiovascular event (myocardial infarction or stroke), according to age, sex, blood pressure, presence or absence of diabetes, and smoking status, for the WHO Eastern Mediterranean Region.

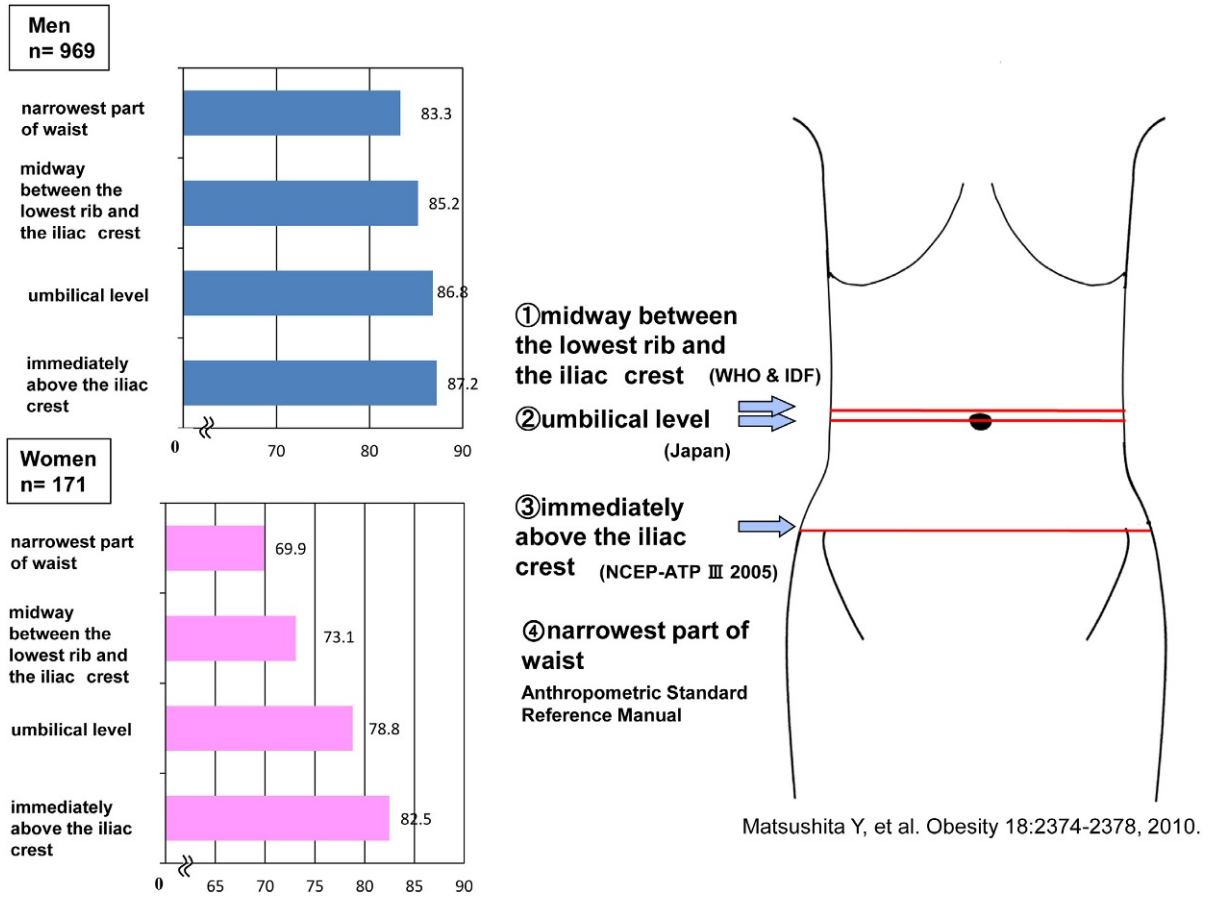

Fig. 3 Comparisons among waist circumference measurements at different sites.

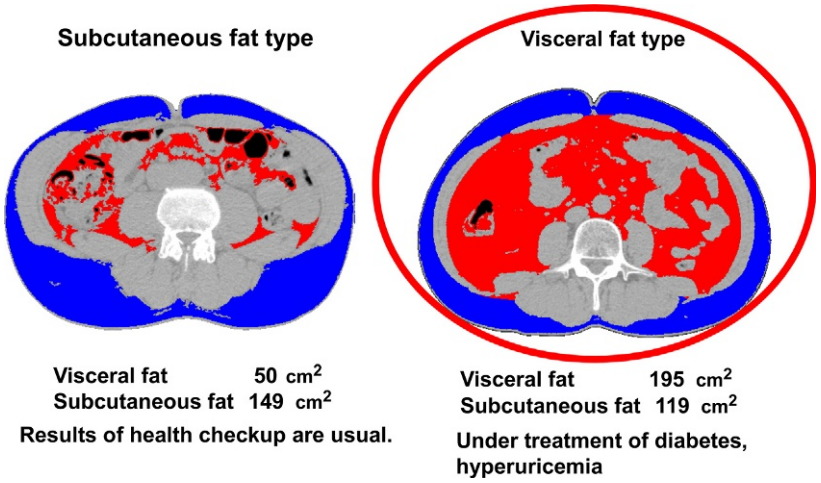

Fig. 4 Although the waist circumferences of these persons are both 86 cm, CT imaging disclosed such a difference.

These are CT photographs of abdomen (Fig. 4). Visceral fat is shown in red. The blue part is subcutaneous fat.

Although the waist circumferences of these persons are both 86 cm, CT imaging disclosed such a difference. We cannot know the inside just by measuring the circumference with a tape. The left is a subcutaneous fat type, and the right is a visceral fat type. The person of a subcutaneous fat type does not show abnormal data in medical checkup, but the person of a visceral fat type is receiving treatment for diabetes mellitus and hyperuricemia. Their pathology is different.

Transverse analysis was conducted on 6292 workers. Based on their CT data, we investigated how visceral fat area, subcutaneous fat area, waist circumference, and BMI are related to each factor of metabolic syndrome (Matsushita et al., 2010b).

For each physique index, the subjects were divided into quintiles, separately for males and females. The odds ratio of persons having multiple risk factors of metabolic syndrome was determined by using the smallest quintile as the standard. Increases in any of the physique indices (visceral fat area, subcutaneous fat area, waist circumference, and BMI) were found to increase the risk of having multiple risk factors of metabolic syndrome. Visceral fat area, which is shown in blue curve, was found to particularly increase the risk. Compared to visceral fat area, waist circumference, which is used as a criterion for metabolic syndrome today, can detect the risk of metabolic syndrome in only 70% in males and 50% in females. There are sex differences in waist circumference, which is shown in red, and BMI, shown in black. It was suggested better to use waist circumference for males and BMI for females (Fig. 5).

As a simple index of metabolic syndrome, waist circumference is used today. However, waist circumference was found to have a limit in detecting the risk.

We also performed a longitudinal study. The relationship between changes in visceral fat area in 3 years and factors of metabolic syndrome and new development of multiple risk factors is shown.

Subjects were 1106 male persons who received abdominal CT scan in 2004 and 2007 and were not receiving treatment for hypertension, hyperlipidemia, or diabetes mellitus during the period (Matsushita et al., 2013).

The subjects were divided into seven groups based on the changes in visceral fat area. The group that had undergone changes of $\pm 10\ cm^2$ or smaller was used as the standard. The odds ratios of developing (1) high triglyceride level, (2) low HDL cholesterol level, (3) high blood pressure, (4) disorder of carbohydrate metabolism, and (5) multiple risk factors of metabolic syndrome in the 3 years were determined. The odds ratio for developing multiple risk factors of metabolic syndrome was significantly high in the group of visceral fat area increase of 50 cm^2 or more. The odds ratio for developing high triglyceride level was significantly low in the group of visceral fat area decrease of 50 cm^2 or more and was significantly high in groups of increases of 30 cm^2 or more (Fig. 6).

The study suggested that suppressing increases in visceral fat would prevent metabolic syndrome.

Risk of CDV

On about 7000 persons in their 20s–70s (including males and females), we investigated the relationship between the amount of visceral fat and the percentage of people having at least two risk factors of lifestyle disease, that is, hypertension, hyperglycemia, and dyslipidemia (or the percentage of people having multiple risk factors of metabolic syndrome) (Matsushita et al., 2014a).

Fig. 6 Odds ratio of metabolic risk factors (defined by NCEP-ATPIII) at the 3-year follow-up survey.

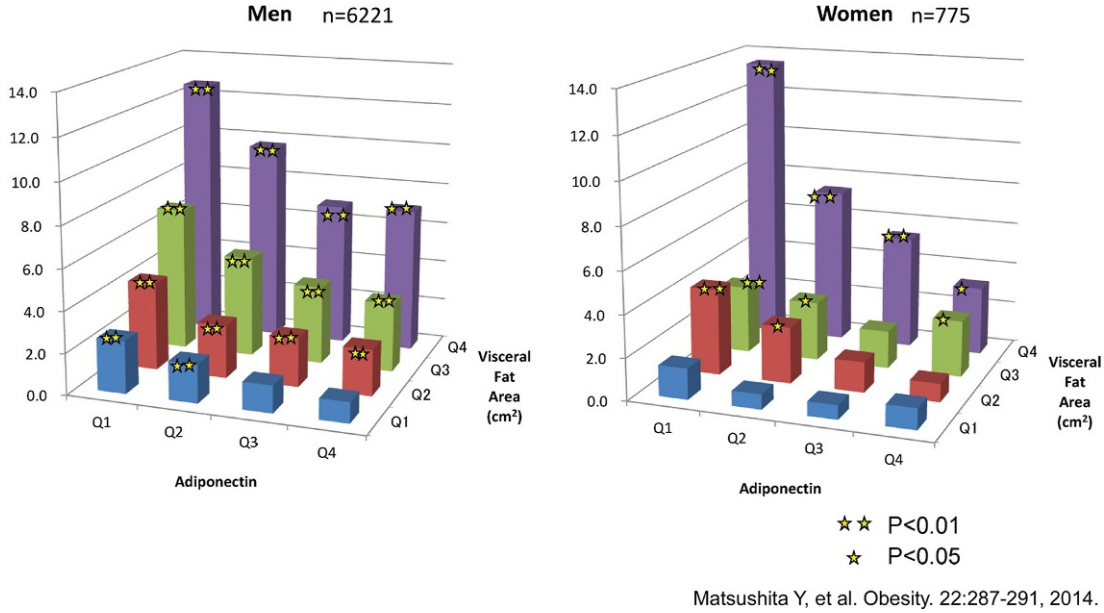

Fig. 7 Odds ratios for multiple risk factors of metabolic syndrome according to combined groups of VFA and adiponectin.

As a result, it was discovered that the risk of developing multiple risk factors of metabolic syndrome of a male who has much visceral fat and low level of a hormone called "adiponectin" in the blood was two times higher compared to a person having high adiponectin level (12.65:7.01 in VFA Q4 (=1.8)) (Fig. 7).

Even in persons having small amount of visceral fat, the risk of developing multiple risk factors of metabolic syndrome was 2.5 times higher in those who have low "adiponectin" level compared to persons having high adiponectin level (2.54:1.00 in VFA Q4).

"Adiponectin" is a hormone secreted by adipocytes and has been shown in animal experiments to prevent arteriosclerosis and stimulate combustion of fatty acids. We discovered that the risk of lifestyle disease in human differed by the level of adiponectin even when the amount of visceral fat is the same.

How Can Waist Circumference Predict the Body Composition?

Each component of the WC may differ between the sexes and generations, even if they have the same WC. Between 2004 and 2009, employees and their spouses working at a Japanese company underwent a health examination after more than 12 h of fasting. We analyzed the data of 11,570 subjects (9874 men and 1696 women), aged from 20 to 76 years, who underwent a computed tomography (CT) examination. VFA, SFA, WC, muscle, intramuscular fat, viscera, and bone were measured using a CT scanner. We conducted stratified analyses by generational age, and calculated the Pearson's correlation coefficients between the VFA and WC, BMI, and VFA plus SFA. To establish the equations for converting the WC to the corresponding VFA and VFA plus SFA, linear regression analyses were used to obtain the regression coefficients and intercepts.

As the generations increased in age, the VFA tended to increase. However, the differences in the WC values of each generation did not coincide with the VFA values in men ($r=-0.275$ and 0.979 for men and women, $n=5$ generations), but did correlate with the difference in the sum of the VFA plus SFA for both sexes ($r=0.915$ and 0.996 for men and women, $n=5$ generations). Older generations had lower WC values when they had the same VFA values as the younger generations (Fig. 8) (Matsushita et al., 2014b).

The WC value corresponding to a certain VFA value differed significantly by generational age. Thus, revised optimal cutoff values for the WC may be needed for each generation.

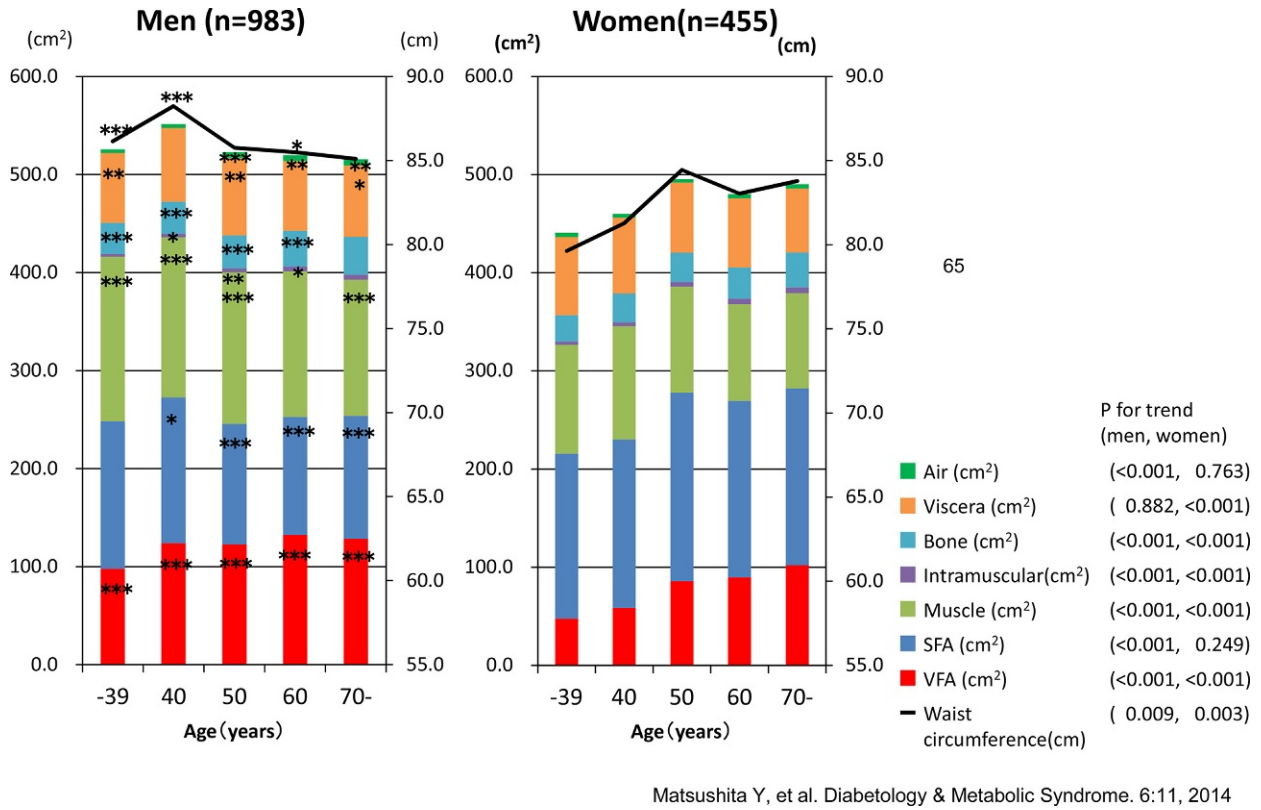

Fig. 8 Mean body components according to the age group measured by CT. $^{*}P<0.05$, $^{**}P<0.01$, $^{***}P<0.001$ for differences in mean values between men and women in each age group by *t*-test.

Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) is a cardiac ion channelopathy with a high risk of sudden death (SD). It is a relatively newly recognized disease, which can easily escape detection and requires a high index of suspicion for timely diagnosis. Advances in our understanding of the genetic etiology and molecular mechanisms have elicited new and exciting therapeutic approaches. In this manuscript the history of the disease, from the earliest descriptive case reports to the most recent large multicenter studies will be reviewed, along with a discussion of the genetic and molecular mechanisms, as well as current and future approaches to therapy.

Diagnosis

The classic diagnostic feature of CPVT is polymorphic or bidirectional ventricular tachycardia (VT) during exercise or stress. There is a typical progression (**Fig. 1**), from a normal resting electrocardiogram (ECG), to the development of single premature ventricular contractions (PVC's), to bigeminy (alternating sinus beats with PVC's), to ventricular couplets, and nonsustained VT (NSVT). Bidirectional VT can often be confused for bigeminy, and is generally relatively slow and well-tolerated. It should be emphasized that the bidirectional/polymorphic VT seen in CPVT is not life-threatening. Indeed, it is usually asymptomatic or minimally symptomatic. Sustained polymorphic VT can degenerate into ventricular fibrillation (VF), which results in syncope or sudden death.

As stated previously, the resting ECG is normal in CPVT, except perhaps for a relative sinus bradycardia seen in some patients, even prior to therapy (Sumitomo et al., 2003). Occasionally patients will not display arrhythmias on exercise testing, but develop polymorphic VT with epinephrine or isoproterenol infusion (Sy et al., 2011). The heart is also structurally normal, and imaging with echocardiography or cardiac MRI is useful to rule out other potential diagnoses in the differential, such as arrhythmogenic cardiomyopathy. Atrial arrhythmias, including atrial ectopic beats, atrial tachycardia, and fibrillation, are also common features of CPVT, and can be adrenergically driven as well. The most common symptom related to CPVT is syncope, followed by cardiac arrest. Symptom onset is typically during childhood, and a delay from first symptom to diagnosis is typically several months to years. Cardiac events that occur during diving or swimming are almost exclusively due to Long QT syndrome type 1 or CPVT (Choi et al., 2004). The true prevalence of CPVT is difficult to determine, as the resting ECG and imaging studies are unremarkable, and diagnosis requires rhythm assessment during exercise, but it has been estimated at roughly 1 in 10,000 (Priori et al., 2013).

History

The earliest cases of what would now be identified as CPVT were reported in the 1960s. Berg described three sisters with frequent ventricular ectopy, two with repeated syncope with exertion, and one who died suddenly at 19 years of age while biking (Berg, 1960). **Fig. 2** shows a recording of bidirectional VT in this subject at 12 years of age, obtained in 1944. This first report made several notable observations, including the presumed cause of syncope due to VT or VF, the familial occurrence, and the absence of "organic heart disease." In 1962 Horan and Venables reported a case of a 5-year-old girl with recurrent syncope while frightened, in whom they recorded various arrhythmias, including bidirectional VT (Horan and Venables, 1962). In hospital they were able to reproduce an episode of VF by "deliberately induced emotional upset, caused by the threat of making her walk downstairs, to which she had a

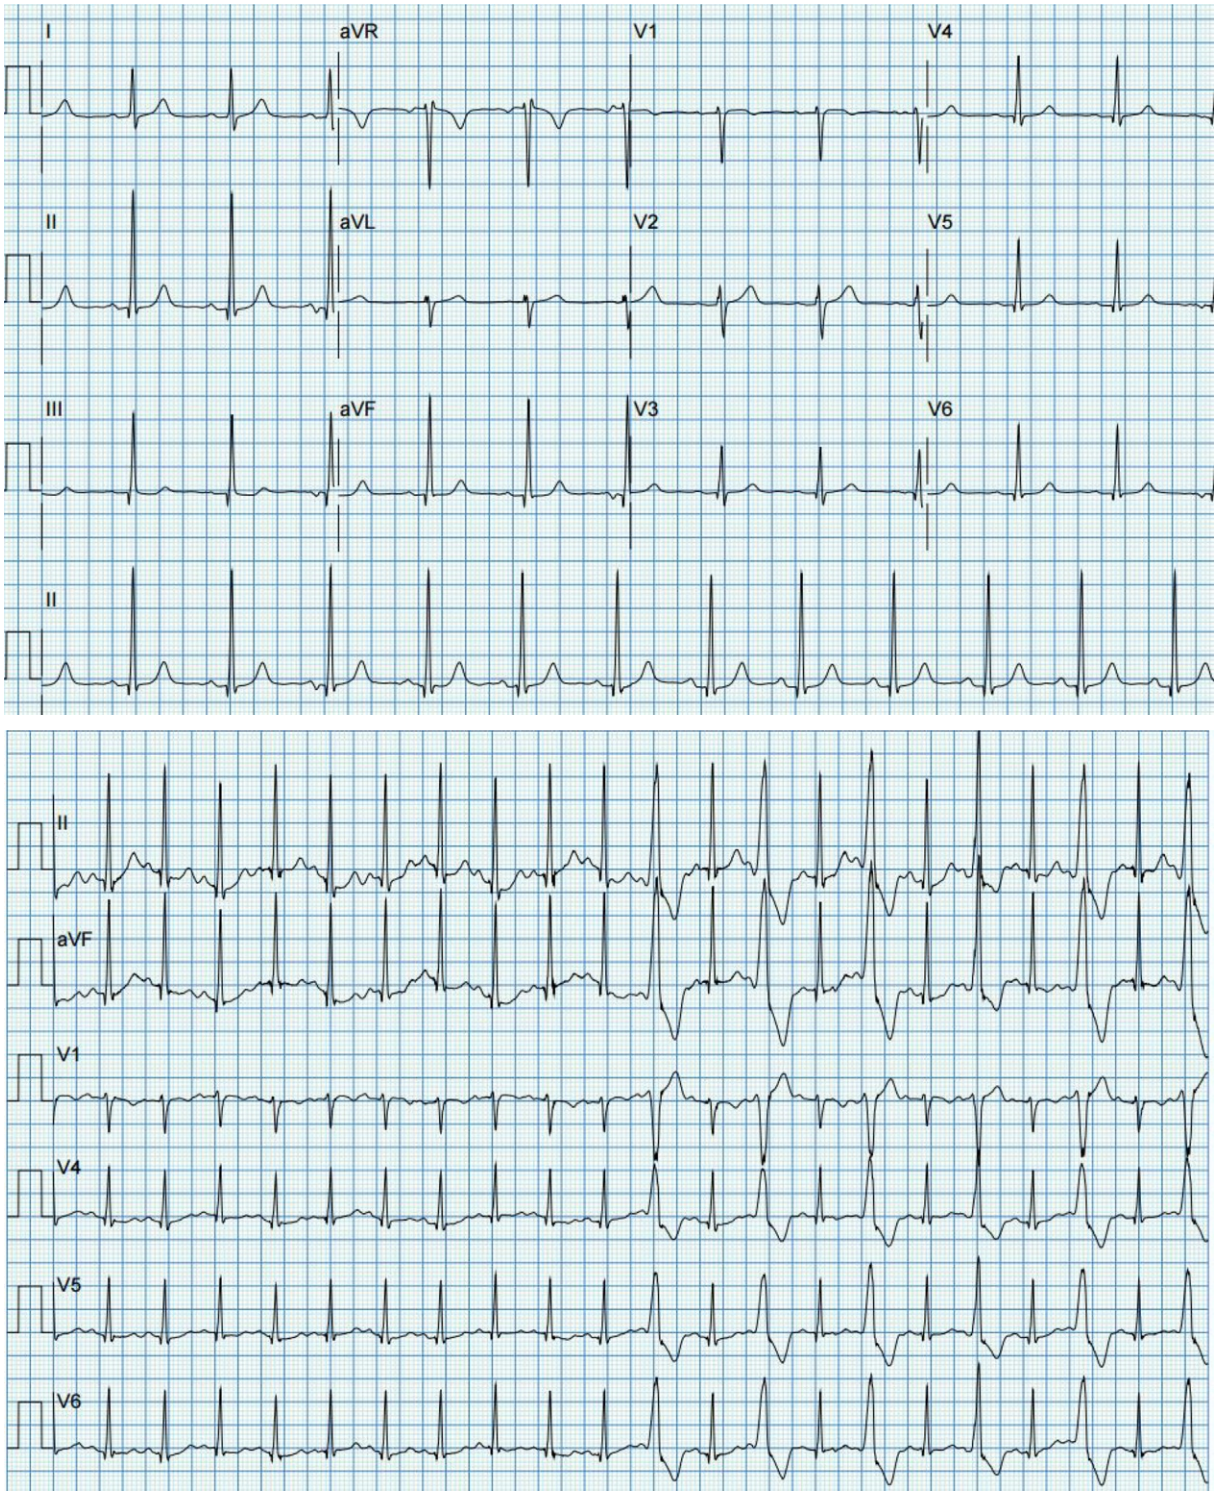

Fig. 1 Classic progression of ventricular arrhythmias in CPVT. The resting ECG is normal. As exercise progresses, single premature ventricular beats begin to emerge in a bigeminal pattern. These can be monomorphic as seen here, or polymorphic. With continued exercise, ventricular ectopy increases and nonsustained or sustained polymorphic or bidirectional VT develops.

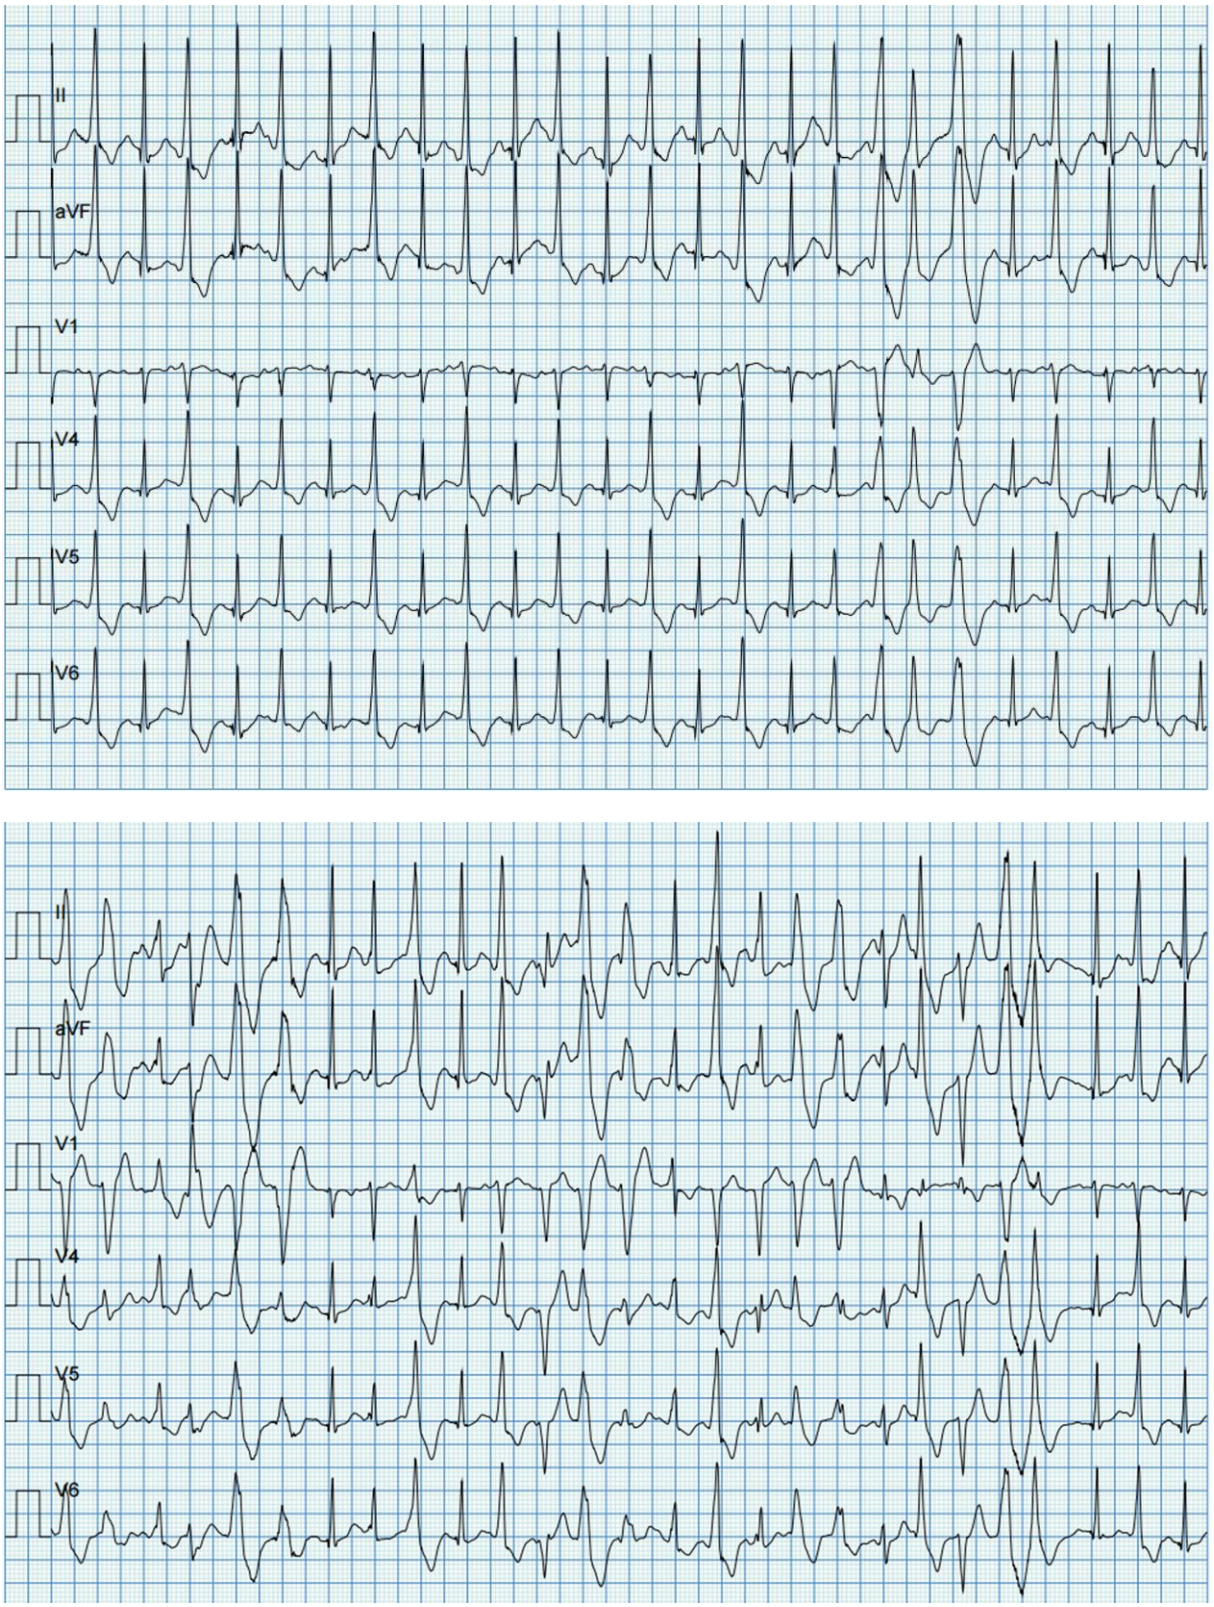

Fig. 1 Cont'd

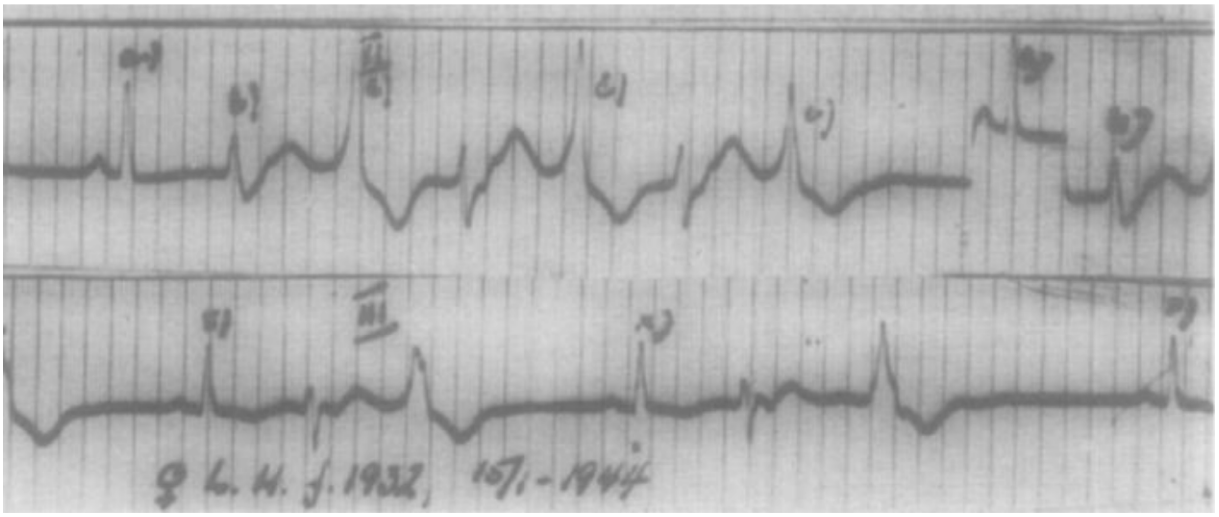

Fig. 2 Recording of nonsustained bidirectional VT from 1944. This ECG was obtained in a 12 year-old girl with a history of syncope who died suddenly while biking at 19 years of age. In retrospect, this was probably the first reported case of CPVT. From Berg K.J. (1960). Multifocal ventricular extrasystoles with Adams-Stokes syndrome in siblings. *American Heart Journal* 60, 965–970.

particular aversion." They too speculated that the etiology involved "excessive liberation of adrenalin combined with a particularly sensitive myocardium." In 1975, His-bundle recording was used in a 6-year old with effort/stress induced bidirectional tachycardia, proving the mechanism was indeed ventricular (Reid et al., 1975). Coumel published the first series in 1978, but the comprehensive series of 21 children published by Leenhardt in 1995 unified the term "CPVT" (Coumel et al., 1978; Leenhardt et al., 1995).

Genetics and Molecular Mechanisms

Under normal conditions, after myocyte depolarization, voltage-gated L-type calcium channels open and a small amount of calcium enters the cytoplasm. This results in calcium-induced calcium release (CICR) from the sarcoplasmic reticulum (SR), where the bulk of intracellular calcium is stored, bound to calsequestrin (**Fig. 3**). Massive amounts of calcium then enter the cytoplasm from the SR through calcium release channels, called ryanodine receptors (see below). Calcium activates the contractile apparatus, and then is taken back into the SR via the sarco/endoplasmic reticulum calcium-ATPase (SERCA2), and a small amount gets extruded via the sodium-calcium exchanger (NCX). The primary arrhythmogenic mechanism underlying CPVT is excessive calcium leak from the SR during periods of adrenergic stress, resulting in delayed after depolarizations (DADs) and triggered activity (Liu et al., 2006).

The Cardiac Ryanodine Receptor

The most common form of CPVT is familial and inherited in an autosomal dominant fashion, resulting from mutations in the gene encoding the cardiac ryanodine receptor (*RYR2*). Ryanodine receptor is an unusual name for an ion channel, and has an interesting etymology (Yuchi and Van Petegem, 2016). In 1796, Danish botanist Martin Vahl described a new plant that he named *Ryania speciosa*, in honor of John Ryan, a physician who had sent him many plant samples. This plant has insecticidal properties, and when the active molecule ($C_{25}H_{35}NO_9$) was isolated in 1948, it was named "ryanodine." This poison binds with high affinity to the major calcium release channels of the sarcoplasmic reticulum, hence the term "ryanodine receptors." The identification of mutations in *RYR2* underlying CPVT was found nearly simultaneously by two independent groups in 2001 (Priori et al., 2001; Laitinen et al., 2001). Current literature suggests that over half of clinically affected CPVT patients carry a putative pathogenic *RYR2* mutation (Hayashi et al., 2009).

The underlying proarrhythmic molecular mechanism in CPVT is excessive calcium release from the SR, leading to DADs and triggered activity. There are multiple mechanisms by which mutations in *RYR2* can lead to excessive calcium release (Watanabe and Knollmann, 2011). One mechanism involves spontaneous calcium release when SR calcium content reaches a critical level [store-overload-induced calcium release (SOICR)]. Certain mutant RyR2 channels have an increased sensitivity to activation by luminal calcium, and thus a lower threshold for SOICR (Jiang et al., 2004). Another mechanism involves a protein called FKBP12.6 (calstabin 2), which normally binds to RyR2 and stabilizes the channel in the closed state. During exercise, calstabin 2 partially dissociates from the channel, resulting in increased calcium release. Certain CPVT-linked mutations in *RYR2* reduce the affinity of calstabin 2 for RyR2 channels and increase single-channel activity (Wehrens et al., 2003). Another mechanism involves defective interdomain interactions of the RyR2 protein. In this hypothesis, the N-terminal domain and the central domain, common sites for disease-linked mutations, interact with each other, effectively closing the channel in the resting state. A mutation in either domain

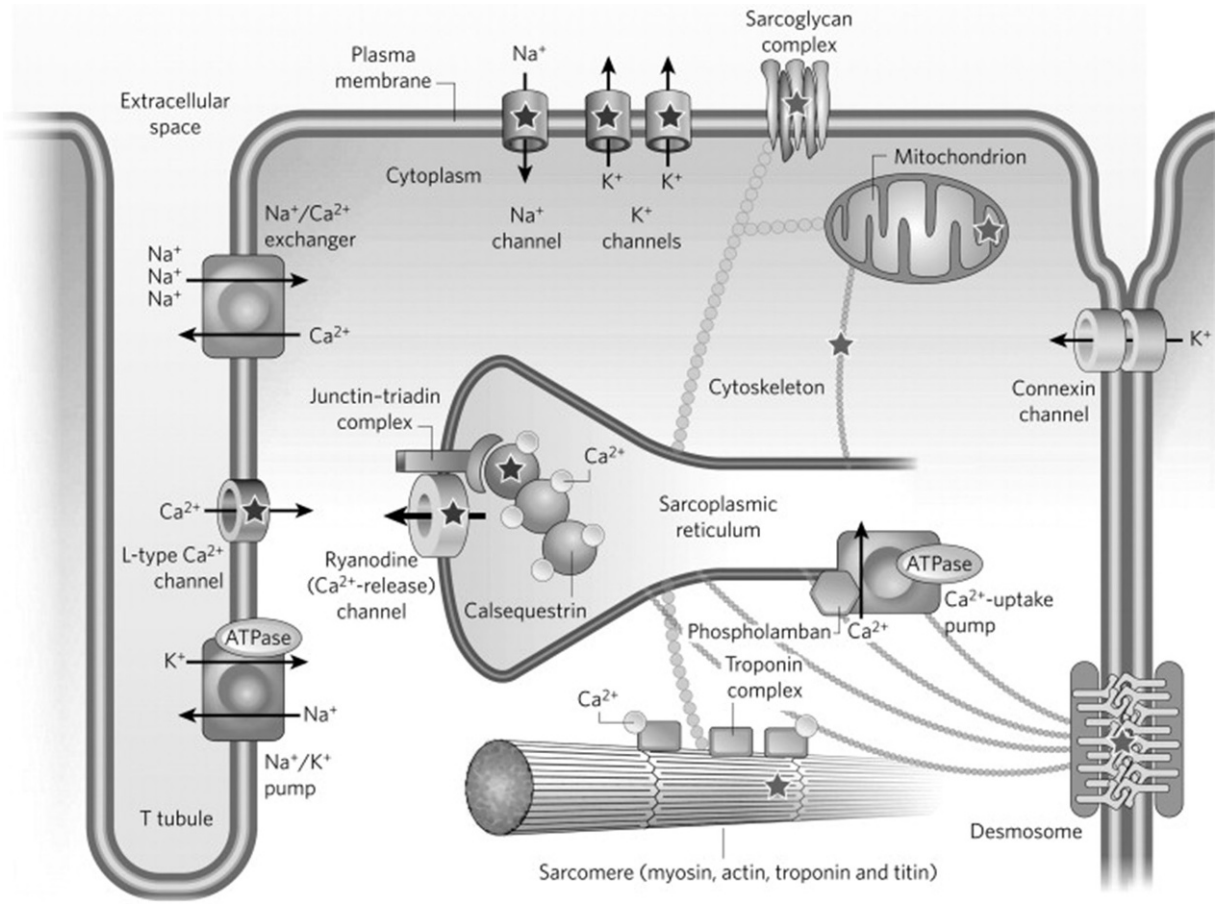

Fig. 3 Protein complexes, cardiomyocyte architecture, and intracellular organelles involved in excitation–contraction coupling. Entry of calcium ions into the cell triggers the release of calcium from the sarcoplasmic reticulum through the RyR2 channel. Calcium then binds to the troponin complex and activates the contractile apparatus (the sarcomere, bottom). Relaxation occurs on removal of calcium from the cytosol via calcium uptake into the sarcoplasmic reticulum where calcium binds to calsequestrin and via calcium transport out the cell by the Na/Ca exchanger. From Watanabe H., Knollmann B.C. (2011). Mechanism underlying catecholaminergic polymorphic ventricular tachycardia and approaches to therapy. *Journal of Electrocardiology* 44, 650–655.

can weaken the interdomain interaction, resulting in domain "unzipping" in the resting state, resulting in activation of the channel and diastolic calcium leak (Suetomi et al., 2011).

Cardiac Calsequestrin

Mutations in the cardiac calsequestrin gene (*CASQ2*) were identified to underlie CPVT in 2001 (Lahat et al., 2001). Cardiac calsequestrin is the major calcium binding protein in the sarcoplasmic reticulum. Classically, *CASQ2*-mediated CPVT is inherited in an autosomal recessive fashion, with disease manifestation in homozygous (or compound heterozygous) individuals, while heterozygous family members appear unaffected (de la Fuente et al., 2008). In some cases, heterozygous family members have been described with a mild phenotype (exercise or catecholamine-induced arrhythmias), and recent work has demonstrated fully penetrant autosomal dominant CPVT from heterozygous *CASQ2* mutations (Postma et al., 2002; Gray et al., 2016). CPVT due to *CASQ2* is reported in several consanguineous families described from one particular geographic region, but it is a relatively uncommon (≈5%) cause of CPVT worldwide. Nevertheless, lack of cardiac calsequestrin in model systems has informed much of the molecular mechanisms underlying CPVT, including some emerging new therapies, as outlined below.

Cardiac Triadin

After a decade with only two identified CPVT genes (*RYR2* and *CASQ2*) mutations in triadin (*TRDN*) were associated with autosomal recessive CPVT in 2012 (Roux-Buisson et al., 2012). The *TRDN* gene undergoes alternative splicing to encode a family of multiple triadin proteins which are expressed in skeletal muscle (TRIadin SKeletal, or Trisk), with one isoform expressed in both cardiac and skeletal muscle (Cardiac Triadin, or CT1/Trisk32). In the initial report, mutations in triadin were identified in 2/97

CPVT probands without mutations in *RYR2* or *CASQ2*, using a candidate gene strategy investigating both triadin and junctin. After the initial report, two other families with autosomal recessive CPVT due to *TRDN* mutations have been reported (Rooryck et al., 2015; Walsh et al., 2016). Most of the reported mutations result in a premature stop or an unstable protein that is degraded, thus it is expected that affected patients have a complete lack of triadin in both cardiac and skeletal muscle. Interestingly, mild skeletal muscle weakness or motor delay has been described in some *TRDN* CPVT patients.

Calmodulin

Mutations in calmodulin have also been associated with autosomal dominant CPVT (Nyegaard et al., 2012). Calmodulin is encoded by three distinct genes (*CALM1* on chromosome 14, *CALM2* on chromosome 2, and *CALM 3* on chromosome 19), but all encode a protein product with the identical amino acid sequence, each of which is expressed in human heart tissue (Crotti et al., 2013). Calmodulin is an essential calcium binding protein that transduces calcium signals in a wide range of biological processes including muscle contraction, by binding to larger proteins and functioning as a local calcium sensor. Initially, a mutation in *CALM1* was identified by linkage analysis in a large CPVT family, and a second CALM1 mutation was identified in an unrelated CPVT proband. Subsequently, mutations in *CALM2* and *CALM3* have been identified in CPVT patients (Makita et al., 2014; Gomez-Hurtado et al., 2016). Mutations in these three genes have also been identified in cases of long QT syndrome (Crotti et al., 2013; Makita et al., 2014; Reed et al., 2015). Calmodulin mutations that cause CPVT promote arrhythmogenic calcium disturbances (Hwang et al., 2014), while those that cause LQTS prevent inactivation of L-type calcium currents (Limpitikul et al., 2014).

TECRL

Recently, homozygous mutations in the trans-2,3enoyl-CoA reductase-like (*TECRL*) gene have been implicated in an arrhythmia syndrome with features overlapping CPVT and LQTS (Devalla et al., 2016). These patients had normal to mild QT prolongation at rest, some with paradoxical QT prolongation during catecholamine infusion, but all had exercise-induced ventricular arrhythmias, more characteristic of CPVT. *TECRL* encodes an endoplasmic reticulum protein expressed predominantly in human heart and skeletal muscle. Investigation of disease-associated mutant *TECRL* in human induced pluripotent stem cell cardiomyocytes (hiPSC-CMs) showed downregulation of RYR2 and CASQ2, and increased propensity for DADs under adrenergic stimulation, as well as mildly prolonged action potential duration. Although it appears to be an uncommon cause of CPVT, *TECRL* could be considered in autosomal recessive CPVT.

Therapy

As patients with CPVT are at risk for syncope, cardiac arrest, and sudden death, therapy is warranted, even in asymptomatic patients. It is recommended that patients with CPVT should limit or avoid competitive sports and strenuous exercise (Priori et al., 2013). Furthermore, beta-blockers (see below) are recommended for all patients with a clinical diagnosis of CPVT. Exercise testing has been shown to provide prognostic information, with persistent ventricular couplets or NSVT portending higher risk of subsequent cardiac events (Hayashi et al., 2009). Additional pharmacologic and/or nonpharmacologic therapies should be considered for patients who continue to have couplets or NSVT on exercise testing despite maximally tolerated nonselective beta-blocker therapy.

Beta-blockers

The benefits of beta-blocker therapy in CPVT have been recognized since the earliest reports (Berg, 1960), and it has been shown that events after diagnosis are significantly reduced by beta-blocker therapy (Hayashi et al., 2009). Currently, nearly all CPVT patients are treated with beta-blockers (Roston et al., 2015). Nadolol, a long-acting nonselective beta-blocker, has been the preferred drug in CPVT, typically at doses of at least 1–2 mg/kg/day. Large cohort studies have suggested a lower event rate with nadolol compared to other beta-blockers (Hayashi et al., 2009). In a study examining the incidence and severity of ventricular arrhythmias during serial exercise tests in 34 CPVT patients, nadolol was superior to metoprolol at equipotent doses (Leren et al., 2016). Of note, exercise-induced arrhythmias during treatment with metoprolol were similar to those observed on no therapy (**Fig. 4**). Current evidence supports using nadolol for CPVT. Where nadolol is unavailable, propranolol has been suggested as the best alternative. While beta-blockers are the mainstay of CPVT pharmacologic therapy, event rates despite beta-blockers remain unacceptably high warranting additional therapy in the subset with persistent ventricular couplets or NSVT on exercise testing (van der Werf et al., 2012).

Calcium Channel Blockers

Excessive calcium release through RyR2 channels, the molecular defect in CPVT, is initiated by calcium influx through the L-type calcium channels. Thus, calcium channel blockers would seem to have a credible role in CPVT therapy. Indeed, prior to 2009, many experts used verapamil in addition to beta-blockers for severely affected CPVT patients. Intravenous verapamil was associated with a decrease in ventricular arrhythmias during exercise testing in six *RYR2* mutation-positive CPVT patients (Swan et al., 2005). Oral

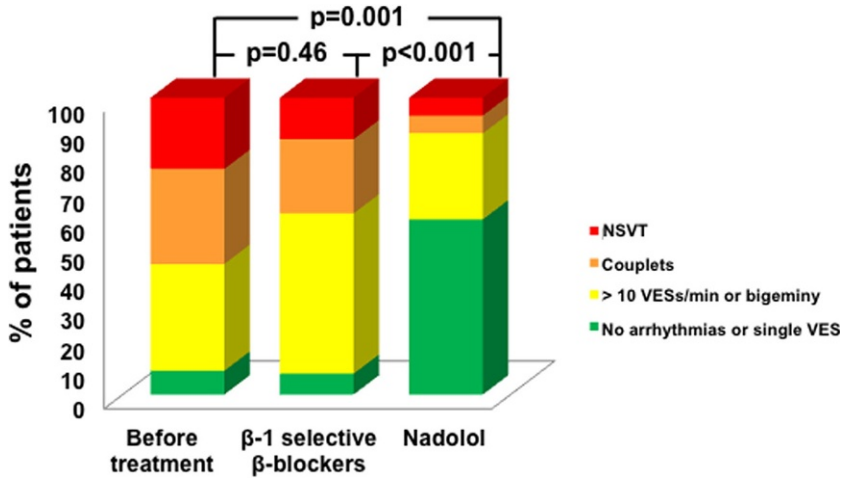

Fig. 4 Incidence and severity of arrhythmias during exercise stress tests in 34 patients with CPVT before the initiation of β-blocker treatment *(left)*, during treatment with β1-selective β-blockers *(middle)*, and during treatment with nadolol *(right)*. Arrhythmias were less frequent and less severe during nadolol treatment than both before the initiation of β-blocker treatment and during β1-selective β-blocker treatment, whereas there was no difference between β1-selective β-blocker treatment and before the initiation of β-blocker treatment. *CPVT*, catecholaminergic polymorphic ventricular tachycardia; *NSVT*, nonsustained ventricular tachycardia; *VES*, ventricular extrasystoles. From Leren I.S., Saberniak J., Majid E., Haland TF2, Edvardsen T., Haugaa K.H. (2016). Nadolol decreases the incidence and severity of ventricular arrhythmias during exercise stress testing compared with β1-selective β-blockers in patients with catecholaminergic polymorphic ventricular tachycardia. *Heart Rhythm* 13, 433–40.

verapamil, when added to beta-blocker, was associated with a decrease in exercise-induced arrhythmias in five CPVT patients, compared to beta-blockers alone (Rosso et al., 2007). Unfortunately, in medium-term follow-up, these patients continued to have arrhythmic events (Rosso et al., 2010), an experience mirrored by other groups (van der Werf et al., 2012). Most practitioners now use flecainide (see below) rather than calcium channel blockers as an additional pharmacologic agent in CPVT.

Flecainide

Flecainide is known primarily as a class IC sodium channel blocker, and was initially FDA-approved for the suppression of VT in 1984. In 2009, it was reported that flecainide directly targets the molecular defect in CPVT by blocking RyR2 calcium release (Watanabe et al., 2009). In a calsequestrin knockout mouse model of CPVT, flecainide was highly effective in preventing exercise-induced VT, and flecainide showed striking efficacy in two severely affected human CPVT patients. The precise mechanism underlying flecainide's efficacy in CPVT is controversial; some groups have implicated sodium channel block and/or the sodium/calcium exchanger, rather than direct RyR2 block by flecainide (Smith and MacQuaide, 2015). Nevertheless, the clinical data supporting a protective effect in human CPVT patients is fairly robust. In three retrospective cohort studies, flecainide added to beta-blockers significantly reduced exercise-induced ventricular arrhythmias compared to beta-blockers alone in 29 genotype-positive (primarily *RYR2*) patients, 12 genotype-negative patients, and 10 *CASQ2* homozygous mutation-positive patients (van der Werf et al., 2011; Watanabe et al., 2013; Khoury et al., 2013). In a prospective, placebo-controlled, randomized crossover clinical trial, flecainide + maximally tolerated beta-blockers (primarily nadolol) resulted in significantly reduced ventricular arrhythmias during exercise testing compared to placebo + beta-blockers (Kannankeril et al., 2017). Flecainide doses in the trial consisted of 100–200 mg twice daily (200–400 mg total daily dose), with target trough serum levels >0.5 mcg/mL. In children aged 1–12 years, doses of 100–200 mg/m^2/day and given at 8 h intervals (three times per day) may be required to achieve effective levels (Perry and Garson, 1992). Flecainide is now recommended for CPVT patients who have incomplete arrhythmia suppression on beta-blockers (Priori et al., 2013). Although it is recommended that all CPVT patients take beta-blockers, flecainide as monotherapy may be an option for patients who are truly beta-blocker intolerant (Padfield et al., 2016).

Propafenone

After the discovery that flecainide blocks RyR2 channels, all class I drugs marketed in the United States were studied with respect to RyR2 channel inhibition (Hwang et al., 2011). Only flecainide and propafenone inhibited RyR2 channels, while quinidine, procainamide, disopyramide, lidocaine, and mexiletine had no effect. Propafenone, also known primarily as a Class IC antiarrhythmic drug, is a racemic mixture of S- and R-enantiomers. Each enantiomer has similar potency for blocking sodium channels, while the S-enantiomer has moderate beta-blocking activity (Stoschitzky et al., 1990). R-propafenone was nearly as potent as flecainide in reducing RyR2 open probability, while S-propafenone was less potent. Reduction in exercise-induced VT in a CPVT mouse model was directly related to potency of RyR2 block, rather than sodium channel block (Hwang et al., 2011). Propafenone use was associated with a significant reduction in implantable cardioverter-defibrillator (ICD) discharges and exercise-induced

ventricular arrhythmias in a single patient (in Turkey, where flecainide is not available for clinical use). Data are limited, but propafenone would appear to be a reasonable alternative to flecainide for CPVT in regions of the world where flecainide is unavailable.

Implantable Cardioverter-Defibrillators

The ICD has been used in the management of CPVT, particularly after aborted cardiac arrest or recurrent VT/syncope despite optimal medical therapy. However, ICD use in CPVT is confounded by several factors. First, the target population is young compared to the general ICD population and younger age is associated with a higher rate of complications. Second, the relatively high rate of supraventricular arrhythmias may lead to inappropriate shocks. Third, the catecholamine surge after an ICD shock (appropriate or inappropriate) may trigger VT storm. Indeed, instances of SD despite an ICD have been reported (Sy et al., 2011). Finally, data from two independent cohorts demonstrate that ICD shocks are highly ineffective for treating polymorphic/bidirectional VT in CPVT (Fig. 5) (Miyake et al., 2013; Roses-Noguer et al., 2014). Combined, these studies analyzed 37 CPVT patients with ICD's who received 236 shocks, 138 of which were appropriate (delivered for VT or VF). ICD shocks in CPVT patients were effective (resulting in primary termination) in 62/66 (94%) VF episodes, but only effective in 1/72 (1.4%) VT episodes. Inappropriate shocks were observed in 43% of the combined cohorts. Presently, many experts avoid ICD implantation in CPVT, favoring beta-blockers in combination with flecainide or left cardiac sympathetic denervation (LCSD) as an alternative. When implanted, ICD programming should be tailored with longer detection times and higher detection rates, ideally to treat VF but not VT. This can be difficult if not impossible in some cases.

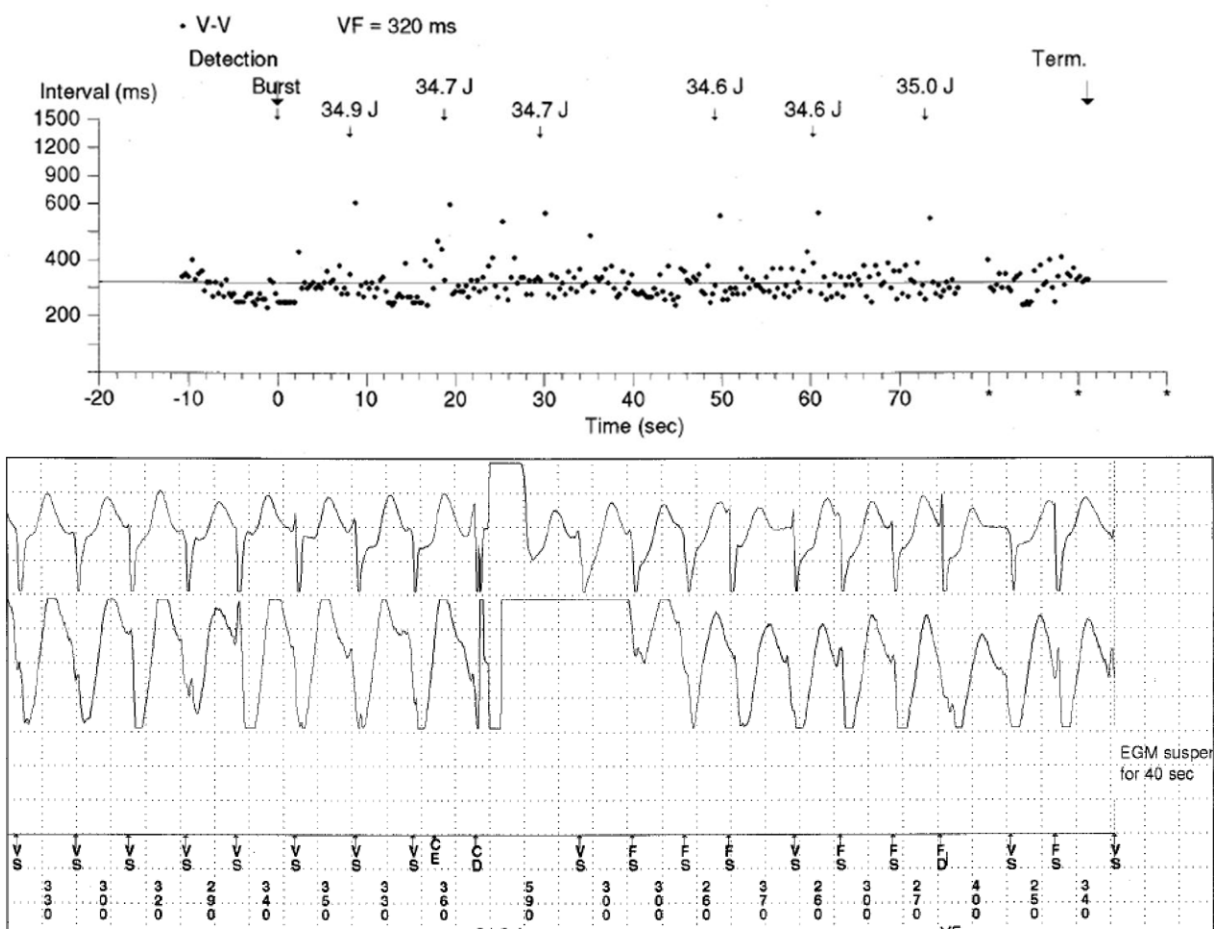

Fig. 5 ICD tracing from a CPVT patient showing ineffective shocks for polymorphic VT. Top panel displays RR interval (ms) on the *Y*-axis and time (s) on the *X*-axis. The RR interval is irregular, and after the programmed 24/32 beats fall below the threshold for tachycardia detection by the ICD, an ineffective burst of antitachycardia pacing (Burst) is delivered, followed by a series of six ineffective shocks (34.9 J, 34.7 J, 34.7 J, 34.6 J, 34.6 J, and 35.0 J delivered). *Bottom* panel displays the near-field *(top)* and far-field *(middle)* electrograms and marker channel *(bottom)* showing polymorphic ventricular tachycardia which is unaffected by the ICD shock. After six shocks, the ICD is not programmed to deliver more therapy, and eventually the VT spontaneously terminates.

Left Cardiac Sympathetic Denervation

LCSD is a surgical procedure which prevents norepinephrine release in the heart and raises the threshold for ventricular fibrillation (Schwartz, 2014). The procedure has evolved from one that required a thoracotomy or supraclavicular incision, to the minimally invasive video-assisted thoracoscopic surgical (VATS) approach. The high thoracic left sympathectomy technique, in which the lower half of the stellate ganglion and the first four or five left thoracic ganglia are removed results in a very low incidence of Horner's syndrome and provides the antifibrillatory effect (Cho, 2016). LCSD in CPVT was first reported in a series of three patients in 2008 (Wilde et al., 2008), followed by other small case series, and one relatively large (63 patients) international report (De Ferrari et al., 2015). The data show a clear reduction, but not complete elimination, of cardiac events post-LCSD in CPVT patients who comprise a relatively high-risk group. LCSD should be considered for CPVT patients with cardiac events despite optimal medical therapy.

Gene Therapy

Preliminary work toward gene therapy for *CASQ2*-mediated CPVT is currently being performed. In 2012, Silvia Priori's group reported successful viral gene transfer of *CASQ2* using an adeno-associated viral vector (AAV9) into neonatal *casq2* knockout mice (Denegri et al., 2012). After 20 weeks, these mice showed normal levels and subcellular localization of calsequestrin and associated proteins, as well as a lack of the typical epinephrine-induced arrhythmias so readily apparent in the *casq2* knockout mouse. Subsequent work from the same group used the AAV9-*CASQ2* construct to deliver normal *casq2* into mice homozygous for the R33Q *casq2* mutation—a model more representative of human CPVT patients (Denegri et al., 2014). A single injection in newborn mice resulted in normalization of calsequestrin protein levels and lack of an arrhythmia phenotype even 1 year after injection. Similar findings were observed when injected into adult mice as well. The lack of an arrhythmia phenotype was observed despite only an AAV9-*casq2* infection rate of only about 40% of myocytes. While there are still several hurdles to overcome, these exciting results open the prospects for gene therapy in *CASQ2*-mediated CPVT.

Outline

Atrial fibrillation (AF) is the most common sustained arrhythmia encountered in clinical practice. The contemporary management of AF is centered on symptomatic improvement, as well as reduction in the AF-associated morbidity and mortality. For many symptomatic patients catheter ablation offers an efficacious alternative to maintaining sinus rhythm when antiarrhythmic drugs have been ineffective, are contra-indicated, or cannot be tolerated. Over the past 15 years, catheter ablation has moved from an "experimental therapy" to the standard of care for the maintenance of sinus rhythm. Unfortunately, while the results of ablation are unequivocally superior to medical therapy, recognized limitations of the contemporary AF ablation procedures have spurred several developments designed to improve the efficacy of the index ablation procedure, while limiting adverse events. The purpose of this review is to discuss the procedural refinements, and technological innovations proposed to improve the outcome of patients undergoing a percutaneous catheter ablation procedure for AF. This article focuses on a high-level review of the methods of a first

procedure for catheter ablation of AF, as it is impossible to provide a detailed discussion of the nuances of each approach to AF ablation in a single review. Moreover, we have not included a discussion on the approach to a repeat AF ablation, or the mapping and ablation of atypical flutter.

Evolution of Current Ablation Strategies and Techniques

Initial attempts at catheter ablation for atrial fibrillation attempted to recreate the surgical maze procedure, which followed the "multiple wavelet hypothesis" of AF (Leitch et al., 1991; Cox et al., 1991). This theory postulated that AF results from the continuous annihilation and regeneration of multiple independent coexisting wavelets that occur simultaneously and propagate randomly throughout the left and right atria. This hypothesis suggested that if the atrium had a sufficient area (or electrical mass) with adequately short refractory periods AF could be initiated and then indefinitely perpetuated. As such, the early attempts at interventional AF treatment aimed to decrease arrhythmia perpetuation by compartmentalizing the atrium into smaller regions incapable of sustaining the critical number of circulating wavelets (i.e., reducing the excitable mass of atrial tissue).

Unfortunately these percutaneous approaches were only marginally successful and carried relatively high complication rates. The discovery in the late 1990s by Haïssaguerre and colleagues that AF was a triggered arrhythmia initiated by rapidly repetitive discharges originating predominantly from the pulmonary veins (PVs) represented a monumental shift in thinking around AF (Haissaguerre et al., 1998). As a result percutaneous procedures designed to isolate these PV triggers were developed. While isolation of the pulmonary veins remains the cornerstone of the invasive management of paroxysmal AF the ablation strategy itself has undergone significant evolution over the past 15–20 years. Initially, the procedure targeted elimination of the focal triggers within the PV however this approach was associated with modest clinical efficacy (frequent PV reconnection), and an elevated risk of complication (PV stenosis). Thereafter the procedure evolved to target the more proximal extensions of the PV myocardial sleeves, whereby the earliest PV potentials were targeted at the tubular ostium of each vein (usually guided by a multipolar, circular catheter). Although this "segmental" or "ostial" isolation resulted in improved outcomes, the recognition that sites of AF initiation and/or maintenance were frequently located within the PV antrum resulted in a shift in ablation strategies to target the more proximal perivenous LA tissue. These early circumferential PV ablation strategies aimed to "compartmentalize" a significant portion of the LA via the creation of wide encircling lines of ablation outside and around the PV antra within the LA body (LACA or WACA). As this approach did not necessarily document electrical isolation of the PVs it was limited by the induction of a high rate of iatrogenic macro reentrant arrhythmias due to residual LA–PV connections. The contemporary AF ablation procedure has evolved to a hybrid of the above approaches, whereby circumferential ablative lesions are placed within the LA myocardium outside of the tubular veins with a goal of electrical pulmonary vein isolation (i.e., bidirectional conduction block documented on a circular mapping catheter placed at the PV ostia). This contemporary approach, as recommended by major heart rhythm societies, therefore targets not only the initiating triggers of AF (the PVs) but also the mass of electrically active LA tissue capable of sustaining the AF perpetuating fibrillatory wavelets (Calkins et al., 2012).

Given the certainty of this endpoint more recent studies have focused on procedural refinements aiming to increase the effectiveness of the lesion set to obtain more durable PVI in paroxysmal AF patients. Specifically, postisolation adenosine testing (to unmask dormant PV conduction or reconnection) and the use of contact force sensing catheters have demonstrated improved clinical outcomes. Likewise, novel technological innovations such as cryoballoon ablation, laser ablation, and multielectrode ablation designed specifically for PVI will continue to evolve in the hopes that alternative energies or delivery mechanisms will lead to improved outcomes.

While the isolation of the PV antra has become the "cornerstone" of all contemporary AF ablation procedures, it may not be sufficient for all patients. In the case of persistent AF, electrical and structural remodeling leads to a preponderance of non-PV triggers as well as a shift in the sites required for AF perpetuation to regions outside the PV–LA junction. Proposed adjunctive ablation strategies include: (1) Linear ablation, which is derived from the surgical Cox MAZE procedure and follows the aforementioned "multiple wavelet hypothesis" for AF; (2) Complex fractionated atrial electrograms (CFAE) ablation, which are local signals during AF that are either at a very short cycle length or fractionated with two or more components. It is postulated that they represent areas of slow conduction, conduction block, or "pivot" points for a local AF perpetuating reentry; (3) "Rotor ablation," which is based on the "localized source hypothesis" that proposes that AF is perpetuated by discrete, organized, and rapid micro reentrant circuits (rotors) or focal impulses that disorganize into fibrillatory waves at their periphery. Several techniques have been proposed to identify these potential pathophysiologic sites including: (a) Shannon entropy analysis of invasive bipolar signal amplitude distribution to differentiate the pivot from surrounding peripheral regions (Ganesan et al., 2013) and (b) simultaneous multielectrode activation analysis using a proprietary 64-electrode catheter and a software algorithm (Focal Impulse and Rotor Modulation, FIRM, RhythmView, Topera, Inc.). With respect to the latter, a spatiotemporal activation analysis of simultaneously recorded electrograms using this panoramic mapping catheter is performed. Using this proprietary technology a digital electroanatomic map is created revealing focal impulses (defined by centrifugal activation isochrones from a point origin) or electrical rotors (defined as sequential isochrones around a center of rotation with waves emanating outwardly) (Ganesan et al., 2013; Cuculich et al., 2010). While the incremental benefit of each of these approaches requires extensive study, it is most likely that the major innovations in the interventional management of more advanced AF will be centered on refining the overall ablation strategy, as well as tailoring the specific approach to the individual patient.

Preablation Management

Patient Selection

In current practice, AF ablation is recommended for patients with symptomatic atrial fibrillation intolerant of, or refractory to ≥ 1 antiarrhythmic drugs. In selective circumstances AF ablation may be considered as a first line therapy in patients who have not trialed antiarrhythmic drug therapy.

Preablation Antiarrhythmic Drug Management

Drug treatment for nonarrhythmic indications is generally continued prior to an AF ablation. In terms of antiarrhythmic drug therapy, there is no consensus with regard to continuation or discontinuation. If the latter approach is chosen then they should be discontinued at least four half-lives prior to the procedure in order to avoid confounding the results of the ablation procedure.

Preablation Anticoagulation Management

An effective anticoagulation therapy is most often required prior to an ablation procedure. The majority of patients undergoing an AF ablation procedure will require preprocedure oral anticoagulation, with the exception of a paroxysmal AF patient with a CHADS Score of 0. All other patients have an indication for continuous anticoagulation owing to elevated stroke risk (CHADS Score ≥ 1) or the need for cardioversion at the time of ablation (persistent AF >48 h prior to ablation). If warfarin is the chosen agent for preprocedure anticoagulation, then current practice would suggest continuation of OAC therapy throughout the procedure (perform the procedure on a therapeutic INR). For patients receiving NOACs there is debate regarding the safety of performing an ablation without interruption. Until clear evidence of safety, most procedures would be performed after NOAC interruption (discontinuation the day prior to the procedure for rivaroxaban, apixaban, and dabigatran, except in the case of dabigatran with an CrCl <50 mL/min in which case the medication would be discontinued 2 days prior).

Preablation Imaging

Transthoracic echocardiogram is usually performed as part of the routine AF management and can be utilized to assess cardiac function, chamber dimension, and to exclude significant valvular pathology. Cardiac CT or MRI imaging can be performed as part of the preprocedure planning in order to define variant pulmonary anatomy, assess PV dimensions and angulation, as well as define atrial scar burden (MR imaging). These cardiac CT or MR images may be integrated with the electroanatomic mapping system. Preablation transesophageal echocardiographic (TEE) imaging may be used to exclude LA thrombus, which is especially useful in those who did not receive adequate preprocedure anticoagulation. If performed in the EP laboratory the TEE (or intracardiac echocardiography) can be utilized to guide transseptal puncture.

Intraprocedural Management

Left Atrial Access

A discussion regarding left atrial access technique is beyond the scope of the current article. In general an AF ablation procedure necessitates 1 or 2 transseptal punctures to facilitate left atrial access for the ablation catheter and the circular mapping catheter. These punctures can be performed with fluoroscopic guidance, intracardiac echocardiographic guidance, or TEE-guidance using standard techniques.

Intraprocedural Anticoagulation

In order to minimize the risk of intraprocedural thromboembolic complication anticoagulation should be administered as soon as left atrial access is obtained. In our practice we administer a bolus of IV unfractionated heparin of 100–130 IU/kg (100 IU/kg for warfarin anticoagulated patients, 120 IU/kg for dabigatran anticoagulated patients, and 130 IU/kg for rivaroxaban and apixaban anticoagulated patients), followed by additional boluses q15–30 min to maintain an activated clotting time (ACT) target of 300–350 s. Alternatively, an infusion of 15–18 IU/kg/h may be employed. The rationale underlying this ACT target is the observation that intravascular sheath thrombus markedly decreased with a target ACT >300 s.

Sheath Management

In our practice the left atrial sheaths are continuously irrigated with heparinized saline at >60 mL/h.

Atrial Fibrillation Ablation—Strategies

At present, multiple approaches have been developed for catheter ablation of patients with paroxysmal and persistent AF. The current techniques of catheter ablation target the elimination of AF initiating triggers and as well as AF maintaining substrate, while

Table 1 Ablation Strategies for Atrial Fibrillation.

Approach	*Techniques*	*Endpoint*
Wide-area or left atrial circumferential ablation (WACA/LACA)	Circumferential point-by-point ablation Multielectrode ablation	Abatement of bipolar voltage by 90% (or <0.05 mV within the encircled area)
PV Isolation Alone	Circumferential point-by-point antral PVI (preferred to ostial or segmental PVI) Multielectrode circumferential PVI (e.g., PVAC, nMARQ) Cryoballoon-based PVI	PV Isolation (bidirectional conduction block)
PVI + defragmentation	Point-by-Point PVI + Complex Fractionated Atrial Electrogram (CFAE) ablation Multielectrode ablation (PVAC + MAAC/MASC)	PVI plus elimination of high-grade CFAE (secondary—AF interruption, AF noninducibility)
PVI + LA Compartmentalization	PVI/LACA + linear left atrial ablation (roof, mitral isthmus) ± cavotricuspid isthmus ● Consider CFAE ± CS isolation if immediate relapse or AF refractory to cardioversion Multielectrode ablation (PVAC + TVAC)	PVI plus bidirectional linear conduction block
PVI + defragmentation + LA Compartmentalization	PVI + CS and SVC isolation followed by CFAE ablation followed by linear ablation (roof, mitral isthmus ± CTI)	PVI plus bidirectional linear conduction block plus sinus rhythm restoration
Scar-based Ablation	Identification and sequestration or elimination of abnormal LA fibrosis	Elimination or isolation of low voltage areas
Rotor Ablation	Ablation at the center of rotation or focal impulse origin	AF termination or ablation time at that source reached 10 min
Non-PV Triggers	Targeted point-by-point ablation of AF initiating triggers	
Autonomic ganglionated plexi ablation	Targeted point-by-point ablation of left atrial gangionated plexi sites	Abolition of vagal reflexes induced by high frequency stimulation

Legend: AF - atrial fibrillation, CFAE - complex fractionated atrial electrograms, CS - coronary sinus, LA - left atrial, MAAC - multi-array ablation catheter, MASC - multi-array septal catheter, PV - pulmonary vein, PVI - pulmonary vein isolation, PVAC - Pulmonary Vein Ablation Catheter, TVAC - tip versatile ablation catheter.

employing the least amount of ablation necessary. The primary endpoint of AF ablation is the completion of the predetermined lesion set, with determination of bidirectional linear block (in order to limit the development of proarrhythmia and late procedural failure). Secondary procedural endpoints include AF termination and/or noninducibility. A summary of the different approaches proposed for catheter ablation of AF, and their procedural endpoints are presented in **Table 1**.

Pulmonary Vein Isolation

Since assuming the dominant ablation strategy for AF, pulmonary vein-based ablation has undergone significant modification over the past 15–20 years. Initially, the procedure targeted elimination of the focal triggers within the PV musculature; however this "segmental" approach was associated with modest clinical efficacy (frequent PV reconnection), and an elevated risk of complication (PV stenosis). Thereafter the procedure evolved to target the more proximal extensions of the PV myocardial sleeves, whereby the earliest PV potentials were targeted at the tubular ostium of each vein. These "ostial" PVI procedures are usually guided by a multipolar, circular mapping catheter (15, 20, or 25 mm fixed diameter, or 15–25 mm variable diamete) positioned at the atrial side of each pulmonary vein ostia. A series of segmental lesions are then created until isolation of the vein can be demonstrated by disappearance of the venous potentials on the circular mapping catheter. Although these "segmental" and "ostial" isolation resulted in improved arrhythmia-free outcomes, the recognition that sites of AF initiation and/or maintenance were frequently located within the PV antrum resulted in a shift in ablation strategies to target the more proximal perivenous LA tissue.

These early circumferential PV ablation strategies aimed to "compartmentalize" a significant portion of the LA via the creation of wide encircling lines of ablation 0.5–2 cm outside and around the PV antra within the LA body. The procedural endpoint for these 3D EAM-guided LACA (left atrial circumferential ablation) or WACA (wide circumferential ablation) procedures was a 90% reduction in local bipolar voltage (or to less than 0.05 mV). As this approach did not necessarily document electrical isolation of the PVs it was limited by the induction of a high rate of iatrogenic macro reentrant arrhythmias due to residual LA–PV connections.

The contemporary AF ablation procedure has evolved to a hybrid of the above approaches, whereby circumferential ablative lesions are placed within the LA myocardium outside of the tubular veins (0.5–2 cm outside the PV ostia), but with a goal of electrical pulmonary vein isolation [bidirectional conduction block consisting of entrance block—the stable absence of conduction from the LA into the PV, and exit block—stable absence of conduction from the PV into the LA]. This contemporary approach, as recommended by major heart rhythm societies, therefore targets not only the initiating triggers of AF (the PVs) but also the mass of electrically active LA tissue capable of sustaining the AF perpetuating fibrillatory wavelets (Calkins et al., 2012).

Waiting Phase

An observation period after completion of PVI may be used to assess and reablate spontaneous recovery of PV-atrial conduction. In recent studies using a waiting period post-PVI, acute PV reconnection was observed in 27% of patients with a waiting period of 20 min (Macle et al., 2015), 33%–48% of patients with a waiting period of 30 min (Rajappan et al., 2008; Wang et al., 2007; Ninomiya et al., 2009), and in 42%–93% of patients with a waiting period of 60 min (Wang et al., 2007; Cheema et al., 2007; Bansch et al., 2013; Kobori et al., 2015). The prevalence of time-induced PV reconnection is most frequent at 30 min, with a significant proportion of patients having further reconnection at 60 min and very few between 60 and 90 min (Yamane et al., 2011). In a retrospective study including patients undergoing a repeat ablation procedure for recurrent AF, ROC curve analysis revealed a strong negative correlation between the observation time after complete PVI during the initial procedure and chronic PV reconnection (Nakamura et al., 2013). This study suggested an optimal cut-off value was 35 min, although the diagnostic accuracy did not seem to be very high (sensitivity 66.9%, specificity 60.6%) (Nakamura et al., 2013). Unfortunately, randomized studies evaluating the utility of a waiting period reported conflicting results. In one study, the success rate of ablation was 60.7% in patients randomized to no observation period, 84.3% in patients assigned to a 30-min, and 86.7% in those assigned to a 60-min observation time post-PV isolation ($p=0.04$) (Wang et al., 2007). Another trial randomly assigned patients to no observation time versus 60 min waiting time post-PV isolation and reported no difference in arrhythmia-free survival between the two groups (Bansch et al., 2013). Based on the available data, monitoring for at least 20 min following initial PVI should be considered. In practice, the main limiting factor for a longer observation period is the impact on the total procedure duration and workflow in the electrophysiology laboratory.

Intraprocedural Assessment of Durable Isolation

Unfortunately, while electrical PVI may be achieved acutely the transient injury induced at the time of index ablation may recover as the acute effects of RF-induced tissue injury resolve, revealing gaps in the initial line of ablation and allowing PV triggers to excite the adjacent LA and induce AF (Kowalski et al., 2012; Ouyang et al., 2005; Verma et al., 2005). As a result several techniques have been proposed to identify regions of incomplete ablation and/or residual gaps within the index ablation line. One such technique is the use of intravenous adenosine (or adenosine triphosphate, ATP) to transiently restore cellular excitability and thus differentiate permanent PV-atrial conduction block from dormant conduction (i.e., viable but latently nonconducting tissue). This is typically achieved by the administration of 12–18 mg adenosine as an IV push to attain one blocked P wave or a sinus pause ≥ 3 s. Sites of dormant conduction, as defined by the re-appearance of PV activity for ≥ 1 beat, are then targeted for ablation until all sites of acute, adenosine-provoked reconnection have been eliminated on sequential adenosine testing (Miyazaki et al., 2012; Matsuo et al., 2007; Kumagai et al., 2007; Macle et al., 2012; Matsuo et al., 2011). This approach was evaluated in the randomized Adenosine Following Pulmonary Vein Isolation to Target Dormant Conduction Elimination (ADVICE) trial, which demonstrated a prevalence of dormant conduction in 53% of patients post-PVI. While the presence of dormant conduction was associated with increased risk of of atrial tachy-arrhythmia recurrence, the elimination of dormant conduction resulted in a 56% relative risk reduction (27% absolute risk reduction, $P<0.0001$) in recurrence of atrial tachy-arrhythmias when compared to those in whom DC was not targeted for ablation.

An alternative strategy is the "pace-capture-guided" approach whereby, after completion of PVI, the antral ablation line encircling the ipsilateral PVs is mapped while pacing at high output from the ablation catheters distal electrode pair (Eitel et al., 2010; Steven et al., 2010). Additional ablation can be performed in areas where local LA capture is identified, with the goal of closure of these residual gaps. While there is a reasonable rationale underlying this latter approach, the evidence base support such a strategy is limited (Eitel et al., 2010; Steven et al., 2010). Specifically a recent randomized study demonstrated that this technique significantly improved arrhythmia-free survival compared to conventional PVI; however, comparable long-term success rates have been observed between an adenosine-guided PVI approach and a pace-capture-guided ablation strategy (Andrade et al., 2013; Steven et al., 2013).

Novel Tools for PVI

While focal point-by-point radiofrequency catheter ablation has shown considerable success, the procedure is time-consuming and highly dependent on operator competency (Calkins et al., 2009). As such, considerable effort has been directed toward developing technologies to achieve safer and more effective PV isolation that is less reliant on operator dexterity.

Contact Force Sensing Catheters

Ablation electrode–tissue contact is important determinant of lesion size and durability. Unfortunately the widely used surrogates of catheter–tissue contact (fluoroscopic imaging of the catheter tip motion, tactile feedback, and local electrogram attenuation, as well as impedance reductions during energy delivery) have poor accuracy when compared to direct assessment. In contrast, contact force sensing technology provides the operator with an accurate real-time quantitative estimation of the contact force between the tip of the catheter and the target myocardium. It is hoped that assessment of contact force will improve efficacy by minimizing the delivery of ineffective lesions with inadequate contact force, as well as decrease the risk of complications. Recent data suggest that

incorporating contact force data into the ablation strategy results in a reduction in procedure time, ablation time, and total energy delivery, with a comparable safety profile to that observed with standard irrigated RF (Reddy et al., 2012; Neuzil et al., 2013). However, the two largest multicenter trials evaluating this technology demonstrated a 1-year success of 68% (TactiCath, TOCCASTAR (Reddy et al., 2015)) and 74% (SmartTouch, SMART-AF(Natale et al., 2014)). In the case of the former the success was no different from that observed with standard noncontact force RF ablation. Interestingly, posthoc analyses of these studies have suggested that the outcomes were improved when the procedure was performed with adequate CF parameters (84% 1-year freedom from AF in the 47% of patients in whom ablation was in the target range $\geq$80% of the time in SMART-AF, and 76% 1-year freedom from AF in the 57% of patients in whom $\geq$90% of the lesions were >10 g in TOCCASTAR). To date, no differences in the incidence of complications have been reported between patients undergoing ablation with the contact force vs. noncontact force sensing RF ablation catheters in randomized (TOCCASTAR) or nonrandomized studies (Reddy et al., 2015; Andrade et al., 2014; Marijon et al., 2014).

Cryoballoon Ablation

The cryoballoon system (Arctic Front; Medtronic, Minneapolis, MN) consists of a steerable 10.5-Fr catheter with distally mounted polyurethane and polyester balloons specifically designed to facilitate PVI. Cryothermal ablation has the advantages of freeze-mediated catheter adhesion ansures catheter stability, which is beneficial when ablating unstable regions such as the ridge between the left atrial appendage and left-sided PVs. Moreover, the lesions resulting from cryothermal ablation have: (1) a well-demarcated and homogeneous border, which is thought to be less arrhythmogenic and may decrease the incidence of post-PVI atrial tachycardia; (2) minimal endocardial surface disruption and are less thrombogenic the lesions produced with RF energy, which may reduce the risk of thromboembolic complications; and (3) a relatively preserved ultrastructural tissue integrity, which should result in a lower acute perforation risk and a lower longer-term incidence of PV (Herrera Siklody et al., 2011; Gaita et al., 2011). Moreover, the use of a large cryoballoon catheter results in a large antral circumferential lesion resulting in both electrical PVI and substantial left atrial substrate modification (mean extent of LA ablation 40.2 $\pm$ 3.9%).

Recently the multicenter, randomized FIRE and ICE trial reported was designed to determine whether cryoballoon ablation was noninferior to RF ablation in symptomatic patients with drug-refractory paroxysmal AF (Kuck et al., 2016). Patients were randomized to cryoballoon ablation (374 patients) vs. irrigated RF ablation (376 patients). The primary efficacy endpoint (documented recurrence of AF > 30s/AT/AFL, AAD prescription, or reablation) occurred in 138 patients in the cryoballoon group and in 143 in the RF group (1-year Kaplan–Meier event rate estimates, 34.6% and 35.9%, respectively; hazard ratio, 0.96; 95% confidence interval [CI], 0.76 to 1.22; $P < 0.001$ for noninferiority). However, the study was not an exclusive comparison of advanced technologies, with the majority of patients receiving noncontact force irrigated RF ablation (284/376 in the RF group) and 90 of 374 patients receiving first generation cryoballoon ablation. Taken together the cumulative experience with this established technology suggests that cryoballoon ablation is efficacious and comparable to RFCA for maintaining sinus rhythm at 1 year in patients with paroxysmal AF undergoing a PV isolation procedure.

Multielectrode Radiofrequency Ablation

Multielectrode catheters are another purpose-built AF ablation toolset that was developed to address the technical difficulties associated with created continuous radiofrequency lesions. The pulmonary vein ablation catheter (PVAC, Medtronic Ablation Frontiers, Carlsbad, CA) is a 9-F deflectable circular multielectrode catheter that enables mapping and circumferential PV ablation (en electrodes with 3-mm interelectrode spacing mounted on a nitinol frame). For persistent AF, two additional catheters, i.e., the multiarray septal catheter (MASC) and the multiarray ablation catheter (MAAC), were developed to facilitate LA mapping and substrate modification for patients with more persistent forms of AF. The accompanying GENius multichannel, duty-cycled RF generator enables the delivery of energy in a unipolar (between electrode and indifferent electrode on the body) or bipolar (between any two adjacent electrodes) configuration to all electrodes simultaneously or individually. Together, the catheters potentially allow the performance of PVI and LA substrate ablation with less effort than standard catheter ablation. Recently the irrigated multi-electrode nMARQ ablation system (Biosense Webster) has been developed. Similar to the PVAC the nMARQ allows multielectrode ablation with any or all of the 10 catheter electrodes. The key difference between the nMARQ system is its integration into the CARTO3 platform allowing full visualization of the catheter loop and electrodes, as well as the fact that the catheter electrode is circumferentially irrigated.

Non-PV Trigger Ablation

Although the PVs are the major site of ectopic AF initiating triggers, recent evidence has demonstrated the importance of nonpulmonary vein triggers. Depending on the population being studied non-PV triggers have been documented in approximately 10%–20% of patients undergoing AF ablation and have been described (in descending order of frequency) in the superior vena cava, the left atrial free wall or left atrial appendage, the coronary sinus ostium, the ligament of Marshall, the crista terminalis or right atrial free wall, the interatrial septum, and rarely a persistent left SVC (Chang et al., 2012; Lin et al., 2012; Chen and Tai, 2005).

Non-PV triggers are found more frequently in female patients, patients with nonparoxysmal AF, patients with more advanced atrial substrate (i.e., dilated or electrically abnormal atrial tissue), and those with more comorbidities (Chang et al., 2012). As the presence of non-PV triggers is independently associated with a worse outcome after catheter ablation (HR 2, 95% CI 1.4–2.85), the elimination of non-PV triggers has been suggested to improve long-term outcomes for patients with persistent AF (Chang et al., 2012; Lin et al., 2012; Dixit et al., 2012). It is important to note only 30% of patients with identified non-PV triggers are able to have them succesfully eliminated due to difficulties with localization; however those in whom the non-PV triggers were eliminated had an improved arrhythmia-free outcome compared to those in whom triggers were idenitifed but could not be eliminated (86% vs. 37%; $P=0.09$).

Non-PV triggers may be noted spontaneously or after the infusion of isoproterenol (1–20 mcg/min). To facilitate the identification of non-PV triggers catheters are typically placed in the left atrial appendage (CMC), the superior vena cava (CMC), the coronary sinus (decapolar catheter), and the inferior right atrium (decapolar). Following the induction of an AF triggering PAC the mapping catheter is displaced toward the trigger origin site, the patient cardioverted and the procedure repeated. Once identified, the procedure for ablation of these non-PV trigger sites is variable depending on the source. Isolation of the superior vena cava or persistent left superior vena cava can be employed in a method similar to PVI, while using great care to avoid inadvertent collateral damage to the phrenic nerve. Ablation of a CS musculature course is performed in a manner similar to other focal sources and does not require CS isolation. Ablation of the ligament of Marshall can often be targeted from the LA endocardium and only rarely requires direct ablation from the CS.

Linear Left Atrial Ablation

Conceptually the rationale underlying linear LA lesions originates from the surgical Cox maze procedure and follows the aforementioned "multiple wavelet hypothesis" (Haissaguerre et al., 1994). Linear lesions are generally deployed across the left atrial roof and/or at the mitral isthmus in an effort to compartmentalize the LA. In doing so they may prevent macro reentrant tachycardias that can occur post-AF ablation, as well as the modify the structures that harbor key "rotor" sites for AF maintenance (e.g., LA posterior wall, roof, mitral annulus, and septum). Unfortunately, the efficacy of linear ablation is dependent on the achievement of complete contiguous and transmural lesions that result in complete conduction block, which can be very difficult to achieve. Thus, whereas complete lines may result in conversion of AF directly to sinus rhythm and prevent recurrent arrhythmias, if incomplete they may be proarrhythmic. There does not appear to be any benefit to the addition of linear lesions in combination with PVI in paroxysmal AF patients (77% 1 year success for PVI + linear ablation versus 73% with PVI alone in one study), although the results are conflicting (Verma, 2011; Hocini et al., 2005). While two small, randomized trials have suggested a slight advantage may be present in persistent AF patients (aggregate arrhythmia-free survival of 54% 1 year success for PVI + linear ablation versus 23% with PVI alone) the large randomized multicenter STAR-AF 2 trial did not demonstrate any clinical benefit (59% freedom from recurrent atrial fibrillation after 18 months with PVI, vs. 46% of patients assigned to pulmonary-vein isolation plus linear ablation; $P=0.15$) (Verma, 2011; Gaita et al., 2008; Verma et al., 2015).

Linear ablation of the left atrial roof is performed for the treatment of a roof dependent perivenous flutter. The line of ablation is extended from the superior margins of the encircling PV lesions using an irrigated RF catheter employing one of three approaches: (1) *Direct extension* from the LSPV to RSPV using a superiorly oriented catheter (perpendicular). The line is extended inferiorly and septally via clockwise rotation and catheter flexion; (2) *Large loop* (parallel tip)—Catheter is looped around the lateral, inferior, septal, and then cranial walls before entering the LSPV ostia. Withdrawal of the catheter drags a line back from the LSPV to the RSPV; (3) *Small loop* (parallel tip)—Catheter is maximally deflected near the left superior PV so that the tip is facing the right PV. Releasing the curve positions the catheter tip adjacent to the right superior PV ostia and allows dragging as the sheath/catheter assembly is pushed toward the LSPV.

Linear ablation of the mitral isthmus is performed for the treatment of perimitral flutter—clockwise or counterclockwise. The line of ablation is extended from the lateral mitral annulus and the left inferior PV ostium. The irrigated RF ablation catheter is introduced through a long sheath and positioned on the lateral mitral annulus (usually at around 4 o'clock in the LAO projection) at an angle between 90 degrees (perpendicular; poor contact) and 180 degrees (parallel; good contact) to the plane of the CS. The lesion is usually commenced at the ventricular aspect of the lateral mitral annulus (targeting an AV ratio of 1:1 or 2:1 on the ablation catheter). The sheath and catheter are rotated clockwise to extend the lesion posteriorly to the ostium of the LIPV (approximately 2 o'clock in LAO). Unfortunately it can be difficult to achieve a transmural lesion across the mitral isthmus due to the myocardial thickness as well as cooling effect of the CS. In approximately 50% of cases ablation will need to be performed within the coronary sinus at a site opposite the endocardial ablation lesions. The catheter should be deflected toward the endocardium to maximize contact with the atrial side of the CS and to reduce the risk of left circumflex artery injury.

Linear ablation of the anterior left atrium is performed for the treatment small anterior reentrant circuits that can occur in persistent or permanent AF. Beginning at the anterior mitral annulus the ablation catheter is progressively withdrawn while the sheath is rotated counterclockwise to increase contact with the anterior and anteroseptal wall of the LA. At the level of the transseptal puncture, clockwise rotation is applied to the sheath, and the ablation catheter is progressively extended to the right PVs or to the roof line. Note that this lesion set may substantially delay activation of the lateral LA and the LA appendage resulting in a significant reduction in the contribution of LA appendage emptying.

Linear Ablation Endpoint

The electrophysiological endpoint of linear lesions is the demonstration of bidirectional line of block, i.e., widely separated local double potentials along the length of the ablation line, with demonstration of activation moving toward the line when pacing from both sides of the line. For the *roof line* the activation pattern should be caudocranial on the posterior wall during left appendage pacing, and the conduction time to the LAA should shorten as the pacing site is moved inferiorly from the ablation line along the posterior wall. For the *mitral isthmus line* the activation sequence of the coronary sinus should invert from distal–proximal to proximal–distal during pacing anterior to the line in the LA close to the mitral annulus. Pacing on the posterior aspect of the line via the CS results in late activation on the opposite side, with progressively shorter activation in the anterior LA (e.g., LAA) as the pacing site is moved toward the septum from distal to proximal CS. For the *anterior left atrium line* pacing at the anterior LA immediately lateral to the ablation line results in activation propagating laterally and posteriorly around the mitral annulus to reach the septal aspect of the LA and the opposite side of the line. As the anterior pacing site is moved further from the ablation line (i.e., toward the lateral LA) the conduction time to the opposite side should correspondingly shorten.

Complex Fractionated Atrial Electrogram Ablation

Complex fractionated atrial electrograms (CFAEs) are local low-voltage (usually <0.25 mV) multipotential signals during AF that are either at a very short cycle length (<120 ms), or are fractionated with two or more components, and/or a continuous perturbation of the baseline. It is postulated that they represent areas of slow conduction, conduction block, or "pivot" points for a local AF perpetuating reentry. The primary goal of the CFAE-guided ablation is complete elimination of these substrate areas, with subsequent conversion to sinus rhythm (or alternatively organization of AF into an atrial tachycardia). Unfortunately, the underlying mechanisms causing CFAEs remain controversial. While fractionation may be recorded close to the core of a rotor, it may also be recorded at the periphery of rotors as well as at sites not actively participating in the AF process (i.e., bystander sites of passive wavelet collision). It is hoped that automated algorithms to facilitate the objective determination of CFAE sites, and/or the coadministration of intravenous ibutilide might facilitate the identification of CFAE sites critical to AF maintenance by eliminating areas of passive atrial activation.

Similar to linear lesion, studies have demonstrated that CFAE ablation as a lone ablation strategy is inadequate for both paroxysmal and persistent AF (Verma et al., 2010; Estner et al., 2008). Likewise, in the paroxysmal AF population there appears to be limited benefit for adjunctive CFAE ablation (three small studies all individually failed to demonstrate significant benefit, however the pooled success was greater in the PVI + CFAE group [83% vs. 72% for PVI alone]) (Verma, 2011; Verma et al., 2010; Deisenhofer et al., 2009; Di Biase et al., 2009). Similar to the results of linear ablation observational and randomized studies have suggested that ablation of CFAE areas in addition to PVI improves the procedural outcome (two positive randomized trials, and one negative randomized trial; pooled single procedure success 51% in the PVI + CFAE group vs. 38% in the PVI alone group); however the large randomized multicenter STAR-AF 2 trial did not demonstrate any clinical benefit (59% freedom from recurrent atrial fibrillation after 18 months with PVI, vs. 49% of patients assigned to pulmonary-vein isolation plus complex electrogram ablation; $P = 0.15$) (Verma, 2011; Verma et al., 2015; Verma et al., 2010; Elayi et al., 2008; Oral et al., 2009).

CFAE Identification

CFAE are typically located in the interatrial septum (57%), PV ostia (40%), LA roof (near appendage; 32%), proximal CS (32%), mitral annulus (20%), and LA posterior wall, with less common sites including the crista terminalis, cavotricuspid isthmus, left atrial appendage. CFAE can be identified using visual inspection, or the aid of an electroanatomic mapping system with automated detection algorithms (**Table 2**). The CARTO (Biosense-Webster) EAM has two automated detection algorithms; (1) The *Interval Confidence Level (ICL)* examines the number of intervals identified between consecutive complexes over a specified duration (i.e., 2.5 s). The more repetitions observed (i.e., higher ICL), the more confident the categorization of CFAE (**Table 3**). (2) *Average Complex Interval (ACI)* examines the average interval between consecutive CFAE complexes (in msec) observed over a specified duration (i.e., 2.5 s). The shorter the interval, the more confident the categorization of CFAE. The NAVx EAM (St. Jude Medical) utilizes a *Fractionation Index*, which examines the averaged time between multiple, discrete deflections ($-dV/dT$; inter-deflection time intervals). The shorter the mean CL of the local EGM during AF the more rapid and fractionated the local EGM.

Table 2 CFAE Severity Gradation by detection algorithm

Fractionation Index	*CARTO—ICL*	*CARTO—ACI*
High grade	High grade ≥17	High grade 50–70
Intermediate	Intermediate 10–17	Intermediate 70–90
Low grade −120 ms	Low grade 3–9	Low grade 90–120

Table 3 CFAE Settings

Parameter	*Rationale*	*NAVx*	*CARTO*
Minimum detection threshold (peak-to-peak sensitivity)	Avoids noise	0.03–0.05 mV	0.05–0.15 mV
Interval Duration			50–120
Internal/external Projection	Avoids collection of EGMs from electrodes that are not in good contact with map shell	4–6 mm	4-6 mm
EGM refractory period	Avoids double-counting of multiphasic EGMs	35–45 ms	
EGM width	Avoids detection of broader, far-field EGMs	15–20 ms	
EGM segment length	Total recording duration at each point Obtains a mean CL for that point	5 s	
Interpolation	Maximum distance between points which will be used to assign average values for a vertex	4–6 mm	

CFAE Ablation and Endpoints

Ablation of CFAE is typically commenced at regions of highest grade CFAE (i.e., shortest intervals). Local ablation is continued until significant attenuation ($\geq$80% decrease) elimination of local EGMs occurs (local voltage $<$0.1 mV). Ablation then shifts to regions with longer grade CFAE until: (1) complete elimination of all areas with CFAE in both atria or (2) conversion of AF to normal sinus rhythm with subsequent noninducibility.

Left Atrial Scar Modification

Experimental models have shown that AF results in progressive structural changes due to electrical and structural remodeling of the atria. These interstitial fibrotic changes promote atrial arrhythmogenesis and increase the likelihood of AF initiation and perpetuation, possibly by acting as anchor sites for micro reentrant circuits or rotors. As such, procedures have evolved to target these regions in an effort to improve ablation outcomes for patients with a predominantly substrate-based arrhythmia (i.e., persistent AF).

To date six studies have evaluated the impact of scar-based ablation for persistent AF (Cutler et al., 2016; Jadidi et al., 2016; Kottkamp et al., 2016; Rolf et al., 2014; Yamaguchi et al., 2016; Yang et al., 2016). These studies are limited by small numbers of patients (31–85 patients) and significant heterogeneity (definition of scar ranging from $<$0.5 to $<$1.5 mV, variable use of multipolar catheters, rhythm during voltage mapping [sinus vs. AF], timing of mapping [before or after PVI], and duration of follow-up). However, given these limitations the success of scar-based ablation was observed to be superior in each of these low-moderate quality nonrandomized studies (27%–57% freedom from recurrent AF in the control arm vs. 69%–80% success in the scar-based ablation arm).

Scar Identification

A multipolar mapping catheter is the preferred modality to create a detailed left atrial endocardial voltage map and identify areas of scarring within the atria. This map should be created in sinus rhythm and should include the acquisition of a minimum of 500 intracardiac points. Normal myocardium is defined as a bipolar endocardial amplitude $>$0.5 mV; dense fibrosis is defined as a voltage $<$0.25 mV; and nontransmural fibrosis is defined as a voltage between 0.25 and 0.5 mV.

Scar Ablation and Endpoints

Ablation should be delivered to sites that demonstrate fibrosis (voltage $\leq$0.5 mV). For regions with an area $<$4 cm^2 the lesion set should be delivered to cover the affected area. For regions with an area $>$4 cm^2 the lesion set should be delivered to encircle the affected area.

Focal Impulse and Rotor Modulation

While the "multiple wavelet hypothesis" proposes that AF perpetuation is maintained by continuous annihilation and regeneration of randomly meandering electrical waves it fails to adequately explain the observed spatial nonuniformities in AF. An alternative "localized source hypothesis" proposes that AF may be perpetuated by organized and fast discrete micro reentrant circuits (rotors) or focal impulses that disorganize into fibrillatory waves at their periphery (i.e., central highly organized activation with surrounding variable propagation and fractionation).

Several techniques have been proposed to identify putative pathophysiologic rotor sites. These include: (1) The use of noninvasive Electrocardiographic Mapping (ECM), which allows global chamber mapping in a single beat through the use of a 252-lead surface ECG combined with computed tomography-scan-based biatrial anatomy (CardioInsight Inc., Cleveland, USA) (Shah et al., 2013); (2) Shannon entropy analysis of invasive bipolar signal amplitude distribution to differentiate the pivot from surrounding peripheral regions (Ganesan et al., 2013); (3) simultaneous multielectrode activation analysis using a novel software mapping system (FIRM, RhythmView, Topera, Inc.). With respect to this latter approach, using a 64-electrode panoramic mapping catheter the fibrillatory wave activity of widely sampled atrial sites is analyzed in the context of rate-dependent atrial repolarization and conduction. Thereafter a spatiotemporal activation analysis of simultaneously recorded electrograms and fibrillatory wave activity is performed, and a subsequent digital electroanatomic FIRM map is created revealing focal impulses (defined by centrifugal activation isochrones from a point origin), or electrical rotors (defined as sequential isochrones around a center of rotation with waves emanating outwardly). Using this approach it has been demonstrated that stable rotors and focal impulses may be the drivers of both paroxysmal and persistent AF in significant number of patients. In the CONFIRM study 2.1 ± 1.0 localized rotors (70%) or focal impulses (30%) were observed in 98 of 101 cases of sustained AF. These were found widespread across locations in the left (76%—including sites outside the pulmonary veins, posterior, inferior, roof, and anterior regions), and in the right atrium (24%—inferolateral, posterior, and septal regions). Ablation achieved AF termination in 20/36 cases (56%) with 4.3 ± 6.3 min of FIRM ablation at the primary source. In the 11/36 cases in whom AF did not terminate, AF slowed by 33 ± 12 ms. By comparison, in the FIRM-blinded group, the acute endpoint was achieved in only 13 of 65 cases with sustained AF (20%) after 43.4 ± 28.0 min of ablation ($p < 0.001$). At a median follow-up of 273 days the FIRM-guided group achieved a significantly greater long-term freedom from AF (82.4% vs. 44.9%). Interestingly, and in contrast to the studies of CFAE ablation, FIRM ablation without PVI has been shown to result in an excellent long-term freedom from recurrent AF suggesting that paroxysmal AF, like persistent AF, may be predominantly a substrate-based disease (PRECISE study).

While the targeting of focal impulses and rotors may represent a new paradigm in the invasive management of AF this approach is not without limitations. While the results of CONFIRM and PRECISE are optimistic, these results have not been widely replicated. Moreover, while FIRM has identified "rotors" in the majority of patients, alternative series have not been as successful (Ganesan et al., 2013; Cuculich et al., 2010). In addition, the temporal stability of proposed rotor sites is variable suggesting that, like CFAE, a proportion of the proposed pathogenic regions represent passive bystanders (Ganesan et al., 2013; Cuculich et al., 2010).

Ablation of Autonomic Ganglionated Plexi

Major left atrial ganglionated have been identified within the perivenous epicardial fat pads. They are located in the Anterior descending LA (anterior to the LAA), Posterolateral LA (along the anterior aspect of the left PVs), Superior LA (posterior wall behind the LSPV and the superior LIPV), Posteromedial LA (posterior wall inferior to the right PVs), Superior RA (anterior RA at the RA–SVC junction), and Posterior RA (posterior to the RA but anterior to the right PVs). They can be identified through high-frequency stimulation (HFS—cycle length 50 ms, 12 V, 1–10 ms pulse width) from the left atrial mapping catheter. This stimulation increases vagal tone, followed by either AF induction or transient bradycardia/AV block. Ablation may then be performed at the sites of positive vagal response to high-frequency stimulation until the response to high-frequency stimulation is eliminated. At this point it is uncertain whether these sites should be independently targeted for ablation, as they often reside within the circumferential pulmonary venous lesions set, or within areas of CFAE. Outcomes have thus been variable.

Postprocedure Management

The immediate postprocedural management consists of supportive treatment, achieving and maintaining hemostasis at the puncture sites, reinitiation and maintenance of anticoagulation, and rhythm monitoring.

Supportive Treatment

Vagal episodes may occur in the early postprocedure period and are typically remedied by fluid infusion and/or atropine. In the event of significant hypotension a hemodynamically significant pericardial tamponade must be excluded. Pericardial chest discomfort may occur during the first few days post ablation. Rarely this is accompanied by a mild self-limited febrile syndrome. If present it should be treated with oral analgesics, and/or anti-inflammatories (ASA, or NSAIDs) with/or without colchicine.

Hemostasis

Hemostasis is usually achieved through manual compression. In some cases percutaneous closure devices have been utilized for large caliber sheaths.

Re-initiation and Maintenance of Anticoagulation

Following the procedure therapeutic anticoagulation should be re-established as soon as possible. For those undergoing procedures without interruption, then OAC therapy should be continued. In those undergoing OAC interruption it is our practice to reinitiate

NOAC therapy 4 h postablation. In those undergoing warfarin interruption then we start LMWH 4 h post procedure and continue this until the INR is therapeutic. For NOACs there is no need for bridging as the anticoagulation effect is reestablished within several hours of the first dose.

Antiarrhythmic Drug Therapy

The use of antiarrhythmic drugs postablation has not been standardized. In some cases the AADs are discontinued prior to ablation and only restarted in the case of symptomatic or sustained recurrence. Others take the approach of prophylactically readministering AAD therapy for the first 8 weeks postablation in order to promote the sustained maintenance of sinus rhythm and facilitate reverse remodeling. As early AF recurrence usually peaks within the first few weeks following PV isolation, the temporary routine administration of antiarrhythmic drugs (AAD) in the immediate postablation period has been proposed as a potential preventive strategy (Oral et al., 2002; Roux et al., 2009). While the true efficacy of this approach is unknown, studies have suggested that transient AAD use does not prevent late arrhythmia relapses (Oral et al., 2002; Leong-Sit et al., 2011). The 5A study randomized 110 consecutive patients with paroxysmal AF undergoing ablation to empirical AAD therapy versus no AAD therapy for the first 6 weeks after RF catheter ablation (Roux et al., 2009). While the authors noted a significantly lower incidence of clinically significant atrial arrhythmias (AF >24 h or associated with severe symptoms), cardioversions, and arrhythmia-related hospitalization during the 6-week treatment period (13% vs. 28% in the AAD vs. non-AAD group; $P<0.05$), there was no difference in the 6-month freedom from recurrent AF (72% vs. 68%; $P=0.84$) (Roux et al., 2009; Leong-Sit et al., 2011). These results were paralleled in the observational study by *Oral et al.* where no difference in the occurrence of ERAT was noted between those discharged on temporary AAD therapy and those without AADs (41% recurrence on AAD [16/39 patients] vs. 32% recurrence off AAD [23/71 patients]) (Oral et al., 2002). As such, a uniform approach of empirical AAD therapy can be expected to reduce morbidity and cost of care early in the post ablation period but does not appear to have an effect on later recurrences. If administered postablation it is our practice to discontinue them 8 week postablation in order to assess for arrhythmia recurrence at the conclusion of the 3-month blanking period.

Conclusion

The invasive approach to AF management is an ever-evolving field, which encompasses several techniques designed to target the triggers and perpetuators of atrial fibrillation.

Introduction

Sustained ventricular arrhythmias are typically a manifestation of significant structural heart disease and often associated with a high risk of sudden cardiac death. Although implantable cardioverter defibrillators (ICD) remain the mainstay of therapy for the prevention of sudden cardiac death associated with these arrhythmias, recurrent ventricular arrhythmias can lead to multiple ICD shocks that are painful, decrease quality of life, and cause posttraumatic stress disorder (Zipes et al., 2006; Sweeney, 2010). Spontaneous ventricular tachycardia (VT) and ICD shocks are also associated with an increased risk of death, and progressive heart failure(Sweeney, 2010). Antiarrhythmic drugs, amiodarone in particular, are useful in reducing arrhythmic events, but have limited efficacy for long-term management, particularly for scar-related reentrant arrhythmias. In addition, antiarrhythmic drugs have the potential for significant adverse effects that include negative inotropy, proarrhythmia, and noncardiac organ toxicities that limit their long-term use. Catheter ablation offers an alternative therapy for preventing arrhythmias, and can be life saving when frequent episodes (VT storm) threaten survival.

Less commonly, VT or repetitive premature ventricular contractions (PVC) occur in the absence of structural heart disease. These arrhythmias are often termed "idiopathic" and generally carry a benign prognosis, but this is a diagnosis of exclusion and structural heart disease should be ruled out. Importantly, ventricular arrhythmias can be the initial presentation of early myocardial disease that is not detectable by echocardiography. Imaging with cardiac MRI or ^{18}F-FDG PET (for detection of sarcoid) might be warranted, especially when underlying disease is suggested by an abnormal resting ECG, family history of arrhythmias or sudden death, or unusual VT QRS morphologies. In addition to symptoms, frequent PVCs or VT, even if idiopathic, can lead to worsening of left ventricular contractile function (Lee et al., 2012).

Mapping and Ablation Technologies and Procedural Considerations

Radiofrequency (RF) current remains the most commonly used energy source. Lesion size is limited by coagulum formation on the electrode when electrode temperature exceeds 70°C. Hence, the use of cooled tip catheters that prevent excessive heating at the electrode/tissue interface has gained popularity as they allow greater delivery of RF energy to achieve deeper lesions. Cooling is achieved by fluid circulated internally or by open saline irrigation of the electrode tip (Stevenson et al., 2008). Open irrigation catheters carry the risk of intravascular fluid overload during ablation but may have a smaller risk for thrombus formation. Newer catheters incorporate feedback on contact force and have the potential for improving catheter contact with myocardium, thereby

 https://doi.org/10.1016/B978-0-12-809657-4.99778-3

potentially facilitating the creation of deeper and more consistent lesions (Ikeda et al., 2014; Hoffmayer and Gerstenfeld, 2015). Despite irrigation, some VTs originate from intramural sources that are difficult to access from the endocardial or epicardial surface. RF energy delivered through extendable, retractable needle electrodes, and via warm saline infusions has been tested in preliminary studies with promising results(Sapp et al., 2013; John et al., 2014). Simultaneous dual site delivery of unipolar RF or bipolar RF delivery across the septum or between the epicardium and endocardium has also been reported to have success in reaching deep circuits in a small number of patients (Iyer et al., 2014).

Cryoenergy delivered via catheters has the advantage of ice formation at the catheter tip with adherence to structures making it useful in situations where catheter stability is difficult to achieve as in ablation of VTs originating from the papillary muscle (Rivera et al., 2015). Experience of this technology in VT ablation is limited.

Electroanatomic mapping systems to create a three-dimensional shell of the chamber of interest improve the appreciation of the arrhythmia substrate to the anatomy and allow for catheter manipulation with limited fluoroscopy. Point by point charting of electrograms can be used to create visual maps of voltage (voltage map) or impulse propagation (activation map). Concomitant use of intracardiac echocardiography aids in the creation of the anatomic shell visualization of valve structures including papillary muscles. It also helps monitor for related complications, such as deteriorating ventricular function and pericardial effusion during the procedure (Rivera et al., 2015).

For endocardial ablations, access to the left ventricle can be obtained either retrogradely via the aortic valve or via a transeptal approach. The latter is the preferred approach for patient with severe peripheral artery disease and is mandatory for left ventricular access in patients with a mechanical aortic valve prosthesis. In a significant number of patients especially those with nonischemic cardiomyopathies and arrhythmogenic right ventricular cardiomyopathy, ventricular arrhythmia may arise from the subepicardium. In such cases, the epicardium can be approached via percutaneous access to the pericardial space. In the absence of prior cardiac surgery or pericarditis, the pericardial space can be accessed via the subxiphoid approach by introducing a needle under fluoroscopy and injection of small amounts of contrast to identify the pericardial space. Once the pericardial space is entered, a guide wire is advanced followed by a sheath for the mapping and ablation catheter. In the absence of pericardial adhesions, catheters can be moved freely on the epicardial surface for mapping (Sosa and Scanavacca, 2005). Prior to any ablation, proximity to the coronary arteries is usually assessed by coronary angiography. Ablation close to a coronary artery (within 5 mm) poses a risk of acute coronary occlusion and should be avoided (Roberts-Thomson et al., 2009). Left phrenic nerve injury is another concern and high output pacing is performed prior to ablation along the anatomical course of the nerve to assess proximity of the nerve. Phrenic nerve protection with an inflatable balloon or instillation of saline into the pericardial space may be needed in some patients. In some cases, a subxiphoid pericardial window created surgically can allow epicardial ablation in patients who have had prior cardiac surgery and have pericardial adhesions (Soejima et al., 2004). If epicardal mapping and ablation is anticipated, it is our preference to obtain access to the pericardial space prior to endocardial access and systemic anticoagulation. If, however, the need for epicardial mapping and ablation becomes apparent after endocardial access, anticoagulation can be reversed prior to pericardial puncture, and reimplemented if there are no bleeding concerns after pericardial access.

The 12-lead ECG tracing of the clinical arrhythmia is helpful in determining potential targets for ablation that can also be assessed during pacemapping (see what follows). While the ECG is often available for patients with idiopathic VT, most patients with structural heart disease will have had their arrhythmia terminated by an ICD. In cases where the ECG of VT is not documented, we often perform noninvasive programmed stimulation using the patient's ICD before induction of general anesthesia (GA) that may suppress inducibility of the arrhythmia. If spontaneous arrhythmia is absent, programmed stimulation and burst pacing with or without isoproterenol infusion or IV epinephrine boluses is utilized to provoke the arrhythmia.

Both conscious sedation and GA can potentially suppress spontaneous or inducible arrhythmia by reducing sympathetic tone. GA, however, has several advantages. Ablation procedures can be complex and can last for several hours, during which the patients are required to remain still. The frequency and depth of breathing plays an important role in determining good catheter contact and stability. Epicardial access is often easier when respiratory motion can be controlled as under GA. In general, we have adopted the use of GA for mapping and ablation of most scar-related VTs and start with conscious sedation for idiopathic PVC/VT.

Approximately two-thirds of patients with structural heart disease who are referred to us for ablation have hemodynamically unstable VT precluding extensive mapping and pacing during induced VT. In addition, patients with severe LV dysfunction can experience hemodynamic deterioration during prolonged procedures under GA. To secure hemodynamic stability during VT ablation, the availability of hemodynamic support is important. Inotropic infusions are used most commonly. An intraaortic balloon pump is the most commonly used assist device. It can improve stability after recovery from induced VT and under anesthesia, but has limited efficacy for maintaining hemodynamic stability during VT. Percutaneous LV assist devices have the advantage of maintaining end-organ perfusion during tachycardia enabling longer periods of mapping(Reddy et al., 2014). However, vascular complications are a significant concern and the overall outcome does not appear to be significantly better. Extracorporeal membrane oxygenation offers biventricular support (4–6 L/min) and can be useful during VT storms associated with hemodynamic instability. Right ventricular function can be critical in the outcomes of VT ablation; patients with severe right ventricular cardiomyopathies can deteriorate hemodynamically due to myocardial stunning even if blood pressure is maintained during induced VT (Ujeyl et al., 2013).

VT in Patients With Structural Heart Disease

The mechanism of ventricular arrhythmia is a major consideration in selection of patients for ablation. Scar-related VT is the most common mechanism of sustained monomorphic VT associated with heart disease. Reentry involving channels formed by surviving muscle bundles within or adjacent to areas of fibrosis is often the cause. Scar that supports reentrant arrhythmias can be due to prior myocardial infarction, cardiomyopathies, inflammation, infiltrative disorders, familial cardiomyopathies, or prior cardiac surgery. A single scar can support multiple reentry circuits giving rise to multiple VT morphologies. Progressive ventricular remodeling can alter the substrate for ventricular arrhythmias over time, such that the frequency and nature of arrhythmias can change. Hence, ablation of VT/VF in structural heart disease is primarily aimed at reducing episodes and ICD shocks and is usually not stand-alone therapy, without an ICD. A small number of patients with structural heart disease will have VT that involves the Purkinje system, most commonly reentry within the bundle branches that can be easily abolished by ablation.

Catheter ablation should be an early consideration for patients with recurrent monomorphic VT that requires therapy to prevent episodes (**Table 1**). For recurrent polymorphic VT, ablation is largely reserved for patients who have an identifiable triggering focus, often recognized from spontaneous PVCs that can be targeted for ablation (Alliot et al., 2009). The exception is the ventricular arrhythmias associated with Brugada syndrome. Low voltage areas are often identified in the anterior free wall and outflow tracts of the right ventricular epicardium and ablation of these areas can abolish the characteristic repolarization changes of the Brugada syndrome and prevent VT and ventricular fibrillation (VF) inducibility (Brugada et al., 2015).

The recurrence rate for sustained monomorphic VT after ablation is high with more than 40% of patients experiencing at least one recurrence over the next 2 years, but the frequency of VT is reduced for most patients (Kuck et al., 2010). Initial studies in patients with drug refractory, recurrent VT showed that catheter ablation reduced VT recurrences in over two-thirds of patients(-Stevenson et al., 2008). The VANISH trial randomized patients with prior MI and recurrent sustained monomorphic VT despite antiarrhythmic drug therapy to ablation or escalation of antiarrhythmic drug therapy. Ablation was superior to escalation of drug therapy in the combined endpoint of death, ICD shocks, or VT storm (Sapp et al., 2016).

In view of the safety and efficacy, patients are no longer required to exhaust antiarrhythmic drug therapy or present with a VT storm (commonly defined as 3 or more VT episodes within 24 h) in order to be considered for ablation. The recognition that VT is associated with adverse outcomes despite the presence of an ICD raises the question as to whether ablation should be performed early, after initial development of an arrhythmia, in patients who are receiving an ICD. The substrate mapping and ablation in sinus rhythm to halt ventricular tachycardia (SMASH-VT) study included patients presenting for the first time with VF, hemodynamically unstable VT, or syncope with inducible VT during invasive electrophysiological testing (Reddy et al., 2007). Ablation to modify the arrhythmia substrate significantly reduced the incidence of appropriate ICD therapy. The ventricular tachycardia ablation in coronary heart disease (VTACH) study included patients with ischemic heart disease, and spontaneous VT who were receiving an ICD (Kuck et al., 2010). Patients randomized to VT ablation prior to ICD implant had a 40% relative reduction in VT recurrences and fewer hospitalizations during follow-up, although approximately half of the patients treated with ablation still had at least one episode of VT. Although these studies were too small to address the effect of VT ablation on mortality, they provide support for a strategy of early intervention in centers with substantial experience in VT ablations.

Table 1 Indications for catheter ablation for ventricular tachycardia

Patients with structural heart disease
1. Symptomatic sustained monomorphic VT that recurs despite antiarrhythmic drug therapy or when drugs are not tolerated or desired
2. Incessant VT or VT storm that is not due to a reversible cause
3. Frequent PVCs, nonsustained VT or VT that is presumed to cause ventricular dysfunction
4. Bundle branch rentry or interfascicular reentrant VTs
5. Recurrent polymorphic VT or VF refractory to antiarrhythmic drugs when there is a suspected trigger that can be targeted for ablation

Patients without structural heart disease
1. Symptomatic monomorphic VT with severe symptoms
2. Monomorphic VT when antiarrhythmic drugs are not effective, not tolerated, or not desired
3. Sustained polymorphic VT or VF that is refractory to antiarrhythmic drugs when there is a suspected trigger that can be targeted for ablation

Catheter ablation for VT is contraindicated
1. Mobile ventricular thrombus in the chamber from which VT originates (epicardial ablation or alcohol ablation can be considered)
2. Asymptomatic PVCs or nonsustained VT that are not causing or contributing to ventricular dysfunction
3. VT due to transient reversible causes, such as torsade de Pointes VT related to prolonged QT

Adapted from reference Alliot, E. M., Stevenson, W. G., Almendral-Garrote, J. M., et al. (2009). EHRA/HRS Expert consensus on catheter ablation of ventricular arrhythmias. Europace, 11, 771–817.

Mapping and Ablation Techniques for Scar-Related VT

A 12-lead ECG offers multiple clues to the VT mechanisms and potential sites of origin. A left bundle branch block configuration in Lead V1 (dominant S wave) suggests an exit site in the right ventricle or the interventricular septum. A dominant R wave or right bundle branch block pattern in V1 indicates a left ventricular exit site. The QRS axis defines VT origins in the vertical plane; an inferiorly directed QRS axis suggests a superior or anterior wall exit, whereas a superiorly directed axis indicated an inferior wall exit. The precordial leads are more indicative of directionality in the horizontal plane. Deep S waves in the apical leads (V3 to V6) indicate earliest activation in the LV apex, whereas prominent R waves in these leads point to a basal origin of activation. Areas of scar, conduction block, and abnormal ventricular anatomy reduce the validity of these general rules. In patients with nonischemic heart disease, subepicardial origin of VT is suggested by wider QRS complexes and delayed initial upstrokes in the precordial leads (Valles et al., 2010). Areas of scar containing the reentrant circuits can extend over several centimeters. With current technology, it is often impossible to use mapping during VT to identify all potential sources of VT within a scar. Hence, other techniques have been developed to identify potential reentrant circuit sites.

Mapping and Ablation During VT

Scar-related VTs usually utilize a central isthmus bordered by anatomical or functional conduction barriers (Stevenson et al., 1993). When VT is hemodynamically stable, mapping during VT can often identify the isthmus where a focal ablation can terminate VT and usually render it noninducible. The location of the exit site from an isthmus is usually along the scar border and determines the QRS morphology of the VT. In the exit recordings during VT demonstrate electrograms that precede the onset of the surface QRS complexes. Early, diastolic electrograms during VT are consistent with sites proximal to the exit in the central or proximal isthmus of the circuit (**Fig. 1**). However, electrogram timing alone is not entirely reliable as a guide to successful ablation sites due to the frequent presence of multiple conduction channels, some of which may be bystanders or blind loops and other abnormal areas. Hence, additional information is sought with pacing maneuvers. Capture during pacing from the tip electrode in contact with the tissue of interest indicates electrically excitable tissue.

During VT, pacing at a rate slightly faster than the VT rate will result in continuous resetting (entrainment) of a reentrant VT. If the pacing site is within the circuit, the interval from the last paced complex to the first return cycle (postpacing interval (PPI) will approximate the tachycardia cycle length (**Fig. 1**)). Ablation is more likely to terminate tachycardia if the PPI is within 30 ms of tachycardia cycle length, but short PPIs can occur at outer loops in a broad reentry circuit where ablation is often not effective. The degree of fusion between paced and VT complexes is helpful in further refining assessment of the pacing site location relative to an isthmus involved in the VT. QRS fusion occurs if the stimulated wavefront alters activation over a large area to change the ECG. If pacing is performed from the isthmus, the stimulated wavefront emerges from the circuit replicating ventricular activation during VT, a process termed entrainment with concealed fusion (ECF) because the fusion between stimulated antidromic and orthodromic

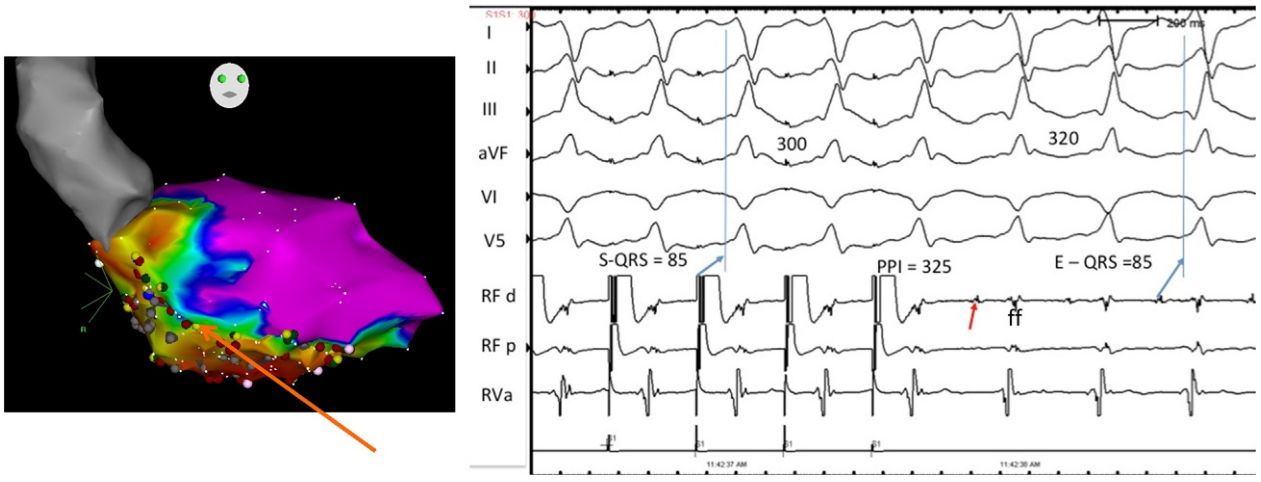

Fig. 1 Entrainment of ventricular tachycardia in a critical isthmus. Left panel—An electroanatomic map of the left ventricle in a 50 year-old male with a prior inferior myocardial infarction and sustained monomorphic VT is shown. Voltage is represented by colors overlaid on an anatomical shell of the chamber in right anterior oblique view. Normal voltage is represented by *purple* and progressively lower voltage is represented by *blue*, *green*, *yellow*, and *orange* with *red* representing scar area. Nonexcitable areas are marked with *gray dots*. Right panel: Pacing is performed at a cycle length of 300 ms during induced VT (CL 320 ms) from the septal border of a large inferior wall scar (*orange arrow* in left panel). The tachycardia is accelerated to the paced cycle length with minimal change in QRS morphology indicating concealed fusion and the site of pacing as a critical isthmus for the VT. On cessation of pacing, the tachycardia continues and the postpacing interval (PPI) approximates the tachycardia cycle length (see text for details). The *red arrow* indicates a mid-diastolic potential that is captured by the pacing; the subsequent adjacent electrogram is a far field signal (ff). The stimulus to QRS duration (S-QRS) equates the mid-diastolic potential to the QRS (E-QRS) duration of 85 ms. Ablation at this site was successful in terminating tachycardia.

wavefronts are confined in or near the circuit and is thereby concealed in the surface ECG (Fig. 1). During ECF, the S-QRS indicates the conduction time between the pacing site and the reentry circuit exit and matches the local electrogram to QRS during VT (Almendral et al., 2013). The stimulus to QRS interval (S-QRS) interval is indicative of the conduction time from the pacing site to the exit. A short S-QRS suggests a stimulus closer to the exit, whereas a long S-QRS is consistent with a more proximal pacing site location, as near the entrance to the isthmus.

Substrate Mapping During Sinus or Paced Rhythm

In patients with hemodynamically unstable VTs or in whom VT is not reliably inducible, the substrate for the arrhythmia can be targeted for ablation during sinus rhythm or a paced rhythm. For substrate mapping, a 3-D electroanatomic mapping system is used to define areas of scar by charting electrogram amplitude in a voltage map. In the ventricular endocardium, peak-to-peak bipolar electrogram voltage less than 1.5 mV is generally used as representative of areas of scarred myocardium (Fig. 1). Areas of slow conduction and late potentials within these areas of low voltage have been correlated with critical isthmus sites for reentry. Pacing from within the scar is useful to identify areas of slow conduction indicated by long stimulus to QRS time (usually >40 ms). Pacemapping in the exit site region will usually replicate the QRS morphology of the VT. A stimulated wavefront that emerges from the exit with a long S-QRS and complexes that are similar to the morphology of the VT is strongly suggestive of an isthmus involved in the reentrant VT (Bogun et al., 2006).

Several strategies for modifying the VT substrate have been described. These include targeting of sites with late potentials or fractionated electrograms that are likely to represent channels that are poorly coupled to the surrounding myocardium, circumferential ablation of the scar area, circumferential core isolation around critical VT circuit elements, or "homogenization" of the scar with extensive overlapping ablation lesions (Kuhne et al., 2010; Jais et al., 2012; de Chillou et al., 2014; Vergara et al., 2012; Tilz et al., 2014; Tzou et al., 2015; Di Biase et al., 2012; Berruezo et al., 2015). However, the optimal strategy resulting in effective ablation while minimizing unnecessary RF application and procedure time is unclear. Anatomically ablating unexcitable scar might not be necessary and abnormal electrograms may arise from tissue remote from the ablation catheter (Tung et al., 2013; Baldinger et al., 2015).

At our center, substrate modification of the scar is performed targeting regions of slow conduction evident as late or fractionated potentials. We aim for sites where pacemapping approximates the morphology of an induced clinical VT and has a stimulus to QRS delay >40 ms (Fig. 1). Ablation is usually performed with a contact-sensing catheter aiming for 10–20 g of contact force and impedance drop of 10–15 Ω during ablation. As an acute endpoint we aim to achieve noninducibility of all sustained monomorphic VT by rendering the whole scar or scar areas felt to be involved in VT circuits unexcitable to pacing (10 mA at 2 ms pulse width) or to disconnect them from healthy myocardium.

Epicardial Approach to VT Ablation

In approximately 15% of patients with VT who are referred for ablation, circuits are found to be intramural or subepicardial and not accessible with an endocardial catheter (Sacher et al., 2010). Epicardial ablation has become an essential component of ablation strategies especially for VT due to nonischemic cardiomyopathies. In ischemic heart disease, epicardial ablation is usually performed after failed endocardial ablation. An initial endo-epicardial approach can be beneficial in selected patients.

The presence of endocardial or epicardial scar can sometimes be suspected based on analysis of voltage maps created from endocardial unipolar electrograms. Unipolar signal amplitude of less than <8.3 mV may identify potential intramural or epicardial substrate (Sacher et al., 2010; Hutchinson et al., 2011). Once access to the pericardial space is obtained as described (see above), the approach is generally similar to endocardial mapping techniques. Epicardial fat can insulate the myocardium and overall, voltages tend to be lower, especially in close vicinity to large epicardial vessels and valve structures. Bipolar electrogram voltages for defining scar on the epicardium are similar to the endocardial EGM although an abnormal epicardial bipolar voltage of <1.0 mV may be more specific than 1.5 mV (Cano et al., 2009).

Transcoronary Ethanol Ablation

Deep intramural VT substrates can be difficult to interrupt permanently with endocardial, epicardial, or even simultaneous dual site ablations. Transcoronary ethanol ablation (TCEA) can be helpful in such situations (Yoshida et al., 2011). Success of TCEA depends on the presence of a patent vessel supplying the area of interest. Once a suitable branch is identified, its relationship to a critical portion of the VT circuit has to be established by observance of termination of VT with injection of iced saline or by occlusion of the branch by balloon inflation. Then, 1 cm^3 of absolute alcohol is injected distally into the branch after balloon occlusion to prevent reflux into other branches. In a series from our center, acute clinical success was obtained in 56% of patients; all VT recurrences were prevented in 36% and improved arrhythmia control was achieved in an additional 27% (Tokuda et al., 2011a). Complications include heart block and extension of infarction with further deterioration of LV function. However, in patients with intractable VT unresponsive to traditional ablation techniques, this approach can be life saving.

Other VTs

Purkinje System-Mediated Ventricular Arrhythmias

The Purkinje system can be involved in VT in approximately 10% of patients with structural heart disease and recurrent arrhythmias (Tokuda et al., 2011a). VT may be due to catecholamine sensitive automaticity or reentry involving the Purkinje system. Monomorphic PVCs, usually from the Purkinje system, have been shown to be a trigger for initiation of VF in rare patients with idiopathic VF and no recognized structural heart disease as well as in patients with various forms of cardiomyopathy including amyloid cardiomyopathy (Lopera et al., 2004; Haissaguerre et al., 2002; Bansch et al., 2003). There are also reports of successful catheter ablation of inciting PVCs in electrical storms associated with the long QT syndrome and the Brugada syndrome (Bansch et al., 2003). Suppression of recurrent VF can be achieved with catheter ablation of the local Purkinje network origin of the triggering PVCs.

Bundle Branch Reentry

Sustained monomorphic VT may be due to reentry between bundle branches (Tan et al., 2012). Usually, the circulating wavefront propagates up the left bundle and antegrade via the right bundle resulting in VT with typical LBBB pattern. This VT can be entrained from the RV apex with postpacing intervals approximating the tachycardia cycle length. A constant relationship of the His deflection preceding the QRS is seen, usually with any oscillation in the H–H interval preceding V–V cycle length alteration. Less commonly, the circuit revolves up the right bundle and down the left producing a typical RBBB type VT. Ablation of either of the bundle branches will lead to termination of the VT; ablation of the right bundle is easier and preferable to avoid induction of ventricular dysynchrony from LBBB. Most patients have evidence for conduction system disease and a third of patients will develop heart block requiring pacing support. Many patients also have other scar-related VTs requiring additional therapy.

Idiopathic Ventricular Tachycardia

Idiopathic VT, a diagnosis made after exclusion of significant structural heart disease, is usually due to focal automaticity, or reentry between fascicular bundles. Focal automaticity often results in isolated or repetitive monomorphic PVCs or VT. Catheter ablation, when successful, is often curative in these patients.

Outflow Tract VT

Approximately 80% of outflow tract VTs arise from the RV outflow tract, the majority from an area adjacent to pulmonary valve or within the proximal pulmonary artery musculature (Alliot et al., 2009; Blanck et al., 1993). VT from the RV outflow tract has a left bundle branch block pattern with transition in the precordial leads at V3 or V4. A free wall (rightward) focus is suggested by wider QRS complexes (>140 ms) and notching in the inferior leads. A more leftward focus produces deeper S waves in leads 1 and aVL, whereas a lower focus in the RV closer to the His bundle is indicated by positive QRS in aVL (Alliot et al., 2009). Precise mapping for ablation requires inducible VT or PVCs to allow activation mapping. Earliest activation at successful ablation sites precedes the surface QRS by 15–45 ms. Bipolar electrograms often show sharp rapid deflections and unipolar recordings demonstrate a QS pattern. Pacemapping to identify the site where pacing reproduces the VT QRS can be effective in guiding ablation when the arrhythmia is not present for activation mapping; but it should be recognized that exact pacemaps can sometimes be generated from sites within 4–5 mm of earliest activation (Liu et al., 2014). RF application often induces acceleration of VT before complete suppression and noninducibility of the arrhythmia.

Less frequently, outflow tract VTs originate from the LV outflow tract. These include sites in the aortic sinuses in close relation to the right and left coronary cusps or the commissure between these cusps. The noncoronary aortic sinus being in proximity to the atrial musculature is rarely the origin of these arrhythmias. Other LV outflow sites of origin are the LV summit, the region of aortomitral continuity or LV epicardium often clustered around the course of the great cardiac vein or anterior interventricular branch of the coronary sinus. QRS complexes demonstrate an inferior axis but show prominent R waves in V1 or V2. Proximity to coronary arteries often limits application of RF energy in these regions (Azegami et al., 2005; Hachiya et al., 2002).

Aortic cusp VTs emanate from extensions of the ventricular myocardium above the aortic annulus. These foci are approached from the left or right sinus of Valsalva and defined by early activation rather than pacemapping (Hachiya et al., 2002). Typically, a double component electrogram is seen in sinus rhythm due to late activation of this muscle bundle. During PVCs or VT, the second component becomes early preceding the QRS by 30–40 ms. Ablation of these targets requires that the origin of the coronary arteries be clearly defined and a safe distance between the ablation site and the arteries (>4 mm) established. Intracardiac echocardiography is useful to define the origins of the coronary arteries and in conjunction with an electroanatomic mapping system, to define the relative locations for safe ablation. Coronary angiography may be necessary for precise definition.

It is important to recognize that the electrocardiographic morphology of PVCs or VT may not be accurate in predicting the location of the initiating focus. A systemic approach is essential. In our laboratory, we begin with systematic mapping starting with the RVOT, and progress sequentially to the great cardiac vein, aortic root, and LV outflow tract including the aortomitral continuity,

and in selected cases, the epicardium based on clues from the ECG and initial mapping. In markedly symptomatic patients or those with tachycardia-induced cardiomyopathy, we have, in rare cases, utilized a surgical approach using cryoablation after mobilizing coronary vessels away from the area of interest (Lerman, 2015).

VT Arising From the Tricuspid Annulus and RV Body

In a recent report of 278 patients undergoing ablation for idiopathic PVCs or VT, 29 (10%) had VT from the lower RV body with half of them arising from regions within 2 cm of the tricuspid valve annulus (Choi et al., 2015). All had LBBB morphology. Ablation was effective in preventing long-term recurrence of PVCs or VT in 80% of patients. It is particularly important to exclude arrhythmogenic RV cardiomyopathy in such patients; voltage maps of the right ventricle can be helpful in excluding endocardial areas of RV scar, but epicardial areas of scar can escape detection during endocardial mapping.

Mitral Annulus VT

Focal VTs from the region of the mitral annulus accounted for 5% of idiopathic VTs in one series(Van Herendael et al., 2011). Areas of the valve annulus included the anteroseptal region in 58%, and posterior or posteroseptal in the remaining. Similar to aortic cusp VT, a delayed potential is observed during sinus rhythm at the valve annulus. During VT, this potential preceded the QRS by as early as 70 ms. The possibility of a remnant of the atrioventricular ring of conduction tissue has been suggested as the potential mechanism for these annular VTs. Endocardial ablation is usually successful in suppressing VT; occasionally, an approach via the coronary sinus may be necessary.

Interfascicular VT

Belhassen and coworkers demonstrated that a RBBB, left axis VT occurring in patients with structurally normal hearts could be terminated with intravenous verapamil (Tada et al., 2005). This VT typically involves the posterior fascicle in the left ventricular septum and comprises the majority of idiopathic LV VTs. Reentry involving, in part, the fascicle of the left bundle branch can be demonstrated by multielectrode mapping that often identifies the circuit along the inferoseptal aspect of the LV. Two other forms of verapamil sensitive VTs have been described; a left anterior fascicular VT with RBBB right-axis deviation and an upper septal fascicular VT with a narrow QRS configuration and a normal or right-axis deviation(Belhassen et al., 1981). For the typical posterior fascicular VT, RF ablation is usually directed at the anterograde Purkinje potentials more apically rather than proximally to avoid injury to the left bundle. Barotrauma from catheter manipulation can terminate tachycardia and render them noninducible. Empiric lines of ablation along the region may be successful in preventing recurrence.

Papillary Muscle VT

Idiopathic VT arising from an LV papillary muscle is a distinct subgroup but can demonstrate QRS morphology similar to fascicular VT(Yamada et al., 2010). The arrhythmias can be exercise induced and catecholamine sensitive, but most commonly present as PVCs rather than sustained VT. They appear to have a focal automatic mechanism. Differentiation from fascicular VT is based on absence of early Purkinje potentials, spontaneous variations in QRS morphology, and early activation located in the region of the papillary muscle identified by echocardiography. Variations in QRS morphology can be subtle and may be due to preferential conduction to different exit sites or multiple regions of origin(Yamada et al., 2010). Ablation is technically challenging due to unstable catheter contact with the contracting papillary muscle; the use of intracardiac echocardiography is helpful for visualization of catheter positioning. The use of a cryo-catheter for better catheter contact with the papillary muscle has been reported to have a higher success rate (see above) (Rivera et al., 2015).

Outcomes of Ablation

Outcomes vary depending on the presence or absence of structural heart disease. For VT associated with structural heart disease, ablation typically aims at palliation to reduce recurrent arrhythmias and prevent defibrillator shocks. Hence, interpretation of results of ablation is often clouded by the presence of inducible VTs that have not been seen to occur spontaneously and that are not targeted by ablation. The target VT is rendered acutely noninducible in 70%–90% of patients (Alliot et al., 2009; Yamada et al., 2010). The success rate of abolishing all inducible VTs is significantly lower (approximately 50%) (Yamada et al., 2010). A meta-analysis of four randomized and one observational study of VT ablation for structural heart disease demonstrated a significant 38% reduction in VT recurrence compared with medical therapy (Tanner et al., 2010). In addition, adjunctive catheter ablation showed a trend toward reduction in electrical storms provoking multiple ICD shocks. Ablation did not influence mortality in this patient population; over a mean follow up of approximately 2 years, 12% in the ablation group and 14% in medical therapy group died.

Even after acutely successful VT ablation, 30%–50% of the patients may subsequently have a recurrence, although the frequency of VT episodes is substantially reduced for the majority (Stevenson et al., 2008; Yamada et al., 2010). Patients should be aware of the need for repeat ablations and/or the continued use of antiarrhythmic drugs and to temper expectations. In patients with VT storm,

catheter ablation can be life saving (Mallidi et al., 2011). Patients who have recurrent VT after ablation are at greater risk for death than those whose VT is controlled.

Success rate for ablation of idiopathic VT is higher although, when sites other than the right ventricular outflow tract or aortic sinuses are involved, these arrhythmias can be difficult to localize for successful ablation. When success from ablation is defined as at least an 80% reduction in ectopic activity, rates are lower than previously published. In a recent multicenter retrospective analysis of 1185 patients undergoing ablations at 8 specialized centers, acute overall procedural success was 84%. However, when these patients were followed with postprocedure Holter monitoring, success rate without antiarrhythmic drugs was 71% (Bansch et al., 2003). Predictors of success were RVOT origin (82% success), a nonepicardial focus, and absence of multiple morphologies. Repeat procedures were required in 22%, most commonly for arrhythmias of epicardial origin that required a mean of 1.6 procedures. Another common reason for failure is the inability to induce the arrhythmia for adequate mapping.

Risks and Complications in VT Ablation

Catheter ablation of VT can be challenging but is generally safe in large volume centers. Complications occur in approximately 6% of patients, most related to vascular access. Procedure mortality is less than 1% (Latchamsetty et al., 2015; Tung et al., 2015). Cardiac tamponade occurs in about 1% of patients (Bohnen et al., 2011). The majority of ablation-related mortality is due to uncontrolled ventricular arrhythmia and associated heart failure.

Planning for VT ablation is crucial in preventing complications. Patients with severe LV dysfunction can have major hemodynamic consequences following prolonged procedures. The risk of hemodynamic deterioration can be reduced by optimization of heart failure therapy prior to the procedure, intraprocedural monitoring of filling pressures, hemodynamic support if necessary, attention to sedation and anesthesia management, and careful attention to fluid management. Preprocedure echocardiography should be routine to exclude intracardiac thrombus in patients with structural heart disease who are undergoing LV mapping and attention to anticoagulation is mandatory to preventing thromboembolic complications. The HRS/ EHRA VT consensus report recommend a target ACT level of ≥ 250 s during procedures involving the LV (Alliot et al., 2009). Anticoagulation with warfarin for 6 weeks is often employed in cases with extensive ablation, but there are no data evaluating warfarin or aspirin. Limiting RF power with attention to reducing power if marked impedance falls are observed during ablation in areas vulnerable to rupture such as RV free wall can potentially avoid "steam pops" that are a cause of cardiac tamponade(Bohnen et al., 2011; Tokuda et al., 2011b). Prompt cardiac surgery can be lifesaving in event of cardiac perforation and onsite surgical backup is an important safeguard (Bohnen et al., 2011). In cases of epicardial access, a safe distance from epicardial coronary arteries and the phrenic nerve has to be established by angiography and high output pacing, respectively, prior to ablation.

Summary

Catheter ablation is an effective therapy for reducing VT recurrence in patients with structural heart disease and often curative in idiopathic VT. However, the procedure can be complex especially when patients are hemodynamically unstable or in VT storm. It is essential to plan in advance with the team participating in the procedure. Careful planning and knowledge of the various techniques, approaches, and management of complications are the key components for successful VT ablation.

Introduction

In order for blood to be delivered properly to the tissues of the body, the heart has to contract in an organized and coordinated fashion. The mammalian heart consists of both contractile (i.e., "working") cardiomyocytes (located in the atria and ventricles) as well as specialized pacemaker and conduction system cells that demonstrate automaticity (present at specific locations within the heart). The precise activity of the specialized cell types demonstrating automaticity in the heart results in the coordinated excitation of the contractile cardiomyocytes in the atria and ventricles, thereby ensuring proper pump function of the heart.

The components of the heart that demonstrate automaticity include the sinoatrial node (SAN), the atrioventricular node (AVN), and the His-Purkinje network (**Fig. 1**). Myocytes in each of these locations are capable of generating spontaneous action potentials (APs). Under normal conditions, the SAN demonstrates the highest rate of intrinsic spontaneous activity (and hence is normally the primary pacemaker of the heart). The AVN has a lower rate of intrinsic spontaneous activity and normally functions to transmit electrical signals (i.e., APs) from the atria to the ventricles. The His-Purkinje network, located in the ventricles, demonstrates the lowest rate of intrinsic spontaneous activity and is responsible for the rapid delivery of electrical signals to the working ventricular myocardium. Abnormal activity in any of these specialized components of the heart can result in cardiac arrhythmia.

Anatomy of the SAN and AVN

The SAN is a small, condensed area of tissue located subendocardially, adjacent to the cristae terminalis, and within the intercaval region of the right atrium (Keith and Flack, 1907; Boyett et al., 2003; Dobrzynski et al., 2007; Mangoni and Nargeot, 2008; Liu et al., 2007) (**Fig. 1**). Developmentally, the SAN and AVN are formed from specific populations of progenitor cells and are regulated by specific transcriptional pathways that result in the specification and differentiation of the SAN and AVN. The reader is referred to excellent reviews on the topic of patterning of the SAN and cardiac conduction system for additional information on these topics (Christoffels et al., 2010; van Weerd and Christoffels, 2016; Vedantham, 2015).

SAN myocytes are smaller than atrial myocytes and exist in a number of morphologies including spindle shaped, elongated spindle shaped, or spider cells (Anderson et al., 2009; Boyett et al., 2000; Mangoni and Nargeot, 2001). The SAN is a heterogeneous structure that can be divided into the SAN center, which most frequently contains the leading pacemaker site, and SAN periphery

(Dobrzynski et al., 2007). SAN myocytes in the center are smaller compared with those in the periphery, and have distinct molecular and electrophysiological properties that will be discussed further throughout this chapter.

There is considerable variability in the structure of the SAN between different species. In the human and canine heart, the SAN is commonly "cigar shaped" with the head located lateral to the crista terminalis near the opening of the superior vena cava and a tail that extends toward the opening of the inferior vena cava to varying extents. In the rabbit heart, the SAN spans the region between the superior and inferior vena cava (Inada et al., 2014). In contrast, the mouse SAN is "comma shaped," with a dense region at the top of the comma near the superior vena cava and a tail that runs adjacent to the cristae terminalis (Liu et al., 2007). SAN myocytes are interspersed within a network of connective tissue that serves as an insulator (Opthof, 1988; Dobrzynski et al., 2007; Boyett et al., 2003; Chandler et al., 2009). This connective tissue, along with the SAN arteries and adipose tissue, insulate the SAN from the surrounding atrial myocardium (Fedorov et al., 2009, 2012). The mouse SAN contains relatively low levels of connective tissue and has finger-like projections that are one to three cells long and one to two cells wide, which extend into the surrounding atrial myocardium to a length of $\sim$200 μm (Liu et al., 2007).

The anatomy of the AVN was first detailed in 1906, where Sunao Tawara meticulously detailed the cardiac conduction system in various mammals, including humans (Tawara, 2000). The AVN is often separated into two regions including the compact node and the lower nodal bundle (**Fig. 2**). The compact node is a half-oval shaped, small, dense region of interweaving spindle-shaped cells situated at the apex of the triangle of Koch adjacent to the central fibrous body (Hucker et al., 2008; Dobrzynski et al., 2013; Meijler and Janse, 1988; Inoue and Becker, 1998; Anderson and Ho, 1998). Morphologically, cells within the compact node are small and spindle or ovoid shaped (Munk et al., 1996). The anterior portion of the AVN is occupied by the lower nodal bundle and includes the rightward inferior nodal extension (INE). INEs are regions of specialized tissue that extend from the coronary sinus ostium and are continuous with the compact node, which have been identified in the dog and human heart (Hucker et al., 2008; Inoue and

Structure, function and clinical relevance of the cardiac conduction system, including the atrioventricular ring and outflow tract tissues. Pharmacology and Therapeutics 139, 260–288.

Becker, 1998; Anderson and Ho, 1998). Cells located in this region are smaller than atrial myocytes, yet larger than those in the compact node. They are tightly packed and organized in a parallel configuration. Surrounding the compact node and INE are transitional cells. These cells have a unique cellular phenotype as they exhibit morphological and electrophysiological characteristics of cells within the compact node as well as the surrounding myocardium in which they are located (Anderson and Latham, 1971; Anderson et al., 1974; Temple et al., 2013; Efimov et al., 2004). Electrophysiology studies have identified three cell types within the AVN including the atrio-nodal, the nodal, and the nodo-his cells (Nikolaidou et al., 2012).

SAN and AVN Conduction

In the intact SAN, the leading pacemaker site is the location of initial breakthrough of electrical activity and is most commonly located within the intercaval region (Dobrzynski et al., 2007; Mangoni and Nargeot, 2008). It is estimated that the leading pacemaker site accounts for roughly 1% (approximately 5000 cells) of the SAN in the rabbit heart (Bleeker et al., 1980; Kodama and Boyett, 1985). In response to physiological and pathophysiological conditions, the location of the leading pacemaker site can change. For example, a superior shift occurs in response to sympathetic nervous system activation with β-adrenergic receptor (β-AR) agonists (Fedorov et al., 2012; Azer et al., 2014). Similarly, activation of the parasympathetic nervous system or application of muscarinic (M_2) agonists produces an inferior shift in leading pacemaker site (Fedorov et al., 2012; Vinogradova et al., 1998; Krishnaswamy et al., 2015). Circulating hormones, such as natriuretic peptides (NP), can also modulate SAN function in association with shifts in leading pacemaker site (Azer et al., 2014). Furthermore, in the aged mouse heart it has been shown that the location of the leading pacemaker site can alternate between a superior and inferior position in subsequent beats and change as a function of frailty (Moghtadaei et al., 2016a). It has been proposed that these shifts in leading pacemaker site alter heart rate because of different properties of SAN myocytes at the different locations within the SAN.

Conduction across the SAN spreads from the leading pacemaker site toward the periphery of the SAN at the cristae terminalis where it excites the surrounding atrial myocardium. Interestingly, there is a band of nonexcitable tissue, commonly referred to as a "block zone," at the periphery of the SAN, which slows or prevents conduction toward the left atrium (Boyett et al., 2000, 2003; Bleeker et al., 1980; Nikolaidou et al., 2012). Myocytes at the center of the SAN exhibit poor electrical coupling, which has been attributed to cell orientation, increased levels of connective tissue, and gap junction protein expression patterns (Boyett et al., 2000, 2003; Dobrzynski et al., 2007; Chandler et al., 2009).

Connexins (Cxs) are critical proteins in the SAN (and AVN) that facilitate the spread of electrical signals between adjacent cells via gap junctions and are expressed heterogeneously in the SAN (and atria). The center of the SAN expresses the low conductance Cx45, but lacks expression of Cx40 and Cx43 (Boyett et al., 2000; Coppen et al., 1999; Verheijck et al., 2001). In the SAN periphery, both Cx43 and Cx45 are expressed, resulting in both an increase in electrical coupling between myocytes and increased conduction velocity (Coppen et al., 1999; Verheijck et al., 2001). Heterogeneity in Cx expression results in a slower conduction velocity within the SAN center compared with the periphery as well as the surrounding atrial myocardium and contributes to protecting the SAN from the hyperpolarized atrial myocardium (Joyner and van Capelle, 1986; Boyett et al., 2000; Mangoni and Nargeot, 2008; Bartos et al., 2015). Cxs are also critical for the activation of the atria by the SAN whereby the coupling of Cx45 expressing regions of the SAN communicate with Cx40 and Cx43 positive regions of the atria (Verheijck et al., 2001). It has been proposed that the SAN

communicates with the surrounding atrial myocardium via distinct exit pathways in the SAN (Fedorov et al., 2012; Csepe et al., 2016).

The AVN serves as a gateway to the ventricles as APs generated in the atria must pass through the AVN to excite the ventricular myocardium. Conduction throughout the AVN is much slower than the atria, which has been attributed to numerous factors including cell orientation, intracellular coupling, and ion channel expression. In larger animals, including humans, two distinct pathways of conduction through the AVN have been identified based on electrophysiological characteristics and molecular properties. These are referred to as the fast and slow pathways because of the ease with which conduction spreads through each, which is correlated with Cx43 expression (Hucker et al., 2008; Kurian et al., 2010; Temple et al., 2013). The fast pathway demonstrates relatively rapid conduction velocity, a long refractory period, and has very little to no Cx43 expression. This pathway includes the transitional cells, leftward INE, and compact node (Temple et al., 2013; Hucker et al., 2008; Greener et al., 2011; Efimov et al., 2004; Mani and Pavri, 2014). In contrast, Cx43 is expressed throughout the slow pathway (Cx43 positive region), which includes the rightward INE and the lower nodal bundle, and is continuous with the His bundle (Hucker et al., 2008). As the name suggests, conduction velocities are slow in this pathway (Mani and Pavri, 2014).

Sinoatrial Node Action Potentials

The quintessential feature of the SAN is its ability to generate spontaneous APs characterized by the presence of a slow diastolic depolarization (DD) between successive APs (**Fig. 3A**). The DD occurs during diastole and is characterized by a gradual increase in resting membrane potential, starting from the maximum diastolic potential (MDP) until the threshold for the next AP is reached (DiFrancesco, 1993; Irisawa et al., 1993). In SAN myocytes the AP upstroke velocity (V_{max}) is slower, the overshoot (OS) is smaller, and AP duration (APD) is longer compared to the surrounding contractile atrial myocytes (Monfredi et al., 2010; Dobrzynski et al., 2007). AP morphology is also heterogeneous within the SAN from center to periphery (**Fig. 3B**). Using small ball preparations of consecutive regions within the SAN, intrinsic differences in AP morphology have been characterized. Specifically, from the periphery to the center of the SAN, there is a gradual decrease in AP V_{max}, OS, and MDP (Kodama and Boyett, 1985; Kodama et al., 1997; Boyett et al., 1999). Furthermore, there is an increase in APD from the periphery toward the center of the SAN (Kodama et al., 1997; Yamamoto et al., 1998; Boyett et al., 1999).

Morphologically, APs recorded from the periphery of the SAN have some resemblance to atrial APs while still retaining properties of spontaneously active SAN myocytes (Yamamoto et al., 1998) (**Fig. 3B**). For example, peripheral SAN myocytes have a prominent DD and display automaticity; however, V_{max} is faster and APD is shorter in peripheral versus central SAN myocytes (Boyett et al., 1999; Dobrzynski et al., 2007). Collectively, these AP differences across the SAN result in the leading pacemaker site depolarizing first, but repolarizing last (Yamamoto et al., 1998; Boyett et al., 2000). This is of functional importance because it prevents re-entrant activity.

Atrioventricular Node Action Potentials

APs within the AVN are unique compared with other regions in the heart. Specifically, AVN myocytes generate spontaneous APs that are characterized by much lower V_{max} values compared to the working myocardium. Furthermore, APs in AVN myocytes are shorter in duration compared with ventricular myocytes, but not atrial myocytes (Munk et al., 1996). While AVN myocytes are

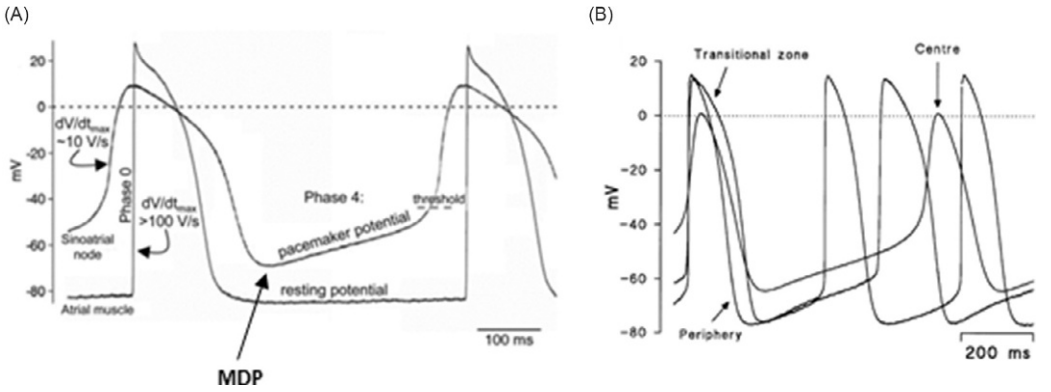

Fig. 3 Action potential morphologies in the sinoatrial node and atrial myocardium. (A) Overlay of representative action potentials from the working atrial myocardium and the sinoatrial node. In comparison to atrial muscle, sinoatrial node action potentials are characterized by a depolarized MDP, a diastolic depolarization (DD; also referred to as a "pacemaker potential"), a reduced upstroke velocity (V_{max}, dV/dt_{max}), lower action potential amplitude and longer action potential duration. (B) Heterogeneity in spontaneous action potential morphology in the center, transitional zone, and periphery of the sinoatrial node. (A) Modified and reproduced with permission from Boyett, M. R. (2009). "And the beat goes on." The cardiac conduction system: The wiring system of the heart. Experimental Physiology 94, 1035–1049. (B) Reproduced with permission from Boyett, M.R., Honjo, H., Yamamoto, M., Nikmaram, M.R., Niwa, R. and Kodama, I. (1999). Downward gradient in action potential duration along conduction path in and around the sinoatrial node. The American Journal of Physiology 276, H686–H98.

spontaneously active, their APs are characterized by slower spontaneous beating rates, reduced DD slopes, more negative MDPs, and reduced AP thresholds compared with SAN myocytes (Marger et al., 2011b).

Regional differences in AP morphology have been characterized in atrio-nodal cells (rod-shaped cells) and compact node or nodo-his cells (ovoid cells) isolated from the rabbit heart. Compact AVN cells are characterized by the presence of a rounded AP OS (Munk et al., 1996). Furthermore, these compact AVN cells have the lowest V_{max}, OS, APD, and MDP compared with the other regions of the AVN (Munk et al., 1996). In contrast, AP morphology of atrio-nodal cells demonstrates characteristics of both AVN and atrial myocytes (Munk et al., 1996; Yuill and Hancox, 2002).

Ionic Basis for SAN APs

The unique morphology of the SAN AP comes about due to the activities of a number of underlying ionic currents in SAN myocytes. These include the hyperpolarization-activated current (I_f) carried by hyperpolarization-activated cyclic-nucleotide gated (HCN) channels, T- and L-type Ca^{2+} currents, a number of voltage-dependent K^+ currents, a sustained inward current (I_{st}), and a Na^+–Ca^{2+} exchange (NCX) current (I_{NCX}) driven by the release of Ca^{2+} from the sarcoplasmic reticulum (SR) (Mangoni and Nargeot, 2008; Lakatta et al., 2010). Other currents and ion channels that have been shown to affect SAN AP firing include sodium channels, two pore K^+ channels, inward rectifier K^+ channels, Ca^{2+} activated K^+ channels, transient receptor potential (TRP) channels, and stretch-activated ion channels. A terminology that has seen widespread adoption is that ionic currents across the plasma membrane that affect SAN AP potential firing may be collectively referred to as a "membrane clock," while the SR Ca^{2+} release/I_{NCX} mechanism may be referred to as the "Ca^{2+} clock" (Lakatta et al., 2010). There has been considerable debate regarding whether any one ionic mechanism is essential for automaticity (i.e., generation of the DD) and regarding the relative importance of each of the ionic mechanisms that underlie spontaneous activity in the SAN (Lakatta and DiFrancesco, 2009). There is currently no consensus on these issues; however, when considered collectively, it appears that there is some redundancy in the ionic mechanisms that generate the DD and automaticity in the SAN.

HCN channels

The hyperpolarization-activated current, also known as the "funny" current (I_f), is encoded by HCN channels and contributes to the DD phase of the AP. Multiple HCN isoforms are expressed in the heart, including HCN1–4. HCN4 is thought to be the predominant isoform in the SAN with contributions from HCN1 and HCN2 as well. Functionally, HCN isoforms assemble into heteromultimeric complexes and the resulting I_f current has biophysical properties consistent with this structural arrangement (Monfredi et al., 2010; Accili et al., 2002; Bucchi et al., 2012). In many species, including mouse, rabbit, and dog, HCN4 expression accounts for upward of 80% of the total HCN expression in the SAN (Shi et al., 1999; Zicha et al., 2005; Liu et al., 2007). However, in the human SAN, HCN1 is highly expressed in addition to HCN2 and HCN4 (Chandler et al., 2009; Li et al., 2015).

As their name suggests, HCN channels are activated by hyperpolarization of the membrane potential and play a role in the early phase of DD (Baruscotti et al., 2010; DiFrancesco and Borer, 2007). I_f channels conduct both Na^+ and K^+, are blocked by Cs^+ in a voltage-dependent fashion, have a reversal potential between −10 and −20 mV, and exhibit slow activation and deactivation kinetics (Baruscotti et al., 2010; DiFrancesco and Borer, 2007; Accili et al., 2002). Inside-out patch-clamp experiments have shown direct activation of I_f channels by cAMP (i.e., independently of protein kinase A (PKA) phosphorylation); therefore, these channels are activated by both membrane voltage and cAMP (DiFrancesco and Tortora, 1991; Wainger et al., 2001). Physiologically, these effects allow for cAMP-dependent regulation of I_f channels, which functions to shift the voltage dependence of activation of HCN channels, increasing I_f currents and DD slope in SAN myocytes. In isolated rabbit SAN myocytes, 2 mM Cs^+ almost completely blocks I_f (Denyer and Brown, 1990). Interestingly, the same concentration of Cs^+ slows AP firing frequency by ∼30% rather than causing a complete cessation of AP firing. Similarly, in isolated rabbit SAN myocytes, ivabradine, a selective I_f blocker, reduced the spontaneous beating rate by 16%, which was attributed to a 32% reduction in early DD slope (Bucchi et al., 2007). Similar effects of Cs^+ on I_f and AP firing have been reported in the human heart (Verkerk et al., 2007).

Strong evidence of a role for I_f in the SAN, as well as the involvement of specific ion channel isoforms in its generation, comes from studies using genetically modified mice. For example, HCN1 knockout mice display a significant reduction (∼30%) in I_f density and spontaneous AP firing frequency in isolated SAN myocytes (Fenske et al., 2013). Furthermore, HCN1 knockout mice are characterized by bradycardia, impaired SAN conduction, and sinus pauses in vivo. Collectively, these findings confirm that HCN1 is present in the SAN and contributes functionally to I_f current generation.

Genetic deletion of HCN2 channels also results in a reduction in I_f density (∼30%) in isolated SAN myocytes as well as a slowing of I_f activation, indicating that HCN2 contributes to I_f in the mouse SAN (Ludwig et al., 2003). HCN2 knockout mice do not show a change in heart rate, but they are characterized by enhanced SAN-mediated arrhythmias, suggesting that HCN2 is important for normal SAN function.

Consistent with the hypothesis that HCN4 is the major isoform in the SAN, global deletion of HCN4 is embryonic lethal; embryos lacking HCN4 die by day 12 post coitum (Stieber et al., 2003). Prior to day 12 HCN4 knockout embryos show near complete absence of I_f and slow heart rates (Stieber et al., 2003). The impacts of inducible and tissue-specific HCN4 ablation have also been investigated. In one study, Cre-lox methods were used to delete HCN4 from the adult mouse SAN, which reduced I_f by ∼75% (Herrmann et al., 2007). Isolated SAN cells from these mice displayed irregular patterns of AP firing, but this could be restored to normal upon application of isoproterenol (ISO), indicating that the cells were capable of beating spontaneously despite the loss of I_f. The authors concluded that HCN4 was necessary for stable basal automaticity, especially at low heart rates

(Herrmann et al., 2007). A second study that investigated inducible, cardiac-specific deletion of HCN4 in mice reported a more severe phenotype in which mice were characterized by severe bradycardia, as well as AV node block, ultimately resulting in death within 5 days of deletion (Baruscotti et al., 2011). Isolated SAN myocytes from these mice exhibited reductions in I_f of ~70%, while spontaneous AP firing was reduced by 60%. Taken together, the available data clearly demonstrate that I_f is importantly involved in generating automaticity in the SAN, although there is still continued debate on whether it is essential for this function.

T-type and L-type calcium channels

Voltage-gated calcium channels are expressed in the SAN and contribute to the DD in SAN myocytes (Mangoni et al., 2006a; Marionneau et al., 2005). In the heart, L-type calcium current ($I_{Ca,L}$) is encoded by two subunits, $Ca_V1.2$ and $Ca_V1.3$, while the T-type calcium current ($I_{Ca,T}$) is encoded by the subunits $Ca_V3.1$, $Ca_V3.2$, and $Ca_V3.3$ (Marionneau et al., 2005). These α subunits show distinct patterns of expression in different parts of the heart, as noted later.

With regard to $I_{Ca,L}$ channel expression, studies have revealed that $Ca_V1.2$ is expressed through the myocardium including in the SAN, while $Ca_V1.3$ has a more restricted expression pattern, being present in the SAN, AVN, and atrial myocardium, but absent from the ventricular myocardium (Mangoni et al., 2003). Functionally, $Ca_V1.3$-mediated $I_{Ca,L}$ is activated at more negative membrane potentials (compared with $Ca_V1.2$-mediated $I_{Ca,L}$), which correspond to membrane voltages during the DD (Mangoni et al., 2003; Mesirca et al., 2016b). $Ca_V1.2$, on the other hand, is primarily active during the AP upstroke. Bradycardia is observed in $Ca_V1.3$-deficient mice, which is attributed to a significant increase in the cycle length between successive APs in association with a reduction in the slope of the DD (Mangoni et al., 2003; Torrente et al., 2016). $Ca_V1.3$-deficient mice display a 60%–70% reduction in $I_{Ca,L}$ density and a positive shift in $I_{Ca,L}$ activation kinetics in SAN myocytes consistent with the remaining $I_{Ca,L}$ being generated by $Ca_V1.2$ (Mangoni et al., 2003). Combined, these data indicate $Ca_V1.3$-mediated $I_{Ca,L}$ contributes importantly to SAN pacemaker activity during the late phase of the DD and that this is the predominant L-type Ca^{2+} channel contributing to automaticity. $Ca_V1.2$-mediated $I_{Ca,L}$, while contributing importantly to the generation of the AP upstroke, does not appear to be a major participant in the generation of the DD.

For $I_{Ca,T}$, both $Ca_V3.1$ and $Ca_V3.2$ mRNAs have been found in the SAN; however, $Ca_V3.1$-mediated $I_{Ca,T}$ appears to play a more prominent functional role (Mesirca et al., 2014; Mangoni and Nargeot, 2008). $I_{Ca,T}$ demonstrates slower activation kinetics and accelerated inactivation kinetics compared with $I_{Ca,L}$ (Mesirca et al., 2014; Mangoni and Nargeot, 2008). Furthermore, $I_{Ca,T}$ activates at more negative membrane potentials than $Ca_V1.2$- and $Ca_V1.3$-mediated $I_{Ca,L}$ and the peak $I_{Ca,T}$ density is lower than that of $I_{Ca,L}$ in SAN myocytes. Nevertheless, $Ca_V3.1$-mediated $I_{Ca,T}$ has been shown to contribute to pacemaker activity in the SAN. Specifically, mice lacking $Ca_V3.1$ completely lack detectable $I_{Ca,T}$ in SAN myocytes, which resulted in a 37% reduction in spontaneous AP firing frequency (Mangoni et al., 2006b). Functionally, while basal heart rate was unchanged in $Ca_V3.1$ knockout mice, intrinsic heart rate (measured in the presence of autonomic nervous system blockade) was reduced by 10%. The precise mechanisms by which $I_{Ca,T}$ affects the DD are still unclear, but may involve the generation of a window current or the coupling of $I_{Ca,T}$ to intracellular Ca^{2+} handling.

Sarcoplasmic reticulum Ca^{2+} release and Na^+–Ca^{2+} exchange

Evidence of a role for sarcoplasmic reticulum (SR) Ca^{2+} release in cardiac automaticity was first shown in latent pacemaker cells in the atria and in the SAN, whereby application of ryanodine was found to slow spontaneous pacemaker activity (Rubenstein and Lipsius, 1989; Rigg and Terrar, 1996; Li et al., 1997). Since then, this phenomenon has been explored in great detail in the mammalian SAN (Lakatta et al., 2010). The central tenet of this hypothesis is that localized subsarcolemmal Ca^{2+} release (LCR) events from the SR occur during the late DD. These LCRs occur rhythmically and lead to the activation of NCX, which extrudes this Ca^{2+} from the SAN myocytes, thereby generating an inward current (I_{NCX}) during the DD. This SR Ca^{2+} release/I_{NCX} mechanism appears to depend on a high level of basal PKA activity in the SAN and is controlled by phosphodiesterases, which are responsible for hydrolyzing cAMP (Vinogradova et al., 2006, 2008). It has been proposed that the LCR events present during the DD occur spontaneously and do not depend on membrane depolarization (Lakatta et al., 2010). On the other hand, more recent evidence has demonstrated that $Ca_V1.3$ Ca^{2+} channels are colocalized with ryanodine receptors in the SAN (Christel et al., 2012) and it has been suggested that Ca^{2+} influx via $Ca_V1.3$ channels during the DD may lead to the opening of ryanodine receptors by Ca^{2+}-induced Ca^{2+} release (Torrente et al., 2016). There has been considerable debate on the relative importance of this Ca^{2+} clock mechanism in SAN automaticity with some studies ascribing it a dominant or even essential role and others concluding that the Ca^{2+} clock is an important contributor, but that spontaneous activity in the SAN can continue without it, albeit with reduced rates and/or stability (Lakatta and DiFrancesco, 2009; Honjo et al., 2003; Lakatta et al., 2010). Nevertheless, the evidence is overwhelming that SR Ca^{2+} release occurs during the late DD and this leads to the activation of I_{NCX}, which increases the rate of depolarization during diastole and thus enhances spontaneous AP firing in the SAN.

Further evidence of a role for SR Ca^{2+} release in automaticity comes from studies of IP_3 receptors (IP_3Rs) in the SAN. All three IP_3R subtypes (IP_3R1, IP_3R2, and IP_3R3) are expressed in the heart and IP_3R1 and IP_3R2 have both been detected in the SAN (Ju et al., 2011, 2012). Activation of IP_3Rs with either membrane-permeable IP_3 or indirectly via application of endothelin-1 (which increases endogenous IP_3 levels via the phospholipase C signaling pathway) caused a significant increase in Ca^{2+} spark frequency near the cell membrane, indicating SR Ca^{2+} release. Furthermore, these IP_3R agonists also increased spontaneous AP generation in the SAN (Ju et al., 2011). Consistent with these findings, IP_3R2 knockout mice as well as pharmacological inhibition of IP_3Rs result in a reduction in spontaneous Ca^{2+} spark frequency and SAN AP firing rate (Ju et al., 2011; Kapoor et al., 2015). Combined, these data indicate IP_3R2-mediated SR Ca^{2+} release can contribute to pacemaker activity in the SAN.

Sustained inward current

The sustained inward current, I_{st}, is a current carried by Na^+ that activates at ~−70 mV and peaks at ~−50 mV. I_{st} is enhanced by β-AR agonists, is insensitive to TTX, and is blocked by dihydropyridine receptor antagonists as well as divalent cations (Mg^{2+}, Ni^{2+}) (Mitsuiye et al., 2000; Cho et al., 2003; Shinagawa et al., 2000; Toyoda et al., 2005). I_{st} has been detected in SAN myocytes and, interestingly, appears to be present only in spontaneously beating, but not quiescent, SAN cells (Mitsuiye et al., 2000; Zhang et al., 2002). Based on its biophysical and kinetic properties, I_{st} has been predicted to contribute to the generation of the DD, particularly in the central regions of the SAN were I_{Na} is small or absent (Shinagawa et al., 2000). The molecular identity of the channels responsible for I_{st} has not yet been identified and until this is accomplished it will remain difficult to determine the precise role of I_{st} in the SAN.

Sodium channels

The heart expresses multiple sodium channel isoforms that can be categorized based on their sensitivity to tetrodotoxin (TTX). The dominant cardiac sodium current (I_{Na}) is carried by the TTX-resistant $Na_V1.5$ channels. $Na_V1.5$ is absent from the center of the SAN (Lei et al., 2004, 2005, 2007), which is consistent with the low V_{max} characteristic of central SAN myocytes. In contrast, $Na_V1.5$, and the resulting I_{Na}, is detected in the larger cells of the peripheral SAN.

TTX-sensitive sodium channels (sometimes referred to as neuronal sodium channels) are also expressed in the heart, including in the SAN. Specifically, $Na_V1.1$ and $Na_V1.3$ subunits have been detected in the mouse SAN (Maier et al., 2003) and $Na_V1.1$, $Na_V1.3$, and $Na_V1.6$ have been identified in the rat SAN (Huang et al., 2015). There is now evidence to suggest that TTX-sensitive Na^+ channels play an important role in pacemaker activity in the SAN. For example, in Langendorff perfused mouse or rat hearts, low concentrations of TTX result in a significant reduction in heart rate (Maier et al., 2003; Huang et al., 2015). Furthermore, in the isolated rabbit SAN, application of nanomolar concentrations of TTX results in a reduction in spontaneous AP firing frequency (Lei et al., 2004).

Detailed investigations have identified differential roles for TTX-sensitive and resistant sodium channels in cardiac pacemaking. In optical mapping studies, nanomolar concentrations of TTX (which would only affect neuronal Na^+ channels) elicit an increase in SAN cycle length, which is consistent with a slower heart rate, but no change in SAN conduction velocity. In contrast, application of micromolar concentrations of TTX (which would block $Na_V1.5$ as well as neuronal Na^+ channels) resulted in a greater increase in cycle length as well as a reduction in conduction velocity across the SAN (Maier et al., 2003). Consistent with these observations, $Na_V1.5$-deficient mice have impaired SAN function resulting in a reduced heart rate attributed to slowed SAN conduction at the peripheral regions of the SAN (Lei et al., 2005). Central SAN myocytes from $Na_V1.5$ knockout mice showed no changes in AP morphology or automaticity while larger peripheral SAN myocytes from $Na_V1.5$ knockout mice had reduced spontaneous AP firing and smaller AP peaks. Collectively, based on these findings, it has been suggested that TTX-sensitive I_{Na} contributes to pacemaker function whereas, TTX-resistant I_{Na} does not contribute to automaticity in the central SAN, but can affect heart rate by modulating conduction through the peripheral SAN and into the atrium (Lei et al., 2004, 2007).

Inward rectifier potassium channels

The inward rectifier K^+ current (I_{K1}) is carried by K^+ channels made up of $K_{ir}2.1$ and K_{ir} 2.2 subunits. I_{K1} is importantly involved in maintaining the resting membrane potential in working contractile myocytes; however, it is largely absent in SAN myocytes. The lack of I_{K1} partly explains the more depolarized MDP in SAN myocytes relative to the hyperpolarized resting membrane potential in contractile myocytes of the surrounding atrium (Mangoni and Nargeot, 2008). It should be noted that while not present in central SAN myocytes, I_{K1} can be measured in peripheral SAN myocytes although at much lower densities than in the working myocardium (Cho et al., 2003; Mangoni and Nargeot, 2001).

Delayed rectifier potassium channels

The ether-a-go-go family of proteins are responsible for the rapidly activating delayed rectifier potassium current (I_{Kr}), which is blocked by compounds such as E-4031 and dofetilide. The slow delayed rectifier K^+ current (I_{Ks}) is encoded by KCNQ1 in the heart and is sensitive to chromonol 293B. Both of these delayed rectifier currents have been described in the SAN, with some species differences as noted later.

In mouse SAN myocytes, three splice variants for mERG1 (1a, 1a′, and 1b) are expressed (Clark et al., 2004). E-4031 application results in depolarization of the MDP, a reduced AP amplitude and can completely prevent spontaneous AP firing in SAN myocytes (Ono and Ito, 1995; Verheijck et al., 1995). Experiments performed in rabbit heart indicate that a gradient of I_{Kr} is present across the SAN such that the effect of E-4031 is greater in the center of the SAN compared with the periphery (Kodama et al., 1999).

Functionally, I_{Kr} contributes to repolarization of the AP and determines the MDP in SAN myocytes (Clark et al., 2004; Verheijck et al., 1995). Furthermore, kinetic analysis of I_{Kr} indicates that these channels have an accelerated rate of deactivation, but I_{Kr} may not deactivate fully during the cardiac cycle so that a sustained current may be present throughout the DD. Inhibition of I_{Kr} shifts the MDP and prolongs AP repolarization resulting in a slowing of spontaneous AP firing. This slowing effect is largely due to less activation of I_f and Ca^{2+} channels.

While I_{Kr} appears to the dominant delayed rectifier K^+ current in rabbit and rodent SAN, in the pig SAN I_{Ks} has been found to be responsible for repolarization of the SAN AP (Ono et al., 2000). In the pig, I_{Ks} appears to function in the same way as I_{Kr}. Consistent with this, block of I_{Ks} in pig SAN with chromanol 293B halts spontaneous AP firing in a similar fashion to E-4031 in rabbit SAN.

Transient outward potassium channels

The transient outward potassium current (I_{to}) plays a critical role in the working myocardium, but is less well understood in the SAN. I_{to} is characterized by fast activation and inactivation kinetics and can be subdivided into fast and slow components based on differences in inactivation kinetics. The fast component of I_{to} ($I_{to,f}$) is encoded by $K_V4.2$ and $K_V4.3$, whereas the slow component ($I_{to,s}$) is encoded by $K_V1.4$ (Nerbonne and Kass, 2005).

I_{to} density is significantly lower in rabbit SAN myocytes as compared to atrial myocytes (Uese et al., 1999). Within the SAN, sensitivity to the I_{to} channel blocker 4-aminopyradine (4-AP) was correlated with cell size such that larger SAN myocytes (presumably from the peripheral SAN) exhibited larger responses to 4-AP compared with the smaller cells from the center of the SAN (Lei et al., 2000). Consistent with these observations, 4-AP also results in AP prolongation in isolated SAN, but the effect is more pronounced in larger SAN myocytes. Collectively, these findings demonstrate that I_{to} is functional in the SAN, perhaps more prominently in the SAN periphery, but more studies are needed to determine the precise role of I_{to} in regulating SAN function.

Two-pore potassium channels

Two-pore domain potassium channels (K_{2P}) are a family of K^+ channels with emerging roles in the heart. Functionally, they facilitate stabilization of the resting membrane potential and AP repolarization in cardiomyocytes (Wiedmann et al., 2016). K_{2P} channels are not voltage dependent; rather they continually conduct currents throughout the various phases of the AP and are hence referred to as background K^+ currents. Regulation of these channels is diverse, and includes factors such as temperature, pH, lipids, and membrane stretch. Six subfamilies of K_{2P} channels exist with the TWIK (two-pore domain weak rectifying potassium channel), TREK (TWIK-related potassium channel), and TASK (TWIK-related acid-sensitive potassium channel) subfamilies being expressed in the heart (Wiedmann et al., 2016; Gaborit et al., 2007).

Emerging evidence is suggestive of a role for K_{2P} channels in SAN electrophysiology. For example, the stretch-sensitive TREK channel is expressed in the mouse SAN and TREK-1 knockout mice have a reduced heart rate (Unudurthi et al., 2016). SAN myocytes isolated from TREK-1-deficient animals exhibit an increased rate of DD and spontaneous AP firing rate as well as an increase in APD at 50% repolarization. Furthermore, background K^+ current was significantly reduced in isolated SAN myocytes from TREK-1 knockout mice. Thus, TREK-1 contributes to SAN automaticity by altering the rate of DD. Additional studies are needed to further investigate the role of K_{2P} channels in the SAN.

Calcium-activated potassium channels

Three types of calcium-activated K^+ channels have been categorized based on their single-channel conductance, including the big conductance (BK), intermediate conductance (IK), and small conductance (SK) channels. These channels are coupled to L-type Ca^{2+} channels and, as their name suggests, are activated by an increase in intracellular calcium levels (Schmitt et al., 2014). Relatively little is known about the role of these channels in the SAN, however emerging evidence is suggestive of a role for BK channels in SAN excitability. Both pharmacological inhibition and genetic ablation of BK channels in isolated SAN myocytes leads to a significant reduction in spontaneous AP firing with a corresponding increase in DD duration (Lai et al., 2014). A role for SK channels has also been proposed in the SAN (Weisbrod et al., 2016).

TRP channels

TRP channels are a large and diverse family of ion channels divided into a number of subfamilies, including the short canonical (TRPC) channels, the vanilloid receptor (TRPV) channels, the melastatin (TRPM) channels, the Ankyrin-repeat (TRPA) channels, the polycystin (TRPP) channels, and the mucolipin (TRPML) channels (Clapham et al., 2001, 2003). Within each of these subfamilies a number of channel isoforms exist. Several TRP channels have been implicated in SAN function including TRPM7, TRMP4, and TRPC channels.

TRPM7 channels are permeable to divalent cations and generate an outwardly rectifying current. Furthermore, TRPM7 is expressed in the SAN and TRPM7 currents are readily detectable in isolated SAN myocytes (Sah et al., 2013). Targeted global knockout of TRPM7 as well as inducible SAN restricted deletion of TRPM7 in mice results in the generation of sinus pauses and AVN block (Sah et al., 2013). Consistent with these observations, TRPM7 knockout mice display a reduction in spontaneous AP frequency in association with a reduction in the DD slope in SAN myocytes. Interestingly the effects of TRPM7 ablation on DD slope appear not to be related directly to the loss of TRPM7 current. Rather, TRPM7 knockout mice display a substantial reduction in HCN channel expression and I_f current density, which appears to account for the reduction in DD slope. Consistent with this hypothesis, a TRPM7 blocker, FTY720, did not affect spontaneous AP frequency in the SAN (Sah et al., 2013).

TRPM4 is a calcium-activated nonselective cation channel that is permeable to Na^+ and K^+, but not Ca^{2+} ions (Little and Mohler, 2013). TRMP4 is activated by intracellular calcium and phosphatidylinositol 4,5-bisphosphate, but inhibited by increases in intracellular ATP. TRPM4 is expressed in the mouse SAN and a nonselective cation current with the properties of TRPM4 currents has been measured in mouse SAN myocytes (Demion et al., 2007). Furthermore, pharmacological inhibition of TRPM4 with 9-phenanthrol or genetic deletion of TRMP4 results in a significant reduction in beating rate within the right atria (Hof et al., 2013). These effects have been attributed to a decrease in the rate of DD as assessed by microelectrode recordings in multicellular atrial preparations. Interestingly, this effect was greater at lower beating rates, thereby suggesting TRPM4 functions in preventing bradycardia. Importantly, the effects of TRPM4 deletion have yet to be studied in isolated SAN myocytes.

The mouse SAN has also been shown to express a number of TRPC channel transcripts, including TRPC1, 2, 3, 4, 6, and 7 and it has been suggested that one or more of these TRPC channels may be involved in mediating Ca^{2+} influx into SAN myocytes in a store operated fashion (Ju et al., 2007). Consistent with this hypothesis, Gd^{3+} and SKF-96355, two compounds known to antagonize several TRPC channels, were shown to block Ca^{2+} entry into SAN myocytes. Furthermore, SKF-96365 reduced pacemaker activity (Ju et al., 2007). While these findings are very interesting, it must be noted that many of the pharmacological agents used in these studies are not specific to TRPC channels and more work is needed to determine the precise role of TRPC channels in the SAN.

AVN Ion Channels

Like SAN myocytes, myocytes isolated from the AVN are characterized by their ability to generate spontaneous APs with DDs. Spontaneous AP frequency in AVN myocytes is lower than in SAN myocytes and less is known about ion channel function in the AVN. At the molecular level, mRNA transcripts for HCN1, HCN4, $Na_V1.1$, $Ca_V1.3$, $Ca_V3.1$, $K_{ir}3.4$, and Cx45 have been detected in the AVN and these transcripts are expressed at higher levels compared with the surrounding atrial myocardium (Greener et al., 2011; Marionneau et al., 2005). On the other hand, $Na_V1.5$, $K_{ir}2.1$, and Cx43 expression was lower in the AVN compared with the atrium.

Consistent with their ability to intrinsically generate spontaneous APs, AVN cells display a prominent I_f, although I_f density in the AVN is ~50% smaller than in the SAN (Marger et al., 2011a,b; Mesirca et al., 2014). While I_f is detected throughout the AVN, regional differences exist such that I_f in nodal or nodo-his cells is significantly higher compared with atrio-nodal cells (Munk et al., 1996; Choisy et al., 2015).

Similar to the SAN, sodium channel expression is variable within the AVN. The compact AVN lacks I_{Na}, which is consistent with the low V_{max} characteristic of the AVN (Efimov et al., 2004; Greener et al., 2011). On the other hand, I_{Na} is detected in all atrio-nodal cells and approximately one-third of nodo-his cells in rabbit and Guinea-pig hearts (Munk et al., 1996; Yuill and Hancox, 2002). Furthermore, both TTX-resistant and TTX-sensitive I_{Na} have been recorded from isolated rabbit AVN myocytes, and blockade of these channels using high levels of TTX can result in cessation of spontaneous AP firing (Marger et al., 2011b).

Multiple K^+ currents have been identified in AVN myocytes. I_{to} density is variable within the AVN such that it is more commonly detected in atrio-nodal cells compared with nodal cells (Marger et al., 2011b; Munk et al., 1996). In mouse AVN, the delayed rectifier I_{Kr} has been identified and found to be larger than in SAN myocytes (Marger et al., 2011b; Efimov et al., 2004). I_{Ks}, on the other hand, was not detected in mouse AVN myocytes. I_{K1} has been recorded in AVN myocytes from mouse and rabbit AVN myocytes (Choisy et al., 2015).

In AVN myocytes, both $I_{Ca,T}$ and $I_{Ca,L}$ contribute to automaticity and AVN function and transcripts for several Ca^{2+} channels can be detected including $Ca_V1.2$, $Ca_V1.3$, and $Ca_V3.1$ (Marger et al., 2011a,b; Marionneau et al., 2005). $I_{Ca,L}$ in the AVN is approximately half the magnitude of that in the SAN and application of L-type Ca^{2+} channel blockers can completely suppress spontaneous APs (Marger et al., 2011a; Greener et al., 2011). $I_{Ca,L}$ density is approximately twice as large in rabbit AVN as compared with mouse AVN (Choisy et al., 2015).

Consistent with an important role for Ca^{2+} channels in AVN function, $Ca_V3.1$ knockout mice are characterized by prolongation of the P–R and P–Q intervals (indicators of conduction through the AVN) and a significant increase in AVN effective refractory period (Mangoni et al., 2006b; Marger et al., 2011a). Furthermore, $Ca_V1.3$ knockout mice show a greater prolongation of the PR interval than $Ca_V3.1$ knockout mice. This prolongation of the P-R interval is exacerbated in double knockouts lacking both Cav1.3 and Cav3.1. In isolated AVN myocytes, the generation of spontaneous APs was reduced by 70% in $Ca_V3.1$ knockout mice and absent in Cav1.3 knockout animals.

SK2 knockout mice exhibit impaired SAN and AVN function, as indicated by a reduction in heart rate and prolongation of the P–R interval (Zhang et al., 2008). AP firing frequency, the rate of DD, and V_{max} were reduced, whereas APDs were prolonged in the AVN of SK2 knockout mice. In contrast, overexpression of SK2 results in the opposite effects, including an increase in spontaneous AP firing rate (Zhang et al., 2008). These effects were attributed to alterations in I_{KCa} densities in AVN myocytes. Combined, these data indicate SK2 channels contribute to AVN function.

SR calcium release also affects AVN function. In isolated rabbit AVN cells, calcium transients correlate with AP generation (Hancox et al., 1994). These Ca^{2+} transients result in an increase in intracellular calcium at the periphery of the myocyte that subsequently spreads throughout the cell. Pharmacological inhibition of SERCA pumps leads to a significant reduction in Ca^{2+} transients and slowed the frequency of AP generation. Furthermore, interfering with SR calcium release by application of ryanodine significantly decreases Ca^{2+} transient amplitude in the AVN. This in turn slows the rate of spontaneous APs in AVN myocytes (Ridley et al., 2008; Choisy et al., 2015). There is also data to suggest SR Ca^{2+} release is coupled to I_{NCX} because inhibition of NCX prevents spontaneous Ca^{2+} transients in AVN (Ridley et al., 2008). Combined, these data indicate both SR calcium release and I_{NCX} facilitate the generation of spontaneous APs in the AVN, although compared to the SAN this is relatively poorly understood.

Regulation by the Autonomic Nervous System

The SAN and AVN are both heavily innervated, allowing heart rate and conduction through the AVN to be altered by the release of neurotransmitters (Pauza et al., 2013, 2014). The autonomic nervous system can be divided into two branches including the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS). Stimulation of the β-ARs by SNS agonists results in an increase in heart rate, whereas stimulation of muscarinic (M_2) receptors by the PNS results in a decrease in heart rate. The

interplay between sympathovagal activity, combined with the intrinsic activity of the SAN, determines the rate of spontaneous AP firing in SAN myocytes and hence the heart rate (Mangoni and Nargeot, 2008).

β-AR activation by catecholamines results in the activation of stimulatory G proteins (G_s) that cause an increase in cAMP production by adenylyl cyclases and an increase in protein kinase A (PKA) activity. Increasing cAMP levels and PKA activity causes a positive chronotropic effect and enhances conduction through the AVN following the activation of a number of targets including ion channels and SR Ca^{2+} handling.

In isolated SAN myocytes, β-AR activation leads to a rapid increase in the slope of the DD and a subsequent increase in spontaneous AP firing frequency without affecting APD (Accili et al., 2002; Irisawa et al., 1993) (**Fig. 4**). I_f is modulated by cAMP following the direct binding of cAMP to HCN channels (DiFrancesco and Tortora, 1991), which causes a positive shift in the I_f activation curve and increases I_f during the DD. These effects of cAMP on I_f have been largely thought to occur independently of PKA, although recent evidence suggests that HCN channels can also be phosphorylated by PKA (Liao et al., 2010).

L-type Ca^{2+} currents contribute to the increase in spontaneous AP firing in the SAN following β-AR activation. Consistent with this hypothesis, ISO can dose-dependently increase $I_{Ca,L}$ in SAN myocytes with similar efficacy to I_f (Zaza et al., 1996). Furthermore, SAN myocytes isolated from $Ca_V1.3$ knockout mice show a blunted response to ISO, including impaired effects on DD slope and AP firing frequency (Torrente et al., 2016). β-AR agonists are thought to modulate $I_{Ca,L}$ ($Ca_V1.2$ and $Ca_V1.3$) in a PKA-dependent fashion (Mangoni and Nargeot, 2008).

SR Ca^{2+} release is also modulated by β-AR agonists and it has been suggested that this makes a major contribution to the effects of the SNS on AP firing in the SAN (Lakatta et al., 2010). Enhancement of intracellular cAMP, PKA, and CaMKII activity following β-AR activation leads to an increase in SR Ca^{2+} spark amplitude, frequency, and SR filling rate (Vinogradova et al., 2006; Gao et al., 2011). These effects have been attributed to increases in phosphorylation of ryanodine receptors and phospholamban. In SAN and AVN myocytes, these effects result in increased SR calcium release, which enhances I_{NCX} during the DD and increases AP firing frequency (Vinogradova et al., 2002; Gao et al., 2011; Hancox et al., 1994). The relative importance of each of these mechanisms (I_f, $I_{Ca,L}$ SR Ca^{2+} release) in mediating the positive chronotropic effects of SNS activation has not been resolved.

PNS (i.e., vagus nerve) stimulation causes a negative chronotropic effect and slowing of conduction in the SAN and AVN following the release of acetylcholine (ACh), which activates M_2 receptors and inhibitory G proteins ($G_{i/o}$) (Irisawa et al., 1993). The α_i subunit of these G proteins inhibits AC activity and cAMP signaling. Reduced cAMP levels decrease the DD slope in SAN myocytes and these effects can involve reductions in I_f, $I_{Ca,L}$, and SR Ca^{2+} release (Mangoni and Nargeot, 2008; Lakatta et al., 2010) (**Fig. 4**). In addition to these effects, the βγ subunits of the $G_{i/o}$ proteins can directly activate GIRK ($K_{ir3.x}$) channels that mediate I_{KACh} currents (Mangoni and Nargeot, 2008). Activation of I_{KACh} hyperpolarizes the SAN myocyte, which also slows spontaneous AP firing. A significant amount of investigation has gone into trying to determine which ionic mechanism(s) are particularly important for the negative chronotropic effects of PNS agonists. For example, $K_{ir3.4}$ or $G_{\beta\gamma}$ knockout mice have significant reductions in PNS responsiveness, indicating that I_{KACh} makes a major contribution to the response (Wickman et al., 1998; Gehrmann et al., 2002; Mesirca et al., 2016a). On the other hand, biophysical studies have suggested that I_f is more sensitive to acetylcholine than I_{KACh} or $I_{Ca,L}$ (DiFrancesco et al., 1989; Zaza et al., 1996). From these studies it was concluded that I_f contributes more importantly to changing pacemaker activity in the SAN. Still other studies have shown that PNS agonists suppress local Ca^{2+} releases from the SR during the DD and this is a major determinant of the slowing in pacemaker activity, including in conditions where I_{KACh} would not be activated (Lyashkov et al., 2009; van Borren et al., 2010). Additional studies will be required to resolve these issues.

Hormonal Regulation of the SAN by Natriuretic Peptides

Natriuretic peptides (NPs) are a family of hormones with a number of potent effects in the cardiovascular system (Potter et al., 2006; Kuhn, 2004). Several members of the NP family have been identified including atrial NP (ANP), B-type NP (BNP), and C-type NP (CNP). Each of these peptides is expressed in the heart and is present in both cardiomyocytes and cardiac fibroblasts (Moghtadaei et al., 2016b).

Three NP receptors, called NPR-A, NPR-B, and NPR-C, mediate the effects of NPs (Potter et al., 2006). NPR-A (which binds ANP and BNP) and NPR-C (which is selectively activated by CNP) are guanylyl cyclase (GC) linked receptors that enhance cGMP

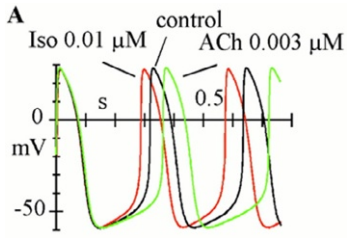

Fig. 4 Effects of the β-adrenergic receptor agonist ISO and the muscarinic agonist acetylcholine (ACh) on spontaneous action potential cycle length and diastolic depolarization slope in the sinoatrial node. Note that these autonomic nervous system agonists modulate action potential cycle length in association with changes in the slope of the diastolic depolarization. Reproduced with permission from Accili, E.A., Proenza, C., Baruscotti, M. and Difrancesco, D. (2002). From funny current to HCN channels: 20 years of excitation. News in Physiological Sciences 17, 32–37.

signaling (Lucas et al., 2000) while NPR-C (which binds all NPs with similar affinity) is coupled to inhibitory G proteins that inhibit AC signaling (Rose and Giles, 2008; Anand-Srivastava, 2005).

NPs can potently regulate heart rate through effects on pacemaker myocytes in the SAN (Springer et al., 2012; Azer et al., 2012; Rose et al., 2007). In isolated SAN myocytes, BNP and CNP each increase spontaneous AP firing frequency in association with increases in the DD slope and APD, but without differences in MDP. These effects on SAN AP firing occurred in association with increases in HR in intact hearts. Voltage clamp studies demonstrate that these changes in AP firing properties were the result of increases in I_f and total $I_{Ca,L}$ in the presence of BNP or CNP along with shifts in the voltage dependence of channel activation ($V_{1/2\,(act)}$). To determine the mechanism for these electrophysiological effects, NPR-C knockout (NPR-C$^{-/-}$) mice and pharmacological approaches have been used. The stimulatory effects of BNP and CNP on spontaneous AP firing, I_f and $I_{Ca,L}$ in NPR-C$^{-/-}$ mice are indistinguishable from wild-type mice in basal conditions. In contrast, the effects of BNP and CNP were occluded by the PDE3 inhibitor milrinone and the effects of BNP were antagonized following NPR-A blockade. Thus, these experiments illustrate that BNP and CNP can potently increase HR and spontaneous AP firing in SAN myocytes by activating the GC-linked NPR-A and NPR-B receptors and inhibiting PDE3 activity (Springer et al., 2012). Consistent with these findings, ANP has also been shown to elicit a cGMP-dependent increase in I_f in human atrial myocytes (Lonardo et al., 2004).

Although NPR-C does not affect SAN function in basal conditions, it does contribute importantly in the presence of β-adrenergic receptor (β-AR) activation (Azer et al., 2012; Springer et al., 2012). Specifically, in the presence of ISO, cANF dose-dependently decreases HR and slows spontaneous AP firing by decreasing the DD slope in SAN myocytes (Azer et al., 2012). These effects of cANF are completely absent in NPR-C$^{-/-}$ mice confirming they are mediated by the NPR-C receptor. To explore the contributions of different NPRs to these responses, we compared the effects of BNP and CNP (which can activate NPR-A/B as well as NPR-C) to cANF (which only activates NPR-C). These measurements show that BNP and CNP increase HR and AP firing in submaximal (10 nM) doses of ISO, but these effects are smaller than those observed in basal conditions because, in the presence of ISO, BNP, and CNP activate NPR-A/B (which mediate an increase in HR and AP firing) as well as NPR-C (which mediates a decrease in HR and AP firing). Interestingly, in the presence of maximum doses of ISO (1 μM) BNP and CNP elicit reductions in HR and cause slowing of spontaneous AP firing in SAN myocytes due to a greater contribution from NPR-C. In agreement with this observation, CNP and cANF can also decrease $I_{Ca,L}$ in SAN myocytes in the presence of maximum doses of ISO (Rose et al., 2004). These changes in ion channel function and AP firing properties correlate with changes in SAN activation and conduction patterns that are also differentially modulated by the GC-linked NPRs and NPR-C (Azer et al., 2014). Collectively, these studies demonstrate that NPs can modulate SAN function via the NPR-A/B receptors (stimulatory) and NPR-C (inhibitory) and that these receptors elicit opposing effects. Because of this, NPs can increase HR and SAN function in some conditions, but decrease HR in others and this is dependent on the extent of β-AR activation and the relative contribution of each NPR in different physiological conditions (Azer et al., 2012, 2014; Moghtadaei et al., 2016b). In addition to these effects of NPs on SAN myocyte function, NPs also regulate collagen deposition, and hence electrical conduction, in the SAN. Consistent with this, genetic loss of NPR-C results in SAN dysfunction in association with enhanced fibrosis and slowed conduction in the SAN (Egom et al., 2015).

Mechanical Effects on the SAN

Mechanical effects on SAN activity (Quinn and Kohl, 2012) were first recognized in 1915 by Francis Bainbridge, who found that intravenous fluid injections in anesthetized dogs resulted in right atrial distension and increased beating rate (Bainbridge, 1915) (similar effects have been observed since in a wide variety of vertebrates (Pathak, 1973), including human (Donald and Shepherd, 1978)). Stretch-induced increases in beating rate also occur in the isolated (decentralized) heart (Blinks, 1956), SAN tissue (Blinks, 1956; Deck, 1964), and SAN cells (Craelius et al., 1988; Iribe et al., 2007), and are insensitive to ablation of intracardiac neurons (Wilson and Bolter, 2002), block of neuronal Na^+ channels (Chiba, 1977; Wilson and Bolter, 2002), and adrenergic and cholinergic blockade (Blinks, 1956; Brooks et al., 1966; Chiba, 1977; Wilson and Bolter, 2002), indicating that nonneuronal, intracardiac mechanisms must be involved.

Microelectrode recordings in cat and rabbit right atrial tissue have demonstrated that stretch increases SAN MDP, reduces maximum systolic membrane potential, and increases DD rate (Deck, 1964). Patch-clamp recordings in axially stretched isolated rabbit SAN cells, combined with computational modeling, have established that this can be explained by a mechanosensitive whole-cell current with a reversal potential of ∼10 mV (Cooper et al., 2000). This current is presumably carried by cation nonselective stretch-activated channels, which are rapidly activating, with a reversal potential between 0 and −20 mV in cardiac cells (Craelius et al., 1988; Guharay and Sachs, 1984), and whose block causes a reversible reduction of stretch-induced changes in beating rate (Cooper and Kohl, 2005). In fact, even if located outside of SAN cells in electrically coupled nonmyocytes (Quinn et al., 2016), cation nonselective stretch-activated channels can account for stretch effects, as they are found in fibroblasts (Stockbridge and French, 1988), which are coupled to SAN cells in rabbit (Camelliti et al., 2004), and are depolarized by stretch (Kohl and Noble, 1996; Kohl et al., 1994).

Stretch may also affect fundamental components of SAN function. When expressed in oocytes, current amplitude (Calloe et al., 2005) and activation and deactivation rate (Lin et al., 2007) of HCN channels are increased with mechanical stimulation. Similarly, Ca^{2+} ($Ca_V1.2$) (Calabrese et al., 2002; Lyford et al., 2002) Na^+ ($Na_V1.5$ and $Na_V1.6$), and K^+ (Kv1, Kv3, Kv7, and KvCa) (Morris, 2011) channels are mechanically modulated in various expression systems. Axial stretch of guinea-pig (Iribe and Kohl, 2008) or rat (Gamble et al., 1992; Prosser et al., 2011, 2013; Iribe et al., 2009) ventricular myocytes, on the other hand, causes an acute increase in Ca^{2+} sparks (spontaneous Ca^{2+} release from the SR). This effect apparently occurs via augmented ryanodine receptor open

probability (Iribe et al., 2009), which may involve local activation by mechanically induced mitochondrial Ca^{2+} release through the mitochondrial NCX (Belmonte and Morad, 2008), a channel whose current alters beating rate in isolated rabbit SAN cells by affecting Ca^{2+} spark frequency (Yaniv et al., 2012). Thus, if any of these effects occurs also in SAN cells, they may contribute to stretch-induced changes in beating rate.

In the whole heart, stretch of SAN tissue will vary regionally and with time. The SAN is structurally heterogeneous, resulting in regional differences in stiffness. Changes in beating rate during externally applied force correlate best with maximum tissue deformation, which occurs at the periphery of the SAN, a region more distensible than the central node (Kamiyama et al., 1984). This difference could be important for transmission of electrical activity from the SAN to atrium (Garny et al., 2003), as the SAN periphery is where (the possibly mechanosensitive) HCN channels are thought to play the largest role in SAN activity (due to the more negative diastolic potential in that region) (Kreitner, 1985; Nikmaram et al., 1997). At the same time, SAN stretch will be greatest at the end of atrial filling, which is when SAN cells are moving toward AP initiation. In this way, mechanical priming of SAN cells could adjust function on a beat-by-beat basis to diastolic load, contributing to the matching of cardiac output (beating rate × stroke volume) to venous return (and may also play a role in respiratory sinus arrhythmia, as it continues to exist in the decentralized, transplanted heart (Bernardi et al., 1989)). Moreover, it appears that physiological loading may be essential to SAN automaticity, as slack tissue often shows no or irregular rhythm, while moderate stretch can restore normal activity (Brooks et al., 1966) (although excessive stretch can induce arrhythmias (Brooks et al., 1966; Hoffman and Cranefield, 1960), so pathophysiological loading during atrial overload may unbalance pacemaker mechanisms). This apparent requirement for a minimum mechanical stimulus is also apparent during ontogenetic initiation of the first heartbeat, as fluid pressure build-up in the quiescent cardiac tube appears to be required for the initiation of its spontaneous activity (Rajala et al., 1977).

There is also evidence supporting an interaction between mechanical and autonomic beating rate modulation. In intact rabbit (Bolter and Wilson, 1999; Bolter, 1994), and isolated atria of rabbit (Bolter, 1996), guinea-pig (Wilson and Bolter, 2001), and rat (Barrett et al., 1998), an increase in right atrial pressure induces both beating rate acceleration and a significant reduction in the percentage response to vagal stimulation. Vice versa, when beating rate is reduced by vagal stimulation the stretch-induced beating rate response is augmented, an interaction that may be mediated by I_{KACh}, as it is reduced with increased right atrial pressure (Han et al., 2010). In this way, parasympathetic control of beating rate may be continuously modified by atrial loading, further contributing to the stretch-induced adjustment of BR to fluctuations in venous return, and helping prevent excessive slowing and diastolic distension, while maintaining cardiac output and adequate circulation (Brooks and Lange, 1977).

Conclusions

Since the discovery of the SAN in 1907 and the AVN in 1906 substantial progress has been made in our understanding of the cellular and molecular mechanisms for spontaneous activity in these specialized pacemaker regions of the heart. These discoveries have been instrumental in facilitating a comprehensive understanding of cardiac electrical conduction. While progress has been considerable, there is still much to be learned, as noted throughout the preceding text. Continuing to unravel the precise determinants of cellular function in the SAN and AVN, and how each is regulated, is of paramount importance because dysfunction in each of these regions can contribute in important ways to cardiovascular disease.

Current treatments for SAN and AVN disease often involve implantation of artificial pacemakers which, while effective, come with a number of attendant risks and limitations. Because of this, and in parallel with the continued generation of novel insight into the mechanisms for automaticity, the field of biological pacing, which seeks to engineer zones of focal spontaneous electrical activity in regions of myocardium that are normally quiescent, has blossomed (Cho, 2015; Rosen et al., 2011). Such approaches, if successful, would free the patient from all hardware associated with traditional artificial pacemakers. Given the challenges associated with correcting SAN and/or AVN disease, motivation should remain high to continue to improve our understanding of the basis for automaticity in the heart with the hopes that this knowledge will inform the next generation of therapeutics targetting these specialized regions of the heart.

Chronic Infective Endocarditis

Definition

Most infective endocarditis (IE) can be classified as acute. However, there are a number of patients, mainly ones with prosthetic valve IE, who develop chronic IE. These patients are often older with multiple comorbidities that preclude definitive removal of their prosthetic valves. Chronic suppressive antibiotics are often prescribed after these patients complete the usual course of intravenous therapy.

Etiologies

In the past, infective endocarditis was classified as either acute or subacute based on the usual progression of untreated disease. This definition is now felt to be mainly of historical interest; most clinicians prefer to classify IE based on organism and type of valve. Native versus prosthetic valve is also of importance (Bennett et al., 2015). The pathophysiology, causative etiologies, diagnostics, and treatment recommendations of acute IE are not discussed in this chapter.

Treatment

Regarding treatment of chronic infective endocarditis, the Infectious Diseases Society of America recommends oral suppressive antimicrobials for fungal endocarditis. It is reasonable to continue this lifelong given the high rate of relapse with fungal infective endocarditis (Baddour, 2001). Similar treatment strategies are employed following acute bacterial endocarditis in patients with prosthetic material such as vascular grafts, artificial or bioprosthetic valves, or prosthetic joints.

Chronic Pericarditis

Definition

Pericarditis is usually diagnosed with the triad of pericardial chest pain, friction rub on auscultation, and diffuse ST-segment abnormalities in the setting of PR depression. However, this triad may be rare in certain disease states such as tuberculous (TB) pericarditis (Mutyaba and Ntsekhe, 2017). Although infectious pericarditis can be classified as acute, recurrent, or chronic these different presentations are driven by etiologies that can result in any of these presentations. Chronic pericarditis, therefore, is a disease state on a spectrum with any of the acute infectious pericarditis syndromes. This discussion will be an overview of the various infectious etiologies of pericarditis with a special focus on the chronic manifestations of these diseases. Chronic presentations can include relapse of pericarditis or progression to development of constrictive or effusive pericarditis.

Approximately one in four patients with acute pericarditis will have at least one episode of relapse (Khandaker et al., 2012). Chronic presentations can include relapse of pericarditis or progression to constrictive or effusive pericarditis.

Etiologies

Viral

Viral pericarditis tends to be a benign and self-limited disease. Most common pathogens include polio, enteroviruses, coxsackie A and B. Constrictive pericarditis is a rare complication of viral pericarditis (Imazio et al., 2007).

The term myopericarditis more appropriately describes viral infections of the heart, as the same viruses are implicated in myocarditis as well as in pericarditis (Smith, 1966). Of these, the most commonly associated with pericarditis are the enteroviruses, especially coxsackie viruses (CV). These infections account for at least one third of all cases of acute viral pericarditis. In these cases, sampling of the pleural fluid for testing presents significant logistical challenges. However, proof of causation exists for all CV-B serotypes along with several A and E serotypes (Guarner et al., 2007). In other serotype infections, the diagnosis of coxsackie myopericarditis is made by establishing infection at an alternative site, for example through stool sampling.

The spread of viruses to the pericardium is usually via a hematogenous route. This triggers an inflammatory process and can lead to an effusion. Many times, patients with acute pericarditis develop recurrent episodes. The mechanism for this has yet to be established but is likely related to immunologic processes rather than active infection.

Clinical manifestations

Enteroviral myocarditis can affect all ages, but particularly places young physically active adolescents and young adults at risk with increased incidence in males compared to females (Sainani et al., 1968). Many of these cases are preceded by a prodrome of upper respiratory infectious symptoms, usually 7–14 days prior to the onset of pericarditis. The clinical syndrome of pericarditis is consistent with presentation of idiopathic pericarditis. This is characterized by a sharp pleuritic chest pain and may be accompanied by friction rub in 35%–80% of cases. 50% of cases may be characterized evidence of pericardial effusion on by enlarged cardiac silhouette on chest X-ray. Gallops or signs of congestive heart failure may be observed in approximately 20% of cases. ECG can support the diagnosis and ST segment changes may accompany associated myocardial disease. Many times, cardiac enzymes may be elevated.

Diagnosis

CV have often been isolated from pericardial fluid during biopsy or autopsy procedures surrounding pericarditis, but this is not a practical clinical test. Many times, cardiac tissue is insufficient for viral culture. The diagnosis must be made through oropharyngeal or stool sampling, if able to be made at all. Real time polymerase chain reaction (RT-PCR) for CV is a promising new diagnostic method, although not yet widely available.

Management, course, and prognosis

The treatment of acute viral pericarditis is largely supportive, with medical management of the potential complications including heart failure and arrhythmias (Feldman and McNamara, 2000). Myopericarditis may be associated with persistent electrical abnormalities. Cardiomegaly with heart failure may develop as a result of myocardial damage and scarring. Chronic constrictive pericarditis is also a potential complication. Multiple infections and noninfectious cardiac insults may progress to dilated cardiomyopathy (DCM) (Codd et al., 1989). There is emerging evidence that enteroviral infection may be detected months to years after the onset of DCM, suggesting a mechanism for the development of a particular subset of DCM (Chapman and Kim, 2008).

Bacterial

Bacterial etiologies usually present as purulent pericarditis. These are rare and usually represent an extension of infection from elsewhere, usually pneumonia or mediastinitis. The exception is mycobacterium tuberculosis (TB) which can occur separately from pulmonary tuberculosis.

Etiologies are often undetermined; 40%–84% of patients with acute pericarditis are listed as idiopathic (Bennett et al., 2015). This continues to be true even when histology, cytology, viral PCR, bacterial, and fungal sequencing are performed (Imazio et al., 2007). Pericardiocentesis may assist in diagnosis, but is negative in most patients. Pericardial biopsy or pericardiotomy may increase diagnostic yield (Bennett et al., 2015).

Tuberculous pericarditis

Tuberculous pericarditis may affect up to 1%–2% of patients with active pulmonary tuberculosis (Larrieu et al., 1980). The HIV epidemic has led to a substantial increase in tuberculous pericarditis (Mutyaba and Ntsekhe, 2017).

A recent series investigated nearly 300 cases of acute pericarditis without clear initial source. Four percent of these cases were eventually diagnosed with tuberculous pericarditis (Sagrista-Sauleda et al., 1988). Constrictive pericarditis developed in six out of seven patients and all of these required pericardiectomy.

Clinical manifestations

While TB primarily manifests as pulmonary disease, it may also develop in extrapulmonary sites including the skin, central nervous system, bones, joints, lymph nodes, liver, and heart. Cardiac involvement can be nearly as devastating as CNS disease in terms of morbidity and mortality.

Cardiac involvement can include TB pericarditis, myocardial TB with or without aneurysm, and TB aortitis with or without aneurysms (Mutyaba and Ntsekhe, 2017). Tuberculosis invades the pericardium via lymphatic, hematogenous, or direct contiguous spread. Pericarditis usually occurs in the setting of very few bacteria. These trigger an aggressive hypersensitivity response with TH-1 helper cells which leads to inflammatory exudative effusion, potentially with tamponade effects. In immunocompromised hosts, the bacterial load is much higher and pericarditis symptoms are often only a portion of diffuse disease.

Diagnosis

Diagnosis of pericarditis itself is often made with chest X-ray, EKG, and echocardiogram. Tuberculous pericarditis can be confirmed by sending pericardial fluid for acid-fast bacterial culture/stain, TB PCR, or via unstimulated interferon gamma (uIFN-γ). Adenosine deaminase (ADA) levels also correlate with disease (Mutyaba and Ntsekhe, 2017). Unstimulated interferon gamma has a 95% sensitivity and 96% specificity, but is more expensive than using acid-fast bacterial (AFB) stains/culture or ADA (Pandie et al., 2014). A scoring system has been developed that uses six clinical and laboratory values with differing weights. These include night sweats, weight loss, fever >38C, leukocytosis less than 10×10^9 (Feldman and McNamara, 2000), and serum globulin >40 g/L. A score of six or more has 36% sensitivity and 85% specificity for TB pericarditis (Reuter et al., 2006).

Management, course, and prognosis

The natural history of TB pericarditis varies widely. Complications can include tamponade, but long-term complications of fibrotic fusion and development of constrictive pericarditis are most concerning. The natural history of this is demonstrated in a recent study. Sixty percent of the control patients required pericardiocentesis despite receiving the standard anti-TB chemotherapy. Of those alive at 12 months, 8% had progressed to constrictive pericarditis and 4% had reaccumulation leading to tamponade (Mayosi et al., 2014). There is evidence to suggest that HIV-positive patients are less likely to progress to constrictive pericarditis.

In some cases, underlying myocardium can become inflamed. This is more likely in HIV-positive patients with CD4 counts less than 100 cells/μL (Syed et al., 2014).

Treatment of TB pericarditis, usually with at least six months of four-drug anti-TB chemotherapy, should be promptly started once alternative diagnoses have been excluded. This is especially true if biomarkers of TB are present and if TB is confirmed at other extrapulmonary sites. Experts suggest treating for TB in endemic areas when no obvious other diagnosis are apparent [KT1] (Mayosi et al., 2005).

Adjunctive steroids reduce hospitalization and may decrease progression to constrictive pericarditis; however, this does not change mortality (Mayosi et al., 2014).

The causative agent of constrictive pericarditis is difficult to diagnose as most patients present with established constriction. An empiric course of anti-TB chemotherapy may be reasonable in patients from high burden areas with concerning recent symptoms of TB and when postoperative pericardial tissue reveals acute inflammation (Mayosi et al., 2005). Unfortunately, the only definitive treatment of tuberculous constrictive pericarditis is surgical pericardiectomy. Mortality rates are significant and can range from 6% to 14% (Mutyaba et al., 2014; Bertog et al., 2004).

Fungal

Fungal causes of chronic pericarditis are infrequently recognized. Disseminated histoplasmosis and coccidiomycosis have been described as causes of acute pericarditis (Bennett et al., 2015). Fungal pericarditis has been reported as a complication of cardiothoracic surgery.

Treatment

Treatment of idiopathic and viral relapsing pericarditis includes high-dose aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) in combination with colchicine (Imazio et al., 2005). Glucocorticoids are often avoided unless symptoms are clearly refractory to NSAIDs and colchicine. Administration of steroids has been associated with an increased risk of recurrent pericarditis (Lotrionte et al., 2010).

Surgical drainage is essential in patients with purulent (bacterial) pericarditis (Bennett et al., 2015). Pericardiectomy is usually reserved for severe constrictive pericarditis, but can be considered in patients with severe relapsing pericarditis. A recent review of patients from Mayo revealed improvement in symptoms (Khandaker et al., 2012) Although there is little data, experts recommend activity restrictions until symptom resolution (Pelliccia et al., 2006).

Chronic Myocarditis

Definition

The acute presentation of myocarditis is covered elsewhere in this publication. Briefly, most patients present with unexplained heart failure, chest pain, or arrhythmias, often preceded by febrile or respiratory tract illness. Chronic myocarditis is often clinically described as ongoing symptoms for more than 14 days.

General Pathophysiology

Much of our understanding of chronic myocarditis comes from mouse models using coxsackievirus (Bennett et al., 2015). Acute changes involve widespread edema and only a few inflammatory cells. This progresses to loss of striation and fragmentation of

myofibers. Immune cells including NK cells, macrophages, T lymphocytes, and polymorphonuclear cells infiltrate the tissue (Beschorner et al., 1990; Chow et al., 1989). Occasionally interstitial fibrosis occurs and there is loss of myofibers. Ongoing viral or bacterial replication is associated with persistent infiltration and worsening of cardiac function (Kuhl et al., 2005a).

Inability to establish effective immune responses can lead to increased replication and may lead to viral or bacterial persistence. Chronic infection and ongoing replication may lead to DCM. Conversely, excessive immune activation may also play a role in progression to DCM as a result of epitope mimicry and damage of healthy cells (Kuhl et al., 2005a).

Around day 14 of acute myocarditis, fibroblasts and myofibroblasts begin proliferating. M2 macrophages produce collagen to form a permanent scar. In cases that progress to chronic myocarditis, the immune system is unable to completely clear all infected cells. In other cases auto-reactive immune cells persist, causing chronic inflammation. This activates matrix metalloproteases that digest collagen and elastin. In conjunction with profibrotic factors, these facilitate progression to DCM (van den Hoogen et al., 2015).

Etiologies

Most organisms that cause acute myocarditis are also associated with chronic myocarditis. Progression to chronic myocarditis is most often documented in infections involving coxsackieviruses, HIV, and Chagas disease (*Trypanosoma cruzi*).

Viral

A multitude of infectious agents have been reported to cause myocarditis. While bacterial and fungal causes exist, the bulk of acute and chronic myocarditis is virally mediated. Key viruses include coxsackieviruses (members of the enterovirus family), influenza, mumps, measles, polio, and enteroviruses. Adenovirus and parvovirus B19 have also been frequently isolated as causes of myocarditis. Real-time PCR has improved our ability to isolate viral causes, and about two thirds of patients with cardiomyopathies previously designated as idiopathic harbor viral genomes such as Parvovirus, human herpes virus 6 (HHV-6), enteroviruses, adenovirus, EBV, and CMV (Kuhl et al., 2005b). Although these viruses are also found often in samples from asymptomatic patients, viral RNA replicative intermediates were only found in patients with ongoing inflammation.

Diagnosis

Diagnosis begins clinically, usually with a young patient who presents with rapidly progressive cardiomyopathy, arrhythmias, or symptoms of cardiac ischemia in the setting of normal coronary arteries (Dec et al., 1992). In subacute and chronic myocarditis, anticardiac autoantibodies and immunoglobulins can be detected in blood samples (Caforio et al., 2013)

Endomyocardial biopsy (EMB) can be used to obtain tissue for viral pathogen identification. Histopathologic analysis is based on the "Dallas criteria" but this can be open to interpretation and does not provide prognostic assistance (Caforio et al., 2013). The European Society of Cardiology recommends EMB as early as possible while the American College of Cardiology/American Heart association advises EMB when "a specific diagnosis is suspected that would influence therapy" (Fung et al., 2016; Yancy et al., 2013)

Cardiac magnetic resonance (CMR) imaging now provides a noninvasive diagnosis of myocarditis. Hallmarks include edema, early and late enhancement. These can differentiate between myocarditis and myocardial infarction (Childs and Friedrich, 2011). CMR was found to be more accurate in suspected acute myocarditis than in chronic myocarditis (Lurz et al., 2012).

Management, course, and prognosis

Prognosis has been linked to immunohistological signs of inflammation and lack of beta-blocker therapy, but not to histology or detection of viral genomes (Kindermann et al., 2008). Recently, a number of micro RNAs were found to be involved in the progression of viral myocarditis toward DCM (Xu et al., 2014).

Unfortunately the current treatments for advanced DCM involve heart transplantation or mechanical assist devices. Investigations are ongoing regarding treatment via pathogen inhibition, immune modulation, and heart failure therapy (Fung et al., 2016). In mice, novel antiviral agents including astragaloside have been shown to decrease fibrosis and increase survival rate. Other therapies using recombinant proteins and microRNAs have been limited to animal models thus far (Chen et al., 2011). Recent murine study suggests that ivabradine may prevent the progression from viral (coxsackievirus B3) myocarditis to DCM by inhibiting p38 MAPK pathway, downregulating inflammatory responses, and decreasing collagen expression (Yue-Chun et al., 2016).

In a recent double-blinded phase II study in humans, immunomodulatory IFN-β-1b treatment led to more rapid virus elimination, improvement in NYHA functional class, and improved quality of life without increase in adverse events when compared to placebo (Schultheiss et al., 2016). Other promising therapies include immunosuppressants. In one trial, use of azathioprine and prednisone improved left ventricular ejection fraction and New York Heart Association functional class in patients with symptoms for more than 6 months (Wojnicz et al., 2001). NSAIDs have shown to increase myocardial inflammation in viral myocarditis. Intravenous immune globulin has been given, but data is not conclusive. While immunomodulatory drugs appear beneficial for subacute stages of viral myocarditis, use in early stages may have detrimental effects (Fung et al., 2016).

Other viral causes: HIV

HIV has been well documented as a cause of chronic cardiac disease with most data collected from the pre-antiretroviral (ART) time period. It is still not clear what role HIV versus treatment for HIV plays in the development of coronary artery disease. Protease

inhibitors and specific nucleoside reverse transcriptase inhibitors have been associated with an increased risk of cardiovascular disease, but a clear causal relationship has not yet been established (Llibre and Hill, 2016). Even in subjects with suppressed viral loads, cardiac MRI revealed myocardial fibrosis in 82.1% of HIV-infected patients, but only in 27.3% of healthy controls (Luetkens et al., 2016).

Early studies during the AIDS epidemic reported that up to 50% of patients would develop a cardiomyopathy during their lifetimes (Milei et al., 1998). However, it is not fully known whether HIV directly infects the cardiac myocyte leading to dysfunction. In addition, other cardiotropic viruses have been isolated from AIDS patients with cardiomyopathy (Bennett et al., 2015). Other HIV-positive patients demonstrate autoantibodies against myocardial proteins (Currie et al., 1998).

Bacterial

The broad topic of rheumatic heart disease will not be reviewed in this chapter.

Most bacterial cardiac infections manifest as endocarditis. Bacteremia from any pathogen can result in cardiac abscess. Usual pathogens include streptococci, staphylococci, meningococci, salmonella, campylobacter, brucellosis, tularemia, and bartonella. However, myocarditis secondary to toxin production was the most common cause of death in diphtheria. More rare etiologies include legionella, mycoplasma, chlamydia, and rickettsial infections (Bennett et al., 2015). Lyme disease may present as conduction system disturbances, but usually resolves with appropriate treatment and does not result in chronic cardiac changes.

Tuberculosis has been implicated in sudden cardiac death, but this organism usually infects the pericardium rather than the myocardium (Liu et al., 2012). However, there have been reports of extension of pericardial inflammation to myocardial disease. Following the HIV epidemic, TB myopericarditis is most often described in HIV-positive patients from Africa.

Fungal

Fungal myocarditis is not well documented. There have been reports of myocardial involvement in the setting of invasive candida disease, but isolated fungal involvement of the myocardium is rare (Nosanchuk, 2002).

Protozoa

The major protozoan known to cause chronic cardiac disease is *Trypanosoma cruzi*. The clinical manifestations of infection, known as Chagas disease, were described by Carlos Chagas in 1909 (Kropf and Sa, 2009).

An estimated 8 to 12 million people are infected with *T. cruzi* with 10,000 deaths annually. These flagellated protozoa are transmitted mostly by triatominae insects, but transmission also occurs via contaminated blood transfusion, contaminated organ transplant, accidental needlestick, consumption of insect-contaminated foods, or congenital exposure (Mensah et al., 2015). Although Chagas disease is endemic only to South and Central America, changes in human migration are quickly making this a global disease. For example, the CDC estimates that more than 300,000 people with *T. cruzi* infection live in the United States. Screening blood transfusions, kidneys, and livers for *T. cruzi* is recommended if potential donors were born in Mexico, Central America, or South America (Chin-Hong et al., 2011).

Clinical manifestations

Chagas disease follows three phases: acute, indeterminate, and chronic. Approximately 20%–30% of those infected will develop chronic cardiovascular Chagas disease (Stanaway and Roth, 2015). Many patients with the chronic form remain asymptomatic for years. Organ damage occurs as a result of both parasitemia and immune response to parasites. Immune-mediated injury occurs when mononuclear cells infiltrate and release damaging cytokines. Often these are triggered by persistent parasite presence, but autoimmune mechanisms including molecular self-mimicry, polyclonal activation, and shared epitopes also contribute (Rassi et al., 2017). Initial myocarditis from Chagas can be diffuse with necrosis, interstitial edema, vasculitis, and inflammatory cell infiltration. This differs from chronic Chagas cardiomyopathy which is characterized by extensive reactive fibrosis in the setting of few inflammatory infiltrates and mild parasitemia. Although often not seen by histology, *T. cruzi* antigens have been identified via PCR in cardiac tissues of patients with chronic Chagas (Rassi et al., 2017).

Host factors such as genetic polymorphisms may result in changing expression of immune modulators. Patients with enhanced expression of regulatory CTLA-4 system often do not progress to severe Chagas cardiomyopathy (de Oliveira et al., 2015).

Chronic Chagas cardiomyopathy can manifest as abrupt onset heart failure, atrial and ventricular arrhythmias, sudden cardiac death, and thromboembolic events (Mensah et al., 2015). Historically, the heart often demonstrates saccular apical ventricular aneurysm or an overall "flabby" appearance (Johnson et al., 1971; Bennett et al., 2015). In addition, inflammatory markers that are elevated in chronic Chagas disease are also associated with increased risk of stroke. Most patients with chronic Chagas disease die of heart failure, but there is emerging data that cerebral vascular accidents may also be associated with Chagas (Guedes et al., 2016).

Diagnosis

Chagas disease can be diagnosed by microscopic observation of the parasite in a blood smear. However, this is more accurate in the acute rather than the chronic phase of disease. Diagnosis of chronic Chagas disease is often made using two different serological tests: indirect fluorescent antibody and commercial enzyme immune assay. Sensitivity and specificity are variable due to cross reactivation with leishmaniasis antigens. Molecular diagnosis is reserved for cases of transfusion related disease, for acute disease when parasitemia is expected to be high, or when there is concern for reactivation in the setting of immunosuppression (Parasites, n.

d.). ADA and serum C-reactive protein have been shown to increase linearly in regard to disease phase and may serve as surrogate markers for inflammation (Bravo-Tobar et al., 2015).

Electrocardiogram (EKG) is recommended when evaluating potential chronic Chagas disease. In patients with normal EKG and normal radiography of chest and abdomen, patients are listed as "indetermined chronic form." EKG findings include ventricular repolarization, prolonged QTc, left atrial enlargement bundle branch blocks, low QRS voltage, sinus tachycardia, or atrial fibrillation (Dias et al., 2015). Echocardiogram is also recommended. Holter monitoring may also be indicated depending on the level of ventricular dysfunction or prior episodes of ectopy (Dias et al., 2015).

Management, course, and prognosis

Two drugs, benznidazole and nifurtimox, are effective against *T. cruzi*. However, these are not approved by the United States Food and Drug Administration and are only available via investigational protocol from the Center for Disease Control. Treatment is strongly recommended for all children and for adults up to age 50 in the absence of advanced Chagas cardiomyopathy. After age 50, individual factors such as age, clinical status, and overall health should be considered prior to prescribing. Both medications have been shown to have adverse side effects. Benznidazole may cause dermatitis, peripheral neuropathy, and weight loss while nifurtimox commonly causes polyneuropathy, nausea, vomiting, dizziness, and anorexia. Both are contraindicated in severe hepatic or renal disease and have not been studied in breastfeeding infants (Parasites, n.d.). Antiparasitic treatment has not been shown to be beneficial in patients with severe chronic phase Chagas disease.

In terms of other treatments for Chagas disease, trypanocidal therapy with benznidazole in patients with established Chagas' cardiomyopathy significantly reduced serum parasite detection but did not significantly reduce cardiac clinical deterioration through 5 years of follow-up (Morillo et al., 2015).

Ventricular arrhythmias associated with Chagas disease are usually treated with amiodarone. Arrhythmic focus catheter ablations, surgery, and implantable cardioverter defibrillators have been used with success in patients with SVT and those who recover from sudden cardiac death. The treatment of bradyarrhythmias is similar to standard care. Likewise, heart failure due to chronic Chagas cardiomyopathy responds to current heart failure pharmacotherapy (Dias et al., 2015).

Prevention efforts began in the 1990s and included the Southern Cone Initiative, the Andean Pact Initiative, and the Central America Initiative. These programs encouraged efforts to eradicate vectors and reservoirs, monitor blood donations, and screen pregnant women. (Mensah et al., 2015). As a result, transmission of *T. cruzi* was certified as "interrupted" in Uruguay, Chile, Brazil, Guatemala, Honduras, El Salvador, and Nicaragua. The vectors have been eliminated from homes in Brazil, Chile, Argentina, Bolivia, Paraguay, and Uruguay (Mensah et al., 2015). The number of deaths attributed to *T. cruzi* infection also decreased, from 45,000 deaths a year in the 1980s to 14,000 in 2001 to 10,000 most recently (Schmunis, 2007).

Introduction

Cardiovascular disease is a leading cause of mortality and morbidity worldwide (Prevention WicwtUCfDCa, n.d.). According to the World Health Organization, cardiovascular disease was estimated to be responsible for approximately 17.5 million deaths in 2012, or 31% of all global deaths in that year. Of these deaths, an estimated 7.4 million were caused by coronary heart disease and 6.7 million were due to stroke (World Health Organization, 2014). It has been well acknowledged that the traditional cardiovascular risk factors—namely, hypertension, diabetes, dyslipidemia, tobacco use, unhealthy diet, obesity, physical inactivity, and harmful use of alcohol—contribute to the etiology of cardiovascular disease (Expert Panel on Detection, 2001; Asia Pacific Cohort Studies Collaboration, 2005; Woodward et al., 2003). Therefore, the optimal management of these risk factors is known to be effective for preventing the development of cardiovascular disease.

Chronic kidney disease (CKD) is now recognized as a significant and rapidly growing global health burden. CKD is chiefly defined as either kidney damage (e.g., albuminuria >30 mg/d, urine sediment abnormalities and electrolyte and other abnormalities secondary to tubular disorders) or a glomerular filtration rate (GFR) of <60 mL/min/1.73 m^2 for a period of 3 months or more. The prevalence of CKD has been estimated to be more than 10% of the population in many countries worldwide (Eckardt et al., 2013). CKD is caused by lifestyle-related disease such as hypertension, diabetes, obesity, and metabolic syndrome, and various less common diseases that mainly affect the kidney (e.g., glomerulonephritis) (Gansevoort et al., 2013). Since CKD patients have a high prevalence of cardiovascular risk factors (Goldstein et al., 2006), it may be reasonable to consider CKD patients to be a high-risk population for cardiovascular disease. Indeed, growing evidence from numerous epidemiological studies suggests that the lower estimated glomerular filtration rate (eGFR), even in patients with mild-to-moderate kidney impairment, is associated with an increased risk of mortality and cardiovascular morbidity in the general populations (Matsushita et al., 2010). Since CKD patients have a greater prevalence of traditional cardiovascular risk factors, it is important that appropriate treatments, such as blood-pressure-lowering and glucose-lowering therapy and use of statins, be administered to those with CKD in order to reduce the risk of cardiovascular disease (Gansevoort et al., 2013; Goldstein et al., 2006).

In this article, we discuss the current status of epidemiological evidence of the excess risk of cardiovascular diseases, such as coronary heart disease, congestive heart failure, arrhythmia, and cerebrovascular disease (including subclinical cerebral abnormalities), among patients with CKD, taking its prevention and management into account.

Epidemiological Evidence of Excess Cardiovascular Risk in People With CKD

Growing epidemiological evidence suggests that patients with CKD have a greater incidence of cardiovascular disease (Herzog et al., 2011). It is well acknowledged that high cardiovascular mortality is the major cause of reduced life expectancy in dialysis patients (Ritz and Bommer, 2009). According to the United States Renal Data System (USRD), cardiovascular disease contributed to 40% of all deaths among patients who received dialysis in 2009–11 (Collins et al., 2011). The risk of CVD mortality or incidence in patients undergoing hemodialysis or peritoneal dialysis is approximately 10–20 times higher than in the general population (Foley et al., 1998; Seliger et al., 2003). Kidney disease and cardiovascular disease share traditional cardiovascular risk factors, such as aging, diabetes, hypertension, and hyperlipidemia(Goldstein et al., 2006). Intriguingly, it has been reported that stroke events early after starting dialysis therapy were more likely to develop among patients with kidney failure caused by either nephrosclerosis or diabetes mellitus than patients with chronic glomerulonephritis, most of which experienced stroke events more than 36 months after starting dialysis therapy (van der Sande et al., 2004). Supportive findings from the Chronic Kidney Disease Japan Cohort (CKD-JAC) study of 2977 patients with eGFR of 10–59 mL/min/1.73 m^2 showed that patients with diabetic nephropathy or nonchronic glomerulonephritic kidney disease had a

 https://doi.org/10.1016/B978-0-12-809657-4.99612-1

higher brachial-ankle pulse wave velocity, which is a marker of atherosclerotic disease than those with chronic glomerulonephritis (Imai et al., 2010). This finding supports the hypothesis that kidney impairment in combination with other cardiovascular risk factors accelerates atherosclerosis and raises the risk of cardiovascular disease in the predialysis and dialysis stages.

The increased cardiovascular risk in patients with kidney disease was reported not only among the dialysis patients, but also among patients with all-stage CKD. Go et al. revealed that the multivariable-adjusted hazard ratio (HR) for cardiovascular events was 1.4 (95% confidence interval [CI] 1.4–1.5) for eGFR of 45 to 59 mL/min/1.73 m^2, 2.0 (95% CI 1.9–2.1) for eGFR of 30–44 mL/min/1.73 m^2, 2.8 (95%CI 2.6–2.9) for eGFR of 15 to 29 mL/min/1.73 m^2, and 3.4 (95%CI 3.1–3.8) for eGFR of $<$15 mL/min/1.73 m^2 in a large-scale population-based study involving 1,120,295 adults from a large, integrated system of health care delivery in whom serum creatinine had been measured between 1996 and 2000 and who had not undergone dialysis or kidney transplantation (Go et al., 2004). Similar inverse associations have been observed for the risk of premature death and hospitalization. In a pooled analysis using 22,634 participants from community-based longitudinal studies including the Atherosclerosis Risk in Communities (ARIC) Study, Cardiovascular Health Study, Framingham Heart Study, and Framingham Offspring Study, subjects with eGFR below 60 mL/min/1.73 m^2 had a higher incidence of cardiovascular disease than those with eGFR of $\geq$60 mL/min/1.73 m^2 (42.1 vs. 16.4 events per 1000 person-years). This significant association remained unchanged after adjusting for traditional cardiovascular risk factors (HR 1.19, 95%CI 1.07–1.32) (Weiner et al., 2004). Similarly, in a pooled analysis using the individual data from 30,657 participants from 10 community-based cohort studies in Japan, the multivariable-adjusted HR for the development of cardiovascular disease increased gradually with lower eGFR levels: the HR was 1.57 (95% CI 1.14–2.15) in subjects with eGFR of $<$60 mL/min/1.73 m^2, as compared to those with eGFR of $\geq$90 mL/min/1.73 m^2 (Ninomiya et al., 2008).

In addition to lower eGFR, proteinuria and albuminuria are also good indicators for cardiovascular risk assessment in the general population. A literature-based systematic review from community-based cohort studies demonstrated that the presence of proteinuria or albuminuria was significantly associated with 1.5–2.0 times greater risk for coronary heart disease and stroke (Perkovic et al., 2008; Ninomiya et al., 2009). In addition, the Chronic Kidney Disease Prognosis Consortium (CKD-PC) performed a collaborative meta-analysis of the association between CKD and cardiovascular mortality in a general population cohort that included 105,872 participants from 14 studies employing urine albumin-to-creatinine ratio (ACR) measurements and 1,128,310 participants from seven studies that used urine protein dipstick measurements (Matsushita et al., 2010). This study clearly demonstrated that lower eGFR levels and higher ACR levels were log-linearly associated with the greater risk of cardiovascular mortality. The association between ACR level and cardiovascular mortality was significant within the normal range of ACR (i.e., ACR $\geq$ 1.1 mg/mmol) without threshold effects. In addition, eGFR and ACR were multiplicatively associated with the risk of cardiovascular mortality without evidence of interaction. Similar findings were recorded in the studies with dipstick measurements. Overall, the findings of this study provided strong evidence that eGFR and albuminuria (or proteinuria) are significant independent risk factors for cardiovascular disease in the general population, and both indicators must be evaluated for the early detection and management of the high-risk population for cardiovascular disease.

Possible Mechanisms Underlying the Relationship Between CKD and Cardiovascular Disease

There are several possible explanations for the association between CKD and cardiovascular disease (**Fig. 1**) (Sarnak et al., 2003; Toyoda and Ninomiya, 2014). As mentioned earlier, CKD is associated with a high prevalence of traditional cardiovascular risk factors, such as aging, hypertension, diabetes, smoking habits, and dyslipidemia. Several meta-analyses assessing the association between CKD and cardiovascular disease found that the magnitude of the risk estimates was reduced after adjusting for known traditional cardiovascular risk factors as compared with age-adjusted risk estimates. These findings suggest that an accumulation of traditional cardiovascular risk factors in patients with CKD increases the risk of stroke. In addition, large-scale meta-analyses demonstrated that CKD was a significant risk factor for cardiovascular disease, independent of known cardiovascular risk factors. CKD may also be associated with an increase in "novel" risk factors such as hyperhomocysteinemia, inflammation, asymmetric dimethyl arginine, oxidative stress, anemia, thrombogenic factors, left ventricular hypertrophy, endothelial dysfunction, and arterial stiffness (Sarnak and Levey, 2000; Lau et al., 2016). These traditional and novel risk factors may also play a role of developing process of systemic atherosclerosis. As another possible explanation, impaired kidney function may reflect the duration and severity of hypertension, diabetes or other diseases giving rise to the cardiovascular diseases. Lastly, the results from several previous studies may imply either that CKD itself is a causal factor in the pathogenesis of cardiovascular disease, or that CKD is simply a marker of systemic vessel pathology. The kidney, heart, and brain share unique susceptibilities to vascular injury, so that some vascular risk factors such as hypertension, diabetes, and heart disease may cause similar vascular injuries in these organs.

Association Between CKD and the Subtypes of Cardiovascular Disease

Coronary Heart Disease

Patients undergoing dialysis have been acknowledged to have a greater risk of coronary heart disease (Collins et al., 2011). Some autopsy studies have shown that coronary artery plaques are common in patients undergoing dialysis (Ansari et al., 1993; Schwarz

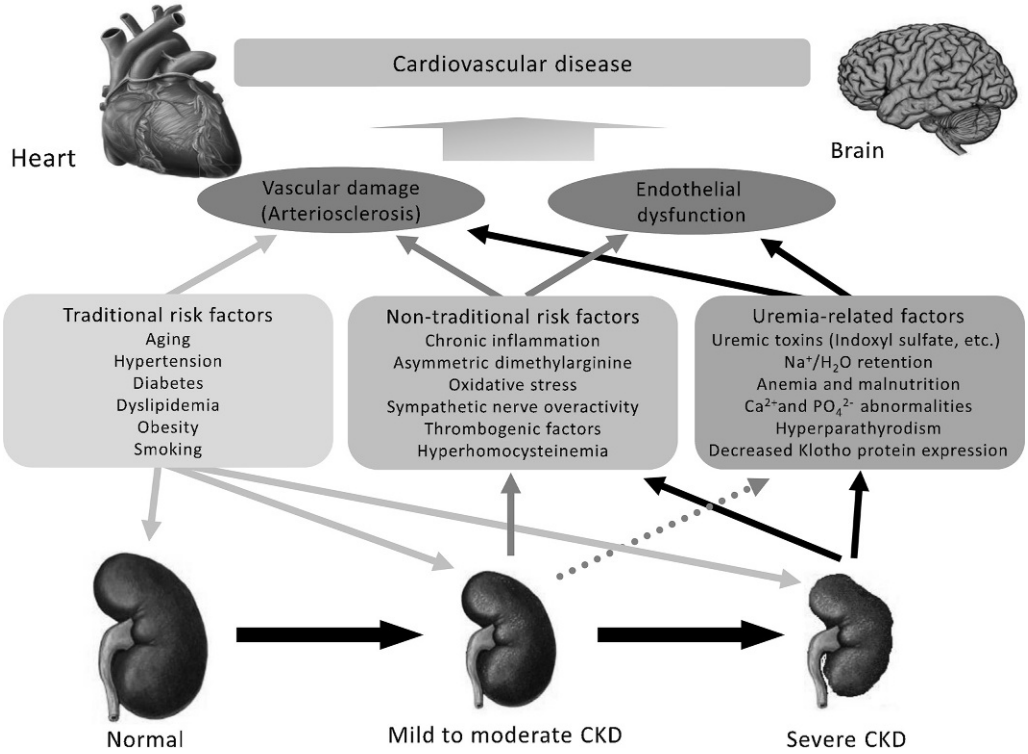

Fig. 1 Traditional and nontraditional risk factors for stroke and kidney disease. Modified from Toyoda, K., Ninomiya, T. (2014). Stroke and cerebrovascular diseases in patients with chronic kidney disease. *Lancet Neurology* **13**, 823-833.

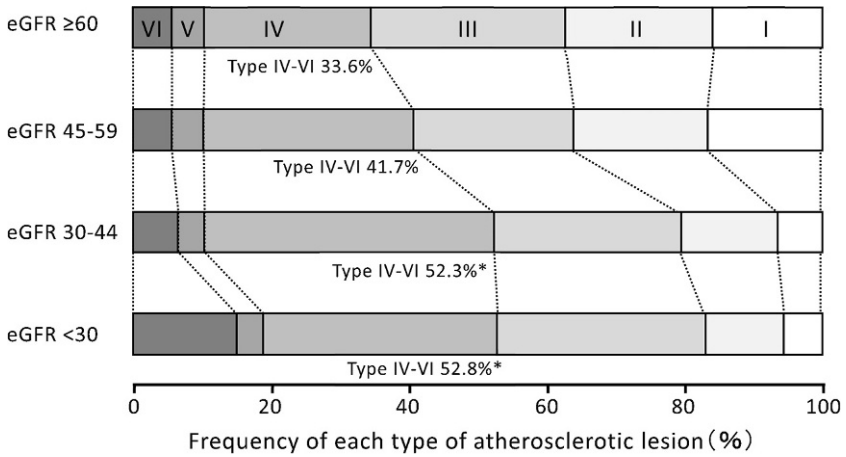

Fig. 2 Frequencies of each type of coronary atherosclerotic lesion according to estimated eGFR level in 126 community-based autopsy samples. The types of atherosclerotic lesion were determined according to the American Heart Association classification. Advanced atherosclerotic lesions were defined as types IV–VI. The frequencies were adjusted for age and sex. $^*P < 0.05$ vs. eGFR ≥ 60. Modified from Nakano, T., Ninomiya, T., Sumiyoshi, S., Fujii, H., Doi, Y., Hirakata, H., Tsuruya, K., Iida, M., Kiyohara, Y., Sueishi, K. (2010). Association of kidney function with coronary atherosclerosis and calcification in autopsy samples from Japanese elders: The Hisayama Study. *American Journal of Kidney Diseases* **55**, 21–30.

et al., 2000). Moreover, an increased risk of coronary events among patients with CKD not undergoing dialysis has been reported in several epidemiological studies (Weiner et al., 2004; Ninomiya et al., 2005, 2008). In the aforementioned pooled analyses from community-based longitudinal studies in the United States and Japan, subjects with CKD had an approximately 2.0–2.5 times greater risk of coronary heart disease than those without CKD after adjusting for traditional risk factors (Weiner et al., 2004; Ninomiya et al., 2008). In support of this finding, a clinical study using coronary angiography found that patients with CKD were more likely to have at least one significant coronary lesion and severe coronary lesions (i.e., three-vessel and/or left main disease) than those without CKD (Chonchol et al., 2008). A cross-sectional study using community-based autopsy samples in Japan has

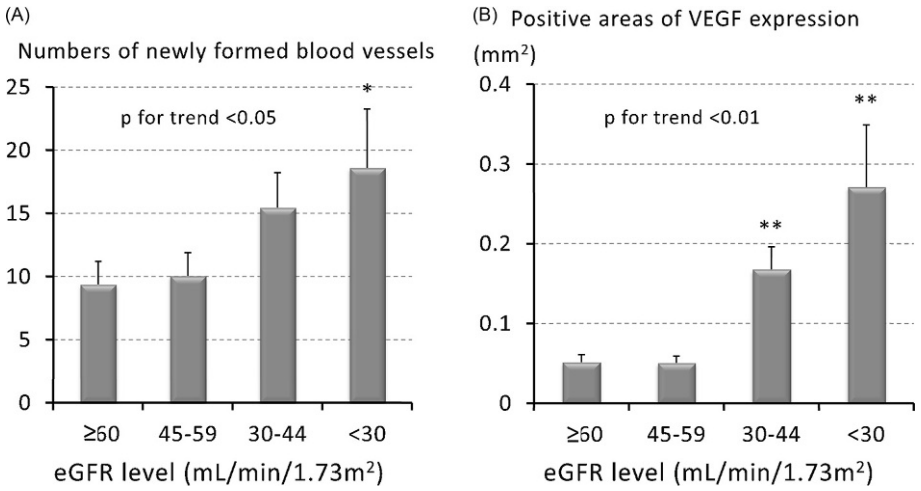

Fig. 3 Numbers of newly formed blood vessels and positive areas of VEGF expression in the intima of coronary arteries according to estimated eGFR level in 126 community-based autopsy samples. *eGFR*, estimated glomerular filtration rate; *VEGF*, vascular endothelial growth factor. The estimates were adjusted for age, sex, hypertension, HbA1c, LDL cholesterol, HDL cholesterol, calcium, phosphate, hemoglobin, smoking, and drinking. $^{*}P<0.05$, $^{**}P<0.01$ vs. eGFR $\geq$60. Modified from Nakano, T., Ninomiya, T., Sumiyoshi, S., Onimaru, M., Fujii, H., Itabe, H., Nakashima, Y., Sueishi, K., Tsuruya, K., Oda, Y., Kitazono, T., Kiyohara, Y. (2013). Chronic kidney disease is associated with neovascularization and intraplaque hemorrhage in coronary atherosclerosis in elders: Results from the Hisayama Study. *Kidney International* **84**, 373–380.

been reported that the severity of coronary atherosclerotic lesion increases with GFR decline (Nakano et al., 2010, 2013). The frequency of advanced atherosclerotic lesions of coronary arteries (defined as the American Heart Association classification types IV–VI) increased gradually with lower eGFR levels (33.6%, 41.7%, 52.3%, and 52.8% for eGFRs of $\geq$60, 45–59, 30–44, and <30 mL/min/1.73 m^2, respectively; *P* for trend = 0.006) (**Fig. 2**) (Nakano et al., 2010). Lower eGFR levels were significantly associated with greater positive areas of oxidized low-density lipoprotein (oxLDL) and vascular endothelial growth factor (VEGF) expression and increased numbers of newly formed blood vessels in the intima (**Fig. 3**) (Nakano et al., 2013). These relationships remained substantially unchanged after adjustment for confounding factors. Together, the results suggest that patients with CKD have intimal neoangiogenesis and an increased risk of intraplaque hemorrhage in the coronary arteries, possibly due to the local accumulation of oxLDL and VEGF. CKD is also known to be prognostic for poor outcomes after percutaneous coronary intervention for coronary heart disease. A hospital-based study revealed that patients with moderate CKD or end-stage kidney disease (ESKD) undergoing PCI have an approximately three times greater risk of in-hospital mortality than those with preserved kidney function (odds ratio [OR] 2.92, 95%CI 1.91–4.46 for moderate CKD; OR 3.68, 95%CI 1.62–8.36 for ESKD) (Parikh et al., 2012). These findings suggest that coronary atherosclerotic lesions must be evaluated carefully in patients with CKD for prevention of premature cardiac death by the early detection and management of coronary heart disease and its risk factors.

Congestive Heart Failure

Cardiac morbidity and mortality rates are high in patients with CKD. Patients with CKD have an increased prevalence of coronary artery disease, silent myocardial ischemia, complex ventricular arrhythmias, atrial fibrillation, left ventricular hypertrophy, mitral annular calcium, and aortic valve calcium compared to those without it (Das et al., 2006). On the other hand, there is limited evidence of the prevalence and incidence of congestive heart failure and the mortality from heart failure in patients with CKD. According to a report from the USRD, the event rate of heart failure was higher in elder subjects with eGFR of <60 mL/min/1.73 m^2 than in those with normal eGFR (176 vs. 56 events per 1000 person-years): the relative risk for heart failure was 1.68 (Shiba and Shimokawa, 2011). The 1-year mortality of subjects with eGFR of <60 mL/min/1.73 m^2 was approximately 25%. The ARIC study also reported showing that the incidence of heart failure in middle-aged US adults was threefold higher for subjects with eGFR of <60 mL/min/1.73 m^2 than those with eGFR $\geq$90 mL/min/1.73 m^2 (18 vs. 6 per 1000 person-years) during a mean follow-up of 13.2 years (Kottgen et al., 2007). The multivariable-adjusted hazard ratio of developing heart failure was 1.94 (95%CI 1.49–2.53) for subjects with eGFR of <60 mL/min/1.73 m^2 as compared to those with eGFR $\geq$90 mL/min/1.73 m^2. The excess risk of heart failure has been recognized to be attributable to hemodynamic factors (e.g., pressure and volume overload) and CKD-related nonhemodynamic factors (e.g., inappropriate activation of the renin–angiotensin system, increased oxidative stress, inflammation, anemia, and raised production of growth factors for collagen and muscle cells) (Cerasola et al., 2011; McCullough, 2004). Pressure overload is largely caused by long-standing hypertension and arterial stiffness (McCullough, 2004). Therefore, cardiac function should be managed carefully in patients with CKD, considering the similar pathophysiologic nature between the kidneys and heart (Shiba and Shimokawa, 2011).

Atrial Fibrillation

Patients with CKD are known to experience a wide spectrum of arrhythmias ranging from premature atrial contraction to atrial fibrillation and flutter, premature ventricular contraction, and ventricular tachycardia, with atrial fibrillation being the most common. According to the data from the international Dialysis Outcomes and Practice Patterns Study (DOPPS), atrial fibrillation was present in 13% (ranging from 6% in Japan to 25% in Belgium) of patients undergoing dialysis, and its prevalence increased with age and was higher in all age categories than in the general population, and new-onset atrial fibrillation developed in 1.0% of the study population during follow-up (Wizemann et al., 2010). This excess risk of atrial fibrillation is also observed in patients in the predialytic stage of CKD. In the Chronic Renal Insufficiency Cohort Study (CRICS), the prevalence of atrial fibrillation in subjects with CKD was 18% in the study population, which was similar to that in patients undergoing dialysis, and was two to three times higher than that reported in the general population of the United States (Soliman et al., 2010). A community-based cross-sectional survey in Japan revealed that multivariable-adjusted OR for prevalent atrial fibrillation was 2.66 (95%CI 1.07–6.60) in subjects with eGFR of <60 mL/min/1.73 m^2, as compared to those with eGFR of ≥ 90 mL/min/1.73 m^2 (Ohyama et al., 2013). With regard to the incidence of atrial fibrillation, the ARIC study clearly demonstrated that lower eGFR levels were associated with the risk of new-onset atrial fibrillation after adjusting for potential confounding factors during a median follow-up of 10.1 years in a general US population: the multivariable-hazard ratios of new-onset atrial fibrillation were 1.27 (95%CI 1.02–1.58), 1.57 (1.19–2.07), and 2.84 (1.70–4.73) for subjects with eGFR of 60–89, 30–59, and 15–29 mL/min/1.73 m^2, respectively, as compared with subjects with eGFR of 90 mL/min/1.73 m^2 (Alonso et al., 2011). Similarly, higher ACR levels were significantly associated with the risk of incident atrial fibrillation, which was 1.89 (95%CI 1.49–2.41) and 2.69 (95%CI 1.82–4.00) for ACR of 30–299 and 300 mg/gCr, as compared to ACR of <30 mg/gCr (Alonso et al., 2011). In addition, the risk of incident atrial fibrillation increased multiplicatively with lower eGFR and higher ACR levels without evidence of interaction (**Fig. 4**) (Alonso et al., 2011). The cases of patients with CKD are likely to be complicated by various metabolic disorders, alterations in the cardiovascular system, and impaired autonomic nervous dysfunctions which facilitate the incidence of atrial fibrillation.

Stroke

There is conflicting evidence as to whether lower eGFR is a risk factor for stroke independent of traditional cardiovascular risk factors. In the aforementioned pooled analyses from community-based longitudinal studies in the United States and Japan, subjects with eGFR of <60 mL/min/1.73 m^2 had a higher incidence of stroke, but this excess risk of stroke in lower eGFR was attenuated, with the result that the association did not quite attain the conventional levels of significance after adjusting for the traditional risk factors (Weiner et al., 2004; Ninomiya et al., 2008). However, these nonsignificant associations between lower eGFR and the risk of stroke arise from insufficient statistical power. A recent meta-analysis of 21 articles derived from 33 prospective studies among 284,672 people experiencing 7863 stroke events, in which multivariate-adjusted relative risks were pooled, suggested that the risk of incident stroke was increased by 43% (95% CI 31%–57%) in subjects with eGFR of <60 mL/min/1.73 m^2 (**Fig. 5**) (Lee et al., 2010). Lower eGFR was a risk factor for both ischemic and hemorrhagic stroke. In addition, 11 of the 33 prospective studies reported both age- and sex-adjusted estimates and the risk estimates adjusted for other known cardiovascular risk factors. A sensitivity analysis using this subset of data revealed that the age- and sex-adjusted summary estimate was 1.64 (95%CI 1.45–1.85), which after further

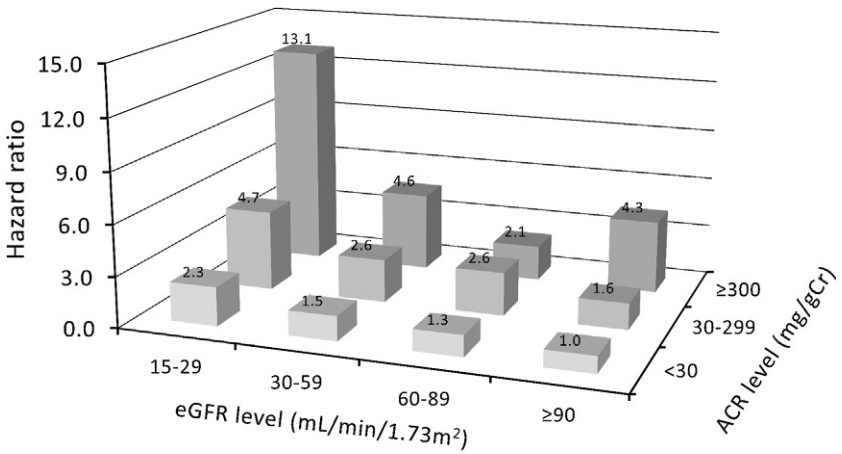

Fig. 4 Multivariable-adjusted hazard ratios for new-onset atrial fibrillation according to estimated eGFR level and ACR level. *eGFR*, estimated glomerular filtration rate; *ACR*, urine albumin-to-creatinine ratio. Hazard ratios were adjusted for age, sex, race, study site, education, income, height, smoking, drinking status, diabetes mellitus, systolic blood pressure, use of antihypertensive medication, body mass index, high-sensitivity C-reactive protein, prevalent coronary heart disease, and prevalent heart failure. Modified from Ohyama, Y., Imai, M., Kurabayashi, M. (2013). Estimated glomerular filtration rate and proteinuria are separately and independently associated with the prevalence of atrial fibrillation in general population. *PLoS One* **8**, e79717.

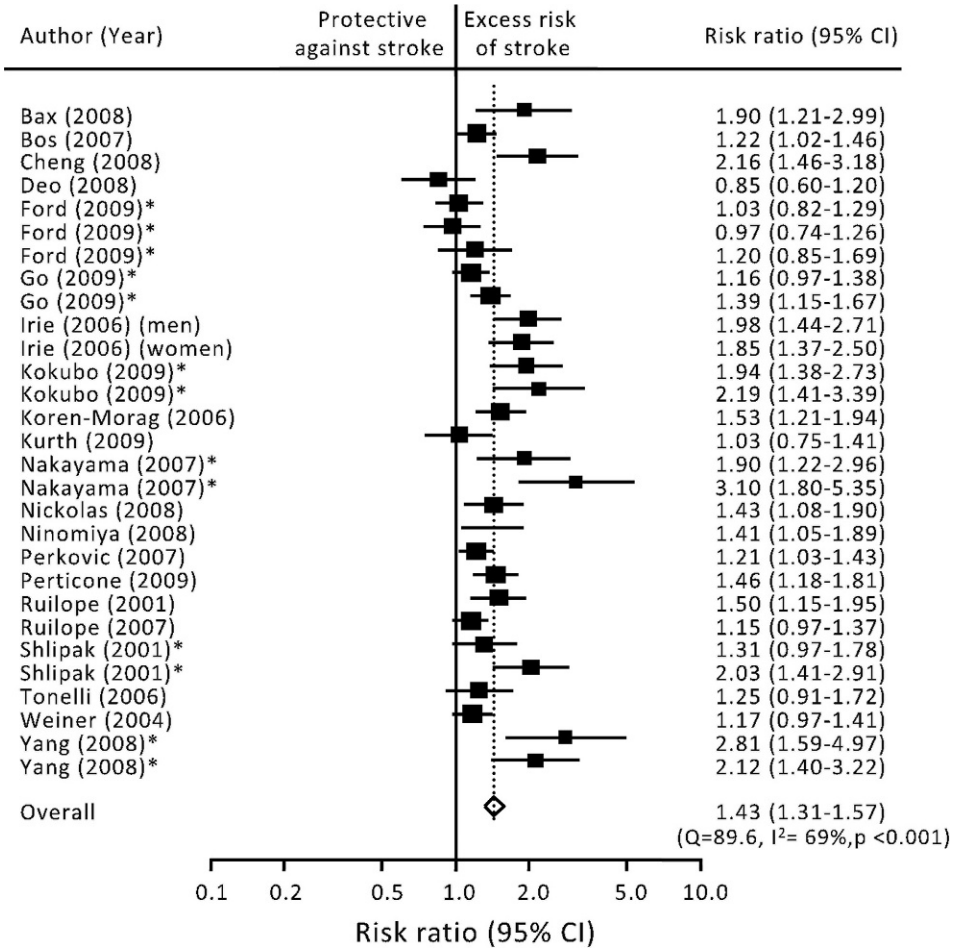

Fig. 5 Overall risk ratio for association of an estimated glomerular filtration rate of <60 mL/min/1.73 m^2 with the risk of stroke in prospective cohort studies. CI, confidence interval. *Subgroups of estimates with eGFR of <60 mL/min/1.73 m^2. Modified from Alonso, A., Lopez, F. L., Matsushita, K., Loehr, L. R., Agarwal, S. K., Chen, L. Y., Soliman, E. Z., Astor, B. C., Coresh, J. (2011). Chronic kidney disease is associated with the incidence of atrial fibrillation: The Atherosclerosis Risk in Communities (ARIC) study. *Circulation* **123**, 2946–2953.

adjustment for other cardiovascular risk factors was reduced to 1.45 (95%CI 1.26–1.68). These findings provide epidemiological evidence that not only an accumulation of traditional cardiovascular risk factors, but also the additional "novel" risk factors play a certain role in the excess risk of stroke among patients with CKD.

Subclinical Cerebral Abnormalities

Subclinical cerebral abnormalities—namely, white matter lesions and silent brain infarcts in the brain, are considered to represent the damaging process of a small vessel disease mediated by endothelial dysfunction, ischemic arteriosclerosis, low perfusion, neurovascular coupling, and diffuse blood–brain barrier disruption (Wardlaw et al., 2009; Fazekas et al., 1993). Several population-based cross-sectional studies have demonstrated that subjects with lower eGFR had a greater volume of white matter lesions and an increased prevalence of silent brain infarcts, as evaluated by MRI (Khatri et al., 2007; Ikram et al., 2008; Seliger et al., 2005; Wada et al., 2008). In the Northern Manhattan Study, the association between CKD and the volume of white matter lesions was investigated in 615 stroke-free participants who underwent magnetic resonance imaging (MRI) (Khatri et al., 2007). eGFR of 15–60 mL/min/1.73 m^2 was significantly associated with an increased log-transformed volume of white matter lesions (β 0.322 [95%CI 0.080–0.564]) after adjusting for traditional cardiovascular risk factors. The Rotterdam study also revealed that subjects with lower eGFR had a greater volume of white matter lesions (difference per 1-SD decrement: 0.14 [95%CI 0.03–0.25]) in the elderly (Ikram et al., 2008). Additional adjustment for traditional cardiovascular risk factors yielded similar findings. Similarly, silent brain infarcts are common in patients with CKD. A cross-sectional survey in the Cardiovascular Health Study found a negative linear association between 1/cystatin C and the prevalence of silent brain infarcts (per 1-SD decrement: multivariable-adjusted OR 1.20 [95%CI 1.09–1.32]) in the elderly (Seliger et al., 2005). The hospital-based studies also indicated that lower eGFR was significantly associated with silent brain infarcts, and patients with more advanced stages of CKD had a greater prevalence of silent brain infarcts (Wada et al., 2008; Shima et al., 2011; Kobayashi et al., 2004). The microvasculature of the brain and kidney has a

similar anatomic as well as functional vasoregulatory (Mogi and Horiuchi, 2011). Both organs share a low vascular resistance system that allows continuous high-volume perfusion and common vascular risk factors including hypertension and diabetes (O'Rourke and Safar, 2005). Kidney impairment is characterized by glomerular endothelial dysfunction and lipohyalinosis, both of which are features of white matter lesions and silent brain infarcts in the brain (Kang et al., 2002). Therefore, it is reasonable to suppose that CKD is a risk factor for cerebrovascular small vessel diseases (white matter lesion and silent brain infarcts) and microangiopathy in the brain.

Prevention and Management of Cardiovascular Disease in Patients With CKD

Strategies for the prevention and management of cardiovascular disease specific to patients with CKD have not been determined. There is limited evidence to inform efforts to prevent new-onset cardiovascular disease or premature cardiovascular mortality among patients with CKD, especially the advanced stage of CKD, because these patients are often excluded from trials. Therefore, we have little choice but to extrapolate preventive goal and management strategies in this population from available information for the general population, small clinical studies, and subgroup analysis of major trials. The first step for the prevention and management of cardiovascular disease in patients with CKD should be similar to that for the general population; that is, intensive control of cardiovascular risk factors—namely hypertension, diabetes, dyslipidemia, smoking, and less exercise (Herzog et al., 2011; Cai et al., 2013). In particular, optimal blood pressure control and glycemic control are of clinical importance in patients with CKD.

For optimal blood pressure control, life-style modifications (i.e., dietary salt reduction, exercise, weight loss, and smoking cessation) and antihypertensive agents together with angiotensin converting enzyme inhibitors or angiotensin receptor blockers are reasonable interventions for any stage of CKD (Herzog et al., 2011). Certainly, these interventions are likely to show benefit against not only atherosclerotic disease, but also heart failure and arrhythmia. On the other hand, evidence of the target level of blood pressure-lowering specific to patients with CKD is still limited. Nevertheless, if we are focused mainly on the prevention of cardiovascular disease, blood pressure lowering itself may be a more pressing concern than the classes of antihypertensive agents. The Blood Pressure Lowering Treatment Trialists' Collaboration, which was a meta-analysis of 26 clinical trials of blood pressure-lowering therapy, revealed that blood pressure lowering significantly reduced the risk of cardiovascular disease by 17% (95%CI 10%–24%) per 5 mm Hg decrement in systolic blood pressure in patients with moderately reduced eGFR, but there was little evidence to support the preferential choice of particular drug classes for the prevention of cardiovascular disease in CKD (Ninomiya et al., 2013).

Diabetes is the primary cause of kidney failure worldwide. Optimal glycemic control can reduce the risk of cardiovascular disease and premature death (Patel et al., 2008; Turnbull et al., 2009). Every effort should be made, therefore, to maintain an HbA1c of <7.0% among patients with CKD, while avoiding hypoglycemia, as recommended by the American Diabetes Association (American Diabetes Association, 2015). At the same time, it is necessary to pay attention to the choice of antiglycemic agents. Dose adjustment of insulin is frequently required along with the progression of kidney impairments, because insulin clearance in the kidney decreases with such progression. Use of metformin and the first-generation sulfonylurea agents should be avoided among patients with advanced CKD, in light of the increased risk of metabolic acidosis and prolonged hypoglycemia (Snyder and Berns, 2004). Careful choice and dose adjustment of antiglycemic agents and frequent monitoring to avoid hypoglycemic events may be necessary, due to the impaired gluconeogenesis and compromised dietary intake as kidney impairment progresses.

The benefit of lipid-lowering therapy in patients with advanced CKD is an area of controversy. Several large-scale clinical trials, such as the 4D, AURORA, and SHARP trials, have presented conflicting results: some trials have shown benefit, while others have shown no effect, in patients undergoing dialysis (Wanner et al., 2005; Fellström et al., 2009; Walker et al., 2011). Although these results are difficult to interpret, they suggest that the patterns of cardiovascular pathology may vary in advanced CKD, with vascular stiffness and calcification, structural heart disease, and sympathetic overactivity contributing to an increasing risk of cardiovascular disease (Foley et al., 1998). However, a recent systematic review of clinical trials demonstrated that statin therapy reduced the relative risk for major cardiovascular events by 23% (95%CI 16%–30%) (Hou et al., 2013). Significant risk reductions were also observed for coronary heart disease and cardiovascular death. Intriguingly, the magnitudes of the relative risk reduction of statin therapy were significantly decreased with the lower eGFR level (P for trend <0.001). This study thus provided strong evidence that statin therapy is beneficial for reducing cardiovascular risk across a broad range of CKD, but the evidence in patients undergoing dialysis is limited.

Finally, the evidence is sparse regarding the effects of antiplatelets and anticoagulants therapy on the development of cardiovascular disease in patients with CKD. A post-hoc analysis of the Hypertension Optimal Treatment (HOT) trial demonstrated that aspirin reduced the risk of major cardiovascular disease by 66% (95%CI: 33%–83%) in hypertensive patients with eGFR of <45 mL/min/1.73 m^2 than in normal kidney function, although the incidence of bleeding was also raised (Jardine et al., 2010). With regard to anticoagulants therapy, this modality has been proven effective for the reduction of morbidity and mortality from stroke and other thromboembolisms among patients with a mild stage of CKD and atrial fibrillation, but its benefit in patients undergoing dialysis is still controversial (Lau et al., 2016). Since both greater thromboembolic and bleeding risks exist among patients with advanced-stage CKD requiring dialysis, it is necessary to carefully choose the treatments and types of agents appropriate for individual patients, while striking a balance between harm and benefit. Large-scale randomized control trials are needed to provide recommendations for antiplatelets and anticoagulants among patients with CKD.

Conclusions

Epidemiological evidence suggests that CKD is a significant risk factor for cardiovascular disease. This excess risk worsens with the severity of kidney impairments. Therefore, patients with CKD should be considered a high-risk population for cardiovascular disease. As the number of elderly increases, the identification of this high risk population will become more important for the prevention and management of cardiovascular comorbidities and related risk factors among patients with CKD or dialysis.

Introduction

Clinical cardiac electrophysiology, a subspecialty of cardiology, focuses on patients with symptoms of, and evidence for, cardiac arrhythmias. It is based on a large body of evidence, observations, and clinical and basic science that consider arrhythmia mechanisms, evaluation of symptoms, approaches to diagnoses, and, ultimately, treatment. A wide range of outcome measures, including amelioration of symptoms, improvement in functionality and cardiovascular physiology, reduction in risk of arrhythmic, sudden and total mortality, and others, occur with effective arrhythmia management. While many specific recommendations are incorporated into guidelines and consensus documents, clinical assessment remains a challenge (Epstein et al., 2008, 2013; European Heart Rhythm A et al., 2006; Gillis et al., 2012; January et al., 2014; Page et al., 2016; Sheldon et al., 2015).

The approach to a patient with arrhythmias is far from simple as arrhythmias are diverse, occur with wide range of conditions, and have various clinical cardiac and extracardiac manifestations. Symptoms related, or due to, cardiac arrhythmias can be nonspecific, vague, difficult to diagnose, or even absent. Alterations in autonomic tone, or other medical conditions, may explain symptoms that appear to be due to an arrhythmia. These, and other, issues have expanded the reach of management outside the realm of arrhythmia assessment and treatment alone. Frequently, there is a direct connection between autonomic perturbations, comorbidities, and arrhythmia manifestations. Therefore, diagnostic considerations, and therapeutic interventions, are complex, difficult, and challenging making clinical assessment individualized rather than an exact science extending beyond the reach of arrhythmia management alone.

Clinical assessment thus involves more than just evaluation of the arrhythmia. It involves understanding the relationship between the arrhythmia and underlying comorbidities and processes that trigger, or exacerbate, the arrhythmia. As such, autonomic triggers are often considered part of the assessment. Furthermore, comorbidities, without even a primary cardiac arrhythmia diagnosis, can be in the forefront of the assessment of the cardiac patient. Additionally, nonspecific symptoms suspicious for an arrhythmia may be due to other causes for which the clinician must be vigilant and utilize scrutiny.

This introductory chapter focuses on the clinical assessment of the patient with suspected cardiac arrhythmias.

Arrhythmias—What Are We Talking About? (Table 1)

Identification of a suspected rhythm disturbance is only one first step in managing the patient with an arrhythmia. The clinical presentation affects the approach (**Table 2**). Are symptoms severe? Is an arrhythmia present? Is the arrhythmia harmful, does it portend worse things to come, or will it progress to a more serious problem in the future? Does it indicate a serious cardiac or other underlying problem? Is it symptomatic and, if so, does it require intervention? Will the intervention eliminate symptoms? Is the problem debilitating? Is it recurrent?

Arrhythmias range from potentially life-threatening ventricular fibrillation/cardiac arrest to benign, but annoying, premature atrial contractions (PACs). Even premature beats, however, can cause problems. PACs can potentially initiate atrial fibrillation (and cause stroke) (Jensen et al., 2004; Larsen et al., 2015), and premature ventricular contractions (PVCs) and nonsustained ventricular tachycardia may be premonitory signs of more serious or life-threatening arrhythmias (Frolkis et al., 2003; Hohnloser et al., 1999). Frequent PVCs can cause an arrhythmia-induced cardiomyopathy (Gopinathannair et al., 2015).

Sinus tachycardia, the most common and ubiquitous, supraventricular tachycardia, can be due to catecholamine excess, exercise, or various underlying medical problems. Inappropriate sinus tachycardia is a condition in which the sinus rate is out of proportion to physiological demands and otherwise unexplainable (Olshansky and Sullivan, 2013a). Postural orthostatic tachycardia syndrome is an autonomic disorder in which there is sinus tachycardia in a standing position due to orthostatic intolerance (Nwazue et al., 2014; Raj, 2013).

Other forms of supraventricular tachycardia include: AV node reentry, AV reentry (due to an accessory pathway), atrial tachycardia, atrial flutter, sinoatrial reentry, and, the most common pathologic supraventricular tachycardia, atrial fibrillation (Page et al., 2016).

Table 1 Arrhythmia types

- Sinus bradycardia
  - Vagal effect
  - Sick sinus syndrome
  - Tachy-brady syndrome
- AV block
  - First degree
  - Second degree
    - Mobitz Type I ("Wenckebach")
    - Mobitz Type II
    - High-grade
  - Third degree—complete
- AV dissociation
- Tachycardia
  - Sinus tachycardia
    - Appropriate
    - Inappropriate
    - Postural orthostatic tachycardia syndrome
  - Supraventricular tachycardia
    - AV nodal reentry
    - AV reentry and other accessory pathway tachycardias
    - Atrial
    - Sinoatrial reentry
    - Atrial flutter (right or left)
    - Atrial fibrillation
  - Ventricular tachycardia
    - Polymorphic
      - Long QT at initiation—Torsade des pointes
      - Normal QT
    - Monomorphic—single or multiple morphologies
  - Ventricular fibrillation
- Escape rhythms
  - Atrial
  - Junctional
  - Ventricular
- Ectopy
  - Atrial ("PAC")
  - Junctional ("PJC")
  - Ventricular ("PVC")

Table 2 Clinical presentation of arrhythmias

Acute, new-onset, long-standing recurrent, chronic
Predictable, nonpredictable
Paroxysmal—nonsustained, intermittent
Persistent—sustained
Permanent

Ventricular tachycardias can be idiopathic or associated with underlying structural disease including valvular, ischemic, non-ischemic, or infiltrative cardiomyopathies (European Heart Rhythm A et al., 2006). Ventricular tachycardias are classified as monomorphic or polymorphic and can be nonsustained or sustained. Ventricular tachycardia can degenerate into ventricular fibrillation dependent on the rate and underlying cardiac condition with which it is associated. Often, urgent and long-term preventive therapy is required.

Bradycardias manifest as asystole, sinus pauses, sinus bradycardia, and/or AV block may or may not be pathologic. An athlete can have marked sinus bradycardia, a normal physiological response to intermittent intense exercise, that elevates vagal tone and yet for some, sinus bradycardia due to sinus node dysfunction can be so debilitating that a pacemaker is required. However, all bradycardia, including episodic asystole caused by a vagal response and manifesting as syncope, may not necessarily respond to pacing. Thus, as part of the evaluation, it is necessary to identify the arrhythmia, correlate it with symptoms, and understand the risk for serious outcomes and base treatment on the causal mechanism, the risk for recurrence and the expected consequences.

Specific Rhythm Disturbances

Ectopic Beats

Ventricular or atrial ectopic beats (PVCs or PACs) may cause episodes of hard heartbeats or extra beats or feel as though there is a skipped or missed heartbeat. Frequent episodes can initiate dyspnea, chest discomfort, and/or weakness. Ventricular ectopic beats can cause low cardiac output and physiologic bradycardia as the ventricles might not fill or eject blood during the ectopic beat.

Bradycardias

Several mechanisms explain bradycardia. A slow heart rate, by itself, may or may not cause symptoms necessarily. It can be difficult to determine for some individuals if symptoms are due to bradycardia or not. Bradycardia can cause dizziness, lightheadedness, and weakness, even syncope. The critical issue is to correlate the symptoms with the arrhythmia. Athletes, and those in excellent physical condition, may have chronic slow heart rates that do not cause any symptom whatsoever. Chronic bradycardia, without symptoms, is associated with robust long-term survival.

For those who have symptomatic bradycardia, the type of bradycardia must be identified, and then, consideration is required for therapy based on whether bradycardia is due to a reversible cause (such as, a medication) or not. If not, a pacemaker may be indicated to assuage severe symptoms. Bradycardia, especially of an intermittent nature, and, especially at night, may be due to autonomic perturbations that do not require, or respond well to, pacing necessarily.

Tachycardias

Several mechanisms can explain tachycardias and, while some if not many of these tachycardias are benign and even physiologic, pathologic tachycardias, whether they be sustained or nonsustained may have prognostic significance and cause a variety of recurrent and severe cardiac symptoms including collapse and cardiac arrest in some instances. Depending on the type of tachycardia whether it is supraventricular or ventricular, long-term therapy is likely to be indicated and various therapies are possible depending on the problem. Treatments can be curative with ablation for some patients, but other patients require long-term prophylactic preventative measures such as an implantable defibrillator to prevent the risk of sudden cardiac death.

Symptoms and Conditions Due to or Associated With Cardiac Arrhythmias

One important reason to evaluate arrhythmias is due to the symptoms that may occur. Arrhythmias can cause various bothersome but often nonspecific symptoms and problems including: (1) palpitations, (2) dyspnea, (3) chest pain, (4) dizziness, (5) lightheadedness, (6) weakness, (7) syncope or collapse, (8) fatigue or loss of energy, and (9) cardiac arrest (**Table 3**). In some instances, it can be difficult to distinguish whether symptoms are due to an arrhythmia, due to fluctuations in autonomic tone, or due to some other cause entirely.

Symptoms can be severe even if the arrhythmia is benign. Occasionally, ventricular or atrial ectopic beats fit that category. Even sinus tachycardia may be symptomatic and, yet, of little clinical or physiological consequence. Alternatively, severe cardiac arrhythmias may be under recognized and create tremendous long-term problems. Asymptomatic atrial flutter or fibrillation

Table 3 Symptoms suspicious of an arrhythmia

Palpitations
Dyspnea
Exercise intolerance/inactivity

with rapid ventricular response rates ultimately leading to cardiomyopathy is an example. Part of the clinical assessment, therefore, involves distinguishing benign conditions from those that are more malignant even if symptoms are not present.

It is important to correlate the arrhythmia and the symptom. In some instances, an arrhythmia may appear asymptomatic but really is not and, yet, symptoms may be severe when no rhythm disturbance is diagnosed. Symptoms can be nonspecific or difficult to correlate. Long-standing, persistent atrial fibrillation may appear asymptomatic but, after cardioversion, a patient may feel markedly improved. Alternatively, a patient may have severe palpitations but have only normal sinus rhythm.

Unfortunately, for rhythm disturbances in general, there is no specific scoring system that is used to gauge the severity of the rhythm disturbance for a specific arrhythmia. One has been developed for atrial fibrillation several years ago, the Canadian Cardiovascular Society (CCS) Severity of Atrial Fibrillation (SAF) Scale (Dorian et al., 2006). The CCS-SAF score assesses possible atrial fibrillation-related symptoms (palpitations, dyspnea, dizziness/syncope, chest pain, weakness/fatigue), determines a symptom–rhythm correlation, and assesses the effect of these symptoms on patient daily function and quality of life. The type of atrial fibrillation is also assessed. Despite its availability for more than a decade, it has not achieved widespread use and it is not become available for measuring symptoms due to other rhythm disturbances. Similarly, the European Heart Rhythm Association has developed a methodology to gauge symptoms (Wynn et al., 2014).

There can be an association between an arrhythmia and a clinical condition such as atrial fibrillation and congestive heart failure, in which it is not clear if the two are related, associated, or independent or whether treatment of one condition will improve the other (Dickinson et al., 2014). In some instances, one can cause the other; a chronic rapid ventricular response rate in atrial fibrillation can cause an arrhythmia-induced cardiomyopathy (Nerheim et al., 2004). Alternatively, atrial fibrillation can be simply a consequence of the congestive heart failure, not contribute to its progression, and treatment may have little value to the outcome of the patient. Relationships between the rhythm, the symptoms, and other medical conditions determine what therapies are required for the arrhythmia (and its consequences) and other medical conditions such as heart failure.

A medical condition may be present and suspected to be due to an arrhythmia even if an arrhythmia is not diagnosed. Examples include a stroke of undetermined etiology (Brachmann et al., 2016) or congestive heart failure. Asymptomatic nonsustained arrhythmias may be of concern as premonitory signs of something worse to come and may require careful evaluation even if the arrhythmia is infrequent (Hohnloser et al., 1999; Buxton et al., 1999).

Symptoms and Clinical Presentations

Cardiac Arrest/Transient Loss of Consciousness

A patient who loses consciousness transiently may have had syncope or have had an aborted cardiac arrest due to a life-threatening ventricular arrhythmia and may be at risk for recurrence. This is a critical symptom for which careful consideration regarding an arrhythmia, an autonomic mechanism, or both, is required. Recent guidelines carefully delineate an approach to evaluation and management of the patient who loses consciousness due to syncope (Shen, 2017; The European Society of Cardiology, 2009), but several caveats are in order for this rather common problem: (1) It is important to distinguish transient loss of consciousness due to syncope from other causes for loss of consciousness; (2) the evaluation is clinical and based on the episode itself, specific circumstances of the patient, the number and severity of episodes, and the underlying comorbidities (Raj and Sheldon, 2002); (3) the cause can be difficult to ascertain; (4) there is no gold standard to evaluate syncope aside from an excellent clinical evaluation; (5) treatments have not been well tested for many of the conditions causing syncope; (6) it is important to consider cardiac causes for syncope due to potentially severe consequences (Olshansky and Sullivan, 2013b, 2015; Gopinathannair et al., 2008; Olshansky et al., 2008).

Most episodes of syncope are due to transient autonomic perturbations that may not recur and are often benign. However, evaluation is required to rule out a potentially serious cardiac rhythm disturbance and to assess the potential mechanism of the episode to determine if there is likelihood for recurrence. For a patient who collapses, even without a pulse, the episode could be a vasodepressor response with marked vasodilatation, an episode of sustained ventricular tachycardia or marked bradycardia. Abrupt speeding or slowing of the heart rate is more likely to cause hemodynamic collapse than a chronically slow or fast heart rate. By better understanding the mechanisms responsible for syncope, long-term treatment can be assessed and may be required.

For the patient who has documented cardiac arrest due to ventricular fibrillation, evaluation for recurrence and for underlying cardiac causes becomes critical. If cardiac arrest was due to a problem that is nonreversible, long-term protection is required, but the evaluation must first rule out the possibility of an underlying problem that could be at its core.

Palpitations

Palpitations are a sensation of rapid or hard heartbeats (Barsky, 2001). Palpitations are a common reason to consider arrhythmia evaluation. They could be due to supraventricular tachycardia, a PVCs, PACs, sinus tachycardia, ventricular tachycardia, junctional rhythm, or an ischemic event. Palpitations are also commonly due to anxiety or catecholamine excess and not due to an arrhythmia at all. Palpitations may be due to a psychiatric condition such as panic attacks (Barsky, 1992). There is a wide variation in the sensitivity of any individual to an arrhythmia; whereas some fell every ectopic beat, others feel nothing at all even for sustained tachycardias (Barsky et al., 1994).

Palpitations have various clinical presentations (Zimetbaum and Josephson, 1998). The history of palpitations can help guide the subsequent evaluation. The urgency to treat may depend upon how long episodes have been present and how the sensation of palpitations actually is felt. Not all palpitations are the same. Single ectopic beats may be felt as irregularities are skipped beats, whereas sustained tachycardias may present as rapid fast rates associated with near syncope. For episodes of sustained ventricular arrhythmias, there may be a history of underlying heart disease or abnormalities otherwise noted or seen in the history. For sustained episodes of supraventricular tachycardia, there may be a long history of episodic and paroxysmal rapid heart action that begins abruptly with sympathetic stimulation and ends abruptly with vagal activation. AV node reentry is often associated with a sensation of chest pain, shortness of breath, and palpitations in the neck, whereas AV reentry tachycardia may not be to do the atrial ventricular timing differences. Atrial flutter can have its own specific clinical presentations depending on the rate of the atria and of the ventricles. The rhythm may be perceived as regular and rapid or only rapid with minor activity. There may be a sensation of rapid pulsations in the neck.

Atrial fibrillation tends to be associated with irregular and rapid palpitations. Symptoms may be similar, but frequently those who complain about episodic atrial fibrillation notice a very irregular and often rapid ventricular response rate.

A junctional rhythm may present with episodic weakness dizziness and the sensation of a prolonged hard heartbeat that is not fast.

Weakness, Dizziness, Lightheadedness, Fatigue, Falls

Nonspecific symptoms are not unusual for the clinician to address as they may be arrhythmia related. Unfortunately, the symptoms can be due to a wide range of issues making it difficult to evaluate and then treat the problem. If symptoms are due to assuming an upright position, it may be that the patient has orthostatic hypotension or a specific subset of that problem, neurogenic orthostatic hypotension, that is related to an autonomic disorder that causes orthostatic intolerance with major drop on blood pressure and little change in heart rate (Gibbons et al., 2017).

Weakness and fatigue may be due to atrial fibrillation, but this is also complex since patients with atrial fibrillation may be completely asymptomatic, particularly if they are elderly. However, one of the most common complaints of patients or elderly who have atrial fibrillation is fatigue, and this may be passed off as "just getting older" when, in fact, treatment of the problem may improve symptoms. In some instances, the only way to know if a patient is really symptomatic in atrial fibrillation without specific complaints is to return the patient back to normal sinus rhythm to determine whether improvement is possible.

Symptoms may not be due to an arrhythmia alone but due instead to autonomic fluctuations causing hemodynamic alterations. For example, vasovagal syncope is associated with relative bradycardia and hypotension, but the bradycardia is not to do underlying sinus node disease necessarily. Rather, it is due to high vagal activation, and therefore, treatment would be different than would expect if the problem were due to the sinus node alone.

Additionally, some patients have what appears to be bradycardia, but symptoms of dizziness, lightheadedness, weakness, or even syncope instead are due to neurogenic orthostatic hypotension or something else. The relationship between the symptoms and any suspected arrhythmia or blood pressure fluctuation is critical.

Additional History and Comorbidities

To understand and evaluate the patient with an arrhythmia better, it is important to recognize the context in which the suspected rhythm disturbance exists. Presence of underlying heart disease, myocardial infarction, ventricular hypertrophy, valvular heart disease, etc., can set the stage for, or act as a prognosticator of, the specific arrhythmia diagnosed. For example, nonsustained ventricular tachycardia can have prognostic meaning in a patient with ventricular dysfunction or a patient with a channelopathy, such as the long QT syndrome, but may not have meaning in a patient without any heart disease at all.

Similarly, the presence of disease condition not directly related to the heart may be a trigger of the rhythm disturbance, such as atrial fibrillation in a patient with a pulmonary embolism or pneumonia. Other cardiac and noncardiac comorbidities can also act as a benchmark upon which further therapies may need to be undertaken, for the arrhythmia problem itself and for its long-term risks. For example, the CHA2DS2VASc score is used to determine the need for anticoagulation in patients with atrial fibrillation as specific factors and comorbidities increase the risk of stroke and mortality when atrial fibrillation exists (January et al., 2014; Larsen et al., 2012).

Regarding further evaluation, it is critical to understand how the arrhythmia affects long-term risk of mortality and recurrent severe symptoms. Thus, while nonsustained ventricular tachycardia that is asymptomatic and not associated with any underlying structural heart problem may not require treatment, in the presence of severe left ventricular dysfunction, it will have prognostic importance.

Similarly, a severe symptom, such as syncope, without any underlying structural heart disease, may have a benign long-term prognosis. Syncope in the presence of severe ventricular dysfunction raises major concerns. Thus, it becomes important to link the clinical conditions, the medications, and the comorbidities with the arrhythmia itself to determine what the best long-term treatment plan may be. Therefore, the arrhythmia alone is not the only deciding factor with regard to requirements for treatment nor is the need to reduce symptoms the only deciding factor as a patient who is even asymptomatic may be at great risk for sudden cardiac death due to the presence of an arrhythmia in lieu of underlying cardiovascular abnormalities that are present.

Physical Evaluation (Table 4)

The physical examination can provide insights into the diagnosis of the rhythm disturbance in the acute setting and can provide a roadmap to further evaluate and treat the patient. Acutely, physical findings can help identify ectopy, atrial flutter, ventricular tachycardia, and other rhythm disturbances. Chronically, the need for further curative therapy can be assessed based on the underlying conditions and state of the patient.

The physical examination also helps guide the evaluation and the approach to the best long-term therapy. An otherwise healthy, young-appearing individual with highly symptomatic atrial fibrillation is a better candidate for a curative ablation than is an older-appearing demented patient even at the same age with similar comorbidities. Similarly, a patient with long-standing atrial fibrillation who denies any symptoms but presents with substantial peripheral edema and neck vein distention requires careful consideration for aggressive treatment, especially if there is no other explanatory cause as patients may underestimate the severity of their condition.

The physical examination depends, in part, on the place and circumstances under which the evaluation occurs. If the patient is acutely decompensated due to an arrhythmia, the approach is different from in the patient who is coming in for a casual evaluation. In either case, the initial approach begins with the vital signs. For those with orthostatic type symptoms, vital signs should be measured in various positions. This includes blood pressure and heart rate. For the patient who presents acutely and is potentially experiencing a rhythm disturbance, clues in the physical examination can help diagnose the arrhythmia. A variable S1 in a patient who is tachycardic potentially indicates ventricular tachycardia. Flutter waves may be seen in the neck veins. Acutely, for patients who are experiencing a rhythm disturbance, the most pressing issue is the presence of hemodynamic collapse that would require acute treatment of the rhythm disturbance.

For the patient who has had a rhythm disturbance the evaluation should be careful to consider cardiac and noncardiac issues. The overall appearance the patient becomes important with regard to perfusion and evidence for congestive heart failure. There may also be evidence for medical conditions that may interact with symptoms that are caused by an arrhythmia. A patient may be markedly obese and have difficulty breathing suggesting the possibility of sleep apnea. A patient may have muscle weaknesses consistent with myotonic dystrophy indicating the presence of a potentially severe bradycardia or tachycardia with life-threatening process. There may be evidence for valvular heart disease, congestive heart failure, fluid overload, diabetes, severe hypertension, vascular disease, and peripheral edema, for example.

Clinical Acumen

More important than obtaining a history and performing a physical examination is the overall assessment piecing together relationships between the arrhythmia, the condition, and the symptoms. Listening carefully to the patient to understand relationships between symptoms and events is often underemphasized. In one such example, a patient who had an extensive evaluation for syncope and multiple unnecessary hospitalizations turned out to have deglutition syncope that was diagnosed by having him drink a cold carbonated beverage while being monitored. Simply by hearing the patient's story, it was possible to avoid unnecessary, extensive, and repeated evaluations (Olshansky, 1999).

Heart rate and rhythm
Blood pressure
Orthostatic vital signs
General—overall appearance
Neck—internal jugular distention and pulsations
Cardiovascular—murmurs, rhythm, and gallops
Peripheral—edema, perfusion

Diagnostic Tools (Table 5)

The Electrocardiogram (Table 6)

After the history and physical examination, the first clinical tool to evaluate the arrhythmia patient is the electrocardiogram (ECG). It can be used to diagnose the arrhythmia, if present at the time of symptoms, but it can also determine the presence of accessory pathways, conduction system abnormalities, repolarization abnormalities, and the presence of myocardial damage or infarction. An ECG is required for all patients who have suspected cardiac arrhythmia problems. The ECG may not be diagnostic if the rhythm abnormality is not present, and it may be difficult to determine the arrhythmia mechanism even if it is present.

Electrocardiographic Monitoring (Table 7)

For the patient not at imminent risk of death or sudden death or who is mildly or moderately symptomatic, monitoring is often the next step (Rosero et al., 2013; Mittal, 2014). This can be telemetry in the hospital or outpatient monitoring. The type of monitoring used depends on the arrhythmia suspected and its frequency and severity (**Table 8**) (Mittal, 2014; Zimetbaum and Josephson, 1999; Ruwald and Zareba, 2013). For those patients who have daily symptoms, a 24-h Holter monitor may be all that is required whereas for those patients who are intermittent episodes every several days, long-term external loop recorders may be valuable. For patients who have intermittent syncope, an implantable loop recorder may be required to diagnose the potential cause (Krahn et al., 2001, 2003).

Mobile cardiac outpatient telemetry (MCOT)
Implantable loop recorder
Implantable pacemakers/defibrillators

Tilt-Table Testing

For patients with syncope, the evaluation must be directed at the suspected cause for syncope. If the history is not enough to make a diagnosis and the symptoms are severe and/or recurrent enough, aside from monitoring, other tests may be considered. For patients who have a suspected neurocardiogenic causes for syncope, a tilt-table test may prove valuable, but the test is not a "gold standard" to make the diagnosis of vasovagal syncope (Sutton, 2015; Moya et al., 2001).

Exercise Testing

The exercise test may help diagnose a symptomatic arrhythmia triggered by physical activity, but the test itself may not necessarily reproduce the clinical or physiological circumstances under which an arrhythmia, or symptom, develops. The exercise test may also be helpful to rule out other conditions such as ischemia or valvular abnormalities that could potentially exacerbate or create symptoms or even act as triggers for arrhythmias. For patients who have exercise-induced syncope and are suspected to have an arrhythmia, exercise testing may be valuable. Any provocative test attempting to initiate the symptom and/or the arrhythmia has a sensitivity and specificity that makes the test by itself not perfectly diagnostic.

Electrophysiology Testing (Table 9)

Electrophysiology testing can be diagnostic, prognostic, and potentially therapeutic. A clinically significant arrhythmia can be initiated by premature extrastimulus testing delivered during a train of paced beats (induced), and its mechanism can be determined by analysis of electrogram relationship and "mapping." The tissue responsible for a rhythm disturbance can be better understood, and mapping procedures can help localize specific sites that can be treated with ablation techniques and cured. Electrophysiology testing is used occasionally to determine location of block when there is an AV conduction defect or to assess sinus node function.

Electrophysiology testing is used primarily in patients who have an arrhythmia diagnosed. Occasionally, if a patient presents with palpitations that appear to be consistent with or highly suspicious of a supraventricular tachycardia, then an electrophysiology test may be useful without further diagnostic evaluation. For the most part, electrophysiology testing is used as a means to induce a tachycardia that has already been detected but for which more insight is required to determine its mechanism or an approach to treatment. It is more likely to be used to evaluate and treat patients with ventricular tachycardias, supraventricular tachycardias (AV nodal reentry, AV reentry, sinoatrial reentry, atrial tachycardia, atrial flutter, and atrial fibrillation), and PVCs.

Electrophysiology testing can assess the prognosis of patients at risk for sustained ventricular tachycardia and/or ventricular fibrillation cardiac arrest (Buxton et al., 1999; Thomas and Josephson, 2008; Nazari et al., 2014). In years past, it was used more for this purpose but now for select patients with coronary disease who have moderate ventricular function (ejection fraction between 35% and 40%) and nonsustained ventricular tachycardia, it still has a role.

The electrophysiology test may be useful to initiate some supraventricular and ventricular arrhythmias, but a negative electrophysiology test does not completely determine the presence or absence of an arrhythmia in a patient with symptoms that are consistent with an arrhythmia. The test has its own sensitivity and specificity dependent upon the rhythm disturbance, medical therapy, autonomic tone, and the underlying type and degree of heart disease present.

Additional Testing

Any arrhythmia analysis may require assessment of the presence of structural heart disease. This may include echocardiography, exercise testing, cardiac catheterization, noninvasive and an invasive evaluation for coronary artery disease, MRI scanning, or even CT scanning.

Part of the evaluation of the patient and the arrhythmia is to understand if the arrhythmia is a prognostic marker of something worse. Patients with an arrhythmia require an understanding of the presence or absence of structural or genetic conditions that could have consequences. The diagnosis of the underlying process becomes critical. No set evaluation is required regarding the prognosis. This depends up on the arrhythmia, the symptoms, and the conditions being evaluated.

For a middle-aged man with syncope and a left bundle branch block, the evaluation may include an echocardiogram to look for left ventricular dysfunction, a cardiac catheterization to rule out coronary artery disease, and even an electrophysiology test, whereas

Table 9 Reasons to consider electrophysiology testing

Diagnosis
Arrhythmia induction for patients with highly suspicious symptoms
Determining cause for a narrow QRS complex tachycardia/rhythm
Determining cause for a wide QRS complex tachycardia/rhythm
Assessment of the mechanism of a tachycardia
Mapping activation of and pathways responsible for a tachycardia
Evaluating level of block in the AV conduction system
Evaluating sinus node function
Prognosis
Induction of clinically significant ventricular arrhythmias
Assessment of refractoriness of accessory pathways
Assessment of speed of AV conduction during induced atrial arrhythmias

for a young woman with syncope who has delayed activation of the QRS and T-wave inversions in ECG leads V1–V3, an MRI scan may be useful to rule out the presence arrhythmogenic right ventricular dysplasia. Similarly, for a young male who has an ECG consistent with hypertrophy and syncope and there is a family history of sudden cardiac death or for a young woman with syncope who has a borderline long QT syndrome and a similar family history, genetic screening may provide some useful data even though there are no specific randomized controlled clinical trials demonstrating the need to undertake genetic screening under specific circumstances.

Many clinical decisions are difficult as they are in a gray zone, but the proper choice of therapy can have life or death consequences. Differences of opinions for aggressive therapeutic intervention can exist; therapies have their own serious consequences. Furthermore, the treatment, such as an implantable defibrillator, may not prevent the symptom itself (e.g., syncope) but even if the risks of implant are low, the necessity of its implantation is based upon its value in prolonging life in lieu of the difficulties in living with the device.

Evaluation of Patients With Implanted Devices

Interrogation of implantable devices (pacemakers and implantable cardioverter defibrillators) in the clinic or remotely can provide important information regarding the arrhythmia diagnoses (Varma et al., 2014). For a patient with an implantable defibrillator who presents with syncope, one of the first maneuvers is to interrogate the device to determine if there was an arrhythmia present at the time and what that arrhythmia may be. Furthermore, interrogation of the devices will determine if there was a failure of the pacemaker or defibrillator to act appropriately.

Device interrogation will provide some evidence for the "burden" of the arrhythmia and determine rates that may be important with regard to the need for further therapy. For example, in a patient with a high burden of atrial fibrillation, anticoagulation may be required but for a patient who is status post ablation of atrial fibrillation in whom no atrial fibrillation has been detected subsequently, the need for long-term anticoagulation may be reconsidered.

Genetic Testing

Genetic testing does not yet have an established role in the management of arrhythmia diagnosis or treatment but for select cases of patients with channelopathies or hypertrophic cardiomyopathy, for example, prognostic and even diagnostic information may be gleaned in patients with symptoms or who have borderline phenotypic expression of a condition that may be present.

Treatment (Table 10)

Once a patient is properly assessed and an arrhythmia is diagnosed or ruled out, treatment must be contemplated using drugs (for rate and rhythm control) (Epstein et al., 2016; Van Gelder et al., 2016), cardioversion (Botkin et al., 2003), device implantation (Epstein et al., 2008, 2013) (and the type (Gillis et al., 2012)), and/or ablation techniques (January et al., 2014; Page et al., 2016; Calkins et al., 2012). Specific acute (cardioversion, drugs) and chronic medical therapy (drugs, device implants, or ablation) is available for most tachycardias and to prevent adverse thromboembolic outcomes (anticoagulation and atrial appendage occlusion devices in atrial flutter and atrial fibrillation). Patients with autonomic conditions that affect blood pressure and heart rhythm are also treatable with conservative and medical therapy as well.

Treatment varies by the rhythm diagnosed, the severity and frequency of symptoms, the risk of the symptom to the patient, the risk of sudden death, the presence of underlying heart disease, the presence of comorbidities, and the general health of the patient. Options vary but treatments can include complete cure with catheter ablation technology for tachycardias, pacemakers for bradycardias, cardiac resynchronization therapy for heart failure (in patients with left bundle branch block), and defibrillators to interrupt a potentially life-threatening tachycardia or sudden cardiac death due to ventricular fibrillation based on calculated risk of reducing total mortality.

Table 10 Arrhythmia treatments

Ablation
AV junctional ablation/pacemaker
Atrial fibrillation
Atrial flutter
AV node reentry
Atrial tachycardias (including sinoatrial reentry)
Accessory pathways
Ventricular tachycardia
Bundle branch reentry
Ventricular ectopy
Ventricular fibrillation
Device implantation
Pacemaker—single, dual, triple chamber
Implantable defibrillators—single, dual, triple chamber
Drugs
Antiarrhythmic drugs (by Vaughan Williams Classification)
Class I
Ia—quinidine, procainamide, dispyramide
Ib—mexiletine, lidocaine, diphenylhydantoin
Ic—flecainide, propafenone
Class II—beta-adrenergic blockers
Class III—dofetilide, amiodarone, sotalol, dronedarone, ibutilide
Class IV—calcium channel blockers
Other antiarrhythmics—digoxin, adenosine, ivabradine, atropine
Drugs for autonomic dysfunction—droxidopa, fludrocortisone, pyridostigmine, midodrine
Anticoagulants—warfarin, rivaroxaban, apixaban, dabigatran, edoxaban, heparin

Conclusion

The evaluation of the patient who may have an arrhythmia involves careful assessment of the symptoms, consideration of underlying cardiovascular and associated comorbidities, correlation of the symptoms with the arrhythmia, risk stratification based on clinical diagnosis and arrhythmia type, and decision regarding the need to treat the symptom and reduce the risk for serious adverse outcomes. Although the field of arrhythmia management has become much more expansive and inclusive of issues related to autonomic disturbances and clinical circumstances that may or may not be due to arrhythmias, the approach to the patient starts with a careful and complete assessment based on the history and physical followed by appropriate testing that has now become fairly well established.

Introduction

There are a number of inherited cardiac diseases that can cause sudden death. These can be broken up into two broad groups: the cardiomyopathies which are usually associated with a structural abnormality and the ion channelopathies which typically do not have cardiac structural abnormalities (Fernández-Falgueras et al., 2017). This article focuses on the inherited arrhythmia syndromes caused by ion channelopathies. While channelopathies are rare, a basic knowledge and understanding of these inherited syndromes by the general clinical professional will lead to earlier diagnosis and, potentially, prevention of sudden death. This article focuses on a review of the diagnosis and treatment of the clinically important inherited arrhythmias as well as the role of genetic testing. Clinical management in light of the 2013 expert consensus statement on inherited arrhythmia syndromes is discussed (Priori et al., 2013). Ion channelopathies are typically due to abnormalities in cardiac action potentials which are created by gradients formed by ionic currents. These predominantly involve inward currents of Na^+ and Ca^{2+}, and the main outward current of K^+. Changes in genes encoding for ionic channels can alter action potentials, electrical impulse propagation, and lead to malignant arrhythmias and death. The most common channelopathies related to sudden death are Brugada syndrome (BrS), long QT syndrome (LQTS), short QT syndrome (SQTS), and catecholaminergic polymorphic ventricular tachycardia (CPVT) (Nerbonne and Kass, 2005). Although a long list of genes have been attributed to each of these conditions, some have more supporting evidence for linkage than others and the yield of genetic testing varies significantly across these conditions. In addition, some genes have been linked to multiple clinical syndromes (**Fig. 1**), sometimes within the same families.

Inherited arrhythmia syndromes are usually suspected after a presentation with syncope, aborted cardiac arrest, or a family history of sudden death. Some patients are diagnosed based on incidental findings on electrocardiograms. These conditions, however, are often misdiagnosed, particularly when the diagnostic testing is difficult to interpret (Taggart et al., 2007; Viskin et al., 2005). There are current diagnostic criteria which have been identified to help in the diagnosis of these conditions. At our institution, patients are referred for evaluation of sudden cardiac arrest or sudden death in a family member; our evaluation is summarized in **Table 1**.

One of the most important first steps in the diagnostic workup in a patient with a suspected inherited arrhythmic condition is to rule out underlying cardiomyopathy. At the Stanford Center for Cardiovascular Diseases, we have found that patients with hypertrophic cardiomyopathy, for example, have a 25% likelihood of having a corrected QT interval greater than 480 ms (unpublished data).

If there are abnormalities in the initial workup, then further testing is usually obtained which may include an MRI and genetic testing. As a general rule, targeted genetic testing is performed after the clinical diagnosis of a disease process has been made. However, in cases of cardiac arrest or sudden death where an inherited arrhythmia syndrome is suspected but cannot be definitively diagnosed, broader genetic testing can be considered. When considering genetic testing, referral to an inherited arrhythmia center where genetic counseling can be an integral part of the evaluation is recommended. Genetic testing can be useful but the results should be interpreted carefully and in context of the clinical presentation. A well-established pathogenic variant can occasionally be helpful in establishing a clinical diagnosis, but its utility and cost-effectiveness are greatest in the subsequent screening of family members (Perez et al., 2011). For most other genetic abnormalities, interpretation must be carefully made in context of the clinical presentation and the evidence for pathogenicity in existing literature and population datasets.

Table 1 Stanford Center for Inherited Cardiovascular Disease: family screening recommendations following a sudden unexplained cardiac arrest or sudden unexplained death

	Children	*Adults*
Family members at 50% risk, Obligate carriers	*Initial evaluation* 0–18 years old – Medical history, physical exam, family pedigree – Non-fasting or fasting lipid panel with direct LDL – Resting EKG, stand-up EKG, Brugada-protocol EKG – Echo – Exercise test – Ambulatory telemetry (24 Hour Holter) *Reflex Tests* – If any abnormalities on echo, reflex to MRI – If death was during sleep, SE Asian ancestry, or suspicious *SCN5A* variant, perform procainamide challenge (even if resting EKG is normal) – If Type 2 or 3 Brugada pattern on resting EKG, reflex to procainamide challenge – If suspect ARVC (based on imaging, or high PVC burden), perform signal average EKG *Ongoing Screening* Tests: – Resting EKG, stand-up EKG, Brugada-protocol EKG – Echo – Exercise test Interval: Every 2–3 years For competitive athletes: Yearly For families with multiple unexplained sudden cardiac deaths: Every 2 years	*Initial evaluation* >18 years old – Medical history, physical exam, family pedigree – Nonfasting or fasting lipid panel with direct LDL – Resting EKG, stand-up EKG, Brugada-protocol EKG – Echo – Exercise test – Ambulatory telemetry (24 Hour Holter, or 2-week Zio Patch if symptoms) – Signal average EKG *Reflex Tests* – If any abnormalities on echo, reflex to MRI – If death was during sleep, SE Asian ancestry, or suspicious *SCN5A* variant, perform procainamide challenge (even if resting EKG is normal) – If Type 2 or 3 Brugada pattern on resting EKG, reflex to procainamide challenge *Ongoing Screening* Tests: – Resting EKG, stand-up EKG, Brugada-protocol EKG – Echo – Exercise test Interval: Every 5 years For competitive athletes: Yearly through college, then every 2 years For families with multiple unexplained sudden cardiac deaths: Every 2 years

Long QT Syndrome

LQTS was first identified in the 1950s in a family with siblings who were deaf and had a prolonged QT interval. This was termed Jervell–Lange-Nielson syndrome and later found to be a recessive form of the disorder (Jervell and Lange-Nielsen, 1957). LQTS is characterized by a prolongation of the QT interval associated with an elevated risk of sudden cardiac death. Fifteen genes have been linked to LQTS, with most families following an autosomal dominant pattern of inheritance. LQT1, LQT2, and LQT3 linked to rare genetic variants in KCNQ1, KCNH2, and SCN5A, respectively, make up more than 92% of patients with the diagnosis of LQTS.

The yield of genetic testing in clinically definitive cases of LQTS is approximately 75%, which is the highest among the inherited arrhythmic disorders (Priori et al., 2013). There is variable penetrance within family members with the same gene mutation. LQTSs are numbered to reflect the order in which new genes were linked to the condition. However, LQT types are sometimes referred by the researchers who identified them: Jervell and Lange-Nielson syndrome (long QT associated with deafness), Andersen–Tawil syndrome (neurologic/musculoskeletal manifestations associated with long QT), and a general term of Romano–Ward syndrome (long QT without deafness) (**Table 2**) (Kaufman, 2011).

Patients typically present with an incidentally identified prolonged QT interval, an arrhythmic event, or a family history of LQTS. Patients who present clinically often have multiple episodes of syncope which place patients at risk for cardiac arrest and sudden death.

Identifying clinical triggers of syncope can suggest a specific genotype of LQTS. LQT1 is classically associated with syncope/arrhythmic events during exercise or stress, LQT2 is associated with syncope/arrhythmic events with sudden noise, and LQT3 is associated with arrhythmic events during acoustic arousal from sleep (Kaufman, 2011). Higher arrhythmic risk correlates with the length of the QT interval, particularly above a corrected QT of 500 ms (Priori et al., 2003).

Morphology of the EKG can also give clues to cardiac risk and suggest genetic variants. The T-wave of LQT1 is typically broad based and monophasic. The T-wave of LQT2 is typically a broad, notched T-wave. LQT3 is associated with a long, flat ST segment and a relatively normal appearing T-wave (Zhang et al., 2000) (**Fig. 2**). The EKG of LQT3 and hypocalcemia can appear very similar. In addition, T-wave alternans is a worrisome finding and denotes electrical instability (Paulussen et al., 2004; Schwartz and Malliani, 1975).

Clinical Diagnosis

LQTS can, at times, be challenging to diagnose. There is an overlap between the higher range of QTc values in normal subjects, and the lower end of values in patients with LQTS. In family members of patients with LQTS, a normal QTc does not exclude the inherited abnormality as up to 25% of those affected can have a normal QTc (Schwartz and Crotti, 2011). The normal QTc range is different for men and women and may be due to hormonal differences. The 99th percentiles for men and women are 470 and 480 ms, respectively (Fernández-Falgueras et al., 2017). However, LQTS is a spectrum and there are those with the inherited defect at risk who have QTc less than the 99th percentile, making it more difficult to diagnose. In the absence of a secondary cause for QT prolongation, LQTS can be diagnosed with a QT_C greater than 500 ms on repeated EKGs. When LQTS is suspected, but the QT_c is less than 500 ms, a LQTS risk score such as the Schwartz score can be used (**Table 3**). This accounts for EKG findings, clinical history, and family history. A score greater than 3.5 meets the criteria for diagnosis (Schwartz et al., 1993; Schwartz and Crotti, 2011)****. Presence of a clearly pathogenic rare genetic variant in one of the LQTS-related genes can also be diagnostic.

Table 2 Subtypes of LQTS and their associated genes, proteins and functional effects

LQT subtype	*Gene*	*Protein*	*Current*
LQT1	*KCNQ1*	KCNQ1 (Kv7.1)	$\downarrow I_{Ks}$
LQT2	*KCNH2*	hERG (Kv11.1)	$\downarrow I_{Kr}$
LQT3	*SCN5A*	Na_v 1.5	$\uparrow I_{Na}$
LQT4 (ankyrin-B syndrome)	*ANK2*	Ankyrin-B	Multichannel interactions
LQT5	*KCNE1*	KCNE1 (minK)	$\downarrow I_{Ks}$
LQT6	*KCNE2*	KCNE2 (MiRP1)	$\downarrow I_{Kr}$
LQT7 (Andersen-Tawil syndrome type 1)	*KCNJ2*	K_{ir}2.1	$\downarrow I_{K1}$
LQT8 (Timothy syndrome)	*CACNA 1C*	Ca_v 1.2	$\uparrow I_{Ca}$
LQT9	*CAV3*	Caveolin 3	$\uparrow I_{Na}$
LQT10	*SCN4B*	Na_v 1.5 β4	$\uparrow I_{Na}$

Table 3 1993–2011 LQTS diagnostic criteria

	Points
Electrocardiographic findings[a]	
A. QTc[b]	
≥480 ms	3
460–479 ms	2
450–459 ms (in males)	1
B. QTc[b] 4th minute of recovery from exercise stress test ≥480 ms	1
C. Torsade de pontes[c]	2
D. T-wave alternans	1
E. Notched T-wave in three leads	1
F. Low heart rate for age[d]	0.5
Clinical history	
A. Syncope[c]	
With stress	2
Without stress	1
B. Congenital deafness	0.5
Family history	
A. Family members with definite LQTS[e]	1
B. Unexplained sudden cardiac death below age 30 among immediate family members[e]	0.5

[a]In the absence of medications or disorders known to affect these electrocardiographic features.
[b]QTc calculated by Bazett's formula where QTc = QT/√RR.
[c]Mutually exclusive.
[d]Resting heart rate below the 2nd percentile for age.
[e]The same family member cannot be counted in A and B.
SCORE: ≤1 point: low probability of LQTS; 1.5–3 points: intermediate probability; ≥3.5 points high probabilty.
(Used with permission, Schwartz, P. J. and Crotti, L. (2011). QTc behavior during exercise and genetic testing for the long-QT syndrome. *Circulation* **124**(20), 2181–2184. https://doi.org/10.1161/CIRCULATIONAHA.111.062182.)

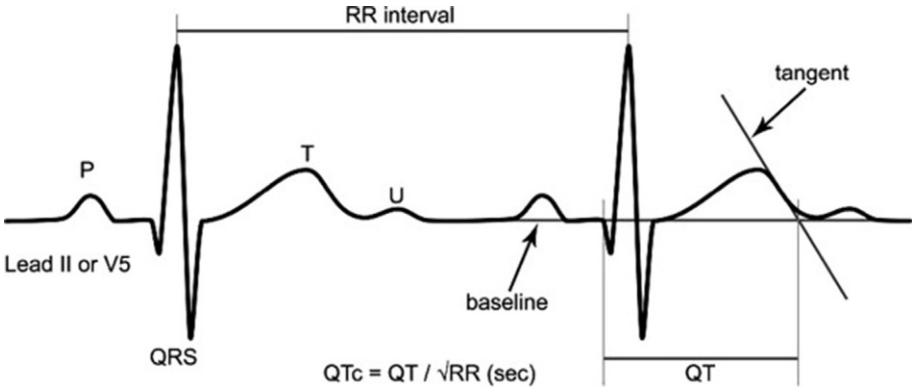

Fig. 3 Measuring the QT interval using the intersection of the tangent method. (Used with permission, Postema, P. G., De Jong, J. S. S. G., Van der Bilt, I. A. C. and Wilde, A. A. M. (2008). Accurate electrocardiographic assessment of the QT interval: Teach the tangent. *Hear Rhythm* **5**(7), 1015–1018. http://dx.dy.org/1018.10.1016/j.hrthm.2008.03.037.)

The mainstay for diagnosis of LQTS is, of course, measuring a prolonged QT on EKG. While in theory this seems relatively easy, there remains some controversy regarding the best way to measure the QT and the best heart-rate-correction formula to use. The 2009 consensus statement on interpretation of EKGs recommends using lead V2 as the mainstay of measuring the QT (Rautaharju et al., 2009). Many of the studies on LQTS have used lead V5 and lead II when measuring the QT and most use Bazzett's formula for correction. For these reasons, this is predominantly the strategy we use at our institution. Nevertheless, in some EKGs, particularly when the T-wave is flat, it can be unclear where the T-wave begins and ends. In these instances, it is sometimes necessary to use a contiguous lead in which the T-wave is more prominent, though this has not yet been validated. The most reliable and reproducible approach in measuring the QT interval is to measure from the beginning of the QRS to the point where the tangent of the initial downward slope of the T-wave meets the horizontal line of the TP segment (**Fig. 3**), and to exclude any U-waves (Postema et al., 2008). Since the QT may be dynamic, it is often helpful to take an average over several beats and to perform ECG measurements on multiple encounters, particularly when the QT prolongation is borderline.

Identifying a prolonged QT interval in the presence of bundle branch blocks and interventricular conduction delay becomes more difficult and problematic. There is controversy on the best approach. One strategy is to use the measurement of the JT interval and identify patients with JTc greater than 360 ms as abnormal. Another is to use the standard QT_c, but use 500 ms as the upper limit of normal. Similarly, challenges remain in correctly measuring the QT interval during atrial fibrillation, without consensus on the most accurate approach. New methods are being devised and validated and it remains to be seen which will become the standard.

To help unmask a prolonged QT, provocative maneuvers can be performed. In patients with LQTS, particularly LQT1, the absolute QT interval tends to remain fixed while the RR interval shortens during tachycardia, resulting in an exaggerated prolongation of the QTc interval. Exercise stress test and measuring the QT interval 3–5 min into recovery, while the heart rate is still elevated, can be helpful. An EKG performed while lying and followed by one after standing for several minutes can also raise the heart rate and can bring out evidence for LQTS (Adler et al., 2012; Wong et al., 2010).

Treatment

One of the hallmarks of treatment is to avoid medications that can prolong the QT. Online resources that maintain updated lists of QT-prolonging medications are available (https://www.qtdrugs.org). Electrolyte abnormalities can exacerbate long QT, correcting these imbalances is important. B-Blockers are the mainstay of medical therapy, even for asymptomatic patients with inherited LQTS to help reduce the patient's sudden death risk. Adrenergic surges modulate repolarization and affect potassium, especially IKs, and calcium handling. Blunting these surges is, at least partially, responsible for the effectiveness of B-blockers and that is why B-blocker therapy is most effective in LQT1, fairly effective in LQT2, but less effective in LQT3. Risk reduction is as high as 67% in LQT1 males and 71% in LQT2 females (Bohnen et al., 2017). A family history of sudden death does not necessarily convey higher risk. ICD implantation is generally indicated in patients who have survived cardiac arrest or who have had recurrent syncope despite B-blocker therapy. As adrenergic drive is a driving trigger, in those who decline ICD therapy or are unable to tolerate beta blocker therapy, left cardiac sympathetic denervation is recommended. Finally, there is mounting evidence that sodium channel blockers can shorten the QT and reduce symptoms in those with a diagnosis of LQT3 (Mazzanti et al., 2016). This is one of the few examples in cardiovascular medicine where genotype can be used to guide medical intervention.

Brugada Syndrome

Brugada syndrome was first described in 1992 by Dr. Brugada (Brugada and Brugada, 1992). The syndrome was characterized by the EKG finding of right bundle branch block with persistent ST elevation and sudden death. Although the prevalence of Brugada syndrome is higher in Southeast Asian populations, it is not limited to this group. There the prevalence of the syndrome is approximately 1–5 in 10,000 in Europe and 15 in 10,000 in Southeast Asia (Gallagher et al., 2008; Rattanawong et al., 2017). The prevalence of the EKG pattern in a meta-analysis was 0.2% in North America and 0.9% in Asia with a worldwide prevalence of 0.4% (Quan et al., 2016). It is found predominantly in the male population with an estimated 9:1 male-to-female ratio (Gallagher et al., 2008; Wilde et al., 2002). Some suggest the male predominance is related to testosterone levels and the more prominent Ito channel found in males (Shimizu et al., 2007; Di Diego et al., 2002).

Clinical Diagnosis

The diagnosis of Brugada syndrome relies primarily on the characteristic EKG morphologies seen in the precordial leads. Although it was previously necessary to manifest a Brugada ECG pattern in the setting of symptoms such as syncope or ventricular arrhythmias to meet diagnostic criteria for Brugada *syndrome*, there was a shift in definition with the 2013 inherited arrhythmia scientific statement. A type I Brugada *pattern* is now necessary and sufficient for diagnosis of BrS. Importantly, there are a number of conditions that can present with Brugada-like patterns. Therefore, when the pattern is present, other conditions should be excluded before a diagnosis of Brugada syndrome is made. Some of these conditions include atypical RBBB, early repolarization, aortic aneurysm dissections, electrolyte disorders, mechanical distortion of the RVOT as it can occur with tumors, pneumothorax, pectus excavatum, muscular dystrophy, myotonic dystrophy, pulmonary embolism, and rarely angina (Shimizu, 2005).

To meet the diagnostic criteria for Brugada syndrome, a patient must demonstrate a type 1 morphology which either occurs spontaneously or is induced with sodium channel blockers and exclusion of other causes of an abnormal EKG as listed above. A type 1 pattern is defined as greater than or equal to 2 mm of ST elevation in leads V1 or V2 with a coved pattern with the leads positioned in the second, third, or fourth intercostal space (**Fig. 4**). Type 2 or 3 Brugada patterns are nonspecific findings, however, in patients with symptoms or family history suspicious for BrS, a provocative test with sodium channel blockers to induce a type one pattern can be performed to establish the diagnosis. A type 2 or 3 Brugada pattern without inducibility of a type one pattern has not been shown to increase risk for sudden death. Other findings that can favor Brugada syndrome include abnormal signal averaged EKG, history of atrial fibrillation, the presence of AV block, and ventricular effective refractory periods less than 200 ms (Priori et al., 2013).

Worrisome clinical symptoms associated with this syndrome include aborted sudden cardiac death, ventricular fibrillation, and syncope. Patients may also complain of symptoms related to ventricular arrhythmias that include palpitations and chest pain. These symptoms typically arise during febrile states or vagotonic conditions and rarely happen during periods of exercise where the adrenergic drive is elevated. In some cases, BrS may be associated with structural abnormalities (Juang and Lin, 2016).

Brugada syndrome is inherited in an autosomal dominant fashion with multiple genes linked to its phenotypic expression. However, the yield of clinical genetic testing is approximately 30%, which is one of the lowest among the inherited arrhythmic syndromes. Nevertheless, genetic testing is recommended in patients with an established history of BrS (Ackerman et al., 2011). The gene with rare variants most commonly attributed to BrS is *SCN5A*, found in up to 18% of individuals with this diagnosis. This gene

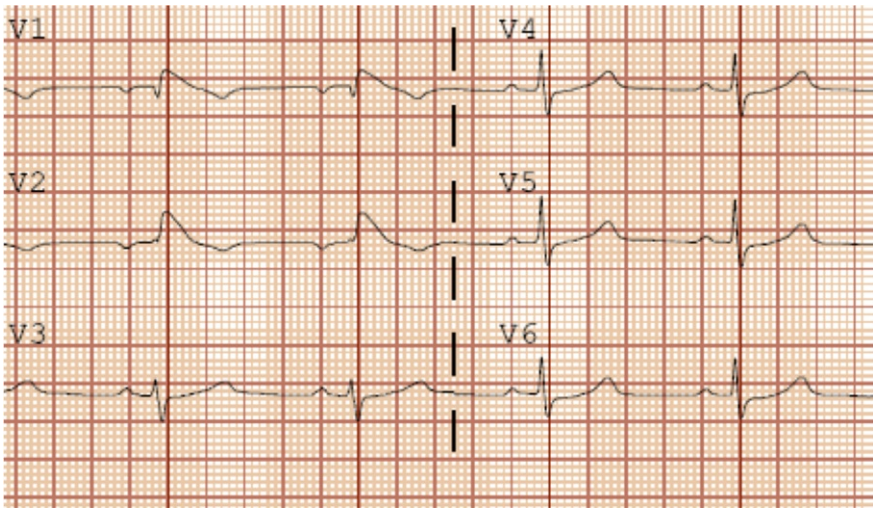

Fig. 4 Precordial leads from patient with a Type 1 Brugada pattern, inducible ventricular tachycardia and a pathogenic variant in *SCN5A* p.Glu1784Lys (c.5350G>A).

encodes the alpha subunit of the cardiac sodium channel and causes a loss or decrease in function (Berne and Brugada, 2012). The use of sodium channel blockers, like procainamide, will exacerbate the typical EKG patterns.

Treatment

The basic treatment for Brugada syndrome, as with all of the channelopathies, is focused on ameliorating sudden death risk. The highest risk marker is a history of sudden cardiac arrest or syncope due to ventricular arrhythmia with a yearly risk of SCD of 10% and 5%, respectively. Consensus recommendations are for these patients to have an ICD placed (Gourraud et al., 2017). ICD therapy can be useful in patients with Brugada syndrome and history of syncope without clear cause which is judged to be potentially due to ventricular arrhythmias. Patients who are otherwise asymptomatic have less than 1% annual risk and defibrillators are not recommended in these individuals.

Electrophysiologic testing is controversial with regard to helping risk stratify asymptomatic patients with a Brugada pattern. While the strategy of placing ICDs in patients who have inducible VF at EPS can be considered, there are conflicting studies arguing for its utility (Gourraud et al., 2017; Priori et al., 2012). Family history of sudden death alone lacks prognostic significance in Brugada syndrome in part due to highly variable phenotypic penetrance (Eckardt et al., 2005). A class III recommendation has been made, stating that an ICD should not be placed based on a family history of sudden death without any of the other high risk markers as stated above (Priori et al., 2013).

Although there is no ideal medical therapy for this syndrome, quinidine may be considered in patients with recurrent ventricular arrhythmias or those who are unable to have a device implant. This medication, however, is not well-tolerated by most patients. For those who present in arrhythmic storms, which may be related to enhanced vagal tone, isoproterenol may be helpful acutely. Epicardial ablation of the RVOT has shown some promise as an adjuvant therapy in patients with refractory ventricular tachycardias (Belhassen, 2016).

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is an adrenergically mediated syndrome causing ventricular tachycardia and ultimately ventricular fibrillation leading to sudden death. Typically, structural evaluation demonstrates a normal heart with the first description of this entity described in the 1960s (Berg et al., 1960). The hallmark of this disease process is the presence of premature ventricular beats which increase in frequency with exercise and have more than one morphology. A finding of bidirectional ventricular tachycardia during exercise is highly suggestive of this condition (**Fig. 5**), though this has also been reported in patients with digitalis toxicity or Anderson Tawil syndrome (LQT7).

The true prevalence is unknown but estimated at 1:10,000 individuals. Typically, patients present in early youth around age 10 typically have structurally normal hearts. However, the first presentation can occur in the third and fourth decades of life (Liu et al., 2008). There is an autosomal dominant inheritance pattern with rare variation in the ryanodine receptor accounting for the majority of cases. An autosomal recessive inheritance pattern has been reported with rare variation in cardiac calsequestrin. The yield of genetic testing in clinically definitive CPVT is approximately 50%. A diagnosis of CPVT can be made with evidence of a clearly pathogenic mutation and in family members of diagnosed individuals with exercise-induced premature ventricular contractions. While it is uncommon to diagnose this in individuals older than the age of 40, if patients have a structurally normal heart and polymorphic exercise-induced premature beats, without other clear etiology, then they would meet criteria for the diagnosis.

Treatment

Current treatment focuses on decreasing adrenergic stimulation. Therefore, beta-blockers are recommended in all symptomatic individuals and should be considered for those who are not symptomatic. Nadolol is the typical B-blocker used due to the long-acting nature of the drug and its lack of intrinsic sympathomimetic activity. Therapy should be intensified if ventricular couplets or more are seen on exercise testing as some studies show an association with arrhythmic events (Hayashi et al., 2009). It is also recommended to avoid strenuous activity and stressful environments to decrease the adrenergic stimulation. If patients have

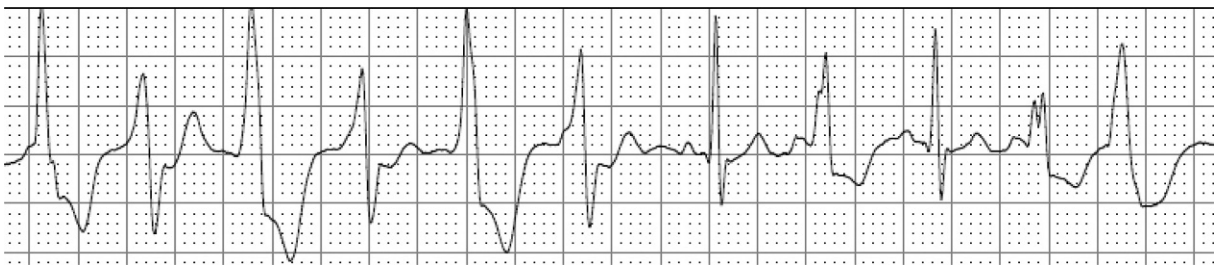

Fig. 5 Bi-directional ventricular tachycardia noted in a patient who had a history of cardiac arrest during rhinoplasty after epinephrine infusion.

experienced cardiac arrest, syncope, or VT on beta blocker therapy, then an ICD is indicated (Priori et al., 2013). However, some question the role of ICD as defibrillation can lead to catecholamine surges which in turn increase the arrhythmia and can lead to poorer outcomes (Miyake et al., 2013). There is mounting evidence that flecainide should be added to B-blocker therapy in those with persistent arrhythmias on B-blocker therapy due to improved outcomes (Roston et al., 2017). For those refractory to or intolerant of therapy, then left cardiac sympathetic denervation can be considered.

Short QT Syndrome

SQTS is a relatively newly defined inherited channelopathy. At the turn of this century, a few families who had a history of early sudden cardiac death were found to also have a short QT (Gaita et al., 2003; Gussak et al., 2000). This syndrome, too, has an autosomal dominant inheritance. The estimated prevalence of this syndrome is less than 1 in 10,000 with a short QT_c defined as less than 330 ms, well below two standard deviations of normal. The diagnosis can be made with a slightly longer QTc (360 ms or less) with one of the following markers: family history of short QT, family history of sudden death younger than 41 years old, a pathogenic mutation or survival of ventricular tachycardia, or ventricular fibrillation arrest. Gollob *et al*. have proposed a scoring system for diagnosis of short QT which has not yet been included in current guidelines (Gollob et al., 2011). The most common forms of SQTS have been shown to be related to potassium channel genes which are also associated with LQTS. As opposed to loss of function causing long QT, a gain of function in these genes causes SQTS (Bellocq et al., 2004; Priori et al., 2005; Brugada et al., 2004). However, loss of function mutations has also been identified in the L-type calcium channel which are also associated with shortening of the QT (Antzelevitch et al., 2007). In contrast to LQTS, SQTS does not appear to have focal triggers like exercise, noise, or sleep (Giustetto et al., 2006).

Treatment

ICDs are indicated in patients with a short QT and who are survivors of cardiac arrest or have documented episodes of sustained VT. Given the small cohort of patients with this syndrome, it becomes challenging to study. Other treatments may be helpful but are not well validated. Although ICD may be considered in patients with short QT and family history of sudden death, this has not been validated. At this point, flecainide, sotalol, ibutilide, and hydroquinidine have all been studied in SQTS. Of those, only hydroquinidine showed some promise in effectiveness (Giustetto et al., 2011).

Conclusion

Technological advances and improvement in genotyping have improved the ability to identify individuals at risk for sudden cardiac death from arrhythmias. Identification of these patients can still be problematic as the inherited channelopathies are relatively rare. More genes continue to be identified and treatment options continue to be refined. Once diagnosis is made, often questions arise regarding screening of relatives. Once identified, first-degree relatives and second-degree relatives engaged in athletic competition should be screened. While specific genetic markers are helpful, a pathogenic variant is not identified in all cases. When an inherited arrhythmia is suspected, such as in cases of sudden cardiac arrest or death, our current practice is to evaluate relatives with an initial screening to include exercise EKG, lying and standing EKG, modified Brugada ECG, signal averaged EKG, and a structural evaluation. Targeted genetic testing is done if family members are found to be affected, otherwise, broad genetic testing is recommended in the proband. If no gene has been identified, interval follow-up is recommended to evaluate for future phenotypic expression.

Key Messages

- Rate control is not inferior to pharmacologic rhythm control with respect to mortality, heart failure, and stroke outcomes. However, pharmacologic rhythm control is only at most 70% successful at maintaining sinus rhythm. Ongoing trials are assessing the efficacy of catheter ablation strategies with respect to "hard" cardiovascular outcomes.
- Regardless of whether a rate- or rhythm-control strategy is chosen, the most important aspect of atrial fibrillation management remains stroke prevention.
- The development of direct oral anticoagulants (DOACs) has significantly advanced the management of AF patients. The four currently available DOACs (i.e., dabigatran, rivaroxaban, apixaban, and edoxaban) have at least equal efficacy as warfarin with respect to stroke prevention. In addition, dabigatran (at a dose of 150 mg twice daily) and apixaban are superior to warfarin. All four DOACs have a significantly lower risk of developing intracranial hemorrhage.
- The goal of upstream therapies is to delay or even reverse the natural progression of AF by targeting factors leading to atrial remodeling. There is randomized control trial evidence supporting lifestyle modification, such as weight loss, in reducing the frequency and burden of atrial fibrillation.

Introduction

The breadth and depth of atrial fibrillation (AF) clinical research have grown exponentially, advancing our understanding and management of patients with AF (**Fig. 1**) (Nishida and Nattel, 2014). Over this past decade alone, clinical trials testing direct oral anticoagulants and left atrial appendage (LAA) closure devices have dramatically increased the therapeutic options for stroke prevention. Other studies have helped to refine the role of and approach to catheter ablation for rhythm management (Gillis et al., 2013).

Yet despite this accumulating body of knowledge, the management of patients with AF continues to be challenging with many clinical questions still unanswered. Fortunately, advancement in our understanding of the basic mechanisms underlying AF and the development of new technologies promise for unprecedented opportunities, which will likely revolutionize AF management in the decades ahead (Nattel and Harada, 2014; Iwasaki et al., 2011).

In this article, we will review the landmark clinical trials supporting the current management of AF. In particular, we will discuss (a) stroke prevention in AF; (b) rate control versus rhythm control; and (c) upstream therapies for preventing the progression of AF including recent evidence supporting exercise and lifestyle modification. We will also discuss current knowledge gaps in the management of AF and ongoing clinical trials that hope to address areas of clinical equipoise.

Anticoagulation for Stroke Prevention in Nonvalvular AF

The association between AF and thromboembolism has long been known (Fisher, 1972). The risk of AF-associated ischemic stroke or systemic embolism is quite variable based on known and emerging risk factors (Gage et al., 2001, 2004; Lip et al., 2010; Hijazi et al., 2013; Oldgren et al., 2016), but appears to be largely independent of the pattern of AF episodes. The substantial benefits of antithrombotic therapy for reducing the occurrence of stroke, systemic embolism, and mortality in patients with nonvalvular AF have been demonstrated in a series of trials of various agents beginning in the late 1980s.

Acetylsalicylic Acid

Low-dose acetylsalicylic acid (ASA) was the first agent to be tested in multiple large, well-designed clinical trials. A 2007 metaanalysis of these studies found that ASA, compared to placebo or no therapy, did not significantly reduce the incidence of stroke or systemic embolism relative risk reduction (RRR) 19% (95% CI −1.0 to 35.0) (Hart et al., 2007). Further, ASA had little effect on reducing the risk of disabling stroke. However, when the analysis was limited to placebo-controlled trials, there was a statistically significant 22% RRR (95% CI 2%–39%) of ischemic and hemorrhagic stroke in patients receiving ASA compared to placebo.

In contrast to warfarin and DOACs, to be discussed later, there appears to be a diminishing role for ASA monotherapy for the prevention of thromboembolic events in patients with nonvalvular AF. Whether ASA is a reasonable antithrombotic monotherapy in very low-risk AF patients (i.e., $CHADS_2 = 0$) has not been well addressed, given that this population is underrepresented in the available clinical trials (Hart et al., 2007; Cooper et al., 2006). This clinical equipoise is reflected in the slightly varying guideline recommendations by major cardiovascular societies in North America and Europe (Kirchhof et al., 2016; Skanes et al., 2012;

January et al., 2014). For example, the 2016 Canadian Cardiovascular Society guidelines for the management of AF recommends use of ASA monotherapy only for patients who are at low to intermediate risk of stroke and have an independent indication for its use such as coronary artery disease (Macle et al., 2016).

Warfarin

Previously, the vitamin K antagonist warfarin was suggested before cardioversion in some patients, but its long-term use was not advocated unless patients had persistent AF in the setting of rheumatic heart disease (Prystowsky, 2008; Wood, 1968). However, the early 1990s witnessed the publication of five landmark trials establishing the benefit of long-term warfarin for stroke prevention in nonvalvular AF: the Atrial Fibrillation, Aspirin, Anticoagulation study (AFASAK), Stroke Prevention in Atrial Fibrillation studies (SPAF I and II), the Boston Area Anticoagulation Trial for Atrial Fibrillation (BAATAF), the Canadian Atrial Fibrillation Anticoagulation study (CAFA), and the Stroke Prevention in Nonrheumatic Atrial Fibrillation study (SPINAF) (BAATAF Investigators, 1990; Investigators SPiAF, 1991, 1994; Ezekowitz et al., 1992; Connolly et al., 1991; Petersen et al., 1989). In a collaboration among the authors of these five trials, the Atrial Fibrillation Investigators pooled their data to conduct a patient-level metaanalysis in 1994 (Investigators, 1994). Together, these trials enrolled about 3000 AF patients with a mean age of 69 years at time of randomization, and prevalence of hypertension and diabetes was 46% and 14%, respectively. Few patients (4.5%) had a prior transient ischemic attack (TIA) or stroke. The annual stroke rate of 4.5% in the control group was reduced to 1.4% in the warfarin group, a RRR of 68% (95% CI, 50%–79%; $p < 0.001$). Furthermore, warfarin was associated with a reduction in all-cause mortality compared to controls (3.6% vs. 5.4%, $p = 0.01$). The annual rate of major hemorrhage (defined as intracranial bleeding or a bleed requiring hospitalization or transfusion of two or more units of blood) was 1.3% for the warfarin group compared a rate of 1.0% for the controls. In summary, warfarin resulted in clinical significant reductions in stroke and death that was not offset by a small absolute increase in hemorrhagic stroke (Investigators, 1994).

The efficacy of dose-adjusted warfarin was also compared with ASA and other antiplatelet agents in several subsequent trials. In a metaanalysis of these studies, warfarin was the superior agent in reducing stroke or systemic embolism, conferring an additional RRR of 52% (95% CI 41%–62%) (Hart et al., 2007).

Subsequent studies assessed the benefit of warfarin in important high-risk subgroups that were underrepresented in the initial Atrial Fibrillation Investigator studies. For example, only 6% of patients enrolled by the Atrial Fibrillation Investigators had a history of TIA or ischemic stroke. The European Atrial Fibrillation Trial (EAFT) ($n = 1007$) sought clarify the efficacy of warfarin or ASA compared to placebo in patients with nonrheumatic AF who had experienced a TIA or stroke within the preceding 3 months (EAFT, 1993). Warfarin led to a highly significant RRR of 66% in annual stroke rate compared to placebo (i.e., an almost identical RRR as in the Atrial Fibrillation Investigator pooled cohort), with an 8% absolute risk reduction in this higher risk group.

Another area of uncertainty that was not addressed by the Atrial Fibrillation Investigators was the benefit of anticoagulation in the elderly AF population (Investigators, 1994). The Birmingham Atrial Fibrillation Treatment of the Aged (BAFTA) Trial was a randomized, open-label study of warfarin compared to ASA in 973 AF patients who were aged 75 years and greater (mean 81.5 years) (Mant et al., 2007). Over a mean follow-up of 2.7 years, warfarin reduced the annual risk of the primary composite endpoint (i.e., fatal or disabling stroke, intracranial hemorrhage, and clinically significant arterial embolism) from 3.8% to 1.8% ($p = 0.003$). There was no difference in prevention of nonstroke vascular events or overall mortality between the warfarin and ASA treatment arms. Surprisingly, the annual risk of major hemorrhage was similar between warfarin (1.4%) and ASA (1.6%). However, it is possible that greater adherence to randomized therapy may have demonstrated a significant difference in bleeding; one third of patients in the anticoagulation treatment arm discontinued warfarin.

Alternatives to Adjusted-Dose Warfarin, Act 1: Low-Dose Warfarin or Clopidogrel

Prior to the randomized trials of direct oral anticoagulants (DOACs) agents, several trials explored alternative anticoagulation strategies with the intent of minimizing the risk of major bleeding, yet maintaining the benefits of stroke and thromboembolism prevention. Various alternative strategies were studied including low-dose warfarin plus ASA, and ASA plus clopidogrel.

The Stroke Prevention in Atrial Fibrillation (SPAF) III trial enrolled 1044 patients with nonvalvular AF and at least one thromboembolic risk factor (Investigators SPiAF, 1996). Patients were randomized to low intensity fixed-dose warfarin plus ASA 325 mg daily, or to adjusted-dose warfarin (INR 2.0–3.0). The trial was terminated early due to the excess of ischemic stroke and systemic embolism in the combination therapy group (7.9% vs. 1.9% per year, $p < 0.0001$). The rates of major and intracranial bleeding were similar in the two treatment groups. After additional similar studies assessing failed to show benefit, this strategy was abandoned (Hellemons et al., 1999; Gullov et al., 1998).

The safety and efficacy of dual antiplatelet therapy (i.e., combination of clopidogrel and ASA) in patients with nonvalvular AF were also assessed in a two large randomized trials by the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) program: ACTIVE-A and ACTIVE-W (Investigators AWGotA et al., 2006; Investigators et al., 2009a). The ACTIVE-W trial used a noninferiority design to compare the effect of the combination of clopidogrel 75 mg daily plus ASA to dose-adjusted warfarin (target INR 2.0–3.0) on the composite endpoint of stroke, non-CNS systemic embolus, myocardial infarction, and vascular death (Investigators AWGotA et al., 2006). ACTIVE-W enrolled 6706 patients with AF plus one or more risk factor for stroke, however, the trial was stopped early due to evidence of warfarin's superiority. After a median follow-up of 1.3 years, the annual risk of the composite outcome was 5.6% in the clopidogrel and ASA group compared to 3.9% with oral anticoagulation (RR

1.44; 95% CI, 1.18–1.76; $p = 0.0003$). Furthermore, there was a higher annual rate of stroke in the combination of clopidogrel and ASA arm compared to oral anticoagulation, without a significant difference in major bleeding.

The ACTIVE-A trial compared the combination of clopidogrel 75 mg daily plus ASA to ASA alone in 7554 patients with AF at increased risk of stroke and for whom vitamin K antagonist therapy was contraindicated (Investigators et al., 2009a). After a mean 3.6 years, the primary composite of any major vascular event (i.e., stroke, myocardial infarction, non-CNS systemic embolism, or death from vascular causes) occurred at an annual rate of 6.8% in the clopidogrel plus ASA treatment arm compared to 7.6% in the placebo group (RR 0.89; 95% CI, 0.81–0.98; $p = 0.01$). The difference was primarily due to a reduction in the rate of stroke in the dual antiplatelet therapy group. However, the rate of major bleeding was increased (2.0% per year with clopidogrel, and 1.3% ASA alone, RR 1.57; 95% CI, 1.29–1.92; $p < 0.001$).

Alternatives to Adjusted-Dose Warfarin Act 2: Direct Oral Anticoagulants

Despite its proven advantages over placebo, ASA monotherapy, and combination antiplatelet therapy, observational studies continued to show that in clinical practice rates of warfarin use in eligible patients remained below 60% (Ogilvie et al., 2010). Barriers to warfarin uptake include its narrow therapeutic window and requirement for ongoing dose adjustment and monitoring. The long search for safe and effective oral anticoagulants that overcome these barriers has culminated in the development and marketing of the direct oral anticoagulants (DOACs), which represent a significant evolution in stroke prevention therapy. Below, we will summarize the landmark studies that compared each of dabigatran, rivaroxaban, apixaban, and edoxaban with warfarin (Connolly et al., 2009; Patel et al., 2011; Granger et al., 2011; Giugliano et al., 2013). **Table 1** compares the trial designs, baseline patient characteristics, and outcomes in these four studies.

The Randomized Evaluation of Long Term Anticoagulation Therapy (RE-LY) trial was a noninferiority trial that assessed the efficacy of dabigatran for the prevention of thromboembolism in nonvalvular AF compared to warfarin (Connolly et al., 2009).

Table 1 Summary of landmark trials comparing direct oral anticoagulants to warfarin for nonvalvular atrial fibrillation

	RE-LY	*ROCKET-AF*	*ARISTOTLE*	*ENGAGE-AF*
DOAC	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	IIa (thrombin)	Xa	Xa	Xa
Half-life (h)	12–17	5–13	~12	9–11
Renal excretion	80%	33%	25%	50%
N	18,113	14,264	18,201	21,105
Study design	Open-label	Double-blind	Double-blind	Double-blind
Median follow-up (years)	2.0	1.9	1.8	2.8
Mean $CHADS_2$	2.1	3.5	2.1	2.8
Dosing	110 mg bid 150 mg bid	20 mg daily 15 mg daily (renal)	5 mg bid 2.5 mg bid**	60 mg OD[a] 30 mg OD[a]
Warfarin time in therapeutic range	64% (mean)	55% (mean)	62% (mean)	65% (mean)
Stroke/embolism (/year)	Warfarin: 1.7% 110 mg: 1.5% (noninferior) 150 mg: 1.1% (superior)	Warfarin: 2.2% Rivaroxaban: 1.7% (noninferior)	Warfarin: 1.6% Apixaban: 1.3% (superior)	Warfarin: 1.5% 30 mg: 1.6% (noninferior) 60 mg: 1.2% (noninferior)
Major bleeding (/year)	Warfarin: 3.4% 110 mg: 2.7% ($p = 0.003$) 150 mg: 3.1% (ns)	Warfarin: 3.4% Rivaroxaban: 3.6% (ns)	Warfarin: 3.1% Apixaban: 2.1% ($p < 0.001$)	Warfarin: 3.4% 30 mg: 1.6% ($p < 0.001$) 60 mg: 2.8% ($p < 0.001$)
Intracranial hemorrhage (/year)	Warfarin: 0.4% 110 mg: 0.1% ($p < 0.001$) 150 mg: 0.1% ($p < 0.001$)	Warfarin: 0.7% Rivaroxaban: 0.5% ($p = 0.02$)	Warfarin: 0.8% Apixaban: 0.3% ($p < 0.001$)	Warfarin: 0.5% 30 mg: 0.2% ($p < 0.001$) 60 mg: 0.3% ($p < 0.001$)
Mortality (/year)	Warfarin: 4.1% 110 mg: 3.8% (ns) 150 mg: 3.6% (ns)	Warfarin: 4.9% Rivaroxaban: 4.5% (ns)	Warfarin: 3.9% Apixaban: 3.5% ($p = 0.047$)	Warfarin: 4.4% 30 mg: 3.8% ($p = 0.01$) 60 mg: 4.0% (ns)

[a]Dose reduction of edoxaban by 50% if one of weight <60 kg, creatinine clearance 30–50 mL/min, or concomitant use of verapamil or quinidine (i.e., potent P-glycoprotein inhibitors) (Connolly et al., 2009; Patel et al., 2011; Granger et al., 2011; Giugliano et al., 2013; Levy et al., 2014).

**Dose reduction of apixaban by 50% if 2 or more of: <= 60 kg, age >= 80 kg creatinine >= 1.5 mg/dL.

RE-LY was an open-label study that randomized 18,113 patients with AF (and ≥ 1 risk factor of previous stroke or TIA, LVEF $< 40\%$, or $\geq$ NYHA II heart failure symptoms) to receive fixed doses of dabigatran (110 or 150 mg twice daily) or open-label warfarin (target INR 2.0–3.0) in a 1:1:1 fashion. After a median 2-year follow-up, the rate of the primary outcome of stroke or systemic embolism was similar in the lower dose dabigatran (110 mg) group compared with warfarin (RR with dabigatran, 0.90; 95% CI, 0.74–1.10; $p < 0.001$ for noninferiority). However, the higher dose dabigatran 150 mg was superior to warfarin with significantly fewer primary outcome events (1.71% in the warfarin group vs. 1.11% in the dabigatran 150 mg group; RR 0.65; 95% CI, 0.52–0.81; $p < 0.001$ for superiority) (Connolly et al., 2010).

In RE-LY, the safety endpoint of major bleeding occurred in 2.9% of the low-dose dabigatran group, 3.3% in the high-dose dabigatran group, and 3.6% in the warfarin group ($p = 0.01$ compared to low-dose dabigatran, and $p = 0.32$ compared to high-dose dabigatran) (Connolly et al., 2010). Importantly, the annual rate of hemorrhagic stroke was significantly decreased with both dabigatran doses compared to warfarin (0.12% with 110 mg of dabigatran, 0.10% with 150 mg of dabigatran, and 0.38% with warfarin). The only adverse event occurring significantly more often in patients receiving dabigatran was dyspepsia (Connolly et al., 2009). Acknowledging the potential interaction between renal function and study results (n.b. dabigatran is 80% renally excreted), RE-LY conducted a prespecified analysis, which found the efficacy and safety of both dosages of dabigatran were consistent with the overall trial irrespective of renal function when stratified by estimated glomerular filtration rates (i.e., eGFR >80, 50–80, and <50 mL/min/1.73 m^2) (Hijazi et al., 2014).

The rivaroxaban-once daily, oral, direct factor Xa inhibition compared with vitamin K antagonist for prevention of stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF) trial was a large, randomized, double-blind, double-dummy noninferiority trial that enrolled 14,264 (mean age 73 years) patients with nonvalvular AF to receive rivaroxaban (20 mg daily, or 15 mg daily in patients with a creatinine clearance of 30–49 mL/min) or dose-adjusted warfarin (Patel et al., 2011). Baseline stroke risk in patients enrolled in ROCKET-AF was higher than in RE-LY: 87% of the patients had a $CHADS_2$ score of 3 or higher, and 55% had a prior TIA or stroke. Over a median follow-up of 24 months, the primary end of stroke or systemic embolism occurred in 188 patients in the rivaroxaban group (1.7% per year) and in 241 patients in the warfarin group (2.2% per year) (HR 0.88; 95% CI, 0.74–1.03; $p < 0.001$ for noninferiority, $p = 0.12$ for superiority). There was no significant difference in the risk of major bleeding between the two groups ($p = 0.44$), although intracranial and fatal bleeding occurred less often in the rivaroxaban group. The trial concluded that rivaroxaban was not inferior to warfarin for the prevention of stroke or systemic embolism in patients with AF.

The Apixaban for Reduction In STroke and Other ThromboemboLic Events in atrial fibrillation trial (ARISTOTLE) study compared the safety and efficacy of apixaban with warfarin in 18,201 patients with AF and at least one additional risk factor for stroke (Granger et al., 2011). Patients were randomized to either adjusted-dose warfarin or apixaban 5 mg twice daily (or 2.5 mg twice daily in patients meeting two or more of the following criteria: age ≥ 80 years, body weight ≤ 60 kg, serum creatinine level ≥ 1.5 mg/dL). Over a median follow-up of 22 months, the rate of the primary outcome of stroke and systemic embolism was 1.27% per year in the apixaban group compared with 1.60% per year in the warfarin group (HR 0.79; 95% CI, 0.66–0.95; $p < 0.001$ for noninferiority; $p = 0.01$ for superiority). The rate of major bleeding was significantly less in the apixaban group (2.13% per year vs. 3.09% per year with warfarin; HR 0.69; 95% CI, 0.60–0.80; $p < 0.001$). Additionally, ARISTOTLE demonstrated a statistically significant mortality benefit of apixaban over warfarin; the rates of all-cause mortality were 3.52% in the apixaban group and 3.94% in the warfarin group (HR, 0.89; 95% CI, 0.80–0.99; $p = 0.047$). Although the absolute risk reduction was small, apixaban was the first DOAC to reduce risk of death from any cause in comparison to warfarin (Granger et al., 2011).

Apixaban was also studied in nonvalvular AF patients for whom warfarin therapy was unsuitable due to difficult-to-control INR, patient refusal, or increased bleeding risk (i.e., a population reminiscent of the ACTIVE-A trial comparing combination ASA and clopidogrel to ASA monotherapy, Investigators et al., 2009a). The Apixaban versus acetylsalicylic acid to prevent StROke in atrial fibrillation PatiEntS who have failed or are unsuitable for vitamin K antagonist treatment (AVERROES) study randomized 5550 AFs patients (average $CHADS_2$ score of 2.1) in whom warfarin therapy was unsuitable, to apixaban (5 mg or 2.5 mg twice daily) or ASA (81–324 mg daily). The study was stopped prematurely because of the clear advantage of apixaban over ASA in reducing the risk of stroke or systemic events by >50%. There was no increased risk of major bleeding with apixaban over ASA (Connolly et al., 2011). Although there have been no trials comparing apixaban to combination of clopidogrel and ASA in AF patients intolerant of warfarin, an indirect comparison of the AVERROES and ACTIVE-A trials would suggest that apixaban is the preferred agent given the superior efficacy compared to ASA, but without the increased major bleeding risk conferred by combination of clopidogrel and ASA.

Finally, the Effective aNticoaGulation with factor xA next GEneration in Atrial Fibrillation (ENGAGE AF-TIMI 48) was a noninferiority trial ($n = 21{,}105$) designed to compare the efficacy of edoxaban (30 or 60 mg daily) and warfarin in AF patients with respect to the primary outcome of stroke and systemic embolism (Giugliano et al., 2013). During a mean follow-up of 34 months, both daily doses of edoxaban were noninferior to warfarin. The annualized rate of major bleeding events was 3.43% with warfarin compared to 2.75% with high-dose edoxaban (HR 0.80; 95% CI, 0.71–0.91; $p < 0.001$) and 1.61% with low-dose edoxaban (HR 0.47; 95% CI, 0.41–0.55; $p < 0.001$). In addition to a lower risk of major bleeding, there was significantly less hemorrhagic stroke in both edoxaban doses compared to warfarin. Finally, edoxaban-treated patients had lower annualized rates of death from cardiovascular causes compared to warfarin: 3.17% with warfarin versus 2.74% with high-dose edoxaban (HR 0.86; 95% CI, 0.77–0.97; $p = 0.01$) and 2.71% with low-dose edoxaban (HR 0.85; 95% CI, 0.76–0.96; $p = 0.008$).

Although clinical trials have demonstrated the efficacy of DOACs as compared to warfarin in reducing the risk of stroke in AF patients, several concerns have hindered their universal uptake in the clinical community (Mohanty et al., 2014). One of these concerns include the lack of a reversal agent, although recently one of the DOAC antidotes was approved for use in Canada, the United States, and Europe. Idarucizumab, a monoclonal antibody fragment, was designed to reverse the anticoagulant effects of

dabigatran. In an interim analysis of the ongoing REVERSE-AD prospective study (Study of the RE-VERSal Effects of Idarucizumab on Active Dabigatran), idarucizumab was found to be effective at reversing the anticoagulant effect of dabigatran based on the determination of direct thrombin time or ecarin clotting time (Pollack et al., 2015). Furthermore, the results of phase III studies are highly anticipated for andexanet alfa, a reversal agent for the direct factor Xa inhibitors (i.e., apixaban, rivaroxaban, and edoxaban) (Ghadimi and Welsby, 2016; Siegal et al., 2015).

Other challenges of DOACs include the need for dose adjustment in both renal and hepatic impairment. Furthermore, DOACs are contraindicated in patients with end-stage renal disease (with or without renal replacement); patients with creatinine clearance 30 mL/min were excluded from the seminal DOAC clinical trials (Connolly et al., 2009; Patel et al., 2011; Giugliano et al., 2013), with the exception of ARISTOTLE which excluded patients with a serum creatinine of 2.5 mg/dL or calculated creatinine clearance of <25 mL/min (Granger et al., 2011).

Furthermore, it is important to note that DOACs are not indicated in valvular AF (i.e., AF related to rheumatic valvular disease or prosthetic heart valves) as this population was excluded from the trials comparing DOACs and warfarin. RE-ALIGN (Randomized, phase II study to Evaluate the sAfety and pharmacokinetics of oral dabIGatran etexilate in patients after heart valve replacement) was the one randomized clinical trial that explored the use of a DOAC, specifically dabigatran, in patients with mechanical valves compared to warfarin. Although not exclusively an AF trial (i.e., only 28% of patients had AF), dabigatran was found to be inferior warfarin in terms of efficacy and safety; RE-ALIGN was terminated prematurely due to an excess of thromboembolic and bleeding events among patients in the dabigatran group (Eikelboom et al., 2013).

Left Atrial Appendage Closure Devices

Percutaneous LAA occlusion is a nonpharmacological alternative to oral anticoagulation which has been studied in a few clinical trials. The rationale behind LAA occlusion comes from anatomic and echocardiographic findings identifying the LAA as the site of thrombus formation in over 90% of patients with nonvalvular AF (Blackshear and Odell, 1996). Several percutaneous devices have been developed for the purpose of occluding or excluding the LAA from the circulation.

The WATCHMAN™ LAA closure device (Boston scientific) is the most rigorously studied LAA occlusion device currently available, with two randomized clinical trials supporting its use: PROTECT-AF (the Watchman LAA closure device for embolic PROTECTion in patients with Atrial Fibrillation) and PREVAIL (prospective randomized evaluation of the watchman LAA closure device in patients with atrial fibrillation versus long term warfarin therapy) (Holmes et al., 2009; Whisenant et al., 2014).

PROTECT-AF was a noninferiority trial with an adaptive Bayesian design that randomized 707 patients AF and $CHADS_2 \geq 1$ to either the Watchman device or warfarin (target INR 2.0–3.0) in a 2:1 ratio. Following device implantation, patients were continued on warfarin and ASA for 45 days, and then switched to clopidogrel plus ASA to 6 months, followed by ASA alone indefinitely. After 1065 patient-years of follow-up, percutaneous LAA closure with the Watchman device was noninferior to warfarin with respect to the primary composite endpoint of ischemic stroke, hemorrhagic stroke, cardiovascular death, and systemic embolism; the event rate was 3.0 per 100 patient-years in the Watchman group and 4.9 per 100 patient-years in the warfarin group (probability of noninferiority >99.9%) (Holmes et al., 2009). Subsequent analyses, allowed by the Bayesian design, extended the follow-up to 2621 patient-years and demonstrated a consistent noninferiority of the Watchman device compared to warfarin with respect to the primary outcome (Reddy et al., 2013, 2014).

Several concerns, raised by the U.S. Food and Drug Administration regarding patient selection criteria (i.e., inclusion of patients with $CHADS_2$ score of 1) and early complication rate, necessitated the subsequent PREVAIL trial (Whisenant et al., 2014). PREVAIL was designed with three coprimary endpoints. One of the efficacy endpoints, that evaluated late-ischemic efficacy, found that Watchman implantation was noninferior to warfarin in preventing ischemic events >7 days after implantation. The safety endpoint also achieved its prespecified performance goal with a low rate of procedural complications. However, PREVAIL missed its third coprimary endpoint (composite of stroke, systemic embolism, and cardiovascular death) and failed to show noninferiority to warfarin at 18 months (Holmes et al., 2014). An individual patient-level data metaanalysis of these two trials using a traditional superiority design was conducted by the original investigators (Holmes et al., 2015). They reported that the risk of the primary endpoint of all-cause stroke or systemic embolism was similar among patients with the Watchman versus patients on warfarin (HR 0.79, $p=0.22$). Interestingly, Watchman significantly increased the risk of ischemic stroke compared with warfarin (HR 1.95, $p=0.05$), but significantly decreased the risk of both hemorrhagic stroke (HR 0.22, $p=0.004$) and cardiovascular or unexplained death (HR 0.48, $p=0.006$).

Other LAA occlusion devices are available such as the AMPLATZER™ Amulet™ (St. Jude Medical), the LARIAT® system (SentreHeart, Inc), and the WaveCrest® device (Coherex Medical); however, to date the efficacy and safety of these devices have not yet been evaluated in randomized clinical trials. However, the safety and efficacy of the Amulet device will soon be evaluated in the Amplatzer Amulet Investigational Device Exemption (Amulet IDE) trial, which is an upcoming noninferiority trial against the Watchman LAA closure device (ClinicalTrials.gov identifier: NCT02879448). Nonetheless, the development and clinical study of these newer generations offer a promising future for AF patients, especially those who are unable to tolerate chronic anticoagulation.

In summary, the last quarter century has seen dramatic developments in evidence-based antithrombotic therapy for nonvalvular AF. Oral anticoagulation, either with warfarin or a DOAC, is among the most effective therapies in cardiovascular medicine, and is rightly considered the cornerstone of therapy in patients with elevated stroke risk. Future research is required to refine the optimal agents in specific populations, to maximize adherence to recommended therapy, and to further explore the role of percutaneous therapies.

Rate Control Versus Rhythm Control

There are two strategies used to manage AF symptoms: a "rhythm-control" strategy involves re-establishing and maintaining sinus rhythm with antiarrhythmic medications or AF ablation, whereas a "rate-control" strategy involves controlling ventricular rate with atrioventricular (AV) nodal antagonists or AV nodal ablation.

Rate Control: A Reasonable Approach for Most Patients

In the 1980s and 1990s, the prevailing paradigm was in favor of a rhythm-control approach with the belief that maintenance of sinus rhythm circumvent the potential long term adverse consequences of AF: the deterioration in hemodynamics secondary to increased heart rate and loss of AV synchrony, an increased risk for stroke from left atrial thrombi, and progressive left ventricular dysfunction (Falk, 2005; Waldo, 1999).

This paradigm was challenged by several randomized controlled trials (Carlsson et al., 2003; Hohnloser et al., 2000; Opolski et al., 2004), including the AF Follow-up Investigation of Rhythm Management (AFFIRM) (Wyse et al., 2002) and the Rate Control versus Electrical Cardioversion (RACE) (Van Gelder et al., 2002). These landmark studies failed to conclusively show that one strategy is superior to the other in terms of morbidity and mortality (**Table 2**) (de Denus et al., 2005).

AFFIRM, the largest trial comparing rate- versus rhythm-control strategies, randomized 4060 patients with recurrent AF to either rate control (using digoxin, beta-blockers, and calcium channel antagonists) or rhythm control with the most effective antiarrhythmic drug (primarily amiodarone, sotalol, or propafenone). All patients were initially anticoagulated, but those in the rhythm-control arm who maintained sinus rhythm could stop warfarin. Over a mean follow-up of 3.5 years, all-cause mortality, the primary endpoint of the study, was not significantly different between the two treatment arms, although there was a trend toward an increased risk of death in the rhythm-control arm compared to rate control at 5 years (23.8% vs. 21.3%, $p = 0.08$) (Wyse et al., 2002).

The RACE trial was a smaller trial ($n = 522$) that also compared rate- and rhythm-control approaches. Patients in persistent AF were randomized to a strategy of repeat cardioversion and antiarrhythmic drugs to maintain sinus rhythm, or to a rate-control approach. At a mean follow-up of 2.3 years, there was no difference in the primary composite endpoint of cardiovascular death, heart failure, thromboembolic complications, bleeding, pacemaker insertion, or severe adverse effects of drugs.

AFFIRM and RACE were practice-changing studies of their time for several reasons. Firstly, they both challenged the belief that rhythm control conferred additional benefit over rate control. Not only was there no difference in mortality, neither trial revealed a difference in quality of life measures (Hagens et al., 2004; Jenkins et al., 2005). Secondly, AFFIRM and RACE added to the growing body of literature that questioned the notion that maintenance of sinus rhythm obviated the need for anticoagulation (Hart et al., 2000). The rates of stroke were not significantly different between treatment arms, but the majority of thromboembolic events occurred due to subtherapeutic INR or after discontinuation of anticoagulation therapy allowed by study protocol after normal rhythm had been achieved and maintained (Hagens et al., 2003; Sherman et al., 2005).

Table 2 Summary of landmark trials comparing rate versus rhythm strategies in atrial fibrillation

Trial	*N*	*Age (years)*	*Mean follow-up*	*Primary outcome*	*Primary outcome (rate vs. rhythm)*	*Mortality*[a] *(rate vs. rhythm)*	*Thromboembolism (rate vs. rhythm)*
PIAF (2000)	252	60.5	1.0	Symptomatic improvement	60.8% vs. 55.1% (ns)	na	na
AFFIRM (2002)	4060	69.7	3.5	All-cause mortality	25.9% vs. 26.7% (ns)	25.9% vs. 26.7% (ns)	5.5% vs. 7.1% (ns)
RACE (2002)	522	68.0	2.3	CV death, HF, bleeding, pacemaker implantation, thromboembolism, AAD adverse effects	17.2% vs. 22.6% (ns)	6.8% vs. 7.0% (ns)	5.5% vs. 7.9% (ns)
STAF (2003)	200	65.8	1.6	All-cause mortality, cerebrovascular event, CPR, systemic embolism	10.0% vs. 9.0% (ns)	8.0% vs. 4.0% (ns)	1.0% vs. 5.0% (ns)
HOT-CAFÉ (2004)	205	60.8	1.7	All-cause mortality, systemic embolism, major bleeding	2.0% vs. 5.8% (ns)	1.0% vs. 2.9% (ns)	1.0% vs. 2.9% (ns)
J-RHYTHM (2008)	823	64.7	1.6	All-cause mortality, stroke, systemic embolism, major bleeding, HF hospitalization, physical/psychologic disability relating to treatment	22.0% vs. 15.3% ($p = 0.01$)	0.7% vs. 1.0% (ns)	2.9% vs. 2.3% (ns)

Abbreviations: *CV*, cardiovascular; *HF*, heart failure; *CPR*, cardiopulmonary resuscitation; *na*, not available; *AAD*, antiarrhythmic drug (Carlsson et al., 2003; Hohnloser et al., 2000; Opolski et al., 2004; Wyse et al., 2002; Van Gelder et al., 2002; Ogawa et al., 2009).

[a]Percentages reported are for all-cause mortality, except in the RACE trial, which reported CV mortality.

Rate Control for Patients With Heart Failure

Between 30% and 50% of patients with AF have concomitant heart failure (Chiang et al., 2012). The pathophysiology of AF and heart failure are closely aligned, and the development of both conditions results in a poorer prognosis (Kotecha and Piccini, 2015; Wang et al., 2003). Since few patients with heart failure were included in the prior rate versus rhythm trials, the optimal approach in managing these high-risk patients remained unclear. The Atrial Fibrillation Congestive Heart Failure (AF-CHF) trial (Roy et al., 2008) was an open-label, randomized trial comparing pharmacologic rate- and rhythm-control strategies in 1376 patients with symptomatic heart failure and a left ventricular ejection fraction of 35% or less. For patients randomized to rate control, a resting heart rate of <80 beats per min and <110 beats/min during 6-min walk test were targeted using primarily beta-blockers and digoxin. For patients randomized to the rhythm-control arm, aggressive therapy to prevent AF and maintain sinus rhythm was recommended, which included electrical cardioversion within 6 weeks of randomization, and repeated at 3 months if sinus rhythm was not achieved. The majority of patients in this arm were started on amiodarone (82%), but sotalol and dofetilide were also used in selected cases.

Over a mean follow-up of 37 months, there was no difference between the two treatment groups in the primary outcome of cardiovascular death (25% for rate control and 27% for rhythm control; hazard ratio [HR] 1.06; 95% confidence interval [CI], 0.86–1.30; $p=0.59$. Further, there were no significant differences in prespecified secondary outcomes of all-cause mortality, stroke, or worsening heart failure. However, there was a trend toward increased hospitalization in the rhythm-control group (64% vs. 59%, $p=0.06$) due to recurrent AF and bradyarrhythmias. Therefore, the AF-CHF trial showed that the paradigm of adopting an initial strategy of rate control in patients without severe AF symptoms, introduced by the AFFIRM and RACE trials, could be extended to those with heart failure. However, it is important to note that 21% of patients crossed over to rate control because sinus rhythm could not be maintained despite antiarrhythmic drug therapy and serial cardioversions.

Rate Control: What is the Optimal Target Heart Rate in Permanent AF?

As rate-control became more widely adopted, it remained unclear whether the intensity of rate control affected outcomes. Intuitively, the use of strict rate control was thought to reduce symptoms from AF and improve quality of life, reduce the incidence heart failure and improve survival. On the other hand, the enthusiasm for strict rate control was tempered by the required increase in drug doses that had the potential for adverse effects such as bradycardia, syncope, and pacemaker implantation. A post hoc analysis pooling the AFFIRM and RACE cohorts showed no benefit of strict versus lenient rate control, although neither study was designed specifically to address this issue (Van Gelder et al., 2006).

Thus far, only one randomized clinical trial has evaluated different rate-control strategies. The Race Control Efficacy in Permanent Atrial Fibrillation: a comparison between Lenient and Strict Rate Control II (RACE II) trial enrolled 614 patients with permanent AF, younger than 80 years of age, and had a resting heart rate greater than 80 beats/min (Van Gelder et al., 2010). Patients were randomized to strict rate control (defined as a resting heart rate of <80 beats/min and <110 beats per min during moderate exercise) or lenient rate control (defined as <110 beats per min at rest).

RACE II revealed that a lenient rate-control approach was noninferior compared to a strict rate-control approach with respect to the primary composite outcome of cardiovascular death, hospitalization for heart failure, stroke systemic embolism, major bleeding, and life-threatening arrhythmic events at 3 years of follow-up. There were also no differences in symptom burden, quality of life, or hospital admissions (Van Gelder et al., 2010; Groenveld et al., 2011). However, it is important to note that the target heart rates were achieved only 67% of the strict rate control group compared to 98% of the lenient group, resulting in a modest difference in mean achieved heart rate (approximately 10 beats/min) during follow-up. To address this concern, an exploratory analysis was conducted where the strict rate control group was stratified by achievement of target heart rate, finding no difference in the primary outcome between patients in the lenient control arm compared to patients who actually achieved strict rate control targets (Groenveld et al., 2013).

Catheter Ablation: A New Hope for the Rhythm-Control Approach

Although prior trials have not demonstrated a benefit of rhythm control over a rate-control strategy, this may be due to the limited efficacy of current antiarrhythmic therapies at maintaining sinus rhythm (**Fig. 2**). Only two-thirds of patients are able to maintain sinus rhythm at 12–16 months with amiodarone, the most effective antiarrhythmic currently available (Roy et al., 2000). Other currently available antiarrhythmic agents are even less effective, with only 30%–50% of patients maintaining sinus rhythm at 12–16 months (Roy et al., 2000; Nichol et al., 2002). Thus, the failure of the rhythm-control strategy may indicate more about the inadequacies or toxicities of pharmacological antiarrhythmic therapy than it does about the rhythm-control strategy itself.

With the advent of catheter ablation, there has been a renewed interest in exploring the potential benefits of rhythm-control strategy. A metaanalysis of 11 studies comparing catheter ablation to antiarrhythmic therapy found that there was a 36% absolute risk reduction in the recurrence of atrial tachyarrhythmias in patients treated with catheter ablation (RR 0.40; 95% CI, 0.31–0.52; $p<0.001$). Catheter ablation appeared to be superior to antiarrhythmic drug therapy in patients with AF who were drug resistant or intolerant; however, there was a twofold increased risk of major adverse events in the catheter ablation group (Khan et al., 2014).

Several studies examined the utility of ablation as first-line therapy including the Medical Antiarrhythmic Treatment or Radiofrequency Ablation in Paroxysmal Atrial Fibrillation (MANTRA-PAF) and the Radiofrequency Ablation versus Antiarrhythmic

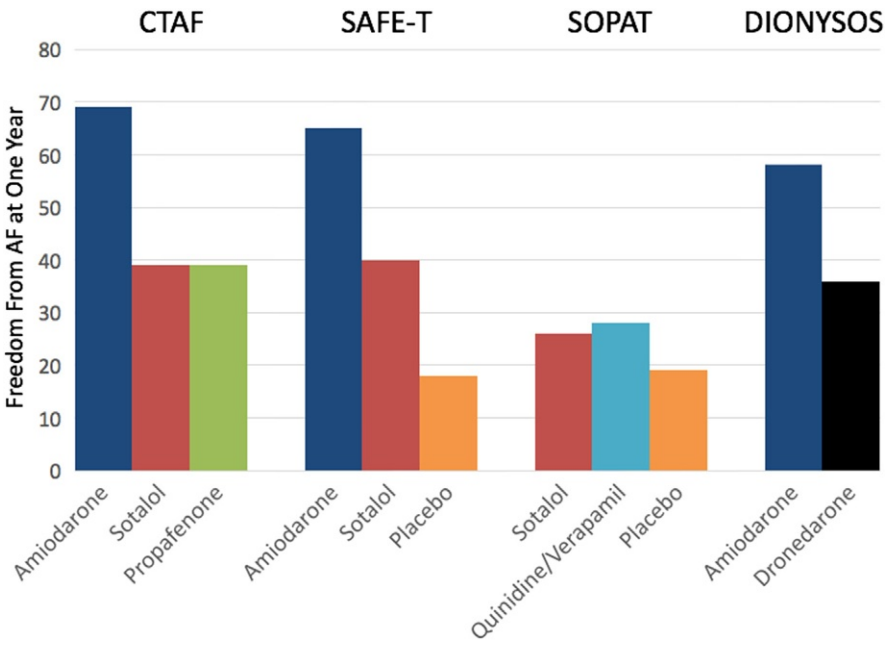

Fig. 2 Selected studies of comparative efficacy of antiarrhythmic drugs for maintenance of sinus rhythm: Abbreviations: *AF*, atrial fibrillation; *CTAF*, Canadian Trial of Atrial Fibrillation; *SAFE-T*, Sotalol Amiodarone Atrial Fibrillation Efficacy Trial; *SOPAT*, Suppression of Paroxysmal Atrial Tachyarrhythmias; and *DIONYSOS*, efficacy and safety of dronedarone versus amiodarone for the Maintenance of Sinus Rhythm in Patients With Atrial Fibrillation (EAFT, 1993; Roy et al., 2000; Le Heuzey et al., 2010; Patten et al., 2004; Singh et al., 2005).

Drugs as First-Line Therapy of Atrial Fibrillation 2 (RAAFT-2) (Cosedis Nielsen et al., 2012; Morillo et al., 2014). MANTRA-PAF randomized 294 antiarrhythmic drug-naive patients with paroxysmal AF to an initial strategy of catheter ablation or therapy with class IC or class III antiarrhythmic agents. There was no significant difference in the primary endpoint of cumulative burden of AF (i.e., percentage of time in AF on Holter monitor); however, at 24 months, significantly more patients in the ablation group were free from any AF (85% vs. 71%, $p=0.004$) and from symptomatic AF (93% vs. 84%, $p=0.01$) (Cosedis Nielsen et al., 2012). Similarly, RAAFT-2 randomized 127 treatment-naïve patients with paroxysmal AF to either antiarrhythmic therapy or ablation. At 2 years, the primary efficacy outcome (i.e., recurrence of any atrial tachyarrhythmia greater than 30 s) occurred more often in the antiarrhythmic drug group compared to ablation groups (72.1% vs. 54.5%, $p=0.02$). Although ablation resulted in a significantly lower rate of recurrent atrial tachyarrhythmias at 2 years, recurrence was frequent in both groups (Morillo et al., 2014). It is currently not known whether catheter ablation of AF reduces outcomes such as mortality or stroke, which is currently being explored by ongoing trials, including: CABANA (Catheter Ablation Versus Antiarrhythmic Drug Therapy for Atrial Fibrillation) trial, which recently completed enrolment (ClinicalTrials.gov identifier: NCT00911508); and EAST (Early Therapy of Atrial Fibrillation for Stroke Prevention) Trial (ClinicalTrials.gov identifier: NCT01288352). Furthermore, the results of two studies assessing the utility of catheter ablation in patients with heart failure are highly anticipated: CASTLE-AF (Catheter Ablation Versus Standard Conventional Treatment in Patients With Left Ventricular Dysfunction and Atrial Fibrillation) (ClinicalTrials.gov identifier: NCT00643188) and RAFT-AF (A Randomized Ablation-based Atrial Fibrillation Rhythm Control Versus Rate Control Trial in Patients With Heart Failure and High Burden Atrial Fibrillation) (ClinicalTrials.gov identifier: NCT01420393).

Alternate Energy Sources for Ablation: Hot or Cold?

Catheter ablation most commonly uses radiofrequency (RF) energy to isolate pulmonary veins (PVI) with a "point-by-point" approach. Novel balloon-based and multielectrode-based ablation technologies have been developed as an alternative to RF ablation, with the advantage of achieving PVI with a single circumferential energy application. The most widely available alternative is the cryoballoon (Arctic Front, Medtronic) which uses cryothermal energy rather than RF. Evidence over the past few years has supported the use of the cryoballoon as a viable alternative to RF ablation. The first randomized, multicenter trial assessing the efficacy of the cryoballoon was the STOP-AF trial (A Clinical Study of the Arctic Front Cryoablation Balloon for the Treatment of Paroxysmal Atrial Fibrillation). STOP-AF reported a superior efficacy of first generation cryoballoon ablation compared with antiarrhythmic medications in patients with paroxysmal AF (Packer et al., 2013).

The largest trial to date directly comparing RF ablation to cryoballoon was the FIRE and ICE trial, which enrolled 762 patients with drug refractory paroxysmal AF to determine if cryoballoon ablation was noninferior to RF ablation (Kuck et al., 2016). After a mean follow-up of 1.5 years, cryoballoon was noninferior to RF ablation with respect to first documented clinical failure (i.e., recurrent of atrial tachyarrhythmias, use of antiarrhythmic drugs, or repeat ablation) within 90 days after index ablation.

Furthermore, there was no significant difference between the two methods with regard to overall safety (Kuck et al., 2016). However, cryoballoon ablation led to an increased risk of phrenic nerve palsy (2.7% vs. 0%), though the majority of cases were transient.

In addition to the large outcome studies mentioned previously, much work remains in optimizing the safety and effectiveness of AF catheter ablation. Active areas of research include the impact of AF catheter ablation on stroke risk, the role of imaging and other biomarkers in optimizing patient selection, the role of novel AF mapping algorithms in identifying key targets, such as rotors or focal sources, for AF substrate ablation, and identifying the most effective ablation strategy in patients with persistent AF or AF that recurs after complete PVI.

Upstream Therapies

Although there has been much progress in elucidating the basic mechanisms underlying AF over the past several decades, our understanding remains incomplete. AF is thought to result from the interaction between triggers (i.e., initiating electric stimuli from the PVI) and substrate (i.e., vulnerable tissue allows AF to be induced and sustained) (Woods and Olgin, 2014). Furthermore, substrate is rendered vulnerable as a result of continuous remodeling of the atria, which involves both electrical and structural changes, altered metabolism, and fibrosis (Kourliouros et al., 2009; Goette and Lendeckel, 2008; Burstein and Nattel, 2008).

There has been a great interest in "upstream therapies" that intend to delay or even reverse the natural progression of AF by targeting factors leading to atrial remodeling (Savelieva et al., 2011a,b). A variety of pharmacologic therapies have been explored, including renin–angiotensin inhibitors (Goette et al., 2012; Investigators et al., 2009b; Yamashita et al., 2011), aldosterone antagonists, statins (Liu et al., 2008; Almroth et al., 2009; Negi et al., 2011), and $n-3$ polyunsaturated fatty acids (Macchia et al., 2013; Nodari et al., 2011). Unfortunately, most of these therapies have not proven beneficial at reducing the recurrence or burden of AF in patients with paroxysmal AF when directly assessed in randomized clinical trials.

One of the largest of these studies was the GISSI-AF (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico-Atrial Fibrillation) trial, which examined the role of valsartan (compared to placebo) in AF prevention in 1442 patients with documented symptomatic AF and in sinus rhythm at time of randomization (Investigators et al., 2009b). At one-year of follow-up, there was no significant difference between valsartan and placebo in the proportion of patients who had more than one episode of AF (51 vs. 52%) or in the median time from randomization to the first recurrence of AF (295 vs. 291 days).

Although pharmacologic therapies for the prevention of AF have not been efficacious when assessed in randomized trials, lifestyle interventions, such as exercise and weight loss, are emerging as a promising upstream therapy. In a single-center, partially blinded, randomized control trial, 150 patients were assigned to either a physician-led weight loss program (intervention group) or general lifestyle advice (control group) (Abed et al., 2013). Both groups underwent intensive management of cardiometabolic risk factors. Over a follow-up period of 15 months, the intervention group showed a significantly greater reduction in weight when compared to control (14.3 kg and 3.6 kg, respectively; $p<0.001$) and in AF symptom burden scores (11.8 and 2.6 points; $p<0.001$), and symptom severity scores (8.4 and 1.7 points; $p<0.001$). Additionally, there was a significant reduction in number of AF episodes in follow-up (-2.5 vs. no change; $p=0.01$) and duration of episodes when monitored by 7-day Holter monitor (692 min decrease and 419 min increase; $p=0.002$). The authors concluded that weight reduction with intensive risk factor management resulted in reduction of both AF symptom burden and severity. The postulated mechanism was thought to be mediated by favorable cardiac remodeling inferred based on significant reductions in interventricular septal thickness and left atrial area on serial transthoracic echocardiography (Abed et al., 2013). While all patients should be encouraged to adopt a healthier lifestyle, these promising results need verification in independent studies before the intensive risk factor modification program used in these studies can be broadly recommended.

Conclusions

Our understanding of AF has significantly advanced over the past few decades. Landmark studies have disrupted underlying assumptions in areas of clinical practice such as the selection of rate- or rhythm-control approaches, and the decision to initiate anticoagulation in patients with paroxysmal, persistent, or permanent AF. Furthermore, the development of technologies, such as RF and cryoballoon ablation, has provided new opportunities for the management of patients with AF.

Yet despite our accumulating body of knowledge, the management of patients with AF continues to be challenging. The debate of rate control versus rhythm control has re-emerged with the development of catheter ablation of AF due to the potential for more durable maintenance of sinus rhythm than antiarrhythmic drugs. Furthermore, advancement in our understanding of basic AF mechanisms promises for more efficient and successful ablation strategies. Research into targeting localized sources of AF, such as complex fractioned atrial electrograms and rotors, by computed signal analysis represents an important step in this direction (Woods and Olgin, 2014; Haissaguerre et al., 2004).

Additionally, we have much to learn about the role of anticoagulation in high-risk populations such as patients with end-stage renal disease. Despite the prevalence of AF in this population, patients with end-stage renal disease have not been well represented in the major anticoagulation trials. The relative paucity in the literature is reflected in the discordance among various guidelines regarding anticoagulation in patients on dialysis (Kirchhof et al., 2016; January et al., 2014; Verma et al., 2014). Our strategies for anticoagulation also remain unclear in other patient populations with a significant AF prevalence, such as patients with recent acute

coronary syndrome on dual antiplatelet therapy, and patients with postoperative AF following cardiac and noncardiac surgery. Nevertheless, if the pace of progress we have seen in the past few decades of research continues, we can be optimistic that solutions to these problems will emerge, and the care of patients with AF will continue to improve.

Introduction

Cardiovascular disease (CVD) is the single most important noncommunicable disease and causes the greatest number of deaths worldwide. The World Health Organization estimates that 17.6 million people died from CVD in 2012 accounting for 31.43% of global mortality (McAloon et al., 2016). Of this, ischemic heart disease accounts for approximately 7.4 million deaths which is 13.2% of deaths due to CVD (McAloon et al., 2016). Contemporary research on coronary heart disease (CHD) in women shows that the popular belief "heart disease is a man's disease" is wrong. CHD has often been considered to predominantly affect males due to the earlier onset of symptoms, a greater clustering of typical clinical manifestations, and traditional risk factors. In contrast, CHD in women has long been ignored due to atypical symptoms and nontraditional risk factors. However according to current statistics, CHD is the leading cause of death among women in every major developed country and most developing nations (Wenger, 2012). The generally accepted "norm" is that age-dependent decline in health status coupled with postmenopausal decline in estrogen levels contribute to morbidity and mortality from CHD in older women (Savonitto et al., 2016). However, recent studies demonstrate that young women have poorer prognoses after myocardial infarction compared with their male peers (D'Onofrio et al., 2015). A common key factor underlying CHD in both sexes is metabolic syndrome. This is a spectrum of metabolic and vascular derangements including obesity, insulin resistance, dyslipidemia, and hypertension which collectively identify individuals at risk of CHD (Wilson et al., 1999; Isomaa et al., 2001). Pregnancy can be considered a cardiovascular stress test for women because the normal maternal physiological response to pregnancy represents a transient excursion into metabolic syndrome (Fig. 1).

Maternal Physiological Adaptation to Pregnancy

Pregnancy is a period of unique hemodynamic and metabolic adaptation with maternal physiology changing throughout gestation to support the demands of the growing fetus. These changes pose a substantial burden on blood pressure regulation, glucose and lipid metabolism, and immune tolerance. During pregnancy, under the influence of estrogen and progesterone, the maternal vascular system undergoes many changes. There is an increase in plasma volume of 45%, red cell mass increases by 20%, heart rate by 25%, stroke volume by 25%, and consequently the cardiac output increases by 35%–50% toward the third trimester (Heidemann and McClure, 2003). Increased circulating estrogen and progesterone and the increase of the angiogenic factors including vascular endothelial growth factors and placental growth factor cause vasodilatation leading to a reduction in systemic vascular resistance which in turn will reduce systolic and diastolic blood pressures by mid-pregnancy which gradually return to prepregnancy levels by term (Heidemann and McClure, 2003; Troisi et al., 2008). Pregnancy is also characterized by resetting of glucose and lipid homeostasis that manifests as decreased insulin sensitivity, increased circulating triglycerides, and low-density lipoproteins mimicking the pathological changes seen in metabolic syndrome (Heidemann and McClure, 2003). In addition,

pregnancy is a prothrombotic and hypercoagulable state with an increase in fibrinogen and most clotting factors (Heidemann and McClure, 2003). Normal pregnancy also involves upregulation of the inflammatory cascade and an increase in the white cell count which are recognized as additional risk factors for cardiovascular disease (Chandra et al., 2012). Markers of inflammation including C-reactive protein, interleukin-6, and raised white cell count are independent predictors of cardiovascular events and diabetes (Haffner, 2001). These multiple hemodynamic and metabolic responses in pregnancy add further to the notion that pregnancy is a stress test for the female cardiovascular system.

Pregnancy Complications and Risk for Vascular Disease

In the last decade, an accumulating body of research has shown that several pregnancy complications are associated with subsequent CVD morbidity and mortality. Most of this evidence comes from large data linkage studies that have assessed the relationship between adverse pregnancy outcomes and CVD. A summary of the findings is detailed in **Table 1**.

Hypertensive Disorders of Pregnancy

Hypertensive disorders of pregnancy (HDP) are a leading cause of maternal and infant morbidity and mortality and can be divided into gestational hypertension (GH) and preeclampsia. Worldwide, several definitions are used in the diagnosis of HDP. According to the International Society for the Study of Hypertension in Pregnancy, GH is defined as a systolic blood pressure $\geq$140 mmHg or a diastolic blood pressure $\geq$90 mmHg measured at least on two occasions after 20 weeks of gestation in a previously normotensive

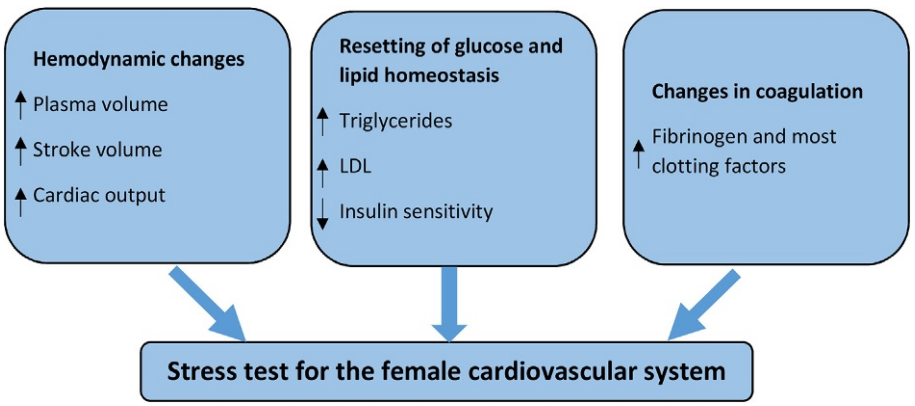

Fig. 1 Pregnancy as a stress test for the female cardiovascular system.

Table 1 Relative risk for vascular diseases after pregnancy complications

Pregnancy complication	*Developing a CV disease*	*Ischaemic heart disease*	*Stroke*	*Hypertension*	*Type 2 diabetes*	*Dyslipidaemia*
Preeclampsia (overall)	2.15 (1.76–2.61)	2.06 (1.68–2.52)	1.53 (1.21–1.92)	2.76 (1.63–4.96)	2.27 (1.55–3.32)	1.07 (0.74–1.54)
Early preeclampsia	9.5 (3.5–20.3)					
Gestational hypertension	1.89 (1.31–2.72)	1.44 (1.30–1.60)	1.41 (1.20–1.65)	2.87 (0.84–9.77)	2.10 (1.45–3.04)	1.07 (0.74–1.54)
SGA pregnancy	1.66 (1.26–2.18)	1.68 (1.31–2.14)	1.62 (1.51–1.74)	1.23 (1.16–1.30)	0.96 (0.86–1.06)	
Spontaneous preterm birth	2.06 (1.58–2.68)	1.38 (1.22–1.57)	1.71 (1.53–1.91)	1.29 (1.24–1.35)	1.77 (1.46–1.15)	
Recurrent miscarriage		1.99 (0.94–4.19)	0.98 (0.80–1.21)			

The above results are from the most recent systematic review and metaanalyses by Heida et al., 2016; Hypertensive diseases of pregnancy (preeclampsia and gestational hypertension)—metaanalysis of 28 cohort and 20 case–control studies, sample size of individual studies ranged from 40 to 1030,000, follow-up ranged from 3 to 37 years; SGA (small for gestational age)—metaanalysis of 9 studies, sample size of individual studies ranged from 6608 to 1,400,000, follow-up ranged from 11.8 to 37 years; Spontaneous preterm birth—metaanalysis of 11 cohort studies, sample size of individual studies ranged from 446 to 923,686, follow-up ranged from 12 to 35 years (results are after excluding or correcting for preeclampsia and SGA); Recurrent miscarriage—metaanalysis of 3 cohort and 2 case–control studies, sample size of individual studies ranged from 123 to 267,000, follow-up ranged from 11 to 19 years.

woman. Preeclampsia is defined as the same pattern of elevated blood pressure but with proteinuria of ≥300 mg/24 h or any multisystem complication of preeclampsia or with fetal growth restriction (Tranquilli et al., 2014). Preeclampsia is also classified according to time of onset with early onset being regarded as <34 weeks of gestation and late onset >37 weeks of gestation. A recent systematic review and metaanalysis that has assessed studies published until the end of 2012 demonstrates that preeclampsia is associated with an increased risk of developing or dying from overall CVD (relative risk; RR 2.15, 95% CI 1.76–2.61), ischemic heart disease (RR 2.06, 95% CI 1.68–2.52), and stroke (RR 1.53, 95% CI 1.21–1.92). The likelihood of developing risk factors for CVD including hypertension (RR 2.76, 95% CI 1.63–4.69) and diabetes (RR 2.27, 95% CI 1.55–3.32) is also increased among women who develop preeclampsia compared to women who have normotensive pregnancies (Heida et al., 2016). These findings are comparable with the results of a previous metaanalysis (Bellamy et al., 2007). The risk factors for CVD are evident 10–14 years after a preeclamptic pregnancy, therefore, increasing the risk for premature CVD among these women (Bellamy et al., 2007). Only a few studies have stratified preeclampsia into early versus late disease. Based on these studies, early preeclampsia is associated with nearly an 8-fold increased risk of ischemic heart disease (RR 7.71, 95% CI 4.4–13.52) compared with normotensive pregnancies (Bellamy et al., 2007). In addition women with severe preeclampsia (blood pressure >160/110 mmHg plus proteinuria >0.3 g/24 h or diastolic blood pressure >110 mmHg plus proteinuria >5 g/24 h) have a greater risk of later ischemic heart disease (RR 2.86, 95% CI 2.25–3.65) compared with women with mild preeclampsia (RR 1.92, 95% CI 1.65–2.24) (Bellamy et al., 2007). According to the same systematic review, GH is also shown to associate with an increased risk of developing or dying from overall CVD (RR 1.89, 95% CI 1.31–2.72), ischemic heart disease (RR 1.44, 95% CI 1.30–1.60), and stroke (RR 1.41, 95% CI 1.20–1.65) (Heida et al., 2016). Therefore, women who develop gestational hypertensive diseases are at approximately twice the risk of subsequent CHD compared to women who have uncomplicated pregnancies. Interestingly, in a Norwegian cohort of 836,147 women, Skjaerven and colleagues showed that the rate of cardiovascular mortality among women with preterm preeclampsia was 9.2% after having only one child, the rate falling to 1.1% for women with two or more children (Skjaerven et al., 2012). Among women with only one lifetime pregnancy, the increase in risk of cardiovascular death was higher than for those with two or more children after term and preterm preeclampsia (Skjaerven et al., 2012). The finding that cardiovascular death in women with preeclampsia in their first pregnancy is concentrated mainly in women with no additional births could be due to health problems or the experience of a pregnancy complication that discourage or prevent subsequent pregnancies rather than to preeclampsia itself (Skjaerven et al., 2012).

Pregnancies Complicated by Small for Gestational Age Infants

Small for gestational age (SGA) is defined as birth weight below the 10th percentile of the referent population. SGA can complicate a normotensive pregnancy or can occur as a complication of a hypertensive pregnancy. The link between birth weight and adult cardiovascular health was first highlighted by David Barker and colleagues in the late 1980s. It was shown that infants born with a low birth weight had a higher mortality rate due to cardiovascular disease compared to infants born with a normal birth weight (Barker et al., 1989). Since then this finding has been confirmed by many other large studies (Eriksson et al., 2001; Lawlor et al., 2005). In addition to the risk for the child, women who deliver SGA infants are at an increased risk of later life CVD (Ngo et al., 2015). Delivery of a SGA infant is associated with an increased risk of developing or dying from overall CVD (RR 1.66, 95% CI 1.26–2.18), ischemic heart disease (RR 1.68, 95% CI 1.31–2.14), and stroke (RR 1.62, 95% CI 1.51–1.74) (Heida et al., 2016). The risk of CVD is also shown to increase in a stepwise manner with delivering one SGA infant is associated with a RR of 1.41 (95% CI 1.36–1.46), two SGA infants with a RR of 1.74 (95% CI 1.58–1.93), and three or more SGA infants with a RR of 1.86 (95% CI 1.35–2.57) (Nilsson et al., 2009). Therefore, women who give birth to SGA infants appear to be at 1.5 times higher risk of CVD compared to women who have uncomplicated pregnancies.

Spontaneous Preterm Birth (sPTB)

Spontaneous preterm delivery is defined as delivery before 37 weeks of gestation and complicates 5–11% of pregnancies in the developed world (Zeitlin et al., 2013). Worldwide, sPTB is the commonest cause of neonatal and early-life morbidity and mortality (Liu et al., 2015). Recent evidence demonstrates an increase CVD risk among women who deliver preterm. sPTB was associated with an increased risk of developing or dying from overall CVD (RR 2.06, 95% CI 1.5–2.68), ischemic heart disease (RR 1.38, 95% CI 1.22–1.57), and stroke (RR 1.71, 95% CI 1.53–1.91) (Heida et al., 2016). Therefore, women who deliver preterm are at twice the risk of developing CVD compared to women who deliver at term.

Recurrent Miscarriage

Miscarriage is a common pregnancy complication with a risk of 12%–15% in each pregnancy and is defined as the premature loss of a fetus up to 20 weeks of gestation in most countries. Recurrent miscarriage has been defined as three or more consecutive miscarriages, but this is increasingly being revised to two or more miscarriages. The incidence of recurrent miscarriage is 1%–3%. Women with a history of miscarriage are shown to be at a higher risk of CHD compared to women who have not experienced miscarriage. Women with a history of miscarriage are shown to be at 45% risk of CHD, while those with a history of recurrent miscarriage have a 2-fold increased risk of CHD (Oliver-Williams et al., 2013). Although a link between recurrent miscarriage and CHD has been reported, most studies on miscarriage have not classified miscarriage phenotypically, and a recent systematic review

and metaanalysis failed to show an association between recurrent miscarriage and CHD (Heida et al., 2016). Since a large proportion of early miscarriage may be due to anembryonic losses, it is difficult to draw conclusions from the above findings. Furthermore, whether miscarriage occurs in first trimester or second trimester may be influential.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) complicates approximately 5.8% of pregnancies (Lavery et al., 2016). In most cases, the blood glucose returns to prepregnancy levels after delivery. However, there is a strong relationship between GDM and subsequent type 2 diabetes mellitus (Bellamy et al., 2009). In addition, women who develop GDM are also more likely to experience other CHD risk factors including obesity, hypertension, and hyperlipidemia (Fraser et al., 2012). Current evidence suggests that GDM is associated with an increased risk of CHD but whether this association is independent of the increased risk due to type 2 diabetes is inconclusive due to limited data (Archambault et al., 2014).

Link Between Pregnancy Complications and CHD

The above shows robust evidence that women who develop these pregnancy complications are at a higher risk of CHD. But whether these complications are independent risk factors for CHD or whether a shared risk factor profile contributes to both pregnancy complications and subsequent CHD remains to be determined.

Shared Risk Factors Leading to Pregnancy Complications and Subsequent CHD

Established cardiovascular risk factors including obesity, hypertension, hyperlipidemia, and insulin resistance are also risk factors for pregnancy complications. Women who embark on a pregnancy with these preexisting risk factors and a superimposed genetic predisposition could develop pregnancy complications. If the risk factors persist after pregnancy, these women could develop CHD in later life. Therefore, pregnancy complications and CHD can be considered a spectrum of disorders that manifest at different time points during the life course. Hence, the concept that pregnancy can be considered as a vascular and metabolic stress test for women, which some pass (have an uncomplicated pregnancy) and some fail (develop one or more pregnancy complications), has been proposed (Williams, 2003).

Pregnancy Complications as the Cause for CHD

An alternative hypothesis is that pathophysiological changes that occur during complicated pregnancies may persist predisposing to later life vascular diseases, a theory that has mainly been conceived with respect to preeclampsia. There are many theories regarding the cause of preeclampsia, and current literature supports a multifactorial etiology. The most likely underlying pathogenic mechanisms include abnormal development of the placenta and an imbalance between proangiogenic and antiangiogenic proteins with a predominance of antiangiogenic factors. This angiogenic imbalance is proposed to result in maternal systemic endothelial dysfunction which could persist after pregnancy predisposing to later life vascular diseases. This hypothesis was recently tested in a mouse model of preeclampisa (Pruthi et al., 2015). A preeclampsia-like state was induced in pregnant CD1 mice by overexpressing soluble fms-like tyrosine kinase-1, a circulating antiangiogenic protein that induces hypertension and glomerular disease resembling human preeclampsia. Two months postpartum, features of preeclampsia were completely resolved. The mice were then challenged with unilateral carotid injury. "Preeclampsia"-exposed mice had significantly enhanced vascular remodeling with increased smooth muscle cell proliferation and vessel fibrosis compared to mice with uncomplicated pregnancies (Pruthi et al., 2015). These suggest that vessels exposed to preeclampsia retain a persistently enhanced vascular response to injury despite resolution of preeclampsia after delivery which may contribute to increased subsequent cardiovascular risk among preeclamptic women (Pruthi et al., 2015).

Placenta as a Link Between Pregnancy Complications and CHD

A successful pregnancy requires the development of an optimal uteroplacental vasculature. In normal pregnancy, the process of placentation is initiated when the blastocyst adheres to the maternal uterine endometrium leading to the formation of a lineage of epithelial cells called the invasive extravillous cytotrophoblasts (EVT). These cells invade the uterine decidua, the inner third of the myometrium (interstitial invasion), and the spiral arteries (endovascular invasion), a process that is highly controlled so that the depth of invasion of the uterus is sufficient but not excessive (Gude et al., 2004). During endovascular invasion, the endothelium and the underlying vascular smooth muscle cells are replaced by EVT resulting in the conversion of narrow-calibre high-resistance vessels into wide-calibre low-resistance vessels capable of supplying enough maternal blood to the placenta to accommodate the increasing demands of the growing fetus. To facilitate this process, cytotrophoblasts make a "switch" in their cell surface adhesion molecules from an epithelial to endothelial phenotype in a process called "pseudovasculogenesis" (Damsky et al., 1994). Failure of

these processes results in "decidual vasculopathy" with small, poorly developed spiral arteries and compromised blood flow to the placenta (Zhou et al., 1993).

Initially, impaired invasion and spiral artery remodeling were thought to lead to defective uteroplacental circulation and subsequent placental ischemia. More recently, it has been shown that true ischemia probably only occurs in more advanced stages and that stressors including inflammation and oxidative stress contribute to the release of soluble factors including soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng) from the placenta that gain entry into the maternal circulation (Andraweera et al., 2012). sFlt-1 is a splice variant of the vascular endothelial growth Factor (VEGF) receptor and binds to both VEGF and placental growth factor (PlGF) preventing their interaction with the endogenous receptors located on vascular endothelial cells (Andraweera et al., 2012).

Both VEGF and PlGF are potent angiogenic factors that play critical roles in maintenance of a healthy vascular endothelium throughout the body (Andraweera et al., 2012). Endoglin is typically expressed on the surface of placental syncytiotrophoblasts and endothelial cells and acts as a coreceptor for the proangiogenic transforming growth factor β (Andraweera et al., 2012). Endoglin regulates nitric oxide-dependent vasodilatation. Proteolytic processing of the membrane-bound endoglin results in soluble endoglin which inhibits TGF β signaling and deleteriously affects vascular tone by blocking the activation of endothelial nitric oxide synthase (Andraweera et al., 2012). Increased sFlt-1 and sEng along with decreased serum VEGF and PlGF have been demonstrated to precede the clinical onset of preeclampsia and is used as biomarkers of preeclampsia (Andraweera et al., 2012). During a preeclamptic pregnancy, sFlt-1 and sEng produced by the placenta gain entry into the maternal circulation resulting in systemic maternal endothelial dysfunction (Andraweera et al., 2012) (**Fig. 2**). In theory, this endothelial injury may persist predisposing to later life vascular disease. However, recent evidence suggests that the risk for CVD after a preeclamptic pregnancy may be attenuated by a subsequent pregnancy (Morris et al., 2015).

Pregnancy-induced physiological changes to the cardiovascular system are vital for a successful pregnancy. Women who develop preeclampsia are considered to have failed the cardiovascular stress test of pregnancy and are considered to represent a subpopulation in whom the cardiovascular response was inadequate to meet the demands of normal pregnancy (Craici et al., 2008). The risk for preeclampsia is highest for first pregnancies, decreasing with subsequent pregnancies (van Rijn et al., 2006) assuming the woman maintains the same partner (for a detailed account of the role of the father in preeclampsia see Dekker et al., 2011).

A longer time interval between subsequent pregnancies is associated with an increasing risk for preeclampsia suggesting a protective effect of pregnancy that decreases overtime (Mikolajczyk et al., 2008). A recent study examined women prior to the first pregnancy and postpartum up to 33 months to evaluate the effect of pregnancy on cardiovascular physiology and compared women with a subsequent pregnancy to a time matched group of women who did not have a subsequent pregnancy (Morris et al., 2015). Women with a subsequent pregnancy were shown to have significantly decreased blood pressure and increased arterial compliance compared to their prepregnancy evaluation, when compared to those without a subsequent pregnancy (Morris et al., 2015). This suggests a beneficial effect of pregnancy on cardiovascular remodeling that may contribute to the attenuation of risk for preeclampsia in a subsequent pregnancy and is compatible with the findings of Skjaerven and colleagues that the risk for CVD after preeclampsia is mainly concentrated among women who have no subsequent births (Skjaerven et al., 2012).

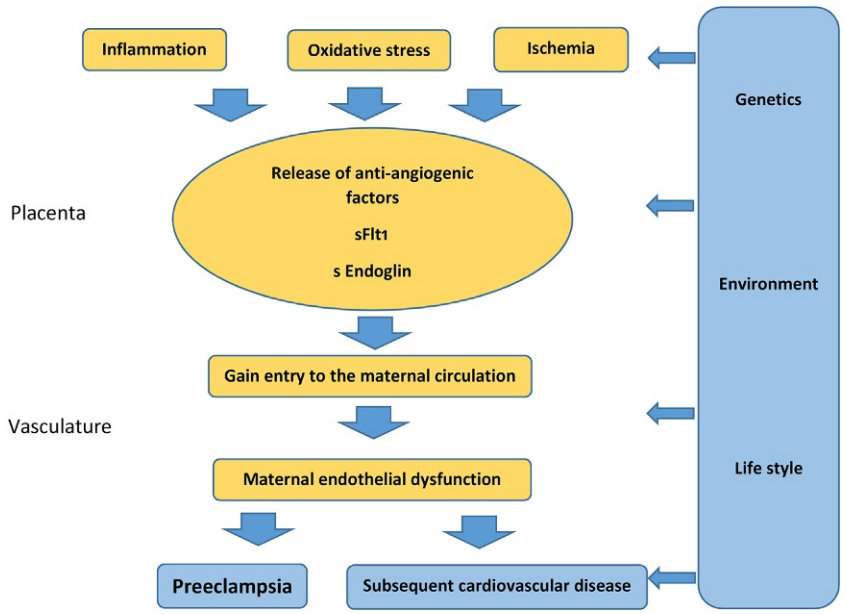

Fig. 2 Placenta as a link between preeclampsia and subsequent cardiovascular disease.

Endothelial Dysfunction Linking Preeclampsia With Subsequent CVD

Endothelial dysfunction is believed to play a critical role in preeclampsia, and the antiangiogenic molecules secreted by the placenta are thought to be key regulators of this process (Andraweera et al., 2012). Endothelial dysfunction precedes the clinical manifestations/clinical detection of preeclampsia. A recent systematic review assessed studies that examined endothelial dysfunction using flow-mediated dilation before, during, and after preeclampsia (Weissgerber et al., 2016). This review demonstrates that compared with women who did not have preeclampsia, women who had preeclampsia have lower flow-mediated dilation before the development of preeclampsia, at the time of preeclampsia, and for 3 years postpartum (Weissgerber et al., 2016). These suggest that vascular dysfunction predates preeclampsia and may contribute to its pathogenesis and may represent the mechanistic link for increased CVD risk subsequent to a preeclamptic pregnancy. This also suggests that similar risk factors may lead to preeclampsia and CVD.

Pregnancy Complications and Subsequent CVD: Common Antecedents

The link between pregnancy complications and increased risk for later life CHD is now well established. However, the unanswered question is whether the increased risk is attributed to factors that originate during a complicated pregnancy or whether prepregnancy risk factors associate with both groups of disorders. At present, the paucity of literature limits our ability to answer this question. A Norwegian study that combined longitudinal population-based data with medical birth records demonstrated that adjustment for prepregnancy classic cardiovascular risk factors including BMI, blood pressure, and lipid profiles attenuated much of the increased risk for future vascular disease after a gestational hypertensive disorder, suggesting that women already programmed to develop vascular diseases also develop placenta-mediated pregnancy complications (Romundstad et al., 2010). As with most multifactorial diseases, a genetic susceptibility can also contribute to both groups of disorders. A recent metaanalysis of microarray data, obtained from blood samples of patients with CVD versus controls and placental samples from women with preeclampsia versus healthy women with uncomplicated pregnancies, demonstrated that 22 differentially expressed genes were common between preeclampsia and CVD (Sitras et al., 2015). Bioinformatic analysis of these genes revealed that among others oxidative stress, inflammation and VEGF signaling pathways were involved in the pathophysiology of both preeclampsia and CVD (Sitras et al., 2015). Genome-wide association studies and candidate gene association studies also show that some gene variations in the above pathways are associated with both preeclampsia and CVD and to a lesser extent other pregnancy complications and CVD (Andraweera et al., 2011; Johnson et al., 2013; Andraweera et al., 2016).

Clinical Implications

The bulk of evidence linking pregnancy complications with CVD has resulted in preeclampsia being recognized by the American Heart Association as a female-specific cardiovascular risk factor (Mosca et al., 2011). Despite the gains that have been made in overall cardiovascular disease prevention, death rates due to CVD among women 35–54 years of age actually appear to be increasing (Mosca et al., 1997; Fuster et al., 2011), the most likely reason being the obesity epidemic. This emphasizes the urgent need for early prevention in target populations. Primary prevention, if applied to risk populations, can reduce the incidence of CVD. However, there is growing concern that many preventive efforts are implemented too late in order to be effective. Therefore, a strategy for "primordial prevention"—prevention of CVD risk factors themselves may prove more effective. In this context, pregnancy provides a unique opportunity to identify women who would most benefit from early preventive efforts.

Approximately, 80% of women in developed countries and 90% of women in developing countries give birth to at least one child (Rich-Edwards et al., 2014). The probability of a woman experiencing any one of the complications during pregnancy including gestational hypertension, preeclampsia, intrauterine growth restriction, gestational diabetes, or preterm delivery is 2%–12% (Rich-Edwards et al., 2014). In the developed world, 36% of first pregnancies and 29% of subsequent pregnancies are complicated by at least one of the above pregnancy complications (Rich-Edwards et al., 2014). Based on recent systematic reviews and metaanalyses, each pregnancy complication is associated with approximately double the risk of CVD. If 80% of women bear children and 30% of them have a pregnancy complication, then approximately 20%–30% of women are at increased risk of future CVD (Rich-Edwards et al., 2014).

This calls for the development of a postpartum referral system where the obstetrician who cared for the woman when she developed a pregnancy complication should initiate a follow-up process where the woman is subsequently cared for by her general practitioner and, when required, by a cardiologist. However, in order to prevent overburdening staff and the health budget, appropriate guidelines need to be formulated on the referral criteria.

Hypertension is one of the strongest risk factors for cardiovascular disease (CVD) worldwide (Rapsomaniki et al., 2014). Recent studies suggested that prevention of hypertension effects not only prevention of CVD but also the management of other diseases, such as dementia, cancer, and periodontal disease (Kokubo and Iwashima, 2015). In light of that concept, when lifestyle modifications recommended by hypertension guidelines are followed, we could expect that these diseases other than CVD could be prevented or ameliorated. Hypertension guidelines have recently been updated in many countries. The components of the various countries' hypertension guidelines include both pharmacotherapy- and nonpharmacotherapy-based recommendations, and the latter are also known as lifestyle modifications.

In this brief review, we organize the reported results that form the basis for the lifestyle modification recommendations for preventing and controlling hypertension that are provided in the major hypertension guidelines, and we indicate how these guidelines' lifestyle modification recommendations resemble those of other countries' guidelines.

U.S., Europe, and Japanese Guidelines

The Eighth Joint National Committee (JNC8) have reported 2014 evidence-based guidelines for the management of high blood pressure in adults (James et al., 2014). However, lifestyle recommendations are shown in a different report (Eckel et al., 2014), which is based on the target for reducing CVD risk factors, such as blood pressure and lipids. We therefore use the previous version from the seventh Joint National Committee (JNC7) (Chobanian et al., 2003), which consists of recommendations regarding weight reduction, adopting the DASH eating plan, dietary sodium reduction, physical activity, and the moderation of alcohol consumption in the present review (**Table 1**). The 2013 guidelines on hypertension from the European Society of Hypertension (ESH) and the European Society of Cardiology (ESC) (Mancia et al., 2013) follow the guidelines jointly issued by these two societies in 2003 (European Society of Hypertension-European Society of Cardiology Guidelines Committee, 2003), and 2007 (Mancia et al., 2007). The lifestyle modifications described by the ESH/ESC are similar to those noted by the JNC7.

In addition, an effective approach to high blood pressure control was approved by a science advisory committee of member of the American Heart Association (AHA), the American College of Cardiology (ACC), and the U.S. Centers for Disease Control and Prevention (CDC) (Go et al., 2014). "Clinical Practice Guidelines for the management of Hypertension in the Community" were also reported by the American Society of Hypertension (ASH) and the International Society of Hypertension (ISH) (Weber et al., 2014). These Guidelines' lifestyle modifications are similar to those defined in the Japanese Society of Hypertension Guideline in 2014 (Shimamoto et al., 2014), although cutoff points differ slightly. These lifestyle modifications consist of appropriate diet (reducing salt intake, eating more vegetables and fruits, reducing saturated fatty acid [e.g., by eating more fish]), moderate drinking, quitting smoking (including avoiding passive smoking), and increasing physical activity.

All of the guidelines systematically summarize the details of the lifestyle modifications needed to prevent and manage hypertension, and they emphasize the importance of comprehensive lifestyle modification. Among the above-mentioned guidelines, only the JSH 2014 guideline promotes adequate guidance/education for the prevention of obesity in children, which may be the one of the most important approaches to prevent hypertension at the population level. In addition, the JSH 2014 recommends modifying not only conventional risk factors for hypertension but also other modifiable lifestyle risk factors such as emotional stress, cold, and other daily activities (e.g., bathing, sexual intercourse) in daily life. However, these lifestyle factors have not been established as risk factors for hypertension, and further evidence must be established to test the effects of modifying these lifestyle risk factors for preventing hypertension.

Table 1 Lifestyle recommendations for the management and prevention of hypertension in the US, European, and Japanese guidelines

	JNC7 (Chobanian et al., 2003)	*2013 ESC/ESH (Mancia et al., 2013)*	*JSH 2014 (Shimamoto et al., 2014)*	*ASH/ISH (Weber et al., 2014)*
Weight reduction	18.5≦BMI≦24.9 kg/m^2	• Reduction of BMI to 25 kg/m^2 • Waist circumference; <102 cm (men), <88 cm (women)	BMI <25 kg/m^2	Weight loss in overweight and obese patients
Nutrients and food	Adopting DASH diet; rich in fruits, vegetables, and low fat dairy with a reduced content of saturated and total fat	• Increase intake of vegetables/fruits (300–400 g/day), low-fat dairy products, dietary and soluble fiber, whole grains, protein from plant sources, and fish (≥2/week) • Reduced intake of saturated fat and cholesterol	• Increased intake of fruit/vegetable and fish • Reduced intake of cholesterol/saturated fatty acid	
Dietary sodium reduction	Dietary sodium intake <100 mEq/L (2.4 g sodium or 6 g salt)	Salt intake <5–6 g/day	Salt intake <6 g/day	Reducing salt intake
Physical activity	Regular aerobic physical activity (>30 min) most days	• Moderate-intensity dynamic aerobic exercise (>30 min) on 5–7 days/week • Resistance exercises on 2–3 days/week	Daily primary periodic (≥30 min) and aerobic exercise	Regular aerobic exercise
Alcohol consumption	≤2 drinks/day (most men), ≤1 drink/day (women and lighter weight persons)	• ≤20–30 mL/day (men), ≤10–20 mL/day (women) • Total alcohol consumption <140 g/week (men), 80 g/week (women)	≤20–30 mL/day (men), ≤10–20 mL/day (women)	≦2 drinks/day (men), ≦1 drink/day (women)
Smoking	Stop smoking for cardiovascular risk reduction	Giving up smoking	• Smoking cessation • Avoiding passive smoking	Stop smoking
Others		Mediterranean type diet DASH diet	• Avoiding exposure to cold • Managing emotional stress	

Other Western Countries Guidelines

Table 2 shows lifestyle recommendations for the management and prevention of hypertension guidelines in Western countries, that is, the guidelines from Canada (Dasgupta et al., 2014), United Kingdom (National Institute for Health and Care Excellence, 2016), France (Blacher et al., 2014), and Australia (Guideline for the diagnosis and management of hypertension in adults, 2016). The basic lifestyle recommendations by these four countries are the same as the major guidelines summarized in **Table 1**, such as weight reduction, nutrients and food types, sodium reduction, physical activity, moderate alcohol consumption, and quitting smoking. Only the Australian guideline recommends physical activity levels according to age category (cutoff 65 years old), and the dietary sodium reduction recommendation is less than 4 g.

Other Countries/Regions Guidelines

Table 3 shows lifestyle recommendations for the management and prevention of hypertension guidelines in China (Kjeldsen et al., 2014; Liu, 2011; Wang, 2015), Taiwan (Chiang et al., 2015), South Korea (Shin et al., 2015), South Africa (Hypertension Guideline Working Group et al., 2014), and Latin America (Sanchez et al., 2009). The basic lifestyle recommendations in these five countries' guidelines are the same as those of the major guidelines in **Table 1**, that is, weight reduction, nutrients and food, dietary sodium reduction, physical activity, alcohol consumption, and smoking. Only Taiwan's guidelines states the possible harm of extreme

Table 2 Lifestyle recommendations for the management and prevention of hypertension in the Canadian, UK, French, and Australian guidelines

	Canada (CHEP) (Dasgupta et al., 2014)	*United Kingdom (NICE) (National Institute for Health and Care Excellence, 2016)*	*France (Blacher et al., 2014)*	*Australia (Guideline for the diagnosis and management of hypertension in adults, 2016)*
Weight reduction	● 18.5 ≦ BMI ≦ 24.9 kg/m^2 ● Waist circumference: <102 cm (men), <88 cm (women)		● Reducing weight if over weight	● BMI <25 kg/m^2 ● Waist circumference; <94 cm (men), <90 cm (Asian men), <80 cm (women)
Nutrients and food	● Emphasizes intake of fruits, vegetables, low-fat dairy products, dietary and soluble fiber,whole grains, and protein from plant sources reduced in saturated fat and cholesterol	● Ascertaining patients' diet patterns ● Promoting lifestyle change (offering appropriate guidance and written/audiovisual materials) ● Discouraging excessive consumption of coffee and other caffeine-rich products	● Adapting a diet rich in fruit and vegetables	● Limiting total fat intake to 20%–25% of energy intake ● 5 servings of vegetables and 2 servings of fruit daily
Dietary sodium reduction	● Sodium intake <2000 mg/day (5 g/day salt)	● Lower dietary sodium intake	● Reducing excessive salt consumption	● <4 g/day salt intake
Physical activity	● 30–60 min of moderate intensity dynamic exercise 4–7 days/week	● Ascertaining patients' exercise patterns ● Promoting lifestyle change; offering appropriate guidance and written/audiovisual materials	● Regular physical activity	(18–64 years old patients) ● Accumulation of 150–300 min of moderate intensity activity/week ● Accumulation of 75–150 min of vigorous activity/ week ● Muscle strengthening activities ≥2 days/ week (>65 years old patients) ● Some form of physical activity ● Accumulation of ≥30 min of moderate intensity physical activity on most days
Alcohol consumption	● ≤2 drinks/day ● ≤14 standard drinks/week (men), ≤9 drinks/week (women)	● Avoiding excessive alcohol intake	● Reducing excessive consumption of alcohol	● ≤2 drinks/day (men), ≤1 drink/day (women)
Smoking		● Stop smoking	● Smoking cessation	● Cessation of smoking
Others	● Stress management			

sodium intake restriction, based on several studies that reported a J-shaped relationship between sodium intake and the composite outcomes (death, major cardiovascular events).

All of the listed guidelines systematically summarize the modifiable lifestyle risk factors based on research evidence. However, most of the guidelines do not describe ways to implement their lifestyle modifications practically, and although the Australian

Table 3 Lifestyle recommendations for the management and prevention of hypertension guidelines in the China, South Korean, Taiwan, South Africa, and Latin American guidelines

	China (Kjeldsen et al., 2014; Liu, 2011; Wang, 2015)	*Taiwan (Chiang et al., 2015)*	*South Korea (Shin et al., 2015)*	*South Africa (Hypertension Guideline Working Group et al., 2014)*	*Latin America (Sanchez et al., 2009)*
Weight reduction	Reduction of body weight	$22.5 \leqq BMI \leqq 25.0$ kg/m^2	Reduce by 1 kg	$18.5 \leqq BMI \leqq 24.9$ kg/m^2	Weight reduction and stabilization
Nutrients and food	Increasing dietary potassium	Recommendation of the DASH diet	Vegetable-based healthy diet habit	● Recommendation of the DASH diet ● Reduced intake of saturated fat and total fat	● Increase in fruits/ vegetables ● Decrease in saturated ant total fat intake ● Increase of potassium intake >6 g/ day
Dietary sodium reduction	Sodium reduction	● Sodium intake of 2–4 g/day ● Alerting possible harmless of too aggressive sodium restriction to <2 g/day	Salt intake; <6 g/ day	<100 mmol or 6 g NaCl/day	Salt intake <6 g/ day
Physical activity	Increasing physical activity	Aerobic, at least 40 min/day, and at least 3–4 days/week	30–50 min/day for more than 5 days in a week	30 min brisk walking most days	Recommending physical exercise
Alcohol consumption	Reduction of alcohol intake	<30 g/day for (men), <20 g/day (women)	<2 glasses/day	$\leqq$2 drinks/day	Reduction of excessive alcohol intake
Smoking	Smoking cessation	Smoking cessation	Smoking cessation	Complete smoking cessation	Smoking cessation
Others			Controlling of emotional stress		

guidelines attempt to show how to modify one's lifestyle in practice, the evidence for this modification is lacking. For both healthcare providers and patients, the methods that can be used for achieving lifestyle modifications are of interest, and a further accumulation of evidence regarding efficient methodology for lifestyle interventions is needed.

Appropriate Diet

Many epidemiological studies have shown that salt intake reduction is directly related to decreasing blood pressure. The Dietary Approaches to Stop Hypertension (DASH) diet, which was investigated in a randomized trial comparing the effects of three total salt intake levels (high, intermediate, and low salt intakes) on blood pressure, resulted in significantly lower systolic (SBP) and diastolic blood pressures (DBP) at each salt level, respectively (Sacks et al., 2001). The DASH diet and salt reduction lowered SBP and DBP independently. In addition, a meta-analysis of randomized controlled trials demonstrated that the decreases in blood pressure for a 100-mmol/day reduction in daily sodium excretion were 3.7 and 1.0 mmHg for SBP ($P < 0.001$) and 0.9 and 0.1 mmHg for DBP ($P > 0.05$) in the hypertensive and normotensive trials, respectively (Midgley et al., 1996). A systematic review and meta-analysis showed that reduced sodium intake reduced blood pressure and had no adverse effect on blood lipids, catecholamine levels, or renal function, and moderate quality evidence in children showed that a reduction in sodium intake reduced the children's blood pressure (Aburto et al., 2013).

A meta-analysis of 17 randomized controlled trials evaluated the current evidence on the effect of healthy dietary patterns such as the DASH diet, Nordic diet, and Mediterranean diet on blood pressures in adults (Ndanuko et al., 2016). In this meta-analysis, significant reductions of 4.26 mmHg in SBP and 2.38 mmHg in DBP were observed. When the authors of the meta-analysis considered the nature of intervention, they found that the studies in which weight loss, exercise, and sodium restriction were kept constant had a significant reduction of 4.25 mmHg in SBP and 2.27 mmHg in DBP. The consumption of dietary patterns

characterized by a high consumption of fruit, vegetables, whole grains, legumes, seeds, nuts, fish, and dairy and a low consumption of meat, sweets, and alcohol resulted in significant reductions in blood pressure.

Weight Reduction and Physical Activity

A meta-analysis of 25 randomized controlled trials from different ethnic populations showed a blood pressure reduction of −4.4/−3.6 mmHg for an approximately 5 kg weight loss by means of energy restriction, physical activity, or both (Neter et al., 2003). Larger blood pressure reductions were achieved in populations that included subjects taking antihypertensive drugs. A recent systematic review and meta-analysis of randomized control trials with a meta-regression of potential effect modifiers revealed that exercise was associated with a reduction in SBP of −4.40 mmHg and in DBP of −4.17 mmHg at 3–6 months (Williamson et al., 2016). The observed intervention effect was lost after 12 months of follow-up with no reported benefit over control. These findings indicate that continuing exercise is necessary for lowering blood pressure.

Moderate Alcohol Consumption

Drinking alcohol is associated with increased blood pressure in many epidemiological studies. A meta-analysis of randomized controlled trials showed that a reduction in alcohol intake among heavy drinkers significantly reduced their systolic and diastolic blood pressure (Xin et al., 2001); overall, alcohol reduction was associated with a significant reductions of −3.31 mmHg in SBP and −2.04 mmHg in DBP. A prospective study indicated that moderate drinking reduced the risk of CVD in hypertensive patients and that there was a U-shaped relationship between the volume of alcohol and the risk of CVD (Higashiyama et al., 2013).

Smoking Cessation

Smoking is a risk factor for many diseases including cancer and CVD. Considering that the purpose of hypertension treatment is to prevent CVD, quitting smoking is important regardless of the influence of smoking on blood pressure. Both normotensive and untreated hypertensive smokers present higher daily blood pressure levels compared to nonsmokers (Minami et al., 1999; Groppelli et al., 1992). Even passive smoking increases the risks of cancer and CVD (Makris et al., 2009).

Prevention of CVD

Table 4 shows the lifestyle recommendations for the prevention and management and prevention of CVD from the United States (James et al., 2014), Europe (Piepoli et al., 2016), Japan (Teramoto et al., 2013), Australia (National Vascular Disease Prevention Alliance, 2012), and New Zealand (New Zealand Guidelines Group, 2012). The basic skeleton of the CVD guidelines is almost the same as that of the hypertension guideline. A characteristic feature of the CVD guidelines is that they recommend fish intake (in the guidelines from Europe, Japan, and Australia), and the recommendation encouraging fish eating is also part of the hypertension guidelines of these countries. In the Japanese guidelines, an increased intake of unrefined grains, seaweed, and soy products is part of the JAS other than the hypertension guideline.

Conclusions

The updated hypertension guidelines in major countries consist of the following elements: weight reduction, appropriate food intake (dietary patterns characterized by a high consumption of fruit, vegetables, whole grains, legumes, seeds, nuts, fish, and dairy and a low consumption of meat and sweets), dietary sodium reduction, increasing physical activity, moderate alcohol consumption, and quitting smoking (including avoiding passive smoking). The hypertension guidelines are essentially the same for each country or region, beyond race and culture. The CVD guidelines are very similar to the hypertension guidelines, and the JAS guidelines add the promotion of soy products in the hypertension guideline. Therefore, the various hypertension guidelines mirror the basic skeletons of other disease guidelines. Toward the prevention of cardiovascular diseases, it is of primary importance to improvement the lifestyle modifications described in the hypertension guidelines.

Table 4 Lifestyle recommendations for the management and prevention of cardiovascular disease in the JNC8, ESC, JAS, and Australian guidelines

	JNC8 (James et al., 2014)	*ESC (Piepoli et al., 2016)*	*JAS (Teramoto et al., 2013)*	*Australia (National Vascular Disease Prevention Alliance, 2012)*	*New Zealand (New Zealand Guidelines Group, 2012)*
Weight reduction	• $18.5 \leqq BMI \leqq 24.9$ kg/m^2 • Waist circumference: <102 cm for men, <88 cm for women	• $20 < BMI < 25$ kg/m^2	Maintaining an ideal body weight	• BMI <25 kg/m^2 • Waist circumference <94 cm in men (<90 cm in Asian men), <80 cm (women, including Asian women)	Reducing risks of excessive body weight
Nutrients and food	Emphasizes intake of fruits, vegetables, low-fat dairy products, dietary and soluble fiber, whole grains, and protein from plant sources reduced in saturated fat and cholesterol	• SFA to account for <10% of total energy intake, through replacement by PUFAs • Trans unsaturated fatty acids: as little as possible, preferably no intake from processed food, and <1% of total energy intake from natural origin • 30–45 g/day, preferably from wholegrain products • Fruits ≥200 g/day (2–3 servings) • Vegetable ≥200 g/day (2–3 servings) • Fish 1–2/week, one of which to be oily • Unsalted nuts 30 g/day • Sugar-sweetened soft drinks and alcoholic beverages consumption must be discouraged	• Increase intake of vegetables, fruits, unrefined grains, seaweed, fish, and soy products • Reducing intake of meat fat, dairy products, and egg yolk	• Consume a varied diet rich in vegetables, fruits, wholegrain cereals, lean meat, poultry, fish, eggs, nuts and seeds, legumes and beans, and low-fat dairy products • Limit foods containing saturated and trans fats	Low energy, low glycogenic index/load, and macronutrient approach
Dietary sodium reduction	Sodium intake <2000 mg/day (5 g/day salt)	Salt intake <5 g/day	Reduced intake of food containing too much salt	Salt intake <6 g/day (~2300 mg sodium)	
Physical activity	30–60 min of moderate intensity dynamic exercise 4–7 days/week	• For healthy adults of all ages; ≥150 min/week (moderate intensity) or 75 min/week (vigorous intensity) aerobic PA or an equivalent combination thereof • For healthy adults of all ages; a gradual increase in aerobic • PA to 300 min/week (moderate intensity), or 150 min/week (vigorous intensity), or an equivalent combination thereof	Aerobic exercise ≥30 min daily	At least 30 min physical activity on most or preferably every day of the week	• Increasing periods of physical activity ≥60 min every day • Reducing screen time
Alcohol consumption	• ≤2 drinks/day • Limiting 14 standard drinks/week (men), 9 drinks/week (women)	<20 g/day (men), <10 g/day (women)	Avoiding excessive alcohol consumption	≤2 standard drinks per day	
Smoking		• Smoking cessation • Avoiding passive smoking	• Stop smoking • Avoiding passive smoking	Stop smoking using counseling, and if required nicotine replacement therapy or other medication	
Others	Stress management	Prescribing psychological therapy for psychosocial risk factors and coping with illness

Angiogenesis Overview

The Angiogenic Process

Angiogenesis is the physiological process where new microvessels form from preexisting microvessels (Ribatti and Crivellato, 2012; Djonov et al., 2000). Similarly, arteriogenesis is where new collateral arteries form from preexisting arteries (Helisch and Schaper, 2003; Heil et al., 2006). As angiogenesis and arteriogenesis are similar processes (Heil et al., 2006), albeit at different scales, we use either term interchangeably for the purpose of this review. Angiogenesis occurs in two different forms: sprouting or intussusceptive angiogenesis (Ribatti and Crivellato, 2012; Djonov et al., 2000). Sprouting angiogenesis involves preexisting blood vessels to sprout and form new blood vessels. Sprouting angiogenesis is initiated by extracellular growth factor binding to endothelial cell (EC) surface receptors (Ucuzian et al., 2010). This ligand-receptor binding has dual action: (1) it initiates enzyme secretion from ECs, which break down the basement membrane and (2) it promotes directed EC migration and proliferation (Ucuzian et al., 2010). The migrating ECs result in tube formation and fusion, which are stabilized by pericyte recruitment in microvessels, or smooth muscle cell recruitment in arteries, to result in new, functional blood vessels (Eilken and Adams, 2010; Ribatti and Crivellato, 2012). The majority of current angiogenesis research focuses on sprouting angiogenesis, due to its prevalence in wound healing (Honnegowda et al., 2015) and cancer progression (Welti et al., 2013).

Intussusceptive angiogenesis is the splitting of an existing blood vessel into two blood vessels (Burri et al., 2004; Mentzer and Konerding, 2014; Djonov et al., 2000). Intussusceptive angiogenesis occurs by blood vessel walls continuously extending into the

lumen, forming an intravascular pillar, which eventually splits a single tube into two tubes. Unlike sprouting angiogenesis, intussusceptive angiogenesis is ineffective at vascularizing regions lacking blood vessels, instead primarily adding additional vessels to regions already containing blood vessels (Djonov et al., 2000; Burri et al., 2004; Mentzer and Konerding, 2014). Additionally, intussusceptive angiogenesis does not require EC migration or proliferation (Mentzer and Konerding, 2014). While intussusceptive angiogenesis can be initiated by growth factor stimulation, it also results from mechanical stress produced by blood flow (Makanya et al., 2009). Intravascular pillars seem to specifically form at vessel bifurcations when hemodynamics are altered to cause high flow velocity, but low shear stress (Styp-Rekowska et al., 2011; Jain et al., 2014). As such, intussusceptive angiogenesis is difficult to regulate, as hemodynamics cannot be easily altered and requires invasive procedures (Jain et al., 2014). Further research investigating chemical cues, including any mechanotransduction pathways activated through shear stress, is necessary to develop efficient, noninvasive methods for regulating intussusceptive angiogenesis.

Growth Factor-Directed Angiogenesis

Sprouting and intussusceptive angiogenesis are both critical to normal physiological processes, such as wound healing and embryonic development. Moreover, over 70 diseases, including cancer and occlusive vascular disease, are angiogenesis dependent (Egginton, 2010; Carmeliet and Jain, 2000). In 1971, Judah Folkman hypothesized that tumor growth depends on angiogenesis initiated by a tumor angiogenesis factor (Folkman, 1971). This hypothesis was derived from studies showing that tumors only grow to a dormant state, at 2–3 mm in diameter, in the absence of neovascularization (Folkman, 1970; Gimbrone et al., 1969; Greene, 1941), tumor implantation induces EC proliferation (Cavallo et al., 1972; Folkman, 1971) and formation of new capillaries (Warren and Shubik, 1966; Warren, 1966; Algire et al., 1945), and tumor growth is limited by the rate of EC proliferation (Tannock, 1968, 1970). Since this hypothesis, many studies have been conducted to arrive at our current understanding of tumor angiogenesis: tumor cells promote sprouting angiogenesis to provide the necessary nutrients for further tumor growth and metastasis, reviewed in (Hillen and Griffioen, 2007; Weis and Cheresh, 2011; Carmeliet and Jain, 2000). Inhibiting sprouting angiogenesis is therefore a promising approach to prevent transition of tumors from a benign to malignant stage (Samant and Shevde, 2011; Moreira et al., 2007).

Vascular Normalization

In 2005, Rakesh Jain put forth an alternative hypothesis on tumor angiogenesis: rather than destroying tumor vasculature to deprive the tumor of oxygen and nutrients, antiangiogenic therapies are most effective by normalizing the abnormal tumor vasculature to allow more efficient drug delivery (Jain, 2005). This hypothesis was derived from studies showing that tumor vasculature is structurally and functionally abnormal (Jain, 2004; McDonald and Choyke, 2003; Baluk et al., 2003), that this structural abnormality impairs blood flow and compromises the ability for drug delivery to tumors (Jain, 1998; Ma et al., 2001; Padera et al., 2004), and that normalizing tumor vasculature allows drug delivery deeper into tumors to cause tumor regression (Tong et al., 2004; Wildiers et al., 2003; Winkler et al., 2004). Studies have continued to provide support for this hypothesis, reviewed in (Huang et al., 2013; Goel et al., 2012); a recent clinical trial shows that vascular normalization, measured by pericyte coverage, is associated with improved pathological response to the antiangiogenic drug bevacizumab (Tolaney et al., 2015). Understanding the mechanisms through which antiangiogenic drugs normalize tumor vasculature, and optimizing treatment regimens to best regulate sprouting angiogenesis, is a primary challenge for preventing tumor angiogenesis and tumor progression (Cao, 2016; Vasudev and Reynolds, 2014).

Occlusive vascular diseases stem from a lack of blood flow, resulting in tissue ischemia, loss of limb function, and death (Peach et al., 2012). For occlusive vascular diseases, promoting either sprouting or intussusceptive angiogenesis to reestablish proper blood flow is therefore a promising approach to prevent tissue ischemia (Berger and Hiatt, 2012; Rasmussen et al., 2002). Overall, the ability to control angiogenesis would allow for the prevention and treatment of pathologies: preventing cancer mortality by inhibiting tumor angiogenesis, and treating vascular diseases by promoting angiogenesis.

VEGF Family Overview

The vascular endothelial growth factor-A (VEGF-A) is a key growth factor that promotes angiogenesis. The existence of VEGF-A was first hypothesized by Judah Folkman in 1971, who characterized VEGF-A as an unknown tumor angiogenesis factor (Folkman, 1971). Senger et al. identified this unknown factor as vascular permeability factor (VPF) in 1983 (Senger et al., 1983), and Leung et al. characterized this factor, and termed it VEGF, in 1989 (Leung et al., 1989). Keck et al. showed in 1989 that VPF and VEGF are the same molecule (Keck et al., 1989), demonstrating that this single factor has multiple functions. In 1993, Napoleone Ferrara's laboratory demonstrated for the first time that inhibiting VEGF suppresses tumor growth (Kim et al., 1993) (**Fig. 1**). Since these studies, VEGF has been studied as a promising therapeutic target for cancer and vascular disease, reviewed in (Majesky, 1996; Carmeliet and Jain, 2000).

VEGF Ligands

VEGF-A is now known as one of five related growth factors expressed in humans that make up the VEGF family: VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF) (Ferrara et al., 2003). There are two additional VEGF ligands: viral VEGF (VEGF-E) (Ogawa et al., 1998) and snake venom VEGF (VEGF-F) (Takahashi et al., 2004); these ligands are not expressed in humans, and as such, shall not be discussed in detail in this review. The VEGF growth factors bind with high affinity to three tyrosine kinase receptors, VEGFR1, VEGFR2, and VEGFR3. Many VEGF ligands also contain a heparin-binding domain, in addition to binding neuropilins, coreceptors to the VEGFRs. VEGF-A, often referred to simply as VEGF, promotes angiogenesis through interaction with VEGFR1 and VEGFR2. Conversely, all other VEGF growth factors and VEGFR3 exhibit weak angiogenic potential. VEGF-B and PlGF specifically bind VEGFR1, and have been identified as key promoters in neurogenesis and embryogenesis. VEGF-C and VEGF-D promote lymphangiogenesis through VEGFR3 (**Table 1**).

The VEGF ligands and receptors are also expressed in isoform variants, each having specific interactions and functions. VEGF-A has seven currently known splice variants, in addition to full-length VEGF-A, which are distinguished by amino acid length: VEGF-A_{121}, VEGF-A_{145}, VEGF-A_{148}, VEGF-A_{165}, VEGF-A_{183}, VEGF-A_{189}, and VEGF-A_{206}. A VEGF-A_{110} isoform is also created through proteolytic cleavage of longer VEGF isoforms by plasmin (Keyt et al., 1996). VEGF-regulated angiogenesis research typically focuses on VEGF-A_{165}, the predominant VEGF-A isoform (Ferrara et al., 2003). For this reason, VEGF-A_{165} is often referred to simply as VEGF, a notation we adopt henceforth in this review.

The aforementioned splice variants have recently been typified as the VEGF-A_{xxxa} isoforms, as secondary VEGF-A_{xxxb} isoforms containing the same number of amino acids, but different sequences and function, have emerged. Currently, four VEGF-A_{xxxb} isoforms have been identified: VEGF-A_{121b}, VEGF-A_{145b}, VEGF-A_{165b}, and VEGF-A_{189b}, fully reviewed in (Qiu et al., 2009; Hilmi et al., 2012). Key points to know about these isoforms include: VEGF-A_{165b} is the best studied VEGF-A_{xxxb} isoform; VEGF-A_{165b} binds to VEGFR2 with the same kinetics as VEGF-A_{165}, but does not activate VEGFR2 nor the signaling pathways that VEGF-A_{165} activates (Woolard et al., 2004). Subsequently, the VEGF-A_{xxxa} isoforms are characterized as pro-angiogenic, whereas the VEGF-A_{xxxb} isoforms are antiangiogenic.

Likewise, multiple isoforms of VEGF-B have also been discovered (Olofsson et al., 1996a,b). VEGF-B is considered to primarily be a neuroprotective factor (Falk et al., 2009); VEGF-B has also been identified to act as a myocardium-specific angiogenic factor (Kivelä et al., 2014; Bellomo et al., 2000) and a regulator of energy metabolism by modulating fatty acid uptake (Hagberg et al., 2010), reviewed in (Li, 2010; Bry et al., 2014). The two discovered VEGF-B isoforms are VEGF-B_{167} and VEGF-B_{186}, differentiated by amino acid length (Olofsson et al., 1996a,b). VEGF-B_{167} has been identified as the predominant isoform, with over 80% total VEGF-B being expressed as VEGF-B_{167} (Li et al., 2001). However, other than the fact that VEGF-B_{167} contains a heparin-binding domain while VEGF-B_{186} does not (Li, 2010), the functional differences between VEGF-B_{167} and VEGF-B_{186} are currently unknown.

Conversely, VEGF-C does not exist in multiple isoforms. VEGF-C is considered to primarily promote lymphangiogenesis through interaction with VEGFR3, reviewed in (Su et al., 2007). VEGF-C also interacts with VEGFR2, although VEGF-C/VEGFR2

Currently characterized ligands, receptors, and their isoforms in the VEGF family. Inter-family interactions, function, and discovery of each VEGF family protein are given. I list the general, primary function for each protein; note that specific function may differ depending on cell type or physiological context.

interactions do not appear sufficient to promote lymphangiogenesis (Kodera et al., 2011). VEGFR2 might have an indirect modulatory role in VEGF-C lymphangiogenesis: VEGF-C induces VEGFR2/VEGFR3 heterodimerization, unlike VEGF-A, which differentiates VEGF-C signaling from VEGFR3 homodimers (Deng et al., 2015; Nakao et al., 2011).

Similarly, VEGF-D does not exist in multiple isoforms. VEGF-D is considered to primarily promote lymphangiogenesis through VEGFR3, as reviewed in (Krebs and Jeltsch, 2013). VEGF-D also binds VEGFR2 (Achen et al., 1998), implying that VEGFR2/VEGFR3 heterodimerization might be important for VEGF-D signaling. However, unlike with VEGF-C, lymphatic development does not appear to be affected by VEGF-D deletion (Baldwin et al., 2005). As such, VEGF-D signaling and function remains questionable and additional research is necessary to make any additional assertions about VEGF-D signaling.

PlGF contains four known isoforms, termed PlGF1-4 (Maglione et al., 1993; Cao et al., 1997; Yang et al., 2003). Similar to VEGF, PlGF isoforms result from alternative splicing, each containing a different number of amino acids: 131, 152, 203, and 224. Like the VEGF-B isoforms, PlGF-2 and PlGF-4 contain heparin-binding domains, while PlGF-1 and PlGF-3 do not (De Falco, 2012). Also like the VEGF-B isoforms, the functional difference between PlGF isoforms is not currently known.

VEGF Receptors

Similar to the VEGF ligands, the VEGFRs are also expressed in variant isoforms. Soluble isoforms, truncated full-length receptors without the transmembrane or intracellular domains, were identified for all three VEGFRs (Kendall and Thomas, 1993; Pavlakovic et al., 2010; Singh et al., 2013). These soluble isoforms are considered to contain no signaling properties, acting to sequester free VEGF (Hornig et al., 2000; Pavlakovic et al., 2010). The soluble VEGFR isoforms can dimerize with full-length membrane VEGFRs, which may additionally direct VEGFR signaling (Kendall et al., 1996). Intracellular VEGFR isoforms also exist; intracellular VEGFR1 isoforms containing either the full or partial intracellular domain of full-length VEGFR1 were identified (Mezquita et al., 2010,

2014). It stands to reason that other VEGFR isoforms may yet be undiscovered. Identifying all VEGFR isoforms and functions may be necessary to achieve complete control of angiogenesis.

Dimerization, the binding of two receptor monomers to form a receptor dimer, is a critical step to VEGFR phosphorylation and signal transduction. VEGFR1, VEGFR2, and VEGFR3 all form homodimers: two VEGFR1 monomers bind to form a VEGFR1-VEGFR1 homodimer, etc. Heterodimerization, where two different VEGFR monomers bind, also occurs. VEGFR2 forms hetero-dimers with both VEGFR1 and VEGFR3, whereas VEGFR1 and VEGFR3 are not able to heterodimerize. These homodimer and hetero-dimer pairs can activate different intracellular signaling pathways, leading to differential cell responses.

Overall, this VEGF family overview showcases the large VEGF signaling network. The multiple ligand types, receptor types, isoforms, and dimers complicate our ability to understand and predict how angiogenesis occurs. Furthermore, VEGF signaling cooperates with signaling from other receptors to direct angiogenesis: VEGF-VEGFR and Delta-Notch signaling interact to direct tip/stalk cell selection in sprouting angiogenesis, reviewed in (Blanco and Gerhardt, 2013). Thus, our ability to effectively regulate angiogenesis for cancer and vascular disease therapeutics has relied on methods that delineate this complex VEGF signaling axis to identify key signaling features and targets.

Here, we discuss how systems biology has been used to provide this delineation of VEGF signaling, to identify key VEGF signaling features and targets, in angiogenesis. Systems biology is an iterative approach between mathematical or computational modeling with quantitative experimentation to understand the entire biological system (Chen et al., 2014). Systems biology is also advantageous by being quantitative and predictive in nature, allowing features such as model-directed experiments to quicken discovery of key angiogenesis nodes. Systems biology also has the power to isolate and examine subsystems within angiogenesis, such as receptor signaling pathways to identify critical signaling nodes in angiogenesis (Weddell and Imoukhuede, 2015a). As such, systems biology can examine a system at various scales: angiogenesis can be examined macroscopically, such as sprout formation, or microscopically, such as VEGFR signal propagation.

In this review, we provide an overview of systems biology techniques that have been employed to mathematically or computationally explore angiogenesis (**Table 2**, **Fig. 2**). We review studies employing these systems biology techniques to examine the VEGF family in angiogenesis to provide new biological insights, and to design pro-angiogenic or antiangiogenic therapies. Lastly, we provide a brief overview on the current challenges in manipulating VEGF signaling and angiogenesis and future research directions to achieve complete angiogenic control.

Systems Biology Approaches

Deterministic Kinetic Modeling

Chemical reactions describing the kinetic reaction network are modeled using the law of mass-action: the rate of a reaction is directly proportional to reactant concentration (Eq. 1):

$$[\mathrm{A}] + [\mathrm{B}] \underset{k_r}{\overset{k_f}{\rightleftarrows}} [\mathrm{C}] \tag{1}$$

Table 2 Systems biology modeling approaches

Computational method	*Scale*	*Functional outputs*	*Angiogenesis applications*	*Reference*
Kinetic: deterministic	Molecules in continuum	Temporal concentration	Protein interactions Protein transport Drug PK/PD	(Resat et al. 2009)
Kinetic: stochastic	Molecules	Temporal concentration	Protein interactions Protein transport Drug PK/PD	(Resat et al. 2009)
Agent based	Molecular Cell	Spatiotemporal agent dynamics	Protein or cell motility Protein or cell interactions Cell proliferation	(An et al. 2009)
Molecular modeling	Molecular	Binding potential	Structural analysis Inhibitor identification	(Aloy and Russell 2006)
Finite element	Tissue Fluids	Continuum mechanics	Hemodynamics Vessel sprouting Drug delivery	(Vanegas-Acosta and Garzón-Alvarado 2014)
Multivariate	Cell Tissue	Signal-to-response	Stimuli to cell response	(Kirwan et al. 2012)

Typical computational models used in systems biology, the scale(s) of the quantities they model (i.e. molecules, cell, tissue), functional output(s) given by the model, specific applications to angiogenesis, and references describing the methods in detail.

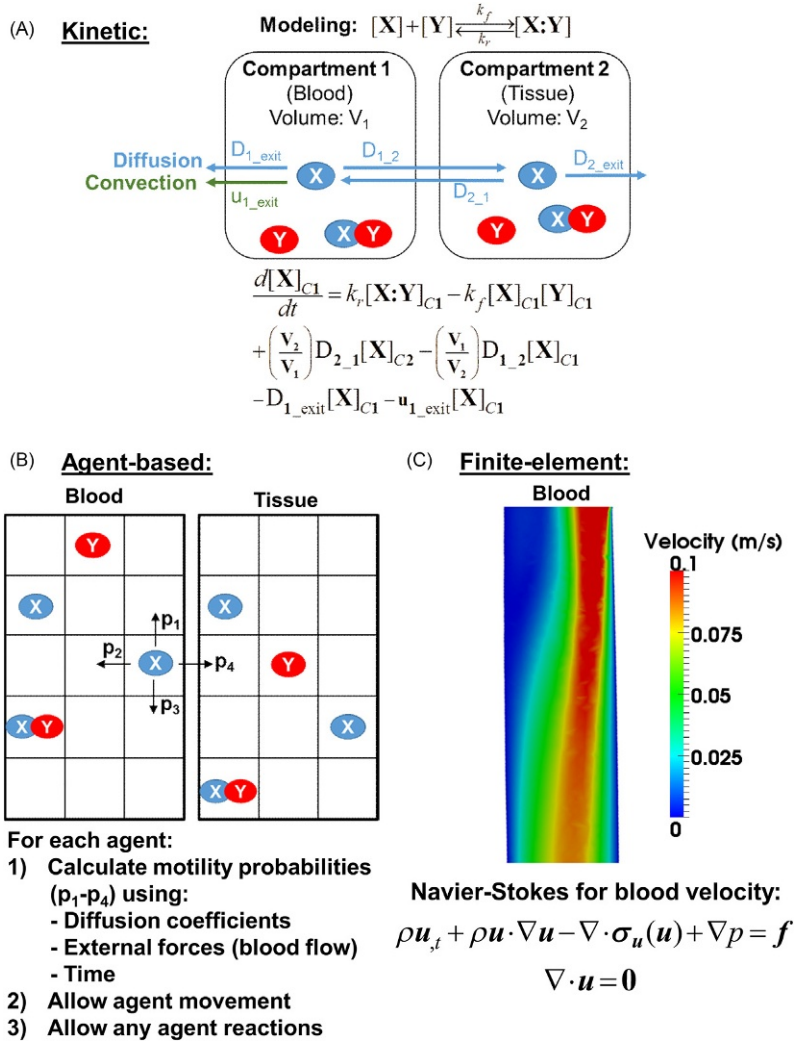

Fig. 2 *Example systems biology techniques to model protein transport and interactions.* (A) A deterministic kinetic compartmental model containing a single chemical reaction involving two molecules [X] and [Y] binding to form [X:Y], all with units of M. The reaction is defined by the forward rate k_f (M^{-1} s^{-1}) and reverse rate k_r (s^{-1}). In this example, X is a free molecule able to move across compartments, while Y is anchored within the compartment. Compartment 1 is blood that is spatially close enough to interact with tissue defined by Compartment 2, both with units of L. *Blue arrows* indicate diffusion, while the *green arrow* indicates convention from blood flow. For this kinetic model, diffusion and convection terms are assumed to have units of s^{-1}. An example ordinary differential equation governing [X] in Compartment 1 is shown. (B) An agent-based model using a grid for spatial discretization. Pseudo-rules are given for directing agent motility and interactions. (C) Example of finite element modeling to determine blood flow velocities, taken from simulations performed in (Weddell et al., 2015). The blood velocity field can be integrated with kinetic or agent-based models to provide more physiologically relevant convection rates or movement probabilities, respectively. Conversely, the tissue could also be modeled with finite elements, and advection–diffusion-reaction could be solved.

Here A, B, and C are species concentrations, A and B interact to form C with forward rate k_f, and C dissociates to form A and B with reverse rate k_r. For systems biology applications, reactions describe interactions between reactants, modeled as biological species such as proteins or genes. For deterministic kinetic models, species are assumed to be contained in a continuous molecular concentration. One typical deterministic kinetic modeling application is to quantify temporal species concentrations using ordinary differential equations (Eq. 2):

$$\frac{d[\mathrm{A}]}{dt} = k_r[\mathrm{C}] - k_f[\mathrm{A}][\mathrm{B}] \tag{2}$$

Eq. (2) indicates the temporal concentration of species A ([A]) defined by the chemical reaction in Eq. (1). Kinetic models are also often employed as compartmental models, where species reactions are bounded within a physical space (compartment), but may transport between other compartments that are physically separated (Fig. 2). In systems biology, a microscale compartmental example is modeling the extracellular and intracellular spaces, which are physically separated by the cell membrane. A macroscale example is modeling compartments as different tissues, such as bloodstream and skeletal muscle tissue, which are physically

separated by the blood vessel walls. A thorough review on kinetic modeling of signaling networks at micro- and macro-scales can be found in Janes and Lauffenburger (2013).

A second typical deterministic kinetic modeling application is to quantify spatial or spatiotemporal species concentrations are using the advection–diffusion-reaction equation modeled with partial differential equations (Eq. 3):

$$\frac{\partial[\mathrm{A}]}{\partial t} = \mathrm{D}\nabla^2[\mathrm{A}] - \vec{v} \cdot \nabla[\mathrm{A}] \pm \mathrm{R} \tag{3}$$

where [A] is the concentration of a species A, D is the diffusion coefficient of species A, ∇ is the spatial partial derivative, $\vec{v}$ is the convective velocity field, and R is any reactions involving species A. In purely kinetic models, modeling species diffusion and convection typically involves compartmental modeling, where species transport between compartments is defined by either constant D and $\vec{v}$ terms, or D and $\vec{v}$ terms that are altered algorithmically.

One primary limitation to kinetic modeling is it requires model parameterization, species concentrations, and reaction kinetics to be defined from biological data. Model parameterization is an essential step to develop physiologically relevant models (Le Novere, 2015; Brodland, 2015; Janes and Lauffenburger, 2013). Species concentrations, such as membrane receptor levels, can be accurately parameterized with quantitative flow (qFlow) cytometry (Pannu et al., 2001; Wang et al., 2006; Imoukhuede et al., 2013; Chen et al., in press), a high-throughput approach that detects receptor expression with a fluorescent affinity probe and quantifies absolute receptor concentrations using fluorescent calibration standards (Pannu et al., 2001; Imoukhuede and Popel, 2011; Chen et al., in press). Recently, qFlow cytometry has been used to obtain data on VEGFRs on ECs in vitro (Chen et al., 2015; Imoukhuede and Popel, 2011), ex vivo (Imoukhuede and Popel, 2012), and from pathological tissues (Imoukhuede et al., 2013; Imoukhuede and Popel, 2014). These VEGFR concentration data have been used to advance several computational models (Yen et al., 2011; Finley et al., 2011, 2013, 2015; Finley and Popel, 2012; Weddell and Imoukhuede, 2014; Tan et al., 2013a,b). Prior to the adoption of this emerging tool for systems biology, most kinetic models contained concentration parameters that were either estimated or generalized across multiple reactions; one such methodology for estimating kinetic parameters from network connectivity is given in (Ko et al., 2009). This limitation in parameters is also seen in the need for kinetic parameters. Due to this limitation, researchers have recently been developing methods for quantifying reaction rates for specific biological processes: Bose and Janes recently developed a method for high-throughput quantification of signal molecule dephosphorylation kinetics via phosphatase activity (Bose and Janes, 2013). Similarly, surface plasmon resonance (SPR) has recently been used to identify new interactions between PDGF ligands and VEGFRs, implicating cross-family signaling in angiogenesis, while simultaneously providing quantitative interaction kinetics that can seed computational models (Mamer et al., 2016). While SPR is low throughput natively, SPR on a chip technology has recently been developed to allow high-throughput, array-based SPR identification of interactions and kinetic rate quantifications (Li et al., 2017; Zhang et al., 2015). Development of such high-throughput methods to completely parameterize kinetic models, from species concentrations to specific kinetics for every reaction, would provide additional insights into the biological system and how it can be manipulated, while maintaining high physiological relevancy.

Stochastic Modeling

Deterministic kinetic modeling always gives the same results given the same reactions, concentrations, and kinetics. However, biological processes have elements of randomness; deterministic modeling particularly fails at low species concentrations, where the assumption that species are contained in a continuous molecular concentration does not hold, and reactions occur stochastically (Buiatti and Longo, 2013; Pilpel, 2011). Stochastic kinetic models incorporate this random element into deterministic kinetic models to predict biological randomness and noise (Wilkinson, 2009). Systems biology typically applies stochastic modeling through the Gillespie algorithm or Monte Carlo simulations. Briefly, the Gillespie algorithm simulates time-dependent trajectories of the species in a chemical reaction network (Wilkinson, 2009). Monte Carlo simulates stochastic reactions by introducing probability distributions for the occurrence of each reaction (Kerr et al., 2008).

Agent-Based Modeling

Agent-based models represent each individual species (i.e., cell or protein) as a discrete agent that follows a certain set of rules. Similar to kinetic modeling, agent-based models in systems biology are typically used to quantify spatiotemporal species information (An et al., 2009). Unlike kinetic modeling, agent-based models do not require kinetic or concentration information; rather, rules define species interactions and transport, which may or may not include kinetic or concentration information (Chen et al., 2014). Cellular automaton is one primary example of agent-based modeling: creating a two- or three-dimensional spatial grid, where each lattice on the grid contains an agent of interest, and simulating the spatiotemporal agent movements and interactions across the grid.

Agent-based models are advantageous as they incorporate stochasticity, and provide spatiotemporal information on individual agents, without requiring complex mathematical equations (such as Eqs. 2, 3) relationships to be defined and solved. However, defining the rules for agents to follow requires knowledge of the system mechanisms, simulating many agents is highly expensive computationally (Cosgrove et al., 2015). Thus, agent-based models are primarily useful for quantifying the behavior of a system with known mechanisms, whereas kinetic modeling can be useful for uncovering the system mechanisms (An et al., 2009).

Molecular Modeling

Molecular modeling simulates the three-dimensional structural interactions between atoms and molecules (Aloy and Russell, 2006). For the purposes of this review, we focus on molecular modeling in the context of computational drug screening: identifying potential VEGF inhibitors (Hoi et al., 2015). Computational drug screening is an approach to identify novel therapeutics for targeting signaling proteins. Potential drugs targeting the signal protein of interest are predicted by screening through different molecules, and quantifying their binding strength to the signal protein. Binding strength is typically determined through docking analysis, predicting the ability of a molecule to bind the signal protein through preferred orientation, size, flexibility, predicted interaction kinetics, and atomic structure. The therapeutic efficacy of these drugs is then examined in vitro or in vivo (Hoi et al., 2015).

Finite Element Modeling

Finite element modeling is based on similar principles of cellular automaton: a spatial domain is bounded and discretized to calculate the quantity of interest within each lattice on the grid temporally (Vanegas-Acosta and Garzón-Alvarado, 2014). Finite element modeling differs from agent-based modeling in two primary ways: (1) finite element models quantify materials in continuum, such as fluid velocities or temperature fields and (2) finite element models are defined from conservation laws. A typical finite element application is to quantify hemodynamic forces, velocity, pressure, and shear stresses, through the Navier–Stokes equations (Weddell et al., 2015):

$$\rho \boldsymbol{u}_{,t} + \rho \boldsymbol{u} \cdot \nabla \boldsymbol{u} - \nabla \cdot \boldsymbol{\sigma}_{\boldsymbol{u}}(\boldsymbol{u}) + \nabla p = \boldsymbol{f} \tag{4}$$

$$\nabla \cdot \boldsymbol{u} = 0 \tag{5}$$

where ρ is the fluid density, $\boldsymbol{u}$ is the velocity field, $\boldsymbol{u}_{,t}$ is the time derivative of the velocity field, $\boldsymbol{\sigma}_{\boldsymbol{u}}$ is the viscous stress, p is the pressure, and $\boldsymbol{f}$ is the external forces. Eqs. (4), (5) are defined by conservation of momentum and mass respectively. Finite element models could be used to calculate physiologically relevant velocity fields for advection–diffusion-reaction simulations (Eq. 3), allowing multiscale VEGF modeling. Some disadvantages are that finite element models are computationally expensive, and fluid properties must be carefully chosen to ensure accurate velocity fields (Weddell et al., 2015). For angiogenesis applications, finite element modeling is typically used to examine how blood flow stress directs vessel growth or intravenous angiogenic drug delivery.

Multivariate Models

The above computational techniques require no experimental data training for model development—granted such models are typically trained to ensure physiological accuracy. However, these models require high parameterization when the number of reactions and species becomes large and not all species or variables related to the system are typically incorporated into these models. To overcome these challenges, multivariate models seek to provide signal-to-response statistical models derived directly from experimental datasets, which do not require explicit definition of system mechanisms. A commonly used multivariate model in systems biology is partial least squares regression (PLSR). PLSR is a regression technique that correlates independent variables to dependent variables within the system (Kreeger, 2013). An example is building a PLSR model to correlate ligand stimuli (independent variable) to cell response (dependent variable) using experimental observations, and then applying the PLSR model to predict what cell responses will occur from untested ligand stimuli (Kreeger, 2013).

Statistical modeling is another commonly used multivariate approach in systems biology, where the probability of observing some response from a system of interest is calculated given a probability model (Bartocci and Lió, 2016). Statistical distribution mixture modeling is one such approach useful for quantifying biomarker heterogeneity (Chen et al., in press), which can provide insight such as which patient subpopulations are resistant to a drug (Weddell and Imoukhuede, 2014). Bayesian statistics is one such commonly used statistical model; Bayesian statistics infers posterior probabilities of model parameters by model training with empirical data (Eddy, 2004). An example Bayesian model application is predicting receptor signaling cross-talk involved in drug resistance, using empirical gene expression profiles from drug-resistance and drug-nonresistant patients (Azad et al., 2015). Machine learning is a similar statistical modeling approach, which describes a system from empirically derived sample inputs through processing algorithms (Tarca et al., 2007). Machine learning differs from Bayesian statistics in that machine learning does not describe biological mechanisms of a system, rather providing an optimized fit of input data to response. An example machine learning application is mapping tissue gene expressions to disease groups, to allow predictive disease classification from future tissue gene expression screenings (Sommer and Gerlich, 2013).

While multivariate models are powerful at predicting signal-to-responses, they are empirical-based models that are not capable of describing mechanisms of a biological system. Since this review focuses on computational systems biology for understanding angiogenesis mechanisms, we do not review multivariate approaches for angiogenesis.

In the following section, we provide an overview of computational systems biology studies that explore angiogenesis mechanisms and methods for regulating angiogenesis.

Systems Biology for Studying Angiogenesis

Sprouting Angiogenesis

Computational modeling, as a tool to understand angiogenesis, has been applied hand-in-hand with experimental investigation since the field of angiogenesis first emerged in the early 1970s, when Judah Folkman discovered the tumor angiogenic factor (Folkman, 1971). The earliest angiogenesis computational model examined vessel sprouting and network formation by diffusion modeling (Liotta et al., 1977). As VEGF and VEGFRs were not characterized until the late-1980s to early 1990s (Table 1), these initial angiogenesis models examined vessel sprouting in response to the uncharacterized molecule tumor angiogenic factor (Folkman, 1971). Despite not modeling sprouting directly by VEGF, these early computational models offered many important insights into growth factor-directed angiogenesis. Such computational models determined that the presence of an angiogenic factor is necessary to develop high density tumor vascularization, a concept that was contentious for its time (Deakin, 1976; Liotta et al., 1977). Later sprouting models highlighted the importance of an angiogenic factor, finding that directed vessel growth (Stokes et al., 1990) and vessel loop formation (Stokes and Lauffenburger, 1991) require a growth factor gradient. Cellular automaton and random walk approaches were applied to track individual cells throughout sprouting (Chaplain and Anderson, 1996), which captured the proliferative phenotype of cells behind the sprouting tip (Anderson and Chaplain, 1998).

As the roles of VEGF and other factors became defined in angiogenesis, computational models began to examine sprouting as a system comprising multiple driving factors or cell types. Some such recent sprouting models have predicted that basic fibroblast growth factor enhances VEGF-directed angiogenesis by upregulating VEGFR2 (Connor et al., 2015), and that VEGF and angiopoietins coordinate angiogenesis through EC migration and vessel maturation by pericytes (Zheng et al., 2013). Finite element modeling has also been used to identify that traction forces employed by cell growth controls matrix deformation and additional angiogenic growth and remodeling (Edgar et al., 2014). Additional computational systems biology models that have been specifically studied sprouting angiogenesis are reviewed in (Peirce et al., 2012). Overall, such sprouting models have advanced our understanding of how single or multiple growth factor gradients direct angiogenesis. Sprouting models also offer a powerful, macroscopic framework to examine specific subsystems within angiogenesis; as such, sprouting models have been extended to understand how VEGF-mediated tip/stalk cell selection directs angiogenesis.

Tip/Stalk Cell Selection and Vessel Sprouting

Gerhardt et al. defined vessel patterning for the first time in 2003, characterized by tip cells responding to VEGF with guided migration, and stalk cells responding with proliferation (Gerhardt et al., 2003). Vessel patterning has since been well characterized in VEGF-directed sprouting angiogenesis, identified as an important feature for VEGF signaling and lumen formation to create functional blood vessels, reviewed in (Bautch, 2012). As VEGF/VEGFR and Delta/Notch signaling cross-talk was characterized as a key feature in tip/stalk cell selection and vessel patterning (Hellstrom et al., 2007; Hellström et al., 2007), agent-based computational models worked hand-in-hand with experimental investigations to explore this relationship. Insights gained from such agent-based models include identifying that Delta like ligand (Dll)-4 and VEGFR2 expression oscillate to direct sprouting (Bentley et al., 2008), and the validated prediction that tip/stalk cell selection is driven through tip cell filopodia extension (Bentley et al., 2009). Perhaps the most important insight into tip/stalk cell selection given by computational models is that this process is reversible; Bentley et al. first reported that DII4/Notch lateral inhibition between ECs during loop formation causes cell fates to flip (Bentley et al., 2009), a process now validated through further model-directed (Jakobsson et al., 2010) and exploratory (Siemerink et al., 2012) experiments. Recent agent-based modeling, integrated with in vivo experiments, identified that the rate of tip cell selection defines a trade-off between sprout extension and vessel branching, dictating vessel network density (Kur et al., 2016). Model-derived experiments also found that reversible tip/stalk cell selection is present in embryonic neural crest cells, accurately predicting gene expression patterns that different tip and stalk cells (McLennan et al., 2012, 2015). Some examples of inferences recent tip/stalk cell sprouting models have made include: tip cells migrate back and forth to dynamically alter the leading cell based on VEGFR2 expression (Boas and Merks, 2015), stalk cell proliferation is dependent on traction forces applied by tip cell migration (Santos-Oliveira et al., 2015), and that tip cell polarization and directed movement is mediated by the VEGF-VEGFR binding distribution on the cell surface (Jain and Jackson, 2013).

VEGF-VEGFR Kinetic Models

VEGF-VEGFR interaction models at the single cell scale seek to understand how the kinetics of the ligand-receptor interactions dynamically alters protein and complex concentrations. Typically, these concentrations are taken as the functional output of VEGF-VEGFR interaction models, providing inference to angiogenic potential (i.e., higher phospho-VEGFR2 concentrations imply more angiogenesis will occur). VEGF-VEGFR interaction models are powerful as they quantify protein and complex concentrations that are difficult to probe or differentiate experimentally, and allow perturbations (such as ligand or receptor concentration effects) to be easily examined. While ligand-receptor kinetic models were first introduced in the early 1970s (Bell, 1974), VEGF-VEGFR interactions would not be modeled until 2004 (Mac Gabhann and Popel, 2004). This model predicted that the experimental hypothesis that PlGF displaces VEGF from VEGFR1, enhancing VEGF signaling through VEGFR2, was incorrect, and suggested a

functional VEGFR1 signaling role. Later experimental evidence backed up this model result, showing that PlGF upregulates pro-angiogenic factors and induces metastasis (Marcellini et al., 2006; Roy et al., 2005). This initial model showcases the predictive power of VEGF-VEGFR interaction models. VEGF-VEGFR interaction models have been continuously developed throughout the years to explore VEGFR signaling dynamics. We provide an overview of VEGF-VEGFR interaction models based on the subsystems they explore.

VEGF Expression in Hypoxia

Hypoxia inducible factor-1α (HIF-1α) is one of the primary molecules that directs vascularization in response to hypoxic environments by promoting VEGF expression (Masoud and Li, 2015; Ziello et al., 2007), leading to increased tumor cell invasiveness (Du et al., 2008). Computational systems biology has thus investigated HIF-1α activation in response to oxygen concentration, and subsequent VEGF expression for promoting angiogenesis. An initial hypoxia kinetic model developed by Qutub and Popel identified that HIF-1α activation from hypoxia either directs steep, switch-like or gradual cell responses; this dual cell response may be an important consideration for HIF-1α targeting therapeutics (Qutub and Popel, 2006). Another kinetic model examined how VEGF expression is mediated through HIF-1α degradation by two enzymes, prolyl hydroxylase and asparaginyl hydroxylase (Yucel and Kurnaz, 2007). This model identified that prolyl hydroxylase alone is sufficient at abolishing HIF-1α activity, and that regulating prolyl hydroxylase activity may be an effective method for controlling the angiogenesis response to hypoxia (Yucel and Kurnaz, 2007). A recent kinetic model examined the role of miRNAs in hypoxia-induced HIF-1α activity and VEGF expression, identifying that argonaute 1 overexpression decreases VEGF production (Zhao and Popel, 2015). These potential therapeutic targets identified by hypoxia-induced VEGF expression models offer potential options for controlling angiogenesis, and require further investigation.

VEGFR Dimerization Models

VEGF signaling can lead to differential signaling outcomes based on whether it signals through VEGFR homodimers or heterodimers (Roskoski, 2008). VEGFR dimerization formation is difficult to examine experimentally, making the effects of dimerization parameters, such as dimerization rates or ratio of dimer formation, difficult to elucidate. VEGF computational models have provided VEGFR dimerization to be probed, with such findings as that dimerization does not affect complex formation at membrane patches dominated by stochastic VEGF-VEGFR binding (Mac Gabhann et al., 2005). A generalized receptor model showed that homo- versus heterodimer formation is predominantly dependent on relative receptor concentrations (Mamer and Imoukhuede, 2015a), providing therapeutically relevant receptor concentration spaces for tuning dimer formation. This model further found that ligand-receptor binding kinetics also direct homo- versus heterodimer formation (Mamer and Imoukhuede, 2015a), which may be especially important for angiogenesis given the differential binding kinetics of VEGF with VEGFR1/VEGFR2 and the ability for PDGFs to compete for VEGFR binding (Mamer and Imoukhuede, 2015b). While these computational models elucidated how VEGFR dimers form, understanding functional differences in VEGF signaling through VEGFR1 homodimers, VEGFR2 homodimers, and VEGFR1/VEGFR2 heterodimers remains a challenge that systems biology may yet answer.

VEGF Isoform-VEGFR Kinetic Modeling

Similar to VEGF signaling being directed by VEGFR dimer formation, VEGFR signaling is directed by the ligand isoform that binds (Table 1). While computational models have examined VEGF isoforms primarily in the context of pathology (described later), here we highlight studies that have examined VEGF isoforms in normal physiology. An early model examining $VEGF_{165}$- and $VEGF_{121}$-VEGFR binding distributions in skeletal muscle tissue found that NRP potentiates $VEGF_{165}$-VEGFR2 binding, and removing NRP causes equal $VEGF_{165}$- and $VEGF_{121}$-VEGFR2 binding (Mac Gabhann and Popel, 2007a,b). A two compartment blood-tissue model examined $VEGF_{121}$ and $VEGF_{165}$ binding distributions with luminal and abluminal receptors, finding that abluminal VEGF predominantly binds VEGFR1, whereas luminal VEGF predominately binds VEGFR2 (Stefanini et al., 2009). Another study elucidated that VEGF isoform patterning observed in vivo (Grunstein et al., 2000; Ruhrberg et al., 2002) is directed by isoform specific sequestration and degradation through heparan sulfate proteoglycan binding (Vempati et al., 2011). Note that these computational models examined $VEGF_{121}$, $VEGF_{165}$, and $VEGF_{189}$ binding distributions with VEGFRs; no other $VEGF_{xxxa}$ isoforms have been modeled, and no $VEGF_{xxxb}$ isoform models exist to the best of our knowledge. $VEGF_{165b}$ has recently been shown to bind VEGFR2 with higher affinity than $VEGF_{121a}$ (Wittenkeller et al., 2015; Mamer et al., 2016), a commonly studied isoform, indicating that modeling VEGFR binding to $VEGF_{xxxb}$ isoforms may be an essential next step toward understanding angiogenesis.

Kinetic Modeling of VEGFR Intracellular Signaling

While these extracellular models provide a template for identifying key extracellular nodes and processes mediating VEGF-VEGFR interactions, they do not characterize how intracellular nodes mediate angiogenesis. To overcome this limitation, VEGF computational models were extended to examine how extracellular factors and VEGF-VEGFR binding couple with intracellular signaling to direct angiogenesis. The earliest VEGFR intracellular signaling model we identified, developed in 2007 by Alarcon and Page, provides the mathematical basis for modeling VEGF binding a generalized VEGFR, VEGFR internalization, and coupling of a generalized src-homology 2 (SH2) containing kinase to the VEGFR (Alarcón and Page, 2007). Such mathematical techniques have

been applied to examine specific signaling molecules: Mi et al. use model-directed experimentation to show that VEGFR2-PLC_δ directs intercellular Ca^{2+} signaling, mediating cell–cell communication in wound closure (Mi et al., 2008). Napione et al. show through model and experimentation that PLC_γ and Akt phosphorylation depend on VEGFR2 expression, mediated by cell density (Napione et al., 2012). A recently established modeling approach translating adapter phosphorylation to global cell response (Weddell and Imoukhuede, 2015a) showed that VEGFR1 actively promotes cell migration and proliferation through PLC_γ and PI3K activation (Weddell and Imoukhuede, 2015b, 2016b,c), advancing the previous characterization of VEGFR1 as a decoy receptor (Simons et al., 2016; Claesson-Welsh, 2016).

Kinetic Modeling of Internalized VEGFR Signaling

Computational analyses have also identified an important role for receptor internalization in intracellular signaling; computational models quantifying receptor signaling localization throughout endocytosis found that receptors primarily signal from intracellular endocytic vesicles (Weddell and Imoukhuede, 2016a, 2017). Another model indicated that phosphorylation of specific receptor sites may depend on intracellular compartmentalization (Clegg and Mac Gabhann, 2015). Anderson et al. showed through combined model and experimentation that heparin-bound VEGF increases VEGFR2 phosphorylation by slowing and lengthening the endocytosis process (Anderson et al., 2011). Together, these VEGF-VEGFR interaction models provide systemic information on the VEGF signaling axis: mapping entire extracellular and intracellular processes that mediate VEGF signaling and subsequent angiogenesis.

Multiscale VEGF Kinetic Models

VEGF interaction models have been expanded from the cell surface to macroscale. These systemic VEGF computational studies model the same VEGF-VEGFR interactions as at the cell scale, but expand the model scope to and interactions to examine VEGF distribution and binding at tissue or whole-body scales. At the tissue scale, $VEGF_{165}$ and $VEGF_{121}$ binding distributions to VEGFRs and NRP1 were modeled in skeletal muscle tissue, providing tissue scale findings such as that $VEGF_{165}$ concentrations in interstitial space does not affect steady-state VEGF binding distributions (Mac Gabhann and Popel, 2007a,b). VEGF interactions are also modeled at the whole-body scale, using compartmental modeling to simultaneously quantify VEGF interactions and transport between biological compartments (Weddell and Imoukhuede, 2014). Whole-body VEGF models first emerged by examining VEGF in tissue and blood compartments, providing the notable insights that unbound VEGF primarily localizes to tissue compartments (Yen et al., 2011), but that soluble VEGFR1, which sequesters unbound VEGF, does not decrease VEGF signaling potential in those tissue compartments (Wu et al., 2009). These macroscopic VEGF-VEGFR interaction models are also regularly used to explore angiogenesis in pathology: understanding both how VEGF signaling is important to pathology, and testing VEGF therapeutics. In the following section, we review modeling approaches to explore and optimize VEGF therapeutics, specifically pro-angiogenic therapeutics for vascular disease, and antiangiogenic therapeutics for cancer.

VEGF Models for Exploring Therapeutic Approaches in Pathology

Pro-Angiogenic Therapies

Pro-angiogenic treatments have exhibited continuous success at vascularizing ischemic tissue in animal models, but such treatments have not translated to clinical benefits (Cao, 2010). Computational models for pro-angiogenic therapies seek to optimize VEGF signaling to vascularize ischemic tissue and provide clinically effective options for treating vascular diseases. Pro-angiogenic computational models first examined VEGF gradients in rest and exercise, as exercise is the most effective preventer of vascular disease (Myers, 2003). Some key findings from these computational studies include that skeletal muscle VEGF gradients result in heterogeneous VEGFR activation, which may define the mechanism for stochastic sprout locations (Mac Gabhann et al., 2007b), and that VEGF signaling and subsequent tissue vascularization is most effective within the first week of starting exercise regimes (Ji et al., 2007). Unfortunately, patients with progressed vascular disease are unable to exercise; thus, computational models also examined other pro-angiogenic therapies in severe artery diseases. Such models suggested that injecting myoblasts overexpressing VEGF may effectively promote angiogenesis, and although identified to be less effective than exercise, it may be a promising therapeutic for patients unable to exercise (Mac Gabhann et al., 2007a). A recent model suggests that targeting miRNA, specifically inhibiting miR-15a, may effectively increasing VEGF synthesis and function in peripheral artery disease (Zhao and Popel, 2015). Hemodynamic forces are also an important consideration in the progression of peripheral artery disease (Weddell et al., 2015), and multiscale models quantifying hemodynamics with molecular interactions may provide new insight into vascular disease. Further exploration into computationally derived therapeutic options for vascular diseases may overcome the barrier currently preventing clinical efficacy of pro-angiogenic therapies.

PK/PD Models for Antitumor Angiogenesis

Whole-body pharmacokinetic/pharmacodynamics VEGF interaction models have been developed to systemically quantify VEGF-targeting therapeutic efficacies to inhibit tumor angiogenesis. These tumor angiogenesis models extend compartmental models of VEGF interactions with VEGFRs and extracellular proteins to account for drug administration to the blood stream, absorption into

healthy and diseased tissue, and drug-target interactions. Compartmental models examined VEGF dynamics following anti-VEGF injection (Stefanini et al., 2010; Wilde and Damian, 2014; Finley et al., 2013), identifying that $VEGF_{121}$ inhibition is more effective at reducing tumor angiogenic potential than $VEGF_{165}$ inhibition (Finley and Popel, 2012) and predicted that anti-VEGF efficacy is sensitive to VEGFR levels on tumor cells (Finley et al., 2011). Further investigation into physiological VEGFR heterogeneity identified that high VEGFR1 levels result in ineffective anti-VEGF therapy (Weddell and Imoukhuede, 2014), implicating VEGFR heterogeneity as a drug resistance mechanism. Pharmacokinetic modeling has also identified potential drug interaction mechanisms: the anti-VEGF drug aflibercept may bind NRP-bound VEGF, in addition to free VEGF (Finley et al., 2015). Overall, these systemic VEGF models offer a powerful platform for testing antitumor angiogenesis therapies, which can be applied to study patient-specific therapeutic efficacy, in addition to elucidating mechanisms of drug interactions and resistance.

Computational Drug Screening for VEGF Therapeutics

Computational drug screening has recently been applied to identify possible molecular compounds that selectively inhibit VEGFR2. These screening approaches typically iterate through compounds available in molecular databases, and identify potential novel VEGFR2-inhibitors through a computational structural comparison to an established VEGFR2 inhibitor (Ragno et al., 2015). The compounds exhibiting the greatest therapeutic potential are then tested experimentally. Such structural screening studies have identified a compound, termed HP-14, that exhibits a four-fold higher reduction in HUVEC proliferation than the established VEGFR inhibitor Vatalanib (Schmidt et al., 2008; Nitzsche et al., 2010). Other screening studies have identified compounds that significantly inhibit VEGFR1 and VEGFR2 phosphorylation to prevent HUVEC tube formation in vitro (Gautier et al., 2016), inhibit VEGFR2 kinase activity and HUVEC wound closure without affecting HUVEC proliferation (Kankanala et al., 2012), and inhibit vessel sprouting ex vivo (Latham et al., 2014). Further review of antiangiogenic VEGFR2-targeting therapies identified through computational screening can be found in (Shi et al., 2016). This computational screening approach, linked with experimental validation, offers rapid identification of promising VEGF inhibitors that may allow optimizing patient-specific therapeutics.

Challenges and Future Directions

Overcoming Resistance of VEGF-Targeting Therapeutics

Overall, computational studies and systems biology have driven angiogenic research fundamentally and to direct angiogenic therapeutics. Many challenges remain to be overcome to obtain complete control of angiogenesis. Overcoming anti-VEGF drug resistances is a large challenge in providing effective cancer treatment by inhibiting angiogenesis (Meadows and Hurwitz, 2012; Kubota, 2012; Lu and Bergers, 2013). Such therapeutic resistance was connected with heterogeneity in EC protein profiles (Aird, 2012), leading to systems biology studies that provided mechanistic insight into anti-VEGF resistance: high VEGFR1 cell subpopulations result in ineffective anti-VEGF treatment (Weddell and Imoukhuede, 2014), a result observed clinically (Paiva et al., 2015; Dhakal et al., 2012; Lambrechts et al., 2013). Despite such advances, anti-VEGF and other VEGF-targeting therapeutics are still met with resistance in many patients (van Beijnum et al., 2015). Adopting the approach to connect cell heterogeneity with therapeutic resistance (Weddell and Imoukhuede, 2014) may allow such drug resistances to be overcome. However, such an approach requires effective isolation of single cell types and cell biomarker quantification to characterize patient subpopulations and provide accurate model parameterization (Chen et al., 2014). These hurdles may be overcome by applying newly established technologies: the secondary anchor targeted cell release system for effective cell isolation (Ansari et al., 2015, 2016), and quantitative flow cytometry (qFlow) to quantify cell biomarkers (Lee-Montiel and Imoukhuede, 2013; Imoukhuede and Popel, 2014; Chen et al., 2015). The secondary anchor targeted cell release system quickly, efficiently, and gently isolates specific cell types without altering biomarker expression, while qFlow cytometry detects biomarker expression with a fluorescent affinity probe and quantifies absolute receptor concentrations using fluorescent calibration standards (Pannu et al., 2001). These high-throughput approaches ensure accurate model parameterization, an essential step to develop physiologically relevant models (Le Novere, 2015; Janes and Lauffenburger, 2013; Brodland, 2015), while also providing data specific to the cell, biological system, or patient to be modeled.

Quantifying VEGFR Signaling Throughout Endocytosis

One primary challenge in achieving complete angiogenic control is to understand the relationship between endocytosis and VEGFR signaling. Recently, intracellular-based receptors have emerged as key signal transducers (Irannejad et al., 2015; Tomas et al., 2015). Recent computational models have quantitatively shown that receptors primarily signal intracellularly (Weddell and Imoukhuede, 2017), and undergo significant nuclear translocation (Weddell and Imoukhuede, 2016a), underscoring a need to better understand the function of internalized receptors. Furthermore, the high intracellular expression of VEGFR1 and VEGFR2 (Zhang et al., 2010) indicates that intracellular VEGFRs endocytosis may have a crucial role in mediating VEGFR signaling.

Mapping the VEGF Isoform Functions

Another primary challenge in controlling angiogenesis is elucidating the function of all VEGF proteins. Specific functions for most VEGF isoforms remain undefined. While systems biology has identified differential $VEGF_{165}$ and $VEGF_{121}$-VEGFR binding and function, few of the other VEGF isoforms have been studied computationally or experimentally. $VEGF_{xxxb}$ functions in particular remain undefined, but may be important for angiogenesis as at least one binds VEGFR2 with higher affinity than $VEGF_{xxxa}$ isoforms (Mamer et al., 2016). Additionally, a recent study identifying that $VEGF_{165b}$ alters Dll4 expression (Ye et al., 2016), together with evidence that targeting Delta-Notch signaling may be effective anticancer therapeutic (Briot and Iruela-Arispe, 2015), implies an important $VEGF_{xxxb}$ role for tumor angiogenesis. $VEGF_{xxxb}$ may also have higher expression than $VEGF_{xxxa}$ in certain diseases (Lim et al., 2016), further highlighting the necessity to understand $VEGF_{xxxb}$ functions. Unlocking the mechanisms that mediate VEGF isoform expression, binding, and signaling may be the key to overcoming VEGF therapeutic resistance.

Uncovering the VEGFR1 Signaling Role

Classically, VEGFR1 has generally been ignored due to its decoy status in angiogenesis; VEGFR1 is thought to exhibit no intracellular signaling, serving to bind VEGF with high affinity to module VEGF binding and signaling through VEGFR2. However, a recent modeling approach (Weddell and Imoukhuede, 2015a), coupled with experimental investigation, showed that VEGFR1 natively functions to promote the angiogenesis hallmarks of cell migration and proliferation through PLC_{γ} and PI3K pathways (Weddell and Imoukhuede, 2015b, 2016b,c). This modeling approach can next be applied to quantify VEGFR1 signaling in different cancers and vascular disease. Indeed, emerging evidence implies quantifying VEGFR1 signaling is especially important in these diseases: membrane VEGFR1 is upregulated during vascular reperfusion stages in ischemic tissue (Imoukhuede et al., 2013), hypoxic tumor cells, and tumor ECs (Imoukhuede and Popel, 2014), and VEGFR1 tyrosine kinase-deficient mice exhibit reduced angiogenesis (Murakami et al., 2008). Furthermore, PlGF stimulates EC growth and migration (Fischer et al., 2008; Adini et al., 2002), and inhibiting PlGF prevents tumor growth and metastasis (Fischer et al., 2007).

VEGF Signaling Models for Clinical Applications

Toward using systems biology to guide angiogenic therapeutics, developing clinically relevant models that allow patient-specific investigation are essential (Neal and Kerckhoffs, 2010; Chen and Snyder, 2012). Developing such personalized models is a nontrivial task (Walpole et al., 2013), necessitating multiscale modeling approaches to capture all clinical features relevant to angiogenesis, such as VEGF interactions at the microscale and hemodynamics at the macroscale (Galie et al., 2014; Baeyens et al., 2015; Weddell et al., 2013). Integrating macroscale blood flow stress with microscale VEGFR signaling may be an important clinical consideration as well, since shear stress induces VEGFR signaling (dela Paz et al., 2012) and directs vessel patterning (Anderson et al., 2015). Choosing which modeling approach to use also must be balanced between computational complexity and physiological accuracy; take hemodynamic modeling as an example: while modeling blood properties as Newtonian is less mathematically complex than modeling the shear thinning properties of blood, Newtonian models do not provide physiologically relevant hemodynamics (Weddell et al., 2015). Comprehensive angiogenesis computational models that guide therapeutic development for clinicians in an accessible, clinically relevant way is a large challenge in systems biology today, but would provide a platform for effective personalized medicine that no other approach can.

Introduction

Congenital valvular disease has an incidence of around 2% (Rose, 1996). However, half of the individuals born with a congenital heart abnormality will avoid surgical intervention in early childhood. A minority of patients recognized early will eventually need treatment, while others will only be diagnosed in adulthood. Congenital valvular abnormalities can involve any one of the four valves (Figs. 1–5). Congenital valvular abnormalities identified in adulthood most commonly affect the aortic valve (AV). This chapter will discuss a variety of congenital valvulopathies, their clinical management, pathology, and indications for treatment.

Bicuspid Aortic Valve and Aortic Stenosis

Definition

Congenitally bicuspid AV (BAV) occurs when only two valve leaflets arise in aortic valvulogenesis. This abnormality is usually well tolerated unless adulthood is associated with other structural abnormalities. A unicuspid AV is characterized by a single cusp and a small (usually stenotic) central orifice. It is often found with a single commissural attachment to the aortic wall. Although these valves tend to be narrow at birth, symptomatic obstruction may not present until later in life (Fig. 6).

Epidemiology

Four post-mortem studies provide only epidemiology data of the BAV in the adult population. Only 15%–28% of those with a BAV found post mortem are normally functioning (Roberts, 1970; Osler, 1886). The others are associated with aortic stenosis (AS)

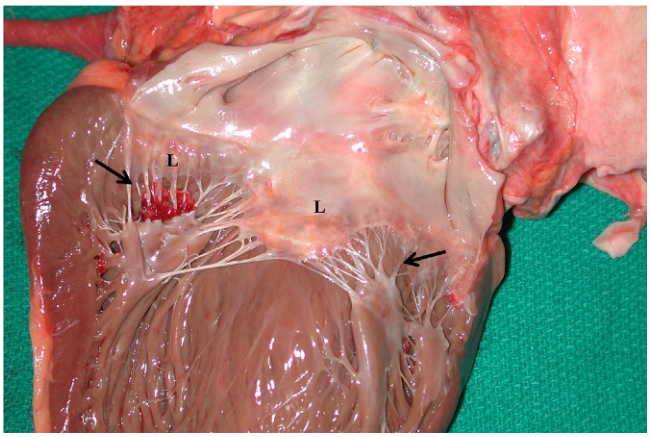

Fig. 1 A normal mitral valve. Note attachments of the leaflets (L) and of the chordae tendinae (*arrows*).

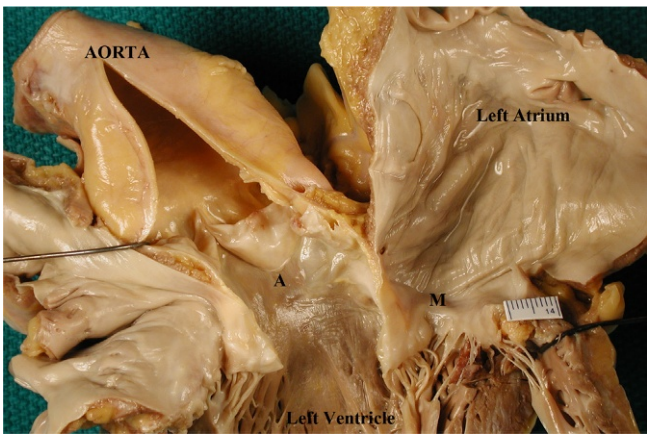

Fig. 2 Normal 3-cusp aortic valve. Note the left ventricular (LV) inflow tract and mitral valve (M) and the LV outflow tract and aortic valve (A).

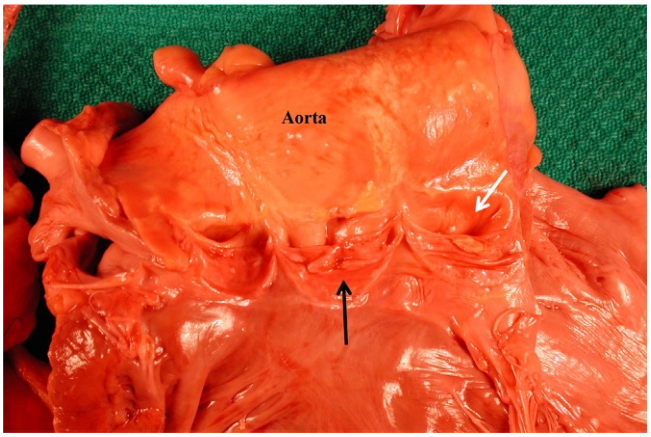

Fig. 3 Normal aortic valve. The three semilunar cusps are seen (*arrow*) and the coronary arteries arise from the sinuses of valsalva (*white arrow*).

Fig. 4 Surgically excised Mitral Valve, anterior mitral leaflet with chordae tendinae (*arrow*). The leaflet is normal, but was excised because of dysfunction related to nonvalvular causes, related to a previous myocardial infarction and papillary muscle dysfunction.

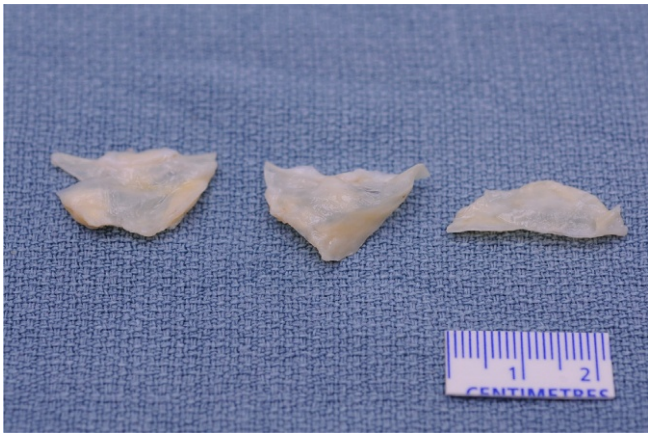

Fig. 5 Surgically excised aortic valve. 2 left cusps show the flow surface, while the 3rd shows the nonflow surface. The semilunar cusps are largely normal in structure, and were excised because of valvular incompetence, related to aortic and ascending aortic aneurysmal dilatation.

(15%–71%) (Roberts, 1970; Grant et al., 1928), aortic regurgitation (1.5%–3%) (Roberts, 1970; Grant et al., 1928), infective endocarditis (9.5%–40%) (Roberts, 1970; Julian et al., 1996), and aortic dissection (5%) (Julian et al., 1996). Based on this data, the accepted overall incidence is quoted as 1%–2% in the general adult population (Ward, 2000). Even though BAV is the most common cause of isolated valvular AS in adults, it can also be associated with dilation, aneurysm, dissection, or rupture of the aorta as it has been shown that there is abnormal maturation of the vascular wall in these patients (Grewal et al., 2016).

Fig. 6 (A) Congenitally bicuspid aortic valve. Surgically excised aortic valve showing the sinus surface of two cusps with marked thickening and nodular calcification. In addition one cusp (*the larger one*) shows a ridge (*raphe*) of calcification (*arrow*) which starts at about half way up the cusp and extends beyond the base of the cusps. The flow surface of the cusps was fairly smooth. The larger cusp had the appearance of a "birds wings in flight," typical of many congenitally bicuspid aortic valves.

Clinical Presentation

Most common clinical feature of BAV is AS with or without concomitant regurgitation. The disease can be asymptomatic if mild. Symptoms may develop with progression of disease and include angina, presyncope or syncope with exercise, or dyspnea on exertion, mostly due to valve calcification and/or thickening with subsequent narrowing. Often, these symptoms develop at the time when AS becomes severe. In the early stage, detection of AS can first be found by a thorough physical examination. In a patient with severe AS, the murmur is typically in the 2nd–3rd intercostal space on the right side, with mid-late peaking harsh systolic ejection murmur. Along with a soft and single or paradoxical S2, an S3 or S4 may be present. Carotid upstroke is of small volume and weak, termed "parvus et tardus." Other findings include apical-carotid and brachial radial delay, which also suggests severe AS.

Investigations

An electrocardiogram (ECG) often shows nonspecific findings. As a result of chronic pressure load on the left ventricle (LV), left ventricular hypertrophy is a common finding. If aortic stenosis is suspected, transthoracic echocardiography (TTE) with Doppler measurements can provide information regarding valve morphology, ascending aorta, aortic sinuses, aortic annulus, and degree of stenosis and regurgitation. In addition, degree of LV dilation and LV systolic function are important measures, which may assist with timing of intervention.

When noninvasive strategies are unable to delineate degree of severity, or if clinical assessment is discordant, cardiac catheterization can be another modality to assess valve severity. Concurrent angiography should be performed to identify flow limiting coronary artery disease. If a patient is found to have severe AS, and is asymptomatic, exercise testing could be used to assess for symptoms. A dobutamine stress echocardiography can be used in the select patient population with LV ejection fraction <40%, if there is a question regarding the true severity of AS and the presence of contractile reserve. There is limited use of computed tomography (CT) or magnetic resonance imaging (MRI) in this patient population in assessment of severity of stenosis, but could be used for more accurate measurements of the aortic sinus, sinotubular junction (STJ), and ascending aorta (Nishimura et al., 2014).

Management

In all patients with AS, optimizing hemodynamics remains the standard of care. Managing hypertension as well as optimizing volume status is most helpful when patients become symptomatic. Though there is data to support the use of beta-blocker and ACE inhibitor therapy in patients with Marfan syndrome to prevent aortic root dilation (Lacro et al., 2014), there is no data to support this in patients with BAV. In addition, rate control of atrial arrhythmias is also instrumental in allowing adequate cardiac output.

If the patient is symptomatic with evidence of severe AS by either history of exercise testing, intervention is indicated (class of recommendation (COR) I, level of evidence (LOE) B). In addition, in asymptomatic patients with severe AS and LVEF <50%, or those undergoing other cardiac surgery, intervention is also indicated (class of recommendation I, level of evidence B). The other indications with variable COR and LOE can be found elsewhere (Nishimura et al., 2014). If the patient is an acceptable surgical candidate, AV replacement is the mainstay of treatment, with documented improvement of symptoms, and improving life expectancy. The type of prosthetic valve used is based on discussions with the patient and the cardiovascular surgeon, and is often a balance between patient age, comorbidities, and ability for safe anticoagulation. If the root also needs to be replaced, then

other surgical considerations need to be considered. Typically, this is indicated when the aortic sinuses or ascending aorta measures >5.5 cm or if >5.0 cm in conjunction with a family history of aortic dissection or a rate of increase in diameter of ≥0.5 cm/year (Nishimura et al., 2014).

If a patient is deemed to be too high risk for surgery, transcatheter aortic valve implantation (TAVI) allows AV implantation without a sternotomy, or cardiopulmonary bypass and is associated with a shorter "in-hospital" stay. Though these patients were not originally included in the early TAVI studies (Leon et al., 2010), due to the elliptical shape of the annulus, its use in BAV patients has been reported with similar mortality rates compared to those with a tricuspid AV (Phan et al., 2015; Kochman et al., 2014). The rate of perivalvular leaks was also not significantly higher in patients with BAV (Phan et al., 2015).

Balloon aortic valvuloplasty is an alternative option to surgery in some patients with a BAV with AS. Its use can be applied to young patients with commissural fusion without significant leaflet calcification. Indications include those with symptoms and a peak-to-peak gradient of >50 mmHg at the time of catheterization or if asymptomatic with peak-to-peak gradient >60 mmHg with ECG changes of ST or T segments in the lateral leads (Nishimura et al., 2014). However the recurrence of the clinical symptoms has to be kept in mind as the need for repeat intervention is common.

If a patient does not meet criteria for intervention either due to the degree of stenosis or aortic dilation, annual evaluation is recommended in patients with aortic dilation (>4.5 cm), a rapid rate of change in aortic diameter, and in those with a family history of aortic dissection. If the aortic root measures between 4 and 4.5 cm, less frequent reimaging is suggested (Nishimura et al., 2014).

Patients with valvular AS are at increased risk of bacterial endocarditis. Antibiotic prophylaxis is not recommended in recent guidelines regarding the management of these diseases. Good oral hygiene with regular dental assessments is standard of care (Nishimura et al., 2014; Wilson et al., 2007).

Pathology

Inequality of cusp size, presence of a raphe (fibrous ridge) typically found on the sinus surface between the two portions of the V-shaped cusp (often resembling a "birds wings in flight"), and smooth cusp margins are the three hallmarks of the BAV (Roberts, 1970; Peacock, 1865). In the early stages, the cusps may be near normal, structurally, except for the presence of the raphe and the accompanying fibrosis around it. As the patient ages, the valve leaflets undergo progressive changes especially around the areas of the raphe, with resulting grossly evident fibrocalcific nodules resulting in stiffened cusps and in irregular cusp surfaces. These nodules may rupture or ulcerate, allowing for deposits of thrombus and development of inflammation as well as a potential for infection. The valve tissue around the calcific nodules often shows neoangiogenesis (new thin-walled vessels usually with no supporting smooth muscle) as well as chronic inflammation. A frequently seen additional and interesting feature is the presence of varying degrees of osteocartilagenous metaplasia. The reasons underlying these morphologic changes include the structural abnormality (absence of one or more raphe), the flow abnormalities, and the altered and high mechanical stresses on a bicuspid AV leading to valvular endothelial cell dysfunction, possibly with deposition of low-density lipoprotein particles that trigger inflammation and the deposition of platelets. This results in fibrosis and osteoblastic transformation. Close inspection of excised valves will usually reveal one raphe or at times two narrow strand-like or chord-like raphe or partial commissures with the latter believed to be a stage in the development of the raphe. The raphe may sometimes be difficult to appreciate, in the presence of "massive calcification," and the nodular calcium may make the placement of the usual models of TAVI prostheses difficult. The cuspal tissue around the commissures often shows a moderate degree of fibrosis and thickening.

The congenitally unicommissural valve has a "linear or exclamation mark"-shaped orifice, two raphe, and one commissure (Fig. 7). This congenital abnormality usually presents earlier in life. Another congenital abnormality is the "acommissural or dome"-shaped aortic valve, which has only one sheet of aortic tissue with no commissures and often manifests in the first or second decades of life.

Subvalvular and Supravalvular Aortic Stenosis

Definition

A small proportion of patients with subvalvular aortic stenosis (SAS) and supravalvular aortic stenosis (SVAS) will present for the first time as adults. They are more commonly seen in the symptomatic adult after the recurrence of a previously treated lesion. Although the physical findings of SAS and SVAS are similar, as they both are along the spectrum of left ventricular outflow tract (LVOT) obstruction, their epidemiology, natural history, and treatment are markedly different.

Subvalvar Aortic Stenosis

Epidemiology

SAS, a type of LVOT obstructive lesions is found in 6% of children with congenital heart disease (Hoffman and Christianson, 1978). It can be a fixed or a dynamic lesion. It typically consists of a membranous or a fibromuscular ring beneath the AV generally at the most convex part of the interventricular septum (IVS). The membrane becomes a ring when it extends onto the ventricular aspect of

Fig. 7 A nonflow surface of a surgically excised aortic valve from a 45-year-old male. This valve, a congenitally unicommissural valve, shows diffuse fibrosis and thickening with 2 incomplete commissures or raphe (*arrows*). Tissue around and between the raphe shows marked thickening and calcification. The changes are consistent with significant dysfunction. (B) Flow surface of the valve.

the anterior mitral leaflet. Although it can be found as an isolated lesion, it has been found to coexist with other abnormalities in 50%–65% of cases, which include, but not exclusively, patent ductus arteriosus, ventricular septal defect, aortic coarctation, and pulmonary stenosis (PS) (Leichter et al., 1989).

Clinical Presentation

If this lesion occurs in isolation, it is not often detected in childhood. Given its incidence with more significant defects, it is most often found on echocardiography. When present, most patients present when the lesion is severe, when a murmur is appreciated on clinical examination. In severe cases, exertional dyspnea, chest pain, or syncope may be present. On auscultation, a systolic ejection murmur can be appreciated on the left sternal border in most cases. Valsalva maneuvers could differentiate a fixed lesion (softer with maneuver) from a dynamic lesion (louder with maneuver).

Investigations

An ECG often shows LV hypertrophy (LVH), akin to the changes seen in valvular AS. Other findings are typically nonspecific. TTE remains the standard modality for its identification. Visualization of the membrane or ridge can be seen. The aortic and mitral valves should be assessed for attachment points. LV dimensions and function should be assessed to gauge the degree of compensatory LVH. In some cases, an area of muscular thickening (tunnel type) may be seen. Continuous wave (CW) Doppler should be used to assess the gradient through the lesion, if any, and provocative maneuvers should be employed to assess for a dynamic lesion. If patients have exertional symptoms, gradients can be assessed post exercise. If visualization is difficult with TTE, transesophageal echocardiography (TEE) can be employed. Similar to AS, cardiac catheterization can be employed if there is discordance between clinical examination and imaging.

Management

In adults, management is controversial. Some groups advocate for more aggressive surgery earlier as to circumvent damage to the AV and the rate of recurrence. One group studied patients who underwent surgical repair and dichotomized the group based on peak gradients of either $\leq$40 or >40 mmHg. The authors found that early repair could prevent recurrence and the need for redo surgery as well as progressive aortic disease (Brauner et al., 1997). Other groups argue that surgical repair should be completed when the gradient is >40 mmHg or if $\leq$40 mmHg, in the presence of symptoms (Stassano et al., 2005).

If surgery is indicated, the nature of the lesion dictates the type of surgical repair. For a discrete lesion, a "membranectomy" can be performed with a myectomy if needed. If the AV is affected, the surgery would also include repair or replacement of the aortic valve. Though there is much debate regarding the addition of a myectomy in preventing recurrence, one study found that only preoperative LVOT gradient, tunnel-type lesion, and younger age predicted those who would have recurrence (Brauner et al., 1997). Mortality in the adult population has been quoted at 0%–3.8% (Brauner et al., 1997; Stassano et al., 2005). In patients with significant narrowing, a Konno procedure may be needed. This surgery involves replacement of the AV and widening of the ventricular septum in the region of the valve with a patch.

Recurrence has been found to occur in 20%–30% of patients, with redo operation in 15%–20% of these patients. Intervention prior to the gradient exceeding 40 mmHg has been found to reduce the rate of recurrence and has been found in one study (Brauner et al., 1997). Others have found that close proximity to the AV, preoperative Doppler gradients $\geq$60 mmHg, and involvement of leaflet tissue requiring "surgical peeling" increase risk of recurrence of obstruction (Geva et al., 2007).

Patients with documented SAS do not require infective endocarditis precautions as per the most recent AHA guidelines (Nishimura et al., 2014; Wilson et al., 2007).

Pathology

The most common clinical presentation is as a fibrous crescent or ring that completely encircles the LVOT to produce a discrete obstructive lesion (type I). The obstruction can also be caused by a tunnel-like fibromuscular band (type II). Histological examination reveals a "hood"-like layer of fibroelastic tissue (collagen and elastic fibers) with the deeper layers showing muscle fibers. Most resections do include a rim of myocardium.

If the AV is involved due to "jet lesions" from flow through the narrowed and obstructed LVOT, the leaflets can be thickened and show focal calcification and with fibrous attachments connecting them to the membrane itself (Teis et al., 2010).

Supravalvar Aortic Stenosis

Epidemiology

Supravalvar AS is the least common among the lesions that occur in the LVOT. It is seen in 1:20 000 live births (Metcalfe et al., 2000). SVAS is classified as either discrete (type I) where the narrowing is a localized hourglass constriction diffuse (type II) where there is narrowing at the STJ junction and ascending aorta and may extend to the aortic arch and descending aorta (Deo et al., 2013). The most common anatomic variant is the type I. Its occurrence is thought to be due to a genetic abnormality in the elastin gene (7q11.23) which causes an aortopathy (Merla et al., 2012). This genetic abnormality has been reported in patients with the Williams syndrome, either by a familial form or in sporadic cases. Similar to the SAS, SVAS is often found with other defects, and includes abnormal AV morphology, coarctation of the aorta with coronary artery stenosis, and pulmonary artery stenosis (Stamm et al., 1997; Stamm et al., 2001; Wren et al., 1990). Those with Williams syndrome can have either type of SVAS.

Clinical Presentation

Patients with Williams syndrome often present during childhood since it is associated with distinctive facial abnormalities, termed "elfin facies," which include an upturned nose, long philtrum, wide mouth, full lips, and micrognathia. In some cases, a white lacy pattern can be seen on their iris. These children are often of low stature, and present with hypertension and hypercalcemia along with developmental delay (Collins, 2013).

Symptoms of SVAS are similar to AS and SAS (dyspnea, angina, and syncope), but given its involvement with other vascular beds, patients can present with a variety of findings. Hypertension is usually present due to lack of vessel distensibility but occasionally, this can also be associated with concurrent renal artery stenosis (Merla et al., 2012).

Coronary artery abnormalities can also be found in these patients, and can include ostial and diffuse coronary artery stenosis, coronary artery dilation due to long standing hypertension, or obstruction to the coronary vessel from an abnormal AV (Collins, 2013). A patient presenting with symptoms of ischemia should have urgent angiography.

In patients with Williams syndrome, sudden cardiac death can occur and its incidence is 25–100 times greater than the general population (Bird et al., 1996). Its pathophysiology is not known, but it has been proposed that it is a result of LVOT obstruction, coronary artery disease, and prolongation of the QT interval on ECG (Collins, 2013).

Supravalvar stenosis can be detected by typical findings in cardiac auscultation. A systolic ejection murmur can best be heard at the 1st intercostal space on the right side. The second heart sound may be louder due to higher pressures proximal to the narrowing.

Thrills can also be heard in the suprasternal area. If there are other arterial involvements, a patient can have asymmetric carotid pulsation or a significant blood pressure differential between the arms (seen in two thirds of patients) (Flaker et al., 1983).

Investigations

If there is a suspicion of William's syndrome, genetic testing should be undertaken to confirm the abnormality (Collins, 2013).

To delineate the extent of stenosis, similar to SAS, TTE can identify the degree of obstruction using Doppler, the degree of LV hypertrophy and dilation, and the presence of other congenital lesions. Similarly, if there are limitations to a surface study, catheterization can be completed. If other vascular beds are involved, magnetic resonance angiography (MRA) can provide more detailed assessment.

Management

Management of these patients is not clear as no guidelines for surgical intervention exist given the rarity of the abnormality. In the infant, surgical intervention is typically done when the gradient >30 mmHg (Jonas et al., 1994). Others have found that earlier intervention, when the gradient exceeds 20 mmHg, is helpful to avoid progression post surgery (Wessel et al., 1994). Surgical repair consists of enlarging the aortic root and STJ with a patch repair, as well as correction of any other concomitant abnormality (coronary involvement, AV repair, or right ventricular outflow tract repair). Other methods of surgical repair have been developed and can be found elsewhere (Deo et al., 2013). Though balloon dilation and stenting has been reported in the literature, long-term outcomes do not exist (Pinto et al., 1994; de Lezo et al., 1996). The operative mortality has been quoted to be as high as 9% (Stamm et al., 1999). Patients with diffuse obstruction and those with other congenital abnormalities often do worse (van Son et al., 1994).

Patients with SVAS do not require infective endocarditis prophylaxis as per the most recent AHA guidelines (Nishimura et al., 2014; Wilson et al., 2007).

Pathology

Supravalvar stenosis can be present as an hourglass deformity superior to the sinuses of Valsalva, or as a more diffuse disease in the aorta. The defining feature of this condition is a fixed aortic narrowing at the level of the STJ, which typically produces an hourglass narrowing of the aorta. A wide range of other anatomic variations are seen, including hypoplastic SVAS and membranous SVAS. The obstruction may extend a variable distance along the aorta, and a generalized arteriopathy affecting both systemic and pulmonary arterial systems may be seen. Histologically, there is a fibrotic, thickened intima with disorganized medial elements (thick, irregular elastic fibers, swirling collagen, and hypertrophied smooth muscle cells) (O'Connor et al., 1985).

Ebstein's Anomaly

Definition

Ebstein's anomaly (EA) occurs when the posterior and septal leaflets of the right atrio-ventricular or tricuspid valve (**Fig. 8**) are malformed and attached lower down in the right ventricle (RV), closer to the apex, so that these leaflets are significantly larger than is usual (Ebstein, 1866). It is believed to occur due to a failure of the leaflets to delaminate in utero and results in adherence of the leaflets to the myocardium partially or wholly (Lamers et al., 1995), though the entire mechanism is not well elucidated (**Fig. 9**). It is

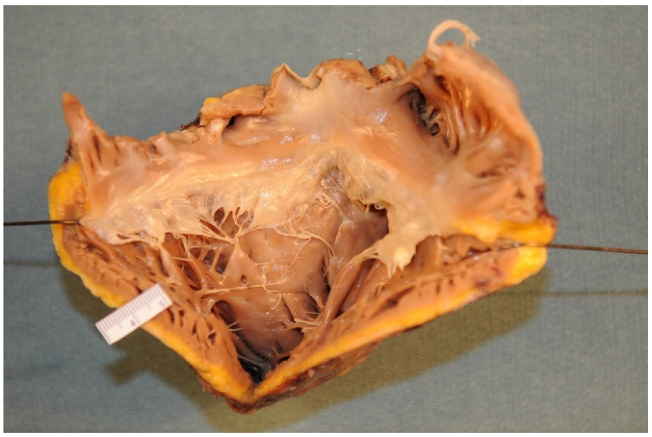

Fig. 8 A normal right atrio-ventricular or trileaflet valve.

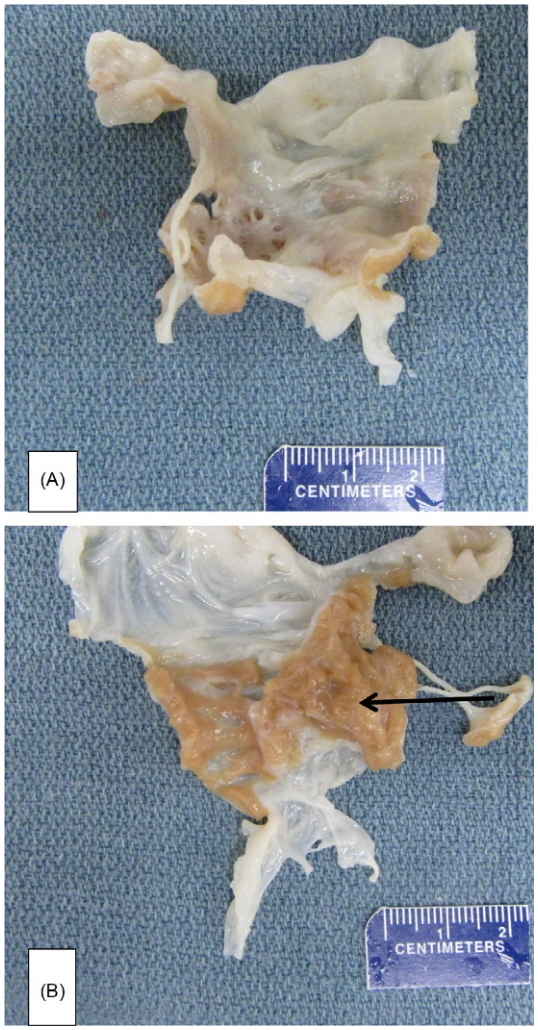

Fig. 9 A surgically excised tricuspid valve leaflet (A) from a 23-year-old lady who had an Ebstenoid tricuspid valve, consistent with significant dysfunction. This anterior leaflet is much larger and voluminous than normal and reached virtually to the right ventricular apex. (B). The nonflow surface of the same leaflet shows the same features and in addition shows attached tan-colored muscle from the areas at which the leaflet was adhesed to the endomyocardium (*arrow*).

also believed to be associated with a sporadic mutation(s) of chromosomes 1p36 and 8p23.1 (Digilo et al., 2011). Its clinical presentation varies dramatically. If severe, this malformation can be discovered in a newborn, and if less severe, can be found in the adult population.

Epidemiology

EA has been reported in 1 in 200,000 live births and accounts for <1% of congenital heart disease (Nora et al., 1974). There is no sex predilection and it is often found with other cardiac anomalies. These include patent foramen ovale (PFO)/atrial septal defect (ASD) which has been reported to occur in 80% of patients (Brickner et al., 2000). Others include pulmonary atresia/stenosis, aortic coarctation, ventricular septal defect, tetralogy of Fallot, atrioventricular septal defect, and mitral valve prolapse (Osiro et al., 2013).

Clinical Presentation

Clinical presentation is typically dictated by the severity of the anomaly, which can range from asymptomatic to severely symptomatic during infancy. If diagnosed in infants, they often present with cyanosis, once the ductus arteriosus closes. In most patients, clinical symptoms can occur in their teen and adult life. The most common includes arrhythmias and right-sided heart failure (Safi et al., 2016).

Investigations

An ECG is often abnormal in this patient cohort, and at times, can be diagnostic in adults. Most often, there are tall and broad p waves due to right atrial enlargement, along with first-degree AV-block and right bundle branch block. There could be a fragmented QRS complex due to abnormal conduction through the AV node. Atrial arrhythmias are common, found in 20%–30% of patients, and often are the cause of adults seeking medical attention (Vacca et al., 1958). In addition, type B Wolff Parkinson White syndrome has been reported to occur in 5%–25% (Hebe, 2000).

TTE remains integral to the diagnosis as well as to assess severity of disease. Assessment should include the tricuspid valve leaflets, insertion points to the RV, the RV, as well as the right ventricular outflow tract. The echocardiogram is most useful to look at the septal leaflet as the tricuspid valve. MRI can also be used, and can visualize the posterior leaflet of the tricuspid valve and assess RV size and function, if TTE proves to be difficult (Attenhofer Jost et al., 2012). If arrhythmias are suspected, a Holter monitor would be helpful to identify these.

Management

Adult patients can benefit from follow-up with regular testing for signs of deterioration of cardiac function. Mild symptoms can be treated with medication for right-sided heart failure (HF). Surgical intervention is suggested if patients have symptoms or decreased exercise capacity, cyanosis (O2 saturation <90%), paradoxical embolism, or progressive RV dilation or dysfunction (Warnes et al., 2008). Most experienced centers prefer valvular repair with plication of the atrialized RV over bioprosthetic valve replacement (Safi et al., 2016). If arrhythmias are present, one can consider a concurrent MAZE procedure or ablation of accessory pathways. If an interatrial communication is present, closure during the surgery can also be performed. Peri-operative mortality remains low at experienced centers, at 2.7% at 30 days (Brown et al., 2008). Redo surgery is advised in a symptomatic patient with reduced exercise tolerance (NYHA class III/IV), severe tricuspid regurgitation leading to RV dilation and dysfunction, bioprosthetic valve stenosis (gradients >12 mmHg) in the absence of reduced functional status or symptoms (Warnes et al., 2008).

Pathology

Most of the pathology of Ebstein's anomaly has been studied in 15 cases from the Mayo clinic (Anderson and Lie, 1978). In the tricuspid valve, when visualized from the atrial side, the anterior leaflet is attached to the atrio-ventricular (AV) junction in the anatomically correct position. The septal leaflet is seen displaced toward the apex and is often attached to the interventricular septal endocardium rather than to the AV junction. A portion of the ventricle is then exposed (often triangular shaped). The posterior leaflet is often attached to the ventricular surface where the septal leaflet lies. Its opposite side then meets the anterior leaflet at the AV junction. Though the attachment points of the anterior leaflet are normal, the leaflet is often larger and its attachment points to the papillary muscles are not normal. The septal and posterior leaflets vary in shape and are dependent on the degree of displacement toward the apex. Their chordae are also tethered to the ventricular wall.

The RV was then divided based on the insertion of the posterior and septal leaflets, and are called the proximal (atrialized) and distal RV. The proximal portion is often thick, fibrous, and smooth. The posterior portion was often aneurysmal and microscopically, would have sparse muscle fibers. The distal RV is often dilated and thin walled and in some cases, there was RV hypertrophy. The latter features are thought to be physiologic and secondary to the valvular abnormality and are thought to correlate with advanced disease. A PFO or ASD can also be found.

Pulmonary Valvular Stenosis

Definition

Similar to AS, PS can occur in the supravalvular, valvular, or subvalvular position. In this section, we will only discuss valvular pulmonic stenosis, as the others are commonly seen in infants and children, in association with other significant congenital cardiac conditions, such as the tetralogy of Fallot. In these patients, the valve is typically trileaflet, but has been reported to be bileaflet in <20% of cases (Keith et al., 1978). The narrowing is believed to be due to thickening of the leaflets and fusion of the commissures, thereby restricting flow during systole. This has been associated with tetralogy of Fallot, Noonan syndrome, and congenital rubella syndrome.

Epidemiology

This is a common congenital defect that has been quoted to occur in 10% of children born with congenital heart disease (Rocchini and Emmanouilides, 1995). The incidence of valvular stenosis compared with the other two (sub and supravalvular) is not known. Children with isolated congenital valvular pulmonic stenosis often survive into adulthood without any interventions. If unrecognized during childhood, the adult patient often presents with this isolated anomaly.

Clinical Presentation

Once the severity of stenosis increases (typically peak gradient >30 mmHg), patients can present with mild dyspnea to symptoms of severe right-sided heart failure, which include dyspnea with exertion, fatigue, abdominal bloating secondary to ascites, and marked peripheral edema. Physical exam findings are often helpful to delineate the severity of stenosis. S2 is often split due to the delay in ejection through the stenosed valve, with degree of split correlating with severity. A pulmonary ejection click and a right-sided S4 could also be appreciated as well. The murmur is a systolic ejection murmur best heard at the left sternal border, with its duration signaling the degree of severity. Late peaking systolic murmurs typically occur when the stenosis is severe. In addition, there could be an RV heave secondary to RV hypertrophy.

Investigations

TTE remains the preferred investigation for the management of PS (Nishimura et al., 2014). The peak and mean gradients measured by pulse and CW wave Doppler are integral for planning for intervention if needed. The valve leaflets are often thickened and immobile. Along with this, the degree of RV hypertrophy, dilation, and dysfunction are also an important part of the ultrasound assessment. Presence of other congenital anomalies would be useful as well. The use of TEE is not useful for evaluation of PS.

Other tests including an ECG can document RV hypertrophy or a right bundle branch block pattern. Cardiac catheterization may be a useful adjunct if the clinical symptoms or examination are discordant with the findings on TTE. It can also be useful to differentiate between valvular and subvalvular stenosis. Lastly, MRI can be useful for a more thorough assessment of the RV.

Patients with mild disease should be followed every 5 years, whereas patients with moderate disease should be examined every 2–5 years if asymptomatic (Warnes et al., 2008).

Management

Management for valvular s is typically driven by the presence of symptoms and the peak gradients measured by TTE. The 2008 AHA/ACC guidelines suggest balloon valvotomy in asymptomatic patients with a domed pulmonic valve and peak instantaneous Doppler gradient >60 mmHg or a mean Doppler gradient >40 mmHg or symptomatic patients with a domed pulmonic valve and peak instantaneous Doppler gradient >50 mmHg or a mean Doppler gradient >30 mmHg (both, in association with <moderate pulmonic valve regurgitation). In other cases where there are other congenital anomalies, which can include an associated hypoplastic pulmonary annulus, severe pulmonary regurgitation, subvalvular PS, or supravalvular PS, surgery is indicated (Warnes et al., 2008).

Pathology

Congenital pulmonary stenosis is either categorized as dome-shaped acommissural or dysplastic. In the domed-shaped type, the valve is typically dome shaped with a central aperture. The ridges that are seen are the areas of malformed commissures. In the dysplastic type, the cusps are thickened and rubbery. The valve annulus is small and the commissures are not fused (Waller et al., 1995). On microscopic examination, there are extensive, irregularly arranged aggregates of acid mucopolysaccharide staining material and fibrous tissue (Waller, 1984a; Waller, 1984b).

Congenital Mitral Stenosis

Definition

Congenital anomalies of the mitral valve (MV) are very rare. The valve is either malformed or malpositioned, or there may be anomalies of the papillary muscles. Most are associated with other congenital abnormalities such as the ostium primum ASD and present in infancy. MS may be due to valvular, subvalvular, or supravalvular causes, though we will only be discussing valvular MS. Congenital valvular mitral stenosis (MS) is a rare condition and may be due to one or more of several causes, such as hypoplasia of the MV annulus, double orifice mitral valve (DOMV), abnormal chordae tendinae (usually short and thick), or a parachute MV, where there is one papillary muscle supplying chordae tendinae to both leaflets. These lesions may occur by in isolation, or may be found with other congenital cardiac lesions such as aortic coarctation, AS, and SVAS.

Epidemiology

Abnormalities of the MS have an incidence of lower than 0.1% among individuals with congenital heart disease. Echocardiograms of 13,400 individuals showed an incidence of 0.5% (Bannerjee and Kohl, 1995). If severe or if associated with other major congenital cardiac lesions, manifest during infancy or childhood and are managed at that time. We will consider those conditions, which are relatively mild and therefore not operated in infancy or childhood. There is no mention of any gender difference in their incidence or of any ethnic predilection.

Clinical Presentation

In any of the conditions associated with MS, the presenting symptoms are usually those of heart failure and include dyspnea, orthopnea, and nocturnal dyspnea. Dilatation of the left atrium, which occurs may lead to palpitations, atrial fibrillation, thrombus formation in the atrial appendage and subsequent thromboembolism. If MS is undetected, pulmonary hypertension can occur which can lead to hemoptysis. Later effects of biventricular failure include hepatic congestion and hepatomegaly, and tenderness can be found. On physical examination, the murmur of MS is best heard at the apex with the patient lying on his/her left side. The murmur is pan-diastolic with presystolic accentuation if the patient is in sinus rhythm. It is low pitched and described as a "rumbling" sound. The murmur is typically preceded by an opening snap.

Investigations

Echocardiography (TTE) is the main modality to highlight MS severity. Focus on hemodynamic severity (mean gradient, mitral valve area, and pulmonary artery pressure) is important to record. In addition, the size of the left atrium and ventricular function should be analyzed as well. If atrial thrombus needs to be excluded or if the severity of MR is not well assessed by TTE, TEE would be necessary. Exercise testing can also be employed if clinical symptoms are not in keeping with echocardiographic findings. If symptoms are discordant to severity seen on TTE/TEE, cardiac catheterization can be used to assess hemodynamics. If surgical intervention is planned, coronary angiography should be done to ascertain coronary anatomy.

Management

General symptomatic treatment of heart failure and pulmonary edema would include adequate decongestive therapies. If left atrial thrombus is detected, anticoagulants are needed to prevent systemic embolization. Hypoplastic mitral valve would likely need surgical replacement with a mechanical or biological prosthesis. Once patients become symptomatic, mitral valve surgery is indicated if they are NYHA class III-IV with severe MS (defined as mitral valve area <1.5 cm^2 with a transmitral mean gradient >5–10 mmHg at a normal heart rate). In addition, surgery is indicated in asymptomatic patients with severe MS if undergoing cardiac surgery for another indication (Nishimura et al., 2014). Class IIa and IIb indications can be found elsewhere (Nishimura et al., 2014). Percutaneous options are not ideal as the anatomy is quite complex.

Pathology

The normal mitral valve is a complex structure comprised of the mitral annulus, the leaflets, the chordae tendinae, the papillary muscles, and the two left-sided cardiac chambers. These must function appropriately and synchronously for the valve to function well and normally. The mitral leaflets are unequal structures, which control blood flow from the pulmonary veins to the systemic circulation. Surgically the leaflets are divided into the P1, P2, P3, and A1, A2, A3 segments, which surgeons use as landmarks for mitral valve repair (Charpentier et al., 1998). The subvalvular structures are comprised of the chordae tendineae and the anterior and posterior papillary muscles. The chordae tendinae are attached to the base (strut chordae), rough zone or zone of coaptation, and the free margin (marginal chordae). All chordae "arise"from the papillary muscle tips (Bharati and Lev, 1996a).

Congenital mitral valve stenosis is rare and is associated with thickening of the mitral leaflets, especially the anterior leaflet (Bharati and Lev, 1996b). The mitral orifice will be smaller than usual. In addition most cases will show left atrial hypertrophy and dilatation, RV hypertrophy, and dilatation. The papillary muscles may be fused into one rim of muscle and therefore give rise to a "parachute" papillary muscle. The chordae tendinae may be short and in fact, the papillary muscle tips may be very close to or flush with the edge of the leaflets.

Cor Triatriatum or Double Left Atrium

Definition

This is strictly speaking, not a congenital valvular disease. However its presentation and symptoms may be those of mitral stenosis and thus, the reason for mentioning it here. In this lesion, there is a fibromuscular membrane across the left atrium, in essence dividing the LA into an upper chamber into which the pulmonary veins open and a lower chamber which has the mitral valve at its distal end. There may or may not be any other associated congenital cardiac lesion.

Epidemiology

This is a rare condition, being seen in 17 hearts out of 6300 congenitally malformed hearts (Bharati and Lev, 1996b). In this series, the male to female incidence was approximately 2:1.

Clinical Presentation

The membrane may have 1–2 large perforations or several small perforations, in which case the patient may have no symptoms. Auscultation may not reveal any murmurs and an echocardiogram may show the membrane. The patient may remain asymptomatic and the diagnosis made incidentally or present with features of mitral stenosis.

Management

The TTE or TEE would likely pick up the lesion incidentally or in a symptomatic patient. The management would depend on the severity of the lesion and could include surgical excision of the membrane.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) and resulting mitral valve incompetence are said to be present when the mitral valve leaflets extend at least 2 mm beyond the long axis annular plane of the mitral valve during systole (Abadir et al., 2009). It is usually secondary to degenerative changes and is the most common form of mitral valve dysfunction in developed countries. However, it does occur within patients with Marfan syndrome and is associated with other congenital cardiac lesions including as ostium secundum ASD, Ebstein's anomaly, and hypertrophic cardiomyopathy.

Cleft Mitral Leaflet

This anomaly is rare, but would be associated with mitral valve incompetence.

The presence of a division (cleft) in a mitral leaflet is typically found on the anterior leaflet. This may occur in isolation or may occur with AVSD (Abadir et al., 2009). Isolated cleft in the posterior leaflet is even rarer and usually occurs in segment P2 (Kent et al., 2001).

The lesion can be seen on TTE or TEE. The appearance is that of a slit hole in the AML. Surgical repair of the MV cleft is the preferred mode of definitive treatment. At times, this may not be feasible (i.e., leaflet edges markedly thickened and retracted) and a replacement has to be performed with an appropriate prosthesis.

Conclusion

In this section we have highlighted and discussed some of the commoner congenital valvular abnormalities seen in adults. The impact of valvular abnormalities is usually progressive and significant, at times culminating in congestive heart failure. Their symptoms are often similar, though the signs can be different. Most valvular lesions are fairly easily treated with currently available prosthetic devices. Most, though not all, devises today are fairly long lasting.

Mechanical heart valves have great durability but need lifelong anticoagulation, while tissue prostheses will fail, one day, but do not usually need any anticoagulants. Today it is the surgeon and the patient who decide which type of prosthetic heart valve is best suited to a patient.

Introduction

Coronary circulation is unique to vertebrates; no invertebrates have a coronary circulation. Among the vertebrates, mammals, reptiles, and avians possess coronary circulations with both arterial and venous systems.

The coronary arteries are the first branches of the aorta, arising usually from two of the three aortic sinuses of Valsalva.

Embryology of the Coronary Circulation

Initially, coronary circulation does not exist; the nutrients and oxygen, which nourish the endocardium and myocardium, are extracted by diffusion from the blood flowing through the lumen of the heart tube, which is initially extensively trabeculated. However, with increase in thickness of the heart tube, by the third week, a dedicated vascular system begins to form from the epicardial surface. Coronary vasculature forms by an elaborate process involving vasculogenesis, angiogenesis, and arteriogenesis (Tomanek, 2015; Bernanke and Velkey, 2002).

The proximal ends of the coronary arteries are formed when strands from a peritruncal ring of vascular structures penetrate the aorta by ingrowth, at the right and left sinuses of Valsalva.

Epicardial cells are derived from the proepicardial organ, which lies in the region of the sinus venosus. The initial channels are formed predominantly within the epicardial covering but are scattered throughout the myocardium mediated by the ventricular epicardial growth factor. At this time, there is no continuity between the separate vascular structures, and they are not connected with systemic circulation. However, subsequently, the vessels coalesce to form the early vascular plexus (in a process termed epithelial-to-mesenchymal transformation), which is initially seen within the subepicardial layers of the atrioventricular and interventricular grooves, and around the ventricular outflow tract. Following this, a complex network develops throughout the myocardium by sprouting from the primary plexus, driven by the hypoxic gradient.

Relatively late during the embryonic stage, the network gains access to the aortic root by ingrowth, subsequent to the process of aortopulmonary rotation. The sudden exposure to pulsatile flow and improved perfusion initiate the arterialization of this vascular network (embryonal arteriogenesis). This arteriogenesis includes (a) the migration of smooth muscle cells and pericytes from the epicardium and the aortic root, (b) the assembly of these cells with the primitive vascular structures to form stable vessels, and (c) radial growth and regression along with (d) apoptosis. This process occurs in a base-to-apex direction.

The precursors of the coronary veins have been seen to develop similar to the coronary arteries, as a capillary plexus, which then grows toward and into the wall of the sinus venosus. The connection to the coronary sinus or atrial lumen occurs only during the last stage of development. The muscularization of coronary veins, like that of arteries, is dependent on the establishment of coronary flow and is a late feature. The venous side of the capillary plexus precedes the arterial side in making connection with the luminal circulation. The left coronary artery formation precedes that of the right.

Thus, coronary blood vessels are a developmental mosaic, including cells derived from different embryonic sources. Sinus venosus endocardium mostly accounts for the makeup of coronary veins, whereas ventricular endocardial sprouts and epicardial-derived endothelial cells are the main contributors of the arterial components of the coronary tree.

Histology of Coronary Arteries

Like all other arteries, coronaries have three layers—intima, media, and adventitia. The endothelial cells of the intima lie on the subendothelial layer of connective tissue and smooth muscle cells. They are aligned to the long axis of the artery and are attached by occluding and communicating junctions. The intimal layer is separated from the media by the internal elastic lamina. The media consists of multiple layers of smooth muscle cells (about 40 layers) and connective tissue (consisting of elastic fibers and collagen). External elastic lamina separates the media from the adventitia and is composed of elastin and is considerably thinner than the internal elastic lamina. The adventitia is composed of fibrous tissue surrounded by vasa vasorum, nerves, and lymphatics (Waller et al., 1992a).

Normal Coronary Anatomy

Normal coronary anatomy is discussed in the articles by Loukas et al. (2009a, 2013) and Patel (2008).

Aortic Origin (Ostia) of the Coronaries

The two sinuses adjacent to the pulmonary trunk give rise to the major coronary arteries, the right coronary artery and the main stem of the left coronary artery. The origins of these arteries can vary significantly in relation to the sinotubular junction and the aortic valve commissures. It is exceedingly rare for a coronary artery to originate from the aortic sinus that is not adjacent to the pulmonary root (noncoronary sinus). The coronary arteries and their branches are normally embedded within the loose connective tissue and the adipose tissue of the subepicardial space (Almuwaqqat et al., 2012).

The right coronary artery arises from the right coronary aortic sinus of the right anterior surface of the aortic root. In many instances, two arterial ostia are present in this sinus, with the second ostium most often giving rise to the infundibular (conal) artery, but less frequently to the artery of the sinus node. The right coronary ostium is at the level of the free margin of the cusp in majority (>70%) of cases, above in about 20% and below the sinotubular junction in the rest.

The main stem of the left coronary artery arises from the left sinus of Valsalva just below the sinotubular junction, but in some, it has a high takeoff.

The right and left coronary ostia are placed under the sinotubular junction in about 55%; right ostium below and the left above in about 30%; right ostium above and left below in 8% and both ostia above in 6% of cases. The radial separation of the right and left coronary ostia in humans is about 123 degrees.

The ostia that are within 1 cm of the sinotubular junction in the adult heart are considered normal variations, whereas origins >1 cm relative to the junction are known as ectopic origins, or high takeoffs. It is very unusual for a major coronary artery to take origin from the aortic sinus distant from the pulmonary trunk (noncoronary sinus). A takeoff that is >2.5 cm above the sinotubular junction is considered an ectopic ostium. The combination of high takeoff with atherosclerotic changes in the coronary artery can be associated with an increased incidence of sudden cardiac death. When the arterial orifice is within 5 mm of the zone adjacent to the peripheral attachment of the aortic leaflets at the sinotubular junction, it is termed commissural origin.

Abnormal ostia due to slit-like openings, acute angle of takeoff, or fibrous valve-like ridges can cause flow impairment.

Right Coronary Artery

The right coronary artery occupies the right atrioventricular groove (Adams and Treasure, 1985). Its first part extends to the acute margin of the ventricular mass, where it gives rise to the acute marginal artery, giving rise to many atrial branches from its cranial

surface. It extends to the apex forming anastomoses apex between the anterior interventricular (left anterior descending) artery. It also gives rise in this part of its course to the infundibular artery (in half the population), unless it arises directly from the aorta, and in just over half the population, to the artery supplying the sinus node (in two-fifth of the population, it arises from the circumflex vessel). In some, the infundibular artery anastomoses with an infundibular branch of the anterior descending artery—called arterial circle of Vieussens.

The right coronary artery itself then continues to encircle the tricuspid valve, reaching the crux. It gives rise to the right inferior ventricular branches, which supply the diaphragmatic wall of the right ventricle from this segment. In nine-tenths of the population, having reached the crux, the right coronary artery gives rise to the inferior interventricular (posterior descending) artery and the artery to the atrioventricular node—right dominance. Atrioventricular nodal artery forms a U-loop forming the floor of the triangle of Koch. This artery, along with the septal branches from the anterior descending artery, supplies the proximal portion of the atrioventricular conduction apparatus. The right coronary artery then continues to supply variable portion of the diaphragmatic wall of the left ventricle.

The posterior descending (inferior interventricular) artery arises from the right coronary artery in all of the 90% of individuals with right coronary arterial dominance, and from the circumflex artery in the remaining one-tenth (more common in males). There are anastomoses from this artery with parallel branches of the right marginal artery and perpendicular branches of the anterior descending artery in the inferior atrioventricular groove and at the apex. Perforating branches from the artery supply the inferior part of the muscular interventricular septum, the adjacent ventricular walls, and the posteromedial papillary muscle of the mitral valve in those individuals with right coronary arterial dominance. Rarely, the anterior descending artery can extend into the inferior interventricular groove, wrapping over the apex, supplying the territory usually tended by the posterior descending artery.

There are variations to the origin of the posterior descending artery; it can originate at the crux as in most instances (approximately 60%) or can branch off before the crux runs along the acute margin of the right ventricle before reaching the posterior interventricular groove (approximately 30%). In some instances, the acute marginal artery itself reaches the distal part of the posterior interventricular groove.

The Left Main Stem

As the left main stem exits from the aortic sinus, it enters the left margin of the transverse sinus, between the left atrial appendage and the pulmonary trunk. It has a length rarely more than 1 or 2 cm in the adult, after which it divides into the circumflex and anterior descending branches. The main stem usually measures between 5 and 10 mm in diameter (Medrano-Gracia et al., 2016).

It supplies a larger mass of myocardium—most of the left ventricle, the muscular ventricular septum, and the anterolateral papillary muscle of the mitral valve, the left atrium, and in about half the population gives rise to the sinus nodal artery. In around one-quarter of the population, the main stem also gives rise to an intermediate branch and rarely to two intermediate arteries.

When there are separate origins of the anterior descending and circumflex arteries, the main stem is evidently absent. This exists in 0.41%–0.52% of individuals and carries no hemodynamic consequences.

The left main bifurcation angle is 89 ± 21 degrees for cases with and 75 ± 23 degrees for those without an intermediate (ramus) artery.

The Left Anterior Descending Artery

The left anterior descending artery emerges on the anterosuperior surface of the heart, coursing around the base of the pulmonary trunk to lie in the anterior interventricular groove. It then runs to the ventricular apex, in some individuals continuing around the apex and extending to variable distance within the inferior interventricular groove. It supplies the apex of both right and left ventricles. It gives rise to two groups of vessels, the diagonal arteries and the septal perforators; both sets vary in their number and course. During its course, the anterior descending artery can give rise to as many as three to four diagonal branches, coming off at acute angles to supply the lateral wall of the left ventricle. There are also a variable number of septal perforating branches. The deep septal perforators branch at right angles to the anterior descending artery and supply the anterior two-thirds of the muscular ventricular septum. The first and rarely the second or third of these also supply the atrioventricular conduction axis. The anterior descending artery can also give rise to an infundibular branch, leading to an anastomotic circle around the infundibulum.

The Circumflex Artery

The circumflex artery passes posteriorly from the main stem, running in the posterior atrioventricular groove. In most individuals, it runs for a short distance within the groove before ending as the obtuse marginal artery or branches. In minority (10%), it reaches the crux of the heart, giving rise to the atrioventricular nodal artery, and occasionally beyond the crux to supply the diaphragmatic surface of the right ventricle—left coronary arterial dominance. The circumflex artery hence supplies the lateral and posterior walls of the left ventricle and the anterolateral papillary muscle of the mitral valve.

The Intermediate Artery

In some individuals, the left main stem branches into three rather than two arteries. The third branch is called the intermediate or the ramus branch and is of varying size.

Coronary Arterial Dominance and Perfusion Territories

In the majority, it is the right coronary artery that supplies the inferior wall of the right ventricle and the inferior portion of the muscular ventricular septum (Adams and Treasure, 1985), whereas the branches of the left coronary artery supply the majority of the anterolateral walls and the obtuse margin of the left ventricle. In addition, in up to half the population, the dominant right coronary artery also supplies a significant part of the diaphragmatic wall of the left ventricle. In right dominance, it is the branches of the right coronary artery that typically supply the posteromedial papillary muscle of the mitral valve. In case of an extremely dominant right coronary artery (with hypoplastic circumflex artery), the branches of the right coronary artery can supply the entire inferior wall of the left ventricle.

Coronary circulation is right dominant when the posterior descending artery and posterolateral branches originate from the right coronary and left dominant when they both originate from the circumflex vessel. A balanced coronary circulation is defined when the posterior descending artery originates from the right and all posterolateral branches from the circumflex. However, a more accurate definition of dominance is the arterial origin of the atrioventricular nodal artery. The typical right dominant circulation is found in 71%—in this pattern, the RCA supplies ≈15% and the left coronary artery ≈85% of the left ventricle. A left dominant circulation pattern is present in 10%–12% of cases in which the left coronary artery supplies all the flow to the left ventricle, and the circumflex gives rise to the posterior descending artery. The remaining 17% of hearts have balanced circulation.

Despite the earlier generalization, normal variations exist. A long left anterior descending artery that wraps around the left ventricular apex can supply a variable portion of the inferior wall. The circumflex artery usually supplies a variable extent of the lateral wall, depending on the number and size of the obtuse marginal branches, the number and size of diagonal branches from the LAD, the presence of posterolateral branches from the right, and the presence of an intermediate branch. The inferior wall demonstrates the largest variability of vascular supply.

The AHA 17-segment model recommends the following: Segments 1, 2, 7, 8, 13, 14, and 17 are assigned to the left anterior descending artery distribution (Donato et al., 2012). Segments 3, 4, 10, and 15 are assigned to the right coronary when it is dominant, and segments 5, 6, 11, 12, and 16 are generally assigned to the circumflex artery. However, the normal variations in coronary perfusion distribution make these assigned segments inaccurate (Cerci et al., 2012). For example, circumflex artery can be the main artery for the blood supply of the inferior wall segments even if the origin of the posterior descending artery is from the right coronary (Detre et al., 1975).

Coronary Anomalies

The concept of normal variant versus anomaly is based on a definition of coronary anomalies as patterns observed in less than 1% of the population (Waller et al., 1992a,b,c; Pérez-Pomares et al., 2016; Ripley et al., 2014; Altin et al., 2015; Angelini and Flamm 2007; Shriki et al., 2012). In the normal population, there is a wide variation in the absolute origin and course of a particular coronary artery. Coronary anomalies come in various forms—anomalous origins of the arteries, anomalous epicardial course, or other abnormal features such as myocardial bridging or abnormal communications. Clinically relevant variations in the origin and course of the coronary arteries in normal hearts (without congenital defects) are rare. Reported incidence of such anomalies is about 0.3% in an autopsy series and higher at 1.6% in a larger angiographic cohort. Anomalies carry a higher risk for atherosclerosis and could present with cardiac symptoms or sudden death. The task force of the American Heart Association on sudden death attributes one-fifth of such instances in young athletes to coronary arterial anomalies.

Anomalies are more commonly found in patients with congenital cardiac diseases such as tetralogy of Fallot, transposition, and bicuspid aortic valves.

Classification of anatomic variations
Appropriate sinus origin
High
Low
Commissural
Anomalous sinus origin
Right coronary artery arising from left coronary sinus
Main stem of left coronary artery arising from right coronary sinus
Circumflex artery arising from right coronary sinus
Anterior descending artery arising from right coronary sinus

Classification of anatomic variations
Right or left coronary artery arising from noncoronary (posterior) sinus
Ectopic origin of coronary artery
From pulmonary trunk
From right pulmonary artery
From left pulmonary artery
From brachiocephalic artery
Solitary coronary artery
Abnormal distal connections (Fistulas)
Connections with a cardiac cavity
Coronary arteriovenous fistulas
Coronary to extracardiac arterial or venous connections
Anomalies of intrinsic anatomy
Coronary ostial stenosis or atresia
Coronary ectasia or aneurysm
Absent coronary or hypoplasia
Miscellaneous anomalies of intrinsic anatomy
Myocardial bridging
Duplication of coronary arteries

Whatever sinus they originate from, there are three possible proximal routes of the coronaries: (a) retroaortic, (b) interarterial, or (c) prepulmonary. Some have described a fourth pattern, a so-called transseptal course. This so-called transseptal course is a variant of the interarterial route. Here, either the left main stem or the anterior descending artery courses toward the subpulmonary infundibulum but then emerges, entering the basal muscular septum.

Certain combinations of sinus origins and proximal coronary courses stand out as being frequent.

Gender Variations

In a retrospective analysis of nearly 7800 coronary angiograms (Aydar et al., 2011), females were noted to have a higher incidence of specific coronary anomalies than males (4.4 vs. 2.9%). They also presented with a higher incidence of a separate origin of the circumflex artery and left anterior descending artery from the left sinus of Valsalva compared with males (3.1 vs. 1.1%, although this may not be considered as an anomaly by most). There was no difference in the frequencies of the second most common anomaly, that is, circumflex from the right sinus or the right coronary artery, between males and females. Males were found to have a higher incidence of myocardial bridges (1.5 vs. 0.85%). No differences in gender were detected for fistulas.

High-Takeoff Coronary Arteries

A high-takeoff coronary artery is defined as arising at least 1 cm in adults or 20% the depth of the sinus in children above the sinotubular junction. The prevalence of high-takeoff coronary arteries in the general population is about 0.20%. Right coronary arteries make up 85% of reported cases (it is also reported with increased frequency with bicuspid aortic valve). About 4% were noted to have either an acute angulation from the aorta, an interarterial, or an intramural course. In these cases, reduced coronary flow results from (a) intramural intussusception, (b) coronary hypoplasia (including ostial hypoplasia or slit-like aortic ostium), (c) external compression, or (d) combination of factors (Loukas et al., 2015).

The Circumflex Artery Taking Its Origin From Right Sinus

The circumflex artery taking its origin from right sinus most frequently takes a retroaortic course, passing through the transverse sinus of the pericardium to emerge into the posterior atrioventricular groove between the left atrial appendage and the pulmonary trunk. This course is of no clinical significance, unless the origin is intramural. Circumflex arising from the right sinus or right coronary artery, with retroaortic course, accounts for about half of all reported anomalous arrangements—between 0.45% and 0.67% in patients undergoing coronary angiography.

Retroaortic course of a solitary coronary artery is much rarer but may be of clinical significance, as it may preclude to premature atherosclerotic disease. A prepulmonary course running anteriorly across the subpulmonary infundibulum from their anomalous sinus origin is considered benign and is seen most frequently when the left main stem or one of its branches arises from the right sinus or the right coronary artery from the left sinus. The prepulmonary course is of far greater significance in the setting of congenitally abnormal hearts, such as tetralogy of Fallot or transposition.

The interarterial course is of greatest clinical significance, as this "malignant" anomalous pattern is most frequently associated with sudden cardiac death. There are many anomalous sinus origins that can be associated with such an interarterial course. However, the most frequent are those where the coronary artery originates from the opposite sinus, such as the left main stem arising from the right sinus, or the right coronary artery arising from the left sinus. Frequently, the coronary artery itself also takes an intramural course as it exits from the aortic sinus leading to further luminal compromise. When the LAD originates from the RCA or the right sinus of Valsalva, it runs between the aorta and the pulmonary artery in 75% of the cases. Anomalous left coronary connection to the right sinus is considered more malignant because of the larger amount of myocardium at ischemic risk. Causes of myocardial ischemia include (i) increased cardiac output and dilation of the aorta and pulmonary artery, with compression of the anomalous vessel coursing in between; (ii) the acute angle takeoff of the anomalous vessel with further stretch during exercise leading to a flap-like closure of the ostium; (iii) spasm or kinking of the anomalous vessel; and (iv) the course within the aortic wall (intramural) of the proximal segment of the anomalous vessel. Higher rates of major adverse cardiac events have also been reported with a high interarterial course (right coronary ostium located above the level of the pulmonary valve) as opposed to low interarterial course (ostium below pulmonary valve).

Transseptal Course

When a coronary artery arises from the contralateral artery or cusp and takes a course through the septal myocardium, it has a transseptal route. A transseptal artery has a lower position than an interarterial artery and is located caudad to the crista supraventricularis. Usually, the transseptal artery is the left anterior descending artery or the left main vessel.

Intramural Course of Coronaries

Normally, coronary arteries arise at right angles to the wall of the aortic sinus. In the intramural variant, the artery runs for varying lengths within the aortic wall, taking course obliquely before its own discrete walls cover its lumen. Intramural origin can be the result of high takeoff but more commonly is in the plane of the sinotubular junction, where the peripheral aspects of the aortic leaflets are attached; consequently, this part of the aortic wall is thicker. Intramural and/or intussuscepted portions of anomalously coronary arteries are generally hypoplastic, with an ovoid rather than a circular cross-sectional profile.

Ectopic Origins of Coronary Arteries

The most frequent ectopic origin is from the pulmonary trunk or one of its branches although origins from the brachiocephalic or subclavian arteries are reported (more commonly with the right coronary). The pulmonary origin is potentially fatal unless diagnosed and treated surgically, because the coronary artery, and the myocardium it supplies, is fed with desaturated blood. In 90% of cases, the left main is the anomalous artery. The extent of the collateral circulation between the two coronaries is the major determinant of the degree of ischemia, severity of clinical presentation, and outcome.

Solitary Coronary Arteries

Solitary coronary arteries can cause sudden cardiac death and has the potential to precipitate severe ischemic heart disease, including myocardial infarctions, in the young. Their incidence is reported to be approximately 0.024%–0.044% of the general population. Such arteries can originate from the left sinus and divide into an anterior interventricular artery and left circumflex coronary artery as normal. The circumflex that is dominant gives rise to the posterior descending artery and continues through the anterior atrioventricular groove to supply the area usually tended by the right coronary artery. A solitary right coronary artery can take one of two forms. It can continue beyond the crux, run through the posterior atrioventricular groove, and terminate as the anterior descending artery, or alternatively, it can give rise to the left main stem, which can then take either retroaortic, interarterial, or prepulmonary course before branching into the anterior descending or circumflex arteries. The interarterial pattern is the most pathologically significant.

Coronary ostial stenosis or atresia is a rare condition, with most of the reported cases discovered at angiography and involving the left main. Clinical presentation is usually early in the first year of life.

Abnormal Distal Connections

Coronary Artery Fistulas

Coronary artery fistulas are rare and lead to a direct communication between a coronary artery and (a) one of the cardiac chambers, (b) the coronary sinus, (c) a venous structure, or (d) a pulmonary artery. Fistulas between the coronary arteries and either the

coronary venous system or the cardiac chambers are seen in up to 0.5% of individuals. They are of functional importance as the abnormal communication bypasses the myocardial capillary bed frequently (in 90%) causing a left-to-right shunt. With larger fistulas, a diastolic "coronary steal" may exist, drawing blood away from the normal coronary tree, leading to myocardial ischemia. They can be remarkably tortuous, and the right coronary artery is more commonly involved than the left. The most common fistulous sites occur in the right ventricle in 41%, right atrium in 26%, pulmonary artery in 17%, coronary sinus in 7%, left ventricle in 3%, and superior vena cava in 1% of cases.

About half of the patients remain asymptomatic; the other half develop complicating features such as infective endocarditis, myocardial ischemia, pulmonary hypertension, high-output cardiac failure, and rupture. Most fistulas grow over time, and large fistulas may lead to heart failure associated with high-flow shunting.

Collaterals

Collateral arterial circulation typically occurs as a response to ischemic myocardium in the setting of severe atherosclerosis (Loukas et al., 2009b), suggesting the development of the collateral arteries to be strongly associated with slowly developing coronary arterial obstruction. It is only when circulation is impaired that the collateral vessels, through the process of arteriogenesis, attain functional role. The process of arteriogenesis converts the preexisting collateral arterioles to mature into functional muscular arteries. There is increase in luminal pressure, proximal to the collateral branch as vascular obstructions develop. This rise in pressure widens the lumen of the collaterals, allowing for physiologically relevant flow. This shear stress essentially induces the formation of collateral arteries from a preexistent network.

The collateral arteries arise from the same tissue components as the native coronaries during development, and as such are histologically indistinguishable. However, the native coronary arteries develop from base to apex, along the direction of blood flow—larger arteries develop first, and the branching follows. The collateral arteries do not follow this pattern, and these bridging vessels can allow flow in both directions.

Endomural collateral arteries are found between coronary arteries, whereas extracardiac collateral arteries take origin most commonly from the bronchial or internal thoracic arteries. Collaterals from the bronchial arteries typically occur at sites of pericardial reflections and communicate most frequently with the circumflex artery and can be found in up to one-fifth of normals. Collaterals originating from the internal mammary arteries typically occur between the right internal mammary and right coronary arteries or between the left internal mammary and the posterior descending artery, in response to myocardial ischemia.

Research suggests a strong protective role for a well-developed collateral coronary arterial circulation. During acute coronary occlusion, long-term cardiac mortality is reduced to 25% when compared with patients without collateral supply. Well-developed collaterals are ready to resupply the myocardium within minutes to hours if reocclusion occurs.

Myocardial Bridging

Myocardial bridge is the second most common type of the coronary artery anomaly. During their passage in the epicardium, epicardial portions of the coronary arteries can dive to form an intramyocardial course, reemerging more distally—known as myocardial bridging (seen in up to one-third of patients on CT). The anterior descending artery has been reported by some to take a partially transmural course in up to four-fifths of individuals. Bridging of arteries other than the anterior descending branch, nonetheless, should probably be considered as anomalies rather than normal variations. The length of the myocardial bridges in the males is noticeably longer than that of the females. Symptoms and ischemia tend to occur specifically when the bridging segments are long (2–3 cm) and deep (2–3 mm) within the myocardium.

Three main conditions can lead to ischemia in myocardial bridging: (a) the "spillover" phenomenon—persistence of narrowing in early diastole—the more severe the systolic narrowing, there is higher likelihood of "spillovers" occurring; (b) periods of tachycardia, in which systole occupies a greater percentage of the cardiac cycle due to shortening of the diastolic period; and (c) microvascular compression. The tunneled segment is often spared from atherosclerotic disease, although the presence of atherosclerosis is frequently seen in the segment proximal to the bridge.

Duplication of Coronary Arteries

Any of the three coronary arteries can be duplicated, but most frequently, it is the anterior descending artery that has this pattern—in up to 1% of the population. It is frequently seen as a short artery that terminates proximally within the anterior interventricular groove, and a longer one that extends to the apex.

It is important to note that any of the indicated coronary anomalies can coexist with congenital heart malformations.

Age-Related Changes in the Coronaries

In fetal coronaries, the intima and the adventitia are less well developed. However, the media is well developed with a circular layer of smooth muscle cells and fine elastic fibers. The intima is a continuous single layer of endothelial cells. After birth, the internal elastic lamina fragments with proliferation of fibroblasts and increase in the ground substance in the subendothelium. This leads to a "musculoelastic" layer between the intima and the media. The external elastic lamina forms by 6 months of age (Waller et al., 1992b).

In normal human coronaries, the amount of smooth muscle cells and fibroelastic tissue is a function of age. Intima progressively thickens, and by late adolescence, it is as thick as the media; beyond this age group, it becomes thicker than the media. By the middle age, the intima shows evidence of atherosclerosis, and the overlying media thins with discontinuation, fragmentation, and/or disappearance of the internal elastic lamina. Degenerative changes such as calcium deposition take place in the intima but rarely in the media. With older age, the arteries become tortuous, and the calcific deposits increase.

Coronary Blood Flow

Coronary anatomy alone is never sufficient to predict physiological status at the level of the myocardial bed (Schelbert, 2010; Gould, 2009). The coronary circulation has in effect two compartments, the large epicardial conduit vessels and the resistance vessels, typically less than 300 μm in diameter. Whereas the conduit vessels exert little if any resistance to flow, resistance to flow progressively increases as the vessel diameter of the resistance vessels declines from about 300 μm in the small arteries to less than 100 μm in the arterioles. Intracoronary pressures decline along the microvasculature (with most of the pressure dissipating in the 300–100 μm diameter vessels) until reaching a pressure of 20–30 mmHg, still adequate to maintain a gradient across the capillaries.

Myocardial flow increases are initiated by a metabolically mediated decrease in microvascular resistance, possibly involving adenosine as a metabolite of adenosine monophosphate and causing vascular smooth muscle relaxation. The resulting flow increase is augmented by endothelium-dependent factors; higher flow velocities exert greater shear-stress forces upon the endothelium with stimulation of the endothelial nitric oxide synthase and release of the smooth muscle relaxing nitric oxide (NO). Endothelial cells interact with vascular smooth muscle cells to regulate the vessel diameter to changes in flow velocities ("flow-mediated dilation"), both at the level of the microvessels and the epicardial conduit vessels. In addition, both endothelial and vascular smooth muscle cells have adrenoreceptors and thus respond to regional and systemic sympathetic stimuli. This finely tuned interaction between vasoconstrictive (vascular smooth muscle-dependent) and vasodilator forces (mostly endothelium-related) regulates the vessel diameter against the flow velocity to minimize resistance to flow, thereby increasing myocardial flow.

Myocardial flow reserves of less than 2.0 or 2.5, based on findings with intracoronary flow velocity probes, are now accepted as the lower limit of normal. Flow reserves of <1.5 are predictive of poor long-term outcomes (increase in mortality and progression to heart failure). Flow responses to vasodilator stress in coronary artery disease may differ from those during physical exercise. Instead of an attenuated or absent flow-mediated conduit vessel dilation, physical stress may, as mentioned earlier, actually lead to a decrease in the vessel lumen or the stenosed vessel diameter, possibly due to increased α-adrenergically stimulated smooth muscle constriction (local release of norepinephrine from adrenergic nerve terminals in the coronary arteries and release of catecholamines from the adrenal glands into the circulation) or release of vasoactive substances from the endothelium.

Flow limitation depends not only on the degree of luminal narrowing but also on the length of the stenosis, its eccentricity, its in- and outflow angles, and surface properties. In addition, functional adaptations to structural disturbances do happen.

Microvascular disease in the absence of apparent coronary vessel disease can occur. Conditions that cause this include diffuse luminal narrowing without discreet coronary stenosis, systemic vasculopathies associated with inflammatory disorders, transplant vasculopathies, and microangiopathies (e.g., in diabetes), or in hypertrophic cardiomyopathy.

Introduction

The purpose of this article is to give the reader, a scientist or a scientist in training, an overview of coronary artery bypass grafting from the clinician's point of view. Accordingly, it is written and edited with that in mind explaining some of the clinical terms in what is close to lay terms, while taking liberties at times with some of the fascinating science behind the clinical events, using terms more familiar to scientists. The article starts with a brief look at the embryology of the human heart, a description of the anatomy, especially with regard to the myocardial circulation, and the coronary arteries. After an introduction to the pathophysiology of coronary artery disease, specifically atherosclerosis, the discussion of CABG begins, starting with the history of CABG, cardiopulmonary bypass, current thinking about the evidence for indications and selection, some basic science aspects of vascular biology that support decision-making, the technique of CABG, and an overview of perioperative management.

Background

Over the past half century, restoring the circulation to the heart (myocardial revascularization) has evolved into a standard of care that has changed and saved and improved the lives of millions of people worldwide. In the context of the changes in the practice of medicine since the industrial revolution, restoring the circulation to the heart when the myocardial blood supply has been compromised has been one of the pivotal advances in medicine and surgery. One tool in that armamentarium has been coronary artery bypass grafting (CABG). While the acronym for this procedure, CABG (pronounced "cabbage"), has been decried by some as degrading as it is the name of a common vegetable, it has stuck and has been accepted over its nearly 50 year history.

Embryology and Anatomy

The heart is a four-chambered dual pump (Fig. 1). It is a double pump responsible for blood flow to both the lungs (the pulmonary circulation for gas exchange) and the rest of the body (the systemic circulation primarily for delivery of oxygen and nutrients).

Embryologically, in keeping with the concept that ontogeny recapitulates phylogeny, the human heart begins with a tube (much like that of a fish) that eventually folds and compartmentalizes into two separate hearts (Fig. 2). Those two hearts ultimately fuse into a four-chambered interdependent muscular pump supplying two separate and connected circulations, pulmonary and systemic. In cardiac hemodynamics, this tandem arrangement is truly interdependent, as the flow through the pulmonary circulation (right side of the heart) in the normal healthy person must equal that of the systemic circulation (left side of the heart).

The right side of the pump generates flow to the pulmonary circulation, while the left side pumps to the systemic circulation. Approximately five liters of blood each minute courses through this double pump as it generates blood flow through both the pulmonary and systemic circuits. The left (systemic) side of the heart pumps oxygen (O_2)-rich blood through the arterial system to the tissues of the body to support aerobic metabolism. Having delivered its load of O_2, the deoxygenated red blood cells along with a plasma load of dissolved carbon dioxide return to the right (pulmonic) side of the heart to be pumped to the lungs for gas exchange then return to the left heart to repeat the process (Fig. 3).

While this huge volume of blood courses through the chambers of the heart each minute, the heart's share of that blood is delivered to the myocardium, the heart muscle, via its own circulation, the coronary arteries. The coronary arteries are so named as they course over the top and sides of the surface of the heart much like a crown named by the early anatomists who used the Latin for crown (corona). While the anatomical pattern is generally consistent, there is usually normal and occasionally abnormal variability (Fig. 4).

Atherogenesis

The coronary arteries in some individuals develop atherosclerosis, commonly called hardening of the arteries. In fact, calcified atherosclerotic plaques feel hard to the touch. Touching of the heart was limited to postmortem examinations in early days, and since the advent of cardiac surgery, expanded to the operating room.

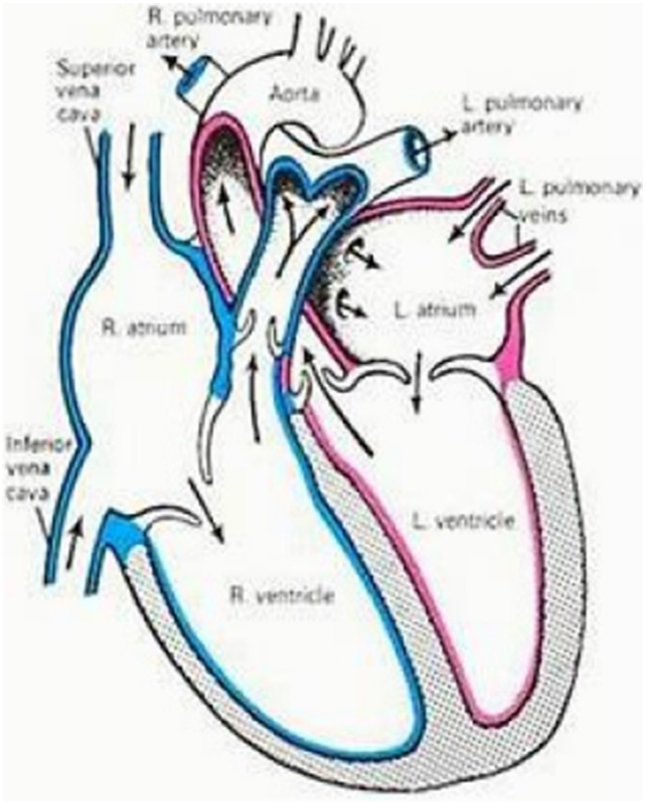

Fig. 1 The four chambers of the heart and the tandem nature showing the direction of blood flow and depicting the chambers and vessels with oxygenated blood in red and those with deoxygenated blood in blue.

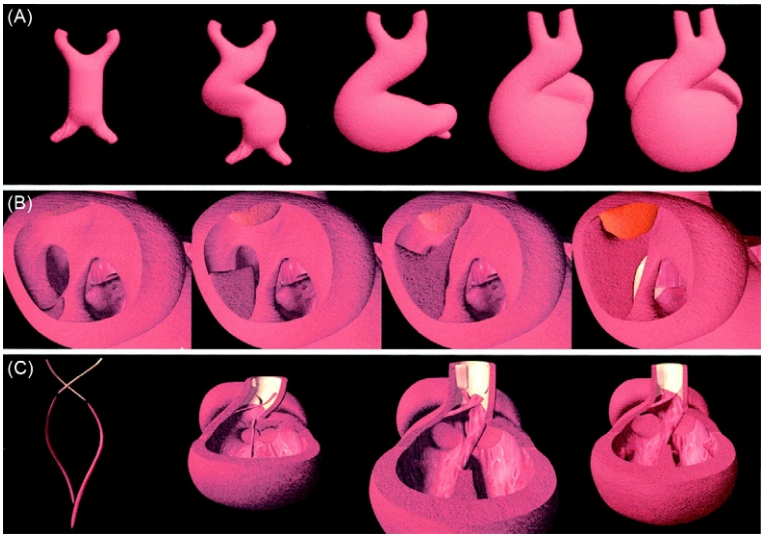

Fig. 2 Embryogenesis from days 21 to 28: (A) The cardiac loop is formed. The heart tube is folded into an S-shaped dextro-ventral convexity. (B) The atria are partitioned. The septum primum (*in brown*) grows from the inferior part of the atria to the top, leaving a foramen called the ostium primum. The septum secundum (*in orange*) comes from the top. The ostium primum will be closed at the end of the fifth week by an expansion of tissue coming from the endocardial cushions (*in yellow*). (C) The conus and the truncus are partitioned. The dextrodorsal and sinistroventral conus ridges, which are isolated in the first picture, partition the conus by a helical outgrowth into two cavities: the subpulmonary and the subaortic coni. The truncus is partitioned from the bottom upward from aorticopulmonary swellings, leading to the formation of the aorta and pulmonary arteries. The term atherosclerosis is derived from Latin and Greek roots meaning "gruel or pasty" (athero) and hard (scler), ultimately gaining acceptance as the lay term, "hardening of the arteries." The deposition of this pasty material in the coronary arteries, a consequence of the metabolism of some types of cholesterol, ultimately becomes calcified with time, and becomes firm or hard. In its early stages atheromas consist of soft plaque that can rupture and promote thrombosis, occluding the coronary artery, interrupting myocardial blood supply, and potentially causing a myocardial infarction (heart attack). In its more chronic and progressive form, the atheromatous plaque results in coronary insufficiency, a supply-demand problem, where the blood supply through narrowed coronary arteries to a segment of the heart is not adequate to meet metabolic demands (Figs. 5 and 6).

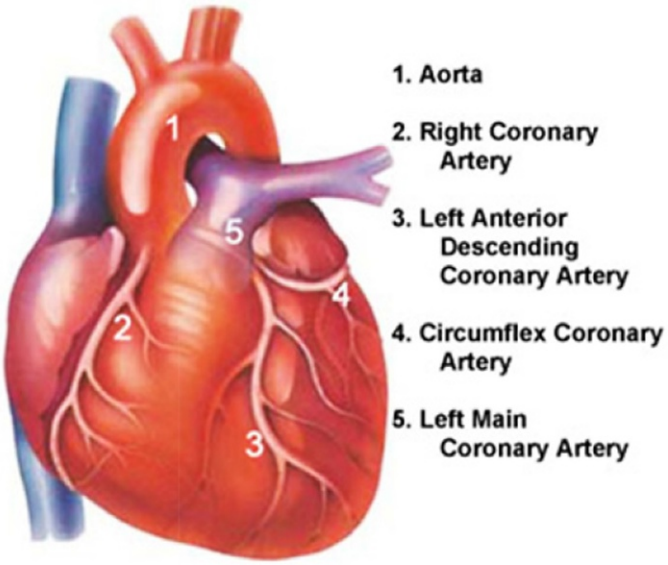

Fig. 4 This illustration depicts the usual distribution of the coronary arteries. Note that the major vessels are epicardial, coursing over the surface of the heart, making them easily accessible to the cardiac surgeon for revascularization. From daviddarling.info.

Fig. 5 Plaque is shown beneath the lining of the artery, showing how the artery's lumen is accordingly narrowed, and the lining of the vessel is still intact.

Fig. 6 Plaque rupture is shown from the vantage point of the cellular elements coursing through the artery with platelets aggregating at the rupture site to begin the formation of a clot. From Crystalgraphics.

The clinical presentations of coronary artery disease range from patients who are virtually asymptomatic to those who experience sudden death with little or no warning. On one end of the spectrum, patients may present with chest discomfort (angina) with exertion or at rest to more extreme acute coronary syndromes, including myocardial infarction. Treatment that consisted of medical management with rest and medications such as nitroglycerine was all there was to offer to these patients until the late 1960s and early 1970s, the time when CABG surgery was conceived and implemented. During the first half of the 20th century, innovative surgical strategies to restore blood supply to those hearts were suboptimal. By the early 1960s there were a few reports of success surgically bypassing occluded and stenotic (narrowed) vessels. The advent of a reliable method to visualize the coronary artery anatomy (coronary angiography) in that decade led to the beginning of the CABG era.

Diseases addressed by cardiac surgery are divided into two main categories: congenital/genetic and acquired. Congenital and genetic cardiac disorders are driven by events that result in structural abnormalities that become apparent very early in life, even in utero, or genetically acquired defects that may effect cardiac and great vessel structure later in life. Clarity in categorizing diseases is often challenging because of overlap. While coronary artery disease (CAD) is considered to be in the category of acquired cardiac disease, there is a clear genetic component with offspring of parents with premature CAD (Khurram et al., 2007) having a higher predilection for acquiring CAD than others. The multifactorial etiology of CAD is apparent as atherogenesis is driven by multiple factors: genetics, lifestyle (smoking, diet, and exercise), and metabolism (such things as diabetes and obesity).

Atherogenesis (the formation of atherosclerosis from the root "gen," meaning to form) is a disorder of the artery wall that may be the result of a chronic inflammatory fibroproliferative process that has become excessive and in its excess this protective response becomes the disease state, a maladaptive response. The process starts with the adhesion of monocytes and lymphocytes (white blood cells) to the luminal side of the endothelial cell lining of the coronary arteries. Those monocytes migrate into the subendothelial space and differentiate into macrophages. Once those macrophages ingest low-density lipoproteins (LDL), the LDL is modified in such a way (such as oxidation) that cholesterol esters accumulate inside and form "foam cells," which are really dead macrophages engorged with LDL. When foam cells combine with T lymphocytes the fatty streak is formed, the beginning of the atherosclerotic plaque is formed by migration of vascular smooth muscle cells from the media of the vessel to the intima. Eventually a fibrous cap is formed, completing the plaque. Ironically, the body's effort to manage this fatty endovascular deposition results in the proliferation of atherosclerotic plaques. This exuberant response is regulated by inflammatory cytokines released by the foam cells and growth regulatory peptides released by platelets, and in the case of coronary artery disease, the body's protective intent becomes the disease (Ross and Agius, 1992) (**Fig. 7**).

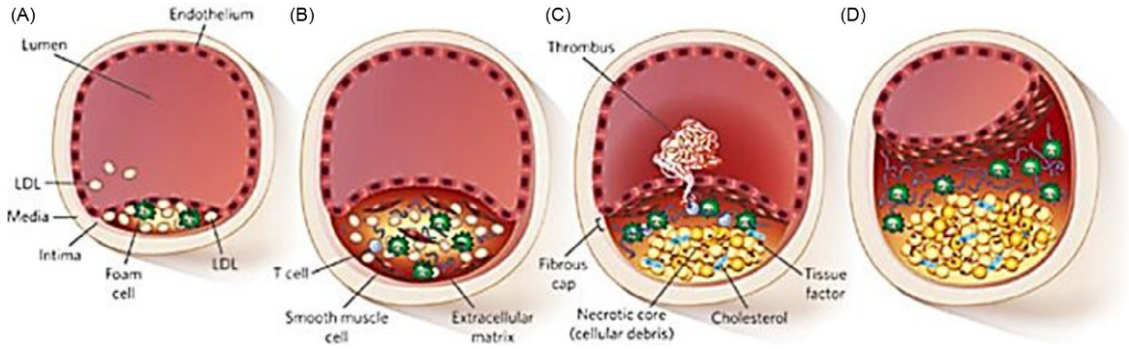

Fig. 7 Atherosclerosis occurs at sites in the arterial tree where laminar flow is disrupted. A lesion begins as a fatty streak (A) and can develop into an intermediate lesion (B), and then into a lesion that is vulnerable to rupture (C) and, finally, into an advanced obstructive lesion (D). A more detailed description of this process is as follows: (A) Atherogenic lipoproteins such as low-density lipoproteins (LDLs) enter the intima, where they are modified by oxidation or enzymatic activity and aggregate within the extracellular intimal space, thereby increasing their phagocytosis by macrophages. Unregulated uptake of atherogenic lipoproteins by macrophages leads to the generation of foam cells, which are laden with lipid. The accumulation of foam cells leads to the formation of fatty streaks, which are often present in the aorta of children, the coronary arteries of adolescents, and other peripheral vessels of young adults. Although they cause no clinical pathology, fatty streaks are widely considered to be the initial lesion leading to the development of complex atherosclerotic lesions. (B) Vascular smooth muscle cells—either recruited from the media into the intima or proliferating within the intima—contribute to this process by secreting large amounts of extracellular-matrix components, such as collagen. The presence of these increases the retention and aggregation of atherogenic lipoproteins. In addition to monocytes, other types of leukocyte, particularly T cells, are recruited to atherosclerotic lesions and help to perpetuate a state of chronic inflammation. As the plaque grows, compensatory remodeling takes place, such that the size of the lumen is preserved while its overall diameter increases. (C) Foam cells eventually die, resulting in the release of cellular debris and crystalline cholesterol. In addition, smooth muscle cells form a fibrous cap beneath the endothelium, and this walls off the plaque from the blood. This process contributes to the formation of a necrotic core within the plaque and further promotes the recruitment of inflammatory cells. This nonobstructive plaque can rupture or the endothelium can erode, resulting in the exposure of thrombogenic material, including tissue factor that stimulates the formation of a thrombus in the lumen. If the thrombus is large enough, it blocks the artery, which causes an acute coronary syndrome or myocardial infarction (heart attack). (D) Ultimately, if the plaque does not rupture and the lesion continues to grow, the lesion can encroach on the lumen and result in clinically obstructive disease. Above quoted from the following article and illustration taken from Rader, D. J. and Daugherty, A. (2008). Translating molecular discoveries into new therapies for atherosclerosis. *Nature* **451**, 904–913. https://doi.org/10.1038/nature06796.

The CABG Era

Currently, CABG surgery is performed on over 400,000 patients in the United States annually, and since its inception has provided myocardial revascularization world-wide to millions. During the first half of the 20th century, strategies to restore cardiac blood supply were manifold and included scarifying the surface of the heart or applying muscle flaps or omentum to induce collateral vessel ingrowth, cervico-dorsal sympathectomy, coronary sinus constriction or arterialization, and internal mammary artery (IMA) ligation. Some of these procedures would occasionally bring symptomatic relief of angina, encouraging proponents, but following an historic randomized trial comparing IMA ligation with a control sham operation of sternotomy alone, the procedure of IMA ligation was shown to be ineffective (Cobb et al., 1959).

The Vineberg Procedure

In 1945, Arthur Vineberg, MD, from Montreal, noting the sinusoidal microcirculation peculiar to the myocardium, postulated that a systemic artery, imbedded in the myocardium, might find adequate runoff into these sinusoids to remain patent and to increase blood flow to the myocardium (Vineberg, 1958) (**Fig. 8**).

During the next four years, he pursued his idea in the animal lab and discovered that, if he rendered the myocardium ischemic by obstructing the flow in the principle artery to the left ventricle (left anterior descending coronary artery or LAD), the implanted left internal mammary artery (LIMA) would not only maintain flow and remain open, but would, over time establish connections to arterial branches of the coronary circulation. In 1950, he performed this procedure for the first time on a patient with severe coronary insufficiency. The patient survived the procedure but died a short time later, before the effect of the procedure could be ascertained. The procedure was repeated on a second patient who lived for ten years and was significantly improved. Dr. Vineberg continued to perform these operations and many of his patients enjoyed dramatic improvement. Many of his colleagues around the world remained skeptical, doubting that meaningful connections were actually being formed to the coronary arteries. There were some advocates of this procedure, including Dr. Bigelow in Toronto and Dr. DeBakey in Houston, who were able to show flow in the heart muscle from Vineberg's operation by using the then new technology of coronary angiography (Bigelow et al., 1966). At this point in history, cardiac surgeons were on the cusp of the CABG era when direct anastomoses of both the mammary artery and saphenous vein graft became feasible and successful, with instant revascularization. The knowledge from coronary angiography that the Vineberg procedure did actually revascularize the myocardium came late and was eclipsed by CABG surgery and has remained so since (Thomas, 1999).

Blood escapes from internal mammary artery into myocardial sinusoids, which is why the implanted vessel remain open until its own branches join the coronary arterioles. From Vineberg, A. (1958). Coronary vascular anastomoses by internal mammary artery implantation. *Canadian Medical Association Journal***78**, 871–879. Copyright © by the Canadian Medical Association.

Coronary Angiography: The Beginning

In 1958, pediatric cardiologist, Mason Sones, at the Cleveland Clinic, while performing a heart catheterization on a 27-year-old patient with rheumatic heart disease, accidentally injected a bolus of dye into his right coronary artery, an error known to be fatal. The result was cardiac arrest and a beautiful picture of the coronary artery. The heart was restarted with a cough, and coronary angiography was born, albeit in the face of vigorous opposition from others in the cardiac field who thought the technique was ethically irresponsible (Sones et al., 1959). Sones and his cardiology fellow, Earl Shirley, perfected the technique and began performing angiograms on hundreds of patients from all over the country, including many patients who had had previous Vineberg procedures, many of which showed dramatic flow from the implanted IMAs into the branches of blocked coronary arteries. These findings stimulated renewed interest in the Vineberg procedure, particularly at the Cleveland Clinic, and in 1968, they published a report on 1100 IMA implants, 92% of which were open and 54% had significant visible connections to the coronaries (Fergusson et al., 1968; Cineangiography, n.d.; Effler et al., 1963).

Peripheral Vascular Surgery Foreshadowed CABG

Beginning in the 1950s, great advances were made in arterial surgery, stimulated by the wartime injuries of WWII and the Korean conflict. Led largely by the advances of Michael DeBakey (DeBakey et al., 1958) in Houston, artificial arterial substitutes were created out of nylon and later Dacron and PTFE (Teflon), and used to replace arterial aneurysms and to bypass occluded or stenotic vessels. Initially, most arterial obstructions were treated by endarterectomy, in which the obstructing cholesterol-laden plaque was surgically removed from the artery. This technique worked well when the obstruction was localized to a short segment of an artery but was less effective when the occlusive disease involved longer arterial segments. For these situations, DeBakey developed the arterial bypass technique, in which an artificial tube graft was connected to the side of the obstructed artery above and below the obstruction, thus increasing blood flow distally while leaving the native circulation intact, in the event that the artificial graft failed and became occluded.

The technique was used first to bypass obstructed iliac arteries, using a bifurcated Dacron graft from the aorta to the common femoral arteries. Later, obstructed superficial femoral arteries were bypassed with Dacron bypass grafts from the common femoral to the popliteal artery. Grafts to these smaller arteries and particularly to those below the knee did not remain open consistently, and surgeons began using the long saphenous vein (from the patient's leg) for the graft, with much better results. While the greater saphenous vein that is harvested for use in CABG, the rest of the venous system that is left in place is more than adequate to provide venous drainage to the leg.

Over time, as surgical techniques improved, vein bypasses were constructed to smaller and smaller arteries further down the leg. These were reasonably successful until, close to the ankle, the recipient artery was no more than 2–3 mm in diameter, and then the graft would usually not stay open. That was, therefore, considered the size limit for a saphenous bypass graft. For this reason, at that time, bypassing the coronary arteries was not considered feasible.

The First CABGs

Between 1962 and 1967, human CABG using autogenous saphenous vein grafts were performed by Sabiston (1962), Garrett (1964), Kahn (1966), and Favaloro (1967). In 1964, surgeon Edward Garrett, working with Dr. Michael DeBakey in Houston, encountered a patient with a relative large, but severely stenotic LAD coronary artery (Cooke, 2015). He performed a vein bypass graft from the ascending aorta to the obstructed artery and it remained open and relieved the patient of his angina (**Fig. 9**).

Subsequent follow-up showed that the graft remained open for at least ten years. At the time, Garrett believed that this was an unusual and lucky case and that it was unlikely that it could be repeated reliably and did not justify the risk, which was then considerable, of subjecting these clinically fragile patients to the hazards of cardiopulmonary bypass. He did not publish a report of this case. It was not appreciated at the time that the patency of these grafts was more dependent on blood flow through the graft as well as the size of the recipient vessel. A few years later, Rene Favaloro, at the Cleveland Clinic, performed the same procedure, in a similar situation to a large right coronary artery, which was also a success. He subsequently reported on his series and ignited an industry (Favaloro et al., 1969).

In the late 1960s, Dr. Favaloro was a cardiothoracic surgery fellow at the Cleveland Clinic. Before he published the series of cases where he was able to revascularize the heart using saphenous veins from patients' legs, many preceding events had to occur and come together for this relatively straightforward solution to evolve. These events included technologic advances in cardiac surgery, peripheral vascular surgery, and diagnostic cardiology. By the 1960s, the heart–lung machine or cardiopulmonary bypass (CPB) was in common use, having been invented in the early 1950s. At the beginning of the CABG era, CPB had improved to the point where it was being used regularly in cardiac surgery centers for congenital heart surgery and valve surgery. In addition, the Sones technique of coronary angiography allowed practitioners to see precisely where occlusions and stenoses were in the coronary arteries. At that point in history, cardiovascular surgeons had much experience in peripheral arterial surgery, in particular, restoring circulation to extremities by using the patient's own veins (autologous) to bypass occluded peripheral vessels, particularly in the legs. With the

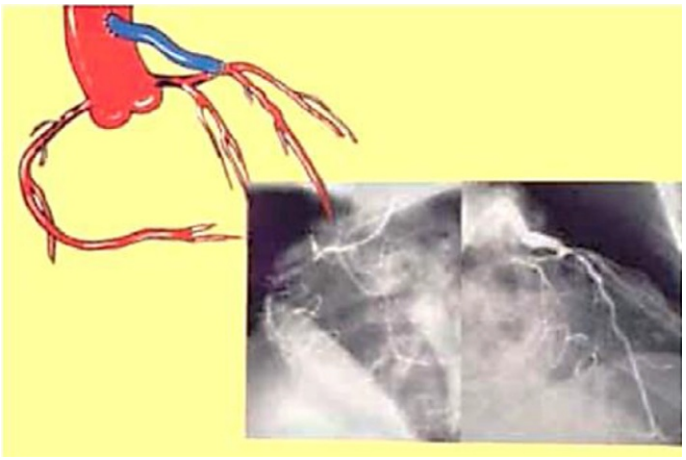

Fig. 9 Images of first coronary artery bypass performed by Doctors Ed Garrett and Jimmy Howell. Image and description from DeBakey, M. E. (2015). Houston hearts: A history of cardiovascular surgery and medicine at Houston Methodist Debakey Heart & Vascular Center. *The Methodist DeBakey Cardiovascular Journal* **11** (3 Suppl.), 5–17.

experience of operating on the heart using the heart–lung machine, the knowledge that vessels could be bypassed with autologous vein, and having a roadmap supplied by the angiographer, CABG became feasible (Fig. 10).

Cardiologists and vascular surgeons were poised and ready for this long-awaited step in the discovery process, and coronary surgery virtually exploded across the western world. Initially, bypass grafts were done to only the largest coronaries with localized proximal disease in relatively young patients. For each distal anastomosis of the vein to the coronary artery, the ascending aorta was cross-clamped and the heart allowed to stop from ischemic arrest. The vein was then carefully sewn to an opening in the side of the coronary artery using magnifying loupes, after which the clamp was removed from the aorta to allow the heart to recover. After a few minutes of recovery time, the process was repeated for the next distal anastomosis to a second coronary, using another segment of vein. When the last distal attachment had been completed, a partially occluding clamp was placed on the ascending aorta (Fig. 11), and the opposite ends of the vein grafts (proximal) were sewn to small openings made in the wall of the aorta. Over time, many

improvements were made in all phases of the procedure, including local and systemic cooling, myocardial preservation, more precise suturing techniques, and improvements in cardiopulmonary bypass equipment and technology.

The concept of temporarily inducing cardiac arrest with cold potassium rich solution injected antegrade into the coronary arteries was introduced in the late 1970s. This solution, coined "cardioplegia" (literally meaning to paralyze the heart muscle) was infused into the coronaries to arrest the heart, literally causing the cells of the heart to hibernate, preserving its function. The high concentration of potassium in the solution literally paralyzes the cells by influencing its electrical properties (by eliminating the potential difference across the cell membrane), and the low temperature induced decreases the metabolic demands of the cells, the combination of which is termed "myocardial preservation" (Yamamoto and Yamamoto, 2013). The surgeon could now work on these tiny vessels in a still, bloodless field. With these improvements, it was possible to do all the distal anastomoses during a single cross clamping of the aorta and significantly shorten the length of the procedure and the time on the heart lung machine. This was particularly important since over time, as surgical techniques were improving, the patients were getting older with more advanced disease, and the number and difficulty of the grafted arteries was increasing.

In 1968, shortly after the onset of the beginnings of coronary bypass surgery, Kolessov, in Russia performed the first bypass from the left internal mammary artery (LIMA) to the left anterior descending coronary artery (Kolessov, 1967). Initially this did not attract much attention, because the vein grafts were quicker and easier and seemed to work as well, at least in the short term. Green, at NYU, was the first in the United States to perform and publish about the use of the LIMA. Over the years, evidence began mounting that the vein grafts were slowly developing atherosclerotic obstructions of their own, and the LIMA grafts, which Green and about 5%–10% of the other surgeons preferred, were remaining free of disease and lasting longer. In 1985, a paper from Montreal reported on a large series of coronary bypass patients who had follow up angiograms 10 years after their initial surgery (Bourassa et al., 1985; Lytle et al., 1983). They found that about 30% of the vein grafts had occluded and that 95% of the LIMA grafts were open and free of disease. These observations led to a dramatic increase in the use of LIMA grafts, particularly to the LAD coronary artery with a noticeable improvement in short- and long-term results, regardless of the age of the patient or associated disease.

Concurrently, a number of surgeons extended this technique to include the right internal mammary (RIMA) and occasionally the gastroepiploic artery anastomosed to the inferior or posterior coronary branches. The gastroepiploic artery courses along the surface of the greater curvature of the stomach. By extending the median sternotomy incision inferiorly and opening the upper abdomen, the stomach can be exposed, the gastroepiploic artery mobilized, and can be extended above the diaphragm to the heart, long enough to reach vessels on the inferior surface of the heart. Radial artery grafts were also employed, particularly when satisfactory veins are not available. To date, radial arterial grafts and free IMA grafts have not consistently demonstrated superiority over the combination of LIMA and saphenous grafts, particularly in combination with cholesterol lowering drugs.

Indications and Selection for CABG Surgery, Shared Decision-Making, and the Heart Team

Modern management of ischemic coronary artery disease and the role of CABG surgery have been in a continual state of flux over the past 50 years. Initial enthusiasm for the broad application of surgical revascularization was tempered by the results of three important prospective randomized trials that were carried out from 1972 to 1979 (VA Coronary Artery Bypass Surgery Cooperative Study Group, 1992; Varnauskas, 1988; Killip et al., 1985). In these studies, patient disease patterns and outcomes were compared between medical and surgical therapy allowing for the stratification of patients with coronary artery disease into low-, medium-, and high-risk groups. The impact of surgical revascularization on these groups proved a clear benefit for CABG in patients with severe left main coronary artery and three-vessel coronary artery disease, while the benefits of CABG surgery were shown in patients with double- and single-vessel disease only if the proximal LAD was involved. In patients with double- and single-vessel coronary artery disease not involving the LAD, medical management was found to be equal to or superior to CABG. As surgical management became standard for specific disease patterns, new medications as well as interventional technologies (percutaneous balloon

angioplasty, bare metal, and drug-eluting stents) were introduced and dramatically impacted decision-making for patients with ischemic heart disease. The RITA, BARI, and SYNTAX Trials provided the evidence for this decision-making (Henderson et al., 1998; Investigators, 2007; Serruys et al., 2009).

The development of the Society of Thoracic Surgeons (STS) database in 1989 (Shroyer, 2015) has further aided surgeons in determining patient risk for CABG and allowed for refinement of individual patient treatment plans based on both the degree of coronary disease and the severity of a number of comorbidities. With the sophistication of current medical, interventional, and surgical options that are available today, a multidisciplinary heart team approach that allows for regular communication between the primary cardiologist, interventionalist (cardiologist that is trained to do interventions such as angioplasties and stents), and cardiothoracic surgeon provides the best opportunity for optimal patient management.

The technological advancements in CABG surgery over the past 50 years have also provided today's surgeon with a number of options in surgical planning. These range from the performance of a standard "on-pump" procedure with a combination of differing conduits to "off-pump" techniques and or hybrid approaches that combine surgical and interventional technologies. The cardiopulmonary bypass machine is often referred to as the "pump." The proper selection from these many operative choices is predicated upon a high-quality, systematic, preoperative assessment of the patient. Such a process is greatly aided by the deployment of a team of supporting nurses, physician assistants, residents, and/or fellows under the guidance of the attending surgeon. The modern reality of practicing medicine in the age of electronic medical records allows providers rapid access to not only the historical details of the patient as documented by their referring physicians during any number of prior encounters but also to their laboratory and imaging studies. The obvious goal of such a record has been to give the provider an efficient source of information that should theoretically decrease the time required to thoroughly evaluate and formulate a proper plan for his or her patient. Though this often works out quite nicely, electronic medical records are only as good as the data that has been uploaded into them and thus are not impervious to collecting inaccurate or incorrect patient information. With that in mind, the most efficient use of the consultant's time is to first thoroughly review the imaging and laboratory studies in the contest of the patient's historical and physical findings.

After reviewing the recent history and physical and progress notes, it is imperative that the consulting surgeon confirm with the patient the details of their history and conduct a thorough review of systems and physical examination. It is incumbent upon the operating surgeon to perform his or her own cardiovascular physical examination with close attention to the presence or absence of cardiac murmurs and vascular bruits, clinical signs of heart failure, discrepancies in brachial (arm) blood pressures, character of peripheral pulses, and the quality of potential primary and secondary conduit choices (greater or lesser saphenous veins and radial arteries). With this approach, the surgeon can confidently determine the patient's angina and heart failure scores, confirm the presence of serious comorbidities, potentially identify missed diagnoses, calculate the risk for CABG surgery (STS or EuroScore) (Shahian et al., 2009; Roques et al., 1999; Roques et al., 2003), and start formulating the surgical plan tailored to the patient's health status, including the patient and family in a shared decision-making process (Lin and Fagerlin, 2014).

Failure to prepare in this manner can result in suboptimal operative planning, avoidable complications, avoidable deaths, and the performance of operations on patients who would have been better off with medical or interventional management. Once the decision for surgery has been made, the details of the operative plan are formulated including selection of arterial targets, grafting strategy, determination of the cardiac support plan, and selection of conduit. In general, the selection of target arteries is based on findings of the coronary angiogram (a cine radiograph of coronary arteries injected with radio-opaque dye through a catheter) in combination with information from any viability scans (imaging using markers that indicate the presence of living myocardial cells in a nonfunctioning area of the heart) that may have been performed. The cardiac support plan is generally based upon the surgeon's preference, status of the ascending aorta, and the presence or absence of major comorbidities.

The most commonly used plan for cardiac support during CABG continues to be cardiopulmonary bypass with cardioplegic arrest. The next most common technique is Off-Pump CABG (OPCAB) in which coronary anastomoses are performed on the beating heart with the aid of special stabilizing devices and occasional intracoronary shunts. In the mid-1990s, as a response to advances in percutaneous revascularization, surgeons developed several different strategies to make direct coronary bypass surgery less invasive. The first was coined Minimally Invasive Direct Coronary Artery Bypass or MIDCAB. In this technique, the LIMA was harvested and anastomosed to the LAD via a left anterior thoracotomy incision through the fourth intercostal space with or without cardiopulmonary bypass support. Though this technique had many successes, revascularization was limited to the LAD, pain from the thoracotomy incision was significant, hemodynamic instability with need for conversion to full sternotomy was not uncommon, and inadvertent grafting of the LAD at the wrong site occurred (Vicol, 2003).

Around the same time, an Off-Pump approach via a full sternotomy with mechanical stabilization techniques (OPCAB) was developed that allowed for complete revascularization with a lower incidence of grafting errors. Both techniques had the goal of not exposing patients to the deleterious effects of CPB. Over time, some centers practicing both techniques reported OPCAB to be the superior method. Several prospective randomized studies have proven the safety of OPCAB, and there are a number of surgeons who prefer OPCAB as their primary method of CABG. Other surgeons feel that their ability to perform a sutured anastomosis is far superior while On-Pump with cardioplegic arrest and selectively utilize Off-Pump CABG in cases of a "porcelain aorta" (an ascending aorta that has so much dense, calcified atheromatous plaque that it feels as firm as porcelain, risky to manipulate for fear of breaking of particles and causing embolic strokes) or severe pulmonary disease. Conflicting inferiority/superiority outcomes from several studies allow for the support of both positions (Hattler et al., 2012; Lamy et al., 2012; Puskas, 2009; Diegeler, 2013; Bakaeen and Puskas, 2014; Taggart et al., 2016).

Over the nearly 50 years of the "CABG Era," evidence has been gathered through these databases, observational analyses, and trials that has, in the aggregate, provided the surgeon with guidance as to what the indications are for surgery and who should be

selected as each patient provides a different context depending on age, comorbidities, and other factors. Armed with the evidence provided by these studies, the first management decision would be to decide whether to offer the patient medical therapy, CABG or "PCI" a percutaneous intervention (angioplasty and stenting). The major drivers of that decision include the patient's coronary anatomy, the presence of diabetes mellitus, the clinical syndrome (stable angina, acute coronary syndrome, acute myocardial infarction (STEMI or NSTEMI)), and left ventricular dysfunction and mitral valve disease. The terms "STEMI" or ST-segment elevation myocardial infarction or "NonSTEMI" define electrocardiographic features of myocardial infarctions that have been found to distinguish the extent of injury and treatment decisions in the context of the coronary anatomy and the other features outlined in **Fig. 12**. These evidence-based factors and decision points are well summarized by Alexander and Smith from their 2016 review article on CABG surgery (Alexander and Smith, 2016).

Indications for CABG that are associated with a survival benefit over medical therapy with or without PCI

Acute STEMI

- Coronary anatomy not amenable to PCI
- Mechanical complications (e.g., ventricular septal defect, rupture of the free wall of the ventricle, or papillary-muscle rupture with severe mitral regurgitation)

Coronary artery disease other than acute STEMI

- Left main coronary artery disease (≥50% stenosis) and high complexity for PCI (SYNTAX score ≥33)
- Three-vessel coronary artery disease (≥70% stenosis) and intermediate or high complexity for PCI (SYNTAX score ≥23)
- Two-vessel coronary artery disease (≥70% stenosis) involving the LAD artery and intermediate or high complexity for PCI (SYNTAX score ≥23)

Factors increasing the survival benefit of CABG

Left ventricular dysfunction (ejection fraction ≤45%)

Diabetes mellitus

Ischemic mitral regurgitation

PCI failure with or without acute myocardial infarction

Indications for CABG when PCI is noninferior to CABG and when PCI or CABG is preferred over medical therapy

Left main coronary artery disease (≥50% stenosis) and low-to-intermediate complexity for PCI (SYNTAX score ≤32)

Three-vessel coronary artery disease (≥70% stenosis) and low complexity for PCI (SYNTAX score ≤22)

Two-vessel coronary artery disease (≥70% stenosis) involving the LAD artery and low complexity for PCI (SYNTAX score ≤22)

Factors increasing the benefit of PCI over CABG

Elevated risk of death with CABG

Elevated risk of stroke

Extreme frailty

Prior CABG

Acute STEMI at presentation

Other indications for CABG

Clinically significant coronary artery disease (≥70% stenosis) in ≥1 vessel and refractory angina despite medical therapy and PCI

Clinically significant coronary artery disease (≥70% stenosis) in ≥1 vessel in survivors of sudden cardiac arrest presumed to be related to ischemic ventricular arrhythmia

Clinically significant coronary artery disease (≥50% stenosis) in ≥1 vessel in patients undergoing cardiac surgery for other indications (e.g., valve replacement or aortic surgery)

Fig. 12 A summary of the indications for CABG surgery from Alexander JH, Smith PK. Coronary-Artery Bypass Grafting N Engl J Med 2016;374:1954-64. The SYNTAX scoring system, developed as part of the Synergy between PCI with Taxus and Cardiac Surgery study, classifies the extent and complexity of coronary artery disease, with a score of 22 or lower indicating low complexity, a score of 23 to 32 indicating intermediate complexity, and a score of 33 or higher indicating high complexity. CABG denotes coronary–artery bypass grafting, LAD left anterior descending, PCI percutaneous coronary intervention, and STEMI ST-segment elevation myocardial infarction (Ong et al., 2006; Sianos et al., 2005). From: Yusuf, S. et al. (2016). Cholesterol lowering in intermediate-risk persons without cardiovascular disease. *New England Journal of Medicine* **374**, 2021–2031.

Coronary Angioplasty and Stenting

In 1977, Andreas Gruentzig, a German cardiologist living in Zurich, first employed a balloon on the end of a cardiac catheter (Matthias et al., 2014; Gruentzig et al., 1979) (**Fig. 13**) to dilate a stenotic lesion in a patient's LAD coronary artery.

Later that year, Dr. Gruentzig presented the results this technique of four such successful balloon angioplasties at the American Heart Association Meeting, which led to widespread acknowledgement of this procedure, and, with successive refinements in technique and devices, by 1990, percutaneous angioplasty became a commonly used method of treating coronary disease by revascularization. Unfortunately, a significant number of these dilated arteries developed recurrent stenosis due to reaccumulation of plaque a few months to a year after balloon angioplasty, requiring another angioplasty or a bypass graft. During the next decade, an expandable wire stent was developed to prevent restenosis of the vessel. Later these stents were coated with antiproliferative drugs to slow or prevent plaque growth (**Fig. 14**).

Several large randomized clinical trials, most notably the SYNTAX Trial (Gulati et al., 2009; Serruys et al., 2009), have helped to define the relative effectiveness of the various revascularization techniques currently available in different situations and, in

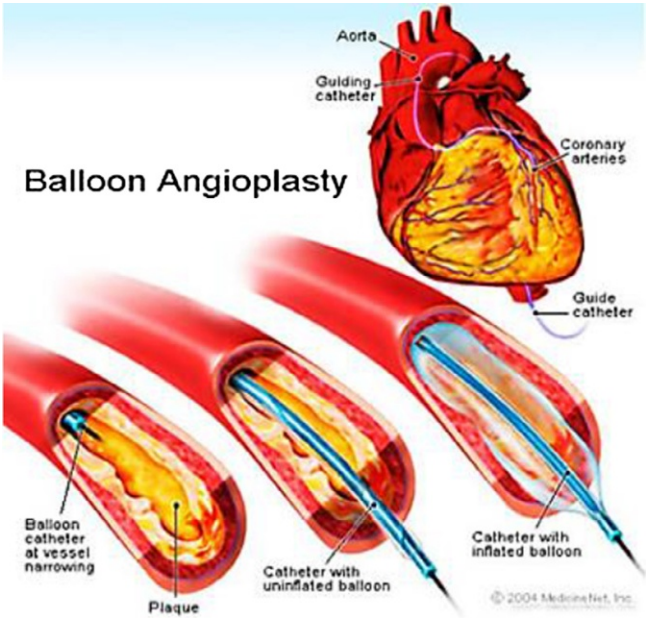

Fig. 13 Illustration depicting a balloon angioplasty where a tiny catheter with an integrated balloon is guided into a coronary artery, the balloon positioned into the area of stenosis, inflated, thereby improving blood flow through that segment. This original procedure has subsequently been enhanced by the addition of drug-eluting stents that discourage restenosis of the vessel. From: MedicineNet.com.

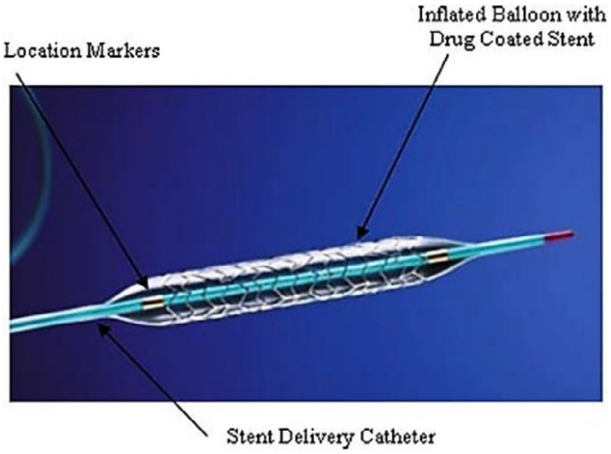

Fig. 14 This is an example of a drug-eluting stent. It is the TAXUS Express Paclitaxel-Eluting Coronary Stent System, which releases paclitaxel, the stent that was used in the SYNTAX Trial. From: Food and Drug Administration—http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/DeviceApprovalsandClearances/Recently-ApprovedDevices/ucm081189.htm, Public Domain, https://commons.wikimedia.org/w/index.php?curid=973844.

particular, which patients are better served by surgery versus balloon angioplasty. Long-term results have shown that diabetic patients and those with multiple coronary blockages appear to do better with coronary surgery, where grafts can be constructed to three or more coronary branches at once, often creating multiple distal anastomoses with a single vein graft. Revascularization is more frequent with stents as opposed to CABG, while strokes are more common with CABG. At this writing, 5-year results from SYNTAX have been published and data on 10-year mortality is currently being analyzed.

As technology has evolved in both surgery and interventional cardiology, the cardiac surgeons who perform the CABG surgery and the cardiologists who perform coronary angioplasties and place stents both have technologies that have been found to suit different subsets of patients requiring coronary revascularization. This commonality has brought the two specialties closer together, forming "Heart Teams" to address coronary revascularization and other complex cardiac issues such as advanced valve therapy and heart failure.

Cardiopulmonary Bypass

The concept of cardiopulmonary bypass (CPB), commonly known as the heart–lung machine, became a reality in the early 1950s when it was used in a succession of patients to correct congenital cardiac problems such as atrial septal defect, the failure of the completion of the formation of a partition between the left atrium and the right atrium. CPB is a form of extracorporeal circulation, meaning circulation outside of the body. Substituting a machine for the heart and lungs to pump the blood and provide gas exchange allowed surgeons to stop the heart and stop ventilation so as to have an opportunity to open the heart and work on its interior, correcting and reconstructing congenital defects. As CPB began to evolve and improve in the first decade of its use, pioneering medical centers and surgical teams began to use it for acquired cardiac problems, such as valve surgery, in addition to correcting congenital defects. By the 1960s, valve replacement surgery became a reality, and at the beginning of the CABG era in the early 1970s, CPB was used as well.

With the ability of the surgeon to stop the heart and work on its interior during this era, the potential to apply lessons learned in peripheral vascular surgery to the coronary arteries became real. The coronary arteries course over the surface of the heart (epicardial) and are visible and palpable. The use of the principles of peripheral aterial bypass to the coronary arteries was applied in the early days of CABG, and with CPB and cardioplegia, the surgeon was now able to work in a still, bloodless field, using familiar techniques in this new setting.

The heart and lungs provide gas exchange and perfusion of more than 37 trillion living cells. The idea of designing a machine that could take over the function of the heart and lungs was conceptualized in 1813 by Le Gallois; however, the first attempts to actually apply the concept occurred in the early 1950s (Groom and Fitzgerald, 2017). The first successful use of cardiopulmonary bypass was in 1953 by a surgeon, John H Gibbon Jr., and his team at Jefferson Hospital in Philadelphia, Pennsylvania (Stammers, 1997). Gibbon used his heart–lung machine to "perfuse the patient" allowing her heart to be stopped while he and his team opened her right atrium and sutured closed her atrial septal defect. The early years following that landmark case were not so promising. Five subsequent procedures at Jefferson Hospital where cardiopulmonary bypass was used by Gibbon were not successful as all five patients did not survive, and he abandoned the use of the heart–lung machine. At least seventeen other cases were performed in the early 1950s using some form of extracorporeal circulation, and only Dr. Gibbon's patient survived. Nonetheless, his one successful case served to inspire others, including John Kirklin at The Mayo Clinic, C. Walton Lillihei at the University of Minnesota, and Denis Melrose at Hammersmith Hospital in London, to press with their research and application the heart–lung machine with CPB techniques that were crude compared to today's standards. (**Fig. 15**).

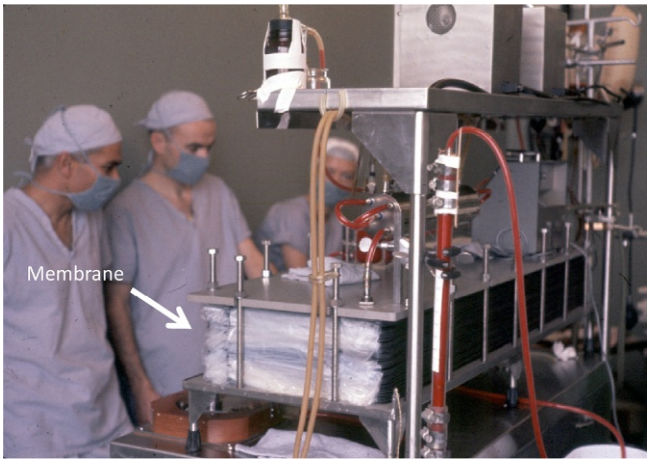

Fig. 15 The Mark-Clowes heart–lung machine with a membrane oxygenator in use at Maine Medical Center in 1959. Sixteen units of donor blood were needed to prime this heart-lung circuit. With permission from Archives of Maine Medical Center.

The accomplishments of these early pioneers in cardiac surgery have been described as being "one of the boldest and most successful feats of man's mind." (Eloesser, 1970).

Since the 1950s, CPB has steadily improved in terms of survival and reduction in complications such as hemorrhage, stroke, and kidney injury. CPB techniques are used for temporary or longer-term support, known as extracorporeal membrane oxygenation (ECMO).

CPB has been designed as an integrated system that provides nutritive solutions with an appropriate hemodynamic driving force to maintain whole-body homeostasis, protecting the patient from ischemic injury. Over the last three decades options for the use of CPB for coronary artery revascularization have been developed such as percutaneous interventions (angioplasty and stenting), and by surgical procedures not utilizing CPB, collectively called off-pump CABG surgery (OPCAB) and procedures using hybrid miniaturized circuits to support the circulation during grafting.

The benefit of CPB was validated in a randomized clinical trial, the Randomized Off-pump or On BYpass (ROOBY) trial, involving 2203 elective or urgent coronary artery bypass grafting (CABG) patients randomized to either off- or on-pump surgery is a testament to the efficacy and safety of CPB as currently practiced. At one year, the on-pump group had significantly better composite outcomes (death, myocardial infarction, or repeat revascularization) than the off-pump group (9.9% vs. 7.4%; $P=0.04$). The overall rate of graft patency was lower in the off-pump group than in the on-pump group as well (82.6% vs. 87.8%; $P<0.01$).

The ROOBY Trial and other trials demonstrated that off-pump CABG yielded no advantage in clinical outcomes and cost over on-pump CABG (Shroyer et al., 2009). A metaanalysis which included 12 randomized clinical trials reported a 38% increased rate of early revascularization with off-pump surgery (Takagi et al., 2013). Moller and colleagues published a systematic review including over 15,000 subjects that reported no clinical benefit in mortality, stroke, or myocardial infarction or increased survival benefit of OPCAB (Møller et al., 2012).

A cardiovascular perfusionist is a specialized healthcare professional who operates the heart–lung machine during cardiac surgery and other surgeries that require cardiopulmonary bypass to manage the patient's circulatory physiology (**Fig. 16**). After a patient's circulation is accessed thru large cannulae (tubing providing connection to the CPB circuit) in the right atrium in the ascending aorta, the perfusionist, under the direction of the heart surgeon, has the ultimate aim of providing satisfactory gas exchange and metabolic needs at the cellular level (Galletti and Brecher, 1962). CPB is being used to provide perfusion for about 1.4 million patients each year around the globe. It has become evident that efforts should be directed toward measuring the adequacy of perfusion at the cellular level and at the end organ level is where we should be focusing our attention as we try to improve patient support with CPB (Ranucci et al., 2005; Demers et al., 2000; de Somer et al., 2011).

The principal component of the Heart–lung machine includes pumps, reservoirs, tubing, and filters. The CPB circuit consists of a number of components for gas exchange, temperature regulation, filtration, monitoring, and safety mechanisms. **Fig. 17** is a diagram of the various components of the CPB circuit (Kim et al., 2013).

Blood drains by gravity or with the use of gentle suction into the oxygenators venous reservoir labeled (B). (A) represents the arterial pump that pumps the blood from the venous reservoir (B) and delivers blood to the membrane oxygenator which is attached to the lower part of the venous reservoir. Once oxygen, carbon dioxide, and heat exchange have occurred the blood is directed thru an arterial blood filter (C). A purge line to the upper most part of the filter and serves for the removal any microemboli that may have been introduced into the blood during its passage through the circuit. The oxygenated blood is introduced back into the patient's circulatory system through a cannulae (a large tube connected to the circuit) placed in the ascending aorta. The line attached to intravenous bags labeled (D) provides a method for priming the CPB circuit with electrolyte fluid or a port for adding blood during bypass. Four roller pumps labeled (E) in the diagram are auxiliary pumps. The one on the far left is used to pump cardioplegia solution with a mixture of blood and additives, labeled (H), used to arrest the heart. This solution is cooled with a separate heat-exchanger labeled (F).

Pumps

Two principle types of pumps are used to propel blood thru the extracorporeal circuit and into the patient's circulation, roller pumps, and centrifugal pumps. These pumps, unlike the heart, provide continuous flow rather than pulsatile flow. Numerous studies over the past three decades have sought to determine if pulsatile flow improved organ perfusion and patient outcomes; however, the evidence is inconclusive (Alghamdi and Latter, 2006; Likosky, 2009). Metaanalysis by Nam (Nam et al., 2015) and Seivert (Sievert and Sistino, 2012) both showed improvements in renal function with pulsatile flow. Sievert further reported that the studies with Intra Aortic Balloon Pump (IABP) generated pulsatile flow had the best results and also noted significant reduction in lactate levels in the pulsatile groups. Zangrillo carried out a metaanalysis of preoperative use of IABP in 625 high-risk CABG patients and reported a significant reduction in 30-day mortality (risk ratio 0.38 p for effect 0.004) (Zangrillo et al., 2015). More recently Lim and colleagues undertook a metaanalysis to look at pulmonary function with pulsatile perfusion and found a significant improvement in pulmonary function and ICU length of stay (Lim et al., 2015). Clearly pulsatile flow is an area ripe for future study. Although the two types of pumps available for arterial blood pumping, the centrifugal pump and roller pump, are capable of producing pulsatile flow, at this juncture pulsatile flow is not commonly utilized.

The dual roller pump is the most common type of pump used for cardiopulmonary bypass. It operates by occluding tubing between a stationary raceway and rotating rollers (**Fig. 18**). The pumping mechanism is referred to as the "pump head," and the tubing that traverses the raceway is referred to as the "pump header." Roller pumps were first proposed for use in cardiovascular medicine in the 1930s by Gibbon (Gibbon, 1937). The mechanism for flow with the roller pump is the displacement of fluid, in a progressive fashion, from suction to discharge, with the capacity of the displacement dependent both on the volume of the tubing occluded by the rollers and on the number of revolutions per minute (rpm) of the roller. The volume displaced per revolution is multiple times the revolutions/minute to calculate the estimated blood flow. This is displayed on a digital readout and is referred to as the output (flow) of the pump. It is measured in liters per minute (**Fig. 19**).

Another common pump used for arterial blood flow is the centrifugal pump (**Figs. 20** and **21**). Although nearly all of the randomized trials show significant benefit to systems designed with centrifugal pumps, it is difficult to separate the improved performance conferred from other characteristics, such as lower prime volume, surface coating, more limited surface area, and reduced air-to-blood contact. A metaanalysis that included 18 randomized, controlled trials comparing centrifugal and roller pumps in adult cardiac surgery suggests no significant difference for hematological variables, postoperative blood loss, transfusions, neurological outcomes, or mortality (Saczkowski et al., 2012).

Centrifugal pumps produce less blood damage; however, this improvement appears to be inconsequential. Nevertheless, recently published Guidelines on Perioperative Blood Transfusion and Blood Conservation in Cardiac Surgery, endorsed by the Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists state that, "It is not unreasonable to select a

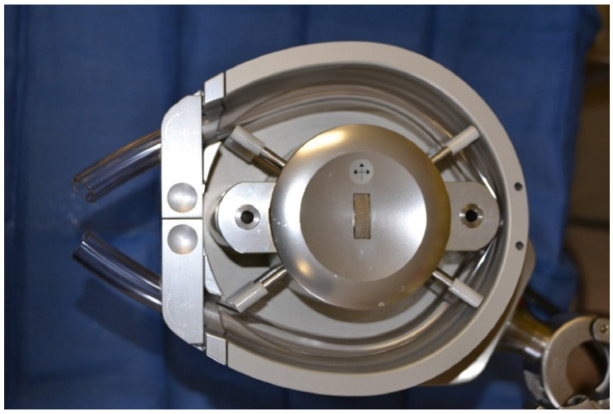

Fig. 18 Twin (dual) roller pump. Occlusiveness of the pump is adjusted by the thumb adjustment knob at the center of the roller assembly. Roller guides hold the tubing in place in the pump race way. With permission from RC Groom, MS, CCP.

centrifugal pump rather than a roller but more so for safety reasons rather than blood conservation" (American Heart Association/ American College of Cardiology Class IIb level of evidence B) (Society of Thoracic Surgeons Blood Conservation Guideline Task Force, 2011).

Oxygenators

Membrane oxygenators operate by diffusion of oxygen and carbon dioxide across a microporous hollow fiber bundle. The gas exchange occurs by diffusion of the gases across microporous fiber surface, oxygen moving from the interior of the hollow fiber into the blood and carbon dioxide diffusing from the blood cross into the interior of the fiber and swept away by the regulated gas flow through the hollow fiber. Blood oxygenators have integrated heat exchangers that allow the circulating blood to be cooled or warmed. The heat exchangers are comprised of stainless steel or polypropylene tubes that are not permeable. Water from a regulated water supply flows through the fibers and heat is transferred from the blood flowing around the tubes into the circulating water. While there have been major improvements in the materials and surfaces that the blood is exposed to in the extracorporeal circuit, there remains hematological changes including the liberation of inflammatory mediators (Hammerschmidt et al., 1981; Chenoweth et al., 1981). Platelets and leukocytes that elicit a complex series of inflammatory and hemostatic reactions that ultimately increase the risk for postoperative complications are activated.

The oxygenator (Fig. 22) represents the largest source of nonendothelialized surface area in the extracorporeal circuit, ranging in size between 0.5 and 2.5 square meters. Other issues identified include the occurrence of gaseous microemboli during cardiac

surgery with CPB (Dickinson et al., 2006; Likosky et al., 2009) that have been managed with in-line filters. These arterial line filters significantly reduce the load of gaseous and particulate emboli. A dose–response relation between these emboli and subtle neurologic injury has been reported, and some studies have demonstrated a protective effect of arterial line filtration on neurologic outcomes. The use of a leukocyte-depleting arterial line filter has been shown to reduce cerebral embolic count and demonstrated a trend toward improved postoperative psychometric test scores and should be used in CPB circuits. Transfer of volatile (inhalational) anesthetic agents does not readily cross this membrane. The inhaled anesthetic during the course of CPB is delivered via the membrane oxygenator, rather than the patient's lungs that are not ventilated during the procedure. Noninhalational agents such as narcotics adequately supplement the inhaled anesthetic during the conduct of the operation.

While many advances in CPB have been realized since the first successful procedure in 1953, there remains a vast areas of research opportunities related to cardiopulmonary bypass including: (1) issues related to material–blood interaction specifically inflammation and coagulation-related issues; (2) patient and organ system responses to cardiopulmonary bypass; (3) the use of hypothermia, brain and myocardial protection; and (4) improving safety.

CABG Technique

As previously mentioned, the fundamental technique for performing CABG surgery was developed by peripheral vascular surgeons who had developed procedures to replace or bypass vessels peripheral to the heart and great vessels. In particular, the ability to bypass lower extremity vessels was developed using the greater saphenous vein. The venous component of the circulatory system is a low-pressure system, while the arterial part of the circuit is pressurized by the contractions of the left side of the cardiac pump. The venous circuit is necessary for the return of blood to the heart without a pump to pressurize it. Venous return to the heart relies on other mechanisms for propulsion such as gravity, in the case of the head, and external muscle pumping, redundancy and valves, in the case of the lower extremities. As seen in the illustration showing the deep and superficial venous circulation, the huge capacity of the venous system allows for the return of as much blood each minute as is being pumped out, roughly five liters per minute. This "forward flow," under normal conditions, allows for adequate oxygen delivery and nutrients to end organs and other tissues.

The large capacity of the venous compartment creates redundancy allowing the reconstructive vascular and cardiac surgeons to relocate some of these veins, the greater saphenous vein being a good example as a conduit for restoring blood flow to both the heart the periphery such as the legs. While it was not designed to function as an artery, the saphenous vein, when reversed because of its valves, provides a useful and readily available conduit for the surgeon. It is the right size, handles easily, and has no issues regarding rejection or foreign body reaction, as it is the patient's own tissue. Thus, with the advent of CABG surgery, the reversed saphenous vein graft became the workhorse conduit of choice for the cardiac surgeon and has remained so after nearly 50 years. As it is designed to work in a low-pressure system, graft patency and longevity is not ideal in this vein graft that was not originally designed to function under such high internal pressures. Early in the experience of CABG surgery, it became apparent that the internal mammary artery (LIMA) was a superior alternative. The LIMA became the favored choice for grafting the left anterior descending coronary artery (**Fig. 23**)

Saphenous Vein Graft: Its Position as Conduit of Choice in CABG Surgery

During the early period of CABG surgery in the United States, the saphenous vein graft was the conduit of choice for coronary bypass surgery. It soon became apparent that the saphenous vein graft was prone to progressive disease and eventual failure as illustrated earlier. During the early experience with myocardial revascularization, no interventional techniques, such as balloon angioplasty, were available to rescue a diseased graft territory, thus patients with early vein graft failure were at risk for a repeat CABG operation if medical management was not successful. In an attempt to alleviate vein graft-related problems, cardiac surgeons adopted and popularized the use of the left internal mammary artery (LIMA) with anastomosis to the left anterior descending coronary artery (LAD).

Use of the LIMA remained a relatively controversial technique until the surgeons from Cleveland clinic (Loop et al., 1986; Loop, 1996; Cameron et al., 1996; Burfeind et al., 2004) and others published papers establishing the evidence that the LIMA was superior to the saphenous vein graft when used in the LAD position in both freedom from recurrence of angina, myocardial infarction, and death. In spite of these landmark papers, universal application was slow. By the early 2000s, the STS data showed still only 90% of cases being done in the country were utilizing a LIMA. In the 1980s and 1990s, studies of the use of bilateral IMAs showed decreased need for reoperation and improvements in survival. Currently, the use of the LIMA is now nearly universal with CABG surgery, while utilization of bilateral IMAs has not been as widely adopted (Puskas et al., 2014; Lytle, 2001, 2013; Buxton et al., 2014; Taggart et al., 2016; Lytle et al., 1985).

The Saphenous Vein Graft: An Imperfect Yet Remarkable Conduit

Though the use of the saphenous vein as a conduit has been shown to be inferior to the left internal mammary artery (Lytle et al., 1985; Loop et al., 1986; Sabik et al., 2003, 2005) it remains a central part of the surgeons assortment of conduit choices in the

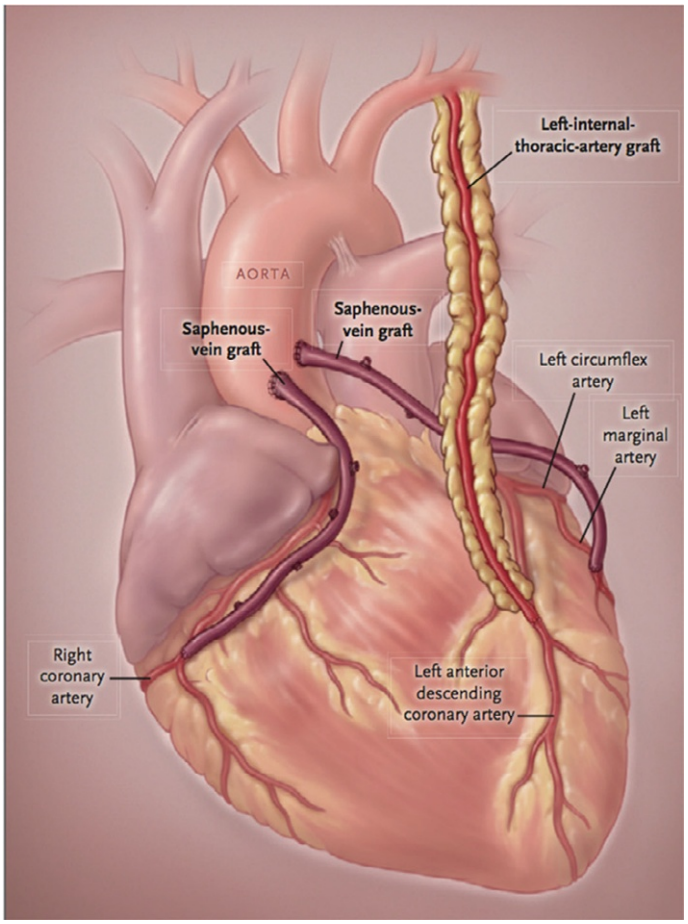

Fig. 23 A depiction of a left internal mammary (LIMA) graft to the left anterior descending coronary artery and saphenous vein grafts to the left marginal and right coronary arteries. From: *N Engl J Med* 2016;374:1955.

performance of modern CABG surgery. In fact, it remains the most commonly utilized conduit by surgeons today (Alexander and Smith, 2016). By the early 1970s, vein graft failure was already well recognized and a pathophysiologic process involving the intima was being described. Endothelial injury that occurs during vein graft harvest followed by and/or additionally caused by exposure of the vein graft to arterial pressure has been associated with platelet deposition, subsequent intimal hyperplasia, atherosclerotic plaque formation, and eventual stenosis and closure. A series of studies over the past 40 years have proven the benefit of antiplatelet therapy with low to intermediate dose aspirin as well as high-intensity statin therapy for lipid management in the interruption of this pathophysiologic process and improvement in vein graft patency. Unfortunately, studies of agents that directly interrupt intimal hyperplasia at the DNA level such as Edifoligide in the PREVENT IV study (2002–03) have not been as successful (Lopes et al., 2012a).

Despite these adverse findings, there are a number of the greater saphenous vein characteristics that make it such a good conduit and help to explain its continued status as workhorse in CABG surgery. These include its length, ease of use, ease of harvest, reasonably matched size in comparison to the targeted coronary artery, immediate capacity for high flow to the target vessel, capacity for sequential grafting, and suitability to the construction of a proximal anastomosis to the ascending aorta. During the early experience with CABG surgery, vein harvesting was universally carried out with either a full open technique or via a series of skip incisions. Dissatisfaction with the rate of wound complications/infections, delayed healing, pain, and cosmetics (appearance) along with advances in minimally invasive surgery led to the development of endoscopic vein harvesting (EVH) techniques by the mid to late 1990s.

Initially, EVH was criticized for a number of drawbacks including increased time of harvest, increased risk of conduit injury, increased potential for retained clot in the harvested vein, increased risk of vein stenosis or graft occlusion, risk of CO_2 (carbon dioxide) embolism, and operator dependence for graft quality. Several prospective studies carried out from 2000 to 2009 produced conflicting results regarding noninferiority of the endoscopically harvested vein graft. Other studies during this era revealed that the clot formation associated with EVH is most likely a result of combined local trauma and stagnant blood (Lopes et al., 2009, 2012b; Poston, 2006; Dacey et al., 2009, 2011). As a result of continued technological advances in operative equipment, increased surgical

experience, earlier intraoperative use of heparin, and associated improvement in the quality of harvested veins, EVH has become the preferred method of greater saphenous vein procurement over the past 10 years (Raja and Sarang, 2013).

During preoperative planning, the surgeon determines the use of conduits based on the number, size, and location of diseased the coronaries. Generally speaking, the LIMA will be placed to the LAD. Based on patient comorbidities, severity of coronary obstruction, acuity/severity of patient illness, and presence of adequate ulnar collateral flow, the surgeon will determine the appropriateness of the use of secondary arterial grafts such as the RIMA as a pedicled (attached to its native source) or free graft, and the left/right radial artery. If appropriate for a particular case, those conduits will be placed to the second or third tier target vessels. Severity of stenosis of the native coronary has been associated with superior saphenous vein graft longevity over arterial conduit choices due to the negative effects of competitive flow. In the case of the RIMA, SVG is superior when grafted to the distal right coronary artery when the stenosis is less than 80–90% because of size compatibility and consequent flow characteristics. Likewise, if the native stenosis is less than 70 or 80%, saphenous vein graft patency is superior to radial artery grafts (Yie, 2008; Taggart, 2013; Athanasiou et al., 2011; Deb, 2012; Sabik, 2008). The practical result of such operative planning is that the distal coronaries that are not going to be grafted by arterial conduits will need to be grafted with saphenous vein.

The Internal Mammary Artery: The Physiology of Arterial Grafting

The internal mammary artery grafted to the left anterior descending coronary artery is a major quality indicator in CABG surgery and gives superior short- and long-term outcomes when compared with saphenous vein grafts (Hillis et al., 2011). Linguistically, the Latin root of the word mammary is "mamma" or breast. Further underscoring the physiologic importance of the breast is the use of the same root in Taxonomy, or the scientific classification of organisms. In this classification system, Mammals represent a major Class within the Animal Kingdom. As the name of this Class implies, its members share a critical survival advantage: The ability to sustain their offspring by providing nutrition in the form of milk from maternal mammary glands. Though the title "internal thoracic artery" is admittedly more anatomically accurate, it can give the impression that the artery has the functional importance of a redundant tributary vein from the superficial venous system of the leg or of a vestigial structure such as the appendix (Conti, 1991).

The title "internal mammary artery" reinforces the concept that this artery serves as a critical support element of Mammalian breast systems and by extension, species survival. Moreover, given the importance of this vascular structure in supporting the level of lactation required for the continuing generation of mammalian species, it is not surprising to find that internal mammary arteries have some unique characteristics when compared with other arteries in the body. From studies of human physiology, we know that a nursing human mother forms about a liter and half of milk per day (Hall, 2016.). In order to support this rate of production, the cardiovascular system provides arterial support to each breast from two main arteries: the internal mammary and the lateral thoracic arteries. A recent study of the blood flow to the lactating human breast revealed that an average of 126 L of blood was supplied to each breast over a 24-h period with 70% of that flow being derived from the left internal mammary artery the artery often destined to revascularize the heart (Geddes et al., 2012). In pregnancy, such flow augmentation can present as a continuous murmur over the front of the chest called the "mammary souffle of pregnancy" (Scott and Murphy, 1958). The capacity of the internal mammary arteries to increase blood flow in response to end organ demand during the pregnant/lactating state has proven to be an excellent conduit characteristic when providing blood flow to an ischemic myocardial zone.

In addition to the ability to increase blood flow, studies have shown that IMAs have specific anatomic and physiologic properties that account for their superiority when used as a coronary bypass graft. These arteries have been shown to be impervious to the transfer of lipoproteins. This characteristic seems consistent with its primary support role as a conduit for optimal oxygen and nutrient delivery, especially lipoproteins, to the lactating breast for production of calorie dense milk and is also likely associated with its remarkable resistance to the development of atherosclerosis. Anatomically, this resistance to the transfer of lipoproteins may be related to an endothelial layer containing fewer fenestrations and lower intercellular junction permeability. Physiologically, IMA endothelial cells (the cells that line the blood vessels) have continuing high levels of heparan sulfate, tissue plasminogen activator (a protein involved in the breakdown of blood clots), and endogenous nitric oxide (a vasodilator) production (Osuka, 2013).

The internal mammary artery (IMA) graft's superior long-term patency could also be partly attributed to the fact that the endothelium of the IMA graft can release prostacyclin. Prostacyclin (also called prostaglandin I2 or PGI_2) is a potent vasodilator that can also inhibit platelet aggregation. Lin et al (Lin et al., 1991). demonstrated that endothelium of IMA grafts could release prostacyclin either in a basal condition or upon stimulation of hypoxia. Subramian et al (Subramanian et al., 1986). found in vitro that segments of the mammary artery (IMA) had a high capacity for PGI_2 synthesis and diminished inhibition of PGI_2 after aspirin was demonstrated for IMA compared with saphenous vein tissue and may be a factor in the improved patency of IMA grafts. Homolay (Homolay et al., 1993) studied the prostacyclin-producing capacity of the IMA using a platelet aggregation bioassay. He concluded that the synthesis of prostacyclin was significantly higher in the internal mammary artery than that was in the saphenous vein.

Many of the factors that contribute to the long-term patency of the LIMA graft are summarized in **Fig. 24** (Bruce Ferguson, 2016). The proinflammatory environment of the diseased heart is "normalized" as the graft stays open for many years by virtue of its endothelial production of endogenous vasodilators (nitric oxide), prostacyclin (PGI_2), along with the production of epoxyeicosatrienoic acids (EET). EETs are cardioprotective signaling molecules formed within various types of cells by the metabolism of arachidonic acid.

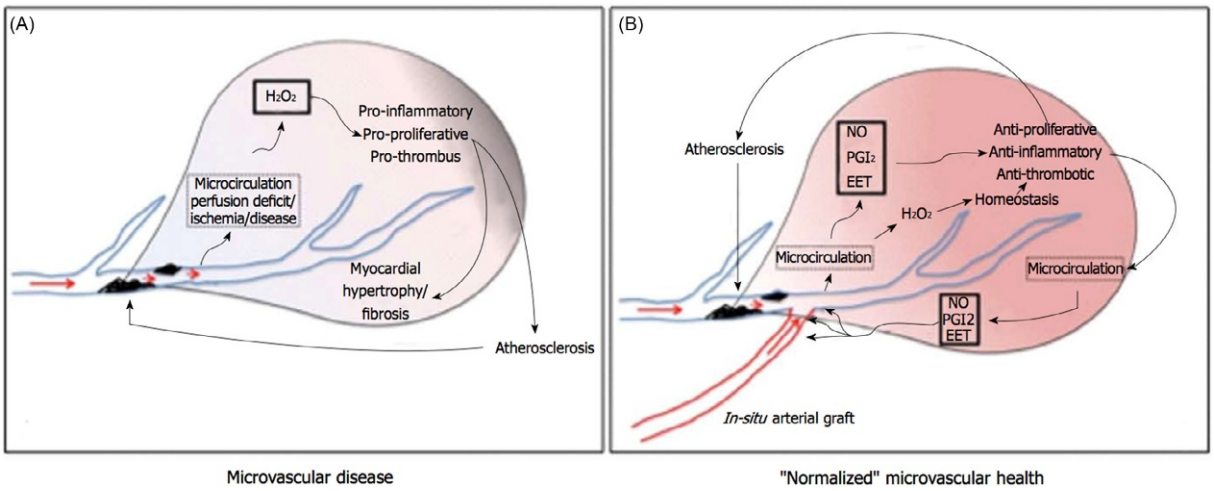

Fig. 24 In a healthy heart, arteriolar endothelium produces NO (nitric oxide), prostacyclin (PGI2, and EETs) as well as low levels of hydrogen peroxide, which support a quiescent nonproliferative state. With the onset of disease (A), flow through the microvasculature releases hydrogen peroxide, creating a proinflammatory environment throughout the organ, potentially leading to hypertrophy, fibrosis, and atherosclerosis. In (B), with bypass grafting of ischemic myocardium, the microvascular health of the myocardium is "normalized." *NO*, nitric oxide; *PGI2*, prostacyclin; *EET*, epoxyeicosatrienoic acids. From: *World J Cardiol* 2016; 8(11): 623–637.

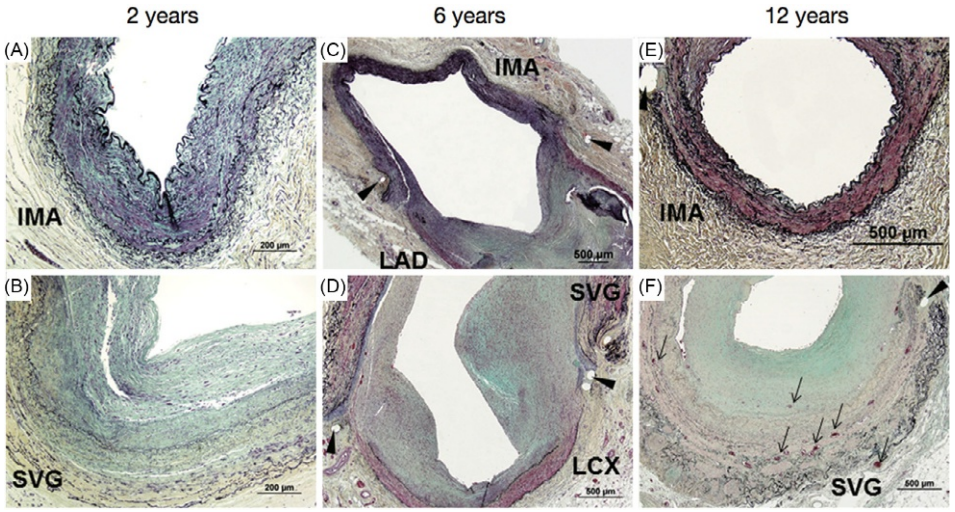

Fig. 25 Histologic changes observed in the internal mammary artery (IMA) graft as compared to the saphenous vein graft (SVG). (A, B). Histologic sections showing IMA and SVG obtained from a 76-year-old man who underwent coronary artery bypass graft (CABG) surgery 2 years antemortem. IMA shows no or rare intimal smooth muscle cells (SMCs), whereas SVG exhibits moderate neointimal growth with few SMCs but rich in matrix which consists of proteoglycans and collagen. (C, D). Histologic sections showing IMA and SVG obtained from a 69-year-old man who underwent CABG surgery 6 years antemortem. Note the absence of intimal thickening in IMA. (C) versus the presence of moderate neointimal thickening in SVG from SMCs and proteoglycan-collagenous matrix at the site of anastomosis (arrow heads indicate suture sites) with left anterior descending artery (LAD) or left circum ex artery (LCX) (D). (E, F) IMA graft and SVG from a 77-year-old woman who underwent CABG surgery 12 years antemortem. While the IMA shows minimal intimal thickening, SVG exhibits moderate to severe neointimal growth with proteoglycan–collagen matrix and angiogenesis (*arrows*). All sections were stained with Movat pentachrome. Illustration From: Osuka, F. (2013). Why as the mammary artery so special and what protects it from atherosclerosis? *Annals Cardiothoracic Surgery* **2** (4), 519–526.

The combination of these attributes along with an ideal size match to target coronary arteries and associated decrease in turbulent flow helps to account for the superior performance of the IMA as a bypass graft relative to the saphenous vein graft as illustrated in Fig. 25.

The Radial Artery

The utilization of a radial artery free graft was first described by Dr. Alain Carpentier, in Paris, France, one of the pioneers of modern cardiac surgery (Carpentier et al., 1973). After initial intense interest, reports of radial artery graft failures with profound narrowing

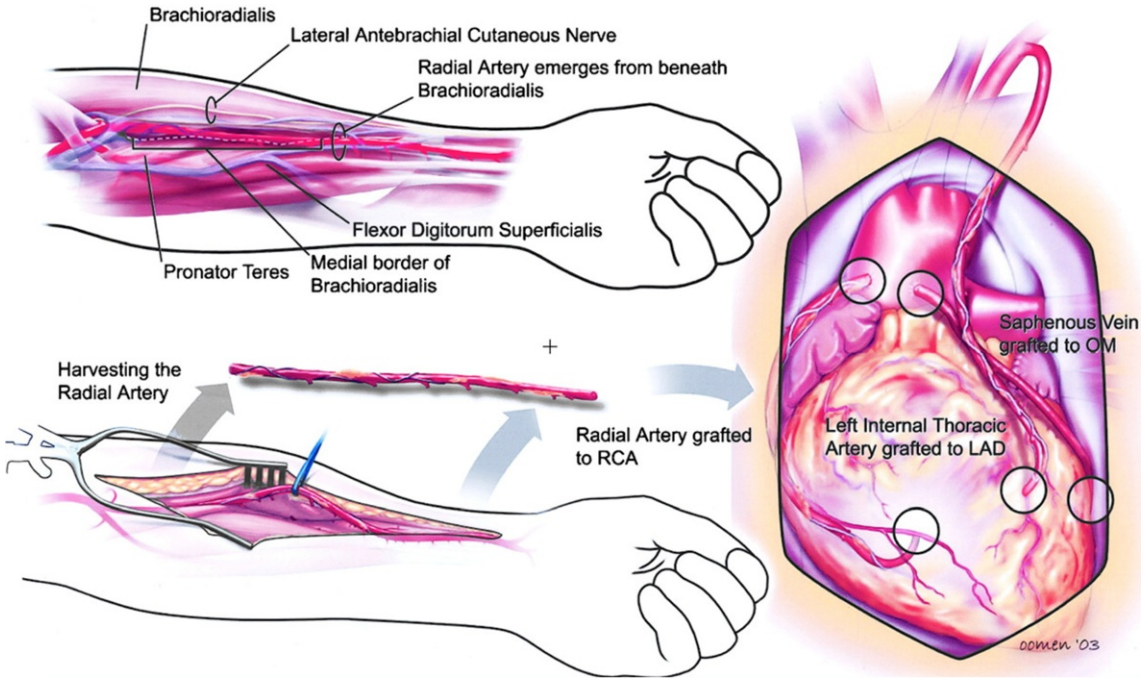

Fig. 26 The radial artery (RA), harvested as a pedicle, is dissected through a skin incision starting 3 cm distal to the elbow crease lateral to the biceps tendon, stopping 1 cm before the proximal crease at the wrist level, centered over the radial pulsation, between the flexor carpi radialis and the radial tubercle. Care is taken to avoid damaging the lateral antebrachial cutaneous nerve (sensory), which crosses obliquely from medial to lateral. After incision of the skin and fatty tissue, the RA can be seen in the distal third of the forearm beneath the fascial layer and is completely exposed by lateral mobilization of the brachioradialis. All side branches are ligated and the artery is irrigated topically with dilute papaverine solution during the dissection. Compared with the LIMA, the RA has a much thicker muscular media that likely contributes to its increased propensity to go into spasm. The RA may be proximally anastomosed to the LIMA, forming a composite graft, or to the ascending aorta to bypass all coronary territories. Illustrated is the use of a free RA graft anastomosed proximally to the ascending aorta to bypass a lesion in the right coronary artery, the LIMA anastomosed to the LAD, and a saphenous vein graft to the first obtuse marginal branch (OM). From: Verma et al Circulation. 2004;110:e40–e46.

of the graft (so-called angiographic string sign) discouraged utilization of the radial artery for CABG surgery. However, long-term follow-up of these arteries revealed that vessels that had at one point shown a string sign showed with reassessment progression to be widely patent (Verma et al., 2004). As arterial spasm might be a contributing factor, the use of the radial artery was resurrected along with intraoperative and postoperative vasodilator therapy to decrease vasospasm in the vessel. As long-term vasodilator therapy could result in atrophy of the muscular component of the radial artery, the vasodilators are given for a limited amount of time (Verma et al., 2004). Fig. 26 depicts the harvesting and use of the radial artery.

In some centers, all arterial grafting has become the ideal operation, while others have not adopted that philosophy. In fact, most patients do not receive all arterial grafts as most surgeons have not adopted all arterial grafting as a primary myocardial revascularization strategy. These competing philosophies reflect one of the current major controversies in surgical myocardial revascularization.

Conduct of the CABG Operation

Shortly after induction of general anesthesia, the greater saphenous veins are assessed and proposed incision sites are marked in the leg(s). Ultrasound can be used to augment physical exam information and accurately predict sites of branching, varicosity, and duplication. The patient is then "prepped" with a topical antiseptic from the chin down to the level of both ankles and then covered with sterile drapes, leaving only the surgical incision sites exposed. A longitudinal midline sternotomy is made, aided by a surgical saw, cutting in the midline of the sternum, allowing for a precise closure, securely repairing the bone and the rest of the wound at the close of the procedure (Fig. 27). The midline has no muscle to cut through and at the completion of the procedure the sternum is repaired with sternal wires or other methods of firm secure closure, allowing the bone to heal much like any other orthopedic repair of bone with various types of hardware. The discomfort during healing is well tolerated in general and affords the patient less pain than other major incisions such as thoracotomies (between the ribs) or laparotomies (large abdominal incisions)

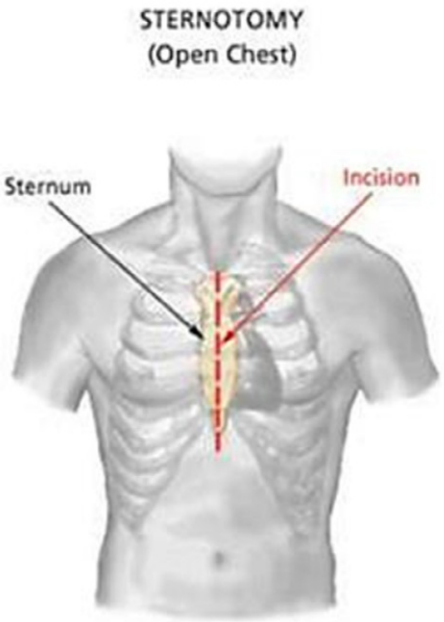

Fig. 27 The sternotomy incision that is typically used in CABG surgery and other types of cardiac surgery. From www.surgery.usc.edu. IAC Publishing, LLC ("Ask") provides the Ask.com site (the "Site") and the offered services and features (the "Services") subject to these Terms of Service ("Terms of Service").

Conduct of the CABG Operation

Shortly after induction of general anesthesia, the greater saphenous veins are assessed and proposed incision sites are marked in the leg(s). Ultrasound can be used to augment physical exam information and accurately predict sites of branching, varicosity, and duplication. The patient is then "prepped" with a topical antiseptic from the chin down to the level of both ankles and then covered with sterile drapes, leaving only the surgical incision sites exposed. A longitudinal midline sternotomy is made, aided by a surgical saw, cutting in the midline of the sternum, allowing for a precise closure, securely repairing the bone and the rest of the wound at the close of the procedure (Fig. 27). The midline has no muscle to cut through and at the completion of the procedure the sternum is repaired with sternal wires or other methods of firm secure closure, allowing the bone to heal much like any other orthopedic repair of bone with various types of hardware. The discomfort during healing is well tolerated in general and affords the patient less pain than other major incisions such as thoracotomies (between the ribs) or laparotomies (large abdominal incisions).

Once the sternum is opened, the mammary artery is harvested after which the sternum is separated with a sternal retractor (Fig. 28), and the pericardium (sac around the heart) is exposed and divided. At this time the heart is exposed with all of its structures, epicardial vessels, and the large veins leading to and great arteries exiting the pumping chambers.

If a radial artery is going to be harvested, the anesthesia team will start either a low dose of intravenous nitroglycerin or a calcium-channel blocker to inhibit potential vessel spasm. The entire operation is performed under conditions of ideal illumination such as an intense headlight, and magnification (surgical loupes that magnify 2.5 to 3.5 times). While the left internal mammary artery (LIMA), right internal artery (RIMA), or both and/or radial arteries are being harvested, a small incision is made over the greater saphenous vein either above or below the knee and eventually exposing the vein. Once the vein has been identified, the patient is given a low dose of intravenous heparin. Endoscopic vein harvesting (EVH) equipment is then deployed to bluntly dissect out the vein creating a carbon dioxide (CO_2) insufflated tunnel that allows for a minimal touch technique, safe branch management, and tunnel hemostasis (control of bleeding) (Fig. 29) (Accord and Maessen, 2011).

The near and far ends of the vein are accessed via additional small incisions and the vein is ultimately removed from the leg. It is then reversed (as it has one-way valves) and flushed with a solution of heparin and saline in order to remove clots and to identify branches, varicosities, defects, or injuries. If the vein is not felt to be adequate, remaining vein on the same leg the other leg is then harvested. In general, branches are clipped or tied at the level of the vein though some surgeons prefer to preserve 2–3 mm of the length on the larger branches for potential use when performing sequential distal anastomoses, allowing more than one coronary artery to be grafted with one section of saphenous vein. Once the vein has been attended to, the leg wounds are inspected for hemostasis, irrigated, and carefully closed in layers. If an inadequate length of vein conduit is available, then a backup plan for harvesting the RIMA or radial arteries is activated. Alternatively, though not ideal, short segments of usable vein from each leg can be sewn together end-to-end in order to create a composite graft of adequate length. A prognostic saphenous vein scoring system that also takes into account the runoff status (size and quality with regard to the amount of atherosclerosis) of the target coronary artery has been described (Sarzaeem et al., 2010). In circumstances in which a compromised vein conduit has to be used in CABG, and/or

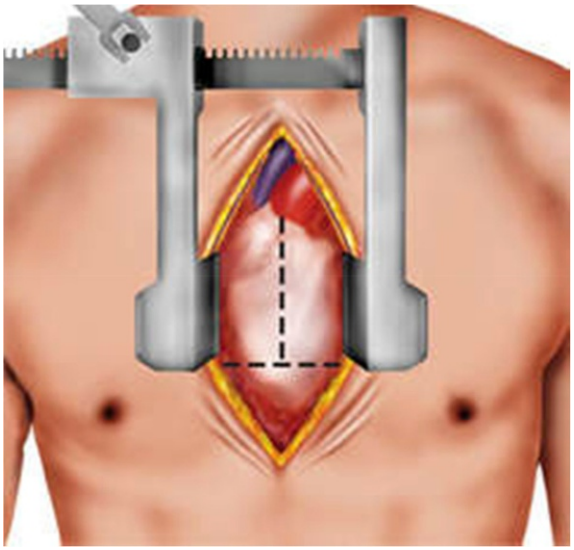

Fig. 28 The sternotomy has been performed and a sternal retractor has been inserted and spread to expose the pericardium with the dotted lines depicting the planned typical pericardial incisions that will expose the heart. the runoff is not ideal, antiplatelet therapy (medications such as aspirin or clopidogrel that decrease platelet aggregation or "stickiness" to discourage the initiation on intraarterial clotting) is reasonable and evidence-based (Une et al., 2014).

A crucial aspect of long-term management of this newly create anatomy is termed "secondary prevention." All of the efforts to revascularize coronary arteries do not cure coronary artery disease, and a comprehensive postsurgical management program must be instituted that includes high-intensity statins, antiplatelet medications such as low-dose aspirin, beta blockers, aldosterone antagonists (if heart failure or left ventricular systolic dysfunction), angiotensin receptor blockers (if diabetes or left ventricular systolic s dysfunction), and lifestyle changes that include regular aerobic exercise, a diet low in saturated fats and carbohydrates and abstention from smoking (Kulik et al., 2015; Fihn et al., 2014).

Once all conduits are prepared and the patient is systemically heparinized, the heart and ascending aorta are inspected. Distal coronary artery targets are confirmed and grafting sites can be marked. Once grafting sites are determined, the length of conduit that will be required to reach the aorta is determined as well as the distance between any sequential anastomoses (the practice of using one conduit for multiple distal connections). Once it is confirmed that adequate conduit is available, the surgeon may use natural branches that may be available for sequential grafting or can fashion an arterial "Y" configured graft with a combination of arterial

or venous conduits. If there are any concerns about quantity or quality of the graft material, the surgical assistant can harvest more saphenous vein as the surgeon initiates bypass and begins to perform distal anastomosis with conduit that has been deemed adequate at this point in the procedure.

CABG Using Cardiopulmonary Bypass

If the CABG is going to be performed with CPB support and cardioplegic arrest as described in the section on CPB, aortic and right atrial cannulation sutures are placed, after which aortic and right atrial cannulae are inserted and secured. A retrograde cardioplegia cannula is inserted into the coronary sinus and an antegrade cannula is placed in the ascending aorta. Appropriate connections are made with the tubing from the CPB and the patient is then placed "on bypass" and usually cooled (actively or passively) using systemic hypothermia (cooling the entire body) while cardioplegia is being prepared. The distal ascending aorta is cross-clamped between the aortic cannula and the antegrade cardioplegia line and induction antegrade/retrograde cardioplegia is delivered (Fig. 30). Depending on surgeon preference, the metabolic rate of the myocardium can be further reduced with topically with chilled saline or ice slush.

Once cardioplegia has been delivered, the heart is ready for grafting. With the heart now flaccid and cooled on CPB, each distal coronary artery or branches thereof (targets) is adequately exposed, the visceral pericardium covering each vessel is dissected away, and the vessel is opened. A bloodless, still, clear sewing field has been created, and the surgeon is now ready to sew the conduit to the coronary artery at a point beyond the stenosis (narrowing) or obstruction. The appropriate conduit (vein or artery) is now tailored to fit the opening in the recipient artery as sutured with a very fine monofilament suture using fine microvascular instruments and intense lighting (headlight) and magnification (surgical loupes). Prior to completion, adequate patency is confirmed, the conduit is deaired and tested for leaks which are repaired if present. More cardioplegia is now given, and this cycle is repeated until each distal anastomosis is completed.

Rewarming of the patient is initiated using the heat exchanger on the CPB machine prior to the performance of the final anastomosis and preparations are made for construction of the proximal anastomoses. Once all of the anastomoses have been completed and with the aortic cross clamp having been removed, the heart begins to warm and regain its usual metabolism and electromechanical properties. Once the patient is adequately rewarmed and the heart is recovered, the patient is weaned from CPB with varying levels of inotropic/pressor support, decannulated, and the surgical wound closed. At this time, the team is dealing with other details of weaning from CPB, primarily hemodynamic support, fluid, and electrolyte balance and management of coagulation abnormalities when they arise. Graft flows are checked with flow probes for adequacy with Doppler flow signals, the most commonly used being transit-time flow meters.

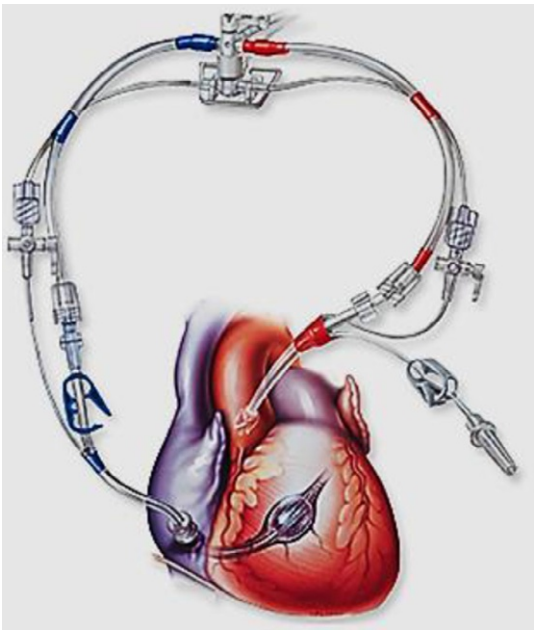

Fig. 30 This illustration depicts the heart with both antegrade (aortic) and retrograde (coronary sinus) catheters placed in the heart and ready to be attached to the CPB circuit for administration of cardioplegia. From: criticalunit.com critical-care-medicine.becoming a better Clinician.

CABG Without Cardiopulmonary Bypass: Off-Pump CABG (OPCAB)

If the operation is going to be performed off-pump, the room is kept warm and intravenous amiodarone (an antiarrhythmic) and low-dose norepinephrine infusions are initiated. Temporary pacemaker wires are placed and tested. All of these measures are taken in order to be prepared for rhythm and hemodynamic abnormalities that must be managed in the course of the operation as the surgeon does not have the advantage of the mechanical support of CPB. Exposure and stabilizing devices are now deployed to optimize exposure on a beating heart with blood continuing to flow in all of its vessels as opposed to the still, bloodless field afforded by the use of CPB, and cardioplegic arrest. Exposure is gained with a combination of deep pericardial retraction sutures, an apical suction universal retractor and judicious use of surgical pads. Communication between the anesthesiologist and the surgeon regarding hemodynamic stability is a top priority to maintain safe conduct of the operation. The role of the cardiac anesthesiologist is demanding and includes constant hemodynamic monitoring, transesophageal echocardiographic (TEE) assessment for ischemia, and quick responses for maintenance of blood pressure and cardiac output and allows the surgeon to safely perform the distal anastomoses. Once the target artery is exposed, it is immobilized with a stabilizing device(s), the visceral pericardium is dissected away, and preparations are made to perform the distal anastomosis. Control of blood flow at the site of the intended anastomosis is afforded by a proximal occlusion method. When the artery is opened, a clear anastomotic site is gained by a combination judicious use of a device that blows CO_2 in a gentle mist. In circumstances where hemodynamic stability is difficult to maintain because of ischemia, an intracoronary shunt can be placed into the anastomosis to provide a blood free zone. Construction of the anastomosis is the same as described in the on-pump CABG section. Once the anastomosis is completed, the conduit is flushed and the proximal occlusion technique is released to ensure deairing and the suture line is tied down. This cycle is completed until all distal anastomoses are performed.

The proximal anastomoses can be performed on the unclamped aorta with a device such as the Heartstring (Fig. 31) or with the aid of a partial occlusion clamp. Bypass grafts can now be tested with a transit time flow probe (Doppler technology), and once grafts are determined to be acceptable, protamine can be administered to reverse the effects of heparin, and the chest closed.

When surgeons are confronted with ischemic coronary beds that are not amenable to CABG due to poor distal targets, hybrid techniques of managing those ischemic zones are available (Gosev and Leacche, 2014). For example, if numerous small branches that arise from a larger artery that is amenable to more proximal percutaneous intervention populate the ischemic zone, then a multidisciplinary approach of traditional CABG and PCI with a drug eluting stent can be performed simultaneously in a hybrid operating room or as separate procedures utilizing both an OR and a cardiac catheterization laboratory.

When an ischemic zone has targets that are not amenable to either CABG or PCI, then transmyocardial laser revascularization (TMR) can be utilized as an adjunct to CABG (Horvath, 2008; Bhimji and Sheridan, 2015). This technique utilizes a carbon dioxide or YAG laser to create multiple full-thickness channels in an ischemic zone that cannot otherwise be revascularized. Though it was initially hypothesized that the laser-created channels would develop into sinusoidal-type structures with direct perfusion of the myocardium from the left ventricle, this has never been found to occur. The relief of angina may be due to an augmented development of collaterals or to a local sympathectomy of the treated visceral epicardium and myocardium. The Society of Thoracic Surgery recommendation is that such an approach is reasonable; however, further investigation is needed as several studies to date have returned conflicting angina benefit and survival results (Bridges et al., 2004; Allen, 2000).

Fig. 31 The Heartstring® is an example of a novel device that allows the surgeon to sew a graft onto a hole created in the aorta for that purpose without having to clamp or manipulate the aorta in a cast of beating heart surgery (OPCAB) or when the aorta is so diseased that minimal aortic manipulation is desired to minimize the stroke risk from dislodging particulate matter from the aorta that could embolize (move from one place to another in the circulation). From: Boston Scientific Corporation.

Controversy exists with regard to many aspects of the practice of medicine and surgery and the ideal technique for the performance of CABG surgery is no exception, subject to conflicting evidence, longstanding practices, and beliefs. While different practices have varying outcomes in different sets of hands, the evidence and the science behind it seem to be sending a message with a common theme: With some exceptions, an all-arterial operation done on CPB is likely to achieve the best short- and long-term outcomes (Puskas et al., 2014; Lytle, 2001; Buxton et al., 2014).

Perioperative Management, Complications

CABG surgery as described is performed in cardiac surgery centers with experienced teams and access to all of the supporting multidisciplinary specialties to guide the patient safely through a defined pathway that is well described, frequently assessed, and provides as much reliability as possible while reducing variability. Decision-making in this context is based upon checklists and algorithms that are agreed upon by the team based on current evidence. Once the patient is referred to the system and placed on the pathway, defined processes are initiated starting with a readiness for surgery checklist that includes everything from demographics, socioeconomic factors, comorbidities, and evidence-based indications. Thinking as far ahead of postacute care considerations is done at this point, especially with so-called complex discharges that may require skilled nursing facilities or rehabilitation. All decisions cannot be based on checklists and algorithms alone and require more complex thinking, many times aided by the multidisciplinary team, especially in the selection process. Checklists and algorithms help to drive preoperative orders that include diagnostic tests such as laboratory studies and imaging. The results of those tests continue to be fed back into the decision-making process. The involvement of family and patient is crucial in the informed consent as they develop an understanding of expectations as best they can.

The care team is extensive, requiring the involvement of specialty nurses, outpatient and inpatient, advance practice providers (nurse practitioners and physician assistants), physicians in training (residents), respiratory therapists, cardiopulmonary perfusionists, physical and occupational therapists, pharmacists, registered dieticians, critical care specialists (surgeons and anesthesiologists), care managers, and an extensive administrative support team usually in the context of a tertiary care hospital.

The CABG operation may take up to 4 or 5 h, including 1–2 h of CPB time and 5 or 6 days in the hospital before discharge to a postacute care facility of home. Full recovery in an uncomplicated case can take up to 12 weeks. All of this timing is dependent on whether there are complications or not. Nearly every feature of the process is carefully documented during the patients hospitalization in the electronic medical record and subsequently entered into an extensive database that is submitted to regional and national databases allowing centers to see their teams' performance compared with centers like theirs. Surgical site infections, strokes, and mortality are key markers as well as each center's ability to rescue patients from multiple other complications that may arise.

In summary, patients are selected after shared decision-making in the context of evidence accumulated through many observational and randomized trials with this operation being done in the setting of an experienced center with a heart team and a multidisciplinary team of caregivers. That center is constantly scrutinizing data compared with like centers in a national database. Outcomes are fed back to front line workers in the multidisciplinary team, establishing and maturing pathways to minimize variability in care and achieve the best outcomes possible.

Summary

CABG surgery has a central place in the effort to revascularize the myocardium, gained after over more than a 50-year history. The knowledge gained by the world experience of cardiac surgeons performing millions of operations using evidence available to guide appropriate selection of patients, the technologic advances gained by the cardiopulmonary perfusionists, understanding of myocardial physiology, myocardial protection, vascular biology, secondary prevention, heart teams, and multidisciplinary teams of perioperative caregivers has and will improve, save and prolong productive lives. As less invasive techniques evolve and translational research leads us to a better understanding of the exuberant, maladaptive systemic inflammatory response with strategies to mitigate it, CABG surgery will continue to evolve to be even safer and valuable.

Introduction

Congenital heart disease occurs in approximately 1% of live births, and approximately 15% of these have cyanotic heart disease (Hoffman and Kaplan, 2002; Mitchell et al., 1971). Infants born with cyanotic congenital heart disease are particularly vulnerable to morbidity and mortality, often requiring intervention in the neonatal period for survival. Prior to 1945, no surgical treatments existed for patients with cyanotic heart disease, and thus, most of these babies did not survive infancy. Advances in surgical techniques have led to dramatic improvements in survival. Today, treatments are available for nearly all infants with cyanotic congenital heart disease. The improvement in survival in recent decades has led to there being more adults than children with congenital heart disease.

Cyanotic congenital heart disease has often been presented as a list of lesions, often aided with mnemonics such as "T"s and "P"s. However, this article will present a framework for understanding congenital heart disease that focuses on principles of physiology and anatomic features that lead to cyanosis, grouping lesions by their common pathophysiologic features. We will discuss representative cyanotic heart lesions, along with available medical, catheter-based, and surgical interventions.

Physiologic Principles of Cyanotic Congenital Heart Disease

An understanding of cyanosis as well as fetal and transitional circulatory physiology aids in understanding the pathophysiology of cyanotic congenital heart disease.

 https://doi.org/10.1016/B978-0-12-809657-4.99825-9

Cyanosis

The eye is not very sensitive in detecting cyanotic heart disease. Detection of cyanosis or blueness of the skin requires the presence of approximately 3 $g dL^{-1}$ of deoxyhemoglobin in arterial blood (Lees, 1970; Nadas, 1992). For a newborn, with a total hemoglobin of 20 $g dL^{-1}$ (just above the normal range), cyanosis would be detectable at an arterial oxygen saturation of about 85% (17 $g dL^{-1}$ of oxyhemoglobin, 3 $g dL^{-1}$ of deoxyhemoglobin), whereas for a 2-month old infant with a total hemoglobin of 10 $g dL^{-1}$ (just below the normal range), cyanosis would not be detectable until the arterial oxygen saturation reached about 70% (7 $g dL^{-1}$ of oxyhemoglobin, 3 $g dL^{-1}$ of deoxyhemoglobin). It is important to recognize that when infants are cold, vasoconstriction decreases flow to the skin, particularly of the hands and feet, resulting in the appearance of blueness of the skin caused by lowering of venous oxygen saturations. This normal phenomenon, known as acrocyanosis, occurs even when arterial saturations are normal (close to 100%), and it does not indicate the presence of cyanotic heart disease.

Cyanosis may be the result of lung disease or heart disease. Often, this distinction is clinically apparent. Infants with cyanosis from lung disease often demonstrate signs of respiratory distress on physical examination, including dyspnea, tachypnea, and retractions, whereas infants with cyanosis from heart disease usually breathe comfortably. Arterial blood gases often show an elevation of P_{CO_2} in infants with lung disease, while those with cyanosis from heart disease often have normal or low P_{CO_2}. Although not directly measurable without cardiac catheterization, the pulmonary venous oxygen saturation is low in infants with pulmonary causes of cyanosis, while it is normal in isolated cyanotic congenital heart disease. As a result of this decreased pulmonary venous oxygen saturation in infants with cyanosis from lung disease, there is often a marked improvement in arterial P_{O_2} while breathing 100% oxygen (FiO_2 of 1.0), while in infants with cyanotic heart disease and normal pulmonary venous oxygen saturations, there is little improvement in arterial P_{O_2} with 100% oxygen, as the pulmonary venous saturation was already nearly 100%. There may be some effect of oxygen on infants with cyanotic heart disease with supplemental oxygen, as a small amount of oxygen can be dissolved in blood, and oxygen is also a pulmonary vasodilator, but it is extremely rare for the arterial P_{O_2} to exceed 150 torr in infants with cyanotic heart disease, even on 100% oxygen. Other clues suggesting congenital heart disease as the cause of cyanosis in neonates include the presence of a murmur, abnormal cardiac silhouette on chest x-ray, and presence of risk factors for congenital heart disease including chromosomal abnormalities, multiple congenital anomalies, maternal diabetes mellitus, and a family history of congenital heart disease (Fig. 1).

Fetal Circulation

In order to understand the pathophysiology of cyanotic congenital heart disease in the hours and days after birth, one must understand the fetal and transitional circulation. In utero, the right ventricle (RV) and left ventricle (LV) work in parallel, both pumping blood primarily to the systemic fetal circuit (from the LV directly to the ascending aorta, and from the RV through the ductus arteriosus to the descending aorta). The fetal RV contributes about twice as much flow to the fetal circulation as does the fetal LV. Lesions affecting inflow or outflow of only one ventricle do not often compromise the fetal circulation, as the unaffected ventricle is able to maintain the circulation.

Fig. 2 depicts the fetal circulation just before birth (Taussig, 1947). The umbilical vein carries oxygenated blood from the placenta to the fetus, draining through the liver via the ductus venosus to the inferior vena cava (IVC). IVC blood flow streams toward the patent foramen ovale (PFO), allowing the most oxygenated blood in the fetus to pass to the left heart and out the ascending aorta, where it supplies the coronary arteries and developing brain. Deoxygenated superior vena cava (SVC) blood is directed through the right heart, much of it flowing from the pulmonary artery through the patent ductus arteriosus (PDA) to the

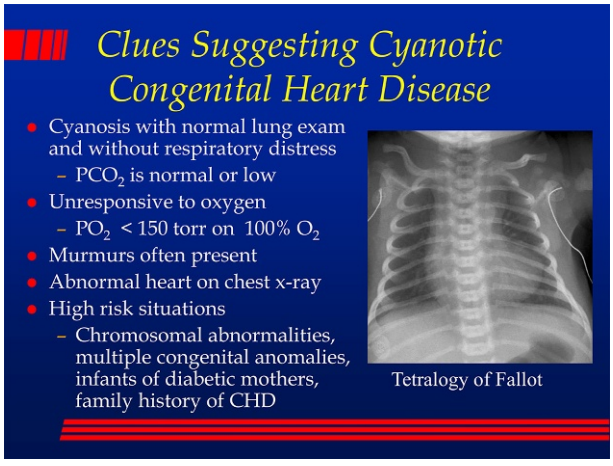

Fig. 1 Clues suggesting cyanotic congenital heart disease. Clinical clues may help differentiate cardiac and pulmonary causes of cyanosis in infants. The chest radiograph of an infant with tetralogy of Fallot demonstrates decreased pulmonary vascular markings, an upturned apex because of right ventricular hypertrophy, and a concave main pulmonary artery segment because of pulmonary stenosis.

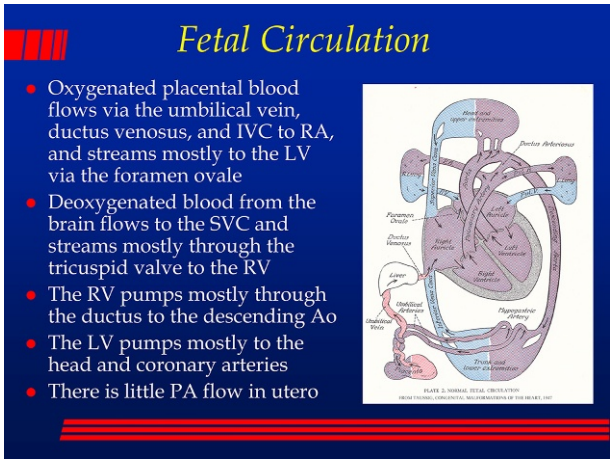

Fig. 2 Fetal circulation. An understanding of the fetal circulation just before birth informs the expected changes in physiology during transition to extrauterine life. The ductus venosus, foramen ovale, and ductus arteriosus serve to maximize blood and oxygen delivery to vital organs and minimize pulmonary blood flow in utero. Pathophysiologic changes allowing recognition of underlying structural heart defects often appear when these structures close after birth (Taussig, 1947).

descending aorta and the umbilical arteries back to the placenta. The fetal lungs receive only a small portion of the combined ventricular output, as they are not the organ of oxygenation of the fetus and do not require a large amount of flow.

Transitional Circulation

With the newborn's first breath, the aeration of the alveolae causes a fall in the pulmonary vascular resistance (PVR), and the increased pulmonary venous return to the left atrium pushes the flap of the foramen ovale (known as septum primum) toward the more muscular superior portion of the atrial septum (known as septum secundum), limiting left-to-right atrial shunting. In the first hours to days of life, the PDA usually closes. Maintaining these communications between the right and left heart is important for the postnatal survival in many infants with cyanotic congenital heart disease. PVR, which is high in utero, usually continues to drop dramatically in the first days of life and continues to fall throughout the first several weeks of life.

An understanding of the transitional physiology informs the expected clinical presentation for most infants born with cyanotic congenital heart disease. Often, these infants appear well as long as the ductus arteriosus allows a source of pulmonary blood flow, even in the absence of normal antegrade flow from the RV to the lungs. In left-sided obstructive lesions (not discussed in detail in this chapter), systemic perfusion may be dependent on flow from the RV through the ductus. It is often at the time of ductal closure, usually 24–48 h after birth, that infants with ductal-dependent pulmonary or systemic blood flow decompensate, prompting evaluation for congenital heart disease. On the other hand, neonates may be profoundly unstable within minutes of birth if their congenital heart disease is dependent on an atrial communication that is not adequate in size and restricts atrial level mixing.

A Framework for Understanding Cyanotic Heart Disease

In cyanotic congenital heart disease, desaturation occurs because deoxygenated systemic venous blood reaches the aorta without first passing through the pulmonary capillary bed (Fig. 3). A site of mixing is necessary but not sufficient for cyanosis to occur. Sites of mixing include abnormal venous connections, atrial septal defects (ASDs), ventricular septal defects (VSDs), and the ductus arteriosus. A site of mixing is not sufficient to cause cyanosis, because in the otherwise structurally normal heart, the pressures in the right heart are lower than those in the left heart, resulting in primarily left-to-right shunting. Thus, there must also be something that makes it easier for systemic venous (deoxygenated) blood to go to the body than to the lungs. We present representative cyanotic heart lesions in three groups:

1. Right heart obstructive lesions
2. Lesions with unfavorable streaming
3. Complete mixing lesions, if the relative pulmonary blood flow is significantly less than systemic blood flow

Representative Lesions With Right Heart Obstruction

Right-sided obstruction makes it hard for deoxygenated caval blood to get to the pulmonary arteries. The authors find it helpful to think of right-sided obstruction in the order of flow through the heart, so we will discuss representative right heart obstructive lesions in order of site of obstruction, from the atrial level to the great arterial level.

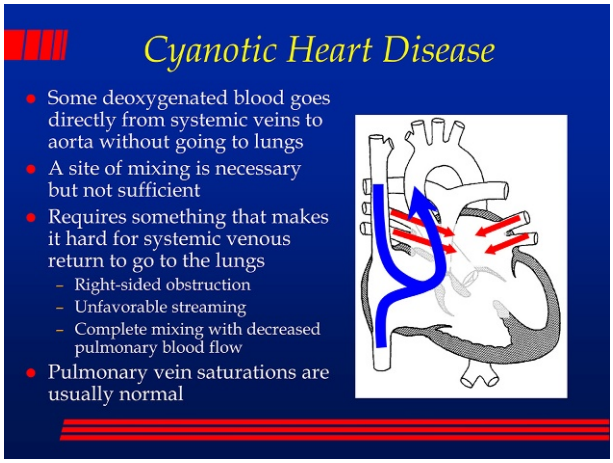

Fig. 3 Cyanotic heart disease. In cyanotic congenital heart disease, some deoxygenated caval blood reaches the aorta without first passing through the lungs.

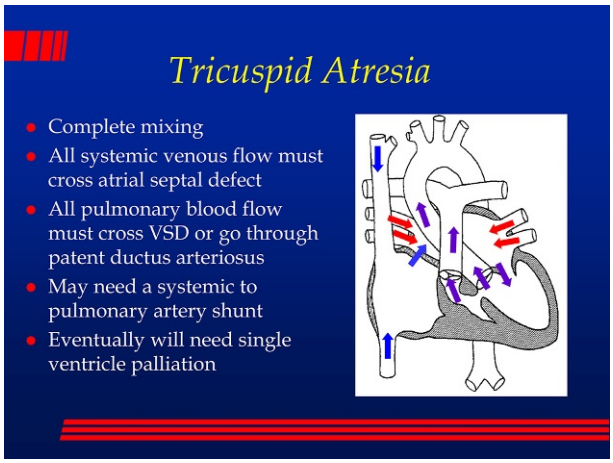

Fig. 4 Tricuspid atresia with normally related great arteries. In tricuspid valve atresia, the systemic and pulmonary venous return mixes in the left atrium before being pumped by the ventricles to the aorta and pulmonary artery, resulting in cyanosis from complete intracardiac mixing.

Tricuspid Atresia

Tricuspid atresia comprises 1%–3% of all congenital heart diseases (Dick et al., 1975; Hoffman and Kaplan, 2002). The cause of tricuspid atresia is unknown. Since tricuspid atresia prevents flow across the tricuspid valve, deoxygenated caval blood preferentially crosses the foramen ovale to the left atrium (Fig. 4).

Arterial oxygen saturation in tricuspid atresia is governed by the relationship of the great arteries, the presence and size of a VSD, and the degree of pulmonary/subpulmonary obstruction. In a little more than half of cases of tricuspid atresia, the aorta and pulmonary artery are normally related, but in the remainder, they are transposed (reversed), with the pulmonary artery arising from the morphologic LV, and the aorta arising from the diminutive RV (Tandon and Edwards, 1974). In tricuspid atresia with normally related great arteries, pulmonary blood flow crosses from the LV across the VSD to the RV and can be limited by restriction at the VSD, the subpulmonary region, and/or at the pulmonary valve. When the great arteries are transposed, there is often little obstruction to pulmonary blood flow. This physiology results in higher oxygen saturations in the short term but leads to pulmonary overcirculation, edema, and congestive heart failure (CHF) over the long term. In tricuspid atresia with transposed great arteries, restriction to flow at the VSD or the right ventricular outflow tract (RVOT) results in limitation of systemic arterial flow, with pathophysiology similar to that seen in other left heart obstructive lesions such as hypoplastic left heart. When there is obstruction either to pulmonary blood flow (as in tricuspid atresia with normally related great arteries) or to systemic blood flow (as in tricuspid atresia with transposition), maintaining patency of the ductus arteriosus allows an alternate route for perfusion of the affected circulation.

Tricuspid Insufficiency and Ebstein's Anomaly

Just as obstruction to forward flow through the tricuspid valve leads to cyanosis from right-to-left shunting of deoxygenated caval blood through the foramen ovale, significant tricuspid valve insufficiency can act as a functional barrier to forward flow to the lungs,

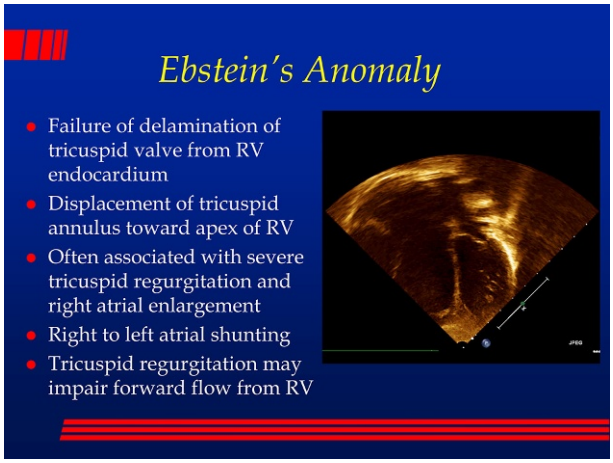

Fig. 5 Ebstein's anomaly. Significant tricuspid regurgitation can result in cyanosis from right-to-left atrial shunting. The echocardiogram on the right shows an apical four-chamber view of an infant with severe displacement of the tricuspid valve nearly into the apex of the right ventricle.

also leading to right-to-left atrial level shunting and cyanosis. Many cases of congenital tricuspid insufficiency are caused by a valve deformity termed Ebstein's anomaly, characterized by failure of delamination of one or more tricuspid valve leaflets from the endocardium during valve development, producing displacement of the septal and inferior valve leaflets in the direction of the right ventricular apex (Fig. 5). Fetuses and infants with Ebstein's anomaly often have massive cardiomegaly before and after birth because of enlargement of the right atrium (RA) and the portion of the RV proximal to the displaced tricuspid valve, known as the atrialized RV. Maternal exposure to lithium, used in treatment of bipolar disorder, is a cause of Ebstein's anomaly, but in the current era, it is not a frequent cause of the anomaly.

Pulmonary Atresia and Stenosis

Pulmonary valve abnormalities are common in patients with congenital heart disease. Pulmonary stenosis (PS) and atresia are collectively quite heterogeneous with respect to their associated lesions and presentation. Although patients with mild-to-moderate PS typically have normal oxygen saturations, severe RVOT obstruction may result in right-to-left shunting of deoxygenated blood at the atrial or ventricular level, resulting in cyanosis.

Pulmonary atresia with ventricular septal defect

In pulmonary atresia with VSD, also described as tetralogy of Fallot (TOF) with pulmonary atresia, the right-to-left shunting occurs at the VSD. In this form of pulmonary atresia, the pulmonary arteries often do not develop normally and may or may not be confluent. Often, there are multiple aorticopulmonary collateral arteries (MAPCAs) that perfuse segments of the lung, and flow through the ductus arteriosus may not be necessary for survival. In that case, the true confluent pulmonary arteries are often very diminutive and may be difficult to see using imaging techniques such as echocardiography. However, these MAPCAs have a tendency to narrow over time, resulting in worsening cyanosis from decreasing pulmonary blood flow. The management of diminutive pulmonary arteries with MAPCAs can be quite challenging, often requiring multiple repeat percutaneous and surgical interventions for rehabilitation after the collateral vessels are unifocalized into reconstructed branch pulmonary arteries. In other cases, the pulmonary arteries may be well formed and confluent, although sometimes, there is a narrowing where ductal flow bifurcates to the right and left pulmonary arteries, and ductal closure may result in discontinuous pulmonary arteries. The management of pulmonary atresia with VSD and well-formed pulmonary arteries is similar to that of TOF, as described in the following text.

Tetralogy of Fallot

Classic TOF is the most common form of cyanotic congenital heart disease, affecting about 1 in 2000 live births (Hoffman and Kaplan, 2002). It was first described as a constellation of four cardiac abnormalities leading to obstruction of pulmonary blood flow and cyanosis. These include PS, a VSD, dextroposition of the aortic valve such that it overrides the ventricular septum, and right ventricular hypertrophy. More recently, these findings have all been attributed to an anterior and cephalad deviation of the outlet septum, resulting in RVOT obstruction and the malalignment of VSD, with hypertrophy of the RV that is the result of the RVOT obstruction (Fig. 6).

The degree of cyanosis in TOF depends on the degree of RVOT obstruction, which affects the degree of right-to-left shunting across the VSD. Neonates with severe RVOT obstruction are cyanotic at birth and sometimes require the patency of the ductus arteriosus to maintain adequate pulmonary blood flow. On the other hand, neonates with mild-to-moderate obstruction may have

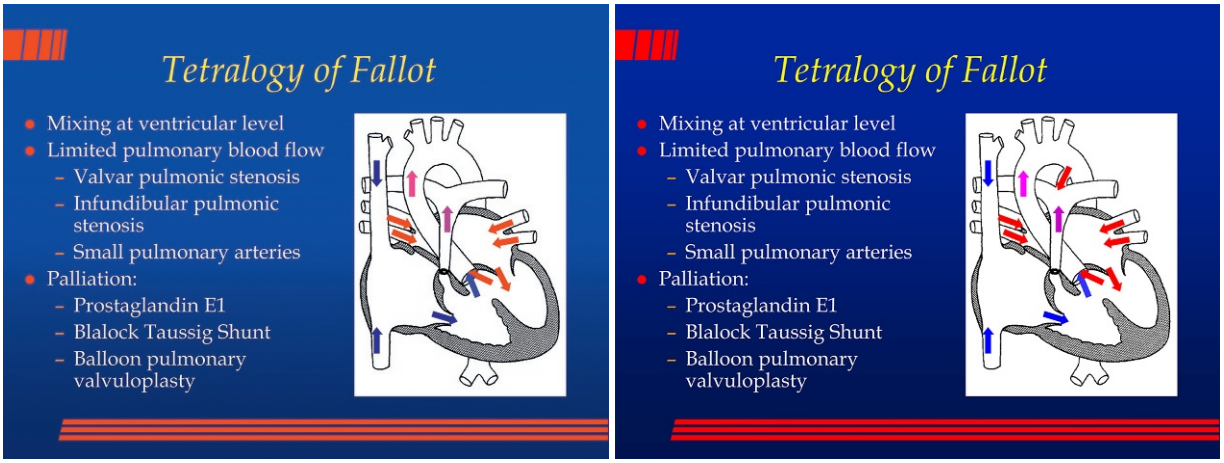

Fig. 6 Tetralogy of Fallot. Cyanosis results from right-to-left ventricular shunting caused by obstruction of the right ventricular outflow tract. Reopening the ductus arteriosus with prostaglandin infusion can allow left-to-right ductal shunting, increasing pulmonary blood flow, and increasing the amount of oxygenated blood in the mixture of systemic and pulmonary venous blood flowing out the aorta, thus improving systemic arterial oxygen saturation.

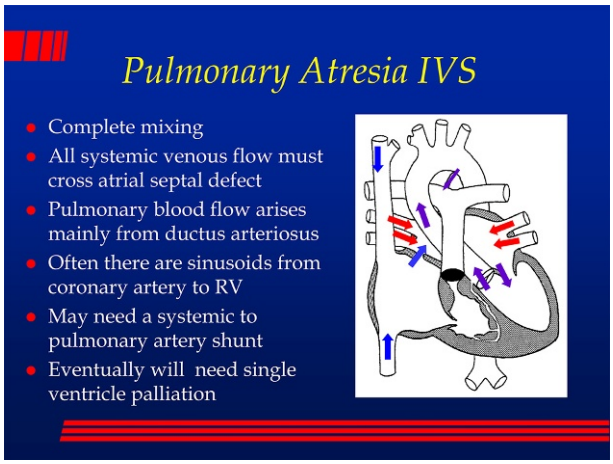

Fig. 7 Pulmonary atresia with intact ventricular septum. Complete mixing occurs at the atrial level because of the absence of forward flow across the pulmonary valve. Obstruction of the pulmonary valve results in high right ventricular pressures, often resulting in right ventricular sinusoids and coronary artery fistulae. Pulmonary blood flow prior to intervention is dependent on ductal patency for left-to-right ductal flow.

no visible cyanosis at rest and are instead diagnosed after detection of a heart murmur or cyanosis with crying. As the PVR declines in the first few days of life, pulmonary blood flow may increase, right-to-left shunting may decrease, and cyanosis may become less apparent. Over weeks to months, however, progressive right ventricular hypertrophy often leads to worsening of subpulmonary infundibular obstruction and increased cyanosis, as well as increased likelihood of acute hypercyanotic episodes known as "tet spells." These episodes are thought to be related to a combination of decreased preload of the RV, increased afterload of the RV, perhaps related to dynamic obstruction from an increased contractile state of the outflow tract, and decreased systemic vascular resistance. Beta-blocker therapy to slow the heart rate, increase diastolic ventricular filling, and decrease dynamic RVOT obstruction may prevent or decrease these spells, but surgical intervention is generally indicated when cyanosis is observed.

Pulmonary atresia with intact ventricular septum

Pulmonary atresia with intact ventricular septum (PA/IVS) occurs in approximately 1 in 15,000 live births (Daubeney et al., 1998; Ferencz et al., 1985). In PA/IVS, the absence of a VSD precludes ventricular right-to-left shunting, resulting in significantly elevated right ventricular pressures, impaired right ventricular diastolic filling, and right-to-left shunting at the atrial level. Pulmonary blood flow is achieved through the PDA (Fig. 7). When the tricuspid valve is competent, the RV is usually diminutive and often quite hypertensive, sometimes suprasystemic (higher than the left ventricular pressure). When there is significant tricuspid insufficiency, the right ventricular systolic pressure is usually not suprasystemic. It is thought that pulmonary atresia that occurs early in right ventricular development results in a diminutive RV, while pulmonary atresia that occurs late in development may be associated with a right ventricular size that is closer to normal size.

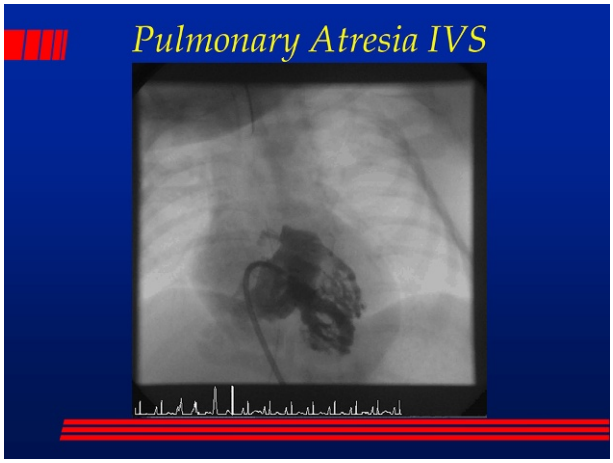

Fig. 8 Pulmonary atresia with intact ventricular septum. An anterior–posterior projection of a right ventriculogram demonstrates retrograde flow through right ventricular sinusoids to the coronary arterial system.

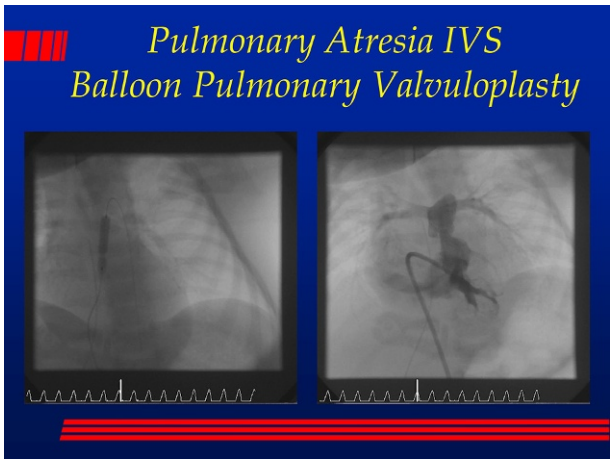

Fig. 9 Pulmonary atresia with intact ventricular septum balloon pulmonary valvuloplasty. Left panel: Following radiofrequency perforation of an atretic pulmonary valve, a balloon is positioned over a wire across the valve and expanded to dilate the pulmonary valve. Right panel: Following valvuloplasty, contrast flows from the right ventricle to the pulmonary arteries.

In utero, the absence of right ventricular outflow through the pulmonary valve may result in retrograde flow through sinusoids connected to the coronary arterial system (Fig. 8). These may be associated with absent aorticocoronary connections, coronary stenoses or interruption of a coronary artery at its aortic origin, as well as coronary-cameral fistulae, in which coronary arteries connect directly to the RV, potentially leading to a steal phenomenon. In these scenarios, coronary arterial flow is dependent on the high-pressured RV, and interventions to relieve the right ventricular pressure may result in myocardial ischemia and death. When there are RV-dependent coronary arteries, heart transplantation is often preferable to surgical palliation or balloon dilatation of the atretic pulmonary valve (Fig. 9).

Critical pulmonary stenosis

The physiology of critical PS is similar to that of PA/IVS, except that elevated right ventricular pressures typically do not lead to the coronary artery abnormalities discussed above. In critical PS, pulmonary blood flow is limited by an abnormal pulmonary valve, often thickened and with decreased valve leaflet mobility (Fig. 10). Similar to TOF, progressive right ventricular hypertrophy also may contribute to RVOT obstruction below the valve. If the RVOT obstruction is severe, impaired diastolic function with decreased ventricular relaxation will lead to impaired ventricular filling and increased right atrial pressure, causing right-to-left atrial shunting across the foramen ovale, and cyanosis.

Obstruction at the Pulmonary Arteries and Arterioles With PDA

When a PDA is present in combination with downstream obstruction to pulmonary blood flow, right-to-left ductal shunting can lead to differential cyanosis, in which blood flow to the upper body is normally saturated but that to the lower body is desaturated.

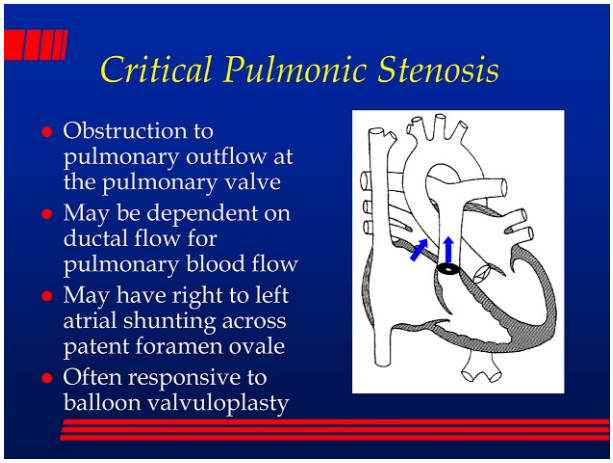

Fig. 10 Critical pulmonary stenosis. Obstruction to pulmonary blood flow results in cyanosis from right-to-left atrial shunting. This lesion is often responsive to balloon valvuloplasty.

Peripheral pulmonary artery stenosis may be seen in Williams syndrome, Alagille syndrome, or congenital rubella infection, among other systemic diseases. If the stenosis is bilateral, peripheral pulmonary artery stenosis can manifest with cyanosis, owing to elevated pressure in the proximal pulmonary artery that leads to right-to-left PDA shunting. However, if the stenosis is unilateral, cyanosis will generally not be present, because flow will simply increase to the unaffected branch pulmonary artery. PDA shunting will be left-to-right in this case.

Elevated PVR in noncardiac causes of pulmonary artery hypertension (PAH) may result in cyanosis from right-to-left shunting across the PDA caused by obstruction of flow within the arterioles of the pulmonary vascular bed itself. There are many causes of PAH, including idiopathic PAH, heritable PAH, persistent pulmonary hypertension of the newborn (PPHN), chronic lung disease, interstitial lung disease, and developmental lung diseases. Premature infants are particularly prone to PPHN early in life and chronic lung disease over time. In addition to right-to-left ductal shunting in infants with PAH, right atrial hypertension is common in these infants, causing right-to-left atrial shunting across the foramen ovale.

Representative Lesions With Unfavorable Streaming

Some relationships of cardiac structures can favor streaming of deoxygenated systemic venous blood to the systemic arterial circulation. This phenomenon is referred to as unfavorable streaming. Transposition of the great arteries (TGAs) is the prototype lesion for this phenomenon, but "transposition physiology" can be seen in other congenital heart lesions.

d-Transposition of the Great Arteries

TGAs account for 5% of all congenital heart defects, with an incidence of approximately 1 per 30,000 live births (Ferencz et al., 1985; Hoffman and Kaplan, 2002). By definition, TGA consists of ventriculoarterial discordance, with the morphologic RV giving rise to the aorta, and the morphologic LV giving rise to the pulmonary artery. In d-TGA, sometimes known as "simple" transposition, the systemic veins return normally to the right-sided systemic venous atrium and the pulmonary veins return normally to the left-sided pulmonary venous atrium, there is atrioventricular concordance with the RA filling the right-sided morphologic RV and the left atrium filling the left-sided morphologic LV (d-looped ventricles), but there is ventriculoarterial discordance. This discordance results in the pulmonary artery and aorta arising from the LV and RV, respectively, resulting in two parallel circulations (Figs. 11–13).

Survival of infants with d-TGA after birth requires mixing between the systemic and pulmonary circulations, as without mixing, oxygenated blood cannot get from the lungs to the systemic circulation. Fortunately, most infants with d-TGA have both atrial mixing at the foramen ovale and great arterial mixing at the ductus. In d-TGA, at steady state, there cannot be any net flow from the systemic circulation to the pulmonary circulation (or vice versa), as net shunting in either direction would result in all of the blood accumulating in one of the two parallel circulations. The shunting from the pulmonary circuit to the systemic circuit must be exactly equal to the shunting from the systemic circuit to the pulmonary circuit. Because the two shunts must be equal, a single site of mixing is usually not adequate, as there would have to be bidirectional shunting at different times in the cardiac cycle. Usually, a VSD or PDA alone is much less efficient in allowing mixing of oxygenated and deoxygenated blood than is an ASD alone, and the most efficient mixing is the combination of a PDA and an atrial communication, with the PDA allowing shunting of deoxygenated blood from the aorta to the pulmonary arteries, and the ASD allowing shunting of oxygenated blood from the left atrium to the RA, RV, and aorta. In the absence of an adequate atrial communication, it is often necessary to perform a balloon atrial septostomy (BAS), discussed in more detail in the following section on interventions (Fig. 14).

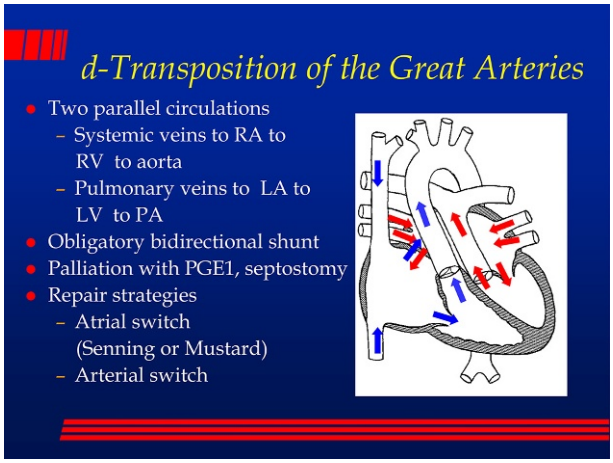

Fig. 11 d-Transposition of the great arteries. Two parallel circulations result when the great arteries are transposed. Because there can be no net right-to-left or left-to-right shunting with parallel circulations, multiple sites of mixing are typically needed for adequate systemic oxygen delivery. Patency of the ductus arteriosus can be maintained with a prostaglandin infusion, and emergent balloon atrial septostomy can improve atrial mixing.

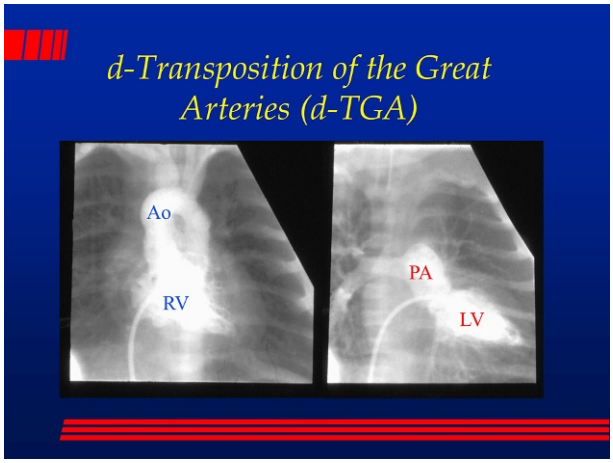

Fig. 12 d-Transposition of the great arteries. Right and left ventriculograms reveal ventriculoarterial disconcordance. Left panel: The right ventricle (RV) gives rise to the aorta (Ao). Right panel: The left ventricle (LV) gives rise to the pulmonary artery (PA).

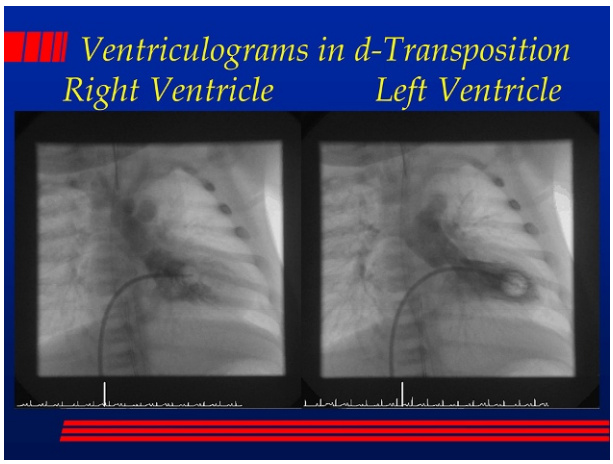

Fig. 13 Ventriculograms in d-transposition. Right and left ventriculograms reveal ventriculoarterial disconcordance. Left panel: The right ventricle gives rise to the aorta, with filling of the pulmonary artery through the patent ductus arteriosus. Right panel: The left ventricle gives rise to the pulmonary artery. In levophase (after the contrast has returned from the pulmonary circulation to the left atrium), there is filling of the right atrium through the atrial septal defect, with subsequent filling of the right ventricle.

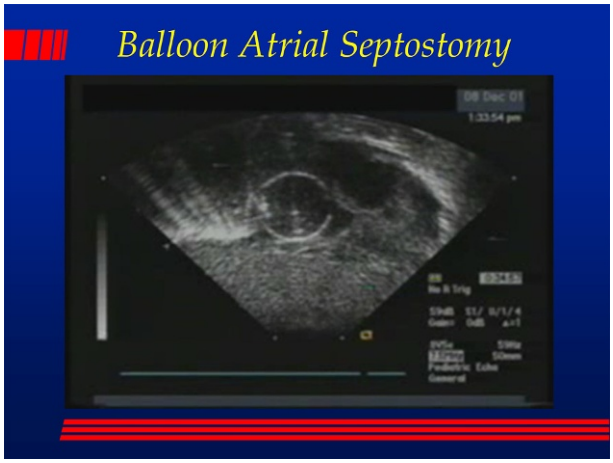

Fig. 14 Balloon atrial septostomy. In a Rashkind balloon atrial septostomy, a balloon tipped catheter is positioned from the femoral or umbilical vein, through the right atrium, across the small atrial septal communication into the left atrium. Under echocardiographic guidance, the balloon is inflated with fluid and is abruptly pulled back to the right atrium, tearing the atrial septum in the process. Dr. William Rashkind, the developer of the procedure, was said to have commented that the most important thing about a balloon septostomy was the "jerk on the end of the catheter."

d-TGA may result in "reverse differential cyanosis," with desaturation and cyanosis of the upper body and higher saturations in the lower body. This phenomenon typically occurs while PVR is high shortly after birth, when oxygenated blood flows from the pulmonary artery to the descending aorta, because PDA flow early on is bidirectional. With a combination of d-TGA and aortic arch obstruction, either from coarctation or from interrupted aortic arch, the flow from the RV through the ductus is the main source of blood flow to the descending aorta, making the reverse differential cyanosis more prominent. Obtaining saturation levels in the right arm and in the legs can be diagnostically useful in suggesting d-TGA when the lower body saturation are higher than the upper body. The other situation in which one may see higher oxygen saturations in the lower body is in infants with totally anomalous pulmonary venous return to the SVC, as SVC flow preferentially streams to the tricuspid valve, resulting in higher oxygen saturations in the pulmonary artery than in the ascending aorta, as discussed in the following.

Other Lesions With Unfavorable Streaming

Other scenarios with unfavorable streaming are relatively rare. For example, persistence of the left cardinal vein in embryologic development results in a left superior vena cava (LSVC) that drains to the RA via the coronary sinus (CS). When the CS is partially or completely "unroofed" to the LA, a left-to-right shunt may occur, similar in physiology to an ASD. However, if the LSVC flow is vigorous and the CS flow is directed into the left atrium rather than through the CS or to the RA, deoxygenated systemic venous blood may enter the systemic cardiac output, resulting in cyanosis.

Representative Lesions With Complete Mixing and Decreased Pulmonary Blood Flow

Although there is conceptual overlap between right-sided obstructive lesions with right-to-left shunting and complete mixing lesions, the authors find it helpful to discuss complete mixing lesions separately.

Atresia of Any Valve

Atresia of any valve results in complete mixing of systemic and pulmonary venous blood, with all of the cardiac output crossing the corresponding nonatretic valve. For example, in tricuspid atresia, all flow must cross the mitral valve, and in pulmonary atresia, all flow must cross the aortic valve. Complete mixing occurs with atresia of left-sided valves as well. Infants with complete mixing lesions may or may be cyanotic depending on the relative pulmonary and systemic blood flows. In complete mixing lesions, the determinants of the arterial oxygen saturation are the pulmonary venous saturation (How red is the red blood?), the systemic venous saturation (How blue is the blue blood?), and the relative amounts of each, expressed as the Q_P/Q_S, or the ratio of pulmonary to systemic blood flow, as illustrated in Fig. 15. Even without changes in the underlying cardiac anatomy, there can be changes in these parameters that dramatically change arterial oxygen saturation, resulting in development or resolution of cyanosis.

For example, in an infant with tricuspid atresia with a restrictive VSD, the oxygen saturation may fall precipitously with ductal closure. One day after birth, when the ductus arteriosus is still patent, there may be much more pulmonary blood flow than systemic blood flow, sometimes resulting in a Q_P/Q_s of about 3/1. Assuming a mixed venous saturation of 60% and a pulmonary venous

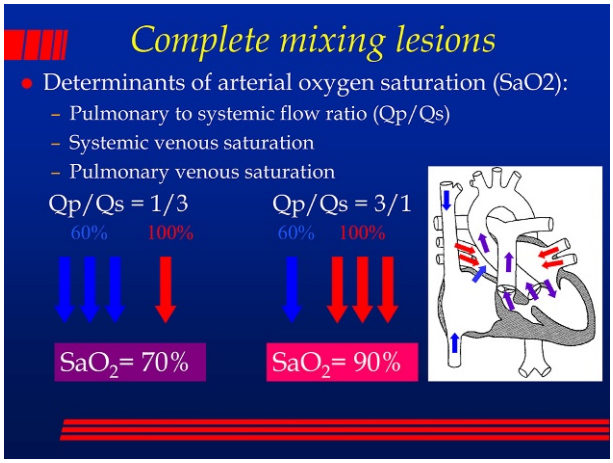

Fig. 15 Complete mixing lesions. Systemic arterial oxygen saturations in complete mixing lesions are dependent on the relative amounts of systemic (Qs) and pulmonary (Qp) blood flow. In this example with 100% pulmonary venous saturation and 60% systemic venous saturation, a systemic arterial saturation of 70% would reflect restricted pulmonary blood flow, with a Qp/Qs of 1/3. A systemic arterial saturation of 90% would reflect exuberant pulmonary blood flow, with a Qp/Qs of 3/1.

saturation of 100%, in this scenario, there would be three parts pulmonary venous blood and one part systemic venous blood in the mix, resulting in an arterial saturation of 90%. When the ductus closes, there would be much less pulmonary blood flow, perhaps resulting in a Q_P/Q_s of 1/3. In that scenario, there would be three parts systemic venous blood and one part pulmonary venous blood, resulting in an arterial oxygen saturation of 70%. This is actually an oversimplification, as the systemic venous saturation would also fall, so the arterial saturation would probably actually be even lower after ductal closure. These principles apply to all variants of valve atresia, with right-sided atresia (tricuspid and/or pulmonary atresia) being more likely to result in cyanosis, and left-sided atresia (mitral and/or aortic atresia) resulting in decreased systemic perfusion with only mild cyanosis.

Truncus Arteriosus, Double Inlet LV, and Other Mixing Lesions With Favorable Streaming

In some lesions, such as truncus arteriosus or double inlet LV, there may not be complete mixing, as there may be favorable streaming of pulmonary venous return to the aorta and systemic venous return to the pulmonary artery. For this reason, truncus arteriosus without branch pulmonary artery stenosis does not usually present with clinical cyanosis because of favorable streaming and increased Q_P/Q_s. Similarly, infants with single ventricle, such as double inlet LV, may have favorable streaming and minimal cyanosis. Although infants with mitral and/or aortic atresia have complete mixing, they often have a high Q_P/Q_s.

Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) to the systemic veins results in nearly complete mixing, with the presence and degree of cyanosis determined by the Q_P/Q_s. In TAPVR, the confluence of the pulmonary veins (also known as the common pulmonary vein) fails to integrate into posterior wall of the fetal left atrium. Thus, the pulmonary veins typically return to a confluence that drains into one of the systemic veins. If the pulmonary venous drainage is obstructed at any level, a life-threatening scenario develops, wherein there is little benefit to medical intervention, requiring emergent surgical intervention to relieve the obstruction and direct the pulmonary venous return to the left atrium.

Three variants of TAPVR are commonly seen. The most common form is supracardiac TAPVR, in which the pulmonary venous confluence drains cephalad via a vertical vein to the left innominate vein (Fig. 16). The vertical vein is usually unobstructed, but external compression can lead to obstruction of pulmonary venous drainage as it passes between the left bronchus and left pulmonary artery. In the second TAPVR variant, the confluence drains directly to the CS. This connection is almost universally unobstructed. The final variant involves caudal drainage from the retrocardiac confluence via a vertical vein to the umbilicovitelline system, typically to the portal vein (Fig. 17). This form of TAPVR almost always involves obstructed pulmonary venous drainage.

In TAPVR, the foramen ovale must remain patent to allow right-to-left shunting to the left atrium. Often, the ductus arteriosus also remains patent, but this may or may not help with hemodynamic stability after birth. With falling PVR in the first few days of life, pulmonary blood flow increases dramatically and commonly exceeds systemic blood flow, sometimes giving a Q_P/Q_s of 3/1 or more. Therefore, when the pulmonary venous drainage is unobstructed, systemic oxygen saturations may exceed 90%. However, neonates with obstructed TAPVR typically present with profound cyanosis as a result of the combination of decreased pulmonary blood flow from the downstream obstruction as well as pulmonary edema from high pulmonary venous pressures. This pulmonary edema does not improve with oxygen therapy. Indeed, pulmonary vasodilators (such as oxygen) can lead to rapidly worsening pulmonary edema by allowing arteriolar dilation with ongoing downstream obstruction (Fig. 18).

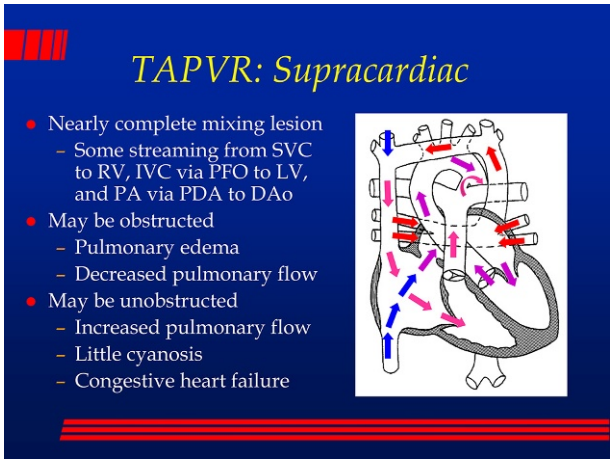

Fig. 16 Supracardiac total anomalous pulmonary venous return (TAPVR). An ascending vertical vein drains the oxygenated pulmonary venous blood to the innominate vein. Preferential streaming of superior vena caval blood through the tricuspid valve to the right ventricle and then through the ductus arteriosus to the descending aorta, and streaming of IV blood across the foramen ovale to the left ventricle may result in reverse differential cyanosis, with higher arterial oxygen saturations in the lower body than in the upper body.

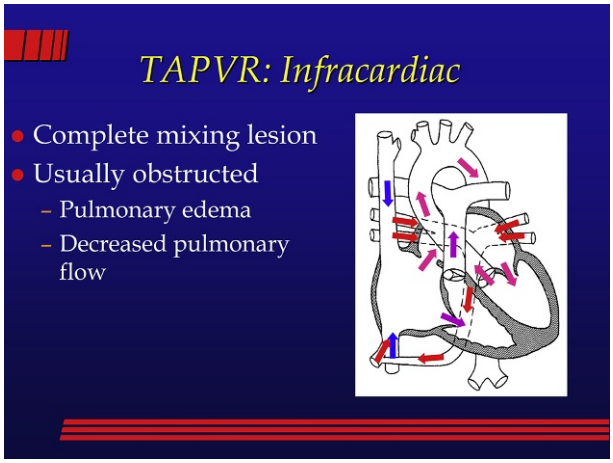

Fig. 17 Infracardiac total anomalous pulmonary venous return (TAPVR). A descending vertical vein drains the pulmonary venous confluence through the liver. This drainage is almost always obstructed, resulting in pulmonary venous congestion.

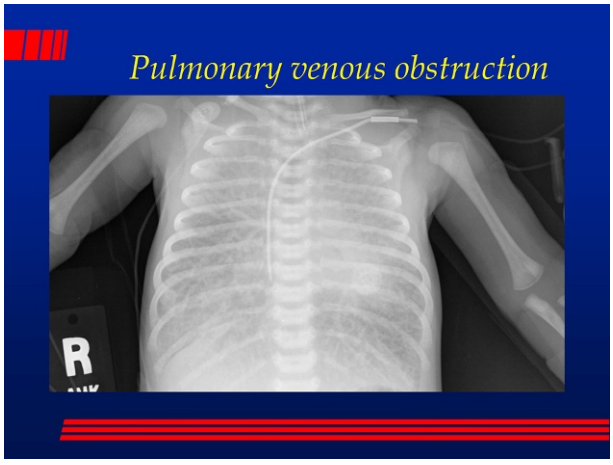

Fig. 18 Chest radiograph showing pulmonary venous obstruction. When total anomalous pulmonary venous return is obstructed, pulmonary blood flow is reduced, and pulmonary edema may further worsen cyanosis because intrapulmonary oxygen diffusion is impaired, causing pulmonary venous desaturation.

Just as d-TGA can lead to reverse differential cyanosis, so can supracardiac TAPVR. In this scenario, highly oxygenated SVC flow that includes the anomalous pulmonary venous return is preferentially directed toward the right heart through the tricuspid valve, and deoxygenated IVC flow is preferentially directed toward the left heart through the PFO. In this scenario, when the PVR is high, oxygenated blood from the pulmonary artery shunts across the PDA from right to left into the descending aorta, resulting in higher oxygen saturations in the lower body than in the upper body.

Interventions for Congenital Heart Disease

Supplemental Oxygen

Often, cyanosis in a newborn infant is the result of lung disease that results in pulmonary venous desaturation. However, infants with lung disease often normalize their arterial oxygen saturations with supplemental oxygen, as the increased partial pressure of oxygen in the alveoli can overcome diffusion barriers and normalize the pulmonary venous saturation. When a newborn with cyanosis does not respond to supplemental oxygen, cyanotic congenital heart disease must be suspected.

Because pulmonary venous blood is normally nearly 100% saturated in the absence of lung disease, in patients with cyanotic heart disease and right-to-left shunting of desaturated systemic venous blood, supplemental oxygen only slightly increases pulmonary venous oxygen content by increasing dissolved oxygen. Even a 300 torr increase in the P_{O_2} results in an increase of only 0.9 mL dL^{-1} (300 torr $\times$ 0.003 mL dL^{-1} $torr^{-1}$) in the oxygen content. For an infant with a normal hemoglobin of 17 g dL^{-1}, a pulmonary venous oxygen saturation of 100%, and an oxygen content of 23 mL dL^{-1} (1.36 mL g^{-1} of hemoglobin $\times$ 17 g hemoglobin dL^{-1}), the pulmonary venous oxygen content increases less than 4%, even with a marked 300 torr increase in the pulmonary venous P_{O_2}.

Since the shunting of systemic venous blood in infants with cyanotic heart disease is minimally affected by supplemental oxygen, there is little change in the arterial oxygen saturation with supplemental oxygen in these infants. This observation is the basis for the "hyperoxia test," in which the P_{O_2} of an arterial blood gas is compared before and after administration of 100% oxygen, with a $P_{O_2} < 150$ torr on 100% oxygen (FiO_2 of 1.0) strongly suggesting the presence of congenital heart disease.

Maintaining Ductal Patency

Often, ductal closure reduces pulmonary blood flow in infants with cyanotic heart disease, and it is at the time of ductal closure that cyanosis is first recognized. Fig. 19 illustrates the impact of ductal closure in tricuspid atresia. If an infant is suspected or confirmed to have cyanotic congenital heart disease, the PDA can be artificially maintained by administration of intravenous prostaglandin E_1 (PGE_1). Commonly observed side effects of PGE_1 therapy are apnea, fever, hypotension, and pulmonary vasodilatation. However, when these side effects are appropriately managed, maintaining ductal patency is often the simplest strategy for stabilizing an infant with a ductal-dependent circulation. Often, reducing the dose of PGE_1 to the minimal effective dose that maintains ductal patency avoids these side effects. Maintaining ductal patency is an effective short-term strategy for cyanotic heart disease, irrespective of whether the cause is limitation of pulmonary blood flow in right-heart obstructive lesions or inadequate mixing in unfavorable streaming in transposition physiology.

In complete mixing lesions, the management challenge lies in appropriately balancing the pulmonary and systemic blood flows through the transition period. PGE_1 is a potent pulmonary vasodilator, as is oxygen. As the PVR drops, pulmonary blood flow

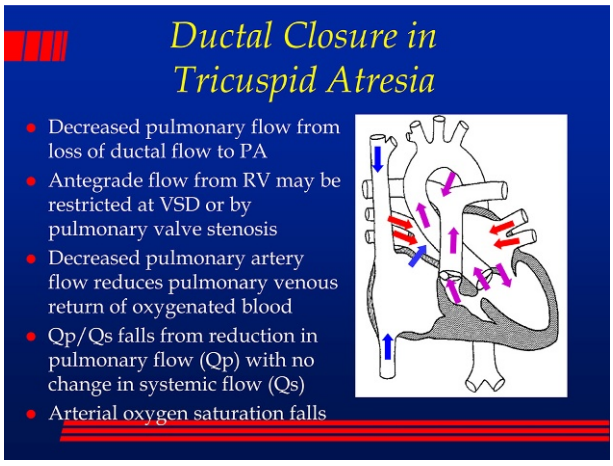

Fig. 19 Ductal closure in tricuspid atresia. When an infant is not prenatally diagnosed with a ductal-dependent cyanotic congenital heart defect, ductal closure results in decreased pulmonary blood flow and systemic arterial saturation. Complete mixing in tricuspid atresia necessitates a careful balance of systemic and pulmonary blood flow, which cannot be maintained if the ductus arteriosus closes.

increases, increasing the overall work of the heart and ultimately leading to CHF. In the presence of a PDA, pulmonary overcirculation not only leads to CHF but also can compromise systemic perfusion of vital organs by allowing shunting of the systemic output to the lungs, decreasing splanchnic perfusion and placing the infant at risk for intestinal ischemia and necrotizing enterocolitis.

Recently, percutaneous placement of a stent in the ductus arteriosus has been used as a more stable alternative to long-term PGE_1 infusions in neonates who require long-term ductal patency and are not anticipated to undergo surgical repair or palliation prior to hospital discharge. However, ductal stenting is not without procedural risk and possibility of complications, for example, from stent migration, misplacement, or subsequent stent thrombosis. In addition, ductal stents may complicate the eventual surgical intervention by distorting growth of the pulmonary arteries.

Balloon Atrial Septostomy

Infants who depend on an atrial communication may require emergent intervention after birth if the ASD or PFO is too small for adequate intracardiac mixing. This is particularly important for transposition physiology and left-sided obstructive disease. In these cases, a BAS procedure enlarges the atrial communication to stabilize the infant. In this procedure, a balloon-tip catheter is placed across the small ASD under fluoroscopic or echocardiographic guidance. The balloon is inflated and pulled back to tear the atrial septal tissue and enlarge the communication (see **Fig. 14**). Over time, the atrial septal tissue may close the artificially enlarged defect. In those infants who require a longer-term solution, a stent may also be placed in the atrial septum to maintain unrestricted atrial level mixing until surgical intervention.

Balloon Pulmonary Valvuloplasty

Balloon pulmonary valvuloplasty is a useful percutaneous intervention for infants with critical PS or a membranous form of pulmonary atresia (see **Fig. 9**). Inflating a balloon positioned in the pulmonary valve annulus tears the valve (typically between fused valve leaflets) to relieve the obstruction to pulmonary blood flow. The major risk of this procedure is valve insufficiency, which over time may cause problems and require further intervention. However, balloon pulmonary valvuloplasty is an effective and well-established procedure to obviate the need for a surgical intervention in the neonatal period.

Select Surgical Interventions

Blalock–Taussig (systemic to pulmonary artery) shunt

Advances in surgical techniques over the last few decades have enabled either palliation or repair of most congenital cardiac lesions. The first noteworthy surgical intervention for cyanotic heart disease is referred to as the Blalock–Taussig (BT) shunt, in reference to the surgeon Dr. Alfred Blalock and cardiologist Dr. Helen Taussig who first described the procedure. Dr. Taussig had sought an intervention to increase pulmonary blood flow in patients with TOF. Dr. Blalock, with the assistance of his lab technician Vivian Thomas, performed the first operation in a human in 1944, effectively launching the field of surgery for congenital heart disease.

The BT shunt is a systemic-to-pulmonary artery shunt, serving as an artificial ductus (**Fig. 20**). Originally performed as a direct anastomosis from the right subclavian artery to the pulmonary artery, it now is generally performed as a "modified" version, using a synthetic tube from the right innominate artery to the proximal right pulmonary artery (RPA). The BT shunt is used either as a bridge

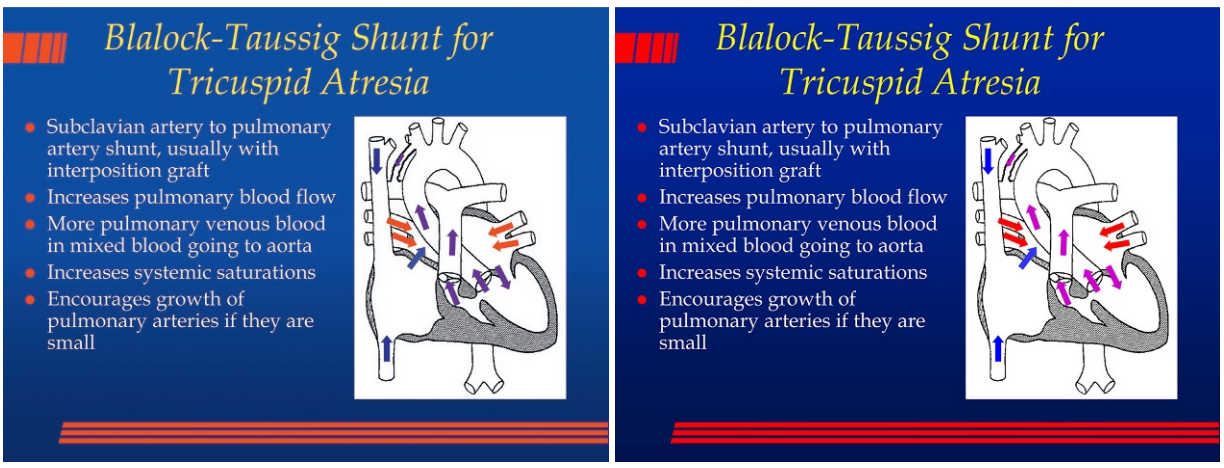

Fig. 20 Blalock–Taussig shunt for tricuspid atresia. If adequate pulmonary blood flow is not achieved without the ductus arteriosus, a Blalock–Taussig shunt may be placed to provide a stable blood supply to the pulmonary arteries. The flow through the shunt increases pulmonary blood flow. With increased pulmonary blood flow, there is more oxygenated blood in the mixture of systemic and pulmonary venous blood, resulting in a higher arterial oxygen saturation.

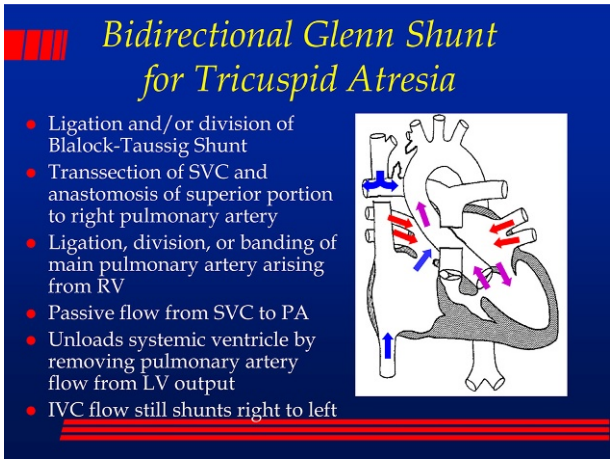

Fig. 21 Bidirectional Glenn shunt for tricuspid atresia. As the second stage of single ventricle palliation, the superior cavopulmonary anastomosis, known as the bidirectional Glenn shunt, allows passive flow from the head and arm veins to the pulmonary arteries.

to more definitive repair or as part of the first operation for single ventricle palliation. BT shunts are not without risk. Thrombosis and shunt occlusion pose a significant risk of sudden death. Therefore, the next operation is typically performed within the first year of life, depending on the patient and the procedure.

Single ventricle palliation

Single ventricle palliation is reserved for patients without two functional ventricles. The operations that follow the initial neonatal intervention (usually the BT shunt with or without another intervention) are typically performed in two additional stages. The operations that comprise staged single ventricle palliation ultimately result in systemic venous blood passively flowing through the pulmonary vascular bed before returning to the heart. Therefore, cardiac catheterization with confirmation of low PVR is typically required prior to each operation. Usually, the superior cavopulmonary anastomosis ("Glenn" shunt) is performed first. Although originally described as a division of the RPA, with an end-to-side surgical anastomosis from the RPA to the SVC, with ligation or division of the connection of the SVC to the RA, it is now generally performed as a "bidirectional Glenn shunt" with division of the SVC, an end-to-side anastomosis of the SVC to the superior surface of the RPA, and closure of the stump of the SVC above its junction with the RA (Fig. 21), around 4–6 months of age. In some circumstances in which the RV is small, but adequate to handle the venous return from the lower body, the bidirectional Glenn shunt may be the final operation, known as a 1½-ventricle repair. However, intrapulmonary arteriovenous malformations tend to form over time in situations where the pulmonary vascular bed is not directly exposed to hepatic venous blood on its first pass.

For this reason, most patients who have undergone the Glenn will undergo connection of the IVC with the pulmonary artery ("Fontan" operation). This operation can be accomplished with an extracardiac synthetic tube or as an intraatrial lateral tunnel (Fig. 22). The same general approach is used in other forms of single ventricle physiology, including double inlet LV, unbalanced atrioventricular septal defect, and hypoplastic left heart syndrome.

Repair of TOF

Patients with TOF typically undergo "complete" repair before 6 months of age. If the pulmonary valve annulus is adequate, a "valve-sparing" repair is used, with the VSD closure and subpulmonary muscle resection performed from a transatrial and transpulmonary approach. However, if the pulmonary valve annulus is too small, repair is usually accomplished with a transannular patch extending from the RVOT to the main pulmonary artery, relieving the RVOT obstruction but resulting in a freely insufficient pulmonary valve (Fig. 23).

Repair of d-transposition of the great arteries

The first successful repairs of d-TGA were atrial switch operations, baffling the systemic venous return to the LV and out to the pulmonary artery, and the pulmonary venous return to the RV and out to the aorta (Fig. 24). There were two common versions of the atrial switch operation: the Senning procedure and the Mustard procedure. While the operative mortality of these operations was quite low, these procedures resulted in the RV serving as the systemic ventricle. This had the disadvantage of an increased risk for ventricular dysfunction developing over time, as well as atrial arrhythmias and caval obstruction. Technical improvements in coronary reimplantation to the "neo-aortic" root in the 1970s and 1980s enabled a shift from the atrial switch to the arterial switch operation (ASO), which is now the standard operation for TGA (Fig. 25). Due to significant heterogeneity in coronary artery anatomy in TGA, the coronary arteries must be well delineated on preoperative evaluation.

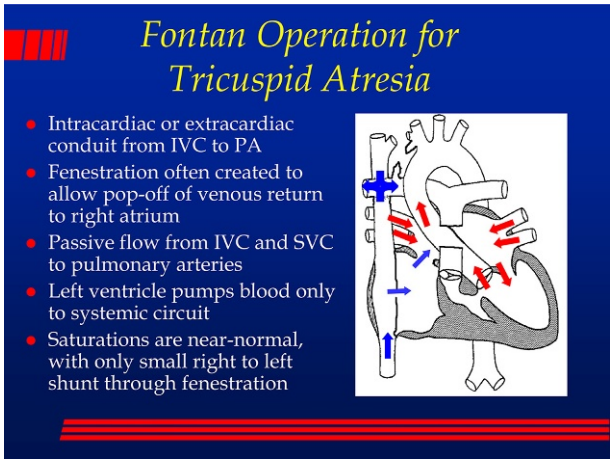

Fig. 22 Fontan operation for tricuspid atresia. Typically the final stage in single ventricle palliation, an inferior cavopulmonary connection is created in the Fontan operation, resulting in almost all systemic venous blood passively flowing through the lungs prior to returning to the heart. The presence of a fenestration allows a small amount of systemic venous return to bypass the lungs, improving stability in the early postoperative period, but causing some cyanosis, usually only mild.

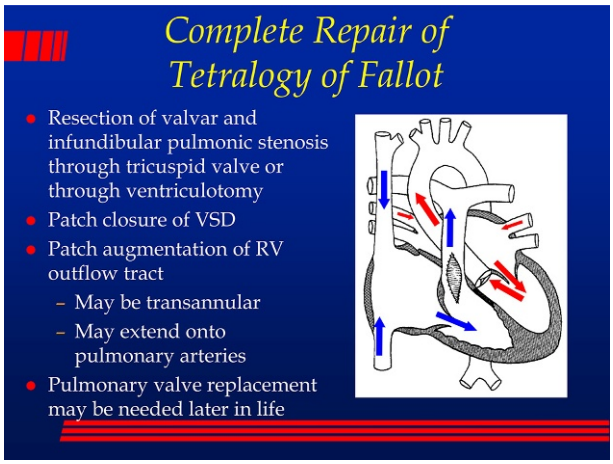

Fig. 23 Complete repair of tetralogy of Fallot. In complete repair of tetralogy of Fallot, the ventricular septal defect is patched closed, and the right ventricular outflow tract obstruction is relieved by resection of infundibular muscle, and patch augmentation of the right ventricular outflow tract, in most cases. Extension of the outflow tract patch across the pulmonary valve results in pulmonary valve insufficiency, which may necessitate pulmonary valve replacement later in life.

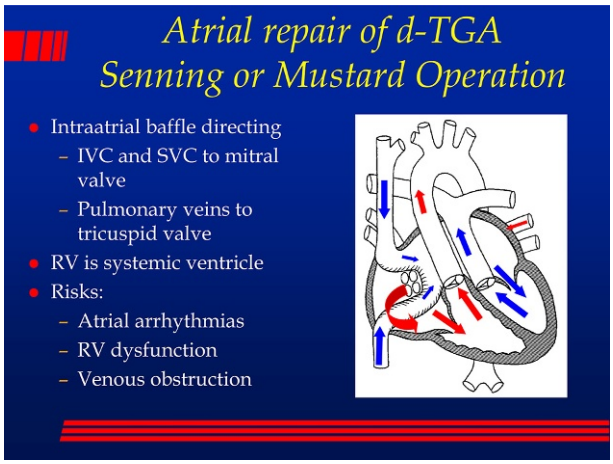

Fig. 24 Atrial repair of d-transposition of the great arteries with the Senning or Mustard operation. Intraatrial baffles are used to direct systemic venous blood to the left ventricle, which pumps it to the pulmonary artery, and to direct pulmonary venous blood to the right ventricle, which pumps it to the aorta. Atrial arrhythmias, right ventricular dysfunction, and venous obstruction are common complications of this approach.

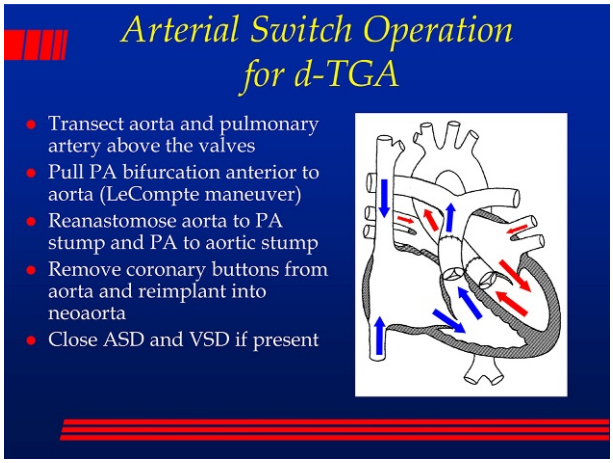

Fig. 25 Arterial switch operation for d-transposition of the great arteries. Advances in surgical technique for manipulation of coronary arteries have more recently enabled the arterial switch operation. This operation results in the systemic ventricle being the left ventricle, which generally has greater longevity than a systemic right ventricle.

Survival and Outcomes

As discussed earlier, advances in medical and surgical interventions have resulted in improved survival. However, even when the surgical repair is considered "complete," many of these children develop long-term sequelae that necessitate lifelong follow-up with a cardiologist.

Long-term complications of single ventricle palliation include arrhythmias, heart failure, protein-losing enteropathy, plastic bronchitis, and liver failure. Survival after Fontan operation depends partly on whether the single functional ventricle is a morphologic LV or RV, with better outcomes in single LVs. Survival after single ventricle palliation for tricuspid atresia is 79%, 62%, and 45% at 10, 20, and 30 years following operation (Pundi et al., 2015).

Outcomes of TOF repair are quite good, with operative survival greater than 96% and 30-years survival above 85% (Alexiou et al., 2001; Murphy et al., 1993). However, progressive right ventricular dilatation from chronic pulmonary insufficiency can lead to right ventricular, and ultimately left ventricular, dysfunction over time. Pulmonary valve replacement is an attractive option in this case, but the optimal timing of this operation is the subject of significant debate, since reoperation is not entirely without risk, and current options for pulmonary valve replacements are unlikely to last as long as patients with TOF are likely to live, necessitating multiple pulmonary valve replacements. The goal of pulmonary valve replacement is to remove the volume load on the RV before there is irreversible impairment of right ventricular function. Over the past 10 years, transcatheter pulmonary valve replacement has become a good option for some patients following repair of TOF.

Outcomes of the ASO for transposition are now excellent, with operative survival approaching 100% in high-volume centers and overall 5-year survival above 96% (Dibardino et al., 2004).

Conclusion

Cyanotic congenital heart disease is a heterogeneous group of abnormalities of cardiac development that result in deoxygenated blood being pumped to the body without first passing through the lungs. This requires both a site of mixing and another factor that preferentially directs blood flow from the systemic veins to the aorta. Obstruction to pulmonary blood flow, unfavorable streaming, and complete mixing with decreased pulmonary blood flow all lead to clinical cyanosis. Fortunately, medical and surgical advances over the past decades have dramatically improved outcomes such that most infants with cyanotic congenital heart disease now have options for interventions that allow survival.

PREFACE

The burden of cardiovascular disease is growing across the globe as the leading noncommunicable cause of morbidity and mortality. This is despite outstanding research that has improved our understanding of cardiovascular biology, the determinants of disease, and development of new therapies. We are optimistic that the next generation of scientists and clinicians will further these efforts and ultimately bring about changes that will reduce risk and improve outcomes for patients worldwide. We have assembled this encyclopedia with the explicit intent to provide this generation with easy access to past and current wisdom, with the hope that this helps to accelerate innovation in cardiovascular medicine.

This encyclopedia represents both a dream and a labor of love. The dream is to create a scientific compendium that recognizes that the methods and tools used to access and study the scientific literature have changed, with a burgeoning impact of digital technology—the so-called pocket book encyclopedia that is accessible on a smart phone fitting into medical overalls, and that can also be read as a textbook at a desk! These changes in the access of publications have been accompanied by the evolving need for studying different aspects of biology and disease as stand-alone chapters not necessarily read sequentially. Furthermore, as editors we recognize the fundamental importance of conveying knowledge through brilliantly illustrated texts that are profusely embedded with links to key references. The critical importance to use multimedia tools and to provide downloadable slides for educational purposes is reflected in this encyclopedia. Additionally, we want to ensure the feasibility of updating text, figures, and other reading material iteratively even after a publication date, recognizing the rapid advent of information and huge strides made in cardiovascular medicine every day. Thus, this work represents the end of the beginning of a live text that will metamorphose over time, being guided by the rapid strides and advances in both cardiovascular medicine and publication science.

Overall, we conceptualized this work as providing broad coverage of science and also serving the expansive needs of a readership that is quite diverse, that is, encompassing medical students, residents, fellows, and postdoctoral scientists interested in cardiovascular medicine. We hope the labor of love of an outstanding team of editors and a stellar group of authors is readily evident to the broad readership we have targeted.

Assembling this compendium had many challenges. Early on we made the choice to cover the broad range of cardiovascular biology, pathophysiology, epidemiology, and treatment of disease. We sought to assure equal coverage to foundational cardiovascular cellular and molecular biology as well as state-of-the-art treatments. Covering the breadth inevitably led to some overlap between some chapters, and yet we certainly have some residual gaps. We hope to have the opportunity to fill these gaps in future editions. There is also inevitable variation in the style and scope of articles in this multiauthor publication. We and the section editors felt it was more important to allow our expert authors freedom in how they chose to present their topic.

We invite feedback on how this encyclopedia can be improved as a resource for trainees worldwide. Undoubtedly, as noted above, there are gaps in content areas that need to be bridged in future iterations of this encyclopedia. We look forward to hearing from and listening to our readership about how the text can be better organized or better compiled to serve their scholarship better in future years.

This project was made possible through the hard work of many people from across the globe. We were pleased to have section editors and authors from around the world. Drs. Kessler and Schunkert, renowned cardiologists with an outstanding record of accomplishment in genetic research, have compiled a series of chapters on genetics and genomics. Dr. Baliga, a distinguished cardiologist and educator, has conceptualized a tour de force of chapters that capture all aspects of the heart failure syndrome, whereas Dr. DiSalvo, a master clinician and educator, has synthesized a fine tapestry of chapters focusing on diagnostic testing with key sections on cardiac imaging, interventions, and device therapy. Dr. Raj, an outstanding clinical investigator and

electrophysiologist, brought together an exemplary collection of chapters that offer coverage of a broad spectrum of topics in cardiac electrophysiology. Drs. Major and Liaw, both highly accomplished basic scientists and educators, were instrumental in identifying topics of fundamental importance to the field of cardiovascular biology and medicine. Dr. Lenihan, a pioneering clinical scientist and outstanding cardiologist, brought together a special set of articles that represent interactions between cardiovascular and other fields of medicine. Dr. Gale, a celebrated cardiologist with expertise in comparative effectiveness research and clinical cardiology, offers a series of stellar chapters underscoring various aspects of the pathogenesis and management of atherosclerotic cardiovascular disease. Dr. Kokubo, a leading preventive cardiologist with specialization in cardiovascular epidemiology, has orchestrated state-of-the-art chapters on cardiovascular epidemiology.

We would like to thank our colleagues at Elsevier who provided steadfast support of an exemplary nature throughout this long journey. Last but not the least, the editors would like to thank their families, their mentors, and their respective institutions for the constant encouragement, advice, and support over the years.

Preface

What Are People Consuming in the World?

Excess fat intake is known as an important risk factor for cardiovascular disease (CVD). In the United States and Europe, intakes of fat and oil are high with a great portion of animal fat. It is also assumed that animal fats significantly rely on dairy products (Parodi, 2011). On the other hand, lesser dairy products are consumed in the Eastern countries; supply source of fat and oil is primarily vegetables (**Table 1**). In Pakistan and India, however, meat consumption is very low, consumption of milk and dairy products is relatively high.

Japan is one of the following countries consuming dairy products a little; after the World War II, milk has been introduced in school meals and then relatively many Japanese become to consume dairy products (**Fig. 1**). Nevertheless, Japanese elderly consume little dairy products. Two of the authors (Y and A) participated in the Fujiwara-kyo study (Okamoto et al., 2010, 2015), a study of successful aging in the elderly (≧65 years), and conducted a survey of food intakes using diaries for consecutive 7 days. We analyzed these diaries with the "Cooked-Dish Codes" method (Amano and Yanagi, 2010). In 1643 males and 1625 females, the median consumption of all dairy products was only 0.8 portion per day (unpublished data).

China consumes a lot of meat but little milk and dairy products. Despite some exceptions, many regions consuming a lot of rice are consistent with regions consuming little milk and dairy products.

Therefore the following text describing the relationship between dairy products and CVDs should be read with caution; there are great differences in lifestyles between any regional, cultural, and ethnic groups.

Prevalence of Overweight in the World

The relationship of CVD and obesity is widely recognized (World Health Organization (WHO), WHO warns of the rising threat of heart disease . . .). Prevalence of overweight is varying in countries; however, they are generally higher in the Western countries. WHO (Obesity and overweight) says:

Table 1 Compositions of food supply and their ranking among some countries

Ranking	*Cereals*	*%*	*Potatoes*	*%*	*Sugar and confectioneries*	*%*	*Beans*	*%*	*Vegetables*	*%*	*Fruits*	*%*
1	Bangladesh	77.1	Nigeria	21.4	New Zealand	17.5	Kenya	7.0	China	7.3	Iran	7.1
