FAOSTAT ("Food Supply", 2015.8.21) modified by Honkawa (Honkawa Data Tribune) and translated by Yanagi.

"Beans" include soy beans and peanut. "Milk and dairy products" include butter and cream.

Comparison among 40 countries: Norway, Sweden, Finland, Denmark, United Kingdom of Great Britain and Northern Ireland, Ireland, Spain, Portugal, France, Italy, Germany, the Netherlands, Switzerland, Czech Republic, Poland, Hungary, Russian Federation, Turkey, Egypt, Kenya, Nigeria, Iran (Islamic Republic of), Pakistan, India, Bangladesh, Thailand, Malaysia, Vietnam, Indonesia, Philippines, China, Republic of Korea, Japan, Australia, New Zealand, Canada, United States of America, Mexico, Brazil, Argentina.

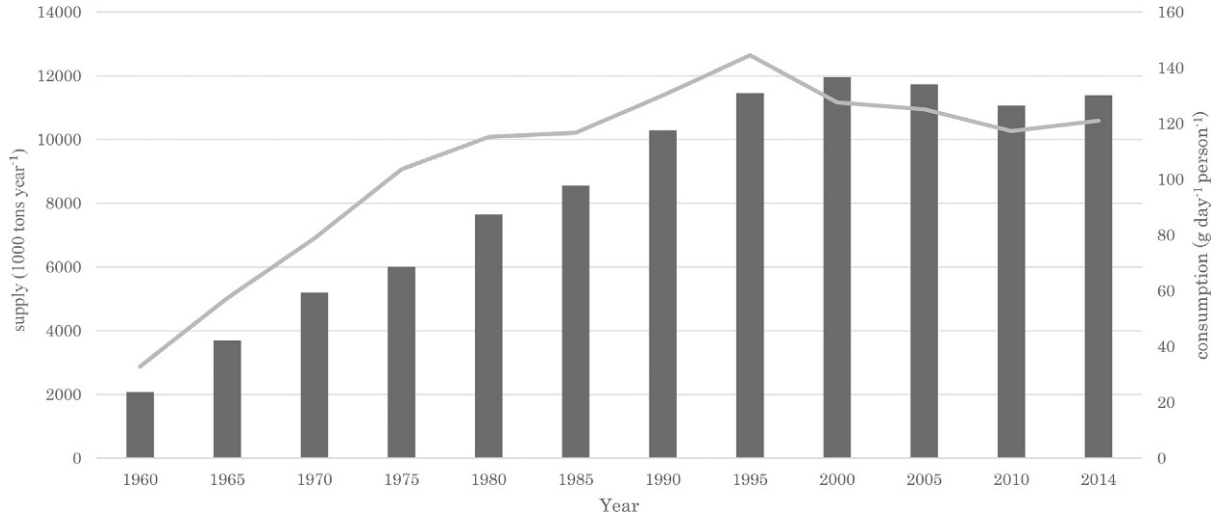

Fig. 1 Trend of milk and dairy supply and consumption in Japan. Bars show supplies and a line shows consumption. Modified from the followings: Table of food supply and demand (2000–14). Ministry of Agriculture, Forestry and Fisheries (MAFF); Milk and dairy product, cumulative long-term data (1960–99). Ministry of Internal Affairs and Communications (MIAC); Food intake by groups, long-term time-series data (1946–2014). Ministry of Health, Labour and Welfare (MHLW).

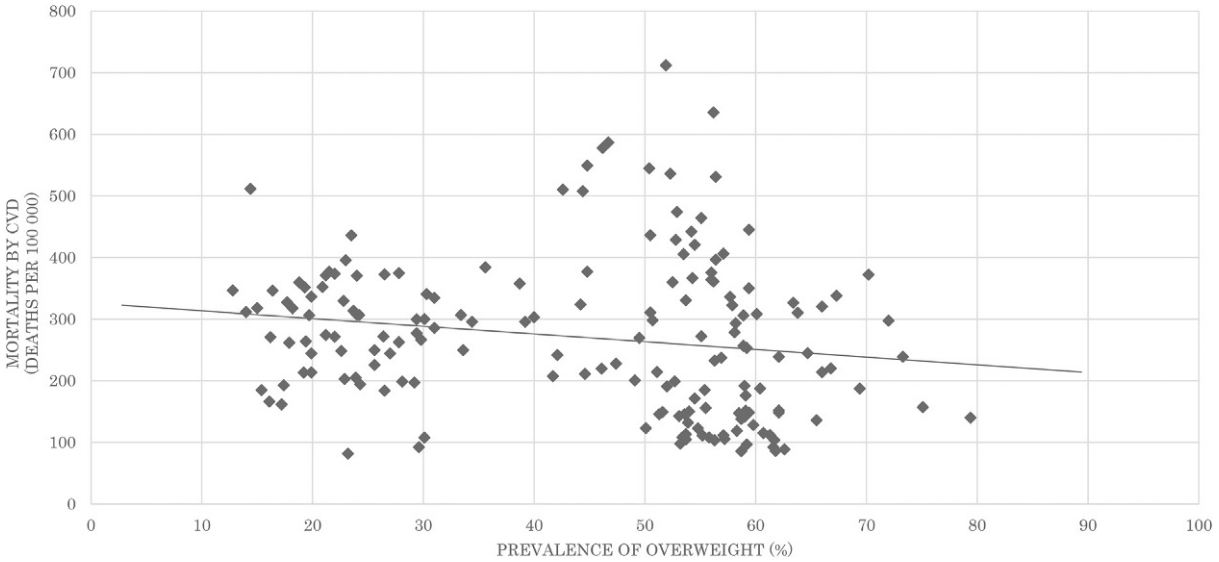

Fig. 2 Relationship between prevalence of overweight and mortality by CVD; 172 countries (modified from Global Health Observatory data. WHO, 2012). $y = -1.251x + 325.9$, $R^2 = 0.029$.

> "The fundamental cause of obesity and overweight is an energy imbalance between calories consumed and calories expended. Globally, there has been:
> an increased intake of energy-dense foods that are high in fat; and . . ."
> "Raised BMI is a major risk factor for noncommunicable diseases such as:
> cardiovascular diseases (mainly heart disease and stroke), which were the leading cause of death in 2012;
> diabetes; . . .
> The risk for these noncommunicable diseases increases, with increases in BMI."

However, the prevalence of overweight does not positively correlate with the mortality by CVD in 172 countries (WHO, Global Health Observatory data; Fig. 2). This ecological data does not seem to support the relationship between obesity and CVD (the "obesity hypothesis").

Another ecological data (WHO, Overweight Data by WHO region) also does not support the "obesity hypothesis" because the life expectancy seems to be longer in the region with a high prevalence of overweight (Table 2). Therefore, any discrepancy or heterogeneity between ecological data and observational data should be considered cautiously when we discuss the relationship between dairy products and CVDs.

Table 2 Relationship between prevalence of BMI ≥ 25, both sexes, 18+ years (age-standardized estimate) and life expectancy (years)

Region	*Overweight (%, 2014)*	*95% CI*	*Life expectancy (2015)*
Africa	30.8	28.7–32.9	60.0
Americas	61.3	58.7–63.8	76.9

Europe	58.6	56.3–60.8	76.8
Eastern Mediterranean	46.8	44.0–49.3	68.8
Western Pacific	33.0	28.7–37.3	76.6

$y = 0.245x + 61.00$, $R^2 = 0.334$.
Modified from WHO regional data (2014, 2015).

Some Reviews of Relationship Between Dairy Products and Prevalence of CVDs

A Review of the Review of Dairy Products and the Incidence of Vascular Disease and Diabetes

According to the review of dairy products and the incidence of vascular disease and diabetes (Elwood et al., 2010):

1. Eight cohort studies analyzing the relationship between dairy products and all-cause mortality were included. A meta-analysis of six studies of them was conducted between the most and the least consuming groups; the adjusted estimates of relative risk (RR) was 0.87 (95% CI 0.77–0.98).
2. Eleven cohort studies analyzing the relationship between dairy products and the incidence of ischemic heart disease were included. A meta-analysis of nine studies of them was conducted between the most and the least groups and RR was 0.92 (0.80–0.99).
3. Eleven cohort studies analyzing the relationship between dairy products and the incidence of stroke were included. They showed a significant heterogeneity. A meta-analysis showed RR was 0.78 (0.68–0.91).
4. Focusing on hemorrhagic stroke, there were five studies showing a significant heterogeneity. The RR was 0.75 (0.60–0.94).

However, this summary should be cautiously interpreted, because;

1. Heterogeneity was not reported in the meta-analyses of all-cause mortality and ischemic heart disease. However, there are seven of eight studies on all-cause mortality that did not show significant differences by themselves, and two of them showed RR exceeding 1.0.
2. In studies on ischemic heart disease, 16 studies were identified and 5 of them were excluded. RRs in the four cohorts of five excluded ones were beyond 1.0 and two of them were statistically significant.
3. The JPHC study, a cohort of Japan (Umesawa et al., 2008), was included in this meta-analysis of incidence of stroke; its RR was 0.70 (0.57–0.86). However, the JPHC study surveyed the association between the dairy calcium intake and stroke but not the consumption of dairy products and stroke. The dairy calcium intake was calculated only from "cheese" and "daily products except cheese" using food frequency questionnaire (FFQ) and there is uncertainty that this calculated dairy calcium reflects the total dairy consumption precisely.

   The other included Japanese cohort, the JACC study (Umesawa et al., 2006) also surveyed the association between the dairy calcium intake and mortality from stroke; multivariate RRs of mortality from stroke were 0.53 (0.34–0.81) for men and 0.57 (0.38–0.86) for women. The dairy calcium intake was also calculated only from milk, yogurt, and cheese using FFQ. Umesawa et al. discussed only calcium intake in this population and there is also uncertainty in the precision of total dairy consumption.

   On the other hand, the Nurses' Health Study (Iso et al., 1999) was included in this meta-analysis. They collected data on usual dietary intake using a semiquantitative FFQ and reported significant inverse association between the total calcium intake and incident ischemic stroke (P for trend: 0.04) but not between the dairy calcium intake and ischemic stroke (P for trend: 0.08). They also reported no association between the total calcium intake and all stroke (P for trend: 0.34).

   Therefore, we would like to say it is difficult to consider an adjustment for calcium intake in the analysis of dairy product as equivalent the analysis of dairy calcium intake.
4. The cohort of Kinjo et al. (1999) was included in the meta-analysis of hemorrhagic stroke. They reported a joint effect of dairy milk, meat, and fish. In the subpopulation of dairy milk consumption one to three times per week or more, meat consumption less than one times per week, and fish consumption less than one times per week, RR was 0.92 (0.82–1.02). They concluded intake of animal protein was considered a major risk factor.

In view of these aspects, it is suggested that protein and calcium intake from sources other than dairy products should be carefully adjusted when discussing the association between dairy products and CVDs.

Results From a Systematic Review of Dairy Consumption and CVD Accompanying Some Problems

A systematic review on dairy consumption and CVD (Alexander et al., 2016) shows summary relative risk estimates (SRRE) as follows:

1. SRRE of total dairy intake and total stroke is 0.91 (0.83–0.99).
2. SRRE of total dairy intake and total CVD is 0.88 (0.75–1.04).
3. SRRE of total dairy intake and total coronary heart disease (CHD) is 0.91 (0.80–1.04).

Only the SRRE of total stroke is statistically significant. However, when you pay attention to some of the included and excluded studies, important problems emerge.

1. Life Span Study (Sauvaget et al., 2003)

   The Life Span Study (LSS) reported a dietary survey using FFQ. The hazard ratio of total stroke mortality between the consuming *dairy products* almost daily versus never groups was 0.75 (0.57–0.90). However, milk and dairy products (butter and cheese, excluding margarine) were interviewed and reported separately (**Table 3**). The subgroup of *dairy products* almost daily in the LSS was a very special population having consumed animal protein a lot.

   We believe the way of citation by Alexander has a clear error. Thus meta-analysis of total daily intake and total stroke should be corrected. The SRRE will be greater than 0.91 and might not be statistically significant.
2. NIPPON DATA80 (Kondo et al., 2013)

   Results in males and females are highly heterogeneous. In the meta-analysis, Alexander described rate ratios (RR) of males (RR 1.49, 95% CI 0.91–2.45) and females (RR 0.60, 0.36–1.00) separately. There were no other studies which showed such heterogeneity between males and females in this review.

   However, Japanese males certainly have a smaller intake of dairy products than the Westerners (**Table 4**), and they also have a lower mortality of CVD (108.0 deaths per 100,000 in 2012) than the Westerners. Moreover, Japanese males in this cohort showed positive relationship between dairy product consumption and CHD incidence (RR 1.33, 0.97–1.82).
3. Some excluded studies from the SRRE

   We would like to comment about some of cohort studies excluded from the SRRE. The Rotterdam study (Praagman et al., 2015) reported 564 strokes and 567 CHD occurred in the 4235 participants whose median intake of total dairy was 397 g day^{-1}. Total dairy, milk, low-fat dairy, and fermented dairy were not significantly related to incident stroke or fatal stroke; incident and fatal CHD were not significantly related, too.

   The Whitehall II study (Soedamah-Muthu et al., 2013) reported 323 CHD occurred in the 4526 subjects whose median intake of total dairy was 378 g day^{-1}. Intakes of total dairy, high- and low-fat dairy, total milk, low-fat milk, fermented dairy products, yogurt, and cheese were not statistically significantly associated with incident CHD.

   There was no clear description why these important studies were excluded from the SRRE; they just commented "Studies required to report a composite variable for total dairy intake and a composite variable for total CVD."

Table 3 Milk and dairy products in the Life Span Study

Food	*Category*	*Cases*	*Hazard ratio*	*All subjects*
Milk	Almost daily	10,371	0.94 (0.79–1.12)	31,832
Dairy products	Almost daily	3690	0.73 (0.57–0.94)	28,662

Dairy products contain butter and cheese but not margarine.

Modified from Sauvaget, C., Nagano, J., Allen, N., Grant, E. J. and Beral, V. (2003). Intake of animal products and stroke mortality in the Hiroshima/Nagasaki Life Span Study. *International Journal of Epidemiology***32**(4), 536–543.

Table 4 Milk and dairy products consumption (g day^{-1}) by tertiles in NIPPON DATA80

	Low	*Moderate*	*High*
Male	18.0 (15.0)	61.5 (11.1)	132.6 (53.3)
Female	22.7 (18.9)	79.0 (14.8)	168.3 (62.2)

Modified from Kondo, I., Ojima, T., Nakamura, M., et al. (2013). Consumption of dairy products and death from cardiovascular disease in the Japanese general population: the NIPPON DATA80. *Journal of Epidemiology***23**(1), 47–54.

As can be seen from the above example, risk estimates of dairy products to CVDs have high heterogeneity. It is also difficult to conclude the dose–response relationship between dairy product consumption and incidence of CVDs. Therefore we would like to summarize that there is no clear evidence which shows benefit or harm for general population to take dairy products ad libitum.

Some Reviews of Relationship Between Dairy Products and Risk Factors of CVDs

Do Dairy Products Have an Antihypertensive Effect?

A review on milk products (Kris-Etherton et al., 2009) concluded calcium in dairy products has an antihypertensive effect. If paying attention to prospective studies in the review, only two of four studies on low-fat milk reported reductions in blood pressure and only one of six studies on whole milk (or simply "milk") reported systolic blood pressure reduction.

We would like to comment about one of included prospective studies showing challenging results. The Women's Health Study (WHS) was an randomized controlled trial (RCT) having used low-dose aspirin and vitamin E. Wang et al. (2008) excluded women with insufficient completion of the semiquantitative FFQ or implausible total energy intake from the WHS population and followed 28,886 women with a mean age of 53.8 years to evaluate the incidence of hypertension. They reported that the RRs of incident hypertension across increasing quintiles of low-fat dairy product intake and showed significant trend of inverse association ($P=0.001$). However, adjustment for dietary calcium significantly attenuated the inverse association of low-fat dairy intake with risk of hypertension (P for trend: 0.61). High-fat dairy product intake showed no significant association (P for trend: 0.17).

Kris-Etherton et al. also reported RCTs loading dairy products; two parallel and three crossover studies. One parallel study showed a significant decrease only in systolic blood pressure (SBP) and the other did not show significant blood pressure reduction. In crossover trials, one showed elevated blood pressure without significance; two other trials showed significant reduction only in SBP.

Summarizing these studies, there is inconsistent evidence to support that dairy products have clear blood pressure lowering effect.

Furthermore, this review mentioned sour-milk drinks containing a lot of peptides (Val-Pro-Pro and Ile-Pro-Pro) and the possibility of an antihypertensive effect. We have a discussion of the sour-milk studies in the next section.

Clinical trials on sour-milk and blood pressure

An RCT of the sour-milk drink was conducted on the blood pressure of 36 hypertensive subjects aged 40–86 years (Hata et al., 1996). However, the decrease in SBP and diastolic blood pressure (DBP) in the sour-milk group tended to be greater than that in the placebo group, there was no statistical analysis of BP between the two groups and these differences probably were not statistically significant.

Another sour-milk study (Itakura et al., 2001) was conducted on the BP of 18 hypertensive (mean age 54 years) and 26 normotensive (mean age 36 years) subjects. In normotensive subjects, both treatments did not affect BP. In untreated hypertensive subjects, SBP decreased significantly from the initial value after ingestion of the sour-milk; however, there was no statistically significant difference between treatment groups.

One more sour-milk study was conducted in Japan (Mizushima et al., 2004) on the BP of 46 borderline hypertensive men aged 23–59 years. In the sour-milk group, change in systolic BP was significant; however, two-way ANOVA did not show significant differences in changes in SBP between the two groups.

Kris-Etherton et al. showed other two studies on milk with peptides that have found no decrease in BP in hypertensive subjects. These studies are enough to discourage you conducting a large RCT on sour-milk drink supplemented with peptides.

Do Dairy Products Induce the Increase of Serum Lipids?

A review on fatty acids and CVD (Parodi, 2011) summarized RCTs of low saturated fat diets and CHD prevention, concluding: "None of the estimates of risk for total and CHD mortality attained statistical significance."

Low saturated fat diets seem to have minimal effect for CHD prevention. However, dairy products contain not a little saturated fatty acid, there is no clear evidence to encourage to avoid dairy products for the prevention of CVD.

Do Dairy Products Induce the Increase of Body Weight?

A meta-analysis on the effects of high- and low-fat dairy foods (Benatar et al., 2013) included 20 RCTs. Primary outcomes were body weight, insulin resistance, low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol, C-reactive protein, and blood pressure. They concluded that a moderate increase in dairy food consumption has no or small effects on the major cardiovascular and metabolic factors. However, mean weight gain of low-fat dairy food was twice that of whole fat dairy food. Therefore we have no evidence to encourage obese individuals having low-fat dairy foods freely.

Controversy on the Relationship Between Consumption of Dairy Products and Prevalence of Type1 Diabetes

There have been more than 25 years since an ecological study suggested cow's milk may contain a triggering factor for the development of type1 diabetes mellitus (T1DM). In fact, Japanese have low T1DM incidence less than 3 persons $100{,}000^{-1}\text{year}^{-1}$ and consume dairy products less than one-third of the Western populations (Dahl-Jorgensen et al., 1991).

A review (Gerstein, 1994) summarized breastfeeding in T1DM. Thirteen relevant case–control studies were meta-analyzed. The odds ratio (OR) of 12 peer-reviewed studies for T1DM patients exposed to less than 3 months of breastfeeding was 1.37 (95% CI 1.22–1.53). The overall OR of five studies for cow's milk exposure before 3–4 months of age in patients with T1DM was 1.57 (1.19–2.07).

Norris and Pietropaolo (1999) argued that these summary ORs are quite small and would not meet the criterion for causation. They also criticized that two cohort studies did not show the difference in duration of breastfeeding between antibody positive and negative high-risk populations. However, one cohort study suggested marginal association between high milk consumption in childhood (⊠3 glasses daily) and more frequent progression to clinical DM in a high-risk population.

These data suggest quite early exposure to cow's milk is not entirely safe. Populations consuming very little dairy products have no need to be encouraged to increase them.

Summary

Dairy products are important for the Westerners because they are the primary source of protein and minerals. There is no clear evidence which shows benefit or harm for general population to take dairy products ad libitum. On the other hand, people who do not consume dairy products routinely cannot be recommended to increase their dairy consumption. So we would like to conclude:

1. In a population approach, consider and respect the dietary habits and traditions of inhabitants, and it is not safe to force a sudden change for the intake of dairy products.
2. In a high-risk approach, consider the probability that dairy products can lead to weight gain, and dairy products are not recommended for some obese individuals. Comparing with other alternative foods, dietary interventions should be individualized.

Acknowledgments

We thank Professor Emeritus Ryoichi Yamamoto and Mr. Taro Suzuki for useful comments.

Diabetes Mellitus as a Global Epidemic

Diabetes Mellitus—Definition and Subtypes

Diabetes mellitus is a group of diseases primarily characterized by chronic hyperglycemia due to a lack of sufficient insulin action. Diabetes is roughly divided into type 1 and type 2. Type 1 diabetes, which was formerly called juvenile-onset or insulin-dependent diabetes (IDDM), accounts for less than 5%–10% (depending on areas of the world) of all diabetes. It occurs due to an acute destruction of insulin-producing beta cells in the pancreas through autoimmune disorders that lead to a sudden and total deficiency of insulin, the only hormone that can lower plasma glucose levels.

Type 2 diabetes, which used to be known as noninsulin dependent diabetes (NIDDM) or adult-onset diabetes (but currently is also common among overweight children), accounts for the vast majority of all diabetes mellitus. In this type, secretion of insulin remains but not in quantities sufficient to keep the glycemic level in a normal range, frequently due to not only decreased levels of insulin secretion but also an inappropriately increased demand for insulin because of the response of the body's cells to decreased insulin. This lowered response to insulin is called insulin resistance and occurs in various situations, typically obesity. In patients with type 2 diabetes, insulin resistance (i.e., insufficient action of insulin) and insulin deficiency (i.e., insufficient secretion of insulin) both contribute to raising plasma glucose levels but in different proportions, varying from patient to patient.

Vascular Complications of Diabetes Mellitus

Diabetes, regardless of its type, gives rise to a variety of systemic complications, most of which are vascular diseases and are associated with diminished expectancy and quality of life. Among them are *microvascular* complications mainly comprised of retinopathy, nephropathy, and neuropathy, all of which are specific to diabetes, and cardiovascular diseases (CVDs) consisting of coronary heart disease (CHD), stroke, and peripheral artery disease (PAD), which are called *macrovascular* complications or *macroangiopathy* of diabetes. Hypertension and heart failure are also more common in diabetic individuals than in nondiabetic individuals.

Global and Regional Prevalence of Diabetes Mellitus

Although plateauing in the increase in diabetes mellitus has been reported recently in some developed countries such as in the United States (Geiss et al., 2014), the world prevalence and incidence of diabetes mellitus are still increasing. A recent analysis of pooled data of population-based studies from 146 countries revealed that global age-standardized diabetes prevalence was estimated to have grown from 4.3% (95% CI 2.4–7.0) in 1980 to 9.0% (7.2–11.1) in 2014 in men and from 5.0% (2.9–7.9) to 7.9% (6.4–9.7) in women. The world adult population with diabetes increased by fourfold from 108 million to 422 million during this period. This enormous increase can be explained by the 28.5% due to the rise in prevalence, 39.7% due to population growth and aging, and 31.8% due to interaction of these two factors (NCD Risk Factor Collaboration, 2016). According to the seventh edition of the *Diabetes Atlas* from the International Diabetes Federation (International Diabetes Federation, 2015), 1 in 11 adults (415 million) in the world currently have diabetes (majority of which are type 2) and this figure is estimated to rise to 1 in 10 by 2040.

Regionally, in the United States, 9.3% of adults have diabetes (1.0% out of 9.3% were undiagnosed) according to the National Health and Nutrition Examination Survey 2005–10 (Selvin et al., 2014). However, three quarters of people with diabetes live in low- and middle-income countries although the disease is often misunderstood to occur predominantly in "wealthy" developed countries (International Diabetes Federation, 2015). It also should be noted that 60% of people with diabetes live in Asia, with almost one-third in East Asia including China; these numbers are still rapidly growing (Nanditha et al., 2016).

In addition to overt diabetes, there are 318 million adults with impaired glucose tolerance (IGT) or prediabetes worldwide who are at greater risk for future type 2 diabetes as well as CVD. Because of their asymptomatic nature, it is very difficult to find IGT and early diabetes except by a health check-up or screening. As a consequence, nearly half of the global diabetic population is undiagnosed, which frequently allows silent progression of complications including atherosclerosis.

Role of Diabetes Mellitus in the Progression of CVD

Insulin Resistance and Metabolic Syndrome

Causes of the substantially increased risk of CVD in diabetic patients are complicated. A variety of underlying atherogenic mechanisms associated with insufficient insulin action commonly cluster within an individual with diabetes and act synergistically to increase the risk of CVDs. As a background of this clustering, insulin resistance, which is explained as the reduced response to the hormonal messenger of insulin signal transduction, plays a crucial role.

Insulin resistance is a pathophysiological basis of not only type 2 diabetes but also metabolic syndrome, which is also a predictor of CVD and its mortality. In fact, because of sharing common soil in their mechanisms, obesity, hypertension, and dyslipidemia, all of which are components of metabolic syndrome, are very common comorbidities in type 2 diabetes (Nelson et al., 2002). In fact, the majority of individuals with type 2 diabetes in the U.S. are overweight (Nelson et al., 2002).

Other Mechanisms That Promote Cardiovascular Damage in Diabetes

The increased oxidative stress due to production of superoxide anions and lipid peroxidation products, along with the decreased availability of antioxidants that are seen in diabetes, are considered to play an important role in the development of diabetes complications (Nishikawa et al., 2000). Oxidative stress, as well as sustained hyperglycemia, also promotes the formation of advanced glycation end-products (AGEs). AGEs, which are produced by nonenzymatic glycation of proteins, can affect or alter the physiological functions of normal proteins. Hyperreactivity of platelets in addition to impaired fibrinolysis and decreased activity of antithrombotic factors also enhance the hypercoagulable status seen in diabetes.

Through these mechanisms that have still not been completely clarified, chronic hyperglycemia causes endothelial or mitochondrial dysfunction, metabolic disturbances, and fibrosis of the extracellular matrix, which lead to functional impairment of myocardium even without significant coronary stenosis and is called cardiomyopathy. In fact, risk of heart failure was significantly increased in patients with diabetes; the annual mortality of patients with heart failure was increased more than 10-fold that in diabetic patients without heart failure (MacDonald et al., 2008.

Diabetic Autonomic Neuropathy and Other Complications of Diabetes

That CHD in diabetic patients is often overlooked or found in advanced stages has been explained by the fact that it is frequently asymptomatic or without typical symptoms because of autonomic dysfunction due to diabetic neuropathy. Among patients with type 1 diabetes, those with cardiovascular autonomic neuropathy have a 1.53 (95% CI, 1.01–2.32)-fold higher incidence of any CVD event (Pop-Busui et al., 2017). Autonomic neuropathy might also be a cause of prolongation of the QT interval and arrhythmia, and the heart rate-corrected QT interval was shown to be an independent predictor of all-cause and CVD mortality in patients with type 2 diabetes (Cox et al., 2014). Among patients with type 2 diabetes who were insufficiently controlled with metformin or sulfonylurea monotherapy, unrecognized Q-wave myocardial infarction was found in 1.9%, which accounted for one-third of the prevalence of myocardial infarction (MacDonald et al., 2011).

Probably because of the sharing of common mechanisms, one could be a predictor of subsequent other complications. For example, retinopathy could be a predictor of macrovascular complications in patients with type 2 diabetes. People with mild to moderate nonproliferative diabetic retinopathy had a higher risk of CHD (hazard ratio 1.69, 95% CI, 1.17–2.97) and stroke (2.6, 1.03–4.86) (Kawasaki et al., 2013).

Impact of Diabetes on CVD

Diabetes as a Risk Factor for CVD

As a risk factor for CVD, diabetes has an enormous impact from the clinical as well as public health point of view considering the global epidemic of the disease. Compared with nondiabetic individuals who were similar in CHD risk factors, diabetic patients had a higher prevalence, extent, and severity of CHD (Rana et al., 2012). Diabetes was estimated to confer a CHD risk equivalent to 15 years of aging (Booth et al., 2006).

Type 2 diabetes has been known to be associated with a several-fold greater risk for CVD. A collaborative meta-analysis of 102 prospective studies concluded that diabetes conferred an approximately two-fold excess risk for a wide range of vascular diseases, independent of other conventional risk factors (Emerging Risk Factors Collaboration, 2010). An analysis of a nationally representative database with information from the past two decades in the United States demonstrated large reductions in the incidence of acute myocardial infarction (AMI), stroke, lower-extremity amputation, and end-stage renal disease (Gregg et al., 2014). Relative risk of these four complications between diabetic and nondiabetic individuals in 1990 and 2010 were 3.8 and 1.8 for AMI, 3.1 and 1.5 for stroke, 18.8 and 10.5 for lower-extremity amputation, and 13.7 and 6.1 for end-stage renal disease, respectively. Especially, the number of cases with AMI among 10,000 diabetic patients declined from 37.5 in 1990 to 25.8 in 2010, which was a 31% reduction, while a 68% reduction was seen in nondiabetic persons during the same period. Although epochal improvement was confirmed, a large burden of the disease continues since the relative risks were significant and prevalent diabetes persists.

Diabetes has long been recognized as "CHD risk equivalent" as a predictor of CHD as strong as prior CHD (Juutilainen et al., 2005). This provided a rationale for treating diabetic patients as aggressively as nondiabetic patients with prior myocardial infarction in consideration that the 10-year mortality from CHD was reported to be more than 20%, which is comparable to that in those with prior CHD (Haffner et al., 1998; Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001).

Additional lifetime healthcare expenditures because of diabetes in the U.S. ranged from $75,000–89,000 per patient (Leung et al., 2015), suggesting that diabetes imposes an enormous health and economic burden globally considering the fact that three quarters of people with diabetes live in low- and middle-income countries (International Diabetes Federation, 2015).

Diabetes as a Risk and Cause of Mortality

Excess cardiovascular mortality risk among Swedish patients with type 2 diabetes was 1.14 (95% CI 1.13–1.15) compared to nondiabetic individuals; the degree of excess mortality was greater in younger than older diabetic persons and in those with worse glycemic control and more severe nephropathy (Tancredi et al., 2015). In the United States, mean life-years lost by diabetes were estimated to be 5.5–6.2 years (depending on ethnic origins) (Leung et al., 2015), and 10.6% and 17.7% of cardiovascular mortality in men and women aged 65–79 years, respectively, are theoretically avoidable with the elimination of diabetes (Patel et al., 2015).

Among people with diabetes, CVD is the most common and major cause of death in many countries although in East Asian countries, cancer is a more common cause (Tseng, 2004; Hotta, 2010). Analysis of a large cohort of more than a million Australians with diabetes also demonstrated the absence of a decline in cancer mortality in spite of a significant decline in all-cause, CVD, and diabetes mortality during 2000–11 and warrants urgent attention (Harding et al., 2016)

Fortunately, the situation has improved (hopefully due to recent advances in screening and care) and CV mortality risk has decreased to 10% over 10 years in a more recent cohort (Howard et al., 2006), which depends largely on coexisting CV risk factors including factors other than hyperglycemia. Age-standardized CVD mortality rate decreased each year by 0.35 (type 1) and 0.15 (type 2) per 1000 person-years between 2000 and 2011 (Donahoe et al., 2007).

Characteristics of CVD in Diabetic Patients

CVDs accompanied by diabetes are known to be more severe and to be associated with a poorer outcome and prognosis compared to those not associated with diabetes. Multiple vessel disease is more common (Waller et al., 1980) and death after AMI was found to be approximately 1.5-fold higher in individuals with diabetes than in those without it (Sprafka et al., 1991; Liang et al., 2014). Mortality at 30 days and 1 year after acute coronary syndrome events was also higher in diabetic patients compared to nondiabetic individuals (Donahoe et al., 2007). Even in the recent "stent era," among patients who underwent percutaneous coronary interventions due to myocardial infarction, patients with diabetes had an approximately 2.5-fold greater risk for recurrent myocardial infarction as well as all-cause mortality during the first 30 days or even at 3 years after the percutaneous coronary intervention compared to nondiabetic persons (Jensen et al., 2012).

Because asymptomatic occurrence and progression of type 2 diabetes is common, a substantial proportion of all CVD incidents are seen in patients with preexisting but undiagnosed diabetes. Oral glucose tolerance testing identified the presence of disorders of glucose metabolism in approximately half of ischemic strokes (Urabe et al., 2009) and half of acute coronary syndrome (Hashimoto et al., 2005) patients without previously known diabetes.

CVD Risk in People With Prediabetes

Unlike microvascular complications, which occur only years after the development of diabetes, the risk of macrovascular complications start to rise even during the prediabetic stage. At this moment, there are several definitions of prediabetes. These include impaired fasting glucose (IFG) according to the criteria of the American Diabetes Association (5.6–6.9 mmol/L) and the WHO expert group (6.1–6.9 mmol/L) and impaired glucose tolerance (IGT) (2 h plasma glucose concentration 7.8–11.0 mmol/L during an oral glucose tolerance test) or elevated HbA1c of 5.7%–6.4% (39–47 mmol/mol) according to American Diabetes Association criteria or 6.0%–6.4% (42–47 mmol/mol) according to the National Institute for Health and Care Excellence (NICE) guidelines in the United Kingdom. However, regardless of definitions, prediabetes was shown to significantly increase the risk of CVD and its mortality by 13%–30% (depending on its definition) (Huang et al., 2016).

Random plasma glucose levels were also shown to be associated with CVD even within normal range in a large Chinese cohort without diabetes (Bragg et al., 2016). The 2-h postchallenge glucose level in an oral glucose tolerance test was shown to be more strongly associated with CVD than fasting plasma glucose; i.e., IGT was a stronger predictor of CVD than IFG (Tominaga et al., 1999). This indicates that postprandial hyperglycemia, which is characteristic of pre- or early-stages of diabetes, could promote the atherosclerotic process.

CVD in Women and Younger Adults With Diabetes

Impact of diabetes on the risk of CVD is significantly greater in women than in men. It is known that the protection that premenopausal women have against CVD is almost lost when diabetes is present (Nathan, 1993). Meta-analysis of 37 cohort studies found that the relative risk for fatal CHD in patients with diabetes (vs. nondiabetic persons) was significantly higher among women (relative risk 3.5, 95% CI 2.7–4.5) than among men (2.1, 1.8–2.3) (Huxley et al., 2006). The same group reported that the additional risk for vascular dementia, but not for nonvascular dementia, was greater in diabetic women than in diabetic men (Chatterjee, 2016). A meta-analysis of 64 cohorts demonstrated that the pooled maximum-adjusted relative risk of stroke associated with diabetes was 2.28 (95% CI 1.93–2.69) in women and 1.83 (1.60–2.08) in men, with a 27% significantly higher incidence in women. These findings indicated that women with diabetes had a 1.27 (1.10–1.46)-fold greater risk of stroke than diabetic men (Peters et al., 2014).

Diabetes has a more profound impact on younger adults than on the elderly in terms of comparison with nondiabetic persons. In contrast to the fact that diabetic men aged 51–60 years have approximately a 2.5-fold higher risk of CHD than nondiabetic men of the same age, diabetic men aged 31–40 years have an approximately 17 times higher risk than nondiabetic individuals (Fujihara et al., 2016).

Risk Factors for CVD in Diabetic Patients

Hyperglycemia and its Control

Despite the fact that diabetes is a well-established predictor of CVD, reported effects of hyperglycemia per se on CVD have differed between observational cohorts and clinical trials of hypoglycemic agents.

Influence of hyperglycemia determined by observational studies

In prospective observational studies, hyperglycemia was shown to be an established independent predictor of CVDs regardless of the ethnic group. A meta-analysis of 18 prospective cohort studies demonstrated that each 1% increase in HbA1c corresponded to an 18% or 12%–14% greater risk for CVD events or all-cause mortality, respectively, of which results were similar between type 1 and type 2 diabetes (Selvin et al., 2004). In another large cohort, every 1-mmol/L (18-mg/dL) increase in fasting plasma glucose predicted a 17% increase in the risk of future cardiovascular events or death (Anand et al., 2012).

Effects of glucose lowering in clinical trials

In spite of these associations between hyperglycemia and CVD in observational studies, the clinical evidence that intensive glycemic control lowers the risk for CVD events or death is relatively limited, notwithstanding the well-established reduced risk of microvascular complications such as retinopathy or nephropathy.

The Diabetes Control and Complications Trial (DCCT) (Diabetes Control and Complications Trial Research Group, 1993) comprised of patients with type 1 diabetes and the UK Prospective Diabetes Study (UKPDS) (UK Prospective Diabetes Study, UKPDS Group, 1998) comprised of patients with type 2 diabetes proved the effect of glycemic control for respective intervention periods of approximately 6.5 or 10 years respectively by insulin and/or oral hypoglycemia agents with a marked reduction in

microvascular complications. Nevertheless, neither study failed to demonstrate the expected significant reduction in CVD risk during observational periods of less than 10 years.

Interestingly, a significant reduction in CVD risk in a therapeutic intervention group compared to a conventional therapy group was finally reached during extended observation of these clinical trials long after finishing the therapeutic intervention for hyperglycemia when HbA1c of both groups had already converged (Nathan et al., 2005; Holman et al., 2008). The phenomenon is called "metabolic memory" or "legacy effect," indicating that glycemic control requires a long time to produce an obvious effect on CVD risk but that the effect continues for years. This could also explain the dissociation between observational and intervention studies. The mechanism of this phenomenon is not completely clarified but is speculated to be at least partly due to an epigenetic process (Miao et al., 2014).

However, strangely enough, three subsequent large clinical trials (Action to Control Cardiovascular Risk in Diabetes (ACCORD) (Action to Control Cardiovascular Risk in Diabetes, ACCORD Study Group, 2008), Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) (ADVANCE Collaborative Group, 2008), and Veterans Affairs Diabetes Trial (VADT) Duckworth et al., 2009), all of which were designed to aim for even better results by further stricter glycemic control, not only failed to demonstrate significant reductions in CVD events but also unexpectedly found increased mortality in the intensive intervention group in the ACCORD study.

The reasons why the intensive hypoglycemic intervention failed to reduce or even increased the incidence of CVD were not fully resolved despite rigorous explanatory analysis including possible candidates such as a higher incidence of weight gain and hypoglycemia accompanying the therapeutic intervention or a too-rapid lowering of HbA1c. Hypoglycemia associated with therapeutic use of hypoglycemic agents, including insulin, is one the causes that might explain the dissociation. A meta-analysis suggested that severe hypoglycemia was strongly associated with a higher risk of CVD (relative risk 2.05, 95% CI 1.74–2.42) (Goto et al., 2013)

Meta-analyses of these clinical trials were also repeated many times to integrate the effects of intensive glycemic control on CVD events and mortality but only showed similar results of modest though significant reductions in mainly nonfatal myocardial infarctions but no significant effect on mortality (Turnbull et al., 2009; Ray et al., 2009; Kelly et al., 2009; Boussageon et al., 2011). These results imply that, at least, concentrating on a rapid and intense lowering of only glucose levels would not necessarily result in a reduction of CVD in patients with diabetes.

Blood Pressure and its Control

Hypertension is more frequent in people with diabetes than in those without it, and the frequency of diabetes is known to also be higher in persons with hypertension than in normotensive individuals. In a historical cohort of the Multiple Risk Factor Intervention Trial (MRFIT), systolic blood pressure was shown to be an independent risk factor for CVD in persons with diabetes (Stamler et al., 1993). In an analysis of Framingham participants newly diagnosed with diabetes, hypertension was shown to be associated with a 72% increase in the risk of all-cause death and a 57% increase in the risk of any CV event in individuals with diabetes. The population-attributable risk from hypertension in individuals with diabetes mellitus was 30% for all-cause death and 25% for any cardiovascular event (Chen et al., 2011).

In clinical trials, each 10-mmHg decrease in systolic blood pressure was associated with reductions in risk of 12% (95% CI 10–14) for any complication related to diabetes, 15% (12–18) for deaths related to diabetes, and 11% (7–14) for myocardial infarctions in the UKPDS (Adler et al., 2000). Similarly seen in a meta-analysis of 40 large-scale randomized controlled trials of blood pressure-lowering treatment that did not exclude patients with diabetes, each 10-mmHg lowering of systolic blood pressure was associated with a significantly lower risk of mortality (relative risk 0.87, 0.78–0.96), coronary heart disease (0.88, 0.80–0.98), and stroke (0.73, 0.64–0.83) (Emdin et al., 2015). However, it is noteworthy that the "legacy effect," which was seen in terms of the effect of glycemic control, was not observed in blood pressure control, implying the necessity of continuous control for prevention of CVD in patients with diabetes (ACCORD study group, 2010a)

At the same time, a U-shaped association was reported between blood pressure and stroke risk among diabetic patients who had undergone a pharmacological intervention, suggesting that too-aggressive control of blood pressure $<$110/65 mmHg was associated with a rather higher risk of stroke (Zhao et al., 2013). Also noteworthy is that, according to the recent meta-analyses of 49 clinical trials (Brunström and Carlberg, 2016), antihypertensive treatment reduced the risk of mortality and cardiovascular morbidity in diabetic patients only in those whose systolic blood pressure was $>$140 mmHg; for those with systolic blood pressure $\leq$ 140 mmHg, further treatment was associated with a rather increased risk of cardiovascular death.

Serum Lipids and Their Control

Dyslipidemia is known to be more common in diabetic individuals compared to nondiabetic individuals. As with people without diabetes, dyslipidemia is one of the most potent risk factors for CVD, especially CHD, in people with diabetes. In particular, the association of low-density lipoprotein (LDL) cholesterol and CVD risk is well established regardless of age, sex, or ethnic group notwithstanding the presence or absence of diabetes.

A meta-analysis of 16 clinical trials of patients with type 2 diabetes showed that the pooled relative risk associated with a 1-mmol/L (39 mg/dL) increase in LDL cholesterol was 1.30 (95% CI 1.19–1.43) for incident CVD and 1.50 (95% CI 1.25–1.80) for

CVD mortality, independently of other conventional risk factors (Wang et al., 2013). This is similar to the results for nondiabetic persons (Cholesterol Treatment Trialists' Collaborators (2008, 2010).

Dyslipidemia in type 2 diabetes is known to be characterized by increased levels of triglycerides and decreased levels of high-density lipoprotein (HDL) cholesterol based on being accompanied by obesity and insulin resistance. In Japanese persons with type 2 diabetes, hypertriglyceridemia had an impact on CHD comparable to LDL cholesterol, and both additively affected the CHD risk (Sone et al., 2011). However, clinical trials using fibrates, agents for lowering triglycerides and increasing HDL cholesterol, indicated relatively limited effects on CVD mortality in diabetic patients compared to trials using statins (Keech et al., 2005; Burgess et al., 2010; ACCORD Study Group, 2010b).

Effects of Control of Combinations of Multiple Risk Factors and Lifestyles

It has been established that simultaneous control of multiple risk factors is essential and effective for preventing CVD and its mortality in patients with diabetes, though accomplishing this is not necessarily easy in clinical settings. It also needs to be mentioned that even by the most efficient way to prevent CVD, it takes nearly 10 years for the mortality difference between groups to reach statistical significance. That differences between groups favoring those receiving a multifactorial intervention over traditional treatment become evident long after the intervention has been discontinued suggests that "metabolic memory" or the "legacy effect" exists not only for glycemic control but also for multifactorial interventions.

In the Steno-2 study, though it involved a limited number of participants, 7.8 years of intensified multifactorial intervention for hyperglycemia and hypertension and the use of lipid-lowering agents and aspirin together with lifestyle modifications was shown to successfully reduce the risk of nonfatal CVD (Gaede et al., 2003) and mortality (Gaede et al., 2008) among patients with type 2 diabetes. During 21.2 years of follow-up, including the intervention period in the first 7.8 years, the hazard ratio for CVD events was 0.55 (95% CI, 0.39–0.77) and median time before the first CVD event after randomization was 8.1 years longer in the multifactorial intervention group than in the conventional therapy group. Hazard ratio for all-cause mortality for multifactorial intervention group was also 0.55 (0.36–0.83) (Gæde et al., 2016).

Lifestyle intervention is also effective in preventing CVD in persons with type 2 diabetes and prediabetes. In the Da-Qing study in China, the lifestyle intervention program for the first 6 years in people with impaired glucose tolerance could reduce the incidence of cardiovascular and all-cause mortality even after 23 years of follow-up (Li et al., 2014). In the Japan Diabetes Complications Study (JDCS), an intervention program focusing on a lifestyle intervention, including telephone counseling, successfully decreased the risk of stroke in patients with type 2 diabetes (Sone et al., 2010). In the same cohort, it was shown that a significant reduction in the hazard ratio in patients in the top ($\geq$15.4 metabolic equivalents [MET] h/week) vs. the bottom tertile ($\leq$3.7 MET h/week) of leisure-time physical activity was observed for stroke (HR 0.55, 95% CI 0.32–0.94) and total mortality (0.49, 0.26–0.91) (Sone et al., 2013).

In spite of this clinical evidence, almost half of adults with diabetes in the United States did not meet the goals recommended by therapeutic guidelines (Ali et al., 2013). Among adults with diabetes, those with optimal levels of blood pressure, LDL-cholesterol, and HbA1c comprised only 7.2% of the study population but were associated with the great reduction in cardiovascular event risk of 62% (Wong et al., 2016).

Conclusions

Diabetes mellitus even in its early- or pre-stages confers a substantial burden on CVD morbidity and mortality worldwide. Because of its asymptomatic onset and progression, population-based screening programs are essential for detection of the disease before the development of vascular complications including CVD.

Introduction

History of Diagnosis in Pediatric Cardiology

Early pediatric cardiologists relied primarily on auscultation, electrocardiography, and chest x-ray for diagnosis. At that time, there were few surgical options available, limiting the need for detailed diagnoses. As surgical techniques advanced, diagnostic methods were forced to keep pace. Cardiac catheterization became the diagnostic method of choice. Catheterization provided valuable hemodynamic data and angiography allowed better delineation of cardiac anatomy. However, catheterization was limited by invasiveness and lack of portability. As ultrasound equipment improved, echocardiography became the modality of choice for diagnosis in congenital heart disease (CHD). While newer techniques, such as cardiac magnetic resonance imaging (CMR) and computed tomography (CT), continue to advance the field, echocardiography remains the mainstay for diagnosis. Other modalities function primarily as adjuncts. As such, this article focuses on diagnosis of various congenital heart lesions using echocardiography. Each section will include a brief overview of various types of cardiac anatomy then review diagnosis by echocardiography. We will then discuss the strengths and weaknesses of CMR, CT, and cardiac catheterization and the situations in which they are most commonly used. This article serves as an overview of cardiac lesions that are fundamental to understanding diagnosis of CHD. For more detailed explanations of cardiac anatomy and to become acquainted with additional lesions not discussed here, please see related articles.

An Overview of Segmental Anatomy

A continued topic of controversy in the world of pediatric cardiology is the correct vocabulary to use when describing complicated cardiac anatomy, such as that of heterotaxy. The two main systems of nomenclature are referred to by the eponyms "Van Praaghian" and "Andersonian." The Van Praaghian method defines the heart based on situs and five cardiac segments. Situs refers to the spatial relationships and chirality of each cardiac chamber. Chirality implies that each cardiac chamber's morphology has fundamental

chiral characteristics that are uniquely "right" or "left." This school of nomenclature divides the heart into five cardiac segments, the three main segments being the atria, ventricles, and great arteries and two connecting segments being the atrioventricular canal and infundibulum. According to Van Praagh, normal cardiac anatomy is labeled as {S, D, S} meaning visceroatrial situs solitis, D-looped ventricles, and great artery situs solitus (Ezon et al., 2015).

The Andersonian system fundamentally differs from Van Praaghian by dividing the heart into three main components, the atria, ventricles, and great arteries. This nomenclature system does not use situs to discuss the spatial relationships of the heart segments. Instead, in this system, both the spatial arrangement of each cardiac component and the way they join to successive components are described. The terms concordant and discordant are used to discuss the relationship of successive components. Using the Andersonian method, a normal heart would be described as usual atrial arrangement, concordant atrioventricular connections, and concordant ventriculoarterial connections (Ezon et al., 2015).

Echocardiography

Physics

While a detailed description of the underlying physics is beyond the scope of this article, a limited understanding can help illuminate the strengths and weaknesses of the modality. Echocardiography uses ultrasound waves to image cardiac structures. An echocardiographic probe emits waves that are reflected, absorbed, or scattered as they contact internal structures. The reflected waves return to the probe and are used to construct an image. The resolution and penetration depend on the frequency of the probe, with higher frequencies providing better resolution but decreased penetration. The larger a patient, the more penetration is needed, decreasing image resolution. Ultrasound waves cannot propagate through air and cannot pass through bone, limiting the available "windows" for visualizing the heart.

Strengths and Weaknesses

Echocardiography has many advantages. It is portable, non-invasive, and fast. Images can be obtained and interpreted in "real-time," allowing rapid diagnosis in critically ill infants and children. Doppler echocardiography (spectral and color flow) allows for accurate assessment of valvar stenosis and insufficiency, vascular obstruction, and ventricular and atrial septal defects (ASDs). Transesophageal echocardiography (TEE) can provide imaging during sterile procedures, such as cardiac catheterizations and cardiac surgery, and provides excellent images with less dependency on imaging windows. Advances in equipment have led to improved image quality, better three-dimensional (3D) imaging, and the ability to assess subclinical dysfunction using myocardial strain. However, echocardiography has many limitations. Accurate diagnosis depends on good image quality, and imaging windows tend to worsen as children and adults grow, an issue exacerbated by the obesity epidemic. In older children, some structures can be extremely difficult to image even with good windows. Quantitation of chamber sizes and function, particularly of the right ventricle, can be difficult and often involves geometric assumptions that limit accuracy. This is somewhat alleviated by 3D imaging, but adequate 3D datasets can be difficult to obtain. Finally, objective hemodynamic assessment is limited. Despite these limitations, the advantages of echocardiography insure that it will remain the modality of choice for diagnosis of CHD for the foreseeable future.

Septal Defects

Atrial septal defects

Background

The atrial septum is the wall between the left and right atria, preventing mixing of blood between chambers. A patent foramen ovale (PFO) is a normal interatrial communication during fetal life that may persist after birth (**Fig. 1**, **Movies 1** and **2**). Usually there is complete anatomic closure of a PFO by adulthood with only about 20%–25% of adults having PFOs (Silvestry et al., 2015). An ASD, on the other hand, is due to a deficiency of atrial septal tissue and is not a normal finding. There are various types of ASDs including the secundum ASD, primum ASD (a variant of AVSD discussed later), sinus venosus defect (often associated with partial anomalous pulmonary venous return), and coronary sinus defect (**Fig. 2**). All types of ASDs lead to left to right shunting across the atrial septum and right-sided chamber dilation. Secundum ASDs are the most common type of ASD comprising approximately 75% of ASDs (Kuijpers et al., 2015) (Yong et al., 2009; Gabriels et al., 2014). This defect is graded as small when less than 6 mm, moderate when 6–12 mm, or large when greater than 12 mm (McMahon et al., 2002).

Diagnosis by ECHO

The goal of transthoracic echocardiography is to determine the location and size of the ASD, measure the defect's margins to determine suitability for transcatheter closure, and assess hemodynamics. This echocardiographic examination relies mainly on 2D imaging and color Doppler. The subcostal acoustic window, which utilizes the orthogonal plane to the atrial septum, is the optimal view to minimize the likelihood of false dropout acoustic signals (**Fig. 3A** and **B**). This contrasts with the apical window, which is at most risk for dropout as a result of the parallel orientation of the ultrasound beam relative to the atrial septum. Hemodynamic assessment should also be completed. This includes color Doppler to assess the directionality of flow across the atrial septum, which

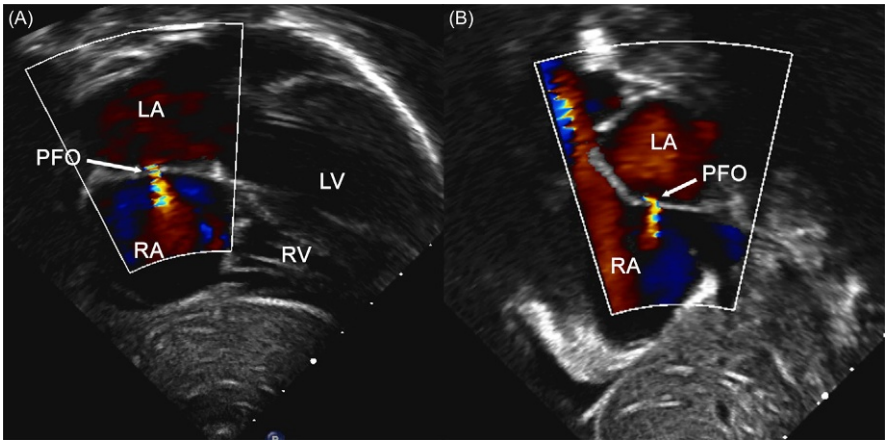

Fig. 1 Subcostal coronal (A) and sagittal (B) views with color flow mapping demonstrating a patent foramen ovale (PFO). Blood flow across the defect, from left atrium (LA) to right atrium (RA), represented by the red jet of color flow moving toward the transducer.

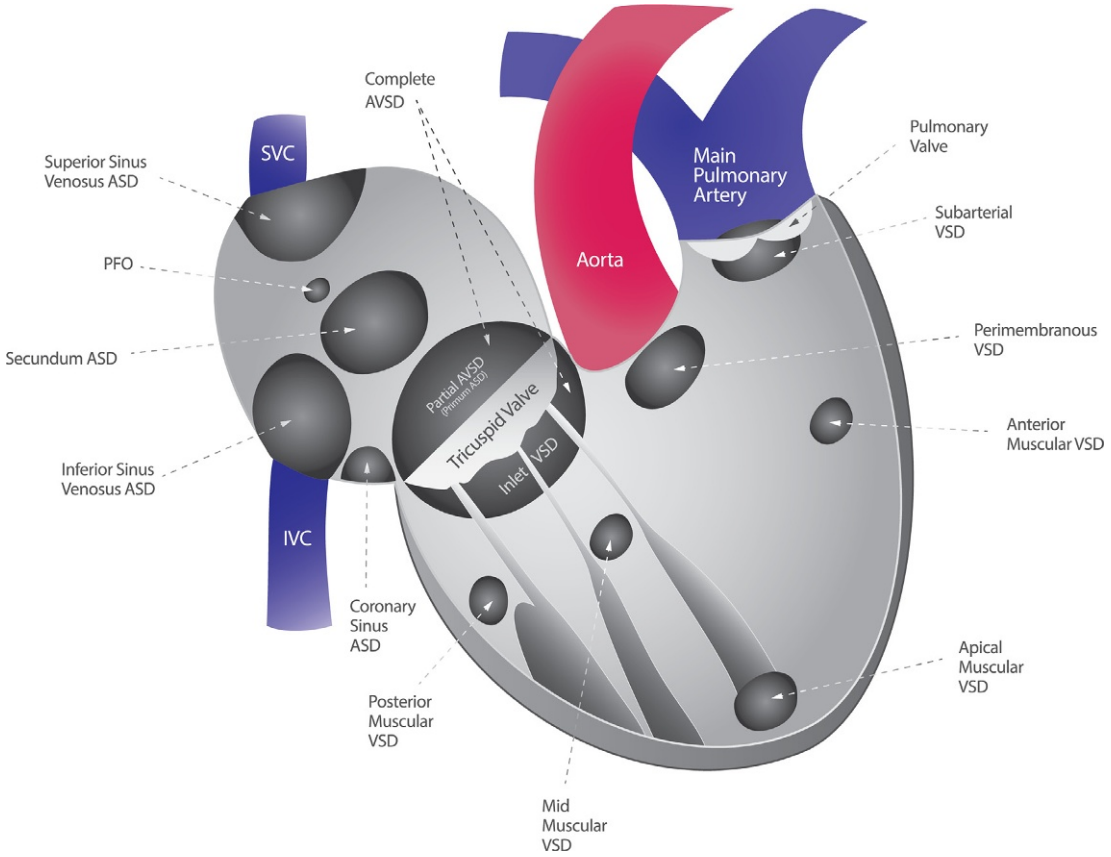

Fig. 2 Drawing of the right atrial and right ventricular surfaces of the atrial and ventricular septae illustrating the multiple names and locations of atrial and ventricular septal defects. Of note, while a primum atrial septal defect (ASD) and an inlet ventricular septal defect (VSD) can each occur in isolation, a complete atrioventricular septal defect (AVSD) is caused by a defect in both. *SVC*, superior vena cava; *IVC*, inferior vena cava.

is usually left to right, and also the degree of right-sided chamber enlargement. Other markers of this increased hemodynamic load include diastolic ventricular septal flattening and increased pulmonary blood flow. TEE can help guide percutaneous or operative closure, and 3D imaging plays an important role in guiding the interventionalist as well as assessing adequate device placement (Fig. 3C and D, Movies 3 and 4).

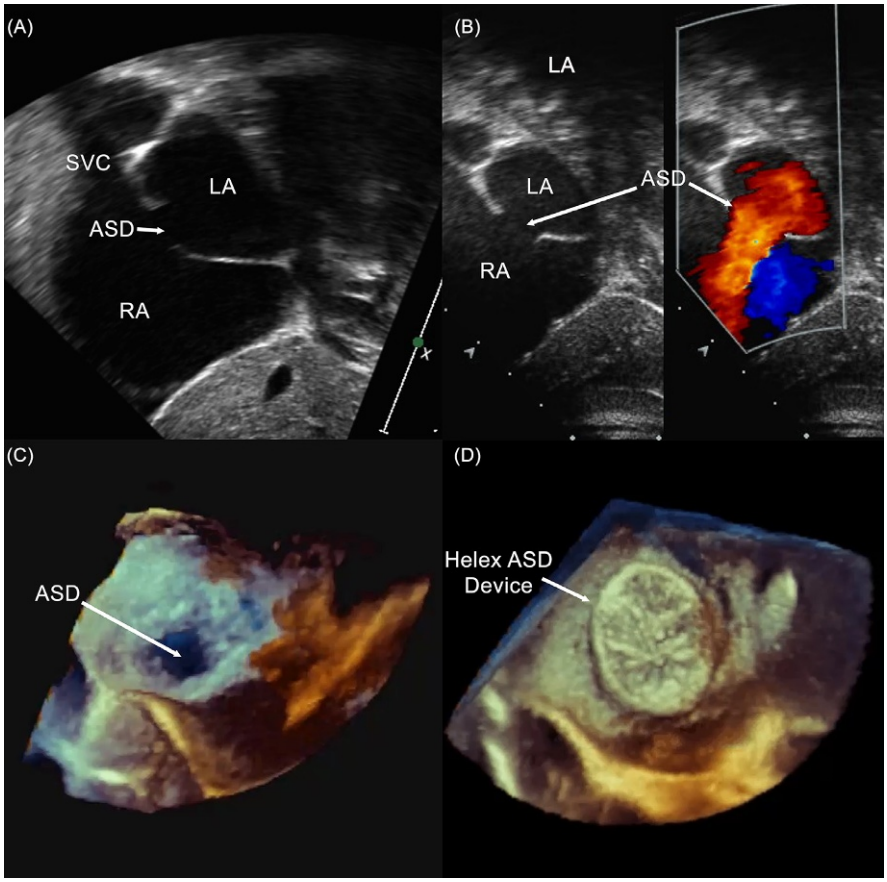

Fig. 3 Atrial septal defect (ASD) as seen in a subcostal sagittal view (A). Similar view with color compare demonstrates left to right shunting from the left atrium (LA) to the right atrium (RA) across the ASD, represented by the red jet of color flow moving toward the transducer (B). Three-dimensional image of an ASD obtained with transesophageal echocardiography (TEE) prior to device closure (C). Three-dimensional image obtained by TEE after device closure with a Helex device demonstrating good placement of the Helex across the ASD (D). *SVC*, superior vena cava.

Ventricular septal defects

Background

The ventricular septal defect is the most common form of CHD in childhood. It occurs in 50% of all children with CHD (Fyler, 1992c; Minette and Sahn, 2006) and in 20% as an isolated lesion (Minette and Sahn, 2006; Moller et al., 1995). Advances in imaging have improved detection of VSDs, increasing the postulated incidence of VSDs to approximately 5 per 100 births from 2 per 1000 births (Minette and Sahn, 2006; Ooshima et al., 1995; Roguin et al., 1995). Following bicuspid aortic valves, VSDs are the most common congenital heart defect in the adult population (Minette and Sahn, 2006; Fyler, 1992b). VSDs can occur in multiple locations, and there are numerous classification methods to describe VSDs (Van Praagh et al., 1989; Soto et al., 1980, 1989; Hagler et al., 1985; Jacobs et al., 2000b). To help decrease confusion related to the multiple naming conventions, the Congenital Heart Surgery Nomenclature and Database Project created a unified nomenclature system (Jacobs et al., 2000b). The following discussion is based on this unified terminology, which divides the ventricular septum into four primary locations: muscular, inlet, perimembranous, and subarterial (**Fig. 2**).

Diagnosis by ECHO

The goals of the TTE examination include clearly identifying the VSD location, size, number of defects, and relationship of the defect to neighboring structures (such as a straddling valve) that may complicate surgical repair. Numerous planes and sweeps are necessary to profile the ventricular septum using both spectral Doppler and color Doppler. A typical VSD echo examination includes the parasternal long- and short-axis views to profile perimembranous, subarterial, and muscular VSDs, the apical four-chamber view sweeping posterior to anterior to examine the inlet septum, trabecular septum, and membranous septum, and the subcostal window to investigate the inlet and membranous septum (**Figs. 4** and **5**, **Movies 5–7**). Finally, the degree of left to right shunting at the level of the VSD can be assessed qualitatively by noting the degree of left ventricular enlargement (**Fig. 5C**), systolic septal flattening, and increased pulmonary blood flow. Careful delineation of VSD location and margins is necessary to guide operative or percutaneous closure.

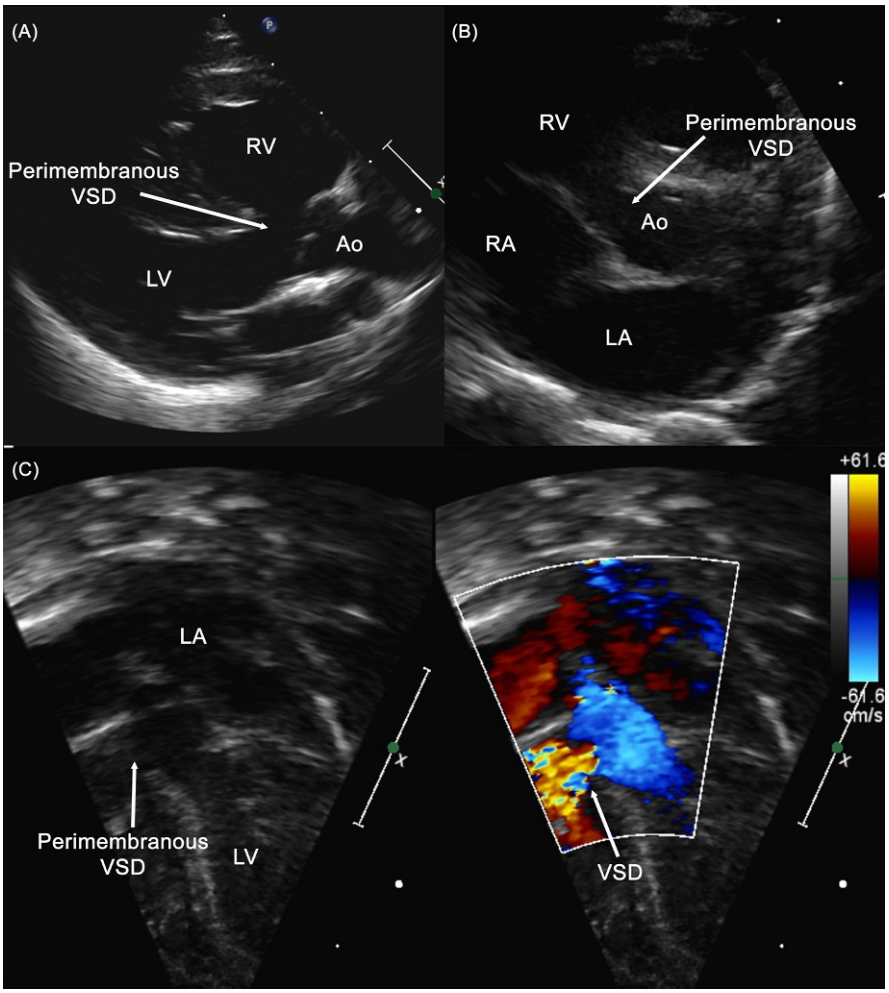

Fig. 4 Long (A) and short (B) axis views of a perimembranous ventricular septal defect (VSD). Apical 4-chamber view with color compare (C) of the perimembranous VSD. The red jet of color flow moving toward the transducer represents left to right shunting across the VSD. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Atrioventricular septal defects

Background

There are many labels used to name the constellation of defects known as atrioventricular septal defects (AVSDs) including endocardial cushion defects and common atrioventricular canals. Here we will be using the name AVSD. This defect is defined as a deficiency in the formation of the cardiac crux (**Fig. 2**) (Calabro and Limongelli, 2006). AVSDs account for about 3% of congenital cardiac malformations and two out of every 10,000 live births (Calabro and Limongelli, 2006; Fyler, 1992a; Ferencz et al., 1997).

AVSDs are most commonly divided into three subtypes: (1) partial, (2) complete, and (3) transitional (Jacobs et al., 2000a). A partial AVSD is defined as a common atrioventricular junction with two separate orifices, a left AVV with three leaflets (cleft) and a primum ASD (Jacobs et al., 2000a). A complete AVSD is defined as a primum ASD, inlet VSD, and a large common valve that spans the defects (Jacobs et al., 2000a). A transitional AVSD is somewhere in between partial and complete, where the AV valve has two orifices but there are both a primum ASD and an inlet VSD (Jacobs et al., 2000a). Despite these distinctions between the partial and complete AVSD, certain anatomic features are shared in all types of AVSDs. Common features include the following:

- Absence of the muscular atrioventricular septum resulting in a loss of the normal offsetting of atrioventricular valves and leading to the left and right AV valves inserting at the same level
- Anterior displacement of the aortic valve, which usually rests between the mitral and tricuspid valves
- Elongation of the LVOT creating a long narrow LVOT referred to as a "gooseneck" deformity

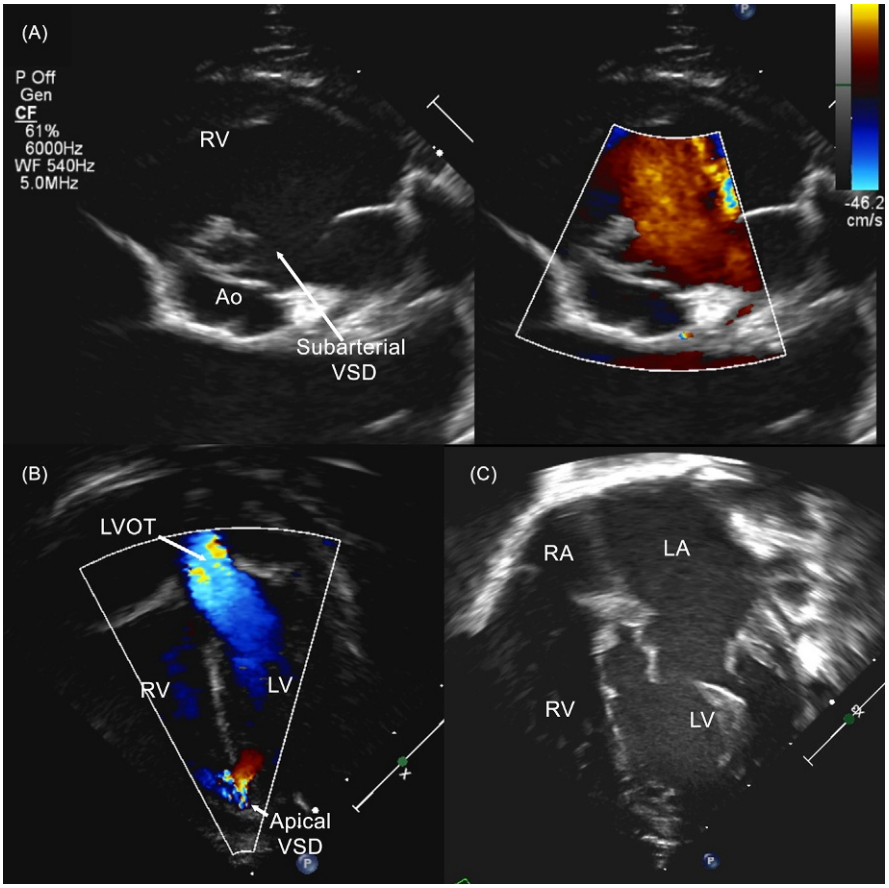

Fig. 5 Short-axis color compare image demonstrating a subarterial ventricular septal defect (VSD) (A). The red jet of flow represents left to right shunting across the VSD. Apical 4-chamber view with color flow mapping demonstrating an apical muscular VSD (B). Apical 4-chamber view in a patient with a large VSD demonstrating significant left-sided chamber dilation (C). *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *LVOT*, left ventricular outflow tract; *RA*, right atrium; *RV*, right ventricle.

Diagnosis by ECHO

Evaluation of AVSD anatomy can be broken down into a few echocardiographic goals: determination of the size of the ASD and VSD, assessing the anatomy of the atrioventricular valve and chordal attachments, and understanding the degree of ventricular balance (primarily in complete AVSDs). The apical four-chamber view visualizes the common AV valve (**Fig. 6**, **Movie 8**) and can further assess AV valve anatomy, including chordal attachments crossing the ventricular septal defect that might preclude biventricular repair. Three-dimensional imaging can aid in assessment of the AV valve prior to and after surgery (**Fig. 7**, **Movies 9** and **10**). The same TTE techniques previously described for evaluation of ASDs and VSDs are employed to visualize the primum ASD and inlet VSD. When diagnosing a complete AVSD, it is also vital to clarify the defect as "balanced" or "unbalanced." When the common AV valve is positioned equally over both ventricles it is referred to as "balanced" versus when the common AV valve is unequally positioned over the right or left ventricle it is called "unbalanced" (Cohen et al., 1996). This is best assessed by imaging the AV valve en face in a modified subcostal coronal view (**Fig. 8**). Balanced AVSDs account for approximately 90% of complete AVSDs. (Cohen et al., 1996; Corno et al., 1988). In general, an AVSD is considered unbalanced if more than two-third of the common valve is committed to one ventricle. Unbalanced AVSDs are often associated with ventricular hypoplasia and are unlikely to be candidates for biventricular repair (Cohen et al., 1996).

The severity of atrioventricular valve regurgitation (AVVR) and LVOT obstruction should be clarified as these have hemodynamic implications. Both partial and complete AVSDs can have varying amounts of AVVR, which can be visualized with color Doppler (**Fig. 9**, **Movie 11**). Clarifying the origin and direction of the regurgitant jet(s) may require multiple imaging planes including apical, subcostal, and parasternal windows. With the elongated LVOT "gooseneck" deformity, LVOT obstruction may occur. The apical 5-chamber view and parasternal long-axis views display the LVOT well and allow for appropriate angles of interrogation to use Doppler and locate the level(s) of obstruction.

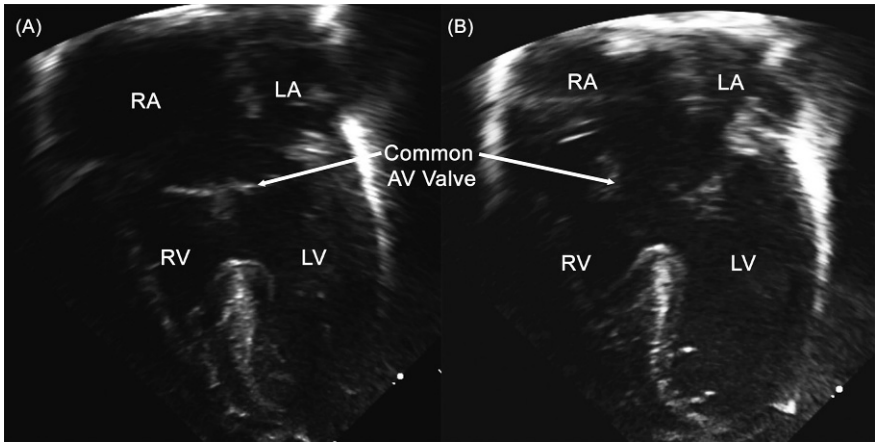

Fig. 6 Apical 4-chamber view demonstrating a complete atrioventricular septal defect with a common AV valve in systole (A) and diastole (B). *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

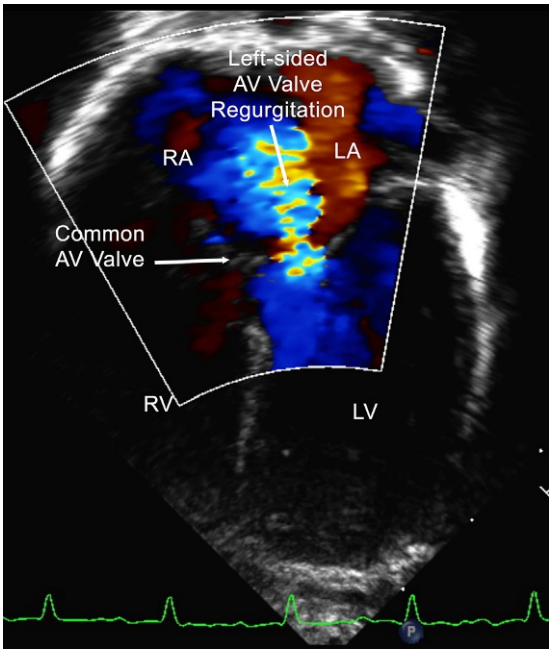

Fig. 9 Apical 4-chamber image demonstrating mild to moderate left-sided atrioventricular (AV) valve regurgitation (blue jet).

Right-Sided Heart Lesions

Tetralogy of Fallot

Background

Tetralogy of Fallot (TOF) was the first formally described cyanotic cardiac lesion (Karl and Stocker, 2016). TOF consists of four anatomic components of variable severity: (1) an anteriorly malaligned VSD, (2) overriding aorta, (3) obstruction of the right ventricular outflow tract (RVOT), and (4) right ventricular hypertrophy (Bailliard and Anderson, 2009). While described as a tetralogy, the displacement of the infundibular septum leads to all four components. TOF occurs in 3 of every 10,000 live births, is the most common cyanotic cardiac disease in patients greater than 1 month of age, and accounts for up to 10% of all congenital cardiac malformations (Bailliard and Anderson, 2009). Patients with TOF are at risk for hypercyanotic episodes (colloquially referred to as "tet spells") where dynamic subpulmonary obstruction and/or pulmonary hypertension lead to decreased pulmonary blood flow, increased right to left shunting across the VSD, and severe cyanosis. Pulmonary atresia VSD (also referred to as TOF with pulmonary atresia) is a more severe variant of TOF with a hypoplastic (or absent) RVOT, atretic pulmonary valve, and pulmonary blood flow supplied exclusively by either a patent ductus arteriosus (PDA) or aorticoopulmonary collateral vessels (Karl and Stocker, 2016). TOF with absent pulmonary valve represents another TOF variant with rudimentary, nonfunctional pulmonary valve leaflets leading to free pulmonary insufficiency (Karl and Stocker, 2016); this lesion is often associated with severe main and branch pulmonary artery dilation and airway obstruction.

Diagnosis by ECHO

TTE is used to both diagnose TOF and investigate for associated anomalies. The parasternal long axis view highlights the malalignment of the conal septum with the overriding aorta (**Fig. 10**, **Movie 12**). The degree of aortic override can be assessed in both the parasternal long- and short-axis views, with greater than 50% of the aorta overriding the right ventricle defined as a double outlet right ventricle. Clear views of the RVOT, dynamic nature of subpulmonary obstruction, size of the pulmonary valve annulus, MPA and branch PAs, and any additional sources of blood flow to lungs are necessary to understand the patient's risk for cyanosis and to appropriately plan the surgical repair (Bailliard and Anderson, 2009). The parasternal short axis is ideal for measuring the size of the pulmonary valve annulus, MPA, and branch PAs (**Fig. 11**). The degree of RVOTO can be assessed in all views using color flow mapping and continuous wave Doppler, though apical 4-chamber and subcostal windows often provide an excellent angle of interrogation (**Fig. 12**, **Movie 13**).

After diagnosis, TOF-associated anomalies must be clarified. Anomalous origins of the coronary arteries occur in one-sixth of patients, the most common being the left anterior descending artery from the right coronary artery. A right aortic arch is present in one-quarter of patients with TOF (Bailliard and Anderson, 2009). After repair, many patients have severe pulmonary valve

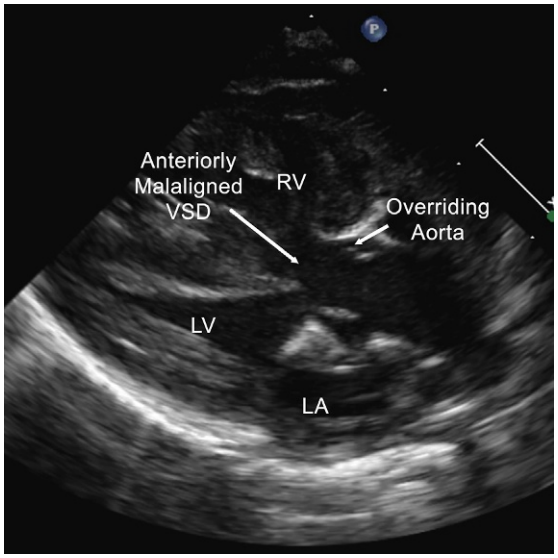

Fig. 10 Parasternal long-axis view in a patient with tetralogy of Fallot demonstrating the overriding aorta and anteriorly malaligned VSD. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

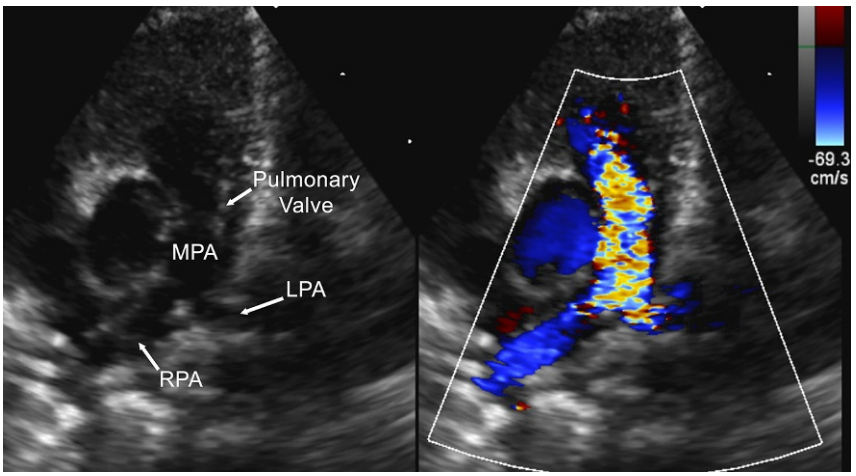

Fig. 11 Parasternal short-axis color compare image in a patient with tetralogy of Fallot demonstrating hypoplasia of the pulmonary valve annulus, main pulmonary artery (MPA), and the right and left pulmonary arteries (RPA and LPA).

insufficiency. These patients need to be followed closely for RV dilation and ventricular dysfunction, and many require pulmonary valve replacement, either in the operating room or using one of the newer percutaneous valves (Valente et al., 2014; Cheatham et al., 2015).

Pulmonary valve stenosis

Background

Isolated pulmonary valve stenosis occurs with an incidence of 1.5–6.5 per 10,000 live births accounting for 2%–13% of all CHD (Waller et al., 1995) (Hoffman and Christianson, 1978). In addition to isolated disease, multiple types of CHD are associated with pulmonary valve stenosis, including TOF, double outlet right ventricle, single ventricle anatomy, and AVSD (Waller et al., 1995). Here we will focus on isolated valvar pulmonic stenosis, though patients can have concurrent subvalvar and supravalvar obstruction and these regions must be assessed carefully. Pulmonary valve stenosis is most commonly associated with commissural fusion but

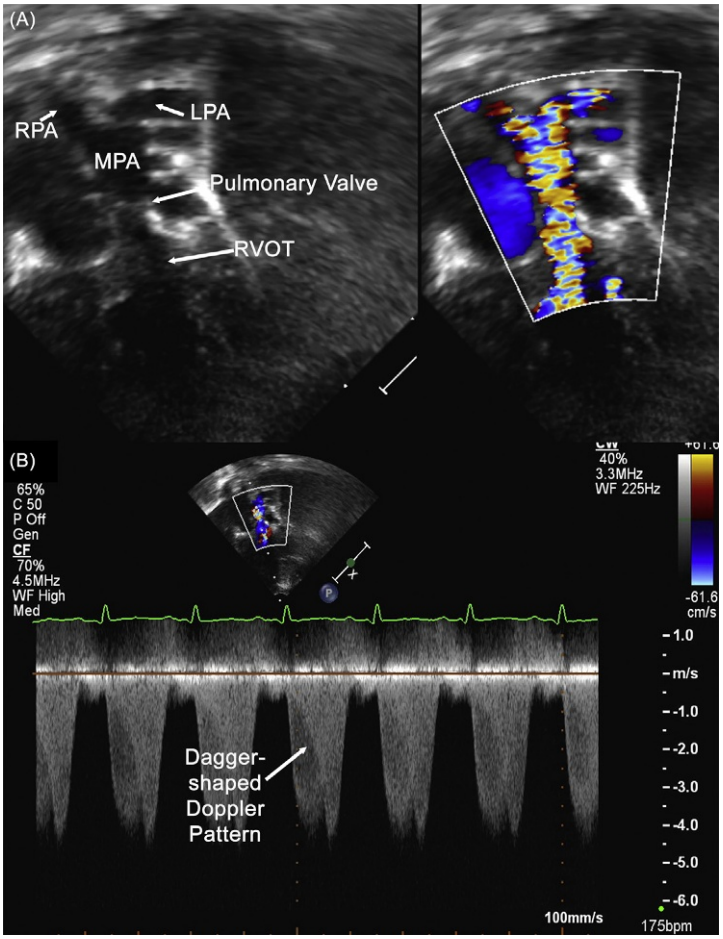

Fig. 12 Apical 4-chamber color compare image in a patient with tetralogy of Fallot demonstrating subvalvar, valvar, and supravalvar obstruction with aliasing throughout the right ventricular outflow tract (RVOT) (A). Continuous wave Doppler across the RVOT demonstrates dagger-shaped pattern, suggesting a component of subvalvar RVOT obstruction (B). *MPA*, main pulmonary artery; *RPA*, right pulmonary artery; *LPA*, left pulmonary artery.

can also be due to pulmonary valve dysplasia. In dysplastic pulmonary valve stenosis, all three cusps of the tricuspid pulmonary valve are thickened and rubbery (Waller et al., 1995; Koretzky et al., 1969); this is often associated with Noonan's syndrome.

Diagnosis by ECHO

Similar imaging planes employed in the diagnosis of TOF are utilized when imaging pulmonary stenosis. The pulmonary valve anatomy, size of the pulmonary valve annulus, size of the main and branch pulmonary arteries, and the subvalvar region must all be documented. Use of both pulse and continuous wave Doppler in the subvalvar, valvar, and supravalvar regions identifies the level(s) and severity of obstruction. Multiple views, including parasternal long and short axis, apical 4-chamber with anterior angulation, and subcostal (coronal and sagittal), should all be employed (**Fig. 13, Movie 14**). Right ventricular hypertrophy may develop in more significant pulmonary obstruction. Estimates of the right ventricular pressure can be made using CW Doppler of the tricuspid insufficiency and the interventricular septal geometry. The presence of an atrial level shunt with flow from right to left is an indicator that there is significantly elevated right ventricular end diastolic pressure.

Truncus arteriosus

Background

Persistent truncus arteriosus (TA) comprises <1% of congenital heart defects (Guenther et al., 2009). This anatomy is a consequence of improper conotruncal septation within the developing heart resulting in a common arterial trunk that gives rise to systemic, coronary, and pulmonary blood flow with an infundibular ventricular septal defect (Rajasinghe et al., 1997). The truncal valve is trileaflet in 70% of cases but can also be quadricuspid (21% of cases), bicuspid (9%), or even more rarely have more than four leaflets (Verhaert et al., 2010). Collett and Edwards (1949) described four types of TA lesions based on the origin of the pulmonary arteries (**Fig. 14**) (Collett and Edwards, 1949). A Type I truncus is defined by a common arterial trunk that gives rise to a short main pulmonary artery that divides into right and left branch pulmonary arteries (48%–68% cases). Type II truncus and Type III truncus are defined by the absence of a main pulmonary trunk. In Type II the left and right pulmonary arteries arise close to one another

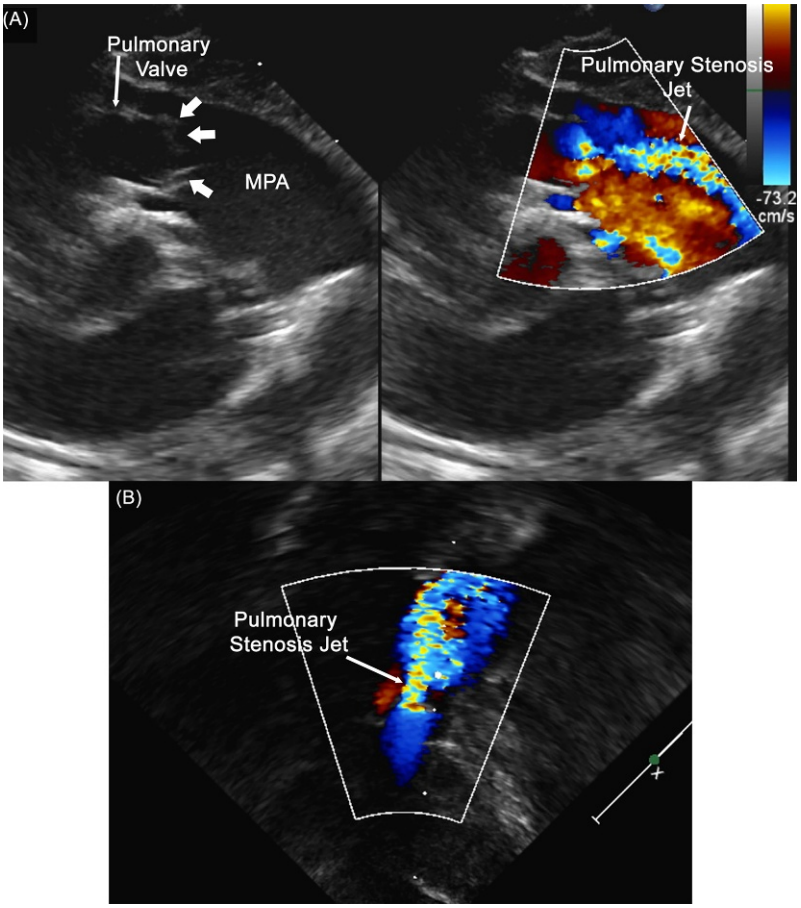

Fig. 13 Modified short-axis color compare image demonstrating the thickened and doming pulmonary valve leaflets (*arrows*) and a systolic pulmonary stenosis jet (*blue*) aimed into the dilated main pulmonary artery (MPA) (A). Apical 4-chamber image with color flow mapping demonstrating a systolic pulmonary stenosis jet (*blue*) (B).

versus in Type III these branch pulmonary arteries arise more distant from one another. Type II is more common than Type III, occurring in 29%–48% versus 6%–10% of cases. Finally, in Type IV truncus the lungs are supplied entirely by aorticopulmonary collaterals with no main pulmonary trunk or branch pulmonary arteries. This last form (Type IV) is now considered to be a variation of pulmonary atresia VSD and no longer considered a form of TA (Verhaert et al., 2010). In the Van Praagh classification of TA, Type A1 is the same as Type I, Type A2 is the same as Types II/III, Type A3 is TA with only one pulmonary artery off the truncal root (the other supplied by a PDA or collateral vessel), and Type A4 is TA with an interrupted arch. After ASDs, coronary artery abnormalities are the most common associated anomaly, occurring in nearly half of the cases (Butto et al., 1986; Mosca, 2010). Aortic arch abnormalities such as right aortic arch and interruption of the aortic arch are also common, occurring 36% and 11% of the time, respectively (Butto et al., 1986).

Diagnosis by ECHO

In order to diagnose TA there should be clear visualization of a dilated single great artery with a single semilunar valve overriding the interventricular septum. The parasternal long-axis view enables visualization of the common great artery overriding the interventricular septum (**Fig. 15**, **Movie 15**). The single great vessel usually overrides an outlet type VSD. The valve morphology should be documented in the short-axis view and the valve should be assessed for stenosis or insufficiency in all views (**Fig. 16**, **Movie 16**). Branch pulmonary artery anatomy should be assessed carefully, primarily in the short-axis and suprasternal notch views, though other views can be useful (**Fig. 17**). Parasternal short axis can also be used to determine coronary anatomy. Arch branching and sidedness should be carefully assessed in the suprasternal notch view.

Ebstein's anomaly

Background

Ebstein's anomaly is a malformation of the tricuspid valve and right ventricle which occurs in approximately 1 per 200,000 live births and accounts for <1% of all CHD (Attenhofer Jost et al., 2007; Dearani and Danielson, 2000). The hallmark of this lesion is the failure of delamination of the septal and posterior leaflets of the tricuspid valve leaving portions adherent to the underlying

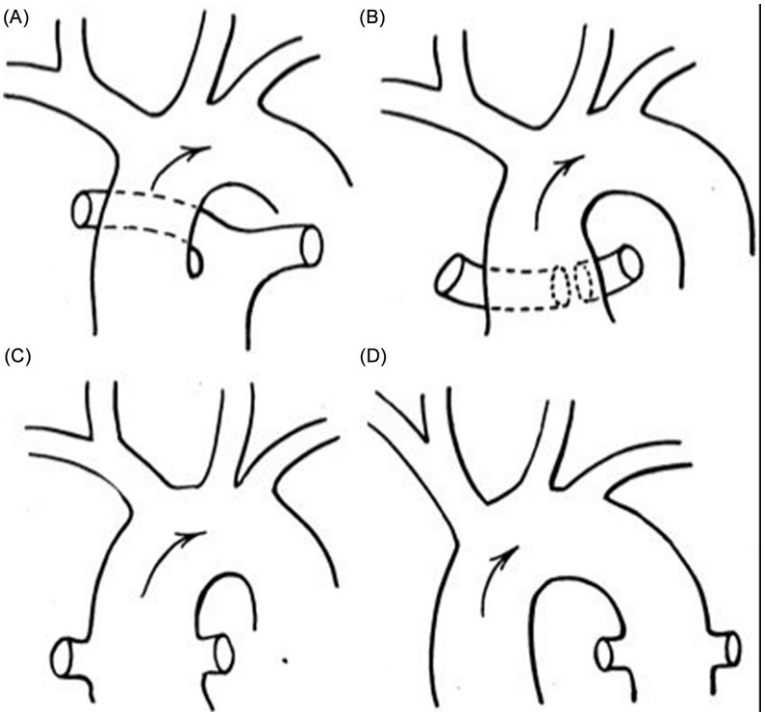

Fig. 14 Original figure published by Collett and Edwards (1949) demonstrating the four types of truncus arteriosus (TA). In Type I TA (A), the common arterial trunk gives rise to a main pulmonary artery that divides into the left and right pulmonary arteries (LPA and RPA). In Type II TA (B), the LPA and RPA arise separately from the common arterial trunk, but in close proximity. In Type III TA (C), the LPA and RPA arise separately from the common arterial trunk and are more distant from each other when compared with Type II. Type IV (D) is no longer considered a variant of TA and is now considered a variant of pulmonary atresia with ventricular septal defect (also called tetralogy of Fallot with pulmonary atresia). Type IV was originally described as TA with both branch pulmonary arteries supplied by aorticopulmonary collateral vessels.

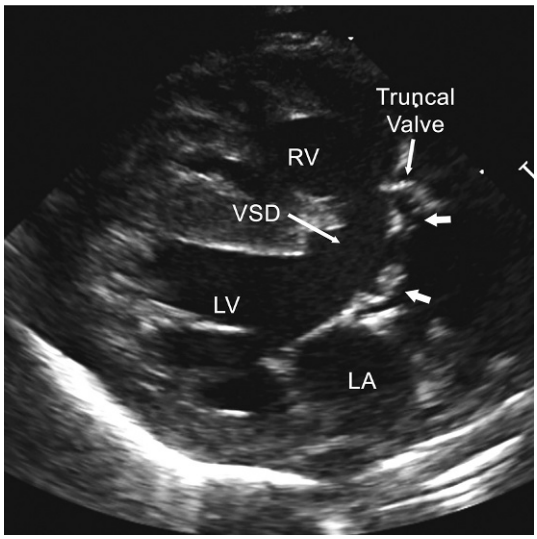

Fig. 15 Long-axis image in a patient with truncus arteriosus. There is a large truncal valve annulus that with thickened and doming truncal leaflets (*arrows*). *LA*, left atrium; *LV*, left ventricle; *RV*, right ventricle; *VSD*, ventricular septal defect.

myocardium. Additionally, there are anomalies of the tricuspid valve anterior leaflet including redundancy, fenestrations, and tethering. With portions of the septal and posterior leaflets adherent to the myocardium there is an overall downward displacement of the functional annulus, dilation of the "atrialized" portion of the right ventricle, and enlargement of the right atrioventricular junction (Attenhofer Jost et al., 2007; van Son et al., 2001; Cohen et al., 1994). Ebstein's anomaly usually results in tricuspid

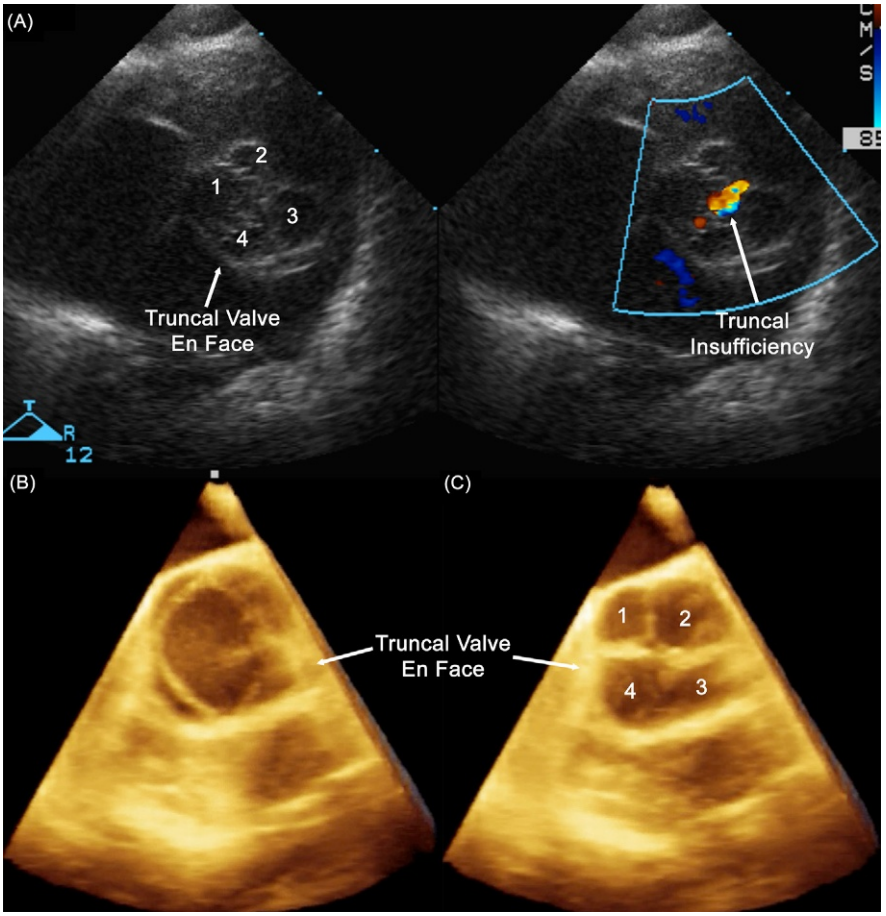

Fig. 16 Short-axis image with color compare demonstrating a quadricuspid truncal valve en face with mild truncal insufficiency, represented by color flow at the center of the valve (A). 3D image of a patient with quadricuspid truncal valve in early systole (B) and diastole (C).

regurgitation and can be associated with pulmonary valve atresia. The severity of disease can be variable, with some infants dying soon after birth (or in utero) and other patients who are essentially asymptomatic.

Diagnosis by ECHO

The echocardiographic examination of Ebstein's anomaly focuses heavily on the apical 4-chamber view which highlights the cardiac crux (**Fig. 18**, **Movies 17** and **18**). This view is used to calculate the displacement index, or distance between the septal insertions of the tricuspid and mitral valves divided by body surface area. Ebstein's anomaly is defined as a displacement index of greater than 8 mm/m^2. Careful attention should be given to the assessment of the complex tricuspid valve anatomy, including location and degree of valvar regurgitation. A thorough understanding of the tricuspid valve anatomy is necessary for appropriate surgical planning. 2D echo should also be used to thoughtfully examine the right ventricle, which is divided into three main regions. The first portion, the inlet portion, is directly involved with the malformation and is functionally integrated into the right atrium. The second and third portions, the trabecular and outlet portions, are not involved and comprise the functional ventricle (Attenhofer Jost et al., 2007). Careful attention should also be given to characterize the pulmonary valve, degree of right atrial enlargement, right ventricular enlargement, and right ventricular dysfunction. Finally, left ventricular anatomy should be assessed closely as left ventricular noncompaction can occur in association with Ebstein's anomaly.

Left-Sided Heart Lesions

Left ventricular outflow obstruction

Left ventricular outflow tract obstruction (LVOTO) includes subaortic obstruction, aortic valve stenosis, and supravalvar stenosis (Aboulhosn and Child, 2006). These lesions often occur concurrently with other types of left-sided obstruction. For example, Shone's complex is a syndrome with multiple left-sided lesions of inflow and outflow obstruction, originally described as a

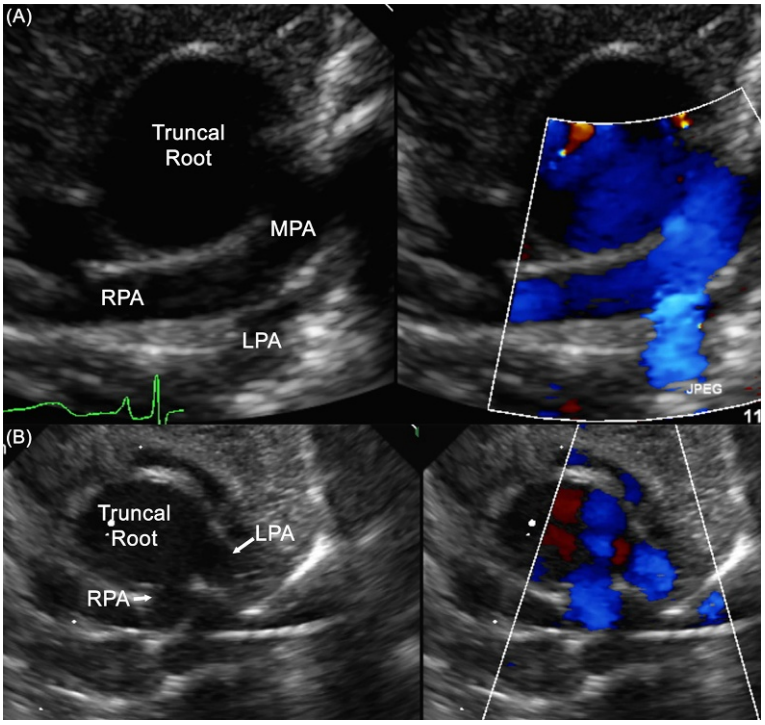

Fig. 17 Suprasternal notch color compare image of patient with truncus arteriosus type I (A) where the branch pulmonary arteries arise from a long main pulmonary artery (MPA) segment; patient with truncus arteriosus type II, where the branch pulmonary arteries arise directly from the common arterial trunk (B). *LPA*, left pulmonary artery; *RPA*, right pulmonary artery.

supraannular mitral ring, parachute mitral valve, subaortic stenosis, and coarctation of the aorta (Shone et al., 1963). Below we will discuss each LVOT obstructive lesion individually. Later, in the single ventricle section, we will discuss hypoplastic left heart syndrome.

Subaortic stenosis

Subaortic stenosis can be dynamic, usually due to hypertrophic cardiomyopathy, or fixed. As hypertrophic cardiomyopathy is covered in a different chapter, here we will focus on fixed subaortic stenosis. Subaortic stenosis is associated with the presence (with

or without spontaneous closure) of ventricular septal defects. It is due to a discrete membrane in 90% of cases but can also be caused by muscular narrowing or a combination of the two (Aboulhosn and Child, 2006; Brauner et al., 1997).

Aortic valve stenosis

Bicuspid aortic valve is the most common form of CHD and occurs in 1%–2% of the general population (Atkins and Sucosky, 2014). The most common type is due to fusion between the right and left coronary leaflets, occurring 71% of the time (Atkins and Sucosky, 2014). This malformed valve may have elements both of stenosis and insufficiency. Aortic valve stenosis can also occur in the setting of unicuspid, bicuspid, tricuspid, or quadricuspid leaflet morphology (Waller et al., 1994).

Supravalvar stenosis

Supravalvar aortic stenosis is usually a focal narrowing that begins at the level of the sinotubular junction, though it can be a more diffuse narrowing (Aboulhosn and Child, 2006). It is often associated with Williams syndrome.

Diagnosis by ECHO

The TTE examination of LVOTO utilizes multiple imaging planes to clarify the subvalvar, valvar, and supravalvar anatomy. The aortic annulus, aortic root, sinotubular junction, and ascending aorta are usually measured in the parasternal long-axis window (**Figs. 19–21**, **Movies 19–21**). The short axis is used to obtain an en face view of the aortic valve, allowing for assessment of aortic

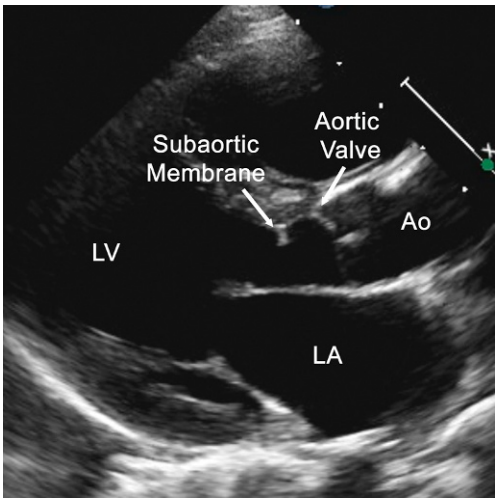

Fig. 19 Parasternal long-axis image in a patient with a subaortic membrane just below the aortic valve annulus. *Ao*, ascending aorta; *LA*, left atrium; *LV*, left ventricle.

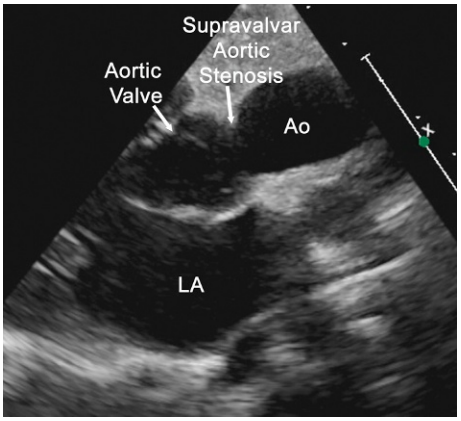

Fig. 21 High parasternal long image in a patient with valvar and supravalar aortic stenosis. The aortic valve leaflets are thickened and doming. There is significant hypoplasia of the ascending aorta at the sinotubular ridge.

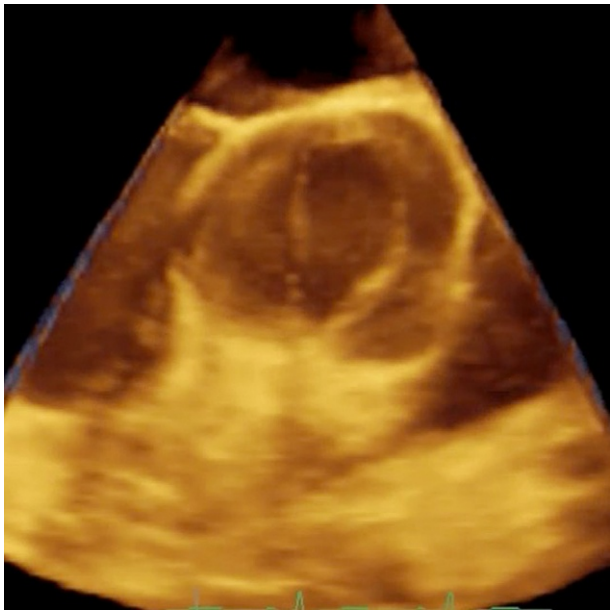

Fig. 22 Three-dimensional transesophageal image of the aortic valve en face demonstrating a bicuspid aortic valve.

valve morphology and estimation of aortic valve regurgitation if present (**Fig. 22**, **Movie 22**). Degree of LVOT obstruction can be assessed using Doppler, most commonly in the apical 4-chamber and suprasternal notch views. Once there is suspicion of LVOTO, all left-sided cardiac structures should be examined carefully. Additionally, hemodynamic effects of obstruction should be evaluated, including left ventricular size and function and presence of endocardial fibroelastosis (Aboulhosn and Child, 2006).

Coarctation of the aorta

Background

Coarctation (CoA) is a narrowing of the proximal thoracic aorta. It most commonly occurs as focal stenosis in the region of the aortic isthmus between the origins of the left subclavian artery and the insertion of the ductus arteriosus (Ho and Anderson, 1979). In addition to the more discrete stenosis, CoA can also be long-segment in nature or result from either transverse arch or abdominal aortic hypoplasia (Torok et al., 2015; Ho and Anderson, 1979; Price et al., 2014; Mullen, 2003). CoA accounts for 5%–7% of all CHD, with an incidence of approximately 3 cases per 10,000 births (Torok et al., 2015; Padua et al., 2012). CoA is also highly associated with a bicuspid aortic valve, with as many as 50%–75% of patients with CoA also having bicuspid aortic valves (Siu and Silversides, 2010; Roos-Hesselink et al., 2003).

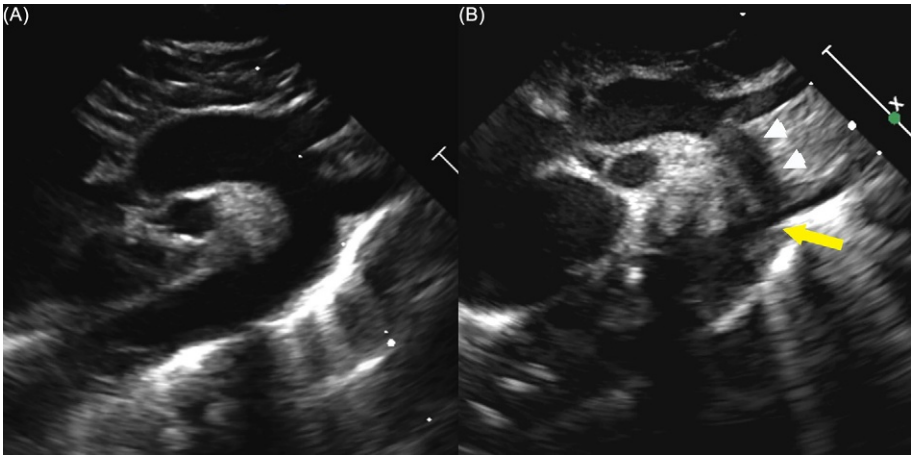

Fig. 23 Suprasternal notch view demonstrating a widely patent aortic arch (A) and long-segment coarctation of the aorta (B) with a posterior shelf (*yellow arrow*) and distal transverse arch hypoplasia (*white arrowheads*).

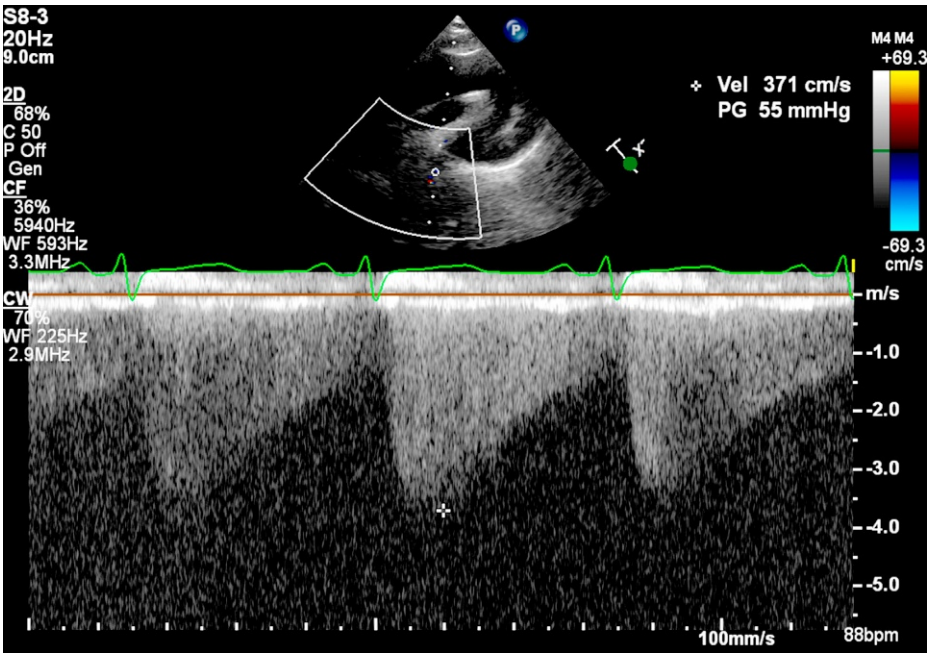

Fig. 24 Continuous wave Doppler in suprasternal notch through descending aorta in a patient with coarctation of the aorta demonstrating a peak gradient of 55 mmHg and a continuous antegrade flow pattern suggestive of obstruction.

Diagnosis by ECHO

The suprasternal notch view allows the best imaging plane of the ascending, transverse, and proximal descending aorta (Fig. 23). 2D imaging allows for careful measurements of each region and identification of features associated with CoA such as a posterior shelf and increased distance between the left common carotid and left subclavian arteries. Color Doppler can be used to demonstrate flow acceleration in the region of hypoplasia, and CW Doppler of the descending aorta can demonstrate continuous low velocity antegrade flow distal to the coarctation (Fig. 24). Subcostal views of the abdominal aorta with CW Doppler may show a loss of pulsatile flow in severe CoA (Fig. 25).

The presence of a PDA can normalize the descending aortic Doppler velocity and aortic arch diameters (Soslow et al., 2013). In these patients, observation until the PDA has closed may be the only option to determine whether or not a CoA is present.

d-Transposition of the great arteries

Background

d-Transposition of the great arteries (dTGA) is a cyanotic congenital heart defect with discordant ventriculoarterial alignment, or the aorta arising from the right ventricle and the pulmonary artery arising from the left ventricle. This anatomy creates two parallel

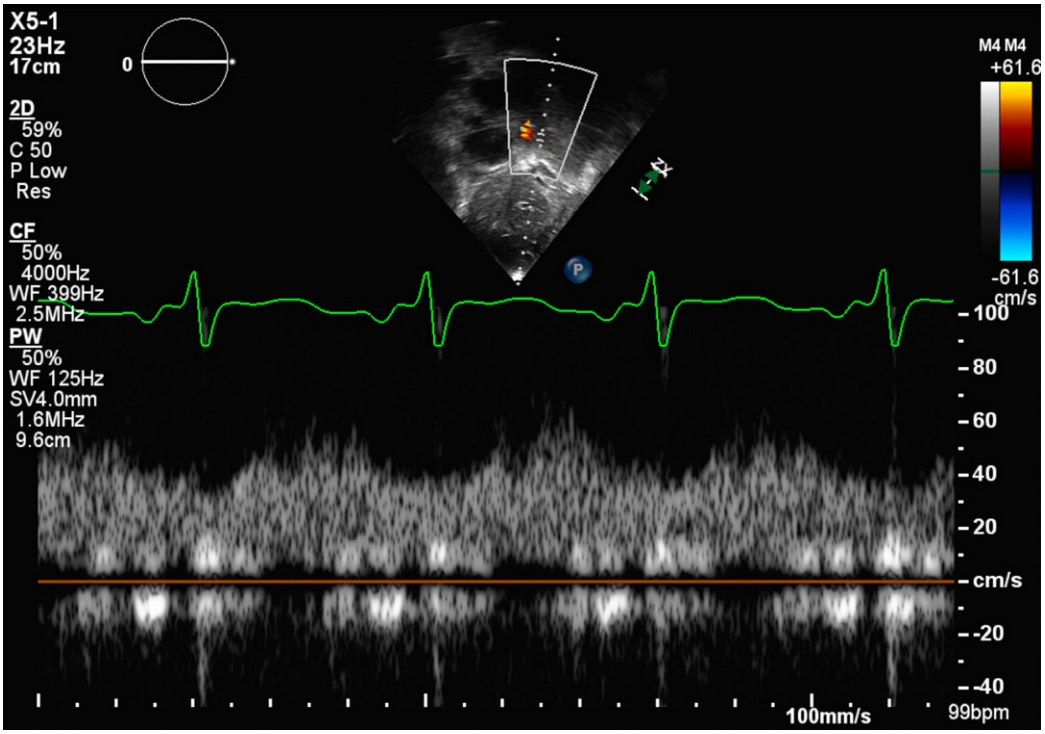

Fig. 25 Pulse wave Doppler in the subcostal sagittal view in a patient with coarctation of the aorta demonstrating poor pulsatility in the descending aorta at the diaphragm suggesting proximal obstruction.

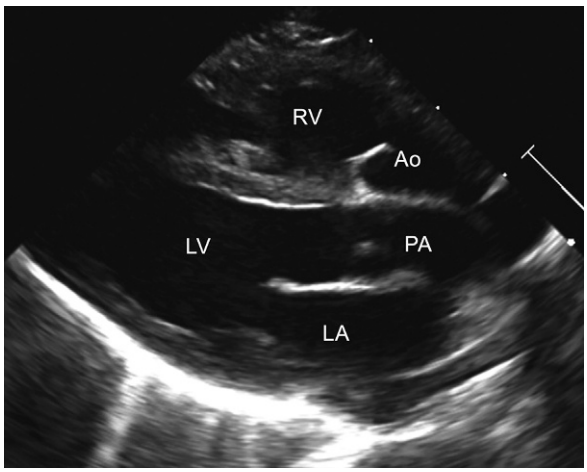

Fig. 26 Parasternal long-axis image in a patient with transposition of the great arteries. The pulmonary artery (PA) arises from the left ventricle (LV) and takes a characteristic posterior course. The aorta (Ao) arises from the right ventricle (RV). The Ao and PA take a parallel course. *LA*, left atrium.

circulations, resulting in significant cyanosis if there is no mechanism for mixing (Cohen et al., 2016). The incidence of dTGA is approximately 3 per 10,000 live births (Hoffman and Kaplan, 2002), and it is the second most common cyanotic heart disease, with TOF being the most common (Cohen et al., 2016; Hoffman and Kaplan, 2002). A myriad of structural abnormalities can occur with dTGA, the most common of which is a VSD, which is present in approximately 40% of patients (Cohen et al., 2016).

Diagnosis by ECHO

The diagnosis of dTGA can be made from either the parasternal long axis or subcostal windows. In the parasternal long axis, the great artery arising from the left ventricle takes a more posterior course than that found in a normal heart (**Fig. 26**, **Movie 23**). In addition, the great arteries spiral around each other as they originate from the two ventricles in a normal heart but take a parallel course in a heart with dTGA (**Fig. 26**) (Cohen et al., 2016). A sweep in the apical 4-chamber or subcostal coronal view demonstrates

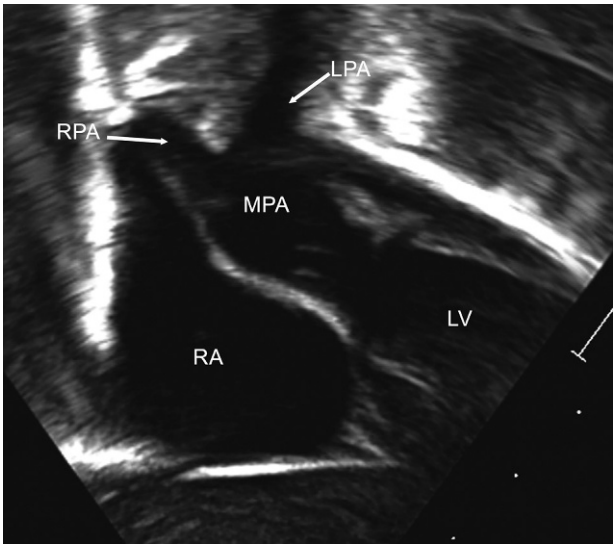

Fig. 27 Subcostal coronal view with anterior angulation demonstrating the main pulmonary artery (MPA) and branch pulmonary arteries arising from the left ventricle (LV). *LPA*, left pulmonary artery; *RA*, right atrium; *RPA*, right pulmonary artery.

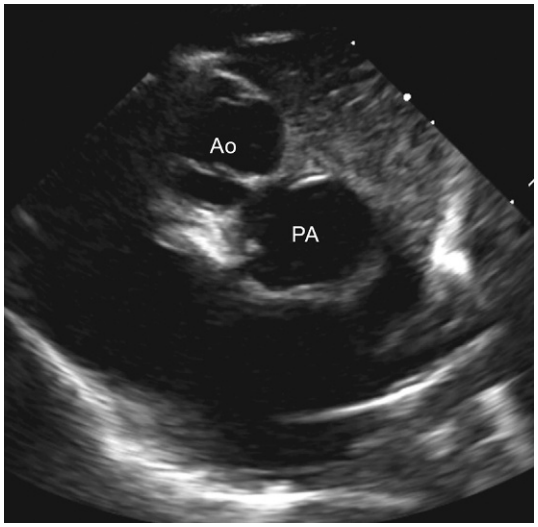

Fig. 28 Parasternal short-axis image of a patient with d-transposition of the great arteries. The aorta (Ao) is anterior and rightward of the pulmonary artery (PA).

branching of the vessel arising from the left ventricle, which establishes this vessel as the pulmonary artery (**Fig. 27**, **Movie 24**). Continuing the sweep anteriorly reveals the aorta originating from the right ventricle (Cohen et al., 2016). The parasternal short-axis view is utilized to determine the positions of the aortic and pulmonary valves relative to each other (**Fig. 28**). The morphology and function of the pulmonary valve requires careful assessment, as this valve will become the "neo"-aortic valve if an arterial switch operation is performed.

Shortly after a diagnosis of dTGA is suspected, it is essential to investigate the atrial septum. Given the parallel circulations, adequate mixing of oxygenated and deoxygenated blood is necessary. This mixing almost always requires a large enough atrial communication, though some mixing occurs across both a VSD and PDA, if present. The subcostal windows allow 2D visualization and measurement of the ASD. Color Doppler and continuous wave Doppler are used to help determine the direction and adequacy of flow across the ASD, though the oxygen saturation is the primary determinant of whether emergent intervention is necessary. If the atrial level mixing is inadequate, then a balloon atrial septostomy with echo guidance will need to be performed (**Movie 25**).

The aorta in dTGA is usually anterior to the pulmonary artery and as a result the coronary arteries are never in the normal position in this lesion (Cohen et al., 2016). This anterior position of the aorta can make visualization of the coronaries difficult. Multiple alternative views are often necessary to clarify the coronary anatomy. Although the most common coronary distribution is the right and left main coronaries arising from the right and left facing cusps, there are many coronary artery variations, including a

circumflex off of the right, single coronary, and one or both coronary arteries with an intramural course. It is important to document variations in this anatomy as these variations, particularly intramural coronary arteries and coronaries arising from a single ostium, can be associated with increased mortality in patients who undergo the corrective arterial switch operation (Pasquali et al., 2002).

Single ventricle

Single ventricle anatomy is potentially the most heterogeneous anatomic group of CHD. This wide anatomic spectrum may involve many of the previously described lesions as associated components. The three prototypical single ventricle lesions, listed from most common to least common, are hypoplastic left heart syndrome, tricuspid atresia, and double inlet left ventricle (**Fig. 29**, **Movies 26–28**). These lesions are rare within the CHD population, with the most common (HLHS) occurring in approximately 2 per 10,000 live births (Khairy et al., 2007; Hoffman and Kaplan, 2002). The most common course for single ventricle physiology is a three-staged palliative surgical route, described in more detail in other articles. The degree of pulmonary and systemic blood flow dictates the design of the first surgical palliation. Usually one or a combination of the following is performed:

- A systemic to pulmonary shunt to augment pulmonary blood flow
- A pulmonary artery band to restrict pulmonary blood flow
- Reconstruction of the left ventricular outflow tract and aortic arch to address concerns of restricted systemic blood flow

The second stage creates a cavopulmonary anastomosis, named the Glenn shunt, connecting the superior vena cava to the right pulmonary artery allowing passive systemic drainage into the pulmonary arteries (Feinstein et al., 2012). Lastly the Fontan procedure completes the total cavopulmonary connection by redirecting the IVC flow into pulmonary arteries and places the systemic and pulmonary circulations in series (Feinstein et al., 2012). Given the significant heterogeneity and the associations with multiple anatomic abnormalities, all of the previously described echo techniques should be employed when evaluating these lesions.

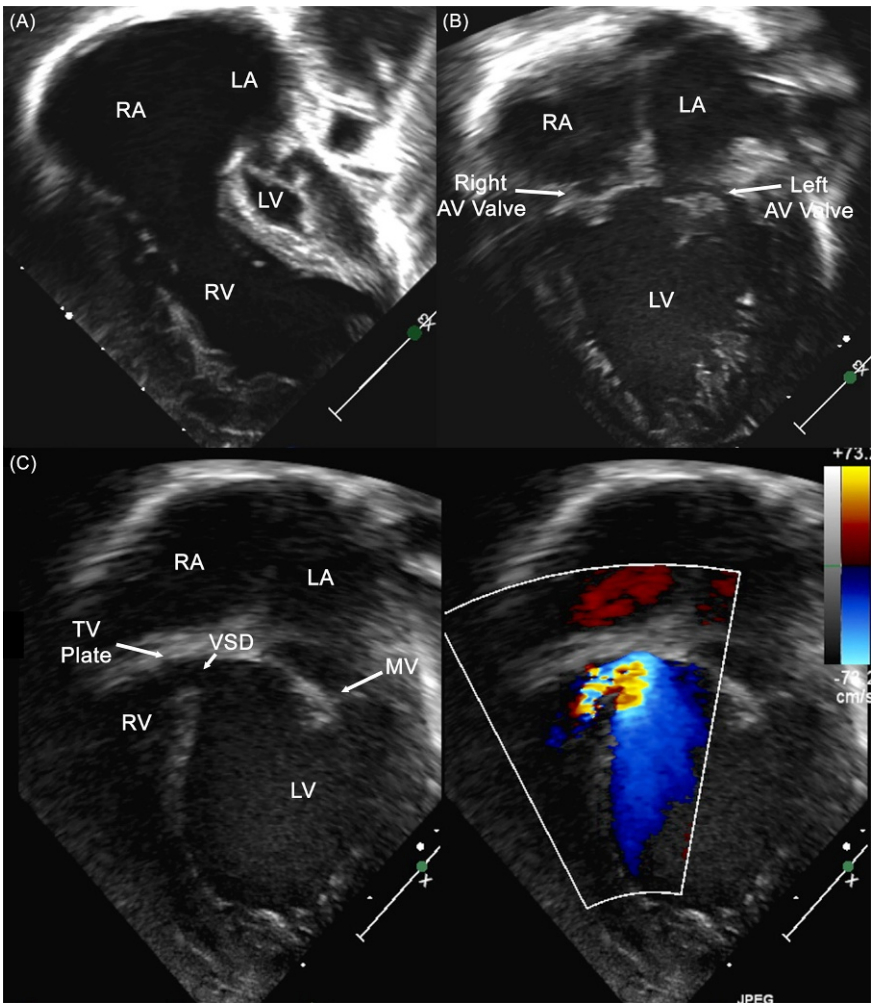

Fig. 29 Apical 4-chamber view of patient with hypoplastic left heart syndrome (A), tricuspid valve atresia (B), and double inlet left ventricle (C). *AV*, atrioventricular; *LA*, left atrium; *LV*, left ventricle; *MV*, mitral valve; *RA*, right atrium; *RV*, right ventricle; *TV*, tricuspid valve; *VSD*, ventricular septal defect.

Fetal Echocardiography

Fetal echocardiography allows new insights into the evolution of CHD in utero and also provides perinatal planning to optimize site of delivery and availability of appropriate resources for children with heart disease diagnosed prenatally (Donofrio et al., 2014). In the current era, multicenter collaborative studies are expanding our understanding of individual lesions, examining the natural history of lesions, and the impact of prenatal and postnatal management strategies (Donofrio et al., 2016; Freud et al., 2015). In addition, fetal echocardiography can be used to diagnose and direct therapy for arrhythmias, screen for development of congenital heart block, and monitor patients during prenatal surgery (Rychik et al., 2015; Strasburger and Wakai, 2010). While in its infancy and still not without controversy, the number of centers performing prenatal cardiac interventions is increasing (Freud and Tworetzky, 2016; Moon-Grady et al., 2015; Araujo Junior et al., 2016).

Although prenatal diagnosis prevents postnatal decompensation, it is unclear whether it truly improves postnatal mortality (Landis et al., 2013); some studies suggest that prenatal diagnosis improves preoperative and/or postoperative mortality in certain types of CHD (Li et al., 2016; Morris et al., 2014; Franklin et al., 2002). Prenatal detection may also decrease the risk of developing postnatal brain injury (Peyvandi et al., 2016). In addition, fetal diagnosis allows families to prepare mentally and financially for complex CHD and may decrease anxiety (Pinto et al., 2016). Although some types of cardiovascular disease cannot be definitively diagnosed prenatally due to fetal circulation, imaging windows, and issues with resolution, most significant lesions can usually be diagnosed prenatally (**Figs. 30** and **31**, **Movies 29** and **30**). It should be noted, however, that an obstetrician must identify a heart abnormality (or have suspicion for a heart abnormality) in order to initiate referral for fetal echocardiography.

Alternative Imaging Modalities

Cardiac Catheterization

While no longer the technique of choice for diagnosis of all forms of CHD, cardiac catheterization remains an integral diagnostic and interventional method. Catheterization has the advantage of supplying both imaging (angiography) and hemodynamic (pressures and saturations) data with the potential for concurrent intervention. Angiography allows for excellent delineation of pulmonary blood flow, including branch pulmonary arteries, surgical shunts, and aorticopulmonary collateral vessels, all of which can be difficult to image using echocardiography (**Fig. 32**). Angiography also allows for assessment of proximal and distal coronary arteries and can be used to assess complex anatomy not otherwise delineated by noninvasive methods (**Fig. 33**). Catheterization remains the gold standard for hemodynamic assessment, including pulmonary vascular resistance, pulmonary to systemic flow ratio (Qp:Qs), cardiac output, and valvar gradients. Early catheterization may be of benefit in critically ill patients with unclear diagnoses, especially those supported by extracorporeal membrane oxygenation (Burke et al., 2017). Limitations of catheterization are that it is invasive, routinely performed under general anesthesia, requires contrast and radiation exposure, and has potential for rare but significant morbidities, including vessel damage, stroke, cardiac perforation, arrhythmia, and death.

Cardiac catheterization has become the interventional method of choice in multiple disease processes as it is less invasive and has a faster recovery than cardiac surgery. If feasible and safe based on the patient size and anatomy, ASDs and PDAs are

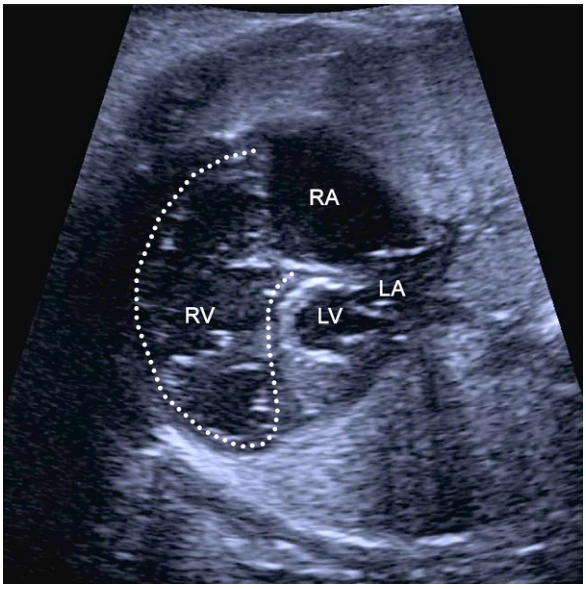

Fig. 30 Fetal echocardiogram of fetus with hypoplastic left heart syndrome with small left atrium (LA) and left ventricle (LV). *RA*, right atrium; *RV*, right ventricle.

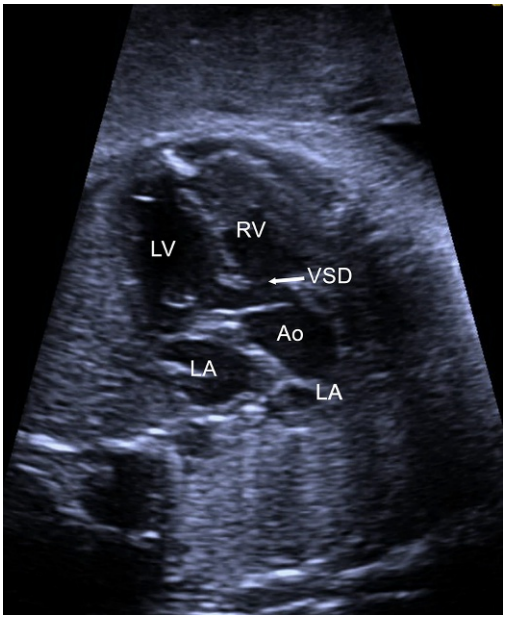

Fig. 31 Fetal echocardiogram in fetus with tetralogy of Fallot. There is a large, overriding aorta (Ao) and large membranous to outlet ventricular septal defect (VSD). *LA*, left atrium; *LV*, left ventricle; *RV*, right ventricle.

preferentially closed percutaneously. Pulmonary and aortic balloon valvuloplasty are preferentially performed in the catheterization laboratory. Interventions on extracardiac vessels, including pulmonary artery rehabilitation and coarctation angioplasty or stenting, are now routinely performed percutaneously. Though VSDs can be closed percutaneously, the frequency of this procedure varies by center and careful patient selection is necessary due to the risk of heart block (Bai et al., 2015). Procedures such as PDA stenting in patients with more complex anatomy are becoming more routine as it averts the need for an operative aorta to pulmonary artery shunt (Santoro et al., 2015). Finally, percutaneous pulmonary valve replacements have good long-term outcomes and have become a relatively common intervention in patients with CHD (Cheatham et al., 2015).

Cardiac Magnetic Resonance Imaging

CMR has many advantages, including excellent delineation of endocardial borders, absence of radiation, and no dependence on echocardiographic "windows" or limitations in image quality due to patient body habitus. CMR is the gold standard for assessment of ventricular volume, mass, and systolic function (**Fig. 34**) (Karamitsos et al., 2009); it is integral to the care of patients with repaired TOF, who require frequent scans to evaluate right ventricular size and function, which cannot be as accurately quantified using echocardiography (**Fig. 35**) (Valente et al., 2014; Geva, 2011). CMR can also assess ventricular adequacy in patients with small

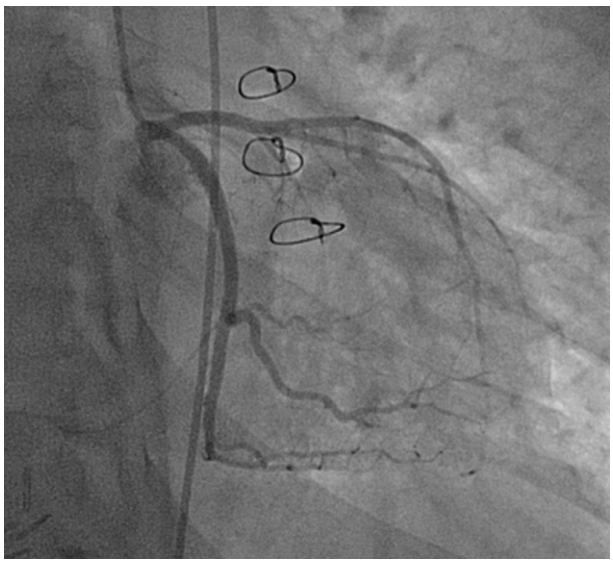

Fig. 33 Coronary artery angiography in the left main coronary artery in a patient with a previous heart transplantation.

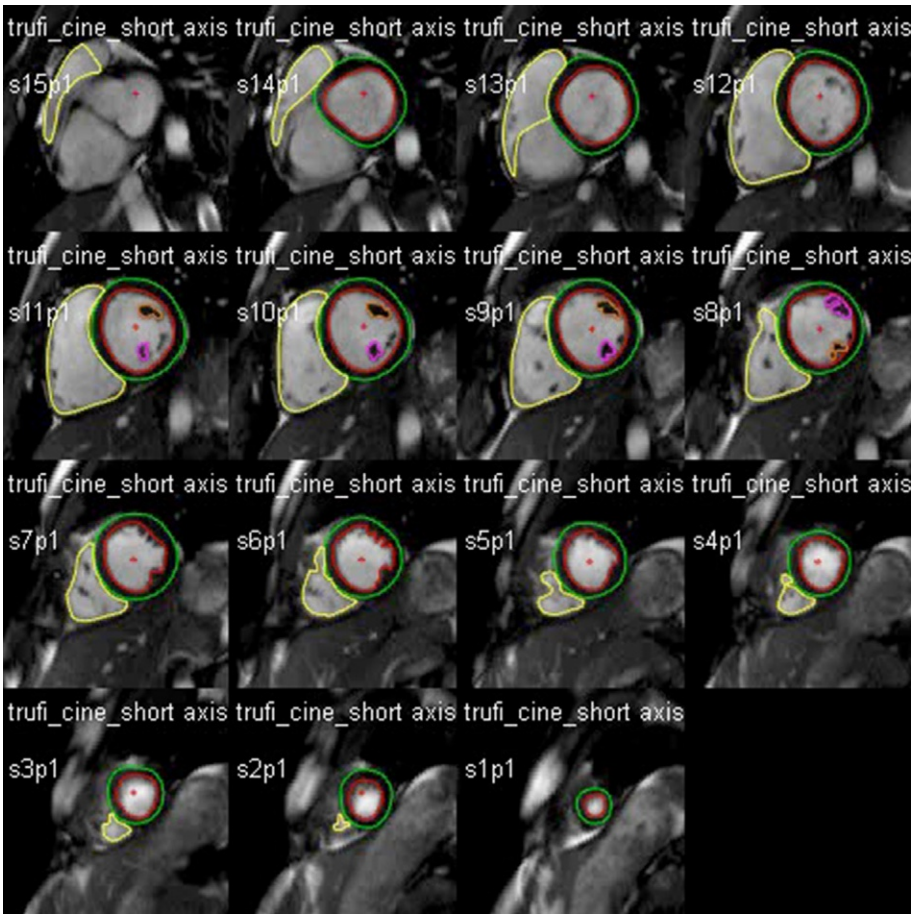

Fig. 34 Example of cardiac MRI contours at end diastole performed on a healthy control patient.

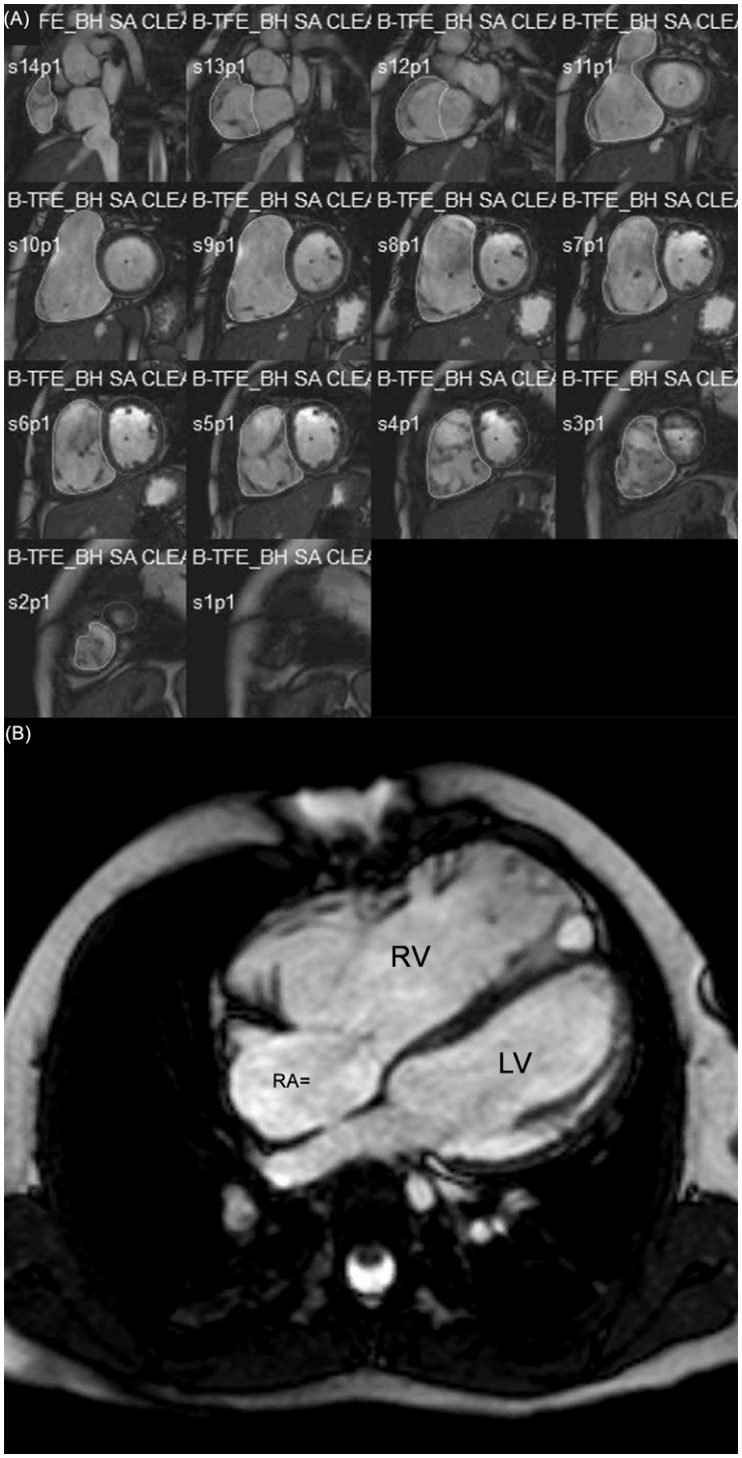

Fig. 35 Example of cardiac MRI contours at end diastole performed on a patient with tetralogy of Fallot and severe RV dilation (A). Four-chamber image in same patient demonstrating severe RV dilation (B). *LA*, left atrium; *RA*, right atrium; *RV*, right ventricle.

left or right ventricles. It provides excellent visualization of extracardiac blood vessel abnormalities, especially with the addition of gadolinium contrast agents. It is particularly useful for patients with pulmonary or systemic venous abnormalities, branch pulmonary artery stenosis, coarctation of the aorta (**Fig. 36**, **Movie 31**), or vascular rings (**Fig. 37**, **Movie 32**). Phase contrast imaging allows for quantification of blood flow, including valvar regurgitation, Qp:Qs, and branch pulmonary artery differential flow.

The shunt curves from the RSCA and connects into the right pulmonary artery (RPA). Maximal intensity projection of the CTA in the axial plane demonstrating proximal right and left pulmonary artery (RPA and LPA) hypoplasia, as represented by *yellow arrowheads*. The main pulmonary artery (MPA) is also hypoplastic.

CMR is unique in that it permits tissue characterization, including assessment of myocardial edema, fibrosis, and perfusion. Tissue characterization with a combination of T2-weighted imaging and delayed enhancement allows for assessment of edema or fibrosis and is particularly useful for diagnosis of myocarditis or any number of causes of ischemia, including coronary artery disease or hypertrophic cardiomyopathy (Friedrich et al., 2009; Weng et al., 2016; Kim et al., 2000). More advanced parametric mapping quantifies the diffuse myocardial fibrosis found in multiple pediatric disease processes (Soslow et al., 2016; Toro-Salazar et al., 2013; Chen et al., 2016; Riesenkampff et al., 2016). In addition, 3D magnetic resonance angiography can be used to create 3D printed models that allow for advanced surgical planning and training in cases of complex CHD (**Fig. 38**) (Vukicevic et al., 2017; Anwar et al., 2016). However, CMR does have limitations. Chief among these is the need for patients to remain still during the examination and hold their breath frequently; younger children may require anesthesia or sedation. Other limitations include significant artifact related to some metallic implants, inability to image in the setting of most pacemakers, lack of portability, long duration of examinations, the need for gadolinium contrast in certain situations, inferior assessment of valvar stenosis compared with echocardiography, and cost.

Cardiac CT

Cardiac CT has many advantages when compared to echocardiography, cardiac catheterization, and CMR. These include rapid acquisitions that rarely require sedation or anesthesia, high resolution, accurate assessment of ventricular function and volumes comparable to that of CMR, and the ability to safely image patients with metallic implants, including pacemakers, with less artifact. In patients with TOF with a contraindication to CMR, CT is an excellent option to evaluate ventricular volumes and function (Valente et al., 2014). CT angiograms (CTA) are especially useful for evaluating congenital coronary artery anomalies and for assessment of extracardiac abnormalities, including coarctation of the aorta, vascular rings, and branch pulmonary artery stenosis

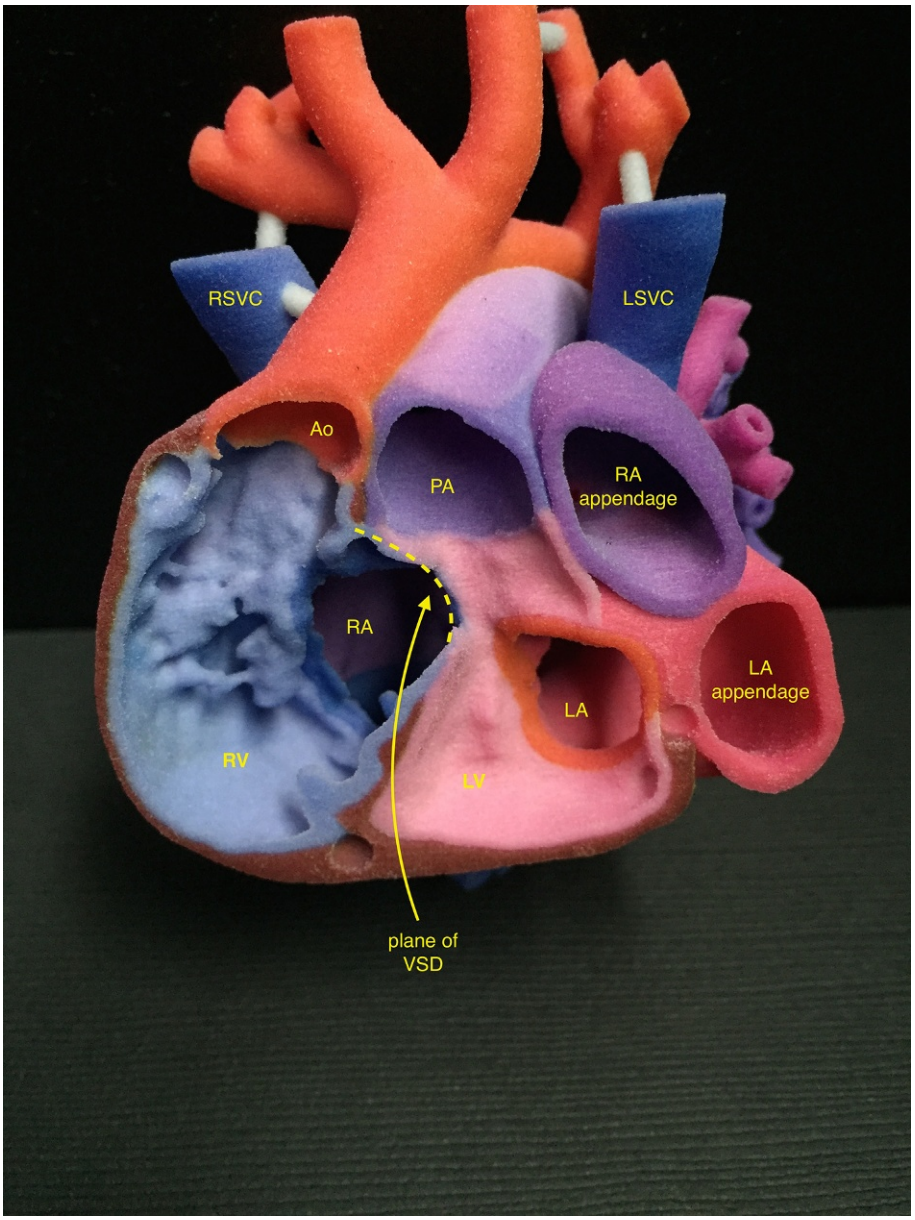

Fig. 40 Three-dimensional print of a neonate with dextrocardia, d-transposition of the great arteries, a ventricular septal defect (VSD), and bilateral superior vena cavae. *Ao*, aorta; *LA*, left atrium; *LSVC*, left superior vena cava; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RSVC*, right superior vena cava; *RV*, right ventricle. Figure courtesy of Shafkat Anwar, MD, Assistant Professor, Pediatrics, Division of Pediatric Cardiology, Washington University School of Medicine.

(**Fig. 39**, **Movie 33**). The high resolution of CTA makes it an excellent modality for obtaining 3D datasets for 3D printing, which can aid in surgical planning and even surgical training (**Fig. 40**) (Yoo et al., 2017; Anwar et al., 2016; Vukicevic et al., 2017). While new scanners are able to provide excellent data with reduced radiation exposure, radiation remains a concern in children where the lifetime effect is greater than adults (Johnson et al., 2014; Meinel et al., 2015; Gao et al., 2016). Other disadvantages include contrast exposure, inability to assess flows with standard CT, and lower temporal resolution than CMR or echocardiography.

Conclusions

The anatomy of CHD can vary widely and many patients have multiple defects. Accurate diagnosis requires careful assessment using echocardiography. When necessary, echocardiographic imaging can be supplemented with adjuncts including cardiac catheterization, CMR, and CT.

Acknowledgments

The authors would like to acknowledge Shafkat Anwar for sharing images of his 3-D prints and Maria Frank for her help with graphic design. We would also like to thank Ann Kavanaugh-McHugh, David Parra, Jason Christensen, and Thomas Doyle for reviewing and commenting on the manuscript.

Introduction

Myocardial infarction (MI) is a major global cause of mortality and is associated with high morbidity. Rates of MI are an indicator of the burden of coronary artery disease (CAD) in various populations and can be the first or repeated manifestation of CAD.

The first definition of MI, proposed by the World Health Organization (WHO) in 1979, was based on symptoms, ECG abnormalities, and cardiac enzymes (1979). Due to several developments such as improvement of biomarker sensitivity and cardiac imaging techniques and improved ECG criteria and the necessity to differentiate between spontaneous and procedure-related MI, a new definition of MI was proposed in 2000 by a joint European and American expert committee (Alpert et al., 2000). An update in 2007 introduced a clinical classification into five types of MI depending on the condition leading to an MI and was endorsed by the European Society of Cardiology (ESC), the American College of Cardiology Foundation (ACCF), the American Heart Association (AHA), and the World Heart Federation (WHF) (Thygesen et al., 2007).

The current 2012 version of the universal definition of MI has been further refined with adapted ECG criteria, a more prominent role of cardiac imaging, slight changes in the classification of the types of MI, and further recommendations on the use of troponin assays (Thygesen et al., 2012).

The World Health Organization (WHO) also recommends the universal MI definition when there are no resource constraints. When measurement of biomarkers and even ECG recordings are not possible due to limited economic resources, the WHO suggests more flexible definitions and standards (Mendis et al., 2011).

An unambiguous and consistent definition of the term MI is necessary, since MI is a frequently used outcome parameter in clinical trials and observational studies and has many legal and psychological implications. Knowledge of the universal definition of MI and current guidelines for treatment of acute coronary syndrome allows clinicians to correctly diagnose or rule out MI.

Definition and Types of MI

For diagnosis of acute MI, objective evidence of myocardial necrosis must be present in the context of acute myocardial ischemia (Thygesen et al., 2012). Cardiac troponin is the preferred biomarker for the diagnosis of MI due to absolute tissue specificity. A rise and/or fall of cTn with at least one value above the 99th percentile upper reference limit (URL) is mandatory to support the presence of an acute event as compared with a chronic process that is indicated by a stable elevation. An MI can only be diagnosed in the presence of myocardial ischemia. Therefore, the criteria for diagnosis of MI are met, when additionally at least one of the following is present:

- Symptoms of ischemia
- New or presumed new significant ST segment–T wave (ST-T) changes or new left bundle branch block (LBBB)
- Development of pathological Q waves in the ECG
- Imaging evidence of new loss of viable myocardium or new regional wall-motion abnormality
- Evidence of intracoronary thrombus by angiography or autopsy

Types of Acute MI

Based on pathophysiological, clinical, and prognostic differences, five types of MI are differentiated (Thygesen et al., 2012, by permission of Elsevier):

Type 1. Spontaneous myocardial infarction—Spontaneous myocardial infarction related to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries leading to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis. The patient may have underlying severe CAD but on occasion nonobstructive or no CAD.

Type 2. Myocardial infarction secondary to an ischemic imbalance—In instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand, for example, coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/bradyarrhythmias, anemia, respiratory failure, hypotension, and hypertension with or without LVH.

Type 3. Myocardial infarction resulting in death when biomarker values are unavailable. Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes or new LBBB, but death occurring before blood samples could be obtained, before cardiac biomarker could rise, or in rare cases, cardiac biomarkers were not collected.

Type 4a. Myocardial infarction associated with PCI is arbitrarily defined by elevation of cTn values $>5 \times$ 99th percentile URL in patients with normal baseline values ($\leq$99th percentile URL) or a rise of cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (i) symptoms suggestive of myocardial ischemia, or (ii) new ischemic ECG changes or new LBBB, or (iii) angiographic loss of patency of a major coronary artery or a side branch or persistent slow or no flow or embolization, or (iv) imaging demonstration of new loss of viable myocardium or new regional wall-motion abnormality is required.

Type 4b. Myocardial infarction related to stent thrombosis—Myocardial infarction associated with stent thrombosis is detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall of cardiac biomarkers values with at least one value above the 99th percentile URL.

Type 5. Myocardial infarction related to coronary artery bypass grafting (CABG)—Myocardial infarction associated with CABG is arbitrarily defined by elevation of cardiac biomarker values $>10 \times$ 99th percentile URL in patients with normal baseline cTn values ($\leq$99th percentile URL). In addition, either (i) new pathological Q waves or new LBBB, or (ii) angiographic documented new graft or new native coronary artery occlusion, or (iii) imaging evidence of new loss of viable myocardium or new regional wall-motion abnormality.

Type 1 Versus Type 2 Myocardial Infarction

Although some cases may be easily explained retrospectively, the prospective classification of a type 1 MI versus a type 2 MI is challenging without information on coronary anatomy such as the presence of plaque rupture, erosion, fissure, or dissection. Although there may be some differences regarding troponin peak concentrations, kinetic changes, and baseline clinical characteristics, a prospective classification is virtually impossible. Reports on the prevalence of type 2 MI are very heterogeneous. Since the diagnostic criteria include a wide range of clinical conditions, these often vary between studies due to variable interpretations of the universal definition (Collinson and Lindahl, 2015; Chapman et al., 2017). A higher prevalence of type 2 MI has been reported for women (Cediel et al., 2017). There are no data showing that a type 2 MI has to be treated the same way like a type 1 MI, that is, no data on the role of dual platelet inhibition, usefulness of ticagrelor or prasugrel, duration of treatment, or adjunctive therapies including anticoagulation and glycoprotein IIb/IIIa inhibitors. Importantly, mortality rates of patients with type 2 MI seem to be higher than mortality rates in patients with type 1 MI (Cediel et al., 2017; Saaby et al., 2013). Since type 2 MI is the only type of MI unrelated to coronary occlusion, some authors have suggested that future MI definitions should be more restrictive and group current type 2 MI with myocardial injury due to nonischemic causes (Nagele, 2016).

Type 4a MI (MI Associated With PCI)

One important update in the current universal definition of MI takes into account the commonly observed troponin elevations after PCI. In the previous definition of MI, 15% of all patients treated with PCI were classified as having type 4a MI, since any elevation above $3 \times$ of the URL was considered as a periprocedural MI even when patients had no symptoms (Testa et al., 2009). The updated and current criteria had the goal of increasing the prognostic relevance of type 4a MI diagnoses, now demanding both clinical signs for myocardial ischemia and elevation above $5 \times$ of the URL when troponin levels are normal before PCI. In patients with elevated troponin levels before PCI, an increase of 20% is diagnostic if troponin levels were stable or falling beforehand.

It now appears that rates of type 4 a MI have declined after introduction of the revised criteria. Myocardial injury, however, is still detectable in a substantial proportion of patients following elective PCI with or without stenting. Causes for periprocedural cTn elevations are multifactorial with a predominance of side branch occlusion (Park et al., 2013). Monitoring of periprocedural myocardial injury is feasible with cTn. However, it should be remembered that considerably higher increases from ULN are

required using cTn or hsTn instead of CKMB in order to predict the same prognostically equivalent amount of injury due to the substantial higher sensitivity of cTn and particularly hsTn (Katus et al., 1991a; Apple, 2009). The thresholds for cTn defining a type 4a MI were set arbitrarily by convention in light of sparse study findings. In order to detect postprocedural myocardial injury or type 4a MI, serial measurements immediately before and up to 48 h post PCI are recommended (Thygesen et al., 2012). The consequences of relevant myocardial injury or a type 4a MI include extended monitoring for arrhythmias and reevaluation of procedural success.

The Electrocardiogram (ECG): First and Crucial Diagnostic Tool

An electrocardiogram (ECG) should be obtained and interpreted by a physician within 10 min after admission (Roffi et al., 2016; Amsterdam et al., 2014).

When patients present with significant ST elevations in at least two contiguous leads, presumed new left bundle branch block, anterior ST depressions indicative of true posterior MI, or ST elevation in aVR in combination with ST depression in eight or more surface leads suggestive of multivessel or left main coronary artery disease, immediate coronary angiography should be performed.

Depending on the localization of infarction, ST segment elevations may be observed in anterior leads (V1–V6), inferior leads (II, III, and aVF), lateral/apical leads (I and aVL), and in leads representing the free wall of the right ventricle (V3R and V4R) or the inferobasal wall (V7–V9).

In the third definition of MI, minor important modifications have been made to the ECG criteria, acknowledging age- and gender-specific differences in leads V2–V3. In these two leads, ST segment elevations are considered significant when the J point is elevated $\geq$0.15 mV in women, $\geq$0.2 mV in men $\geq$40 years, and $\geq$0.25 mV in men under 40 years. In all other leads, an elevation $\geq$0.1 mV is considered diagnostic (**Table 1**).

True posterior MI may present with ST elevation in posterior chest leads V7–V9 and ST depression in V1–V3, which is why additional obtainment of ECG leads V7–V9 in patients with initial nondiagnostic ECG at intermediate/high risk for ACS is recommended. In the opinion of the authors, routine obtainment of V7–V9 should be considered in all patients with suspected MI.

In patients with inferior MI and suspected right ventricular infarction, right precordial leads (V3R and V4R) should be obtained. In these leads, an ST elevation $\geq$0.05 mV ($\geq$0.1 mV in men <30 years) may support the diagnosis (Lopez-Sendon et al., 1985).

Elevations of lead aVR have been shown to be associated with an adverse prognosis (Wong et al., 2010) and when they present in combination with ST depression >0.1 mV in eight or more surface leads, multivessel or left main coronary artery disease should be suspected (Yan et al., 2007) (**Figs. 1** and **2**).

ECG interpretation can be difficult in patients with left or right bundle branch block, early repolarization, and persisting ST elevations due to a residual aneurysm or due to incorrectly positioned leads. In patients with preexisting left bundle branch block (LBBB), comparison with a previous ECG and concordant ST elevations may help detect acute MI (Lopes et al., 2011).

Prior MI

Regardless of symptoms, Q waves and QS complexes in the absence of left ventricular hypertrophy and LBBB suggest prior MI (Savage et al., 1977). The current universal definition specifies any Q wave in V2–V3 >0.02 s or QS complex in V2 and V3 as significant. Furthermore, Q waves $\geq$0.03 s and $\geq$0.1 mV deep or QS complex in two contiguous leads I, II, aVL, aVF or V4–V6 (or V7–V9) are considered significant.

Prior MI may also be diagnosed in the presence of an R wave $\geq$0.04 s in V1–V2 and R/S $\geq$1 with a concordant positive T wave.

New pathological Q waves in asymptomatic patients may be indicative of previous silent MI.

It is important to remember that ST-T abnormalities are frequent in patients with Brugada syndrome, stress cardiomyopathy and early repolarization syndrome, making diagnosis of acute myocardial ischemia solely with ECG sometimes impossible. However, new ST segment elevations for a prolonged period of time in combination with reciprocal ST segment depressions are usually due to acute coronary occlusion (Wang et al., 2003). Other conditions associated with ST-T abnormalities are peri-/myocarditis, pulmonary embolism, hypothermia, intracranial processes, and electrolyte abnormalities.

Table 1 ECG manifestations of acute myocardial ischemia

ST elevation
New ST elevation at the J point in two contiguous leads with the cut points: $\geq$0.1 mV in all leads other than leads V2–V3 where the following cut points apply: $\geq$0.2 mV in men $\geq$40 years, $\geq$0.25 mV in men <40 years, or $\geq$0.15 mV in women
ST depression and T wave changes
New horizontal or downsloping ST depression $\geq$0.05 mV in two contiguous leads and/or T inversion $\geq$0.1 mV in two contiguous leads with prominent R wave or R/S ratio >1

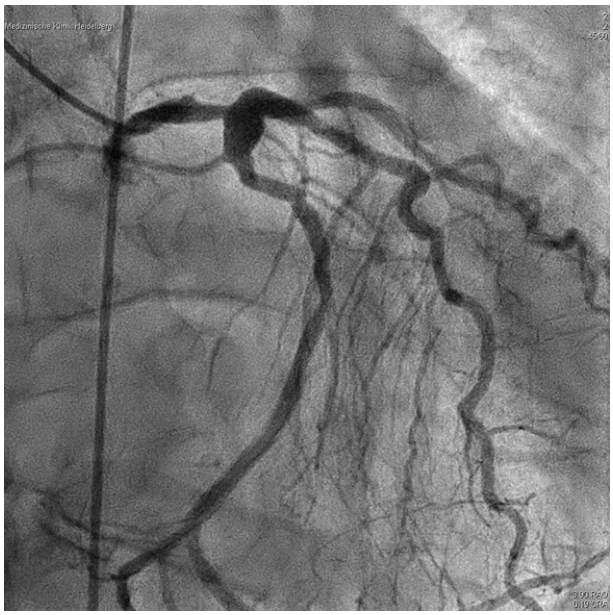

Fig. 2 Coronary angiogram of a patient with left main stem stenosis.

Cardiac Troponin: Preferred and Gold Standard Biomarker

Cardiac troponin is a regulatory protein of the myocardial contractile apparatus. Of its three subtypes (troponin T, I, and C), only cardiac troponin T (cTnT) and troponin I (cTnI) are solely expressed in cardiomyocytes. Elevations of cTnT or cTnI therefore indicate myocardial injury (Katus et al., 1991a). Cardiac troponin is released during the first 24 h from the cytoplasmic pool. A plateau is reached after 48–72 h due to proteolytic degradation of the contraction apparatus (Katus et al., 1991b; Remppis et al., 1994). Rising

and/or falling troponin levels and markedly elevated troponin levels at admission increase likelihood of acute myocardial injury. Stable serial troponin values are indicative of chronic myocardial injury. Laboratories should ensure certain quality standards, including an assay precision $\leq$10% coefficient of variation (CV) at the 99th percentile URL. Several manufacturers improved analytic sensitivities and precision of their assays at the 99th percentile value considerably. By convention, assays are graded by sensitivity and precision. Distinctions are made between guide acceptable, clinically useable, and not acceptable assays. High-sensitivity assays are further classified by their ability to measure cTn in healthy persons. Accordingly, a troponin assay can only be labeled hs if the assay can quantify concentrations in at least 50% of healthy subjects (Apple, 2009).

Cardiac Imaging in Patients with Suspected MI

Diagnosis of MI can be made in the presence of evidence of new regional wall-motion abnormalities in echocardiography, myocardial scars in MRI or in nuclear tests, or an intracoronary thrombus during coronary angiography in combination with a significant rise and/or fall of cardiac troponin even in the absence of clinical symptoms. Transthoracic echocardiography (TTE) should always be available in chest pain units and emergency rooms. TTE allows detection of regional wall abnormalities and helps detect signs of other nonischemic causes of chest pain such as myocarditis, valvular disease, cardiomyopathy, pulmonary embolism, or aortic dissection. Another advantage of echocardiography is the detection of complications of MI such as ventricular wall rupture, secondary mitral valve regurgitation after papillary muscle rupture, or ischemia (Flachskampf et al., 2011). Myocardial disease can best be assessed with cardiac MRI. Multidetector computed tomography for anatomical evaluation of coronary arteries may be helpful in patients with low to intermediate pretest probability for ACS. In such patients, a normal CT scan can exclude coronary artery disease (Samad et al., 2012).

Diagnostic Protocols

Introduction of hsTn assays has reduced the time to collect the second sample from 6–9 h after the first sampling to 3 h (Roffi et al., 2016). In countries and hospitals without access to hsTn, retesting of cTn should be performed 3–6 h after presentation with the use of a contemporary sensitive cTn or after 6–9 h with almost all POCT assays due to the lower analytic sensitivity. More recently, faster diagnostic protocols have been recommended by ESC guidelines as an alternative to the standard 0–3 h protocol. The 0–1 h accelerated diagnostic protocols for rule-out and rule-in are explicitly recommended provided that one of three validated hsTn assays is used (Roche Elecsys hsTnT, Abbott hsTnI Architect STAT or Siemens Dimension Vista hsTnI) (Roffi et al., 2016).

MI can also be ruled out immediately in low-risk patients with undetectable admission levels below limit of detection (LoD) or limit of blank (LoB) without the need for a second sample. As an evolving or small MI may be missed during the short hs troponin blank period, an instant rule-out protocol should not be applied to very early presenters, who are presenting within 1 h after onset of symptoms. Conversely, in patients with very high troponin elevations at time of presentation, the diagnosis of MI is very likely with a positive predictive value of >85%, sometimes obviating the need for a second cTn sample (Mueller-Hennessen et al., 2017). This management cutoff may prompt immediate coronary angiography for suspected large MI in a typical clinical context. However, it is important to always consider other acute myocardial or valvular pathologies or acute endocarditis, which may also present with high initial troponin values and require different management.

In order to increase practicability and permit a safer rule-out and discharge, some algorithms, particularly a 2 h accelerated diagnostic protocol with cTn measurements at 0 and 2 h, recommend implementation of a clinical risk score and ECG criteria (Than et al., 2012). Faster diagnostic algorithms generate an intermediate (or observational) diagnostic zone for patients who neither fulfill criteria for rule-out nor for rule-in. The final adjudicated diagnoses of patients in such an observational zone include NSTEMI but more often myocardial injury due to other reasons than ACS. Such patients often are male, have more comorbidities, are of higher age, have renal impairment, and have underlying cardiovascular disease. Long-term outcomes may be comparable with those of patients with confirmed MI (Nestelberger et al., 2016).

Patients in the observational zone require monitoring, serial cTn testing, and extended diagnostics in order to provide an accurate diagnosis and specific treatment. Cardiac imaging with echocardiography and multislice CT are increasingly important for the diagnostic workup of patients in this subgroup.

When sensitive or high-sensitivity cardiac troponin assays are unavailable, additional measurement of copeptin at admission is recommended. Normal copeptin levels without elevated cardiac troponin levels at presentation allow safe rule-out of MI.

All algorithms should only be used in the context of the overall presentation of the patient. When patients arrive less than 1 h after onset of chest pain, testing after 3 h should be performed. Whenever there is high clinical suspicion or when symptoms persist, additional measurements should be performed.

Age- and Gender-Specific Cutoffs

The introduction of more sensitive cTn assays allows detection of lower concentrations in women than in men, reflecting anatomical and functional differences of the heart between genders. The universal definition of MI recommends the use of

sex-specific cutoffs, but validation in prospective trials is not available, and existing evidence is controversial regarding the relevance of sex-specific cutoffs for diagnostic or prognostic classification. So far, diagnostic protocols recommend a single sex-independent cutoff for the standard 0–3 h algorithm and for the faster alternatives using hsTnT or hsTnI (Roffi et al., 2016). It should be noted that implementation of sex-specific cutoffs may improve diagnosis of MI to a small extent but only at the cost of practicability complicating diagnosis extraordinarily, particularly if other comorbidities such as renal failure, heart failure, or age that can confound the troponin result are considered as well (Mueller-Hennessen et al., 2016).

Conclusion

The current version of the universal definition of MI allows for a precise and consistent diagnosis of MI. Clinicians and researchers are strongly encouraged to study the detailed criteria to correctly diagnose or rule out acute MI.

Heart Failure

Chronic heart failure (HF) is a growing public health problem associated with significant mortality, morbidity, and health care expenditures (Roger, 2013). It affects approximately 5.7 million Americans and carries a 5-year mortality rate of ~50%. The prevalence of HF is expected to rise 46% from 2012 to 2030, due to improvements in medical and nonpharmacological care, allowing more patients to survive acute myocardial infarction and live to an older age (Mozaffarian et al., 2015). At present, approximately 1.5%–2% of Canadians are affected with HF (Ezekowitz et al., 2011).

Heart failure occurs when the heart is unable to maintain an adequate cardiac output to meet metabolic requirements of the rest of the body (Kemp and Conte, 2012). HF induces a systemic response, leading to the activation of neurohormonal systems characterized by an overexpression of the sympathetic and renin–angiotensin aldosterone system. While this is initially beneficial in maintaining renal and organ perfusion, it becomes maladaptive over time and causes the exacerbation of hemodynamic abnormalities found in HF. This results in further remodeling and neurohormonal release and progressive cardiac impairment, leading to excessive sodium and fluid retention (Colin-Ramirez and Ezekowitz, 2016). This disruption contributes to the signs and symptoms seen in patients with HF, greatly affecting health-related quality of life and physical functioning (Yancy et al., 2013). Common symptoms include dyspnea from pulmonary congestion, peripheral edema from impaired venous return, nausea, lack of appetite, and fatigue (Kemp and Conte, 2012).

Diet in Heart Failure

Dietary Sodium Intake Recommendations

The disruption of various complex compensatory mechanisms in patients with HF alters the patient's ability to effectively balance salt intake and excretion, resulting in a significant amount of sodium and fluid retention. An excessive sodium intake can further increase this retention, causing the exacerbation of HF symptoms. Thus, dietary sodium restriction has been considered a major self-care behavior recommended to these patients. However, due to a lack of conclusive evidence regarding the association between reduced sodium consumption and clinical events in the HF population, there is an inconsistency that exists among current recommendations for sodium intake in HF (Colin-Ramirez and Ezekowitz, 2016). The American College of Cardiology (ACC) and the American Heart Association (AHA) recommend decreasing sodium intake in patients with symptomatic HF, based on the association between sodium intake and hypertension, LV hypertrophy, and cardiovascular disease. It is recommended that stage

A and B HF patients restrict their sodium intake to 1500 mg/day, while stage C and D patients consume <3000 mg/day to reduce HF symptoms (Yancy et al., 2013). The Canadian Cardiovascular Society (Malcon et al., 2008), the Heart Failure Society of America (Lindenfeld et al., 2010), and the National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (2011) suggest a sodium intake between 2000 and 3000 mg/day. Lastly, the European Society of Cardiology (ESC) recommends consuming less than 2400 mg/day, although no evidence level has been given to support this recommendation (Ponikowski et al., 2016).

Clinical Studies on Dietary Sodium Intake in HF

Observational data suggested that patients with HF who consume higher amounts of sodium (>2800 mg/day) are at greater risk of an acute decompensated HF (ADHF) event (Arcand et al., 2011), while a recent longitudinal cohort study showed that a sodium intake <2500 mg/day increased risk of HF hospitalization, among patients with HF NYHA class II/III (Doukky et al., 2016). Importantly, generalizability of these results may be limited due to these patients being participants of a RCT of behavioral modification that included several other co-interventions.

Results from previous RCT's have raised concern that sodium restriction may not be beneficial and may even produce detrimental effects in patients with HF (Lennie et al., 2013). Three large-scale RCTs assessing clinical outcomes associated with sodium restriction in patients with HF found that patients with systolic HF following a low-sodium diet (1800 mg/day) had a higher readmission and mortality rate in comparison to those following a moderate-sodium diet (2800 mg/day) in combination with oral furosemide (250–1000 mg/day) and fluid restriction (1 L/day) (Parrinello et al., 2009; Paterna et al., 2008; Paterna et al., 2009). However, it is important to note that the use of this combination treatment may have confounded the association between sodium restriction and clinical outcomes, making it difficult to analyze the direct effect of sodium intake. In contrast to these findings, the results from a recent pilot study suggest that following a low-sodium diet (1500 mg/day) may decrease BNP levels and improve quality of life in ambulatory patients with chronic HF on optimal medical treatment (Colin-Ramirez et al., 2014).

Overall, as a result of conflicting evidence, the optimal level of sodium intake in HF patients remains unclear. A sodium consumption between 2000 and 3000 mg/day appears to be safe and tolerable; however, the effects of reducing intake to less than 1500 mg/day must be elucidated in future large-scale RCTs (Colin-Ramirez and Ezekowitz, 2016).

Fluid Intake

Fluid requirements may vary depending on the stage and severity of HF. According to current major guidelines, fluid restriction of 2 L/day is reasonable in patients with advanced HF to relieve congestive symptoms. However, a routine strict fluid restriction in patients with HF regardless of symptoms or other considerations does not appear to be beneficial (Ponikowski et al., 2016; Yancy et al., 2013).

Macronutrients

Energy and Protein

The cytokine and hormonal derangements associated with the onset of HF leads to a metabolic imbalance favoring catabolism (Rahman et al., 2016). Thus, patients with HF require an increased calorie and protein intake in order to prevent a negative nitrogen balance and tissue breakdown. It has been recommended that clinically stable depleted patients with HF consume a daily intake of 29.5 kcal/kg + 1.1 g protein/kg, while normally nourished patients consume 24.3 kcal/kg + 1 g protein/kg (Aquilana et al., 2003).

Macronutrient Composition of the Diet

There is a growing body of evidence that suggests macronutrient ratios play an important role in minimizing the pathophysiologic disturbances that occur in patients with HF. Results from a recent study found that among 39 patients with HF and right ventricular dysfunction, those following a low-carbohydrate diet (40% carbohydrates, 40% fat, 20% protein) experienced significant weight loss, an increased oxygen saturation, and an improved NYHA functional class, in comparison to the control group (50% carbohydrates, 30% fat, 20% protein) (Olvera et al., 2014). Similar results were found in a study conducted to evaluate the effectiveness of a high-protein diet in promoting weight loss and improving clinical outcomes in 14 obese patients with HF. Patients were assigned to 1 of 3 dietary interventions: a high-protein, low-calorie diet (40% carbohydrates, 30% protein, 30% fat), a standard protein, low-calorie diet (55% carbohydrates, 15% protein, 30% fat), or a conventional, isocaloric diet (55% carbohydrates, 15% protein, 30% fat). After 12 weeks, patients in the high protein, low-calorie group experienced the greatest reduction in body weight and demonstrated improvements in functional status, lipid profiles, and quality of life scores (Evangelista et al., 2009). While these findings are promising, both studies are limited by a small sample size and short duration. A large-scale RCT with a longer follow-up is necessary to determine whether intentional weight loss and favorable outcomes are sustainable and whether there are any adverse consequences, particularly in regard to renal function. Future research evaluating macronutrient ratios in patients with HF must consider common comorbidities within this population, the likelihood of adherence, and patient diversity (Evangelista et al., 2009). Current major guidelines have not provided specific macronutrient

intake recommendations; however, a diet containing 50%–55% carbohydrates, 25%–30% fat, and 15%–20% protein seems to be tolerable in this patient population (Colin-Ramirez et al., 2014).

Omega-3 Supplementation

The role of omega-3 polyunsaturated fatty acids (omega-3 PUFAs) in patients with HF has become a common area of interest in HF management. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico-Heart Failure (GISSI-HF) study, a randomized control trial consisting of 6975 patients, examined the effects of omega-3 supplementation in patients with chronic HF. Subjects who received 1 g of omega-3 PUFAs/day showed a 10% reduction in mortality and a 7% reduction in hospitalizations over 3.9 years (Tavazzi et al., 2008; Masson et al., 2013). Additionally, a recent meta-analysis pooled the results from 4 different studies and found omega-3 supplementation to have a favorable effect on cardiac function, remodeling, and functional capacity (Butler, 2016). However, other recent trials and meta-analysis have not found a significant relationship between omega-3 supplementation and decreased mortality in patients with cardiovascular disease (Rauch et al., 2010; Kotwal et al., 2012). As a result, current ACC/AHA guidelines consider omega-3 supplementation to be a safe and tolerable adjunctive therapy for this patient population, while further research is required to determine optimal dosing and formulation, as well as the effects of consuming omega-3 PUFAs through dietary sources alone (Yancy et al., 2013).

Micronutrients

Factors Related to Micronutrient Deficiency in HF

Patients with HF may be prone to micronutrient deficiencies due to several factors, including oxidative stress (Shetty et al., 2015), poor nutrient absorption and the use of loop diuretics, a common drug therapy that causes an excess urinary loss of thiamine, potassium, magnesium, and calcium (Weber, 2004). In terms of malabsorption, patients often experience abdominal and gut edema with dysfunctional intestinal barriers leading to an increased permeability, exposure to endotoxins, and chronic inflammation, all contributing to the impairment of mucosa function and nutrient uptake (Trippel et al., 2013).

In addition to the factors mentioned above, an inadequate dietary intake may increase the risk of nutrient deficiency in HF. Approximately 50% of patients are considered malnourished and consume a less varied diet, poor in key micronutrients (Rahman et al., 2016). Several factors may contribute to a decreased dietary intake, such as lack of hunger, fatigue, nausea, premature satiety, age-related changes in taste and smell, the consumption of foods with a low nutrient density, and clinically recommended dietary restrictions (Grossniklaus et al., 2018; Lennie et al., 2013).

Results from recent studies have suggested that a sodium-restricted diet ($<$2000 mg/day) can lead to a reduced intake of other important nutrients in this patient population already at nutritional risk (Frediani et al., 2013; Jefferson et al., 2015). A prospective trial, requiring patients with HF to limit sodium intake to less than 2000 mg/day for 1 week, found that a 49% sodium reduction lead to several unintentional dietary consequences, including a reduction in calorie, carbohydrate, calcium, thiamine, and folate intakes. There was also a decrease in saturated fat consumption and a trend to lower fat intakes (Jefferson et al., 2015). However, a pilot study consisting of 35 patients following a low-sodium diet for 6 months found that patients who reduced their sodium intake by $\geq$25% showed a greater increase in folate intake and a larger reduction in calcium intake in comparison to the $\leq$25% sodium reduction group. Other relevant nutrient intakes were not significantly affected and no significant weight loss was documented in either group. These findings highlight the importance of utilizing an individualized and comprehensive dietary approach when counseling patients with HF to lower sodium intake. When the whole diet is considered, sodium restriction can be lowered without significantly compromising other aspects of the diet (Colin-Ramirez et al., 2015).

Micronutrient Recommendations

Given the increased risk of nutrient deficiency in this population, it is crucial that patients follow the Dietary Reference Intake (DRI) for micronutrients (Yancy et al., 2013). However it is important to note that potassium replacement is not required when a potassium-losing diuretic is used with an angiotensin-converting enzyme inhibitor (ACE inhibitor) and a mineral corticoid receptor antagonist (MRA) or an angiotensin receptor blocker (ARB). Additionally, when potassium-sparing diuretics or supplements are used in combination with an ACE inhibitor (or ARB) and MRA, serious hyperkalemia can occur (McMurray et al., 2015).

There is currently no clinical evidence to suggest micronutrient supplementation is effective in improving clinical outcomes or survival rates in patients with HF. As a result, the ESC guidelines only list supplements as a possible treatment for cardiac cachexia, with no proved benefits; and ACC/AHA guidelines do not recommend nutritional supplementation in the treatment of HF, aside from the clinical treatment of documented deficiencies (Yancy et al., 2013; Ponikowski et al., 2016).

Cardiac Cachexia

Cardiac cachexia is an inflammation-related form of malnutrition, common to many chronic diseases, including severe HF. Approximately 5%–15% of patients with HF are cachectic, with an annual mortality rate of 20%–30% (Griva, 2015). It is

characterized as a multifactorial metabolic disorder, involving muscle wasting, fatigue, and weakness. Progressive weight loss includes the loss of lean muscle mass, body fat, and bone (Evans et al., 2008).

The pathophysiology is associated with alterations in neurohormonal and immunological status, an imbalance in catabolic and anabolic pathways, and the activation of proinflammatory cytokines. Additionally, inadequate protein intake, poor enteral nutrient absorption, and physical inactivity contribute to the wasting process. An inadequate dietary intake does not usually trigger the onset of cachexia alone; however deficiencies in micronutrients and macronutrients can lead to disease progression (Griva, 2015).

Diagnosis of Cardiac Cachexia

Due to the complex, multifactorial pathophysiology of cachexia, it is often underdiagnosed and rarely treated until the late stages. The consensus panel outlined a set of diagnostic criteria to allow clinicians and researchers to make a definitive diagnosis of cachexia. The criteria include edema-free weight loss of a least 5% within the past 12 months or a body mass index <20 kg/m^2, in addition to at least three of the following: decreased muscle strength, fatigue, anorexia, low muscle (fat-free) mass, and biochemical abnormalities characteristic of inflammation, anemia, or hypoalbuminemia (Evans et al., 2008).

Treatment of Cardiac Cachexia

There is no current standardized therapy for cardiac cachexia, though it is recommended that cachectic patients or those at risk of developing it undergo comprehensive therapy aimed at increasing muscle mass, strength, and body weight (Griva, 2015). Both ACE inhibitors and B-blockers have been shown to prevent weight loss associated with severe HF. ACEIs have shown a direct effect on muscle wasting by preventing protein degradation. Likewise, data from animal studies suggest that B-blockers may decrease total energy expenditure and increase skeletal muscle mass (Rahman et al., 2016). Other drug therapies such as ghrelin receptor agonists (anamorelin) and selective androgen receptor modulators (enobosarm) have shown promising results in the treatment of cachexia, while research surrounding myostatin antagonists is still underway (Griva, 2015).

Nutritional therapy alone has no effect on the catabolic process of cachexia; however when used in combination with other therapies beneficial effects are more likely. Evidence has shown that protein supplementation acts to increase muscle synthesis, particularly when used in conjunction with exercise (Loncar et al., 2016). The PROTAGE Study Group, an international study group aimed at providing recommendations for optimal protein intake by older people, suggests an average daily intake of at least 1.0–1.2 g/kg of protein to enhance muscle synthesis. Protein quality and timing of ingestion may be relevant to treatment; however further research is required to support specific recommendations (Bauer et al., 2013). Additionally, caloric supplementation has led to weight gain and improved quality of life (Loncar et al., 2016). It is beneficial for patients to receive individualized dietary counseling aimed at ensuring they are consuming enough protein and calories to meet their energy needs, as well as sufficient micronutrients to optimize cellular function (Rahman et al., 2016). Other nutritional interventions such as eicosapentaenoic acid, B-hydroxy B-methylbutyrate, and resveratrol may prevent wasting and muscle loss in animal models, without proven effects on humans (Loncar et al., 2016). In regard to exercise, tolerable endurance and resistance programs are suggested to maintain lean body mass and function (Bauer et al., 2013). Aerobic therapy is the most proven to counteract muscle wasting, and is recommended by HF treatment guidelines (Yancy et al., 2013; Ponikowski et al., 2016).

Dietary Patterns

The Dietary Approaches to Stop Hypertension (DASH) Diet

The DASH diet is a dietary pattern found to have a beneficial effect on preventing and managing risk factors associated with CVD, such as hypertension. Such a diet is typically comprised of fruits, vegetables, low-fat dairy products, whole grains, chicken, fish, and nuts. In comparison to the typical western diet, it is significantly lower in saturated fat, total fat, cholesterol, refined sugar, and sodium (Eilat-Adar et al., 2013). The results from recent studies have suggested that in addition to its protective role in preventing CVD, the DASH diet may be an effective therapeutic tool in HF management (Rifai et al., 2013). A trial evaluating the effects of consuming a sodium-restricted DASH diet (1500 mg/2100 cal) in 13 patients with treated hypertension and HF with preserved ejection fraction found that after a 21 day-follow-up period, patients experienced beneficial changes in ventricular diastolic function, arterial elastance, and ventricular-arterial coupling (Hummel et al., 2013). Additionally, results from a recent RCT showed that adhering to the DASH diet for 3 months lead to an improvement in endothelial function, exercise capacity, and quality of life scores in patients with chronic symptomatic (stage C) HF (Rifai et al., 2013). Given these findings, integrating this combination diet into the dietary habits of patients with HF seems safe and reasonable. Importantly, the DASH diet is varied, nutrient dense, and low in sodium and saturated fat, making it highly suitable for the HF population. Further research examining the effects of the DASH diet in these patients is required, especially in those with concomitant renal disease or on potassium-sparing medications, who may need to restrict their potassium intake (Colin-Ramirez et al., 2014).

The Mediterranean Diet

The Mediterranean diet is characterized by a high intake of fruits, vegetables, nuts, legumes, whole grains, fish, olive oil, and a limited consumption of red meat and high-fat dairy products. Several experimental and observational studies have suggested that this dietary pattern plays a protective role against cardiovascular disease. A recent prospective cohort study found the Mediterranean diet to be associated with a lower risk of sudden cardiac death in postmenopausal women in comparison to the DASH diet (Bertoia et al., 2014). These results are consistent with those of the PREDIMED trial, a primary prevention trial which found that following the Mediterranean diet substantially reduced the risk of major cardiovascular events, including strokes, myocardial infarctions, and death (Estruch et al., 2013). Additionally, a study focusing on the effect of the Mediterranean diet in the primary prevention of HF found that the Mediterranean diet for 1 year was associated with a significant reduction in N-terminal pro-brain natriuretic peptide levels among individuals at high risk of CVD (Fito et al., 2014). Lastly, two population-cohort studies examined the beneficial effects associated with a high adherence to the Mediterranean diet. One study examining men specifically found the Mediterranean diet was associated with a lower risk of developing HF and a lower mortality from HF (Tektonidis et al., 2016); and the second study showed that a high adherence to this dietary pattern lowered the risk of myocardial infarction, ischemic stroke and HF, among women (Tektonidis et al., 2015). Collectively, these studies demonstrate a clear association between a Mediterranean diet and improved cardiovascular health; however, a full examination of the role of this dietary intervention in the management of HF is required.

Conclusion

In addition to fluid and sodium restriction, evidence has suggested that other dietary components may play a critical role in the nonpharmacological treatment of HF. However, there is still a strong need for future research to further clarify the beneficial effects of dietary manipulation in patients with HF. While previous studies have shown promising results, many are limited by small sample sizes and a short duration. Larger, high-quality RCTs that account for differences within this patient population such as the cause and severity of HF, concomitant disease, age, race, body size, among others, are required in order to incorporate evidence-based dietary advice into the clinical treatment of HF. Finally, patient education by a dietitian, who is able to provide nutritional counseling according to patient's individual needs, is key to promote an appropriate nutrient intake among these patients and identify those at risk of malnutrition.

Types and Source of Dietary Fat

Dietary fat is a macronutrient found in food from plants and animals sources and provides energy for the body. Generally, the higher the content of saturated fatty acids, the more the solid nature of fat at room temperature, thus animal fats are solid, whereas plant fats (oils) are liquid at room temperature, except for some seed oils, like coconut oil and palm kernel oil, which are high in saturated fat and therefore solid at room temperature (Dietary Fats, 2005). In a review of data from 28 countries, the contribution of total fat intake to the total energy intake ranges between 11.1% in China to 50.7% in Nigeria (Elmadfa and Kornsteiner, 2009).

Fatty acids are the major form of dietary fat (mainly as triglycerides), and according to the presence and number of double bonds in their carbon chain, they are classified into saturated and unsaturated fatty acids.

Saturated Fatty Acids

Saturated fatty acids (SFA) contain no double bond; this type of fat can be synthesized by the body and its major dietary source is food from animal sources, such as full-fat dairy products, red meat, and poultry. Moreover, there are numerous types of SFA according to length of their chain (contains 4–16 carbon atoms). SFA intake is generally high in Africa and North America and low in East-Asia; the contribution of SFA intake to the total energy intake ranges between 3.1% in China to 25.4% in Nigeria (Elmadfa and Kornsteiner, 2009).

Unsaturated Fatty Acids

Unsaturated fatty acids contain one or more carbon atom in a double bond. The three major types of unsaturated fatty acids are monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), and trans fatty acids.

Monounsaturated fatty acids (MUFA)

MUFA contain one double bond; this type of fat is liquid at room temperature and found in a variety of food and oils, such as olive oil, safflower oil, peanut oil, and corn oil. The contribution of MUFA intake to the total energy intake ranges between 3.5% in China to 22.3% in Greece (Elmadfa and Kornsteiner, 2009).

 https://doi.org/10.1016/B978-0-12-809657-4.99603-0

Polyunsaturated fatty acids (PUFA)

PUFA contain more than one double bond and found mainly in plant-based food and oils. Omega-3 (*n*-3) and Omega-6 (*n*-6) fatty acids is a classification that depends on the position of the first double bond from the methyl terminus of PUFA. The contribution of PUFA intake to the total energy intake ranges between 3.3% in India to 11.3% in Taiwan (Elmadfa and Kornsteiner, 2009).

Omega-3 (*n*-3) PUFA

Omega-3 PUFAs are found in some types of fatty fish like salmon, tuna, trout, mackerel, and sardines. Moreover, seeds like nuts, walnuts, butternuts, and sunflower and oils of canola, flaxseed, and soybean are rich plant sources of *n*-3 fatty acids. Alpha-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid are the three main types of *n*-3 fatty acids involved in human physiology. The contribution of ALA intake to the total energy intake ranges between 0.4% in France to 1.0% in Finland (Elmadfa and Kornsteiner, 2009); while that for EPA and DHA varied between 0.03% in China to 1.05% in Japan (Elmadfa and Kornsteiner, 2009).

Omega-6 PUFA

Omega-6 PUFA, mainly linoleic acid (LA), come from vegetable oils. The contribution of LA intake to the total energy intake ranges between 2.7% in India to 7.2% in Austria (Elmadfa and Kornsteiner, 2009).

Trans fatty acids

Trans fatty acids are unsaturated fatty acids; however, they contain at least one double bond in the "trans" configuration, the thing that makes them more similar to saturated than unsaturated fat. Trans fatty acids are solid at room temperature and occur, in small amounts, naturally in some food. However, most of the solid fats content of trans fatty acids is produced by part hydrogenation of oils, which causes isomerization and relocation of some double bonds giving more solidity to the fat and increasing its trans fatty acids content. Trans fatty acids are high in stick margarine and high content of trans fatty acids can be found in cakes, pastries, doughnuts, and French fries (Litin and Sacks, 1993). The contribution of trans fatty acid intake to the total energy intake ranges between 0.5% and 2.1% in western Europe (Hulshof et al., 1999), 2% the US (Ascherio et al., 1999), and 1%–2% in Netherlands (Oomen et al., 2001).

Function of Dietary Fat

Total Fat

Dietary fats are essential for several biological functions including growth and development via being a major source of energy, working as auxiliary building pieces of the body, conveying fat-soluble vitamins, and involving in crucial physiological procedures in the body (Dietary Fats, 2005; Elmadfa and Kornsteiner, 2009).

Provision of energy

Among the sources of energy in the human diet, fat, carbohydrate, and protein, fat is the most concentrated source providing 9 kcal/1 g consumed, which is more than double the energy content of protein or carbohydrate (4 kcal/g). Fat can be stored in the body's fat tissue, which releases fatty acids when energy is required (Dietary Fats, 2005; Elmadfa and Kornsteiner, 2009).

Structural component

The cell membranes that control the movement of substances in and out of the cells are mainly made of phospholipids, triglycerides, and cholesterol. The human brain is the fattest organ in the body that may consist of at least 60% fat, and the major brain fatty acid is DHA (Dietary Fats, 2005; Elmadfa and Kornsteiner, 2009).

Carrier of vitamins

Fat is a transporter for vitamins A, D, E, and K and enhance their intestinal absorption (Dietary Fats, 2005; Elmadfa and Kornsteiner, 2009).

Other biological functions specific for each type

SFA are a source of body fuel, structural components of cell membranes, and associated with proteins to a degree of being necessary for their normal function. MUFA are important component of cell membrane structure, particularly the myelin sheath of nervous tissue. The human body cannot produce PUFA, for example, LA and ALA, and therefore are called essential fatty acids. Without these essential fatty acids, some vital functions would be compromised, thus they must be provided by the diet. LA and ALA are involved in several physiological processes such as inflammation, blood clotting, and wound healing through engagement with prostaglandins and leukotrienes after being transformed to longer chain fatty acids. LA works as the precursor to arachidonic acid (AA) that involved with regulation of gene expression. Trans fatty acids are not essential and provide no known benefit to human health (Dietary Fats, 2005; Elmadfa and Kornsteiner, 2009).

Associations Between Dietary Fat Intake and Risk of Cardiovascular Disease and Its Risk Factors

Many previous studies have examined the associations of dietary fat intakes and levels of tissue biomarkers of fatty acids with risk of cardiovascular disease (CVD) and the results were inconsistent (**Table 1** for cardiovascular risk factors, **Table 2** for risk of coronary heart disease, **Table 3** for risk of stroke, and **Table 4** for risk of other and total cardiovascular diseases). SFA and cholesterol intakes were associated with higher risk of CVD among women with type 2 diabetes mellitus, while intakes of total fat, MUFA, PUFA, and trans fat were not (Tanasescu et al., 2004). Another study found no association between intakes of total fat, SFA, MUFA, and PUFA with the risk of CVD (Leosdottir et al., 2007); whereas, other studies showed a decreased risk of CVD with higher intake of SFA (Yamagishi et al., 2010, 2013a), MUFA (Guasch-Ferré et al., 2014), PUFA, LA, and ALA (Laaksonen et al., 2005), and with fish and *n*-3 PUFA (Yamagishi et al., 2008a).

The pooled RR of total CVD events reported in meta-analyses were 0.98 (0.92–1.05) for reducing total fat intake from 32% to 20% of energy; 1.00 (0.89–1.11; *P*-trend = 0.95) (Siri-Tarino et al., 2010) and 0.97 (0.84–1.12; *P*-trend = 0.69) (de Souza et al., 2015) for high SFA intake; 0.91 (0.86–0.96; *P*-trend = 0.001) and 0.88 (0.80–0.96; *P*-trend = 0.004) for high MUFA intake (Schwingshackl and Hoffmann, 2014); 0.87 (0.79–0.95; *P*-trend = 0.002) for high *n*-3 PUFA supplementation (Marik and Varon, 2009).

A Scottish study showed that adipose tissue MUFA concentrations were positively associated, while *n*-3 PUFA concentrations were inversely associated, with the risk of incident CVD (Woodward et al., 2011). Neither adipose tissue SFA nor *n*-6 PUFA concentrations were associated with any increased or decreased risk of CVD (Woodward et al., 2011). However, a Swedish study showed that serum concentrations of SFAs, namely, palmitic, palmitoleic, and dihomo-γ-linolenic, were positively and serum concentrations of LA were inversely associated with cardiovascular mortality (Warensjö et al., 2008). Among the biomarkers of dairy fat, concentrations of plasma phospholipid 15:0, but not 14:0 or trans-16:1*n*-7, were inversely associated with the incident CVD (de Oliveira Otto et al., 2013).

Although most CVD share many of the risk factors, the relations of dietary fat with risk of different CVD endpoints are not necessarily the same.

Numerous observational studies have shown a positive association between dietary fat intake and risk of CHD (Esrey et al., 1996; McGee et al., 1984; Kushi et al., 1985; Shekelle et al., 1981), more evident for intakes of SFA (Yamagishi et al., 2013a; Esrey et al., 1996; Ascherio et al., 1996; Hu et al., 1997, 1999; Howard et al., 2006; Kromhout et al., 1995; Jakobsen et al., 2009) and trans fatty acids (Oomen et al., 2001; Ascherio et al., 1994, 1996; Hu et al., 1997; Howard et al., 2006; Kromhout et al., 1995; Oh et al., 2005; Pietinen et al., 1997) intakes; other studies did not find any associations with intakes of total fat (Leosdottir et al., 2007; Hu et al., 1997; Howard et al., 2006; Oh et al., 2005), SFA (Leosdottir et al., 2007; Siri-Tarino et al., 2010; de Souza et al., 2015; Oh et al., 2005; Pietinen et al., 1997), MUFA (Leosdottir et al., 2007; Laaksonen et al., 2005; Schwingshackl and Hoffmann, 2014; Jakobsen et al., 2009; Oh et al., 2005; Pietinen et al., 1997), or PUFA (Tanasescu et al., 2004; Leosdottir et al., 2007; Yamagishi et al., 2008a; Esrey et al., 1996; McGee et al., 1984; Pietinen et al., 1997; Dolecek, 1992); whereas some other studies reported inverse associations with MUFA (Hu et al., 1997) and PUFA (Laaksonen et al., 2005; Howard et al., 2006; Jakobsen et al., 2009; Oh et al., 2005; Iso et al., 2006; Li et al., 2015; Mozaffarian et al., 2010; Farvid et al., 2014). In meta-analyses, the pooled RR for risk of CHD associated with intakes of SFA were 1.07 (0.96–1.19; *P*-trend = 0.22) (Siri-Tarino et al., 2010), 1.15 (0.97–1.36; *P*-trend = 0.10) (de Souza et al., 2015), and 1.02 (0.97–1.07) (Chowdhury et al., 2014); those associated with MUFA intakes were 0.96 (0.90–1.01; *P*-trend = 0.13) (Schwingshackl and Hoffmann, 2014) and 101 (0.96–1.07) (Chowdhury et al., 2014); those associated with PUFA intakes were 0.81 (0.70–0.95; *P*-trend = 0.008) (Mozaffarian et al., 2010) and 0.99 (0.89–1.09) for *n*-6 fatty acids and 0.93 (0.84–1.02) for *n*-3 fatty acids (Chowdhury et al., 2014); while the pooled RR associated with trans fatty acids intakes were 1.28 (1.09–1.50; *P*-trend = 0.003) (de Souza et al., 2015) and 1.16 (1.06–1.27) (Chowdhury et al., 2014).

The associations between plasma cholesterol ester and tissue phospholipids fatty acids composition with risk of CVD should be carefully interpreted. Some fatty acids, such as LA and ALA, cannot be synthesized by the human body and their plasma and tissue levels reflect their dietary intakes; however, other fatty acids, especially SFA, can be endogenously synthesized and their plasma and tissue levels are not valid biomarkers for dietary intakes (Ma et al., 1995; Sun et al., 2007a).

In case-control studies, high plasma, but not erythrocyte, content of biomarkers for dairy fat (C 15:0 and trans 16:1*n*-7) (Sun et al., 2007b) and trans fat (Sun et al., 2007c) was associated with the risk of CHD. Adipose tissue C18:1 trans fatty acids content was not associated with the risk of CHD mortality (Aro et al., 1995). Levels of stearic acid (18:0), dihimo-gamma-linolenic acid (20:3*n*6), and total SFA were associated positively, while AA (20:4*n*6) and total PUFA levels were associated inversely, with CHD risk (Wang et al., 2003). Based on fatty acids' affinity and fluidity, a lipophilic index that summarizes individual fatty acid plasma and erythrocyte levels was associated with risk of CHD (Wu et al., 2013). A meta-analysis showed that lower LA tissue content was associated with increased risk of nonfatal-CHD, while lower DHA and EPA were associated with increased risk of fatal CHD cases (Harris et al., 2007).

As for stroke, some studies reported inverse associations with intakes of total fat (McGee et al., 1985), SFA (Tanasescu et al., 2004; Yamagishi et al., 2013a; McGee et al., 1985), MUFA (Schwingshackl and Hoffmann, 2014), and PUFA (Atkinson et al., 2011; Iso et al., 2001a); others reported no association with intakes of total fat (Atkinson et al., 2011; He et al., 2003), SFA (Atkinson et al., 2011; He et al., 2003), MUFA (Atkinson et al., 2011; He et al., 2003), PUFA (Yamagishi et al., 2008a; He et al., 2003), or trans fat (He et al., 2003), while one study reported positive associations with intakes of trans fat (Kiage et al., 2014).

Table 1 Association between dietary fat intake and some cardiovascular risk factors

Published year/study population/ref no	*Study/cohort name*	*Sample size*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/ outcome*	*Outcome*	*Results*
Mutanen et al. (1992)		59 (29 male and 30 female) normotensive		Randomized crossover trial for 10 weeks	10 weeks	High SFA, high PUFA and Low MUFA diets	SBP and DBP	SBP and DBP after high SFA diet were 122.6 ± 11.5 mmHg and 75.4 ± 7.5 mmHg; decreased to 119.6 ± 10.3 and 73.9 ± 7.4 mmHg after PUFA diet, and was 120.1 ± 11.2 and 72.6 ± 6.4 mmHg, with low MUFA diet
Shah et al. (2007)		6 randomized crossover, 1 randomized parallel, and 3 nonrandomized trials		A meta-analysis of intervention studies		High-carbohydrate versus high MUFA diets	SBP and DBP	Carbohydrate diet associated with higher SPB [$x(-)$ difference: 2.6 (95%CI: 0.4, 4.7) mmHg; $P=0.02$] and DBP [1.8 (0.01, 3.6) mmHg; $P=0.05$] than did MUFA diets.
Ferrara et al. (2000)		23 (10 male and 13 female) hypertensive subjects	25–70 years	Randomized crossover trial for 6 months.	6 months	11 patients assigned to an MUFA dietary regimen and 12 to a PUFA-rich diet	SBP and DBP	SBP and DBP decreased with MUFA compared with PUFA diets; (127 [14] versus 135 [13] mmHg; $P=.05$) and (84 [8] versus 90 [8] mmHg; $P=.01$), respectively. Antihypertensives dose was reduced by 48% (95%CI, −25% to −71%) during the MUFA diet and by 4% (95%CI, −24% to 17%) during the PUFA diet, P-difference $=0.005$
Harris (1989)		928 participants of 44 trials		A systematic review		Fish oil and *n*-3 fatty acids intakes	levels of cholesterol, triglycerides, LDL- and HDL-cholesterol	No change in total or LDL-cholesterol, a 25% decrease in triglyceride levels, and a slight rise in HDL-C (+3%).
Harris (1997)		36 placebo-controlled crossover and 29 parallel design studies		A systematic review	≥ 2 weeks	<7 g *n*-3 fatty acids/d	Lipid profile	5%–10% increase in LDL-cholesterol, 1%–3% increase in HDL-cholesterol and 25%–30% decrease in serum triglycerides. No change in total cholesterol
Morris et al. (1993)		1356 subjects of 31 placebo-controlled trials		A meta-analysis		*n*-3 fatty acids in fish oil	Blood pressure	Mean reduction of −3.0, −1.5 mmHg (95%CI: systolic BP: −4.5, −1.5; diastolic BP: −2.2, −0.8)
Mensink and Katan (1992)		682 (474men and 208 women) of 27 clinical trial between 1970 and 1991		A meta-analysis		Replacement of fat by carbohydrate and SFA with PUFA	Lipid profile	Fat by carbohydrate decreased HDL-cholesterol levels. SFA by PUFA decreased HDL-cholesterol by (0.2 mg/dL) per 1%E. SFA elevated while PUFA reduced LDL-cholesterol

(*Continued*)

Table 1 (Continued)

Published year/study population/ref no	*Study/cohort name*	*Sample size*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/ outcome*	*Outcome*	*Results*
Becker et al. (1983)		12 healthy men		A Feeding trial	4 weeks	Effect of SFA, MUFA, and PUFA	Lipid profile	Total cholesterol 166 mg/dL and LDL-cholesterol 103 mg/dL decreased to 133 and 81 mg/dL (SAF), 127 and 71 mg/dL (MUFA), and 123 and 65 mg/dL (PUFA). HDL-cholesterol changed from 46 to 40 mg/dL (SAF), 43 mg/dL (MUFA) and 45 mg/dL (PUFA)
Nelson et al. (1997)		12 healthy volunteer		A single-blind crossover feeding study	130 days	AA-rich diet 1.7 g/d	lipid profile	No statistically significant effect
Lopez-Garcia et al. (2005)	the Nurses' Health Study I Cohort	730 women	43–69 years	cross-sectional study		Trans fatty acid intake via FFQ	age, BMI, intake of MUFA, PUFA, and SFA, smoking status, physical activity, alcohol intake, and postmenopausal hormone therapy	Among women in the highest versus lowest quintile of trans fat intake, CRP levels were 73% ($P=0.009$) higher. IL-6 levels were 17% higher, sTNFR-25% ($P=0.002$), E-selectin 20% ($P=0.003$), sICAM-1 10% ($P=0.007$), and sVCAM-1 levels 10% ($P=0.001$).
Mensink et al. (1992)		58 healthy men and women		Experimental feeding trial		Replacing SFA by MUFA or PUFA	Lp[a] concentration	MUFA replacing SFA, the median Lp[a] concentration increased by 7 mg/L. PUFA replacing SFA, the median Lp[a] concentration increased by 3 mg/l.
Summers et al. (2002)		17 subjects (6 Type II diabetics, 6 nonobese nondiabetics and 5 obese nondiabetics)		A crossover design	Two 5-week periods	SFA or PUFA diets	Lipid profile and other metabolic concentrations and Subcutaneous and visceral fat areas	For PUFA versus SFA diets: subcutaneous fat area decreased ($P=0.001$), fasting total and LDL-cholesterol concentrations decreased ($P=0.001$ and $P=0.002$) and insulin sensitivity increased ($P=0.02$). Total and visceral fat, HDL-cholesterol, triglyceride, glucose or other metabolite concentrations did not change.
Hodson et al. (2001)		Trial I, $n=29$; and trial II, $n=42$ volunteers		Human clinical trial		High SFA diet replaced by high MUFA or PUFA diet		Replacing SFA with *n*-6 PUFA lowered plasma total cholesterol by 19%, LDL-cholesterol by 22%, and HDL-cholesterol by 14%. Replacing SFA with MUFA lowered plasma total cholesterol by 12%, LDL-cholesterol by 15%, and HDL-cholesterol by 4%.
Howard et al. (2010)	Women's Health Initiative Dietary Modification Trial	2730 Postmenopausal women	50–79 years	Randomized controlled trial	8.1 years	Reducing intake of total fat to 20% of energy intake	Lipid profile, blood pressure and other metabolic factors	LDL-C level changes between the intervention and control groups were of 1.2, 2.8, and 0.9 mg/dL after 1, 3, and 6 years ($P=0.25$, 0.03, and 0.68, respectively). No statistically significant effects on levels of triglycerides or HDL-C; ratio of total cholesterol to HDL-C; levels of non–HDL-C, lipoprotein(a).

Table 2 Associations of dietary fat intake and serum fatty acids levels with risk of Stroke

Published year/ ref no	*Study/cohort name*	*Sample size/Study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/outcome*	*Adjusted variables*	*Results*
Leosdottir et al. (2007)	The Malmö Diet and Cancer Study	28,098 (61% women)	Middle aged	Prospective cohort	8.4 years	Intakes of fat via FFQ	Age, smoking habits, alcohol consumption, socio-economic status, marital status, physical activity, BMI, fibre intake, blood pressure, total fat intake for the ratio between unsaturated- and saturated fats.	HRs of ischemic stroke in the highest quartile of intakes among men were 0.97 for total fat, 1.19 for SFA, 0.82 for MUFA and 1.06 for PUFA, while among women were 0.97, 1.19, 0.82 and 1.06, respectively. No significant associations in multivariable model
Yamagishi et al. (2013a)	The Japan Public Health Center-based prospective Study	38,084 Japanese men and 43,847 women	45–74	Prospective cohort	11.1 years	Dietary SFAs via FFQ	Age; sex; energy intake; cohort; cigarette smoking status; alcohol intake; body mass index; sports at leisure time; walking and standing time; perceived mental stress; energy-adjusted dietary intakes of carbohydrate, protein, cholesterol, vegetables, fruit, and calcium.	HR for total, stroke and ischemic stroke and intraparenchymal haemorrhage in the highest SFA intake were 0.77 (0.65–0.93), 0.84 (0.67–1.06) and 0.61 (0.43–0.86), respectively.
Yamagishi et al. (2010)	The Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	58,453 Japanese men and women	40–79 years	Prospective cohort	14.1 years	Intakes of SFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, *n*-3 and *n*-6 polyunsaturated fatty acids, vegetables, and fruits	RR for total and ischemic stroke and intraparenchmal hemorrhage mortality were 0.69 (0.53–0.89; *P*-trend = 0.004), 0.58 (0.37–0.90; *P*-trend = 0.01) and 0.48 (0.27–0.85; *P*-trend = 0.03), respectively
Yamagishi et al. (2008a)	The Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	57,972 Japanese men and women	40–79 years	Prospective cohort	12.7 years	Intakes of fish and *n*-3 PUFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, and *n*-6 PUFA vegetables, and fruits	RR for total and ischemic stroke and intraparenchmal hemorrhage mortality were 0.91 (0.74–1.13; *P*-trend = 0.40), 0.93 (0.65–1.34; *P*-trend = 0.78) and 0.95 (0.62–1.47; *P*-trend = 0.58), respectively in highest versus lowest quintiles of fish intake, and were 0.93 (0.70–1.22; *P*-trend = 0.46), 1.17 (0.71–1.92; *P*-trend = 0.58) and 0.70 (0.40–1.24; *P*-trend = 0.16), respectively in highest versus lowest quintiles of *n*-3 PUFA intake.
Siri-Tarino et al. (2010)		347,747 subjects of 21 prospective cohort studies published until September 2009		Meta-analysis	5–23 years	Saturated fat intake		The pooled relative risk estimates that compared extreme quantiles of saturated fat intake were 1.07 (95% CI: 0.96, 1.19; *P* = 0.22) for CHD, 0.81 (95%CI: 0.62, 1.05; *P* = 0.11) for stroke, and 1.00 (95%CI: 0.89, 1.11; *P* = 0.95) for CVD.

(*Continued*)

Table 2 (Continued)

Published year/ ref no	Study/cohort name	Sample size/Study population	Age at entry	Study design	Follow-up years	Exposure measures/outcome	Adjusted variables	Results
de Souza et al. (2015)		347,747 subjects of prospective cohort, case-control, nested case-control, or case-cohort studies published until May 2015.		Meta-analysis		SFA and trans fat intakes	With SFA, RR were 0.97 (0.84–1.12) for CVD mortality, 1.15 (0.97–1.36) CHD mortality, 1.06 (0.95–1.17) incident total CHD, 1.02 (0.90–1.15) incident ischemic stroke, and 0.95 (0.88–1.03) for type 2 diabetes. With total trans fat intake RR were (1.28, 1.09–1.50) for CHD mortality, and 1.21 (1.10–1.33) for total incident CHD but were 1.07 (0.88–1.28) for ischemic stroke and 1.10 (0.95–1.27) for type 2 diabetes	
Schwingshackl and Hoffmann (2014)		32 cohort studies (42 reports) of 841,211 subjects		A systematic review and meta-analysis Literature until June 2nd, 2014		MUFA (of both plant and animal origin), olive oil, oleic acid, and MUFA: SFA ratio		High MUFA was associated with a RR of stroke mortality of: 0.83 (0.71, 0.97, $P=0.02$).
Howard et al. (2006)	The Women's Health Initiative Randomized Controlled Dietary Modification Trial	48,835 postmenopausal women	50–79 years	Randomized controlled trial	8.1 years	reduction of total fat intake from $\geq$32%E to $<$20% E		The dietary intervention had no significant effects; HR were 0.97 (0.90–1.06) for incident CHD; 1.02 (0.90–1.15) stroke and 0.98 (0.92–1.05) CVD. Trends toward greater reductions in CHD risk were observed in those with lowest intakes of SFA or trans fat; HR were 0.82 (0.67–0.99) and 0.84 (0.69–1.02), respectively.
McGee et al. (1985)	The Honolulu Heart Program	8006 Japanese men residing in Hawaii		Prospective cohort	10 years	Dietary fat g/d using 24h dietary recall and % Energy as fat	systolic blood pressure, number of cigarettes per day, physical activity, BMI, and age	Fat and SFA as g/d were not associated but % of Energy as fat and SFA were inversely associated with stroke mortality.
Atkinson et al. (2011)	The Caerphilly cohort	2710 men	middle-aged	Prospective cohort	18 years	intakes of total fat, SFA, unsaturated fat, white fish and oily fish via FFQ	Smoking status, adult social class, marital status, alcohol intake, vitamin C intake, vegetable fibre intake, blood pressure, cholesterol, BMI, fasting glucose, diabetes and atrial fibrillation.	HR for risk of stroke in the highest quintile of unsaturated fat and oily fish intakes were 0.66 (0.41–1.05, P-trend $=0.13$) and 0.66 (0.41–1.05, P-trend $=0.09$), respectively.
Iso et al. (2001a)	The Nurse Health Study	79,839 women	34–59 years	Prospective cohort	14 years	Fish and omega-3 polyunsaturated fatty acid intake	Age, menopausal stats and postmenopausal hormone use, vigorous exercise, alcohol intake, use of aspirin, multivitamin use, history of hypertension, BMI, fruits and vegetable, SFA, trans fat, linoleic acid, animal protein and calcium intakes.	HR for total stroke and thrombotic infarction in the highest intake category of fish were 0.48 (0.21–1.06) and 0.49 (0.26–0.93) and those for n-3 fatty acids intake were 0.72 (0.53–0.99) and 0.67 (0.42–1.07), respectively.

He et al. (2003)	Health Professional Follow up Study	43,732	40–75 years	Prospective cohort	14 years	Intake of total fat, cholesterol, and specific types of fat.	BMI, physical activity, history of hypertension, smoking status, aspirin use, multivitamin use, and consumption of alcohol, potassium, fibre, vitamin E, fruit and vegetables, total energy intake, and hypercholesterolaemia	Comparing the highest fifth of intake with the lowest fifth, the RR of ischemic stroke was 0.9 for total fat, 1.20 for animal fat, 1.07 for vegetable fat, 1.16 for SFA, 0.91 for MUFA, 0.88 for PUFA, 0.87 for trans fat, and 1.02 for dietary cholesterol. None was significant
Kiage et al. (2014)	The REasons for Geographic And Racial Differences in Stroke (REGARDS) cohort	17,107 men and women	$\geq$45 years	Prospective cohort	7 years	Trans fatty acids intake	Age, smoking status, race, region, alcohol use, education, waist circumference, level of physical activity, diabetes, ischemic heart disease, hypertension, baseline stroke, heart failure, kidney failure, statin use, regular aspirin use, total energy and energy-adjusted SFA, MUFA, PUFA, and protein.	HR for total and ischemic stroke by 1-SD (2-g/d) increase in trans fatty acids intake was 1.14 (1.02, 1.28) and 1.13 (1.00, 1.28) for men and 0.93 (0.79, 1.11) and 0.93 (0.77, 1.12).for women.
Gillman et al. (1997)	Framingham Heart Study	832 men	45–65 years	Prospective cohort	20 years	Intakes of total fat, SFA, MUFA, PUFA via 24-h DR.	Age, energy, cigarette smoking, glucose intolerance, BMI, blood pressure, blood cholesterol level, physical activity, and intake of vegetables and fruits.	For each 3% increment in total fat, 1% of SFA and MUFA intakes, the multivariable-adjusted RR of ischemic stroke were 0.84 (0.75–0.92), 0.90 (0.83–0.96) and 0.87 (0.81–0.94), respectively.
Sauvaget et al. (2004)	Adult Health Study (AHS)	3731 Japanese men and women	35–89 years	Prospective cohort	14 years	Intakes of total fat, animal fat, SFA, MUFA PUFA and cholesterol via 24-h DR.	Radiation dose, city of exposure, smoking and drinking status, BMI, and history of hypertension and diabetes, fruit and vegetable intake, lymphocyte count, blood cholesterol level, total energy intake and weight.	The risk reduction of cerebral infarction in the highest tertiles on intakes versus lowest were 62% (CI, 82%–18%) for animal fat and 63% (CI, 82%–22%) for cholesterol, respectively.
Seino et al. (1997)		1182 rural Japanese men and 1469 women	$\geq$40 years	Prospective cohort	15.5 years	Dietary lipid via FFQ	Stratified by age and sex, and adjusted for blood pressure- and atrial fibrillation	RR for cerebral infarction in the highest quintiles of total fat, SFA, MUFA and PUFA were 0.94, 0.68, 0.28 and 1.57, respectively. None of which were significant
He et al. (2002)	Health Professional Follow up Study	43,671	40–75 years	Prospective cohort	12 years	Intakes of fish and ώ3 PUFA via FFQ	Age, BMI, history of hypertension, smoking, alcohol consumption, use of aspirin, use of multivitamins, physical activity, potassium, magnesium, fruits, vegetables, total energy, total fat, SFA, trans fat, fish oil and hypercholesterolemia. No significant associations were found between fish or ώ3 PUFA intake and risk of hemorrhagic stroke.	HR of ischemic stroke was 0.57 (0.35–0.95).

Table 2 (Continued)

Published year/ ref no	*Study/cohort name*	*Sample size/Study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/outcome*	*Adjusted variables*	*Results*
Yaemsiri et al. (2012)	The Women's Health Initiative Observational Study	87,025 postmenopausal women	50–79 years	Prospective cohort	7.6 years	Dietary trans fat via FFQ	Age, race, education, family income, years as a regular smoker, hormone replacement therapy use, total MET hours per wk, alcohol intake, history of coronary heart disease, history of atrial fibrillation, history of diabetes, aspirin use, use of antihypertensive medication, use of cholesterol-lowering medication, BMI, systolic blood pressure, total energy intake, dietary vitamin E, fruits and vegetable and fiber intakes.	HR for ischemic stroke in highest trans fat quintile was 1.39 (1.08–1.79, *P*-trend = 0.048). No significant associations were found between intakes of SFA, MUFA, or PUFA
Boden-Albala et al. (2009)	The Northern Manhattan Study (NOMAS)	3183 subjects	≥ 40 years	Prospective cohort	5.5 years	Intakes of total fat, SFA, MUFA and PUFA via FFQ.	Age, race/ethnicity, sex, education, BMI, hypertension, diabetes, coronary artery disease, moderate alcohol consumption, current smoking, previous smoking, physical activity	HR of ischemic stroke 1.6 (1.2–2.3) for total fat >65g/d. HR 1.7 (0.8–2.3) for highest intake quintile of SFA,
Iso et al. (2003)		4775 Japanese	40–69 years	Prospective cohort	14 years	Intakes of fat by single 24-h dietary recall	Age, sex, community, total energy intake BMI, history of hypertension, serum total cholesterol levels, serum glucose, smoking status, ethanol intake, and (for women) menopausal status and the time intervals of the baseline surveys.	HR of intraparenchmal hemorrhage in the highest total fat and SFA quartiles were 0.46 (0.20, 1.04, *P* = 0.05) and 0.30 (0.12, 0.71, *P* = 0.005), respectively.
Iso et al. (2001b)	Nurses' Health Study	85,764 women	34–59 years	Prospective cohort	14 years	Intakes of fat via FFQ	Age, smoking status, time interval, BMI, alcohol intake, menopausal status and postmenopausal hormone use, vigorous exercise, usual aspirin use, multivitamin use , vitamin E use, n3 fatty acid intake, calcium intake, and histories of hypertension, diabetes, and high cholesterol levels and total energy intake.	HR of intraparenchmal hemorrhage in the lowest SFA and trans fat intakes were 2.36 (1.10–5.09; *P* = 0.03) and 2.50 (1.35 to 4.65; P:=0.004), respectively
Yakoob et al. (2014)	The Health Professionals Follow-Up Study; the Nurses' Health Study	594 incident stroke cases and 594 controls of 51,529 men and 121,700 women		Case-control study	8.3 years	Plasma and erythrocyte fatty acids by gas-liquid chromatography	Matched by age, sex, race, and smoking and further adjusted for alcohol, family history of diabetes, parental history of MI, menopausal status in the NHS; postmenopausal hormone use in the NHS; consumption of fish, processed meats, unprocessed meats, fruit, vegetables, whole grains, coffee, sugar-sweetened beverages, glycemic load, dietary calcium, PUFA, and total energy; plasma total 16:0, 18:0 and .trans 18:1 and 18:2.	Pooled RR of total stroke were 0.85 (0.54–1.33) for plasma 15:0, 0.99 (0.67–1.49) for 17:0, 0.89 (0.55–1.45) for trans 16:1 *n*-7, and 1.05 (0.62–1.78) for 14:0. Results were similar for ischemic and hemorrhagic stroke subtypes.

Wiberg et al. (2006)		2313 middle-aged men	50 years	Prospective community based study.	32 years	Serum cholesterol ester fatty acids concentrations	Use of antihypertensive, antidiabetic, and lipid-lowering drugs, hypertension, diabetes, the metabolic syndrome, serum cholesterol, smoking, atrial fibrillation, cardiovascular disease, smoking and physical activity.	HR for brain infarction with higher palmitic (16:0), palmitoleic (16:1), and oleic acid (18:1) in cholesterol esters were 1.14 (01.01–1.29), 1.19 (1.05–1.34) and 1.23 (1.09–1.39), respectively. Whereas that of linoleic acid (18:2 *n*-6) was 0.81 (0.72–0.92).
Iso et al. (2002)		197 incident stroke and 197 control Japanese subjects	40–85 years	Nested case-control.	From 1984 and 1993 to end of 1998	Serum Linoleic Acid (LA) and other FA (SFA, MUFA and PUFA).	Matched by sex, age, community, year of serum storage, and fasting status and further adjusted for BMI, smoking status, ethanol intake, hypertension status, serum total cholesterol levels, and log-transformed triglyceride levels and serum glucose and for selected serum fatty acids.	The multivariate OR associated with a 1-SD increase in LA were 0.72 (0.59–0.89) for total stroke, 0.66 (0.49–0.88) for ischemic stroke, 0.63 (0.46–0.88) for lacunar infarction, and 0.81 (0.59–1.12) for hemorrhagic stroke. The respective odds ratios for 1-SD increase in SFA were 1.13 (1.05–1.65), 1.35 (1.01–1.79), 1.44 (1.03–2.01), and 1.21 (0.82–1.80).
Yaemsiri et al. (2013)	The Women's Health Initiative Observational Study cohort (WHI).	964 matched pairs of postmenopausal women	50–79 years	Nested case-control	Between 1993 and 2003.	Serum fatty acids	Matched by age, race, and length of follow-up and further adjusted for BMI smoking status, diabetes, aspirin use, blood pressure and blood cholesterol	The OR and 99.9% CI of ischemic, evident for lacunar but not cardiometabolic stroke, associated with a 1-SD increment in serum FA concentration were 1.38 (1.05–1.83) for linoelaidic acid, 1.27 (1.06–1.51) for palmitic acid, 1.20 (1.01–1.43) for oleic acid, 0.72 (0.59–0.87) for docosapentaenoic acid, 0.72 (0.59–0.87) for docosahexaenoic acid and 0.81 (0.67–0.98) for arachidonic acid.
Yamagishi et al. (2013b)	The Atherosclerosis Risk in Communities (ARIC) Study	3870 white US (1859 men and 2011 women)	45–64 years	Prospective study.	19.9–22.1 years	Plasma cholesterol ester (CE) and phospholipid (PL) fatty acids	Age and sex, smoking status, cigarette-years and alcohol intake	Age and sex-adjusted HR for ischemic stroke were 1.93 (1.23–3.04, *P* for trend = 0.01) for CE fraction, and 1.64 (1.05–2.57, *P* for trend = 0.03) for PL fraction of SFA. Similarly, those of palmitoleic acid (MUFA) were 1.86 (1.20–2.87, *P* for trend = 0.003) for CE fraction, and 1.52 (0.99–2.34, *P* for trend = 0.005) for PL fraction. Contrary were those for LA (*n*-6 PUFA), HR were 0.64 (0.43–0.97, *P* for trend = 0.13) for CE fraction and 0.69 (0.45–1.05, *P* for trend = 0.24) for PL fraction. No associations of ω-3 and ω-6 polyunsaturated fatty acids with ischemic stroke

Simon et al. (1995)	The Multiple Risk Factor Intervention Trial (MRFIT)	96 men with incident stroke and 96 control subjects	35–57 years	Nested case-control	6.9 years	Serum fatty acids	Matched by age, clinical center, treatment group, and date of randomization and further adjusted for plasma cholesterol level, diastolic blood pressure, and cigarette smoking	1 SD increase in ALA was associated with 37% decrease in the risk of stroke ($P < .05$).
Chowdhury et al. (2012)		794,000 subjects of 26 prospective cohort studies and 12 RCT published until September 2012.	Meta-analysis		Fish consumption and ώ 3 fatty acids.	The pooled RR for cerebrovascular disease in the highest versus lowest tertiles of dietary ώ 3 FA and serum ώ 3 FA concentrations were 0.1.04 (0.90–1.20) and 1.04 (0.89–1.08). In RCT, the RR for cerebrovascular disease in the ώ 3 FA supplement compared with the control group in primary prevention trials was 0.98 (0.89–1.08) and in secondary prevention trials was 1.17 (0.99–1.38).		
Wang et al. (2006)		347,747 subjects Primary CVD prevention reported in 1 RCT, in 25 prospective cohort studies, and for secondary CVD prevention reported in 14 RCT, in 1 prospective cohort study.	Systematic review		Fish or *n*-3 fatty acids intakes.	Trials: fish oil significantly reduced all-cause mortality, myocardial infarction, cardiac and sudden death, and stroke, with benefits of fish oil stronger in secondary than in primary prevention. Cohort studies: fish consumption was associated with lower rates of all-cause mortality and adverse cardiac outcomes. The effects on stroke were inconsistent. *n*-3 FAs from fish or fish-oil supplements, but not of-linolenic acid, reduced the rates of all-cause mortality, cardiac and sudden death, and possibly stroke.		

Table 3 Associations of dietary fat intake and serum fatty acids levels with risk of coronary heart disease

Published year/ ref no	*Study/cohort name*	*Sample size/study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/ outcome*	*Adjusted variables*	*Results*
Oomen et al. (2001)	The Zutphen elderly study	667 men	64–84 years	Prospective cohort	10 years	Trans fat intake via dietary survey	Age, intake of energy, BMI, smoking, alcohol intake, use of vitamin supplements, intake of SFA, MUFA, PUFA and cholesterol and for fibre.	Positive association; RR for a difference of 2% of E in trans fatty acid intake at baseline was 1.28 (95%CI 1.01–1.61) with a RR of 1.33 (95%CI 0.96–1.86) for fatal CHD. RR in highest tertile ($\geq$4.86%E) versus lowest tertile ($<$3.11%E) of trans fat intake was 2.00 (1.07–3.75; *P*-trend = 0.03).
Leosdottir et al. (2007)	The Malmö Diet and Cancer Study	28,098 (61% women)	Middle aged	Prospective cohort	8.4 years	Intakes of fat via FFQ	Age, smoking habits, alcohol consumption, socio-economic status, marital status, physical activity, BMI, fibre intake, blood pressure, total fat intake for the ratio between unsaturated- and saturated fats.	HRs of acute CHD in the highest quartile of intakes among men were 0.77 for total fat, 0.81 for SFA, 1.06 for MUFA and 1.16 for PUFA and among women were 0.99, 1.02, 0.87, and 1.20, respectively. No significant associations in multivariable model
Yamagishi et al. (2013a)	The Japan Public Health Center-based prospective Study	38,084 Japanese men and 43,847 women	45–74	Prospective cohort	11.1 years	Dietary SFAs via FFQ	Age; sex; energy intake; cohort; cigarette smoking status; alcohol intake; body mass index; sports at leisure time; walking and standing time; perceived mental stress; energy-adjusted dietary intakes of carbohydrate, protein, cholesterol, vegetables, fruit, and calcium.	SFAs intake was positively associated with myocardial Infarction; HR 1.39 (0.93–2.08), trend *P* = 0.046.
Yamagishi et al. (2010)	The Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	58,453 Japanese men and women	40–79 years	Prospective cohort	14.1 years	Intakes of SFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, *n*-3 and *n*-6 polyunsaturated fatty acids, vegetables, and fruits	RR for CHD and myocardial infarction mortality were 0.93 (0.65–1.35; *P*-trend = 0.86) and 0.85 (0.56–1.29; *P*-trend = 0.40), respectively
Laaksonen et al. (2005)	The Kuopio Ischaemic Heart Disease Risk Factor (KIHD) Study	1551 men	50–79 years	Prospective cohort	15 years	dietary linoleic and total polyunsaturated fatty acid (PUFA) intake via 4-d DR	Age, year of examination, smoking, alcohol intake, adult socioeconomic status, vigorous physical activity, plasma lipid-standardized αtocopherol levels, plasma ascorbic acid level, and dietary total energy, energy-adjusted SFA and fiber intakes, LDL-cholesterol levels, fasting concentrations of insulin and nonesterified fatty acids and BMI.	HR of CVD death were 0.16 (0.23–0.91, *P* = 0.03) for LA, 0.63 (0.33–1.21, *P* = 0.18) for ALA and 0.45 (0.23–0.90, *P* = 0.02) for dietary PUFA intake.

Yamagishi et al. (2008a)	The Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	57,972 Japanese men and women	40–79 years	Prospective cohort	12.7 years	Intakes of fish and *n*-3 PUFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, and *n*-6 PUFA vegetables, and fruits	RR for CHD and myocardial infarction mortality were 0.86 (0.62–1.19; *P*-trend = 0.41) and 0.77 (0.53–1.10; *P*-trend = 0.22), respectively in highest versus lowest quintiles of fish intake, and were 0.95 (0.62–1.43; *P*-trend = 0.58) and 0.75 (0.47–1.19; *P*-trend = 0.14), respectively in highest versus lowest quintiles of *n*-3 PUFA intake.
Siri-Tarino et al. (2010)		347,747 subjects of 21 prospective cohort studies published until September 2009.		Meta-analysis	5–23 years	Saturated fat intake		The pooled relative risk estimates that compared extreme quantiles of saturated fat intake were 1.07 (95%CI: 0.96, 1.19; *P* = 0.22) for CHD, 0.81 (95%CI: 0.62, 1.05; *P* = 0.11) for stroke, and 1.00 (95% CI: 0.89, 1.11; *P* = 0.95) for CVD. None was significant
de Souza et al. (2015)		347,747 subjects of prospective cohort, case-control, nested case-control, or case-cohort studies published until May 2015.	Meta-analysis		SFA and trans fat intakes	With SFA, RR were 0.97 (0.84–1.12) for CVD mortality, 1.15 (0.97–1.36) CHD mortality, 1.06 (0.95–1.17) incident total CHD, 1.02 (0.90–1.15) incident ischemic stroke, and 0.95 (0.88–1.03) for type 2 diabetes. With total trans fat intake RR were (1.28, 1.09–1.50) for CHD mortality, and 1.21 (1.10–1.33) for total incident CHD but were 1.07 (0.88–1.28) for ischemic stroke and 1.10 (0.95–1.27) for type 2 diabetes	
Schwingshackl and Hoffmann (2014)		32 cohort studies (42 reports) of 841,211 subjects	A systematic review and meta-analysis Literature until June 2nd, 2014		MUFA (of both plant and animal origin), olive oil, oleic acid, and MUFA: SFA ratio	High MUFA was not associated CHD; a pooled RR of 0.96, (0.90–1.01, *P* = 0.13).		
de Oliveira Otto et al. (2013)	The Multi-Ethnic Study of Atherosclerosis (MESA)	2837 US adults	45–84 years	Prospective cohort	10 years	Dairy phospholipid fatty acids including 15:0, 14:0, and trans-16:1*n*7	Age, sex, race/ethnicity, field center, education, cigarette smoking, alcohol, physical activity, intakes of whole-fat dairy, processed and unprocessed meat, total energy, fiber, and fruits and vegetables, and mutually for each dairy fat biomarker (14:0, 15:0, and trans-16:1*n*7).	Each SD-unit of 15:0 was associated with 26% lower CHD risk; RR 0.74 (0.60–0.92).
Esrey et al. (1996))	The Lipid Research Clinics Prevalence Follow-Up Study (LRC)	4546 North American men and women	≥30 years	Prospective cohort	12 years	%E of total fat, SFA, MUFA, PUFA via 24-h DR.	Abstract. No data on confounder full text needed	Among 30–59 year olds RR of CHD mortality with increasing %E intake were 1.04 (1.01–1.08) for total fat, 1.11 (1.04–1.18) for SFA, 1.08 (1.01–1.16) for MUFA and 0.96 (0.94–0.99) for carbohydrate. None of the dietary components were significantly associated with CHD mortality among those aged 60–79 years.

McGee et al. (1984	The Honolulu Heart Program	8000 men of Japanese ancestry	≥30 years	Prospective cohort	10years	%E from macronutrients.	Age, systolic blood pressure, serum cholesterol, cigarettes smoked per day, and physical activity index, carbohydrates, vegetable protein, %E sFA, and %E PUFA	Men who developed CHD also had a higher mean intake of %E from protein, total fat, SFA and PUFA than men who remained free of coronary heart disease. The associations with %E SFA and %E PUFA lost significance in multivariate model.
Kushi et al. (1985)	The Honolulu Heart Program	1001 men of Japanese ancestry	≥30 years	Prospective cohort	20 years	Key and modified Hegsted dietary scores.	Abstract. No data on confounder full text needed	A higher Keys score (a high score indicates a high intake of SFA and cholesterol and a relatively low intake of PUFA) associated with an increased risk of CHD; RR = 1.60.
Shekelle et al. (1981)	The Western Electric study	1900 men	Middle-aged	Prospective cohort	20years	Serum cholesterol and SFA, PUFA intake via Key and modified Hegsted dietary scores.	Abstract. No data on confounder full text needed	Positive association between diet score and serum cholesterol concentration, and a positive association prospectively between mean base-line diet score and the 20-year risk of death from CHD
Ascherio et al. (1996)	Framingham Heart Study	43,757 men	40–75 years.	Prospective cohort	6 years	Intakes of total fat, SFA, cholesterol, LA, ALA and trans fat via FFQ.	Age; BMI; smoking habits; alcohol consumption; physical activity; history of hypertension or high blood cholesterol; family history of myocardial infarction before age 60; profession, fibre intake and for energy.	R for fatal CHD were 2.21 (1.38–3.54) and 1.78 (1.11–2.84) in the highest versus lowest quintile of SFA and trans fat intake. Adjustment for fiber intake attenuated the association greatly. RR for MI for a 1% increase in energy from ALA was 0.41 (0.21–0.80).
Hu et al. (1997)	Nurse Health Study	80,082 women	34–59 years	Prospective cohort	14 years	Intakes of total fat, SFA, MUFA, PUFA and trans via FFQ.	Age; time period; BMMI; cigarette smoking, menopausal status, parental history of myocardial infarction before 65 years of age; multivitamin use; vitamin E supplement use; alcohol consumption, history of hypertension; aspirin use, vigorous exercise, percentage of energy from protein; total energy intake and dietary cholesterol.	Compared with equivalent %E from carbohydrates, the RR for CHD were1.41 (0.97–1.41) for 5%E SFA, 1.93 (1.43–2.61) for 2%E trans fat, 0.81 (0.65–1.00) for 5%E MUFA, 0.62 (0.46–0.85) for 5%E PUFA and 1.02 (0.97–1.07) for 5%E total fat. Replacement of 5% E from saturated or 2% E from trans with equivalent %E from unsaturated fats was associated with 42% and 53% reduction in risk of CHD, respectively.
Hu et al. (1999)	Nurse Health Study	80,082 women	34–59 years	Prospective cohort	14 years	Intakes of short, medium and long chain SFA and PUFA/SFA ratio via FFQ.	Age; time period; BMMI; cigarette smoking, menopausal status, parental history of myocardial infarction before 65 years of age; multivitamin use; vitamin E supplement use; alcohol consumption,	Intakes of longer-chain SFA (12:0–18:0) but not short- to medium-chain SFA (4:0–10:0) were associated with the risk of CHD. The multivariate RR for a 1%E increase from stearic acid was 1.19 (95%

(*Continued*)

Table 3 (Continued)

							history of hypertension; aspirin use, vigorous exercise, percentage of energy from protein; total energy intake and dietary cholesterol.	CI: 1.02, 1.37). The highest versus lowest deciles of PUFA/SFA ratio had a RR of 0.58 (0.41, 0.83; P for trend <0.0001).
Howard et al. (2006)	the Women's Health Initiative Randomized Controlled Dietary Modification Trial	48,835 postmenopausal women	50–79 years	Randomized controlled trial	8.1 years	Reduction of total fat intake from $\geq$32%E to $<$20% E		The dietary intervention had no significant effects; HR were 0.97 (0.90–1.06) for incident CHD; 1.02 (0.90–1.15) stroke and 0.98 (0.92–1.05) CVD. Trends toward greater reductions in CHD risk were observed in those with lowest intakes of SFA or trans fat; HR were 0.82 (0.67–0.99) and 0.84 (0.69–1.02), respectively.
Kromhout et al. (1995)	16 cohorts in seven countries.	12,763 men	middle-aged	case-control study.	25 years	Dietary SFA and trans fat via a FFQ.	Abstract. No data on confounder full text needed	Strong positive associations between CHD death and intakes of the four major SFAs, lauric, myristic, palmitic, and stearic acid ($r>0.8$, $P<0.001$); the trans fatty acid elaidic acid ($r=0.78$, $P<0.001$); and dietary cholesterol ($r=0.55$, $P<0.05$).
Jakobsen et al. (2009)		344,696 persons	$\geq$35 years	pooled analysis of 11 American and European cohort studies	4–10 years	Intakes of SFA, MUFA PUFA and carbohydrates via FFQ.	% E for intakes of MUFA, PUFA, trans fat, protein, and age, baseline year, total energy, smoking,BMI, physical activity, history of hypertension, alcohol intake, intakes of fiber and cholesterol.	For a 5% E lower from SFA, the HR for higher % E from PUFA was 0.87 (0.77, 0.97) for incident CHD and 0.74 (0.61, 0.89) for coronary deaths. For a 5% E lower from SFA, the HR for higher % E from carbohydrate was 1.07 (1.01, 1.14) for incident CHD and 0.96 (0.82, 1.13) for coronary deaths. MUFA intake was not associated with CHD. No effect modification by sex or age was found.
Oh et al. (2005)	Nurse Health Study	78,778 women	35–59 years	Prospective cohort	20 years	Intakes of total fat, SFA, MUFA PUFA and trans fat via FFQ.	Age, BMI, smoking, alcohol, intake, parental history of myocardial infarction, history of hypertension, menopausal status and hormone use, aspirin use, multivitamin use, vitamin E supplement use, physical activity, and energy, protein, cholesterol intake and intakes of SFA, MUFA, PUFA, and trans fat; LA; marine n-3fatty acids; cereal fiber; and fruits and vegetables.	RR for the highest versus. the lowest quintile were 0.75 (0.60, 0.92; $P=0.004$) for LA and 1.33 (1.07, 1.66; $P=0.01$) for trans fat. Total fat, SFA and MUFA intakes were not associated with risk of CHD.

Pietinen et al. (1997)	Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ABTC)	21,930 smoking men	50–69 years	Prospective cohort	6.1 years	Intakes of SFA, MUFA, PUFA, trans fat, cholesterol, LA, ALA and oleic acid via a FFQ.	Age, treatment group, smoking, BMI, blood pressure, intakes of energy, alcohol, and fiber, education, and physical activity.	RR of coronary death were 1.39 (1.09–1.78) for trans fat and 1.30 (1.01–1.67) for ώ-3 fatty acids. No associations between intakes of SFA, MUFA, LA, ALA or dietary cholesterol and the risk of coronary deaths. For major coronary events (first non-fatal MI), similar bur weaker associations were found.
Ascherio et al. (1994)		239 MI patients and 282 controls	<76 years	Case-control study		Fish consumption and ώ 3 fatty acids	Matched for age, sex and resident town and adjusted for smoking, history of hypertension, BMI, alcohol intake, family history of ischemic heart disease, and physical activity, intake of saturated fat, monounsaturated fat, linoleic acid, and cholesterol.	They reported as RR, I think it should be OR for highest versus lowest quintile of trans fat = 2.44; (1.42, 4.19; for trend $P < .0001$) for total subjects, 2.17 (1.11, 4.24; for trend $P = .001$) for men and 3.65 (0.90, 14.70; for trend $P = .02$) for women.
Dolecek (1992)	the Multiple Risk Factor Intervention Trial (MRFIT)	12,866 men	middle-aged	An intervention group and usual care group	10.5 years	Dietary PUFA measured by multiple DR.	Abstract. No data on confounder full text needed	No significant associations with mortality were detected for linoleic acid (18:2*n*-6), the predominant dietary PUFA.
Iso et al. (2006)	The Japan Public Health Center based Study (JPHC)	41,578 Japanese men and women	40–59 years	Prospective cohort	10 years	Fish and *n*-3 PUFA intakes via a FFQ.	Age, sex; smoking status; alcohol intake, BMI; history of hypertension or diabetes, medication use for hypercholesterolemia, education level, sports at leisure time, quintiles of dietary intake of fruits, vegetables, SFA, MUFA, n6 PUFA, cholesterol, and total energy; and public health area.	HR in the highest (180 g/d) versus lowest (23 g/d) quintiles of fish intake were 0.63 (0.38–1.04) for total CHD, 0.44 (0.24–0.81) for definite MI, and 1.14 (0.36–3.63) for sudden cardiac death. Mainly nonfatal coronary events (HR = 0.43 [0.23–0.81]) but not for fatal coronary events (HR = 1.08 [0.42–2.76]). Similar association with *n*-3 FA intake; HR were 0.35 (0.18–0.66) for definite MI and 0.33 (0.17–0.63) for nonfatal coronary events.
Li et al. (2015)	The Nurse Health Study	84,628 women	30–55 years	Prospective Cohort	24–30 years	Intakes of SFA, MUFA PUFA and carbohydrates via multiple FFQ.	Energy intake, the energy contribution from protein, cholesterol intake, alcohol intake, smoking status, BMI, physical activity, use of vitamins and aspirin, family history of MI and diabetes, and presence of baseline hypercholesterolemia and hypertension, dietary intake of fruits and vegetables, the percentage of energy from all fat types simultaneously.	HR was 0.80 (0.73–0.88; *P*-trend <0.0001) for high PUFA. Intake. Replacing 5%E from SFA with equivalent %E from PUFAs, MUFA, or carbohydrates from whole grains was associated with a 25%, 15%, and 9% lower risk of CHD, respectively Replacing SFA with carbohydrates from refined starches/added sugars was not significantly associated with CHD risk ($p > 0.10$).

Table 3 (Continued)

Published year/ ref no	*Study/cohort name*	*Sample size/study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/ outcome*	*Adjusted variables*	*Results*
Mozaffarian et al. (2010)		13,614 subjects of 54 RCT published until June 2009.		A meta-analysis		High intakes of PUFA as a replacement of SFA for at least 1 year.	The overall pooled risk reduction was 19%; RR = 0.81 (0.70–0.95, $P = 0.008$) which corresponds to 10% reduced CHD risk; RR = 0.90 (0.83–0.97) for each 5% E of increased PUFA	
Farvid et al. (2014)		310,602 individuals of 13 prospective cohort studies	>19 years	Systematic review and meta-analysis Literature until June, 2013		Intake of linoleic acid (LA)		A pooled RR of 0.85 (0.78–0.92, $P = 0.004$) for CHD events and 0.79 (0.71–0.89, $P = 0.001$) for CHD deaths.
Chowdhury et al. (2014)		32 observational studies (530,525 participants) of fatty acids from dietary intake; 17 observational studies (25,721 participants) of fatty acid biomarkers; and 27 randomized, controlled trials (103,052 participants) of fatty acid supplementation.					RR in highest versus lowest tertiles of intakes for CHD were1.02 (0.97–1.07) for SFA, 0.99 (0.89–1.09) for MUFA, 0.93 (0.84–1.02) for *n*-3 PUFA, 1.01 (0.96 –1.07) for *n*-6PUFA, and 1.16 (1.06–1.27) for trans fatty acids. For circulating fatty acids were 1.06 (0.86–1.30), 1.06 (0.97–1.17), 0.84 (0.63–1.11), 0.94 (0.84–1.06), and 1.05 (0.76–1.44), respectively. For Supplementations were 0.97 (0.69–1.36) for α-linolenic, 0.94 (0.86–1.03) for *n*-3 PUFA, and 0.89 (0.71–1.12) for *n*-6 PUFA.	
Sun et al. (2007b)	The Nurses' Health Study	166 cases and 327 controls from 32,826 participants	30–55 years	Case-control study.	6 years	Plasma and erythrocyte dairy fatty acids Trans fatty acids in plasma or erythrocyte	Matched for age at blood draw, smoking status, fasting status and time of blood draw, and adjusted further for BMI, postmenopausal status, postmenopausal hormone use, physical activity, alcohol intake, aspirin intake, parental history of MI before age 65y, history of hypertension, diabetes and hypercholesterolemia, and linoleic acid and total	RR in the highest versus lowest tertile of 15:0 concentrations in plasma was 2.36 (1.16–4.78; *P*-trend = 0.03).
Sun et al. (2007c)	The Nurses' Health Study	166 cases and 327 controls from 32,826 participants	30–55 years	Case-control study.	6 years	Plasma and erythrocyte fatty acids Trans fatty acids in plasma or erythrocyte	Matched for age at blood draw, smoking status, fasting status and time of blood draw, and adjusted further for BMI, postmenopausal status, postmenopausal hormone use, physical activity, alcohol intake, aspirin intake, parental history of MI before age 65y, history of hypertension, diabetes and hypercholesterolemia, and linoleic acid and total	RR in the highest versus lowest quartiles of erythrocyte trans fatty acids concentrations was 3.3 (1.50–7.20; *P*-trend = < 0.01).
Aro et al. (1995)		671 men with acute MI and 717 controls	≤70 years	case-control study		Adipose tissue FA, mainly trans isomer (C18:1)	Age, centre, smoking, and BMI, socioeconomic status	The risk of acute MI did not differ significantly across quartiles of adipose C18:1 trans FA: OR in the highest versus lowest quartile = 0.97 (0.56–1.67).

Wang et al. (2003)	The Atherosclerosis Risk in Communities (ARIC) Study	3591 participants	45–64 years	Prospective cohort	10.7 years	Plasma cholesterol ester (CE) and phospholipid (PL) fatty acid composition	Age, sex, smoking status, alcohol intake, sports index, special diet, dietary cholesterol, percentage of energy intake from fat	RR of CHD for the highest versus lowest quintile were 1.42 (*P*-trend: 0.026) for CE SFAs, 1.31 in CE and 1.44 in PL for dihomo-γ-linolenic acid (*P*-trend: 0.05 and 0.017, respectively), 0.59 in CE and 0.65 in PL for arachidonic acid (p: 0.016 and 0.024, respectively) No association with total MUFAs, total PUFAs, *n*-3 PUFAs, or *n*-6 PUFAs.
Wu et al. (2013)	The health professionals follow-up study	459 CHD cases and 879 matched controls	40–75 years	Case-control study	1993–1995–2008	Lipophilic index (LI) by summing the products between FA levels and melting point of each FA	Matched for age and smoking status, and further adjusted for alcohol intake, physical activity, family history of MI, history of hypertension, history of hypercholesterolemia, aspirin use, cholesterol-lowering medication use, antihypertensive medication use, alternative healthy eating index and BMI.	RR in highest versus lowest quintiles was 1.61 (1.03–2.53; *P*–trend = 0.04)
Harris et al. (2007)		25 prospective cohort and case control studies published from 1996 until 2005.	Meta-analysis		Tissue fatty acids composition	Lower LA content was associated with increased risk for non-fatal events. Tissue proportions of DHA (with or without EPA) were significantly reduced in the cases. Both LA and ALA tended ($P = 0.02$) to be depressed in cases In non-fatal endpoint studies, only LA was significantly associated with case status. While in In the fatal endpoint studies, reduced EPA + DHA and DHA alone were both significantly associated with case status.	
Mozaffarian and Rimm (2006)	Systematic review and meta-analysis published through April 2006				Fish intake	Modest consumption of fish (eg, 1–2 servings/wk), higher in the *n*-3 PUFA, and EPA and DHA, associated with reduced risk of coronary death by 36% (20%–50%; $P < .001$).		
Whelton et al. (2004)		19 observational studies (14 cohort and 5 case-control)	Meta-analysis of data published before May 2003		consumption of fish	RR of total and fatal CHD in fish consumers versus non consumers were 0.86 (0.81–0.92; $p < 0.005$) and 83 (0.76–0.90; $p < 0.005$), respectively		
He et al. (2004)		222,364 individuals of 11 studies	Meta-analysis of data published before May 2003	11.8 years	consumption of fish	Compared with nonconsumers, the pooled RR of CHD mortality were 0.89 (0.79–1.01) for fish intake 1–3 times per month, 0.85 (0.76–0.96) for once per week, 0.77 (0.66–0.89) for 2–4 times per week, and 0.62 (0.46–0.82) for 5 or more times per week.

Table 3 (Continued)

Published year/ ref no	*Study/cohort name*	*Sample size/study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/ outcome*	*Adjusted variables*	*Results*
Eshak et al. (2014)	The Japan Public Health Center-based prospective Study	72,012 Japanese men and women	45–74 years	Prospective cohort	15 years	Smoking status and seafood/ fish intakes via 2 FFQ 5 y apart.	Age; sex; public health center; alcohol intake, BMI; histories of hypertension and diabetes; medication use for hypercholesterolemia; sports during leisure time; and quintiles of dietary intake of fruits, vegetables, SFA, MUFA, *n*-6 PUFA, cholesterol, and total energy.	Compared with never smokers, HR in light and moderate smokers were 2.39 (1.60, 3.56) and 2.74 (1.90, 3.95) among low seafood/fish eaters; whereas among high seafood/fish eaters were 1.13 (0.64, 1.99) and 1.29 (0.95, 2.04), respectively. Compared with heavy smokers with a low seafood/fish intake, light smokers with a high seafood/fish intake had substantially reduced risk of CHD; HR = 0.57 (0.32, 0.98).
Chowdhury et al. (2012)	The Caerphilly cohort	347,747 subjects		Systematic review	18 years	Fish or *n*-3 fatty acids intakes.	Trials: fish oil significantly reduced all-cause mortality, myocardial infarction, cardiac and sudden death, and stroke, with benefits of fish oil stronger in secondary than in primary prevention. Primary CVD prevention reported in 1 RCT, in 25 prospective cohort studies, and for secondary CVD prevention reported in 14 RCT, in 1 prospective cohort study. Cohort studies: fish consumption was associated with lower rates of all-cause mortality and adverse cardiac outcomes. The effects on stroke were inconsistent. *n*-3 FAs from fish or fish-oil supplements, but not of-linolenic acid, reduced the rates of all-cause mortality, cardiac and sudden death, and possibly stroke.	

Table 4 Associations of dietary fat intake and serum fatty acids levels with risk of other and total cardiovascular disease

Published year/ ref no	*Study/cohort name*	*Sample size/study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/outcome*	*Adjusted variables*	*Results*
Tanasescu et al. (2004)	The Nurses' Health Study	5672 women with type 2 diabetes	30–55 years	Prospective cohort	1980–1998	Intakes of fat via FFQ	Age, smoking, postmenopausal hormone use, parental history of myocardial infarction, alcohol intake, moderate/ vigorous activities, BMI, total caloric intake, protein intake, fiber intake, multivitamin use, vitamin E supplement use, and medication use.	RR of CVD were 1.37 (1.12–1.68; $P=0.003$) for an increase of 200 mg cholesterol/1000 kcal and 1.29 (1.02–1.63; $P=0.04$) for 5% of energy intake from saturated fat
Leosdottir et al. (2007)	The Malmö Diet and Cancer Study	28,098 (61% women)	Middle aged	Prospective cohort	8.4 years	Intakes of fat via FFQ	Age, smoking habits, alcohol consumption, socio-economic status, marital status, physical activity, BMI, fibre intake, blood pressure, total fat intake for the ratio between unsaturated- and saturated fats.	No significant associations in multivariable model between total fat, SFA, MUFA and PUFA with CVD events.
Yamagishi et al. (2013a)	The Japan Public Health Center-based prospective Study	38,084 Japanese men and 43,847 women	45–74	Prospective cohort	11.1 years	Dietary SFAs via FFQ	Age; sex; energy intake; cohort; cigarette smoking status; alcohol intake; body mass index; sports at leisure time; walking and standing time; perceived mental stress; energy-adjusted dietary intakes of carbohydrate, protein, cholesterol, vegetables, fruit, and calcium.	HR for total CVD in the highest SFA intake was 0.82 (0.69–0.96; $P=0.01$).
Yamagishi et al. (2010)	the Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	58,453 Japanese men and women	40–79 years	Prospective cohort	14.1 years	Intakes of SFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, *n*-3 and *n*-6 PUFA, vegetables, and fruits	RR for heart failure, cardiac arrest and total CVD mortality were 0.99 (0.64–1.52; *P*-trend = 0.83), 0.50 (0.23–1.10; *P*-trend = 0.11) and 0.82 (0.69–0.97; *P*-trend = 0.05), respectively
Guasch-Ferré et al. (2014)	The PREvención con DIeta MEDiterránea (PREDIMED) study	7216 men and women	55–80 years	Prospective cohort	4.8 years	Olive oil consumption via FFQ	Age, sex, intervention group, BMI, smoking status, alcohol intake, educational level, leisure time physical activity, prevalence of diabetes, hypertension, and hypercholesterolemia, use of antihypertensive medication, use of statins. And Mediterranean diet adherence	RR in highest versus lowest tertiles of total olive intakes were 0.65 (0.47–0.89) for incident CVD and 0.52 (0.29–0.93) for total CVD mortality

Laaksonen et al. (2005)	The Kuopio Ischaemic Heart Disease Risk Factor (KIHD) Study	1551 men	50–79 years	Prospective cohort	15 years	Dietary linoleic and total polyunsaturated fatty acid (PUFA) intake via 4-d DR	Age, year of examination, smoking, alcohol intake, adult socioeconomic status, vigorous physical activity, plasma lipid-standardized αtocopherol levels, plasma ascorbic acid level, and dietary total energy, energy-adjusted SFA and fiber intakes, LDL-cholesterol levels, fasting concentrations of insulin and nonesterified fatty acids and BMI.	HR of CVD death were 0.16 (0.23–0.91, $P=0.03$) for LA, 0.63 (0.33–1.21, $P=0.18$) for ALA and 0.45 (0.23–0.90, $P=0.02$) for dietary PUFA intake.
Yamagishi et al. (2008a)	The Japan Collaborative Cohort Study for Evaluation of Cancer Risk (JACC) Study	57,972 Japanese men and women	40–79 years	Prospective cohort	12.7 years	Intakes of fish and *n*-3 PUFA via FFQ	Age, sex, a history of hypertension and diabetes, smoking status, alcohol consumption, BMI, mental stress, walking, sports, educational level, and dietary intakes of total energy, cholesterol, and *n*-6 PUFA vegetables, and fruits	RR for heart failure, cardiac arrest and total CVD mortality were 0.76 (0.53–1.09; *P*-trend = 0.10), 0.73 (0.36–1.46; *P*-trend = 0.16) and 0.82 (0.71–0.95; *P*-trend = 0.007), respectively in highest versus lowest quintiles of fish intake, and were 0.58 (0.36–0.93; *P*-trend = 0.03) and 0.81 (0.67–0.98; *P*-trend = 0.01), respectively in highest versus lowest quintiles of *n*-3 PUFA intake.
Siri-Tarino et al. (2010)		347,747 subjects of 21 prospective cohort studies published until September 2009.		Meta-analysis	5–23 years	Saturated fat intake		The pooled relative risk estimates that compared extreme quantiles of saturated fat intake were 1.07 (95%CI: 0.96, 1.19; $P=0.22$) for CHD, 0.81 (95%CI: 0.62, 1.05; $P=0.11$) for stroke, and 1.00 (95%CI: 0.89, 1.11; $P=0.95$) for CVD. None was significant
de Souza et al. (2015)		347,747 subjects of prospective cohort, case-control, nested case-control, or case-cohort studies published until May 2015.		Meta-analysis		SFA and trans fat intakes	With SFA, RR were 0.97 (0.84–1.12) for CVD mortality, 1.15 (0.97–1.36) CHD mortality, 1.06 (0.95–1.17) incident total CHD, 1.02 (0.90–1.15) incident ischemic stroke, and 0.95 (0.88–1.03) for type 2 diabetes. With total trans fat intake RR were (1.28, 1.09–1.50) for CHD mortality, and 1.21 (1.10–1.33) for total incident CHD but were 1.07 (0.88–1.28) for ischemic stroke and 1.10 (0.95–1.27) for type 2 diabetes	
Schwingshackl and Hoffmann (2014)		32 cohort studies (42 reports) of 841,211 subjects		A systematic review and meta-analysis Literature until June 2nd, 2014		MUFA (of both plant and animal origin), olive oil, oleic acid, and MUFA:SFA ratio		A pooled RR of 0.88 (0.80–0.96, $P=0.004$) for CVD mortality and 0.91 (0.86–0.96, $P=0.001$) for CVD events.

Marik and Varon (2009)		39,044 patients of 11 Prospective, randomized, placebo-controlled clinical trials		Systematic review	15.5 years	Dietary supplements of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)	OR with *n*-3 fatty acids supplements were 0.87 (0.79–0.95, $P=0.002$) for CVD death, 0.87 (0.76–0.99, $P=0.04$) sudden cardiac and 0.92 (0.85–0.99, $P=0.02$) for nonfatal cardiovascular events.	
Woodward et al. (2011)	The Scottish Heart Health Extended Cohort Study	3944 participants	40–59 years	Prospective cohort	19.5 years	Adipose tissue fatty acids by gas chromatography.	Age, sex, total and HDL-cholesterol, systolic blood pressure, smoking, hypertensive medication use, diabetes, socio-economic status and family history.	RR for incident CVD in highest versus lowest quartiles were 1.29 (1.05–1.59; *P*-trend0.004) for adipose MUFA and 0.77 (0.63–0.94; *P*-trend–0.01) for adipose *n*-3 PUFA. No associations with adipose SFA or *n*-6 PUFA.
Warensjö et al. (2008)	The Uppsala Longitudinal Study of Adult Men (ULSAM)	1885 men	50 years	Prospective cohort	3.7 years	Dietary fat biomarkers	Total cholesterol, BMI, smoking, physical activity, and hypertension.	RR for CVD mortality with higher serum concentrations of myristic acid (14:0), palmitic acid (16:0), palmitoleic acid (16:1) and LA (18:2*n*-6) were 1.12 (1.02–1.23), 1.15 (1.04–1.26), 1.18 (1.07–1.30) and 0.85 (0.78–0.94), respetively
de Oliveira Otto et al. (2013)	The Multi-Ethnic Study of Atherosclerosis (MESA)	2837 US adults	45–84 years	Prospective cohort	10 years	Dairy phospholipid fatty acids including 15:0, 14:0, and trans-16:1*n*7	Age, sex, race/ethnicity, field center, education, cigarette smoking, alcohol, physical activity, intakes of whole-fat dairy, processed and unprocessed meat, total energy, fiber, and fruits and vegetables, and mutually for each dairy fat biomarker (14:0, 15:0, and trans-16:1*n*7).	Each SD-unit of 15:0 was associated with 19% lower CVD risk; RR 0.81 (0.68–0.98).
Howard et al. (2006)	The Women's Health Initiative Randomized Controlled Dietary Modification Trial	48,835 postmenopausal women	50–79 years	Randomized controlled trial	8.1 years	reduction of total fat intake from $\geq$32%E to <20% E		The dietary intervention had no significant effects; HR were 0.97 (0.90–1.06) for incident CHD; 1.02 (0.90–1.15) for stroke and 0.98 (0.92–1.05) for CVD.
Nettleton et al. (2008)	The Atherosclerosis Risk in Communities (ARIC) study	14,153 participants	45–64 years	Prospective cohort	13 years	Whole grain, Egg and dairy fat intakes via FFQ	Energy intake, age, sex, race/center, education level, physical activity level, smoking and drinking status, and prevalent disease status: cardiovascular disease, diabetes, and hypertension.	RR of heart failure with higher egg intake was 1.23 (1.08–1.41) and with high-fat dairy was 1.08 (1.01, 1.16)
Mozaffarian et al. (2005a)		4738 adults	$\geq$65 years	Prospective cohort	12 years	Intakes of baked/broiled fish, fried fish via FFQ	Age, gender, race, enrollment site, education, diabetes, BMI, prevalent CHD, prevalent stroke/transient ischemic attack, total caloric intake, intake of either fried fish or tuna/other fish, smoking, leisure-time physical activity, and intakes of SFA, fruits, vegetables, and alcohol.	RR of heart failure in the highest ($\geq$5 times/week) versus lowest (<once monthly) of tuna/other fish intake was 0.68 (0.45–1.03).

(*Continued*)

Table 4 (Continued)

Published year/ ref no	*Study/cohort name*	*Sample size/study population*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure measures/outcome*	*Adjusted variables*	*Results*
Belin et al. (2011)	The Women's Health Initiative study	84, 493 women	50–79 years	Prospective cohort	10 years	Intakes of baked/broiled fish, fried fish, and omega-3 fatty acid (eicosapentaenoic acid + docosahexaenoic acid, α-linolenic acid), and trans-fatty via FFQ	Age, ethnicity, education, physical activity, smoking, alcohol, diabetes, hypertension, atrial fibrillation, MI/ coronary artery bypass graft/ percutaneous transluminal coronary angioplasty, BMI, time-dependent MI, fiber, fruit/vegetable servings, fried fish servings, SFA intake (%), DHA + EPA (%), ALA (%), LA (%), fried food servings, and sodium intake (mg).	RR of heart failure in the highest (≥5 times/week) versus lowest (<once monthly) of Baked/broiled fish intake was 0.70 (0.51–0.95). No significant associations were found between EPA + DHA, ALA, or trans-fatty acid intake and incident HF.
Dijkstra et al. (2009)	The Rotterdam Study	5299 subjects	Mean age 68 years	Prospective cohort	11.4 years	Fish or its *n*-3 fatty acids, 0045PA plus DHA	Age, sex, total energy intake, smoking, BMI, education, and intake of alcohol, fat, saturated fat, trans-fat and meat.	RR of heart failure in the highest versus lowest quintiles of EPA plus DHA intake was 1.00 (0.73–1.36) in men and 0.75 (0.54–1.04) in women. For fish intakes ≥20 g/day, the RR was 0.96 (0.78–1.18) compared with no fish intake.
Levitan et al. (2009)	The Cohort of Swedish Men	39,367 men	45–79 years	Prospective cohort	7 years	Fatty fish and marine omega-3 fatty acids via FFQ	Age, BMI, physical activity, energy, alcohol, fibre, sodium, and red or processed meat consumption, education, family history of myocardial infarction at <60 years, cigarette smoking, marital status, self-reported history of hypertension, and high cholesterol.	RR of heart failure in the moderate (1 time/week) and the highest (≥3 times/week) versus lowest (none) of fatty fish intake was 0.76 (0.60–0.97) and 0.97 (0.61–1.55), respectively. RR in the third and highest versus lowest quintiles of *n*-3 fatty acids intake were 0.67 (0.50–0.90) and 1.00 (0.77–1.29), respectively.
Levitan et al. (2010)	The Swedish Mammography Cohort	36,234 women	48–83 years	Prospective cohort	9 years	Fatty fish and marine omega-3 fatty acids via FFQ	Age, education, BMI, physical activity, cigarette smoking, living alone, postmenopausal hormone use, total energy intake, alcohol intake, fiber intake, sodium intake, intake of red or processed meat, family history of myocardial infarction before 60 years, self-reported history of hypertension, self-reported history of high cholesterol.	RR of heart failure in the moderate (2 time/week) and the highest (≥3 times/week) versus lowest (none) of fatty fish intake was 0.70 (0.53–0.94) and 0.91 (0.0.59–1.40), respectively. RR in highest versus lowest quintiles of *n*-3 fatty acids intake was 0.75 (0.58–0.96).

Djoussé et al. (2012)	176,441 subjects from 7 prospective studies			Meta-analysis Literature until August 31, 2011		Fish and marine omega-3 fatty acids	A pooled RR of heart failure in the highest versus lowest category of fish intake was 0.85 (0.73–0.99, $P = 0.04$), corresponding value for marine *n*-3 fatty acids was 0.86 (0.74–1.00, $P = 0.05$).	
Yamagishi et al. (2008b)	The Atherosclerosis Risk in Communities (ARIC) Study	15,792 persons	45–64 years	Prospective cohort	13 years	Plasma fatty acid composition	Age, sex, BMI, SBP, antihypertensive medication use, plasma total and high-density lipoprotein (HDL)-cholesterols, prevalent diabetes, smoking status, alcohol intake, sports index, education level.	RR of heart failure was 2.71 (1.64–4.45) for myristic acid, 14:0. For women only, AA 0.38 (0.16–0.91) and DHA 0.16 (0.07–0.40) associated inversely with heart failure risk.
Wang et al. (2006)	The Caerphilly cohort	347,747 subjects Primary CVD prevention reported in 1 RCT, in 25 prospective cohort studies, and for secondary CVD prevention reported in 14 RCT, in 1 prospective cohort study.		Systematic review	18 years	Fish or *n*-3 fatty acids intakes.	Trials: fish oil significantly reduced all-cause mortality, myocardial infarction, cardiac and sudden death, and stroke, with benefits of fish oil stronger in secondary than in primary prevention. Cohort studies: fish consumption was associated with lower rates of all-cause mortality and adverse cardiac outcomes. The effects on stroke were inconsistent. *n*-3 FAs from fish or fish-oil supplements, but not of-linolenic acid, reduced the rates of all-cause mortality, cardiac and sudden death, and possibly stroke.	

For risk of ischemic stroke, some studies reported inverse associations with intakes of total fat (Gillman et al., 1997; Sauvaget et al., 2004; Seino et al., 1997), SFA (Tanasescu et al., 2004; Yamagishi et al., 2013a; Gillman et al., 1997; Seino et al., 1997), MUFA (Gillman et al., 1997), and PUFA (Iso et al., 2001a; He et al., 2002); others reported no association with intakes of total fat (Leosdottir et al., 2007; He et al., 2003), SFA (Leosdottir et al., 2007; He et al., 2003; Seino et al., 1997; Yaemsiri et al., 2012), MUFA (Leosdottir et al., 2007; He et al., 2002, 2003; Sauvaget et al., 2004), PUFA (Leosdottir et al., 2007; Yamagishi et al., 2008a; He et al., 2003; Gillman et al., 1997; Sauvaget et al., 2004; Yaemsiri et al., 2012), or trans fat (He et al., 2003), while some other studies reported positive associations with intakes of total fat (Boden-Albala et al., 2009), PUFA (Seino et al., 1997), and trans fat (Kiage et al., 2014; Yaemsiri et al., 2012).

For risk of hemorrhagic stroke (intraparenchymal hemorrhage), some studies reported inverse associations with intakes of total fat (Iso et al., 2003), SFA (Tanasescu et al., 2004; Yamagishi et al., 2013a; Iso et al., 2001b, 2003), and trans fat (Boden-Albala et al., 2009); others reported no association with intakes of total fat (He et al., 2003; Gillman et al., 1997; Iso et al., 2001b), SFA (He et al., 2003; Gillman et al., 1997), MUFA (He et al., 2003; Gillman et al., 1997; Iso et al., 2001b, 2003), PUFA (Yamagishi et al., 2008a; Iso et al., 2001a,b, 2003; He et al., 2003; Gillman et al., 1997), or trans fat (He et al., 2003), while no studies, so far, reported positive associations between intakes of dietary fat and risk of hemorrhagic stroke.

The associations of circulating biomarkers of fatty acids with risk of stroke were much easier to understand than those with dietary fatty acids intake. In one hand, the associations with hemorrhagic stroke were reported in only two studies and there were no associations with serum levels of fatty acids (Yakoob et al., 2014; Wiberg et al., 2006). On the other hand, risk of ischemic stroke associated positively with serum levels of SFA (Wiberg et al., 2006; Iso et al., 2002; Yaemsiri et al., 2013; Yamagishi et al., 2013b), MUFA (Wiberg et al., 2006; Yaemsiri et al., 2013; Yamagishi et al., 2013b), and trans fatty acids (Wiberg et al., 2006; Yaemsiri et al., 2013), but inversely associated with serum levels of *n*-3 and *n*-6 fatty acids, namely, with ALA (Simon et al., 1995), DPA and DHA (Yaemsiri et al., 2013), LA (Wiberg et al., 2006; Iso et al., 2002; Yaemsiri et al., 2013; Yamagishi et al., 2013b), and AA (Yaemsiri et al., 2013). High serum SFA, namely, stearic acid, was associated with increased risk of total stroke in one study (Simon et al., 1995); biomarkers for diary fat (C14:0, C15:0, C17:0, and trans 16:1*n*-7) were not associated with either ischemic or hemorrhagic stroke in one study (Yakoob et al., 2014), and *n*-3 and *n*-6 PUFA were not associated with risk of ischemic stroke in another study (Yamagishi et al., 2013b).

The mechanisms of associations between fat and risk of stroke seem to be affected by several factors which include the usual intake of fat and fatty acids in diet (very low intake versus usual or high intake) (Yamagishi et al., 2013a; Iso et al., 2001b, 2002, 2003), the method of calculating fat intake (gm/d versus percentage of total energy) (McGee et al., 1985), the prevalence of stroke and stroke subtypes in the population (McGee et al., 1985; Atkinson et al., 2011; Iso et al., 2001a,b, 2002, 2003; He et al., 2002, 2003; Kiage et al., 2014; Gillman et al., 1997; Sauvaget et al., 2004; Seino et al., 1997; Yaemsiri et al., 2012, 2013; Boden-Albala et al., 2009; Yakoob et al., 2014; Wiberg et al., 2006; Yamagishi et al., 2013b; Simon et al., 1995), the affected site of stroke (cortical or perforator's artery area) (Iso et al., 2001a,b, 2002; Yakoob et al., 2014; Wiberg et al., 2006; Yaemsiri et al., 2013; Yamagishi et al., 2013b), and by serum cholesterol levels (Leosdottir et al., 2007; Yamagishi et al., 2013a; McGee et al., 1985; Iso et al., 2001b, 2002, 2003; Simon et al., 1995; Atkins et al., 1993).

Dietary fat intakes and plasma fatty acids composition were also related to risk of other cardiovascular disease. SFA intake was not associated with mortality from heart failure or cardiac arrest (Tanasescu et al., 2004). Contrarily, *n*-3 PUFA supplementation was associated with decreased risk of sudden cardiac death (Marik and Varon, 2009); also, fish and *n*-3 PUFA intakes were inversely associated with risk of mortality from heart failure, but not with risk of mortality from cardiac arrest in another study (Yamagishi et al., 2008a). Incident heart failure was associated with intakes of egg and high fat diary, but not with fish intake (Nettleton et al., 2008); however, two studies have shown a decreased risk of incident heart failure with intakes of tuna and other boiled and backed fish, but not fried fish (Mozaffarian et al., 2005a; Belin et al., 2011). A high intake of fish and EPA plus DHA was associated with lower hear failure risk, especially in women (Dijkstra et al., 2009). Two Swedish studies showed that fatty fish rather than total fish intakes were associated with a decreased risk of heart failure in men (Levitan et al., 2009) and women (Levitan et al., 2010). In a meta-analysis, the pooled RR for heart failure in the highest versus lowest categories of fish and *n*-3 fatty acids intakes were 0.85 (0.73–0.99; *P*-trend = 0.04) and 0.86 (0.74–1.00; *P*-trend = 0.05), respectively (Djoussé et al., 2012). Higher plasma levels of SFA, especially myristic (14:0) acid, were associated positively with incident heart failure in men and women of the ARIC study, while higher AA (20:3, ω6) and long-chain *n*-3 PUFA, especially DHA (22:6,ω3), were associated inversely with heart failure in women but not in men (Yamagishi et al., 2008b).

Total Fat/SFA

Several studies confirmed that if total fat intakes exceeded 35% of total energy, it would be difficult to avoid high intakes of SFA. Since Keys' early findings of increased LDL-cholesterol concentrations with increasing total fat/SFA intake (Keys et al., 1957), many studies, based on the fact that high blood cholesterol is a strong risk factor of CVD (Prospective Studies Collaborations, 2007), have investigated the associations of total fat/SFA with risk of CVD (Tanasescu et al., 2004; Yamagishi et al., 2008a, 2013a; Esrey et al., 1996; McGee et al., 1984, 1985; Kushi et al., 1985; Shekelle et al., 1981; Ascherio et al., 1996; Hu et al., 1997, 1999; Howard et al., 2006; Kromhout et al., 1995; Jakobsen et al., 2009; He et al., 2003; Gillman et al., 1997; Seino et al., 1997; Iso et al., 2002, 2003; Yakoob et al., 2014; Wiberg et al., 2006; Yaemsiri et al., 2013; Yamagishi et al., 2013b), and regardless to the logic of beneficial impacts of reducing SFA intake on cardiovascular health, the evidence for a clear positive, independent association is lacking (Leosdottir et al., 2007; Siri-Tarino et al., 2010; de Souza et al., 2015; Hu et al., 1997; Howard et al., 2006; Oh et al., 2005; Pietinen

et al., 1997; Atkinson et al., 2011; He et al., 2003; Gillman et al., 1997; Seino et al., 1997; Yaemsiri et al., 2012; Iso et al., 2001b; Yakoob et al., 2014).

In men, there were no associations of total fat intakes with risk of CHD (Ascherio et al., 1996) or between total fat or specific fat subtypes and risk of stroke (Iso et al., 2002). While in women, two prospective studies (Hu et al., 1997; Oh et al., 2005) showed no association between intakes of total fat or SFA and risk of CHD; the first study (Oh et al., 2005) reported no association, while the second study (Hu et al., 1997) reported a positive association between SFA intake and risk of CHD, which appeared to be evident for only longer chain SFA (12–18 Carbon atoms), but not short to medium chain SFA (4–10 Carbon atoms) (Hu et al., 1999). As the strong positive association between total cholesterol and CHD was only observed among populations with high total cholesterol levels in the Seven Countries Study (Prospective Studies Collaborations, 2007), SFA-CHD association has been generally weak among Asian populations, given lower distribution of SFA consumption compared with Western populations. Only one study showed a positive association between SFA and CHD in Asia (Yamagishi et al., 2013a).

In some studies, total fat and SFA intakes were inversely associated with risk of ischemic (Yamagishi et al., 2010, 2013a; Gillman et al., 1997; Sauvaget et al., 2004; Seino et al., 1997) and hemorrhagic (Yamagishi et al., 2010, 2013a; Iso et al., 2001b, 2003) stroke, while other studies showed no association with either ischemic (Leosdottir et al., 2007; He et al., 2003; Yaemsiri et al., 2012) or hemorrhagic (He et al., 2003; Gillman et al., 1997; Iso et al., 2001b) stroke. Two meta-analyses of prospective cohort studies showed no significant associations of dietary total fat and SFA with an increased risk of CHD, stroke or total CVD (Siri-Tarino et al., 2010; de Souza et al., 2015). SFA intake was not associated with mortality from heart failure or cardiac arrest (Yamagishi et al., 2010), while plasma levels of SFA were positively associated with incident heart failure (Yamagishi et al., 2008b). In a randomized controlled trial of 48,835 postmenopausal women aged 50 to 79 years, a dietary intervention that reduced total fat intake and increased vegetables, fruit, and grain intakes did not reduce the risk of CHD, stroke, or total CVD in postmenopausal women (Howard et al., 2006).

MUFA

Intakes of MUFA and SFA are highly correlated in general; clinical trials with high MUFA diets showed no effect on blood pressure (Mutanen et al., 1992; Shah et al., 2007); however, a hypotensive effect was reported in one study (Ferrara et al., 2000). In a systematic review, a high MUFA diet showed favorable outcomes as regard metabolic syndrome and cardiovascular risk factors (Gillingham et al., 2011). In a meta-analysis of 60 randomized controlled trials, MUFA intake improved the metabolic profile with respect to total cholesterol, HDL-cholesterol, and triacylglycerol concentrations (Mensink et al., 2003). It is worth mentioning here that most of the favorable associations between MUFA and metabolic profile were evident when intakes of MUFA increased and SFA decreased.

Olive oil of Mediterranean diet as a surrogate of high MUFA intake was inversely associated with total CVD incidence and mortality (Guasch-Ferré et al., 2014). An inverse association was reported between MUFA intake and risk of CHD mortality in both men (Jakobsen et al., 2009) and women (Shekelle et al., 1981). Contrarily, one study reported a positive association between high MUFA intake and CHD mortality in men; however, the authors attributed that to a high correlation between MUFA and SFA in their analysis (Hegsted and Ausman, 1988). Some prospective studies could not find any associations between MUFA intake and risk of CHD (Oh et al., 2005) or risk of stroke (He et al., 2003). However, the analysis of other prospective cohort studies revealed an inverse association between dietary MUFA and CHD risk (RR = 0.81; 95%CI 0.68–0.93) (Gillingham et al., 2011). In a 14-year follow-up of women in the Nurses' Health Study, a 5% increase in energy intake from MUFA was associated with a relative risk of CHD of 0.81 (95%CI 0.65–1.00) (Hu et al., 1997). In some studies, MUFA intakes were inversely associated with risk of total (Schwingshackl and Hoffmann, 2014) and ischemic (Gillman et al., 1997) stroke, while other studies showed no association with either ischemic (Leosdottir et al., 2007; He et al., 2003; Sauvaget et al., 2004; Yaemsiri et al., 2012) or hemorrhagic (Iso et al., 2001a, b; He et al., 2003; Gillman et al., 1997) stroke. A systematic review of 32 cohort studies including 841,211 subjects showed a significant stroke risk reduction for the comparison of the top versus bottom thirds of MUFA intake (RR: 0.83, 95%CI 0.71, 0.97, $P = 0.02$) (Schwingshackl and Hoffmann, 2014).

n-3 PUFA

Fish or fish oil intake were widely used as a surrogate for *n*-3 PUFA intake in many epidemiological studies. Despite the growing evidence that dietary *n*-3 PUFA can reduce the risk of CHD, stroke, and heart failure, fish and n3 PUFA-CVD association has been considered generally nonlinear (Mozaffarian and Rimm, 2006); which explains why fish and n3 PUFA-CHD association was more evident in low-intake Western populations (Mozaffarian and Rimm, 2006; Whelton et al., 2004; He et al., 2004) than in high-intake populations like Japanese (Yamagishi et al., 2008a; Iso et al., 2006; Eshak et al., 2014). Most mortality studies (regardless in Western or Eastern populations) showed relatively weak or null associations between fish intake and risk of CHD (Yamagishi et al., 2008a; Mozaffarian and Rimm, 2006; Whelton et al., 2004; He et al., 2004). In Japanese populations, fish and *n*-3 fatty acids intakes showed nonsignificant inverse associations with CHD mortality (Yamagishi et al., 2008a) and a weak inverse association with risk of incident CHD, which was evident for nonfatal but not fatal CHD (Iso et al., 2006), and high fish intake attenuated the smoking-induced risk of nonfatal CHD (Eshak et al., 2014).

Inverse associations of fish and *n*-3 PUFA intakes with risk of stroke, especially thrombotic infarction, were reported among women of the Nurse's Health study (Iso et al., 2001a). In a meta-analysis of 26 prospective studies and 12 randomized controlled trials, fish intake and *n*-3 PUFA supplementation were associated with a modestly reduced risk of stroke (RR: 0.88, 95%CI 0.81–0.96

for ≥5 fish servings a week versus 1 serving a week) (Chowdhury et al., 2012). In another meta-analysis of 7 prospective studies, dietary intakes of fish marine *n*-3 fatty acids were associated with a decreased risk of heart failure; RR (95%CI) was 0.85 (0.73–0.99; $P=0.04$) comparing the highest to lowest categories of fish intake and 0.86 (0.74–1.00; $P=0.05$) for marine *n*-3 PUFA intake (Djoussé et al., 2012). Systematic reviews of prospective, randomized, placebo-controlled clinical trials confirmed the effect of *n*-3 fatty supplementation on risk of CVD (Marik and Varon, 2009; Wang et al., 2006); the multivariable OR (95%CI) were 0.87 (0.79–0.95, $P=0.002$) for cardiovascular deaths, 0.87 (0.76–0.99, $P=0.04$) for sudden cardiac death, and 0.92 (0.85–0.99, $P=0.02$) for nonfatal cardiovascular events (Marik and Varon, 2009). The effect of *n*-3 fatty acids has been proven to be independent from the effect of PUFA in the same diet (Mozaffarian et al., 2005b).

Several mechanisms for the beneficial effects of *n*-3 PUFA on cardiovascular health (Kinsella et al., 1990) have been postulated; reducing atherosclerosis via modulating endothelial function (von Schacky et al., 1999), reducing platelet aggregation (De Caterina et al., 2000) and inhibiting the production of thromboxane A2 (Harker et al., 1993), preventing arrhythmias (Nair et al., 1997), favorable lipid outcome and low triglycerides and increasing high HDL-cholesterol concentrations (Harris, 1989, 1997), reducing inflammatory biomarkers (James et al., 2000), and moderately decreasing blood pressure (Morris et al., 1993).

n-6 PUFA

Higher *n*-6 PUFA intake modified blood lipid concentrations (Djoussé et al., 2012; Keys et al., 1957; Mozaffarian et al., 2005b; Mensink and Katan, 1992). Omega-6 PUFA can suppress key mediators of the atherosclerotic process such as adhesion molecules, chemokines, and interleukins via anti-inflammatory properties (De Caterina et al., 2000). However, in human studies, higher plasma levels of *n*-6 PUFAs were not associated with any beneficial changes of serum lipid or plasma inflammatory markers levels (Becker et al., 1983; Nelson et al., 1997).

Serum and, to a lesser extent, dietary LA and PUFA were inversely associated with CVD mortality and total CVD events in the Kuopio Ischemic Heart Disease Risk Factor (KIHD) Study (Levitan et al., 2010), while in another study serum *n*-6 PUFA concentrations were not associated with risk of CVD (Yamagishi et al., 2008b).

In prospective cohort studies, the associations of *n*-6 PUFA intakes with risk of CHD were inconsistent; no associations ((Esrey et al., 1996; Pietinen et al., 1997; Harris et al., 2007)), nonsignificant inverse associations (McGee et al., 1984; Ascherio et al., 1996; Dolecek, 1992), and inverse associations (Marik and Varon, 2009; Kushi et al., 1985; Shekelle et al., 1981). However, in a meta-analysis of 25 case-control and prospective cohort studies, LA intake was inversely associated with CHD risk, whereas AA intake was unrelated to CHD risk; the effect size (95%CI) was −0.28 (−0.04 to −0.53; $P=0.02$) for LA and 0.03 (0.25 to −0.19; $P=0.81$) for AA (Harris et al., 2007).

An inverse association between serum levels of LA and risk of stroke, especially ischemic stroke, was reported in a nested case-control study of Japanese cohort, the Circulatory Risk in Communities Study (CIRCS) (Iso et al., 2002). On the other hand, in diet studies of total *n*-6 PUFA intake, neither risks of ischemic (He et al., 2003; Gillman et al., 1997; Iso et al., 2001b), hemorrhagic (He et al., 2003; Iso et al., 2001b, 2003), or stroke mortality (Sauvaget et al., 2004) were associated with *n*-6 PUFA intakes.

Higher serum levels of AA were associated with lower risk on incident heart failure in women, but not men of ARIC study (Yamagishi et al., 2008b).

Trans Fatty Acids

Among women of the Nurse Health study, intakes of trans fatty acids were correlated with high levels of plasma biomarkers of inflammation and endothelial dysfunction, such as C-reactive protein, interleukin-6, soluble tumor necrosis factor receptor 2, E-selection, and soluble cell adhesion molecules (Lopez-Garcia et al., 2005). In addition, intakes of trans fatty acids was not only associated with increased levels of LDL-cholesterol, but also with decreased levels of HDL-cholesterol (Mensink et al., 1992, 2003; Mozaffarian et al., 2005b). Similar effects were reported with trans fatty acids content in erythrocytes (Sun et al., 2007c).

Trans fatty acids intakes showed no associations with risk of total CVD in two studies (Leosdottir et al., 2007; Iso et al., 2001b). Contrarily in many literatures, the CHD associations with trans fatty acids intake (Oomen et al., 2001; Ascherio et al., 1994, 1996; Hu et al., 1997; Howard et al., 2006; Kromhout et al., 1995; Oh et al., 2005; Pietinen et al., 1997), plasma (Sun et al., 2007b,c), and adipose tissue (Aro et al., 1995) trans fatty acids biomarkers levels were evident. Trans fatty acids intake was positively associated with risk of total (Kiage et al., 2014) and ischemic (Kiage et al., 2014; Yaemsiri et al., 2012) stroke; however, no associations could be detected in 14-year prospective cohort study of male US healthcare professionals (He et al., 2003). However, trans fatty acids intake was inversely associated with risk of hemorrhagic stroke in one study (Iso et al., 2001b). The serum biomarkers levels of trans fatty acids (Shekelle et al., 1981; Hu et al., 1997), but not the serum levels of trans isomer of dairy fat, trans 16:1*n*-7 (Yakoob et al., 2014), were associated with risk of stroke. However, an increased dairy fat intake was associated with risk of incident heart failure in the ARIC study (Nettleton et al., 2008).

Substitution of Different Types of Fat

Substituting fatty acids for carbohydrates resulted in the reduction of LDL-cholesterol and HDL-cholesterol and increase of triglycerides. However, when MUFA or PUFA replaced SFA, total, LDL- and HDL-cholesterol concentrations have been shown to decrease (Jakobsen et al., 2009; Summers et al., 2002; Hodson et al., 2001). Moreover, substituting PUFA for SFA may have favorable outcomes on insulin sensitivity (Summers et al., 2002). It is worth mentioning here that, regarding their effects on lipids

and lipoproteins, the effect of SFA in diet is generally modulated by content and/or availability of PUFA, and the effects of substituting SFA with carbohydrates differ by the glycemic index and load of the carbohydrate. A review has shown that replacing SFAs with PUFAs was protective against CHD in some, but not all studies (Hu and Willett, 2002), while substituting total carbohydrate for SFA was associated with no or modest higher risk of CHD (Astrup et al., 2011). In a recent prospective study, replacing 5% of energy intake from SFA with equivalent energy intakes from whole grain carbohydrates, MUFA or PUFA, yielded a 9%, 15%, and 25% reductions in risk of CHD, respectively (Li et al., 2015). In a systematic review and meta-analysis of randomized controlled trials, each 5% of energy from SFA replaced by PUFA was associated with a 10% reduction in risk of CHD (Mozaffarian et al., 2010), which confirmed results from a pooled analysis of 11 cohort studies (Jakobsen et al., 2009). Only one study reported the effect of those substitutions on risk of stroke so far and showed that SFA intake was consistently inversely associated with stroke mortality in substitution models; significant or nonsignificant positive associations with stroke mortality were found when SFA was replaced by MUFA, PUFA, or carbohydrate (Yamagishi et al., 2010).

Dietary Pattern With Different Fat Content

Low fat, high carbohydrate diets versus high fat, low carbohydrate diets

The low prevalence of CHD in populations that consume very low fat diets in Asia (Cui et al., 2015) has led to the concept that low fat diets can protect against CHD. However, such populations are physically active and lean. Previously, low fat, high carbohydrate diets, compared with high fat diets, were associated with physically inactive, overweight, or obese populations with the development of atherogenic dyslipidemia (Krauss, 2001) which was characterized by high triacylglycerol and low HDL-cholesterol concentrations. In the Women's Health Initiative Dietary Modification Trial, the replacement of 7%–8% of fat intake with complex carbohydrates over 6 years did not modify the lipid profile (triglycerides, HDL-cholesterol, or lipoprotein subclasses) (Howard et al., 2010) and did not significantly reduce the risk of CHD, stroke, or CVD in postmenopausal women (Howard et al., 2006).

On the other hand, generally any fat that replaces carbohydrate in the diet raises HDL-cholesterol and decreases triacylglycerol concentrations. Moreover, in several long-term prospective studies that have examined the associations between diet and risk of CVD, rates of CHD did not substantially differ across populations that consumed approximately one third of energy from fat (Ascherio et al., 1996; Hu et al., 1997).

Overview

Mobile technology use has seen a massive rise in recent years with mobile data usage expected to grow by more than 50% by 2020 (Statistica, 2016a). Technology has revolutionized the healthcare sector, and mobile health (mHealth) has become an increasingly popular mode of healthcare delivery. Advances in mobile devices coupled with high speed internet means phones are becoming more than communication devices and are acting more as hubs for controlling accessories, as well as portals that other devices can communicate through. In 2013 there were 15 million people who used app-enabled mHealth and wearable mobile-fitness hardware devices, and this number is forecast to rise to more than 95 million by 2018 (Statistica, 2016b).

This article will examine how mobile technology can potentially be used in cardiovascular research and medicine, with emphasis on how it can improve awareness and behavior management on the part of the patient, and allow health care providers to monitor health outcomes.

Social Media

Social media usage has been increasing steadily over the last decade, and this rise has increased exponentially with the increased popularity of internet-capable "smart" mobile devices. In 2015, there were approximately 2.15 billion social media users, and this number is estimated to rise to 2.95 billion by 2020 (Statistica, 2016c). **Table 1** shows the user base for the top 10 current social media platforms.

While penetration is greatest in North America (59% of the population have at least one social media account), usage in developing countries is expected to rise significantly in the future—usage in China and India alone is expected to increase by more than 250 million users by 2020 (Statistica, 2016c). This means that social media provides an ideal platform to target users in countries where the risk of cardiovascular diseases (CVDs) like stroke is on the rise.

While social media is not used as widely by public healthcare organizations as by other industries (such as music and television), they have considerable reach—the American Heart Association, for example, has nearly 900,000 people who "like" their Facebook page, who have access to any information posted by the organization on that page. Using platforms such as Facebook or Twitter to promote relevant healthcare messages provides the best value for money method of information dissemination available.

Awareness

While the prevalence of behavioral and other modifiable risk factors of CVD (O'Donnell et al., 2010) including stroke has reached epidemic proportions worldwide(Go et al., 2014; Feigin et al., 2016), there is evidence that modifying health behaviors is feasible, improves health outcomes, reduces healthcare costs (Spring et al., 2013), and can reduce an individual's risk by up to 90% (Goldstein et al., 2011; Rose, 1981; Feigin et al., 2016; O'Donnell et al., 2016).

However, the level of public awareness of CVDs, such as stroke, its risk factors, and how to manage them is low, particularly in communities with low socioeconomic status, in ethnic minority groups and in rural areas (Alkadry et al., 2011; Ryan, 2010). In addition, current high-risk CVD prevention strategies do not target people with low to moderate risk of CVD, where the majority of strokes and heart attacks occurs (Dalton et al., 2013).

Using social media platforms to promote healthcare messages has been shown to improve health awareness (Lapointe et al., 2014). With the viral, peer to peer nature of social media, the dissemination of information can far outstrip the original audience of the message.

The most successful example of social media usage in recent times would be the "Ice bucket Challenge" for ALS. The statistics associated with this campaign highlight how effective social media can be in spreading awareness about a health condition (even if only temporarily).

- In two and a half months between June and September 2014, more than a million "ice bucket challenge" videos were uploaded to Facebook alone.
- The campaign raised $115 million for the ALS Association in 2014.
- Between July 29 and August 24 2014, donations to the ALS Association more than tripled the total donations received in 2013 ($70 million vs. $18.1 million).
- In August 2014, hits to the ALS Wikipedia page rose from the average of ~160,000 hits to nearly 3 million (McCarthy, 2014).

While this is an extreme example, the ALS campaign highlights what is possible with social media, and any awareness campaigns about cardiovascular conditions will need to incorporate at least a partial social media component in order to facilitate effective dissemination.

Interaction

Health professional–community interactions

In addition to improving awareness, social media can provide an effective method of interaction with other stakeholders (patients, other health professionals, community members) that would not be possible through other means. The peer to peer nature of social media means that health care providers can also seek input from end users to gain ideas about products or services that could be beneficial, or to gain feedback about existing interventions. Health researchers can use similar techniques to promote awareness about research trials, and also as a potential recruitment tool.

The Break Dengue project is an example of using social media to first promote a health project (using Facebook to gain 160,000 followers—nicknamed the DengueBreakers—who then raised awareness about the condition among their own networks), and leveraging this base to launch a prize contest where followers could submit ideas for prevention methods that could then be implemented based on feasibility. Using social media to build the profile for the project allowed the organization to reach a much wider audience to source ideas from (www.Breakdengue.org).

Community–community interactions

Another important aspect of social media interaction is that it lets like-minded people congregate and share ideas and views in a virtual setting.

Sites like PatientsLikeMe (https://www.patientslikeme.com/) allow people with health concerns or conditions to connect with others in similar situations. This provides users with an opportunity to share experiences about living with their conditions, provide support to and receive support from others with the similar illnesses, and compare symptoms and treatments.

For stroke survivors, who can often end up with long-term disabilities, getting supportive social interaction can significantly improve quality of life, and indeed health outcomes (Seeman, 1996). Where there are potential mobility issues which would make

normal face-to-face social interaction difficult, the availability and usage of forums could represent a valuable alternative. A number of major organizations such as the American Heart Organisation (http://supportnetwork.heart.org/stroke) and Stroke Association in the United Kingdom (https://www.stroke.org.uk/forum) have online forums set up to facilitate such interaction, and with higher levels of tech savviness, usage of social media as a tool for social interactions among people with specific health conditions is only likely to grow.

Health professional–health professional interactions

Lastly, social media provides a platform for health professionals to interact and collaborate on an unprecedented level. While "mainstream" social media sites are not ideal for professional collaboration, specialized platforms such as Sermo (http://www.sermo.com/) and Allnurses (www.allnurses.com) allow health professionals to interact with others to facilitate better health outcomes. Platforms such as this are particularly important for sharing important or relevant content (much quicker, and generally with more reach than traditional medical journals) as well as potentially being a portal for getting second opinions about challenging cases from a much larger pool of professionals than a physician or health professional would normally have access to in a short time frame.

Disadvantages of Social Media

As shown above, social media provides a huge opportunity to improve awareness about health conditions and interactions between interested stakeholders; but there are some significant drawbacks that must be taken into consideration.

The most important downside to social media is that the open, peer to peer nature that facilitates knowledge dissemination from health professionals is open to misinformation from third parties. The lack of any regulations about data validity or accuracy means that this incorrect information can also circulate rapidly. It is important as health providers to therefore have a sizeable social media presence wherever possible—this means that patients and general consumers are more likely to check and get health education and information from reputable sources.

Another important consideration is the legal and ethical issues surrounding any information provided through social media, and the privacy and security around health data. While patient-submitted information is usually fine from this perspective, health professionals and researchers need to be extremely careful around the responses they provide. Social media presence also has additional risks around information being stolen through compromised user accounts, data mining, employee's inadvertently positing confidential data online, etc. While these often do not have great health implications, there could be significant legal and commercial implications that need to be carefully considered.

mHealth Technology

While social media is a great tool for improving knowledge about health conditions, it is not an ideal medium for monitoring or managing patients or research participants. The growth of mHealth means that there are a rapidly growing number of tools health professionals, researchers, and the general population can use for these purposes. In broad terms, mHealth tech is split into two main categories, those that are aimed at individuals and those that are aimed at improving functionality within the health sector itself. However, there is often some crossover between the two, with data from end user applications informing healthcare and research organizations and vice versa. We will be using the Stroke Riskometer™ application as an example through this section.

The Stroke Riskometer™

The Stroke Riskometer application was developed by the National Institute for Stroke and Applied Neurosciences to address the lack of awareness around stroke and associated risk factors (Feigin et al., 2015). Users complete a questionnaire and are provided with their risk of stroke using a validated algorithm (Parmar et al., 2015), and identified risk factors. The PRO version of the app also provides management tips to improve user risk. Additionally, users can submit their data as part of the international RIBURST study (**Fig. 1**).

Individual Use

Given the risk factors associated with CVD, there are a lot of applications and technology aimed at generic health factors such as diet and exercise that decrease users' CVD risk despite not being explicitly marketed for this purpose. Activity trackers like Fitbit™ have huge userbases (recent filings indicate there are approximately 19 million registered users with over 9 million "active" users (Goode, 2015), and research indicates that usage of wearable devices such as these does show an increase in physical activity (Cadmus-Bertram et al., 2015; Fritz et al., 2014)). Similarly, diet trackers and calorie counters such as MyFitnessPal™ also show efficacy when used on a regular basis, with research suggesting users of this technology were able to maintain dietary changes better than those who did not use them (Wang et al., 2016). Similar generic applications are also available for blood pressure, smoking cessation, and other associated risk factors.

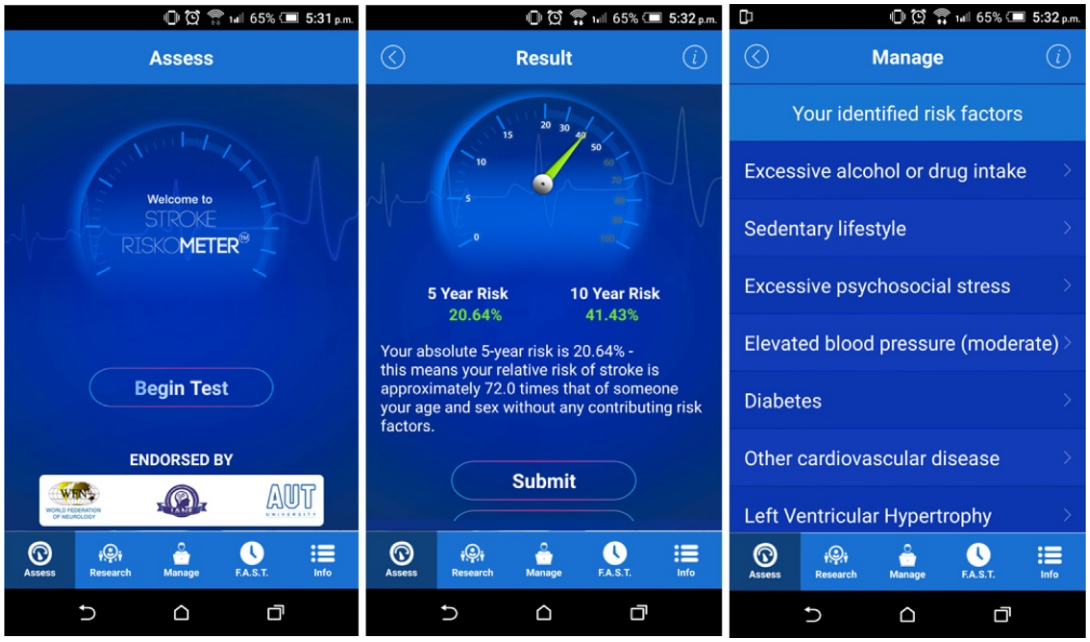

Fig. 1 Screenshots from the Stroke Riskometer™.

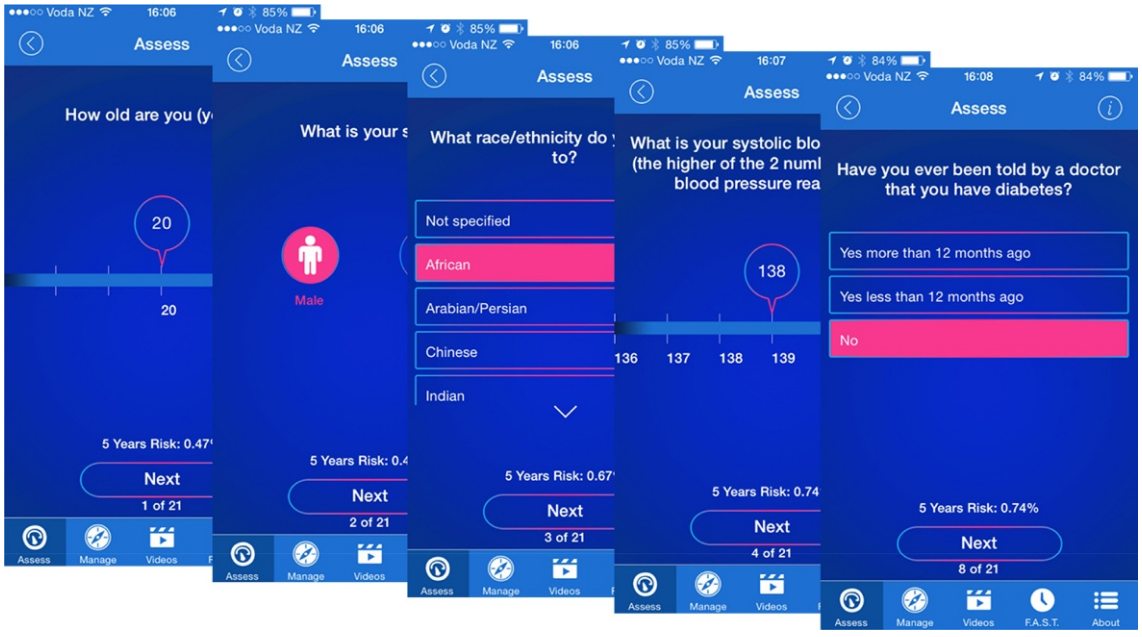

Fig. 2 Questions from the Stroke Riskometer™.

For CVD-specific mHealth applications or devices, the first priority for management needs to be personal risk awareness. While social media is a good medium for improving general awareness, mHealth needs to be more personalized, where the user gains an awareness of his/her own risk factors and identifies what he/she needs to be doing in order to minimize his/her chances of suffering from the relevant condition (Fig. 2).

In addition to personal awareness, ideally the application or device should provide users with information on what they can do to minimize or mitigate any identified risks. This is a potentially complicated issue to address, as ideally the aim should be to not only provide users with as much relevant information as possible, but also to prompt them to seek advice from their health professional when warranted. Fig. 3 shows some of the management advice provided in the Stroke Riskometer app.

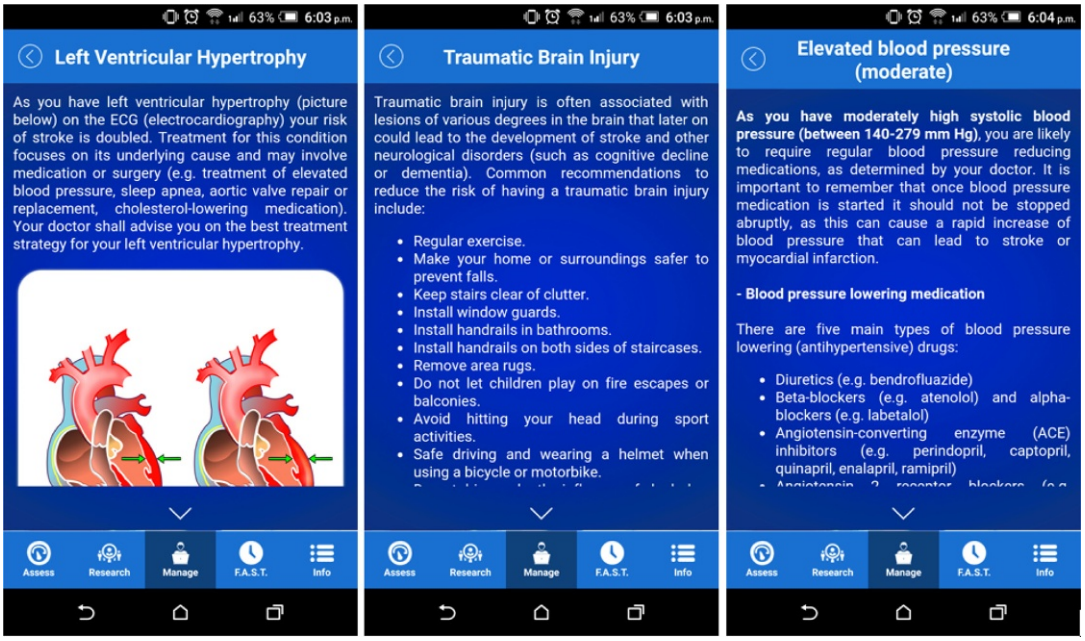

Fig. 3 Management advice from the Stroke Riskometer PRO.

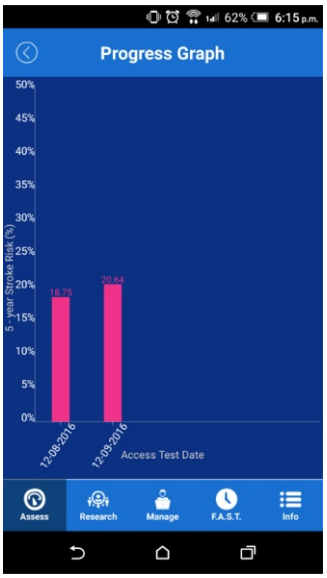

Fig. 4 Stroke Riskometer Progress graph.

Lastly, these applications should have a monitoring component so users can see if they are making progress, and track whether any changes in health behavior lead to changes in the risk of having an adverse event. Fig. 4 shows the Stroke Riskometer progress graph, which users can use to track changes in their risk of stroke.

Health Sector Use

For the health sector, the main emphasis for using mHealth technologies should be data driven. Mobile technology allows aggregation of data (from both individuals and wider population groups) at a significantly lower resource cost than current data collection methods. Collecting and analyzing the data allows the health sector to identify gaps in current health programs, assess the suitability and uptake of promotions being rolled out, and most importantly measure the outcomes of projects to determine whether they are working or not.

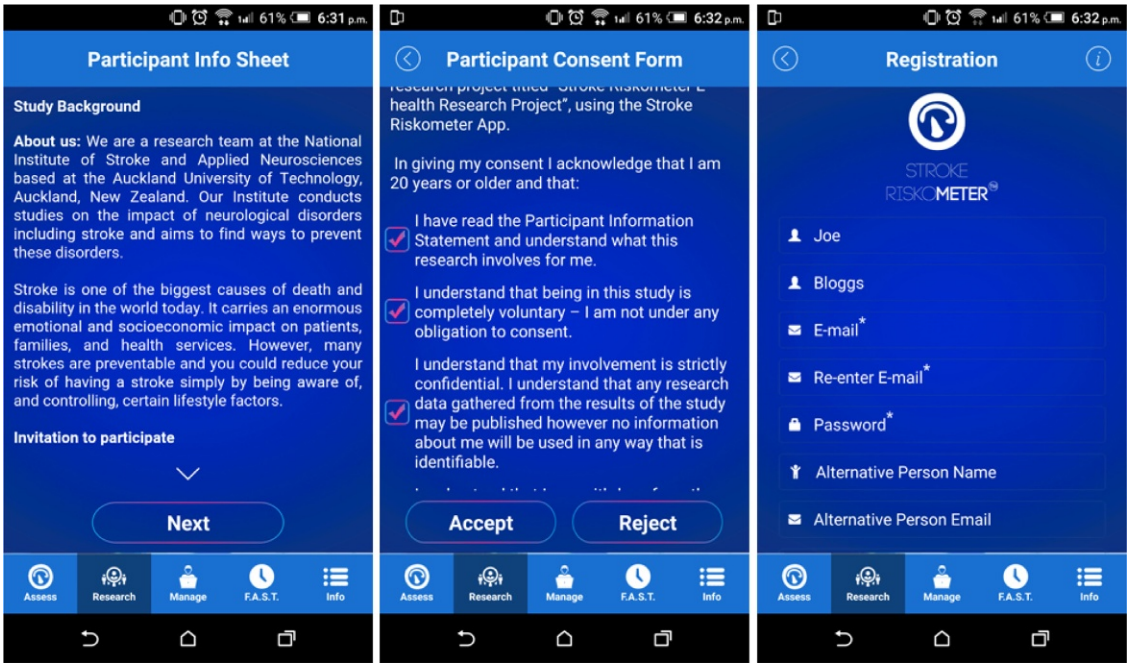

Fig. 5 Consenting process for Stroke Riskometer data collection.

Data collection and mining

As stated earlier, collecting the data from self-use applications and devices allows health professionals to acquire data from the population group without the traditional face-to-face interview method, which saves both time and costs (allocating and training interviewers, time taken for data entry, etc.). However, care needs to be taken to ensure that any intervention meets ethics criteria, which can be tricky particularly for international projects with different levels of ethical thresholds. This is especially important with respect to research data. Health professionals and researchers need to work closely with their commercial and legal teams and ensure any mHealth products or interventions meet all legislative requirements. Fig. 5 shows the consent process used by the Stroke Riskometer for data collection.

Personalized mHealth

On an individual level, mHealth technology can be used to track patients at high risk or those who have been diagnosed with health conditions to ensure that quick action can be taken if their conditions deteriorate. The level of sophistication for this technology is variable, ranging from relatively simple Bluetooth-enabled blood pressure monitors and weight scales that transmitted data when readings were outside preset limits (Logan et al., 2007; Scherr et al., 2006) through to more complicated products like personal monitors which record ECG, compare the readings with reference ECG readings which account for predetermined patient risk factors and clinical data, and send out stratified levels of alarm messages to the users health provider if arrhythmia is detected (Rubel et al., 2005).

Short message service

In developing countries, where internet coverage and usage is still suboptimal, mobile text messaging also provides an opportunity to reach people who may not have access to smart mobile devices or reliable internet connections. Short message service (SMS) messaging has been used extensively for behavior modification programs such as smoking cessation (Haug et al., 2009), diabetes management (Krishna and Boren, 2008), and weight loss (Patrick et al., 2009). SMS-based interventions generally indicate good acceptability and uptake, but demonstrate variable results with respect to changes in health outcomes. However, this method of healthcare provision is a viable option in situations where more personalized or individualized care is not feasible operationally or financially.

What Makes a Good mHealth Product?

With the rapid improvements in mHealth technology, there is a massive scope for development of applications, software, and other devices that could have great potential in informing people about the risks and risk factors associated with CVDs, and monitoring and managing the symptoms of those who suffer from these conditions.

However, for those in the health sector, this technology is often unfamiliar—what works from a commercial standpoint (which is important to get people to accept and use the technology) can often be at odds with what is required for a health or research

Table 2 Key mHealth development considerations

Cost	This is often the most important barrier, but there are more things to consider than simply initial development cost—any new technology should factor in running costs and potential further developments. For example, costs for server space for data storage, database monitoring and upkeep, development time for future changes, etc. can be overlooked during the initial development phase
Maintenance	It is important to have a strategy to make sure there are resources in place for monitoring. Any product should be easy to work with and maintain over the life of the project
Usability and accessibility	This is essential for successful implementation. The product should be straightforward and easy to use—the end user should be able to intuitively use the product with minimal external guidance
Performance	Attention should be paid to ensure that the technology should work fast with good reliability. If the product is slow (i.e., long load times or lag for data submission), users are less likely to continue to engage with and use it
Volume	The backend of any new products should be able to handle high transaction volumes, and quickly respond to requests looking through large amounts of data (this is important at the analysis stage)
Security and privacy	Precaution must be taken to ensure that there are minimal chances of the product being hacked. Ideally all collected data should be encrypted, and access to the data should be restricted and recorded
Compatibility	Any technology should be able to work in all foreseeable environments. Testing should be done to ensure products work across different operating systems, browsers, etc. as well as communicate seamlessly with any linked programs or databases
Reusability and extensibility	For "future proofing," any new technology should be designed so it can be reskinned, rescaled, and used for other projects to maximize cost-effectiveness and utility

perspective (getting enough accurate information to draw meaningful conclusions from). While it is important to work in conjunction with your technical and commercial partners to develop the best all-round application or device, **Table 2** highlights some of the key items that should always be taken into consideration.

Summary

Social media and mHealth have significantly changed the way health care and research can be administered. People have more access than ever to information about their health and what they can do to improve it. Similarly, health providers have access to more information about patient health and lifestyle than ever before. There is very little doubt that social media and mHealth can greatly improve awareness about CVD and risk factors. However, there needs to be more research to determine the actual effectiveness of individual interventions before wide-scale rollouts, as current data suggests the outcomes of mHealth and social media-based health projects have varying levels of success.

Overview

The mitral valve was so-named by Vesalius in the 16th century from comparison of the cusps to a bishop's mitre or hat. An in-depth understanding of the mitral valve's structure and function was clearly evident at that time in the drawings of Leonardo da Vinci.

Extending from a semirigid fibrous frame called the mitral valve annulus are two asymmetric saloon door-like leaflets termed anterior and posterior (although predominantly orientated superiorly and inferiorly). These leaflets are attached by chordae tendineae to papillary muscles which together ensure that the valve stays closed during cardiac contraction. The normal mitral valve area (MVA) is ~4–5 cm^2 and is the portal through which diastolic left ventricular filling occurs via the left atrium.

 https://doi.org/10.1016/B978-0-12-809657-4.99707-2

Guidelines published in 2014 by the American College of Cardiology (ACC) in collaboration with the American Heart Association (AHA) are referenced in this text (Nishimura et al., 2017). These guidelines provide grading based on the strength of evidence supporting each clinical practice and will be referred to as follows:

Class I: Procedure or treatment is supported by sufficient evidence and is recommended.

Class IIa: There is conflicting evidence/divergence of opinion regarding the given procedure/treatment but recommendations are generally in favor of its usefulness/efficacy.

Class IIb: There is greater conflicting evidence over usefulness/efficacy of procedure and recommendations are less well established.

Class III: There is sufficient evidence that the procedure/treatment is not useful/effective and may be harmful in some cases.

Mitral Stenosis

Background

Mitral stenosis (MS) is narrowing of the mitral valve orifice that leads to impaired blood flow from the left atrium to ventricle during diastole. Rheumatic degeneration remains the predominant etiology of MS in the developing world (Carapetis et al., 2005). In contrast, degenerative mitral annular calcification is the predominant etiology of MS in industrialized countries. Rare functional causes of MS include infective endocarditis with large vegetations, and left atrial myxoma. Treatment strategies for MS are based upon patient symptoms, valve anatomy, hemodynamics including consequences for the left atrium and pulmonary circulation and right ventricle as well as concomitant and comorbid disease.

Staging of MS

Stage A patients are at risk of MS and include those with mild valve doming during diastole. Stage B (progressive MS) includes patients with mild or moderate MS where the MVA > 1.5 cm^2, and the morphology may involve more pronounced diastolic valve doming or commissural fusion. Stage C is defined as asymptomatic severe MS (MVA ≤ 1.5 cm^2), while Stage D involves patients with symptomatic severe MS.

Pathophysiology

Following an episode of acute rheumatic fever, patients may remain asymptomatic for decades prior to the development of subclinical rheumatic MS. Repeated episodes of rheumatic carditis eventually lead to fibrosis and thickening of the mitral valve leaflets. The classical rheumatic lesions are fusion of the commissures and subvalvular degeneration which together reduce mitral valve orifice area to cause MS. As the valve area progressively narrows, the diastolic mitral valve gradient rises, which leads to higher left atrial pressure. Chronically elevated left atrial pressure leads to inexorable left atrial enlargement, which can predispose patients to atrial fibrillation (AF) and thromboembolic events including stroke (Chiang et al., 1998, Lee et al., 2014). Elevations in left atrial pressure are transmitted backward to the pulmonary vasculature causing pulmonary hypertension resulting in shortness of breath, orthopnea, and paroxysmal nocturnal dyspnea. Untreated patients may report that these latter symptoms may improve at the same time they develop progressive lower limb edema which denotes the development of right heart failure that may ultimately lead to anascarca.

Signs and Symptoms

Presentation may occur as a consequence of gradual functional decline (e.g., fatigue or exertional dyspnea) or in some cases due to acute deterioration (e.g., acute pulmonary edema, AF, thromboembolism, rarely hemoptysis). In very rare cases, an enlarged left atrium may compress the recurrent laryngeal nerve causing hoarseness and Ortner's syndrome, which accounts for approximately 0.25–0.5% of all cases of recurrent laryngeal nerve palsy. Acute decompensations in previously stable MS patients may occur during exercise, infection, stress, thyrotoxicosis, AF, and pregnancy (which will be discussed later in this section) (Norrad and Salehian, 2011).

Examination findings of mitral stenosis include a malar flush, AF, and jugular venous distension. Characteristic auscultatory findings include a loud first heart sound and the absence of silence during diastole (with namely an opening-snap and a mid-diastolic rumble). The first heart sound may be reduced if the valve has limited mobility from calcification. A loud P_2 can be appreciated if pulmonary hypertension is present. With worsening stenosis and higher left atrial pressure, the opening snap may be heard earlier during diastole therefore prolonging the duration of the murmur. Factors that could reduce flow across the valve and mask the murmur of MS include right heart failure, severe tricuspid regurgitation, or concomitant aortic stenosis.

Diagnosis

Initial electrocardiography may reveal a patient in AF with left atrial enlargement, right ventricular hypertrophy, and right axis deviation due to associated pulmonary hypertension. Chest radiography can exhibit left atrial dilation, enlargement of the main pulmonary arteries, and pulmonary congestion.

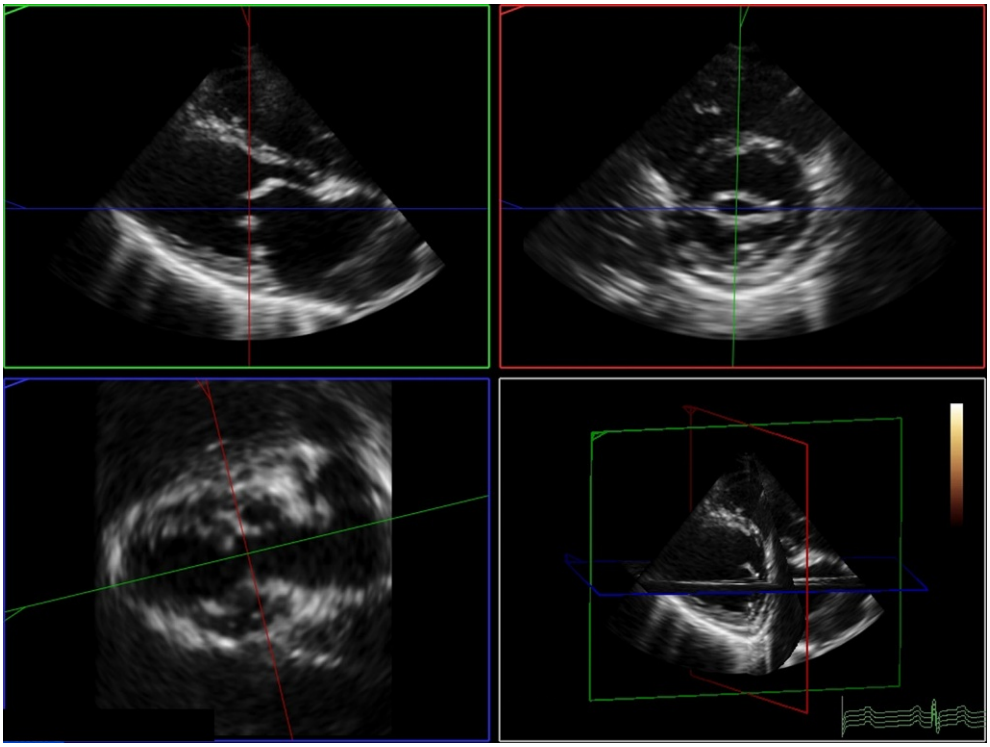

Fig. 1 Three-dimensional echocardiographic planimetry demonstrating how to obtain an accurate mitral valve orifice area in severe rheumatic mitral stenosis by measuring at the leaflet tips during maximal diastolic opening. Characteristic rheumatic anterior mitral valve leaflet doming is evident in the top left image while bicommissural fusion is evident in the top right image.

Transthoracic echocardiography (TTE) is recommended in all patients with suspected MS (Class I) (Nishimura et al., 2017). TTE can establish MS diagnosis and identify hemodynamic severity (mean pressure gradient, MVA, and pulmonary artery pressures). Due to the frequent occurrence of other valvular disease alongside MS, it is important to investigate coexisting valvular lesions, especially the tricuspid and aortic valves. TTE helps determine valve morphology, which is fundamental in developing treatment strategy and suitability for mitral commissurotomy (Class I) (Nishimura et al., 2017). Scoring systems to evaluate significant aspects of valve anatomy including valve mobility, calcification, thickening, deformity, and commissural areas have been developed (Baumgartner et al., 2009).

Transesophageal echocardiography (TEE) is indicated in patients being considered for percutaneous mitral balloon commissurotomy (PMBC) to look for left atrial thrombus and presence of mitral regurgitation (MR) (Class I) (Nishimura et al., 2017). Where there is an equivocal difference or discordance between resting Doppler echocardiography and the severity of symptoms/signs, exercise testing with Doppler or cardiac catheterization can identify the response of mean mitral gradient and pulmonary artery pressures (Class I) (Nishimura et al., 2017). While the transmitral pressure gradient is generally $\geq$10 mmHg in severe MS, this measurement is subject to variations in heart rate and forward flow. MVA is a more consistent parameter for defining MS. Valve area should be measured using planimetry and the pressure half time method (time taken for the peak transvalvular pressure gradient to fall by half, i.e., MVA = 220/ P × ½ t). Three-dimensional echocardiography may enhance evaluation of valve area and morphology (Fig. 1).

Medical Therapy

Anticoagulation with warfarin or heparin is indicated in patients with MS and concomitant AF, left atrial thrombus, or prior embolic events (Class I) (Nishimura et al., 2017). Anticoagulation may also be considered if there is significant left atrial dilation of 5–5.5 mm (Class IIb) (Nishimura et al., 2017). Tachycardia reduces diastolic filling time and may be poorly tolerated by patients with MS. Thus heart rate control with beta-blockers, calcium channel blockers, digoxin, or ivabradine can be beneficial in MS patients with AF and rapid ventricular response (Class IIa) (Nishimura et al., 2017). It is also beneficial in normal sinus rhythm patients who are symptomatic during exercise (Class IIb) (Nishimura et al., 2017).

Patients with a history of rheumatic heart disease are at risk of recurrence. Long-term antibiotic prophylaxis with penicillin is indicated in patients with a history of rheumatic fever, rheumatic carditis, or rheumatic valve disease. Duration of therapy varies widely depending on the extent of cardiac disease, patient age, and timing of most recent episode (Cilliers, 2006). Current guidelines do not recommend routine antibiotic prophylaxis against endocarditis for patients with MS (Wilson et al., 2007).

While medical therapy optimizes patient symptoms and risks for embolic events and recurrent rheumatic valve disease events, it does little to alter the natural progression of MS.

Surgery

There are three surgical options available for MS patients: PMBC, surgical mitral commissurotomy, and mitral valve replacement (MVR).

In 1984, Inoue (a cardiovascular surgeon from Japan) and his colleagues, first described PMBC, a method whereby a balloon catheter is used to fracture fused commisures and restore MVA (Inoue et al., 1984). This method has shown equal or better success rates, equivocal restenosis rates, and larger valve area with improved durability when compared to surgical commissurotomy, all the while being less invasive (Turi et al., 1991, Arora et al., 1993, Dean, 1994, Reyes et al., 1994). There are a number of contraindications that must be considered with PMBC; MVA > 1.5 cm^2, presence of a left atrial thrombus, moderate 2+ mitral leak, severe/bicommissural calcification, and concomitant coronary artery disease requiring bypass surgery. In the absence of contraindications, PMBC has a Class I indication in symptomatic patients with severe MS (MVA less than 1.5 cm^2, Stage D) (Nishimura et al., 2017). It has a Class IIa indication in asymptomatic patients with very severe MS (MVA less than 1 cm^2, Stage C) without contraindication (Nishimura et al., 2017). There are three Class IIb indications for PMBC outlined in the AHA/ACC Valvular Heart Disease Guidelines as follows; asymptomatic patients with severe MS (MVA < 1.5 cm^2, Stage C) and favorable valve morphology for PMBC with new onset AF; in symptomatic patients with MVA > 1.5 cm^2 but evidence of hemodynamically significant MS with a mean mitral valve gradient >15 mmHg or pulmonary artery wedge pressure >25 mmHg on exercise, in severely symptomatic patients (New York Heart Association (NYHA) Class III or IV) with severe MS (MVA < 1.5 cm^2, Stage D) with suboptimal valve morphology and who are poor surgical candidates. Major complications of PMBC include mortality 0.5%–4%, embolism 0.5%–5%, hemopericardium 0.5%–10%, and severe regurgitation in 2%–10% (Vahanian et al., 2012). PMBC can also play a role in the palliative care of patients with poor valve morphology who are not surgical candidates (Fawzy et al., 2005).

Closed surgical commissurotomy was first described by Harken and Bailey in 1948 (Harken et al., 1951). Following the advent of cardiopulmonary bypass, open mitral commissurotomy using a midline sternotomy or left thoracotomy replaced the closed approach in the 1960s and 1970s. However, the closed technique is still widely used in developing countries where rheumatic heart disease is most prevalent. Another surgical option is MVR with mechanical or biological prostheses. Both surgical commissurotomy and MVR have a Class I indication in severely symptomatic patients (NYHA Class III or IV) with Stage D MS who are not high risk surgical candidates and have either failed previous PMBC or have contraindications to PMBC (Nishimura et al., 2017). If a patient with Stage C or D MS is undergoing cardiac surgery for other reasons, mitral valve surgery has a Class I indication (Nishimura et al., 2017). Likewise, mitral valve surgery has a Class IIb indication in patients undergoing cardiac surgery who also have concomitant moderate MS (1.6–2 cm^2) (Nishimura et al., 2017). Lastly, mitral valve surgery with left atrial appendage removal has a Class IIb indication in Stage C or D MS patients who have recurrent embolic events while on anticoagulation (Nishimura et al., 2017). Given the less invasive and less costly approach of PMBC, it is important to consider all options before proceeding to more advanced surgical measures.

Pregnancy and MS

Pregnancy increases plasma volume by approximately 50% and heart rate by 20%–30%, resulting in a rising transmitral gradient that may trigger new onset of symptoms or exacerbation of preexisting symptoms (Norrad and Salehian, 2011). Most patients with MS will experience clinical deterioration during pregnancy (Hameed et al., 2001). Pulmonary edema, AF, and thromboembolic events are not uncommon complications. One study found that pregnant MS patients had a 67% incidence of cardiac events, while there was a 44% incidence of fetal complications such as premature birth, intrauterine growth restriction, or death (Silversides et al., 2003).

When MS is suspected, all patients should ideally undergo TTE before pregnancy in order to identify the best treatment plan prepregnancy and during gestation (Class I) (Nishimura et al., 2017). Those found to have severe valve stenosis of Stages C or D should be seen by a cardiologist with expertise in managing MS during pregnancy and all treatment options discussed (Class I) (Nishimura et al., 2017). Of note, mechanical valve prostheses require continued anticoagulation, which may pose maternal and fetal risks. However, bioprosthetic valves are thought to undergo accelerated degeneration during pregnancy, with 60%–80% requiring replacement within 10 years (Hung and Rahimtoola, 2003). It is recommended that a multidisciplinary team approach of anesthesiologists, obstetricians, surgeons, and cardiologists should be implemented to develop management plans in a tertiary care center (Class I) (Nishimura et al., 2017).

Pregnancy is a hypercoaguable state and patients with concurrent MS and AF should be prescribed warfarin in the second and third trimester (Class I) (Nishimura et al., 2017). Controversy still remains over the most appropriate anticoagulant for the first trimester. Beta-blockers (Class IIa) and diuretics (Class IIb) are reasonable therapies in patients free from contraindication (Nishimura et al., 2017). However, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be avoided due to teratogenic effects (Class III) (Nishimura et al., 2017).

Surgical intervention is recommended before pregnancy for symptomatic patients with MVA < 1.5 cm^2, Stage D (Class I) (Nishimura et al., 2017). While PMBC is the preferred method, surgical commissurotomy and MVR may also be used depending on institutional experience.

Severe MS patients categorized as Stage D during pregnancy and are experiencing NYHA III to IV heart failure symptoms despite medical therapy should be considered for PMBC provided valve morphology is favorable (Class IIa) (Nishimura et al., 2017). Stage D patients without suitable valve morphology may be considered for PMBC if NYHA IV refractory heart failure symptoms are ongoing. Surgery is reserved for severely symptomatic patients unsuited for PMBC, having failed all medical therapies and bed rest. The MS patient who does not have severe heart failure symptoms should not be considered for surgery (Class III) (Nishimura et al., 2017). One study concluded that, where possible, surgical intervention should be delayed until 12–14 weeks gestation to prevent radiation exposure during organogenesis (Hameed et al., 2009).

Mitral Regurgitation

Background

MR is the leakage of blood backward from the left ventricle to the left atrium during systole. MR can be divided into primary (degenerative) and secondary (functional) subtypes depending on the mechanism underlying MR. Primary MR includes all etiologies which affect the mitral valve apparatus such as myxomatous disease, infective endocarditis, radiation heart disease, or rheumatic heart disease. Myxomatous valve prolapse is the most common cause of MR in developed countries and will be discussed later in this chapter. By contrast, in secondary MR the mitral valve apparatus is structurally normal and MR results from distortion from surrounding structures such as left ventricular enlargement and/or annular dilation (**Fig. 2**).

Staging of MR

The stages of primary and secondary MR are assessed separately. In the rare cases where the two mechanisms occur together, one usually predominates and guides therapy. In treating the regurgitant "valve problem" of primary MR, correction is curative (Nishimura et al., 2017). However in secondary MR, where there is a "valve plus a pump problem," the left ventricular component drives the prognosis making the staging and treatment of secondary MR complicated and unclear in comparison to primary disease.

In primary MR, staging is divided into four categories, A through D. Stage A patients have mild valve prolapse and thickening with normal coaptation. There may or may not be a MR jet, if so it is typically small (<20% left atrial area on Doppler). Progressive Stage B MR is present when there is severe valve prolapse with normal coaptation, prior infective endocarditis or rheumatic valve changes with leaflet restriction with loss of coaptation (20%–40% left atrial area on Doppler). Stage C asymptomatic severe MR is seen with severe valve prolapse and flail leaflet, rheumatic changes with loss of coaptation, prior infective endocarditis, and/or thickening of leaflets due to radiation damage (>40% left atrial area on Doppler; regurgitant volume >60 mL). This Stage C classification is divided into C1 and C2, with better left ventricular ejection fractions (LVEF) of >60% and left ventricular end systolic dimension (LVESD) <40 mm in C1, with the alternate values accounting for C2. Patients with severe MR who are symptomatic are categorized as Stage D.

Patients with secondary MR are also divided into four categories from A to D. Stage A patients are at risk of MR and have cardiomyopathy or coronary artery disease but normal mitral valve anatomy. Progressive Stage B patients have regional wall

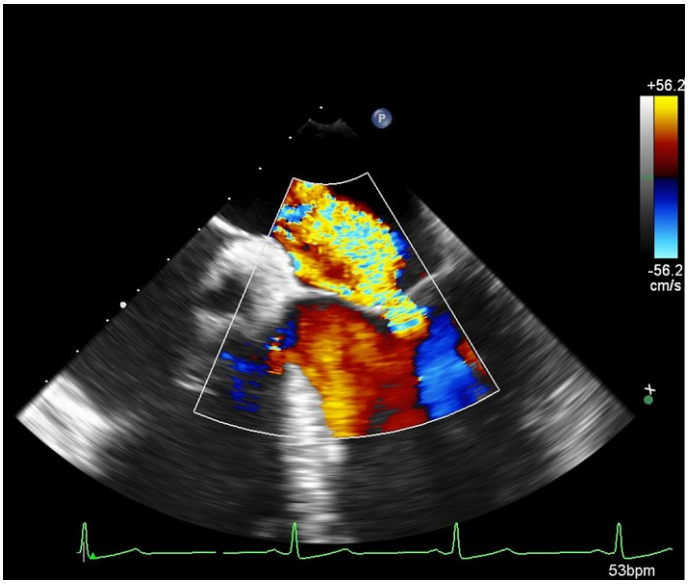

Fig. 2 Color Doppler two-dimensional echocardiographic image of a centrally directed jet of severe functional mitral regurgitation secondary to left ventricular enlargement.

abnormalities with some tethering of valve leaflets, annular dilation, and loss of central coaptation with effective regurgitant orifice (ERO) $<0.2\ cm^2$ and regurgitant volume <30 mL. Severe MR is defined by severe mitral leaflet tethering and severe loss of central coaptation (ERO $>0.2\ cm^2$ with a regurgitant volume >30 mL and characterizes Stage C (asymptomatic patients) and Stage D (symptomatic patients).

Pathophysiology

MR overloads the volume of the left ventricle and atrium with both stroke volume and added regurgitant volume. The way in which the ventricle copes with this added volume depends on the rapidity at which the regurgitation develops. In the acute setting, the ventricle is unable to remodel in size to compensate for higher volumes. Hence, acute MR is characterized by hyperdynamism and tachycardia to maintain stroke volume. Left atrial and pulmonary vasculature pressures may rise resulting in pulmonary congestion and edema. In contrast, with chronic MR the left ventricle dilates gradually over time in order to compensate for the volume load. However, this mechanism does eventually fail resulting in high left atrial and pulmonary venous pressures with eventual pulmonary hypertension late in the course of disease. Development of AF may precipitate the onset of symptoms in the presence of otherwise asymptomatic chronic MR.

Signs and Symptoms

Due to left ventricular remodeling, chronic MR can remain asymptomatic for decades. Later on, symptoms may include dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea, and palpitations produced by AF. However in the acute MR patient, symptoms develop rapidly due to lack of left ventricular compensation (e.g., postmyocardial infarction with papillary muscle rupture and resultant acute MR.

On auscultation, a soft S_1 with a blowing pansystolic murmur is best heard over the cardiac apex in the left lateral position at end expiration. The murmur can be heard radiating to the axilla. Later on, examination findings may include AF, a palpable heave at the left sternal edge, and/or a displaced apex beat.

Diagnosis

A simple electrocardiogram can reveal the presence of AF or left atrial enlargement (P mitrale waves). Chest radiography may show evidence of left atrial or ventricular enlargement. TTE is indicated for investigation of both primary and secondary MR in order to establish etiology, baseline left ventricular functioning, ERO, regurgitant volumes, and estimation of pulmonary vasculature pressures (Class I) (Nishimura et al., 2017).

In primary MR, cardiac magnetic resonance imaging can further evaluate the above parameters if TTE is inconclusive (Class I) (Nishimura et al., 2017). TEE can elaborate on diagnostic information if noninvasive investigations provide inadequate data (Class I) (Nishimura et al., 2017). An intraoperative TEE can help guide repair (Class I) (Nishimura et al., 2017). Where there is discrepancy between symptom severity at rest and upon exertion, exercise hemodynamics via stress echocardiography or cardiac catheterization is reasonable (Class IIa) (Nishimura et al., 2017).

Tests that have a Class I indication for secondary MR include nuclear or positron emission tomography, cardiac magnetic resonance imaging, cardiac CT angiography, coronary arteriography, or cardiac catheterization (Nishimura et al., 2017) to better assess the left ventricular substrate.

Medical Therapy

Acute MR should be ruled out in patients with myocardial infarction experiencing sudden hemodynamic compromise. Such patients require urgent mitral valve surgery. Until then, nitroprusside and nitroglycerin may help to reduce afterload and maintain forward cardiac output. In the hemodynamically unstable, intraaortic balloon pump placement should be considered.

In the normotensive, asymptomatic MR patient with chronic primary MR (Stage B or C1) and normal systolic LV function, vasodilator therapy is not indicated (Class III) (Nishimura et al., 2017). However, medical therapy for systolic dysfunction is reasonable in Stage D patients with ejection fractions less than 60% who are poor surgical candidates.

In patients with secondary MR classed as Stage B, C, or D with heart failure and poor ejection fractions, guideline-directed medical therapy (GDMT) for heart failure should be employed, utilizing medications such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, and aldosterone antagonists. Cardiac resynchronization therapy should be considered in Stages B through D patients who meet criteria for device implantation.

Surgery

Primary

In the symptomatic patient, mitral valve surgery is recommended in Stage D MR with LVEF >30% (Class I) or <30% (Class IIb) (Nishimura et al., 2017). Transcatheter mitral valve repair can be considered in the severely symptomatic Stage D patient (NYHA III or IV) despite optimal GDMT with favorable anatomy and good life expectancy but severe comorbidities that contribute to surgical risk (Class IIb) (Nishimura et al., 2017).

In the asymptomatic Stage C2 patient with LVEF 30%–60% and LVESD > 40 mm, mitral valve surgery is recommended (Class I) (Nishimura et al., 2017). Mitral valve repair is reasonable in Stage C1 patients with LVEF > 60% and LVESD < 40 mm in whom there is a >95% chance of successful repair and <1% risk of mortality when performed under at a Heart Valve Center of Excellence (Class IIa) (Nishimura et al., 2017). In the asymptomatic Stage C1 patient with the aforementioned LVEF and LVESD values, with new onset AF or pulmonary hypertension (pulmonary artery systolic arterial pressure >50 mm Hg) mitral valve repair is also reasonable (Class IIa) (Nishimura et al., 2017). In general, mitral valve repair is preferable to replacement, the latter surgery used either after failed valve repair or if the anatomy is unsuitable for repair (Nishimura et al., 2017). Concomitant mitral valve surgery is indicated in patients undergoing other cardiac procedures with chronic severe (Class I) or chronic moderate (Class IIb) MR (Nishimura et al., 2017).

Secondary

Mitral valve surgery is reasonable in chronic severe Stage C or D patients who are undergoing Coronary Artery Bypass Grafting (CABG) or Aortic Valve Replacement (AVR) (Class IIa) (Nishimura et al., 2017). Mitral valve surgery may be considered in Stage B patients who are undergoing cardiac surgery for other indications (Class IIb) (Nishimura et al., 2017). In the severely symptomatic NYHA III or IV Stage D patient with persistent symptoms despite optimal GDMT, mitral valve surgery should be considered (Class IIb) (Nishimura et al., 2017).

Pregnancy and MR

Patients with MR generally tolerate pregnancy well in the absence of significant left ventricular dysfunction. While plasma volume rises by 50%, the systemic vascular resistance is reduced in pregnancy, therefore reducing the regurgitant volume across the mitral valve. However, patients with preexisting left ventricular dysfunction, pulmonary hypertension, or heart failure may experience exacerbation of MR symptoms. AHA/ACC guidelines recommend that all patients with suspected MR should undergo TTE before pregnancy (Class I) (Nishimura et al., 2017). All patients with severe MR (Stage C or D) should have prepregnancy counseling with a cardiologist with expertise in managing such patients (Class I) (Nishimura et al., 2017). These Stage C or D patients should be followed in a tertiary care center by a Heart Valve Team consisting of cardiologists, surgeons, anesthesiologists, and obstetricians (Class I) (Nishimura et al., 2017). As in patients with MS, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be avoided during gestation (Class III harm) (Nishimura et al., 2017).

In terms of surgical intervention, valve repair or replacement is recommended before pregnancy in Stage D patients (Class I) (Nishimura et al., 2017). Valve repair before pregnancy in the asymptomatic severe MR patient (Stage C) may be considered in patients with suitable valve morphology with whom detailed discussions regarding the operation and associated risks have taken place (Class IIb) (Nishimura et al., 2017). During pregnancy, valve operation is reasonable in the Stage D patient with intractable NYHA IV heart failure symptoms (Class IIa) (Nishimura et al., 2017). There is a Class III harm indication for such patients in the absence of heart failure symptoms (Nishimura et al., 2017).

Mitral Valve Prolapse

Background

Mitral valve prolapse (MVP) is the abnormal excessive motion of part or all of one or both mitral valve leaflets behind the mitral annulus into the left atrium during systole as seen in outflow tract views. It is the most commonly diagnosed valvular disorder and the most prevalent MR etiology requiring surgical intervention (Guy et al., 1980). MVP occurs in around 5% of the general population, with women exhibiting a higher incidence than their male counterparts (Devereux et al., 1986). However, this incidence was seen to be variable with age amongst females in the Framingham Study. MVP rates were found to be as high as 17% in females aged 20–29 years but only 1% in females aged in their 80s. (Savage et al., 1983).

Pathophysiology

MVP is caused by myxomatous degeneration with subsequent expansion and prolapse of the cusp. (Hanson et al., 1996) The chordae tendineae also experience elongation and may rupture with resultant loss of leaflet tethering (Jeresaty et al., 1985). The commonest flail type involves the middle posterior scallop (P2) (**Fig. 3**). These patients can deteriorate from an initially benevolent asymptomatic systolic click to a mid–late systolic murmur, and later to a pansystolic murmur with or without left heart dilation.

While often sporadic, there appears to be a genetic component to MVP with an autosomal dominant mode of inheritance seen in documented familial cases (Hayek et al., 2005). MVP is also seen among inherited connective tissue disorders such as Marfan's and Ehlers–Danlos syndrome.

Signs and Symptoms

Many patients with MVP may remain asymptomatic even in the presence of significant MR. However, a subset of patients may develop a constellation of symptoms including atypical chest pain, panic attacks, palpitations, dyspnea, exercise intolerance, and syncope. On auscultation, a midsystolic click with a late-systolic murmur can be best heard over the cardiac apex.

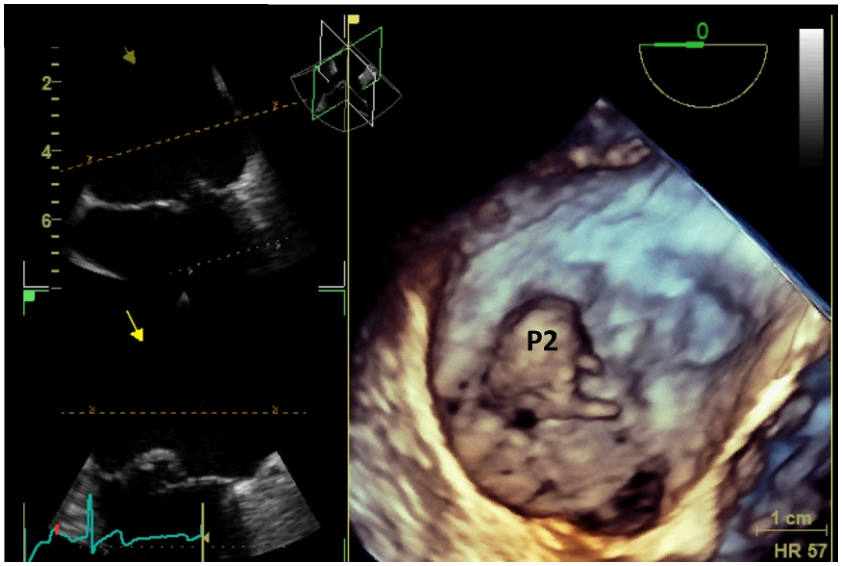

Fig. 3 Three-dimensional echocardiographic view of a flail the middle posterior segment (P2) of the posterior mitral valve leaflet as seen from the left atrium (the surgeon's view).

Diagnosis

TTE is used to investigate MVP (Class I) (Nishimura et al., 2017). Owing to the mitral valve's saddle shape, normal mitral valves may be detected as false positives. To minimize this, diagnosis is most reliable when assessed on parasternal long-axis or apical three-chamber view. Electrocardiography and chest radiographs are likely to be normal with the exception of severe MR.

Medical Therapy

In the asymptomatic patient, no specific treatment is necessary. Nor do they require antibiotic prophylaxis for endocarditis (Nishimura et al., 2017). Beta-blockers may relieve symptoms in certain patients but would not influence disease course (Shah, 2010). Patients with MVP but no MR should be reviewed every 3–5 years. Echocardiography should be performed in the patients with new onset symptoms or suspicious clinical examination. Those with severe MR should have yearly echocardiography performed (Nishimura et al., 2017).

Surgical Treatment

Surgery is indicated in the presence of any severe MR presuming low operative risk and a high likelihood of repair (Nishimura et al., 2017). In general, surgery for MVP is generally associated with low mortality and low reoperation rates (at 10 years, survival was 88.1% and freedom from reoperation was 91.1% in one study) (Glauber et al., 2015).

Introduction

Despite limited evidence, diuretic therapy has become a first-line therapy for the management of patients with acute heart failure (AHF). AHF is a life-threatening clinical syndrome that is characterized by an abrupt onset of symptoms, usually necessitating hospitalization. While this syndrome can occur de novo, it most frequently occurs in patients with a known diagnosis of HF in whom fluid has accumulated over days to weeks. In extreme cases, AHF can lead to cardiogenic shock, due to a low cardiac output state and a low systemic blood pressure, collectively preventing adequate end-organ perfusion. However, a consistent feature across the spectrum of AHF is fluid retention, which can manifest as ankle swelling, ascites, and/or pulmonary edema. Therapeutic strategies to relieve congestion can relieve symptoms and improve a patient's quality of life.

Before modern diuretics therapy was available, fluid retention was managed using rotating tourniquets to reduce cardiac preload, the insertion of Southey tubes subcutaneously to facilitate the drainage of fluid (Southey, 1877), recurrent venesection (Krishnakumar et al., 2007), and use of digoxin (Withering, 1785). In the 1920s, mercury-based therapies were noted for their diuretic effect. First noted by a medical student when these mercury-based agents were used for the treatment of syphilis, Merbaphen (novasurol) became a popular diuretic that could be administered as an intramuscular injection for the management of HF. It was not until the 1950s that more recognizable diuretics were introduced, first with the discovery of thiazide diuretics (Novello and Sprague, 1957) and later, in the 1960s, with loop diuretics (Robson et al., 1964). Such discoveries were considered revolutionary for the treatment of HF.

In the present era, the evidence supporting diuretic usage is lacking. While there is evidence to support their role in effectively relieving congestion and thereby attenuating brain natriuretic peptide levels (Palazzuoli et al., 2015), their effect on cardiovascular and all-cause mortality is largely derived from small under-powered randomized studies (Felker et al., 2009). Nevertheless, diuretic therapy within HF is considered a "class I" recommendation from international guidelines, meaning usage is generally considered beneficial (Yancy et al., 2016; Ponikowski et al., 2016). International guidelines suggest diuretics should be used for the relief of dyspnea and edema in patients with signs and symptoms of congestion, irrespective of left ventricular ejection fraction, with the

specified aim of achieving and maintaining a euvolemic state. They also recommend the use of the lowest possible dose of diuretic to achieve euvolemia to prevent hypotension, worsening renal function and neurohormonal activation. A lower dose of diuretic may enable up-titration of a disease modifying agents such as angiotensin converting enzyme inhibitors or sacubitril/valsartan, beta-blockers, and mineralocorticoid receptor antagonists (Ponikowski et al., 2016; Yancy et al., 2016). In this review, we discuss the evidence base for the use of these modern diuretics in the management of AHF.

Types of Diuretic

There are four pharmacological classes of diuretics used in HF (Fig. 1):

(a) Loop diuretics (furosemide, bumetanide, torsemide, ethacrynic acid)
(b) Thiazide diuretics (hydrochlorothiazide, bendroflumethiazide, Indapamide, or the "thiazide-like" metolazone)
(c) Directly acting potassium-sparing diuretics (amiloride and triamterene)
(d) Mineralocorticoid receptor antagonists (spironolactone, canrenoate, and eplerenone).

Loop Diuretics

Loop diuretics act on the ascending limb of the loop of Henle, blocking the reabsorption of up to 20%–30% of filtered sodium by inhibiting the sodium, potassium, and chloride co-transporter. This results in an intense, and usually short-lived, diuresis. Loop diuretics must be delivered to the lumen of the nephron and its actions are dependent on glomerular filtration being sufficiently preserved.

Loop diuretics can be administered orally, intravenously as a slow injection, or as an infusion. They have a rapid onset of action, working within minutes when given intravenously or within 30 min when given orally (Maxwell et al., 2002). They have a short duration of action, and consequently they may have to be given several times in a day to maintain the diuretic effect and to minimize rebound sodium reabsorption. However, gut edema may alter the rate of absorption of loop diuretics, but this effect is variable across the drug class. For instance, oral bumetanide achieves higher rates of absorption when compared with oral furosemide when administered to patients with gut edema (Sica, 2003). Thus, switching from oral furosemide to oral bumetanide can often lead to a diuresis that would not have been achieved with oral furosemide. Bumetanide is also more potent than furosemide, with 1 mg of oral bumetanide equivalent to approximately 40 mg of furosemide, and demonstrates higher bioavailability (approximately 70%) compared with oral furosemide (varying from 10% to 110%) in patients with marked fluid retention or gut edema. Furthermore, as furosemide is renally excreted, it can accumulate if administered to patients with renal dysfunction. Bumetanide and torasemide undergo hepatic elimination. However, torasemide has a longer half-life (3–4 h), meaning it should be administered less frequently than furosemide and bumetanide.

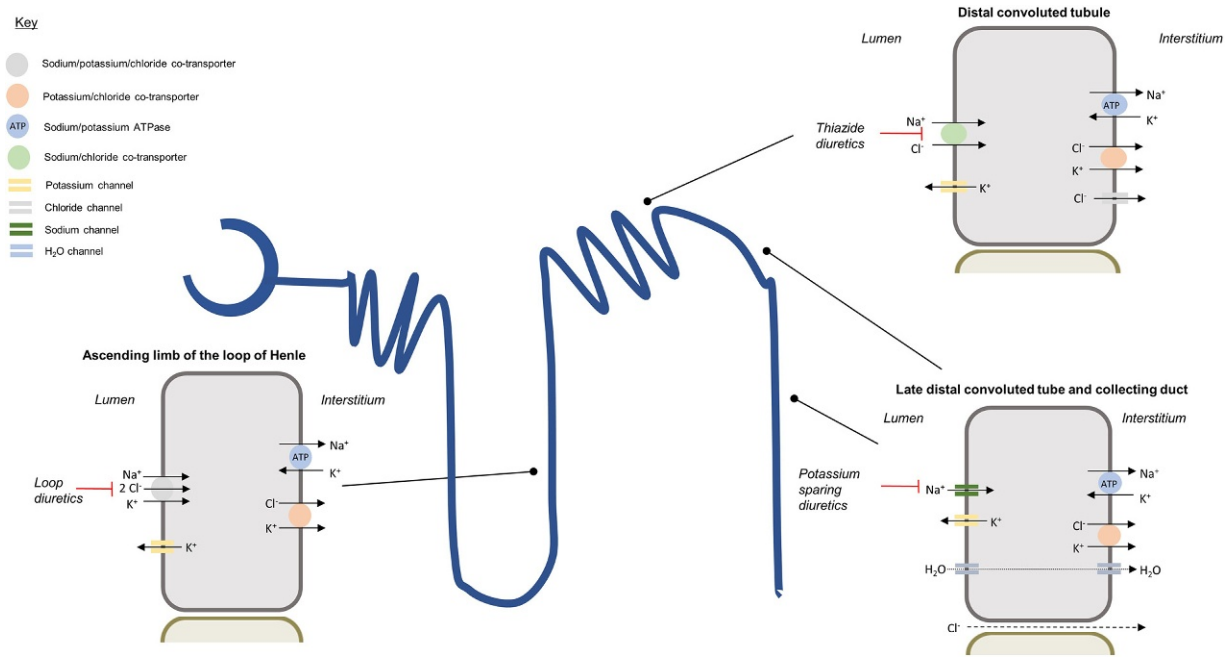

Fig. 1 Highlights mechanisms of actions of the different diuretics on the different areas of the nephron.

Table 1 Summary of common side effects of diuretics in acute decompensated heart failure

Hypokalaemia with loop and thiazides
Hyperkalemia with potassium sparing diuretics
Hyponatremia more frequent with thiazides than loop
Impaired glucose metabolism with loop and thiazides
Ototoxicity with high-dose loop
Acute gout with loop and thiazide
Activation of RAAS and sympathetic nervous system leading to progression of LV dysfunction

RAAS, renin-angiotensin-aldosterone system.

All loop diuretics may cause changes in systemic hemodynamics that are initially unrelated to the degree and extent of natriuresis that they induce. For instance, short-term administration of furosemide can lead to a rapid increase in venous capacitance and a decline in cardiac filling pressure, coincident with a rise in plasma renin activity. This effect predominates over any rise in systemic vascular resistance in patients with pulmonary edema or decompensated AHF (Brater et al., 1984a).

The side-effects of loop diuretics are summarized in **Table 1**, this includes: risk of ototoxicity (highest with ethacrynic acid); transient hearing loss, which may occur in patients receiving rapid intravenous bolus injection—so injection at a rate above 4 mg/min is not recommended; and permanent sensorineural hearing loss, which may occur at doses equivalent to furosemide 1000 mg per day (Rybak, 1985).

Thiazide and Thiazide-Like Diuretics

Thiazide diuretics such as bendroflumethiazide, hydrochlorothiazide, and indapamide act on the distal tubule by inhibiting sodium and chloride reabsorption. This results in a ~10%–15% reduction in sodium reabsorption. Compared with loop diuretics, while associated with a slower onset (1–2 h), they offer a more prolonged (12–24 h) and milder diuretic effect. The combination of a mild diuretic effect and long duration of action produces sodium excretion comparable to loop diuretics throughout 24 h (Vermeulen and Chadha, 1982). However, this also results in side effects such as nocturia, in addition to hypokalemia. Administered as a solo agent, thiazides are ineffective in individuals with a glomerular filtration rate below 30 mL/min. However, when thiazides, or indeed thiazide-like diuretics such as metolazone, are used in combination with loop diuretics, they facilitate sequential nephron blockade and are useful when managing refractory edema. Unlike thiazide diuretics, thiazide-like diuretics also act on the proximal tubule, where 60%–70% of sodium is reabsorbed and therefore can produce a profound diuresis.

Potassium Sparing Diuretics

Potassium sparing diuretics (such as amiloride) produce a mild diuretic effect by blocking the sodium/potassium exchange pump in the distal tubule. This exchanger is highly active in patients with HF who receive both a loop and thiazide diuretic. As potassium sparing diuretics tend to have a weak diuretic effect, they are mainly used in combination with thiazide or loop diuretics to prevent hypokalemia, as they are more effective than potassium replacement (Townsend et al., 1984; Ghosh et al., 1987; Kohvakka, 1988). However, usage is associated with a risk of hyperkalemia, particularly in patients with known renal dysfunction (Krishna et al., 1988).

Low-dose aldosterone (mineralocorticoid) receptor antagonists tend not to be used principally for diuresis in HF, but instead are administered for their potent antifibrotic properties to patients with chronic HF (RALES, 1996). However, in patients with fluid retention associated with right-sided HF, liver impairment, and ascites, very high circulating levels of aldosterone are detectable and high doses of aldosterone receptor antagonists (200–400 mg/day) can be useful in this setting for a diuretic effect.

There is increasing evidence, from multiple small studies, that high doses of spironolactone (>100 mg /day) can induce a potent natriuresis, sufficient to provide a negative sodium balance in patients resistant to loop diuretics (Chamsi-Pasha et al., 2014). The ATHENA-HF (Aldosterone Targeted Neurohormonal Combined With Natriuresis Therapy in HF) trial is a randomized, double-blind, placebo-controlled trial that aims to further evaluate the role of high-dose spironolactone (>100 mg/day) compared with placebo (or continued low-dose spironolactone use) on N-Terminal pro-Brain Natriuretic Peptide (NT-proBNP natriuretic peptide) levels for hospitalized AHF patients (Butler et al., 2016). The investigators of this study hypothesize that in patients with AHF, the early use of higher doses of spironolactone will produce a significant reduction in NT-proBNP, from randomization to 96 h, compared with standard care. This study should provide more insight into the safety and efficacy of higher doses of spironolactone in AHF and substantiate current clinical concerns relating to acute kidney injury and hyperkalemia.

Evidence Base for the Use of Diuretics in AHF

The evidence base supporting diuretic use in AHF is limited. A summary of contemporary trials evaluating diuretic use within acute decompensated HF (e.g., trials containing patients hospitalized with worsening symptoms or those with New York Heart Association II–III characterized by fluid retention) is detailed in **Table 2**.

Table 2 Summary of contemporary trials evaluating diuretic use within acute decompensated heart failure patients

Trials of diuretics for ADHF	*Sample size*	*Population studied*	*Trial design*	*Diuretic drug*	*Outcomes*
Placebo-controlled trials					
Kouroukli, 1976	30	ADHF	Cross-over	Bumetanide vs. furosemide vs. placebo	Effective water excretion with both loop diuretics
Haerer, 1990	60	NYHA II-III	Unblinded, controlled, nonrandomized	Piretanide vs. placebo	Improvement in all clinical and hemodynamic parameters in the absence significant side effects
Kleber, 1990	247	Mild CHF	Multicentre, double-blind, double-dummy, randomized	Oral HCT vs. ibopamine vs. HCT + ibopamine vs. placebo	Greater reduction in body weight with diuretics
Patterson, 1994	66	NYHA II-III	Randomized, parallel, double-blind, multicenter	Oral torasemide 5 mg vs. torasemide 10 mg vs. placebo	Greater reduction with Torasemide
Sherman, 1986	38	Mild-moderate CHF	Double blind, randomized, parallel	Piretanide vs. placebo	At 28 days, improved symptoms with piretanide
Thiazide vs. loop diuretic					
Stewart, 1965	11	ADHF, Resistant edema	Cross-over trial	Furosemide vs. bendrofluazide vs. Ethacrynic acid	Furosemide at doses of 200 mg leads to effective diuresis, similar to ethacrynic acid, and better than bendrofluazide
Crawford, 1988	47	CCF, primary care based	Unblinded	Frusemide-amiloride vs. cyclopenthiazide-potassium	Furosemide lead to better response, more free from PND and orthopnoea
Gonska, 1985	30	NYHA II-III	Open, controlled, randomized study	Piretanide vs. hydrochlorothiazide-triamterene	Significant Weight loss in both groups. Piretanide group were more recompensated (10 vs. 4)
Gabriel, 1981	18	Elderly with cardiac edema	Cross-over trial design	Bendrofluazide, frusemide and bumetanide	Bumetanide least change in plasma potassium compare to bendrofluazide
Comparison between loop diuretics					
Noe, 1999	240	NYHA II-III	Prospective study, randomized	Torasemide vs. furosemide	At 6 months, Torasemide group were heavier but had better quality of life at 1 month only
Stroupe, 2000	193	ADHF	Prospective, randomized, nonblind study	Torasemide vs furosemide	At 1 year Torasemide leads to lower readmission to hospitalization 18 vs. 34%; $P = 0.013$. Torasemide was more cost-effective
Murray, 2001	234	ADHF	Open-label trial	Oral torasemide vs. furosemide	Less readmission with torasemide 32% vs. 19%; $p < 0.01$ at 1 year and more improved dyspnea and fatigue scores
Muller, 2003	237	Primary care NYHA II-IV	Open randomized trial	Oral torasemide vs. furosemide	At 9 months, more clinical improvement and better quality of life in patients with Torasemide
Low dose vs. high dose loop					
Felker, 2011	308	ADHF	Prospective, 2 × 2 factorial design, double-blind, randomized trial	IV furosemide bolus low vs. high dose vs. continuous low vs. high dose	Over 72 h. No difference for symptoms or renal function between IV bolus vs. continuous infusion. Higher dose (2.5 × oral dose at admission) had better secondary outcomes such as relief of dyspnea, change in weight, fluid loss, with worsening renal function, but there was no worse 60-day outcome
Combined thiazide and loop diuretic					
Sigurd, 1975	18	ADHF	Randomized cross-over trial, single dose	Bumetanide and bendrofluazide	More diuresis with combined treatment
Channer, 1994	33	ADHF	Randomized	Iv furosemide and bendrofluazide or metolazone	Bendrofluazide and metolazone were equally effective in establishing a diuresis

Placebo-Controlled Trials of Diuretics

Placebo-controlled, randomized trials that have evaluated diuretic therapy in HF have been limited to a relatively small number of patients, ranging from 3 to 247 patients. These studies reported that diuretics significantly improve symptoms in HF (Kourouklis et al., 1976; Haerer et al., 1990; Kleber and Thyroff-Friesinger, 1990; Patterson et al., 1994; Sherman et al., 1986; Stewart and Edwards, 1965). However, none were powered to estimate the effect on mortality, but a meta-analysis of three short-term studies reporting mortality up to 12 months suggested a 75% mortality reduction [95% CI 16%–93% $P = 0.03$], but the main issue with this analysis was that the number of deaths was low—12 in the placebo group and 3 in the diuretic group—and the majority of the patients were unlikely to have met the contemporary definition of acute decompensated HF (Faris et al., 2002).

Thiazide Versus Loop Diuretics

Several small studies suggest that loop diuretics appear to be more effective at decongestion than thiazides alone in the management of HF (Crawford et al., 1988; Gonska and Kreuzer, 1985; Stewart and Edwards, 1965). Thiazide diuretics have a less harsh onset and longer duration of action, and for this reason they may be more acceptable to patients over loop diuretics (Funke Kupper et al., 1986). However, they are also more likely to result in hypokalemia and hyponatremia (Stewart and Edwards, 1965; Gabriel and Baylor, 1981; Vermeulen and Chadha, 1982).

Comparison Between Loop Diuretics

Comparisons between loop diuretics have principally evaluated torasemide and furosemide, with findings of these studies summarized in **Table 2**. Assessed using a randomized and unblinded study design, oral torasemide appears to offer a lower HF-related readmission rate compared to oral furosemide (Noe et al., 1999; Stroupe et al., 2000; Murray et al., 2001; Muller et al., 2003). It has been suggested that torasemide is also better tolerated by patients, compared with furosemide, with less urinary urgency (Muller et al., 2003). However, international guidelines provide no recommendations between specific loop diuretics.

Dose of Loop Diuretic and Bolus Versus Continuous Infusion of Loop Diuretic

The Diuretic Optimization Strategies Evaluation (DOSE) trial, assessed the initial diuretic strategies in patients with acute decompensated HF (Felker et al., 2011). DOSE used a 2×2 factorial design and randomized 308 acutely decompensated HF patients to receive intravenous furosemide, either as a twice-daily bolus or a continuous infusion, using either a low-dose (intravenous dose numerically equivalent to the patient's oral dose) or a high-dose (an intravenous dose 2.5 times higher than the patient's oral dose) regime. Dose adjustments were permitted following 48 h of intravenous therapy. At 72 h, there were no significant differences in either: (1) global assessment of symptoms or (2) change in serum creatinine; the studies predefined coprimary endpoints. Patients randomized to receive a high-dose intravenous furosemide regime reported an improvement in dyspnea (area under the curve for dyspnea 4478 ± 1550 in low dose vs. 4669 ± 1496 in high dose, $P = 0.04$), reduction in weight (-6.1 ± 9.5 lbs in low dose vs. -8.7 ± 8.5 lbs in high dose, $P = 0.01$), and greater net fluid loss (3575 ± 2635 mL in low dose vs. 4899 ± 3479, $P = 0.001$). However, the high-dose intravenous furosemide regime was also associated with a greater risk of serum creatinine measurements rising by >0.3 mg/dL within 72 h (23% vs. 14%, $P = 0.04$). There was no difference in length of initial hospital stay or in days alive and out of hospital at day 60. In addition, there were no statistically significant differences between continuous infusion or twice-daily bolus injection of furosemide in terms of the patients' global assessment of symptoms, mean change in serum creatinine, net fluid loss, change in weight, or length of hospital stay. This supported findings from a previous study (Allen et al., 2010).

While the DOSE trial did not achieve either coprimary endpoint, secondary outcome measures suggest that high-dose intravenous furosemide can enable rapid decongestion, with concomitant symptomatic relief, at the expense of an increased risk of renal dysfunction, with no medium-term clinically significant consequences.

Door to Diuretic Time and Prognosis

In a prospective registry based study assessing the time taken to give diuretics to patients presenting with acute decompensated heart failure, Matsue et al found that among 1291 patients, door to diuretic time of less than 60 minutes was associated with lower in-patient mortality (2.3 versus 6, P=0.002) and in a multivariate analysis, patients receving diuretics within 60 minutes had lower inpatient mortality (odds ratio of 0.39 95% confidence interval (0.20 to 0.76); p=0.006) (Matsue et al., 2017).

Diuretic Resistance

A frequent problem experienced when treating patients with advanced HF is diuretic resistance. Diuretic resistance is a term used when the diuretic response is either diminished or lost before the therapeutic goal can be reached. Diuretic resistance is common, which occurs in up to one-third of hospitalized patients (Ravnan et al., 2002), and is associated with a poor prognosis (Neuberg et al., 2002). There are several mechanisms that contribute toward diuretic resistance (see **Fig. 2**), including:

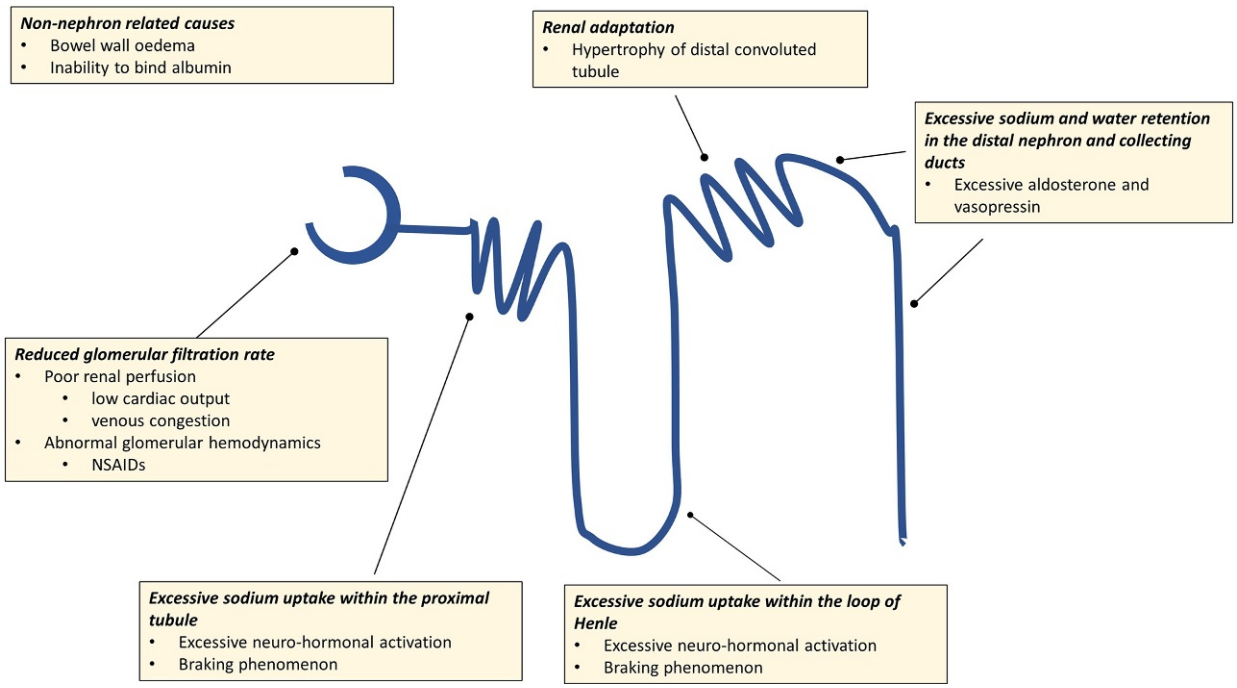

Fig. 2 Highlights the different mechanisms of diuretic resistance. Some are not related to the nephron and some involving different parts of the nephron.

- *Decreased bioavailability of diuretics*: In congested states, bowel wall edema may lead to reduced diuretic absorption. This effect is particularly noticeable with oral furosemide (Brater et al., 1984b; Vasko et al., 1985).
- *Reduced glomerular filtration rate* (*GFR*): A reduction in the GFR can occur due to poor renal perfusion, secondary to either low cardiac output or venous congestion. Additionally, chronic kidney disease or acute kidney injury can also prevent diuretics from entering the nephron's proximal tubule lumen. Both mechanisms reduce the delivery of diuretics and therefore any potentially beneficial diuretic effects cannot be harnessed (de Silva et al., 2006).
- *Excessive sodium uptake within the proximal tubule, loop of Henle, and the distal tubules* may occur secondary to the following mechanisms:
  - *E*xcessive neuro-hormonal activation (renin-angiotensin system and vasopressin) leading to excessive sodium and water retention throughout the proximal and distal tubules
  - The presence of the *Braking phenomenon*. This is a rebound of excessive sodium reabsorption that occurs when there is no diuretic detectable within lumen of either the proximal tubule or the loop of Henle. This typically occurs in the period between boluses of loop diuretics.
- *Renal adaptation*: The chronic use of diuretics may lead to hypertrophy of distal convoluted tubule, which may lead to more sodium and water resorption (Stanton and Kaissling, 1988; Kaissling and Stanton, 1988).
- *Drug interaction*: NSAIDS, aspirin (Bartoli et al., 1980), pioglitazone

Importantly, compliance with diuretic therapy needs to be addressed with the patient, their family, or their careers, prior to establishing a diagnosis of diuretic resistance.

Strategies for Decongestion in AHF Patients with Impaired Diuretic Responsiveness

Several strategies can be employed to aid the decongestion of patients with acute HF who manifest impaired diuretic responsiveness. These include diuretic and nondiuretic strategies.

Diuretic Strategies for Decongestion

1. Changing the route of administration from oral to intravenous (thus overcoming bioavailability issues);
2. Continuous infusion of loop diuretic rather than intermittent bolus injections (although this may only offer a minor improvement);
3. Using higher doses of intravenous loop diuretics to increase the diuretic dose reaching the tubules, particularly in the context of a low GFR;
4. Sequential nephron blockade by using a combination of diuretics (Kiyingi et al., 1990; Sigurd et al., 1975) such as metolazone or bendroflumethiazide in addition to a loop diuretic. This approach requires close monitoring, with attendant risks of marked electrolyte disturbance, hypotension, dehydration, and worsening renal function.

5. Restricting excessive dietary sodium and fluid intake may improve diuretic resistance, as less sodium and water are processed by the nephron. This strategy can be unpleasant for patients and should be limited to not less than 1.5 L of fluid intake daily.

Nondiuretic Strategies for Decongestion (Summarized in Table 3)

1. Renal dose dopamine.

   The exact mechanism through which renal dose dopamine (2–3 mcg/kg/min) increases renal blood flow remains debated, but is likely to involve a combination of increased cardiac output (via beta-1 receptors, traditionally associated with doses of 5–10 mcg/kg/min) and reduced renal and peripheral vasodilation (via peripheral dopaminergic receptors). (Bock and Gottlieb, 2010; Elkayam et al., 2008).

   The addition of dopamine to standard therapy for patients with AHF and a preserved systolic blood pressure have been evaluated in two reasonably sized randomized trials.

   - In the DAD-HF II trial (Triposkiadis et al., 2014), 161 patients with AHF with mean systolic blood pressures of 157 ± 28 mmHg were randomized to dopamine 5 mcg/kg/min with furosemide vs. furosemide alone. The trial was prematurely discontinued due to a high incidence of tachycardia and the lack of benefit within the low-dose dopamine arm, with respect to 60-day or 1-year mortality, hospitalization for HF, or overall change in dyspnea score.
   - In the ROSE-AHF trial (Chen et al., 2013b), patients with AHF and a median systolic blood pressure of 114 (104–127) mmHg received low-dose dopamine at 2 mcg/kg/min, but did not significantly increase their cumulative urine output or improve renal function, as measured by cystatin C levels at 72 h. In addition, there were no significant differences between secondary endpoints such as HF rehospitalization rate, death, or adverse events for 60 days. The incidence of tachycardia was higher in the dopamine group.

   Therefore, current data do not support the use of dopamine in nonhypotensive patients presenting with AHF. However, the role for low-dose dopamine in AHF with hypotension, in the absence of cardiogenic shock, merits further study. In our own clinical practice, we do use renal dose dopamine in congested patients with impaired diuretic responsiveness, who demonstrates a systolic blood pressure of 80–100 mmHg to aid decongestion.

2. *Vasopressin receptor antagonists* (*aquaretics*)

   Aquaretics promote the loss of electrolyte-free water by inhibiting vasopressin 2 receptors, which subsequently prevents recruitment of aquaporin 2 channels to the luminal cell membrane within the nephron's collecting duct. Furthermore, aquaretics use is not associated with many of the side effects seen with traditional diuretics, with no alteration in renal blood flow, glomerular filtration rate, changes in serum potassium, creatinine or osmolality, and no activation of either noradrenaline or plasma renin (Narayan and Mandal, 2012). Aquaretics are particularly useful in the context of euvolaemic or hypervolaemic hyponatraemia (sodium <135 mmol/L). The effectiveness of tolvaptan, a vasopressin 2 receptor antagonist, was assessed in the Efficacy of Vasopressin Antagonism in HF Outcome Study with Tolvaptan (EVEREST) trial. This involved over 4100 patients with AHF, randomized to tolvaptan or placebo. Tolvaptan had no effect on total mortality or HF hospitalization when compared to placebo (Konstam et al., 2007; Gheorghiade et al., 2007). However, tolvaptan did significantly improve hyponatremia in patients with a baseline serum sodium of less than 134 mmol/L and edema score at day 7. The effect on serum sodium was maintained throughout a maximum of 40 weeks of treatment.

3. *Adenosine antagonists*

   Adenosine antagonists can potentially increase glomerular filtration and enhance the diuretic effect of diuretic drugs. The effectiveness of rolofylline, a selective A1 adenosine receptor antagonist, was assessed in the PROTECT trial, in which 2033 patients hospitalized with AHF were randomized to rolofylline or placebo. Rolofylline did not have any beneficial effect and was associated with an increased risk of seizures (Massie et al., 2010).

4. *Hypertonic saline to facilitate effect of loop diuretics*

   Several randomized single-blind studies from a single group have demonstrated that a combination of a hypertonic saline infusion (150 mL of 3% sodium chloride) and 250 mg furosemide infusion is superior to a furosemide infusion alone, in terms of increasing diuresis and serum sodium levels, and in reducing the length of hospital stay. They also reported that there was lower mortality (12.9% vs. 23.8%; $P < 0.0001$) and readmission rate (18.5% vs. 34.2%; $P < 0.0001$) at 57 months of follow-up (Paterna et al., 2011). The mechanism of action is unclear, but expansion of intravascular volume, improved renal blood flow, and shift of fluid from the interstitium into the circulating volume (Tuttolomondo et al., 2011) have been postulated as potential mechanisms. This method of decongestion and diuresis requires replication in other centers and in double-blind studies.

5. *Other alternative strategies aiding diuresis*

Table 3 Trials involving nondiuretic strategies for patients with HF

UNLOAD trial (Costanzo et al., 2007)
ROSE-HF trial (Chen et al., 2013a)
CARRESS-HF trial (Bart et al., 2012)
EVEREST trial (Konstam et al., 2007)
PROTECT trial (Massie et al., 2010)

Several alternative agents may also be helpful in improving responsiveness to diuretics. These include glucocorticoids and levosimendan

- Glucocorticoids may promote diuresis and protect renal function in patients with AHF. Liu and colleagues reported the effects of prednisolone (1 mg/kg/day or 60 mg/day) given over 4 weeks (followed by a tapering-off regimen) in patients with diuretic resistant AHF with mean furosemide dose of 212 ± 25 mg/day in addition to a thiazide and spironolactone in an unblinded uncontrolled study of 13 patients (Liu et al., 2007). They reported an improved diuresis after a 3–4-day lag period, weight loss (9.4 ± 3 kg), and an improved renal function with a fall in serum creatinine (55 ± 49 umol/L) over a median of 20 (11–40) days. The proposed mechanism of action of glucocorticoids includes: (1) increased expression of natriuretic peptide receptor-A (NPR-A) in the kidney and the hypothalamus: a mechanism that appears reduced in patients with HF (Liu et al., 2011) and (2) increasing renal blood flow through dilatation of the renal vasculature via increased renal prostaglandin, nitric oxide, and dopamine production (Massari et al., 2012). Subsequently, an open-label randomized controlled study assessing the effects of prednisolone on outcomes compared to standard care was designed (Liu et al., 2014). This study was terminated prematurely due to poor recruitment as patients were reluctant to receive glucocorticoids. From the 102 patients with AHF who were randomized to receive glucocorticoids or standard treatment, the glucocorticoid arm demonstrated an improvement in renal function at 7 days (serum creatinine -0.14 vs. -0.02 mg/dL ($P < 0.05$)) and improved symptoms. Thirty-day survival was better in the group receiving glucocorticoids compared to standard care; however, the number of deaths was low (3 deaths in glucocorticoid vs. 10 deaths in standard treatment group, $P < 0.05$). Further research is needed to confirm whether glucocorticoids may be beneficial in this setting.
- Levosimendan, an inodilator and calcium sensitizer, was studied in patients presenting with AHF in the REVIVE studies. These showed that when levosimendan was given intravenously, with a loading dose and as 24-h infusion, to patients with AHF, there was improved renal function and improved responsiveness to diuretics leading to rapid relief of symptoms (Packer et al., 2013). However, side effects including an increased risk of arrhythmia and hypotension were also reported. In our clinical practice, levosimendan is given without a loading dose and instead given after 24–72 h at low doses, such as 0.05 mcg/kg/min (**Table 4**).

Table 4 Diuretic trials in progress

Trial	*Sample size*	*Inclusion criteria*	*Trial design*	*Intervention*	*Primary outcome*
Safety and efficacy of the combination of loop with thiazide-type diuretics in patients with decompensated HF (CLOROTIC Trial) Trullas et al (NCT01647932) Change in body and patient reported dyspnoea in 24 h	304	Admission for acute decompensated HF	Double-blind,	randomized, placebo-controlled trial	Loop + thiazide diuretic therapy vs. loop diuretic therapy
Loop diuretic dosage in patients with AHF and renal failure: conventional vs. carbohydrate antigen 125-guided therapy (IMPROVE-HF trial) Nunez et al (NCT02643147) Change in renal function at 24 and 72 h	170	Admission for acute decompensated HF and renal dysfunction	Double-blind,	randomized, placebo-controlled trial	CA 125 guided loop diuretic therapy vs. conventional loop diuretic therapy
Diamox/Aldactone to increase the urinary excretion of sodium: an investigational study in congestive HF (DIURESIS-CHF trial) (NCT01973335) 1. Spironolactone arm: incidence of hypo- (serum potassium <3.5 mmol/L) or hyperkalemia (serum potassium >5.0 mmol/L) [Time Frame: 72 h] 2. Acetazolamide arm: natriuresis 24 h	80	Admission for acute decompensated HF, renal dysfunction and serum sodium <136 mmol/L	Double-blind, factorial	assignment, randomized controlled trial	1. Upfront therapy with spironolactone and loop diuretic vs. loop diuretic 2. Azetolamide + low dose loop diuretic vs. high-dose loop diuretic
Prospective, randomized, parallel-group pilot study comparing IV furosemide to subcutaneous furosemide in acute decompensated HF patients Russell et al (NCT02579057) Urine output: The volume of urine produced in milliliters over the 6 h after drug delivery will be measured	40	History of at least 3 months treated HF (NYHA class II/III/IV), or recent hospitalization for HF; presenting to Heart Failure Bridge Clinic (HFBC) with decompensated HF symptoms	Prospective,	Randomized, Parallel-Group Pilot Study	Intravenous furosemide vs. Subcutaneous furosemide

Conclusions

While the evidence base supporting diuretic therapy in HF is not extensive, they remain a fundamental cornerstone to the management of patients with AHF for symptomatic relief and are endorsed by international guidelines. The initial management strategy likely involves administration of a loop diuretic, such as furosemide, and the evidence suggests that an initial "high dose" strategy either by twice daily bolus injection or continuous infusion is likely to be more successful than a slower, more "ramped" approach. In cases of diuretic resistance, the addition of a thiazide or thiazide-like diuretic may enhance diuresis, but this will require close monitoring of fluid balance and electrolytes. The addition of other strategies to improve the effectiveness of diuretic therapy also appears to have a limited evidence base, but may be useful in some populations.

Introduction

Syncope is a common medical symptom, characterized by an abrupt and transient loss of consciousness and inability to maintain postural tone due to cerebral hypoperfusion, with rapid and spontaneous recovery (Sheldon et al., 2015).

Syncope is indicative of an underlying disease, and a common clinical condition seen by practitioners. In the general population, the estimated lifetime prevalence is approximately 20% (Chen et al., 2006). The incidence has predominantly a trimodal appearance with a peak at 20 and 60 years and at 80 years with the third peak occurring 5–7 years earlier in men (Ganzeboom et al., 2003; Ruwald et al., 2012). Among patients, there is almost a twofold increase in the incidence in patients 70–79 years old versus 60–69 years old (Soteriades et al., 2002). The incidence also is higher in patients with cardiovascular disease than without (Soteriades et al., 2002). In patients with syncope, approximately 3%–10% will have an episode while driving (Li et al., 2000; Maas et al., 2003; Sorajja et al., 2009).

Driving itself carries risk. Worldwide, approximately 1.3 million persons die annually from road crashes, which translates to about 3500 deaths per day. Another 20–50 million persons are estimated to be injured from road crashes. Traffic safety data from the United States compiled from 2014, reported some 6.1 million crashes, involving 32,675 deaths and 2.34 million injured persons. This rate equates to a person dying every 16 min due to a motor vehicle crash (Administration NHTS, 2014). While most accidents are attributed to human error, there remain a number of accidents, approximately 2%–11% that can occur from syncope with the potential for morbidity and mortality (Sorajja et al., 2009; Nume et al., 2016). In fact, patients with syncope have almost double the incidence rate of motor vehicle crashes (Nume et al., 2016). In addition, the amount of motor vehicle crashes related to sudden incapacitation is likely underreported, as many study analysis rely on patients who seek medical attention for their syncope. In one study, 29% of patients with syncope while driving reported an injury, but only 60% of these injured patients sought medical care for their injury (Sorajja et al., 2009).

Causes of Syncope

Previously the occurrence of sudden death while driving most commonly was attributed to coronary artery disease (Antecol and Roberts, 1990; Grattan and Jeffcoate, 1968; Halinen and Jaussi, 1994). More recent data show the etiologies for syncope while driving to be similar to the causes of syncope in the general population, with the most common cause being neurally mediated syncope (**Table 1**) (Sorajja et al., 2009; Blitzer et al., 2003). Tilt table testing in one small series confirmed a neurally mediated origin of syncope while driving (Li et al., 2000). This pathophysiology requires further evaluation, but the mechanism could have contribution from venous pooling, cutaneous vasodilatation from a warm car environment, and strong emotional stimulation while driving (Sorajja et al., 2009). One small study, evaluating patients with syncope with driving, found a vasodepressor response on head-up tilt table testing to be more common (Folino et al., 2012).

Among other identified etiologies, cardiac arrhythmias make up the next largest group (11.8%), with bradyarrhythmias being more common than ventricular arrhythmias, and supraventricular tachycardia (Sorajja et al., 2009). Interestingly, in the Triggers of Ventricular Arrhythmias (TOVA) study (Albert et al., 2007), the risk of ventricular tachyarrhythmias was not elevated during driving, but rather in the 30-minute period after driving. Of note, some patients have potentially more than one etiology, and many patients, approximately 20%–30%, continue to have an unknown cause for their syncope despite evaluation (Sorajja et al., 2009; Blitzer et al., 2003).

Syncope Recurrence

While the majority of patients have only one episode of syncope, approximately 12%–22% have recurrence (Soteriades et al., 2002; Sorajja et al., 2009). The recurrence of syncope mainly depends on correct diagnosis of the etiology and the efficacy of in-place

Table 1 Causes of syncope (Sorajja et al., 2009)

Cause of syncope	*Syncope while driving (n = 381)*	*Syncope not while driving (n = 3496)*	P *value*
Neurally mediated	142 (37.3)	1247 (35.7)	.54
Bradyarrhythmia	25 (6.6)	221 (6.3)	.86
SVT	8 (2.1)	71 (2.0)	.93
Ventricular tachyarrhythmia	20 (5.2)	130 (3.7)	.14
Structural heart disease	1 (0.3)	9 (0.3)	.99
Cerebrovascular disease	14 (3.7)	100 (2.9)	.37
CSH	12 (3.1)	100 (2.9)	.75
Orthostatic intolerance	18 (4.7)	223 (6.4)	.20
Others	87 (22.8)	1044 (29.9)	.004

Table 2 Estimated 12-month risk of syncope (Sumner et al., 2010)

Measure	*Categories*	N	*12-month syncope risk (%)*	*95% CI*	*Log rank statistic (df) (P-value)*
Number of spells in the previous year	0.1	55	21.9	8.8–33.2	33.4 (3)
	2.3	62	40.6	25.2–52.8	$P < .0001$
	4–6	49	49.4	30.3–63.3	
	>6	38	69.1	44.8–82.7	
Life time number of spells	<6	65	35.7	21.1–47.6	26.2 (3)
	6–9	39	31.4	47.2–10.9	$P < .0001$
	10–20	52	33.2	18.3–45.4	
	>20	48	71.1	51.6–82.8	
Frequency of spells prior to the previous year	≤0.15	49	49.6	30.6–63.5	12.1 (3)
	0.16–0.60	52	25.5	11.8–37.1	$P = .0071$
	0.61–1.65	51	41.6	23.8–55.2	
	>1.65	52	55.9	36.6–69.3	

Estimated 12-month survival rates with 95% CI and the log rank statistic.

treatment (Task Force for the Diagnosis and Management of Syncope et al., 2009). For patients with a cardiac cause or neurocardiogenic cause of their syncope, the risk of recurrence is increased compared to other etiologies (Soteriades et al., 2002; Sorajja et al., 2009). For vasovagal syncope, one predictor is the number of syncope events in the prior year. In patients with abnormal tilt table test with less than 2 syncopal episodes in the prior year, a 22% recurrence rate over 1 year was observed. In comparison, those patients with 2 or 3 syncopal episodes in the prior year had a 41% recurrence rate (**Table 2**) (Sumner et al., 2010). However, in a metaanalysis of vasovagal syncope, even among highly symptomatic patients, the spontaneous remission rate is high (Pournazari et al., in press). For patients presenting to an emergency department for evaluation of syncope, one meta-analysis showed recurrence to be almost linear over time increasing from 0.3% at 1 month to 22% at 24 months (Solbiati et al., 2015). For those patients with syncope while driving, the actuarial recurrence of syncope while driving is actually quite low, being 0.7% at 6 months (Sorajja et al., 2009). This recurrence rate overall is similar to those patients who have an index syncopal event not while driving (Sorajja et al., 2009). However, those patients with syncope not while driving tend to have more recurrences in follow-up (**Fig. 1**). In analysis of prospective data from the Prevention of Syncope Trial 1 and 2, the occurrence of syncope while driving was 0.48% and the estimated probability of syncope while driving was 0.62% per year; however it is unknown how much patients actually drove in this study (Tan et al., 2016).

In terms of prediction of morbidity within 7–30 days and mortality within 1 year of initial evaluation, a number of clinical tools are available to try and determine if patients require expedited work-up or not. Many of these risk scoring systems, such as OESIL, SFSR, Boston Syncope Rule, STEPS, and the Syncope risk score, most commonly include age and presence of an abnormal ECG (Colivicchi et al., 2003; Quinn et al., 2004; Grossman et al., 2007; Costantino et al., 2008; Sun et al., 2009). However, these studies are limited by sample size, inclusion of all syncope patients regardless of cause, and inconsistent definitions of syncope and its associated risk across these studies (Colivicchi et al., 2003; Quinn et al., 2004; Grossman et al., 2007; Costantino et al., 2008; Sun et al., 2009). As a general rule, these scoring systems should not replace clinical judgment, but can be considered as an adjunct in decision-making.

Rationale for Driving Privileges and Restrictions

In the United States and many developed countries, motor vehicle travel remains an important means of transportation. On a societal level, driving is a privilege, but for many persons, driving is a necessity due to demands such as from family and work. For a

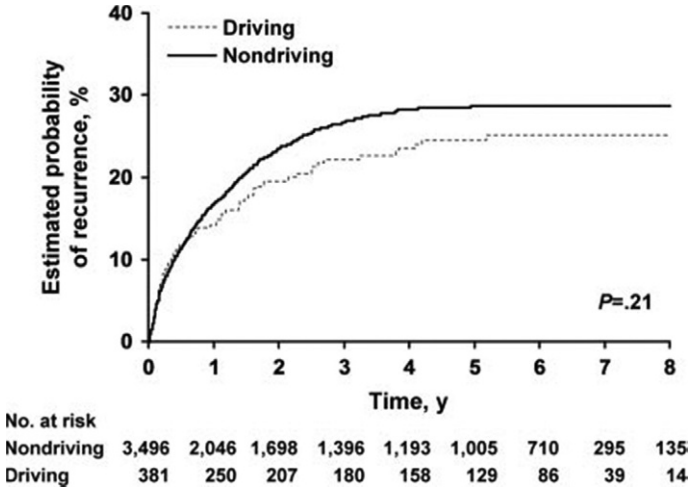

Fig. 1 Recurrence of syncope in syncope while driving and not while driving (Sorajja et al., 2009).

patient to be fit to drive, many factors come into consideration, which include knowledge of road laws, vision acuity, and alertness among others (Sorajja and Shen, 2010).

For the public interest, the main concern is whether a person can drive a vehicle safely enough to avoid causing harm to others. Restrictions on driving and driving guidelines have been developed to prevent or reduce motor vehicle accidents with the outcome being improved personal and public safety. However, accidents still occur and sudden driver incapacitation contributes to 1%–3% of all motor vehicle accidents, and 8%–10% are believed to be due to a heart condition (Petch, 1998; Epstein et al., 1996). Despite the incapacitation, only 2% or less of reported cases result in injury or death to other road users or bystanders (Ostrom and Eriksson, 1987; Parsons, 1986).

Determining Risk of Harm from Syncope While Driving

The determinant principal factors can be summarized in the risk of harm (RH) formula. This formula quantifies the amount of risk that can occur with sudden incapacitation, and then the level of risk can then be judged as acceptable or not. Society recognizes that certain driving groups, such as younger and elderly drivers, are allowed to drive despite their higher risk of potentially harming others (Simpson et al., 2004; Curtis and Epstein, 2009; Larsen et al., 1994). As such, policy should be fair to other higher risk groups, while considering the welfare of others where these higher risk individuals will drive. The threshold of acceptable risk may depend on the eye of the beholder. While a society may accept a limited number of higher risk drivers, the goal should not necessarily be to allow as many high-risk drivers as possible. Conversely, driving restrictions should not be prohibitive to certain higher risk drivers who number far fewer than the cohort of younger and elderly drivers.

The RH formula is derived from 4 components: (1) time spent driving or distance driven in a given time period (TD); (2) size of the vehicle driven (V); (3) risk of sudden cardiac incapacitation (SCI); and (4) the probability that incapacitation will cause a fatal or injury-producing accident (Ac). The formula can be expressed as:

$$\mathrm{RH} = \mathrm{TD} \times V \times \mathrm{SCI} \times \mathrm{Ac}$$

The time spent driving (TD) for noncommercial drivers is usually 4% daily (approximately 1 h) and less than 36,000 km per year or less than 720 h per year. For commercial drivers, the time spent driving is usually 25% daily (approximately 6 h) with longer distances and hours logged than the private driver definition (Simpson et al., 2004). Longer and shorter durations of driving can be accounted for with adjustment in this portion of the formula.

For the size of the vehicle (V), those with a weight over 3500 kg are attributed a value of 1, and this amount includes vehicles such as ambulances, semitrucks, and buses. Vehicles less than 3500 kg are assigned a value of 0.28. A list of representative vehicles and their weights are given in **Table 3**. Of note, motorcycles do not have a "V" assigned, but theoretically would be much lower than 0.28. Conversely, the weight of a bus can increase to 16,000 kg with a load of people and belongings, and the weight of a semi-trailer truck with a trailer can be up to 50,000 kg in the United States. With such a significant amount of mass, the "V" assigned should be theoretically different than a car weighing just over 3500 kg, but this difference is not accounted for in the formula.

The risk of sudden cardiac incapacitation varies among persons depending on their underlying conditions. Common conditions associated with syncope or sudden incapacitation are listed in **Table 4**. For commercial drivers, the risk of sudden cardiac incapacitation (SCI) is acceptable if their annual risk is 1% or less. This threshold is based on prior data from patients who are at least 3 months post-myocardial infarction and are able to complete seven METS on stress testing (Simpson et al., 2004).

Table 3 Types of Motor Vehicles and Weight (Sumner et al., 2010)

Moped/motorcycle	225–500 kg
Compact car	1350 kg
Midsize car	1600 kg
Large car	2000 kg
Compact truck/SUV	1600 kg
Midsize truck/SUV	1900 kg
Large truck/SUV	2500 kg
Ambulance	5500 kg
Semi-trailer truck	10,500 kg
Bus	12,500 kg

Table 4 Causes of syncope and risk of loss of consciousness

Bradycardia: 4%–5% annually (Ng Kam Chuen et al., 2014; Aste et al., 2016)
Brugada syndrome: 28%–40% prevalence (Sacher et al., 2006, 2012)
Carotid sinus syndrome: 7%–40% annually (Gaggioli et al., 1995; Claesson et al., 2007)
Hypertrophic cardiomyopathy: 2%–19% prevalence (Kofflard et al., 2003; Kim et al., 2016)
Long QT syndrome: 17%–34% prevalence, 5% annually (Moss et al., 1991; Goldenberg et al., 2008)
Orthostatic intolerance: 12%–31% prevalence (Atkins et al., 1991; Sarasin et al., 2002; Beckett et al., 1999)
Supraventricular tachycardia: 4%–14% prevalence (Page et al., 2016; Walfridsson and Walfridsson, 2005)
Vasovagal syncope: 40% prevalence, 22%–69% (Sumner et al., 2010; Tan et al., 2016)
Ventricular arrhythmias in primary prevention patient: 2% annually (Thijssen et al., 2011; Freedberg et al., 2001; Bardy et al., 2005)
Ventricular arrhythmias in a secondary prevention patient: 8% annually (Thijssen et al., 2011; Freedberg et al., 2001; Bansch et al., 1998; Kim et al., 2015)

The probability of a fatal or injury-producing accident (Ac) to other road users or bystanders is approximately 2% for all drivers (Ostrom and Eriksson, 1987; Parsons, 1986).

When these data are plugged into the RH formula for a commercial driver:

$$\begin{aligned} \text{RH} &= \text{TD} \times V \times \text{SCI} \times \text{Ac} \\ \text{RH} &= 0.25 \times 1 \times 0.01 \times 0.02 \\ \text{RH} &= 0.00005 \end{aligned}$$

This RH equates to a 1 in 20,000 chance of harm from a commercial driver. As a result, for a noncommercial driver, the SCI resulting in the equivalent RH can be calculated after adjusting for time spent driving (TD) and the vehicle size (V):

$$\begin{aligned} \text{RH} &= \text{TD} \times V \times \text{SCI} \times \text{Ac} \\ 0.00005 &= 0.04 \times 0.28 \times \text{SCI} \times 0.02 \\ \text{SCI} &= 0.22 \end{aligned}$$

While a 22% chance of SCI may be acceptable for most noncommercial drivers, if the time spent driving increases or the size of vehicle increases, this SCI also increases and may no longer be acceptable. Conversely, for commercial drivers, if the time spent driving decreases or the vehicle size decreases, the RH may become acceptable.

Based on this RH formula, many untreated conditions, such as bradycardia or supraventricular tachycardia that result in syncope, would disqualify both commercial and noncommercial driver patients from driving. However, appropriate treatment, such as with a pacemaker or ablation, would reduce these patients' risk of SCI to less than 1% and allow for driving to be resumed (Brunner et al., 2004). Some conditions have a higher rate of recurrence and SCI, which may not allow for patients to drive on a temporary or even permanent basis. While the annual risk of SCI may be less than the 22% threshold, this fact does not preclude the presence of higher risk periods of time where the risk of SCI is excessive. For instance, as the time from a ventricular tachyarrhythmia event increases, the risk of incapacitating ventricular arrhythmias decreases. At some point, the RH may be acceptable for noncommercial drivers to resume driving, but in commercial drivers the acceptable risk threshold may never be reached.

Of note, ventricular arrhythmias should not be taken as an equivalent for syncope. For patients with an ICD who receive an appropriate shock for ventricular tachyarrhythmias, only 31% experience syncope or near syncope during their event (Thijssen et al., 2011; Freedberg et al., 2001). The degree and severity of symptoms including loss of consciousness depend on the rate and duration of the ventricular arrhythmia as well as a patient's underlying cardiac dysfunction (Zipes et al., 2006). For primary prevention patients, using SCD-HeFT data, ICD discharge occurred in 7.5% of patients annually including appropriate and inappropriate shocks. Patients with appropriate shocks comprised 5.1% of the overall cohort (Bardy et al., 2005). So for primary prevention patients, we would expect an annual rate of syncope of 1.6% (or 0.31×0.051). In addition, the presence of an ICD only addresses the risk of SCD, and appropriate ICD therapy is frequently too late to prevent loss of consciousness even when programmed to deliver an immediate defibrillation (Task Force for the Diagnosis and Management of Syncope et al., 2009; Olshansky et al., 2008;

Bansch et al., 1998). For secondary prevention patients, the risk of recurrent ventricular is approximately 25% annually (Fig. 2) (Bansch et al., 1998; Kim et al., 2015). Thus for these patients, we would expect an annual rate of syncope of 7.8% (or 0.31×0.25).

It should be emphasized that the RH formula is one method for determining RH from driving, but it should not replace clinical judgment. As clinicians, patients with the same condition may have very different prognoses depending on comorbidities, therapy, and compliance with therapy. For most conditions, there is incomplete data regarding recurrence of syncope or sudden cardiac incapacitation with and without optimal therapy. Intuitively, patients with syncope are more likely to have a motor vehicle crash, and the data bears that out (Nume et al., 2016). Certain patients are more likely to have a motor vehicle crash from syncope; these include an approximate twofold increased risk for men compared to women, and those patients aged 18–35 years (Nume et al., 2016).

In addition, the RH formula does not supercede local driving regulations. The authors strongly recommend that physicians, who care for syncopal patients, know the pertinent driving laws and restrictions, particularly in regard to the duty of the patient or the physician to report a patient's inability to drive a motor vehicle.

In our large retrospective cohort, the patients with syncope while driving had a more frequent occurrence of injury (28.6% vs. 23.7%) than those without episodes while driving, but there was no significant increase in injuries requiring hospital care (Sorajja et al., 2009). This finding may be related to neurocardiogenic syncope being the most frequent cause, and the presence of a prodrome being a protective factor. As a group, there is no increase in mortality for syncope while driving patients compared to age- and sex-matched controls (Fig. 3). Prior studies have suggested sudden natural death while driving poses no

		Event rate		Risk of SCI

threat to other road users (Christian, 1988), but the presence of underlying cardiac disease, including ventricular tachycardia and myocardial infarction, carries a decreased survival rate similar to what has been shown in other studies (Sorajja et al., 2009; Kapoor, 1990). While some studies show the risk of recurrence to decrease from the index evaluation, one study found the risk of motor vehicle crash to remain elevated through 5 years of follow-up (**Fig. 4**) (Sorajja et al., 2009; Nume et al., 2016; Thijssen et al., 2011).

Ethical Considerations of Driving Restrictions

In the United States, private or noncommercial automobile driving is regulated by individual states which may or may not require reporting of a syncopal event. The laws for driving restrictions are a form of ethical judgments that attempt to balance the rights of the individual and the good of society. The two notions do not necessarily coincide, as an individual is allowed to act in whatever manner they choose as long as that action does not infringe upon the rights of others. Actual harm does not have to occur, as the potential for harm is the real threshold. For instance, drunk driving does not have to result in an accident, but the potential for harm is great enough that driving incapacitated due to alcohol is illegal. For medical providers caring for patients with syncope, the question distills to what is the risk of harm.

As a society, we accept a certain level of risk by letting higher risk drivers continue to drive. For teenagers aged 16–19 years in the United States, 2270 teenagers were killed by motor vehicle crashes and another 221,313 teenagers were injured in 2014 (Prevention CfDCa,https://www.cdc.gov/motorvehiclesafety/older_adult_drivers/). Considering this cohort comprises approximately 7% (22.4 million people) of the US population which was 320 million in 2014 (Bureau USC,https://www.census.gov/popclock/), the RH by teenage drivers is 0.01, which is significantly higher than what is established as acceptable (RH = 0.00005) for commercial drivers.

Similar for elderly drivers, those older than 65 years, in the United States, 50 older adults were killed and 214,000 were injured in motor vehicle accidents in 2012 (Prevention CfDCa,https://www.cdc.gov/motorvehiclesafety/older_adult_drivers/). Older adults make up 13% of the US population, which was 315 million in 2012, resulting in a cohort of 41 million (Bureau USC,https://www.census.gov/popclock/). With these numbers, the RH is 0.005, which is also quite a bit higher than the acceptable risk for commercial drivers.

Put another way, the risk for older adults and teenagers driving is 100–200 times higher than what has been deemed acceptable for commercial drivers. There are also aggravating and mitigating factors too. For instance, younger drivers tend to be more frequently intoxicated, wear seat beats less often, and drive at excessive speed (Halinen and Jaussi, 1994; Simons-Morton et al., 2005; Voas et al., 2012), but with more driving experience, we as a society expect their driving to improve. Elderly drivers, on the other hand, are cognizant of their limitations and tend to drive shorter distances and less so at night (Prevention CfDCa,https://www.cdc.gov/motorvehiclesafety/older_adult_drivers/).

Of note, many patients will not stop driving after being recommended to do so, regardless of how short or long the driving restriction is. Due to occupational and social demands on the patient, the compliance with driving restrictions is simply poor. The driving restriction given by most physicians is at least 6 months (Curtis et al., 1995; Akiyama et al., 2001). In the Antiarrhythmics versus Implantable Defibrillators (AVID) trial, the most common driving proscription was 6 to 11 months. However, 57% of

patients resumed driving within 3 months, and 78% within 6 months did so mainly because being unable to drive represented a "severe hardship" for 59% of the patients (Akiyama et al., 2001). In another study, 79% of patients remembered their physician-recommended driving restriction of 3 to 6 months, but 100% had continued to drive (Maas et al., 2003).

There are benefits to advising a driving restriction, however. Whether patients have or have not been shocked by their ICD, patients may continue to drive, but they impose self-restrictions such as driving shorter distances and only "if necessary"(Conti et al., 1997). In a large Canadian study of patients deemed unfit to drive, those patients who were warned by their physicians about driving had a 45% reduction in the annual rate of crashes (Redelmeier et al., 2012).

The probable need of some sort of driving restriction and the lack of compliance with it poses a legal and ethical morass. One key aspect is the principle of patient–physician confidentiality. Under almost any circumstance, a physician has an obligation to maintain confidentiality for a patient's medical condition. However, if a patient's condition poses a significant risk to others, then this information should not be withheld from the appropriate recipients or authorities. In this situation, the ethical principles of beneficence (doing good for society) outweigh the principle of confidentiality.

Driving Restriction Recommendations By Different Societies

The driving restrictions from American Heart Association, American College of Cardiology, and the Heart Rhythm Society are summarized in **Table 5** (Shen et al., 2017). The European Society of Cardiology (Task Force for the Diagnosis and Management of Syncope et al., 2009) has a separate set of recommendations, summarized in **Table 6**. While these recommendations do not cover all scenarios, they cover the far majority of them, and they still require physician discretion in applying them to patients.

There are several pertinent differences between the different societal recommendations. The main difference is the lack of recommendations for commercial driving in the AHA/ACC/HRS Guidelines. While commercial drivers' licenses are issued by each state and Washington D.C., these drivers are federally regulated in the United States by the Department of Transportation and Federal Motor Carrier Safety Administration who develop and issue the standards that must be met for a person to be a commercial driver. Other differences in the AHA/ACC/HRS include the separation of treatment by pharmacologic means and invasive procedures for a number of conditions such as supraventricular tachycardia, depressed ejection fraction with and without structural heart disease, and ventricular tachycardias (Task Force for the Diagnosis and Management of Syncope et al., 2009; Shen et al., 2017). Of note, whether the episode of syncope occurs while driving or not should not necessarily result in different treatment or driving restrictions (Sorajja et al., 2009; Sorajja and Shen, 2010).

Table 5 Suggested driving restrictions after an episode of syncope per AHA/ACC/HRS (Shen et al., 2017)

Condition	*Symptom-free waiting time*
OH	1 month
VVS, no faints prior year	No restriction
VVS 1–6 faints per year	1 month
VVS >6 faints per year	Not fit to drive until symptoms resolved
Situational syncope other than cough syncope	1 month
Cough syncope, untreated	Not fit to drive
Cough syncope, treated with cough suppression	1 month
Carotid sinus syncope, untreated	Not fit to drive
Carotid sinus syncope, treated with permanent pacemaker	1 week
Syncope due to nonreflex bradycardia, untreated	Not fit to drive
Syncope due to nonreflex bradycardia, treated with permanent pacemaker	1 week
Syncope due to SVT, untreated	Not fit to drive
Syncope due to SVT, pharmacologically suppressed	1 month
Syncope due to SVT, treated with ablation	1 week
Syncope with LVEF <35% and a presumed arrhythmic etiology without an ICD	Not fit to drive
Syncope with LVEF <35% and presumed arrhythmic etiology with an ICD	3 month
Syncope presumed due to VT/VF, structural heart disease and LVEF ≥35%, untreated	Not fit to drive
Syncope presumed due to VT/VF, structural heart disease and LVEF ≥35%, treated with an ICD and guideline directed drug therapy	3 months
Syncope presumed due to VT with a genetic cause, untreated	Not fit to drive
Syncope presumed due to VT with a genetic cause, treated with an ICD or guideline directed drug therapy	3 months
Syncope presumed due to a nonstructural heart disease VT such as RVOT or LVOT, untreated	Not fit to drive
Syncope presumed due to a nonstructural heart disease VT such as RVOT or LVOT, treated successfully with ablation or suppressed pharmacologically	3 months
Syncope of undetermined etiology	1 months

Table 6 Suggested driving restrictions after an episode of syncope per ESC (Task Force for the Diagnosis and Management of Syncope et al., 2009)

Diagnosis	*Group 1 (private drivers)*	*Group 2 (professional drivers)*
Cardiac arrhythmias		
Medical treatment	After successful treatment is established	After successful treatment is established
Pacemaker implant	After 1 week	After appropriate function is established
Successful catheter ablation	After successful treatment is established	After long-term success is confirmed
ICD implant	In general low risk, restriction according current recommendations	Permanent restriction
Reflex syncope		
Single/mild	No restrictions	No restriction unless it occurred during high risk activity
Recurrent and severe	After symptoms are controlled	Permanent restriction unless effective treatment has been established
Unexplained syncope	No restrictions unless absence of prodrome occurrence during driving, or presence of severe structural heart disease	After diagnosis and appropriate therapy is established

Summary

Syncope is a common condition that is implicated with motor vehicle crashes. Most patients have a similar prognosis to the general population, unless they have a cardiac etiology for their syncope. However, neurocardiogenic syncope remains the most common cause. For patients, the RH from syncope while driving can be estimated, but clinical judgment should still be used. While a driving restriction may be beneficial in terms of allowance for therapy to become effective, the majority of patients will resume driving before the end of the recommended restriction. As such, all physicians, who care for patients with syncope, should be familiar with local driving regulations.

Introduction

Heart failure (HF) is a prevalent disease affecting an estimated 5.1 million Americans and carries significant mortality and morbidity (Yancy et al., 2013). Echocardiography is an integral tool for the evaluation and treatment of patients with varying stages of HF or those with symptoms suggestive of HF. As an imaging modality, echocardiography is widely available, does not involve radiation, and provides real-time information with high temporal resolution. In HF, echocardiographic techniques allow for noninvasive assessment of cardiac structure, myocardial function, and hemodynamics for the purposes of initial diagnosis and subsequent clinical management. Early establishment and characterization of HF, whether systolic or diastolic, leads to earlier initiation of therapies that can improve clinical outcomes.

Diagnosis and Initial Evaluation of HF

Heart failure is often suspected in patients who present with nonspecific symptoms such as dyspnea, fatigue, or edema. Although careful physical examination may reveal signs of cardiac dysfunction, these findings may be subtle and insufficient for assessment of volume status or cardiac output. Transthoracic echocardiography with Doppler provides a noninvasive assessment of hemodynamics to establish a diagnosis of HF and characterize its severity. Echocardiography also allows for delineation of cardiac anatomy to help determine the etiology of HF, which is most commonly due to left ventricular (LV) myocardial dysfunction but may also arise from valvular abnormalities, right ventricular (RV) myocardial dysfunction, or pericardial pathology. A wide spectrum of cardiomyopathies due to genetic or acquired factors lead to adverse remodeling of the ventricular myocardium. Subsequent impairment of ventricular contractility or relaxation, which can both be assessed by echocardiography, results in the clinical syndrome of HF.

Hemodynamics and Ventricular Function

Ascertainment of hemodynamic status is paramount in the acute management of heart failure and determination of prognosis. Unlike invasive catheterization, echocardiography allows for serial monitoring of hemodynamic status outside of the intensive care unit. Hemodynamic assessment by echocardiography encompasses measurement of circulatory flow (i.e., cardiac output) as well as evaluation of filling pressures in the cardiac chambers. Global LV systolic function can be described by several echocardiographic parameters including estimation of cardiac output. Diastolic function, assessed noninvasively by echocardiography, provides diagnostic and prognostic information and is also a key component in characterization of overall myocardial performance. In addition, evaluation of right ventricular function and hemodynamics plays an important and increasingly recognized role in the management of all forms of heart failure.

Ejection Fraction

Perhaps the most prevalent metric of LV systolic function is ejection fraction (LVEF), due to its prognostic value and therapeutic implications in heart failure patients (Quiñones et al., 2000; Cintron et al., 1993). LVEF is related to the proportion of the end-diastolic volume that constitutes the stroke volume (volume of blood ejected from the LV per heartbeat). Quantitation of LVEF by two-dimensional echocardiography (2DE) can be performed in multiple different ways. The recommended method is the biplane method of discs (modified Simpson rule), which involves deriving end-diastolic and end-systolic volumes by tracing the LV cavity in the apical 4-chamber and 2-chamber views, as shown in **Fig. 1**. Volumes are calculated by the summation of the volumes of parallel discs along the long-axis of the LV, each of equal thickness and variable diameter, defined by the traced endocardial borders. Alternatively, official recommendations state that LVEF may be calculated by three-dimensional echocardiography (3DE), which avoids geometric assumptions and the potential pitfall of foreshortening the LV apex (**Fig. 2** and **Video 1**). 3DE is more accurate and reproducible than 2DE for measuring LV volumes and calculating LVEF (Zhang et al., 2013; FASE et al., 2012). Progressive improvements in digital measurement algorithms and ease of use have led to increasing adoption of 3DE.

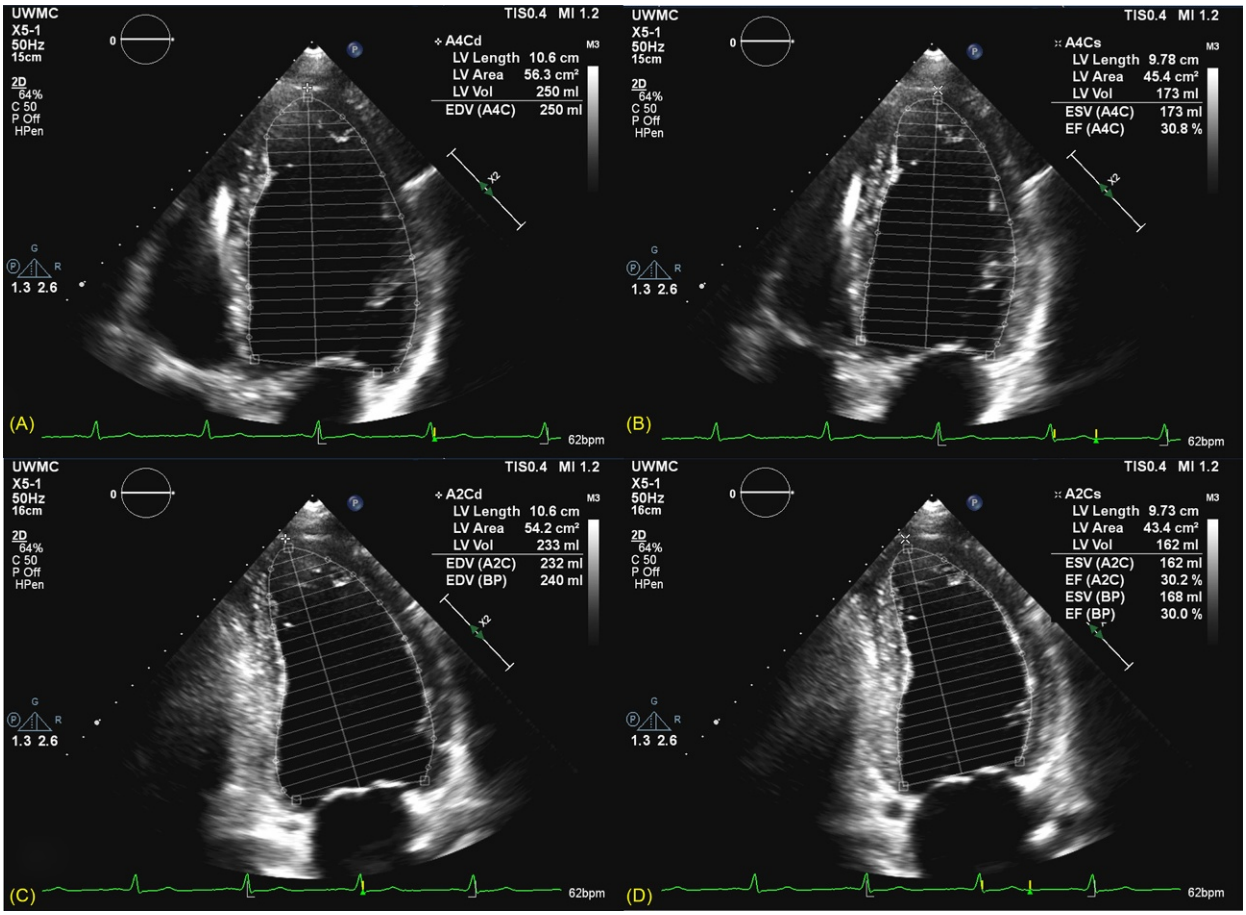

Fig. 1 LVEF by biplane method of discs in a patient with dilated cardiomyopathy. Volumes are derived from endocardial tracing of the LV cavity from the apical 4-chamber and apical 2-chamber views at end-diastole (A and C) and at end-systole (B and D). The difference between the end-diastolic and end-systolic volume yields the stroke volume, which is divided by the end-diastolic volume to yield LVEF. In this patient, the LVEF is moderately–severely reduced at 30%.

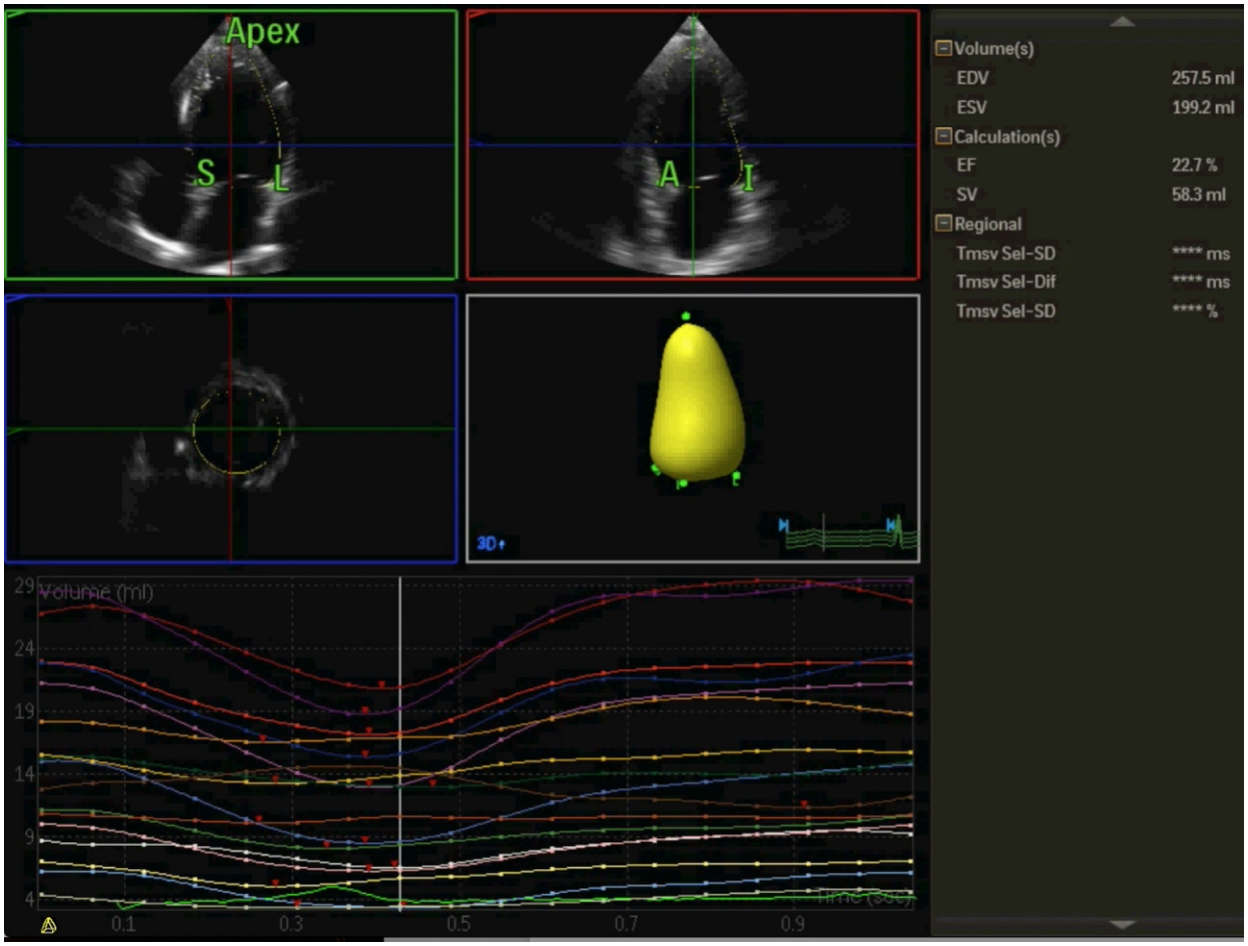

Fig. 2 LVEF by 3D echocardiography (3DE) in a patient with dilated cardiomyopathy. Endocardial tracing of full volume data acquired by 3DE generates a volume-rendered representation of the LV cavity throughout the cardiac cycle. The bottom panel shows volumetric changes over time due to segmental wall motion, divided per the 17-segment model. (See also **Video 1**.).

Other Measures of Systolic Function

Stroke volume may be derived from the change in LV volume from end-diastole to end-systole, using the biplane method of discs. Stroke volume can also be obtained by pulsed wave Doppler at the left ventricular outflow tract (LVOT), as shown in **Fig. 3**. Utilizing this method, stroke volume is calculated as the product of the cross-sectional area of the LVOT and the flow velocity at the LVOT over the duration of flow, or velocity-time integral (VTI). Stroke volume multiplied by heart rate results in cardiac output. Measurement of cardiac output by echocardiography can identify diminished cardiac function, even in the setting of normal LVEF, volume depletion, right ventricular dysfunction, or left ventricular hypertrophy.

Although ejection fraction and cardiac output by echocardiography are valuable and widely used indices of LV systolic function, they are influenced by changes in preload and afterload. The Doppler-derived dP/dt contractility index is a parameter that may be independent of heart rate and less dependent of loading conditions. Impaired contractility causes LV pressure to rise less rapidly during isovolumic contraction. This rate of change in the LV pressure is reflected by the slope of the mitral regurgitation jet by continuous wave Doppler. Systolic dysfunction prolongs not only the isovolumic contraction time but also the isovolumic relaxation time, in addition to shortening the ejection time of the left ventricle. The myocardial performance (or Tei) index can be calculated from these intervals, obtained by spectral Doppler, and represents a measure of combined systolic and diastolic function (Tei et al., 1995). Both the myocardial performance index and dP/dt derived by Doppler have prognostic value in patients with heart failure (Kolias et al., 2000; Dujardin et al., 1998; Arnlöv et al., 2005; Mikkelsen et al., 2006).

Diastolic Function

Heart failure with reduced ejection fraction generally involves impairment of both systolic and diastolic function. There has also been increasing recognition of an entity of heart failure with preserved ejection function (HFpEF) resulting from isolated diastolic

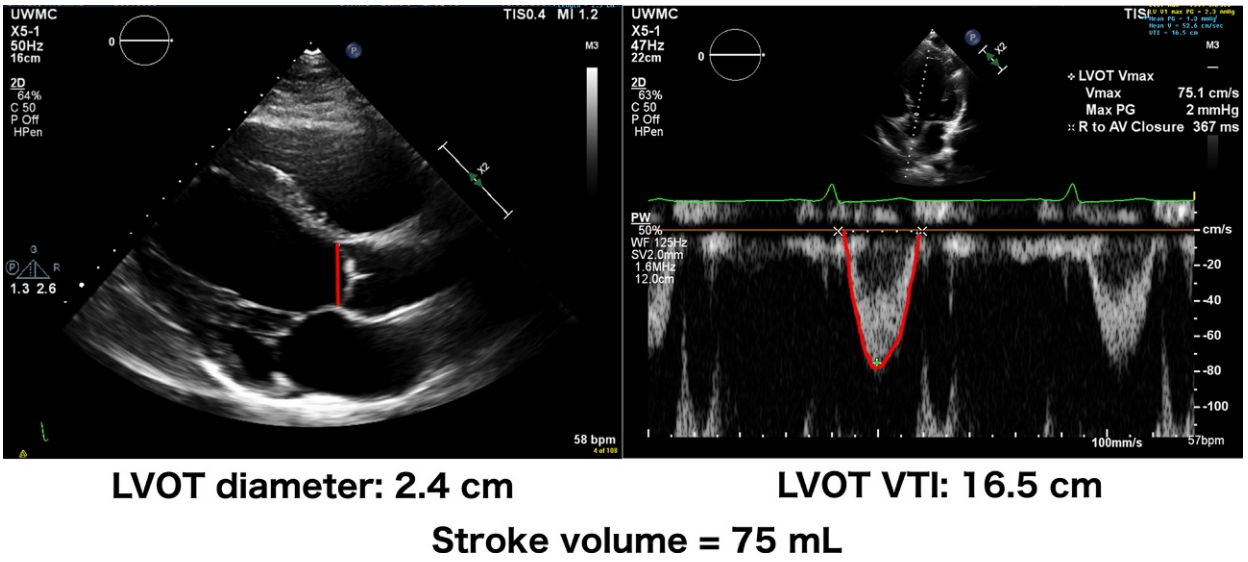

Fig. 3 Stroke volume by LV outflow tract (LVOT) Doppler. Cross-sectional area of the LVOT can be calculated from the LVOT diameter measured from the parasternal long-axis view (left image). Velocity–time integral (VTI) is obtained from pulsed-wave Doppler across the LVOT in the apical 5-chamber view (right image). Using the continuity equation, the LVOT cross-sectional area multiplied by the VTI yields stroke volume.

dysfunction. As evaluated by the integration of various echocardiography parameters, diastolic dysfunction has been shown to be associated with the development of heart failure and worse overall prognosis (Kane et al., 2011; Aljaroudi et al., 2012).

Left ventricular filling can be assessed by the spectral Doppler pattern of mitral inflow velocity, which represents the pressure gradient between the left atrium (LA) and left ventricle during diastole (**Fig. 4A**). Early transmitral flow (E wave) corresponds to active LV relaxation and is influenced by the relative compliances of the LA and LV. Late transmitral flow (A wave) is generated by atrial contraction and affected by the compliance of the receiving ventricular chamber. Impaired LV relaxation leads to a diminished E wave relative to the A wave. Furthermore, the deceleration time of the E wave is prolonged due to the longer time for equilibration of LA and LV pressures. With severe diastolic dysfunction (i.e., restrictive filling), high left atrial pressure causes early diastolic filling to occur rapidly via predominantly passive flow, resulting in a steep E wave with a short deceleration time and a small A wave. Persistence of restrictive filling pattern portends a worse prognosis in patients with heart failure (Pinamonti et al., 1997).

Diastolic function can also be inferred from left atrial size and filling. Chronically elevated left atrial pressure resulting from diastolic dysfunction causes left atrial enlargement (**Fig. 4C**). Pulmonary vein flow pattern on Doppler reflects left atrial filling, which normally occurs predominantly during ventricular systole. During early diastole, the left atrium serves as a conduit that simultaneously fills the left ventricle and receives blood from the pulmonary veins. As diastolic dysfunction progresses, LA pressure increases and the systolic component (S wave) of pulmonary vein flow into the left atrium diminishes as compared to the diastolic component (D wave), as shown in **Fig. 4D**. Atrial contraction during late diastole causes some retrograde flow into the pulmonary veins (Ar wave), which is more pronounced in diastolic dysfunction. Furthermore, prolongation of the Ar wave duration as compared to the antegrade mitral A wave has been shown to be an indicator of elevated LV filling pressure and worsened clinical outcome in heart failure (Dini et al., 2000).

Tissue Doppler of the mitral annular velocity provides yet another method of evaluating diastolic function. Left ventricular contraction causes excursion of the mitral annulus longitudinally toward the LV apex. During myocardial relaxation in diastole, the mitral annulus returns to its initial position, the velocity of which can be assessed by tissue Doppler sampling at the medial and lateral annulus (**Fig. 4B**). The early diastolic wave (e') diminishes to less than the late diastolic wave (a') as diastolic dysfunction progresses. Combined with the mitral inflow Doppler, mitral annular tissue Doppler during early diastolic filling can be used to estimate LV filling pressures. The ratio of E/e' has been shown to correlate well with invasive measurements, such that $E/e' > 15$ is associated with elevated LV filling pressures and $E/e' < 8$ with normal filling pressures (Ommen et al., 2000). Caveats to the measurement of e' velocities include mitral annular calcification, abnormal septal motion from conduction delay, lateral wall motion abnormalities, and mitral valve prostheses.

Right Ventricular Function and Hemodynamics

Determining right ventricular function and hemodynamics plays a central role in not only cardiomyopathies involving primary right heart dysfunction or pulmonary hypertension but also in heart failure due to left heart disease. In patients with left heart failure, right ventricular dysfunction is associated with high mortality and morbidity (Meyer et al., 2010; Di Salvo et al., 1995). Compared to that of the LV, right ventricular performance is more difficult to quantify by 2D echocardiography due to the complex

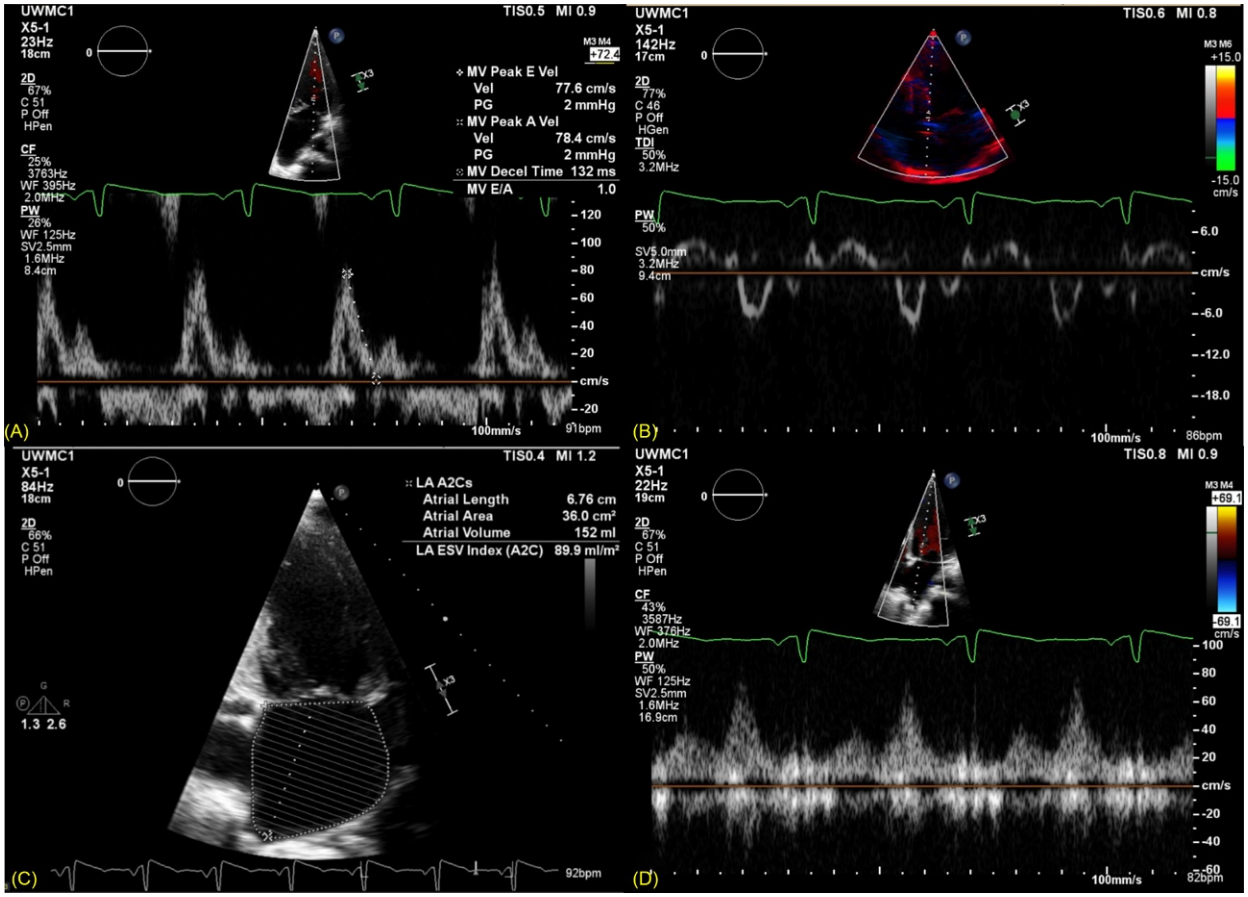

Fig. 4 Diastolic function in a patient with systolic heart failure. A, Mitral inflow shows steep deceleration of the E wave and a relatively diminutive A wave. B, Tissue Doppler of the medial annular velocity shows a reduced e′ and an E/e′ ratio of 13. C, Left atrial volume is severely increased. D, Pulmonary vein flow shows a greater diastolic than systolic component. Taken together, this patient likely has abnormal diastolic relaxation and elevated left atrial pressure.

anatomy of the right ventricle (RV) invalidating geometric assumptions for volume calculations. Given that RV contraction occurs primarily in a longitudinal fashion from base to apex, its systolic function can be gauged by the linear motion of the lateral tricuspid annulus by M-mode echocardiography in a metric known as the tricuspid annular plane systolic excursion (TAPSE), demonstrated in **Fig. 5A**. Similarly, the peak systolic velocity of the tricuspid annulus can be measured by tissue Doppler (s′), as shown in **Fig. 5B**. Despite its one-dimensional measurement and dependency on the angulation of Doppler interrogation, TAPSE has been shown to correlate well with radionuclide-derived RV ejection fraction (RVEF) (Rudski et al., 2010). Another method of assessing RV systolic function is fractional area change (FAC), which is calculated as the difference between the end-diastolic and end-systolic areas of the RV cavity by planimetry from the apical 4-chamber view (**Fig. 5C** and **D**). FAC has been shown to correlate with RVEF by cardiac MRI and is of prognostic value after myocardial infarction (Anavekar et al., 2007). The myocardial performance index used for assessing LV function can also be applied to the RV and is known as the RV index of myocardial performance (RIMP), which is independent of ventricular geometry. Although technical challenges preclude its widespread use, RVEF calculation by 3D echocardiography has been shown to be more reproducible and accurate than 2D methods (Jenkins et al., 2007; Gopal et al., 2007).

Right heart hemodynamics can be characterized by echocardiography in a multitude of ways. Right atrial (RA) pressure is approximated by the size of the inferior vena cava (IVC), which empties into the right atrium, and its change with respiration (**Fig. 6A**). Increased pressure in the right atrium causes dilation of the IVC and decreased inspiratory collapse. The Doppler pattern of hepatic vein flow is also affected, such that there is a predominance of the diastolic wave during which atrial emptying occurs. Right ventricular afterload can be estimated by the peak tricuspid regurgitation velocity by Doppler, which reflects the gradient between the RV and RA during systole (**Fig. 6B**). In the absence of pulmonic stenosis, RV systolic pressure is equivalent to pulmonary artery (PA) systolic pressure. Other Doppler methods can be employed to estimate pulmonary pressures, especially in the absence of sufficient tricuspid regurgitation. End-diastolic pulmonary regurgitation velocity combined with RA pressure estimates PA diastolic pressure (**Fig. 6D**). Similarly, mean PA pressure can be derived from the peak pulmonary regurgitation velocity. Pulmonary hypertension due to backward transmission of elevated LV filling pressures in heart failure can lead to remodeling in the pulmonary vasculature and RV dysfunction. Elevated pulmonary vascular resistance causes early peaking and

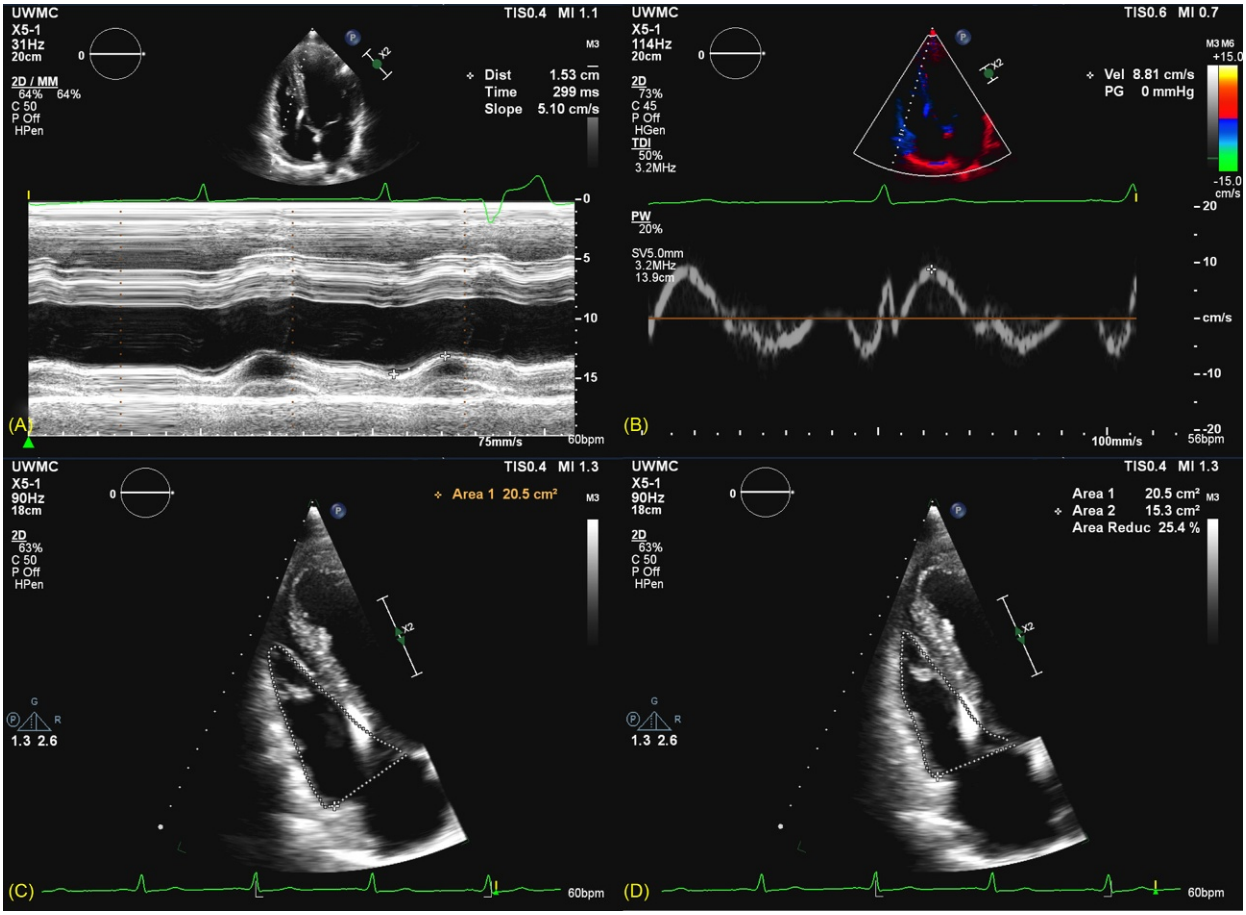

Fig. 5 Right ventricular function in a patient with dilated cardiomyopathy. A, Tricuspid annular plane systolic excursion (TAPSE) is mildly reduced at 1.5 cm. B, Tissue Doppler of the peak systolic tricuspid annular velocity (s′) is also mildly reduced at 8.8 cm/s. Fractional area change (FAC) is calculated from the traced area of the RV cavity from the RV focused view at end-diastole (C) and end-systole (D). In this case, the FAC of 25% is also decreased.

mid-systolic deceleration of flow in the RV outflow tract (RVOT), resulting in a short acceleration time and mid-systolic notching in the Doppler waveform (Fig. 6C). Furthermore, the ratio of the peak tricuspid regurgitation velocity (an indicator of PA pressure) to the RVOT velocity-time integral (an indicator of flow) provides a surrogate marker for pulmonary vascular resistance (Abbas et al., 2003). In patients with heart failure, worse clinical outcomes are associated with pulmonary hypertension and RV dysfunction (Ghio et al., 2013). Estimation of PA pressure and RA pressure by echocardiography thus serves an important role in the hemodynamic assessment of patients with heart failure and can obviate the need for invasive right heart catheterization.

Strain Imaging

Strain imaging assesses systolic and diastolic function of the ventricle by detecting myocardial deformation, which results from lengthening or shortening of myocardial fibrils. Strain and strain rate are expressed in terms of magnitude along a directional vector, which allows for deconstruction of myocardial mechanics into longitudinal, circumferential, and radial components. Using tissue Doppler techniques, strain rate is derived from the difference in tissue velocities at various sample volumes in the myocardium and the distance between the samples. Integrating tissue Doppler strain rate over time yields strain. Due to the one-dimensionality and angle dependency of Doppler interrogation, strain imaging by this technique is limited in accuracy and reliably assesses only longitudinal deformation.

Speckle tracking utilizes the interference pattern of backscattered signals from small structures within the myocardium, termed "speckles," to track myocardial displacement over time. Thus, strain is directly measured in a two-dimensional fashion such that circumferential and radial strain can be assessed, in addition to longitudinal strain. Global longitudinal strain (GLS), the averaged longitudinal strain across the entire myocardium from the apical window, serves as an indicator of myocardial function with several important clinical applications, particularly the detection of systolic dysfunction in the setting of normal LVEF. Because longitudinal strain is affected by endocardial myocardial dysfunction, GLS may detect subclinical myocardial disease prior to transmural involvement, such as in hypertensive or diabetic heart disease (Marwick, 2006; Saito et al., 2016; Mor-Avi et al., 2011). In coronary artery disease, subendocardial ischemia is associated with abnormal segmental longitudinal strain prior to the

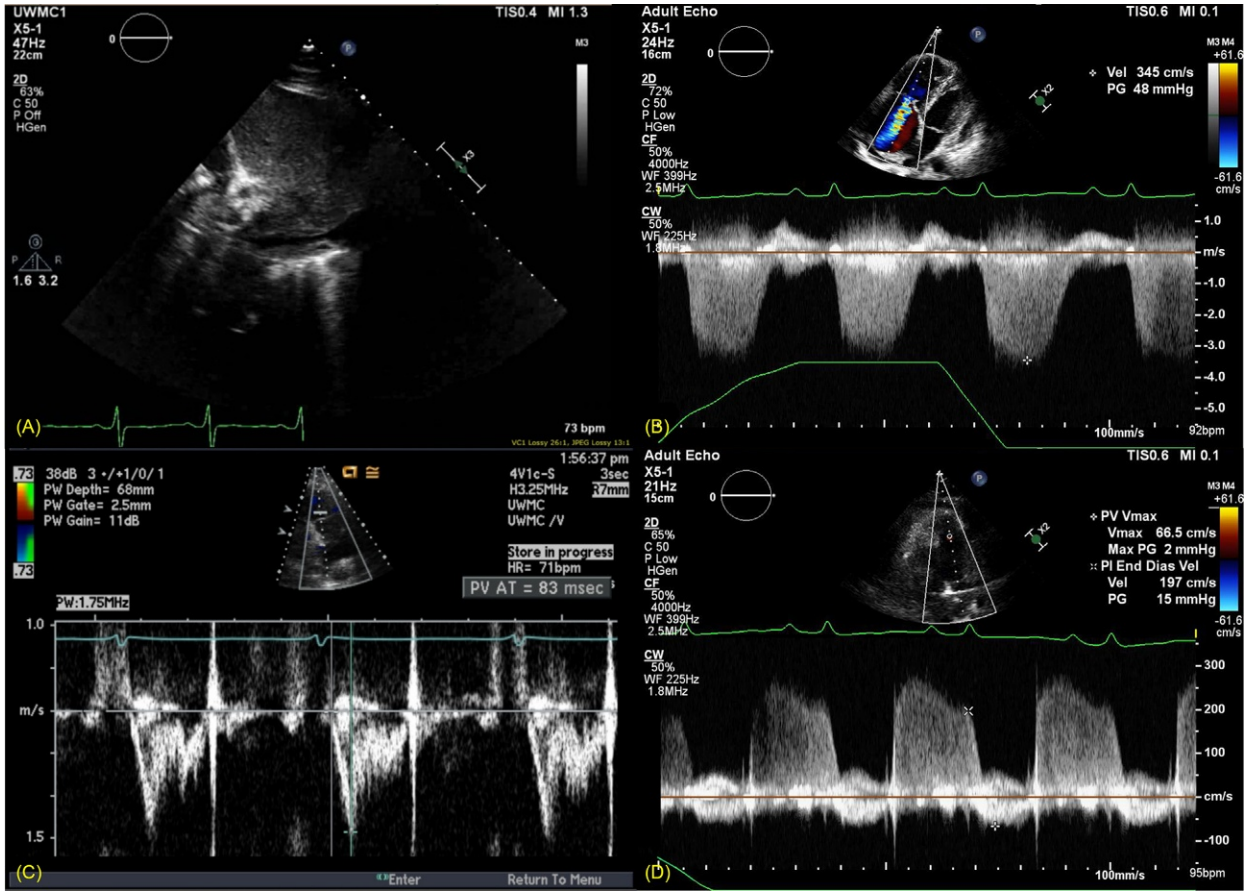

Fig. 6 Right heart hemodynamics in severe pulmonary arterial hypertension. (A) Inspiratory collapse of the IVC of $\geq$50% suggests normal right atrial pressure. (B) Systolic pressure gradient across the tricuspid valve, calculated from peak tricuspid regurgitation velocity by Doppler and estimated right atrial pressure, indicates an elevated PA systolic pressure of 48 mmHg. (C) Doppler profile of the RVOT shows a short acceleration time and mid-systolic notching, suggestive of elevated pulmonary pressures and pulmonary vascular resistance. (D) End-diastolic velocity of the pulmonary regurgitation jet indicates an elevated PA diastolic pressure of 15 mmHg above RA pressure.

development of visually evident hypokinesis (Montgomery et al., 2012). Strain imaging also allows for early detection of chemotherapy-induced cardiotoxicity in oncology patients (Sawaya et al., 2012; Negishi et al., 2014; Thavendiranathan et al., 2014). Reduction in GLS in hypertrophic cardiomyopathy can differentiate it from physiologic hypertrophy in athletes and serves as a predictor of adverse events (Reant et al., 2015). Regardless of the etiology, restrictive cardiomyopathy is invariably associated with reduced GLS. However, in cardiac amyloidosis, there is a characteristic pattern of reduced strain at the base with sparing of the apex (Phelan et al., 2012), as shown in **Fig. 7** and **Videos 2–4**. In patients with systolic heart failure, global longitudinal strain predicts the occurrence of major adverse cardiac events (Nahum et al., 2010).

Myocardial Structure and Morphology

Left Ventricular Chamber Size

In patients with systolic heart failure, impaired myocardial contractility causes the LV cavity to progressively dilate as an adaptive measure to increasing end-diastolic volume. Evidence of LV remodeling can be seen by echocardiography via estimation of its chamber size, which is commonly reported as a linear dimension from the parasternal long-axis view, biplane-derived volume from the apical window, or a 3D volume. End-diastolic dimension, 2D end-diastolic volume, and 2D end-systolic volumes have all been shown to have prognostic value (Lee et al., 1993; Solomon et al., 2005). Dilation of the other cardiac chambers typically accompanies that of the left ventricle. Remodeling due to heart failure also results in transformation of the LV cavity into a more spherical, rather than ellipsoid, shape (Konstam et al., 2011). Sphericity index, derived from the ratio of the lengths of the LV major and minor axes, has been shown to correspond to exercise capacity in patients with systolic heart failure (Tischler et al., 1993).

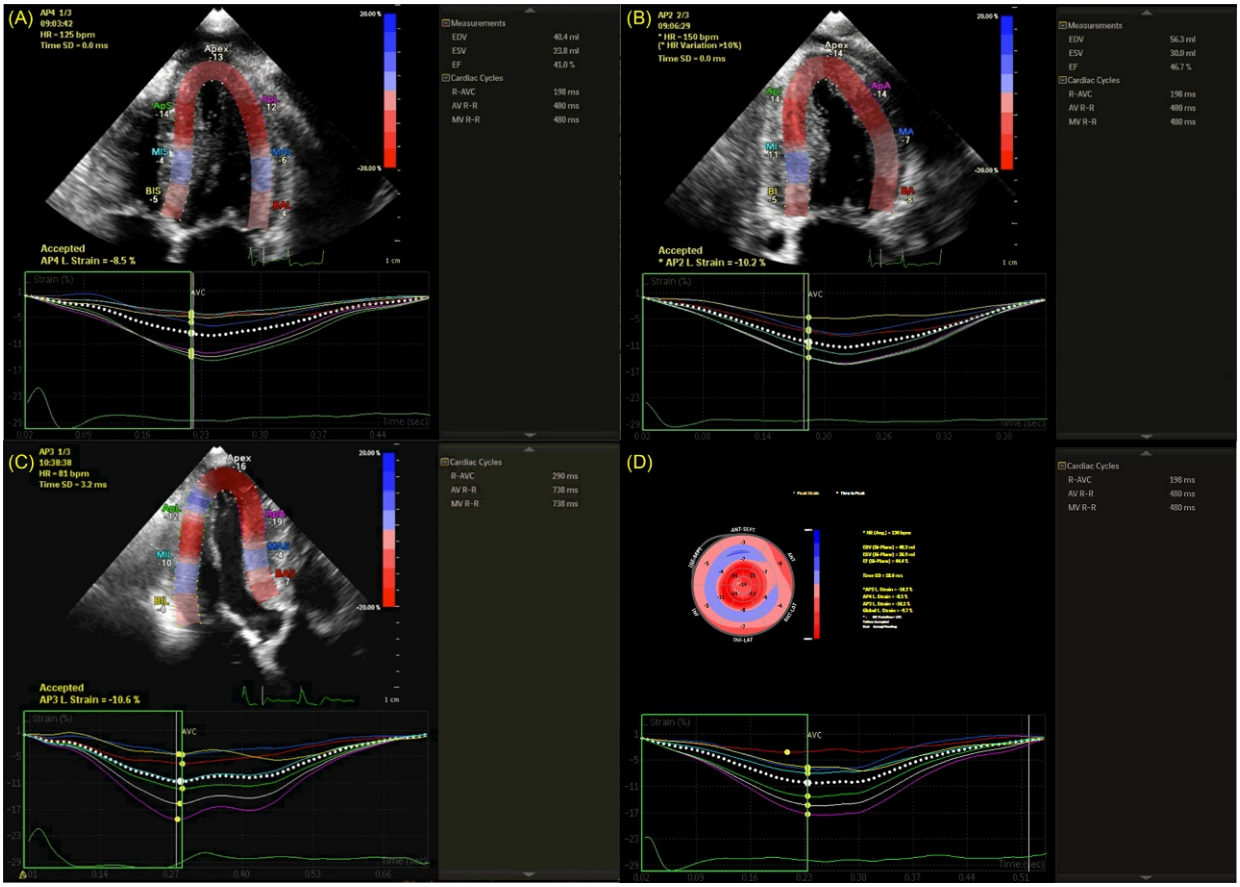

Fig. 7 Speckle tracking longitudinal strain in cardiac amyloidosis. Regional longitudinal strain is obtained by speckle tracking echocardiography from the apical 4-chamber (A), 2-chamber (B), and 3-chamber (C) views. Polar map, or bull's eye plot, of the peak systolic strain (D) shows a pattern of apical sparing characteristic of amyloidosis. Global longitudinal strain was reduced at −9.7%. (See also **Videos 2–4**).

Left Ventricular Geometry and Mass

The pathologic response to myocardial injury and hemodynamic changes associated with heart failure is a combination of hypertrophy and elongation of cardiomyocytes. This maladaptive response, in addition to cardiomyocyte necrosis and fibrosis in the extracellular matrix, results in macroscopic changes in the LV geometry. Not only does the ventricular cavity dilate but LV wall thickness may diminish. Left ventricular wall thickness with respect to chamber size is reflected by the echocardiographic measure of relative wall thickness (RWT). Distinct patterns of ventricular geometry caused by remodeling have been described, based on relative wall thickness and LV mass (LVM). The pathologic classifications are termed concentric remodeling (normal LVM with increased RWT), eccentric hypertrophy (increased LVM with normal RWT), and concentric hypertrophy (increased LVM and RWT). Compared to normal LV geometry, each of these patterns is associated with worse cardiovascular outcomes, particularly concentric hypertrophy (Verma et al., 2008).

The remodeling process in heart failure typically results in an increase in the LV mass, which can be estimated by echocardiography. Using linear measurements of posterior wall thickness, septal wall thickness, and the end-diastolic dimension, the LV mass may be calculated. LV mass can also be derived from the difference between the areas bound by the epicardium and the endocardium, using either the area-length method or truncated ellipsoid method by 2DE. Direct volumetric measurements by 3DE may yield more accurate estimation of LV mass, as compared to 2D or linear methods, but has yet to gain widespread use (Mor-Avi et al., 2004; Chuang et al., 2000). Increased LV mass, indexed to body surface area, has been associated with worse cardiovascular outcomes and also higher mortality in patients with heart failure (Quiñones et al., 2000; Armstrong et al., 2012; Verma et al., 2008).

Regional Remodeling and Fibrosis

In addition to altering the global LV geometry, remodeling due to heart failure can also cause regional changes in the myocardial architecture, particularly in ischemic cardiomyopathy. Ischemic myocardial injury due to obstructive coronary artery disease

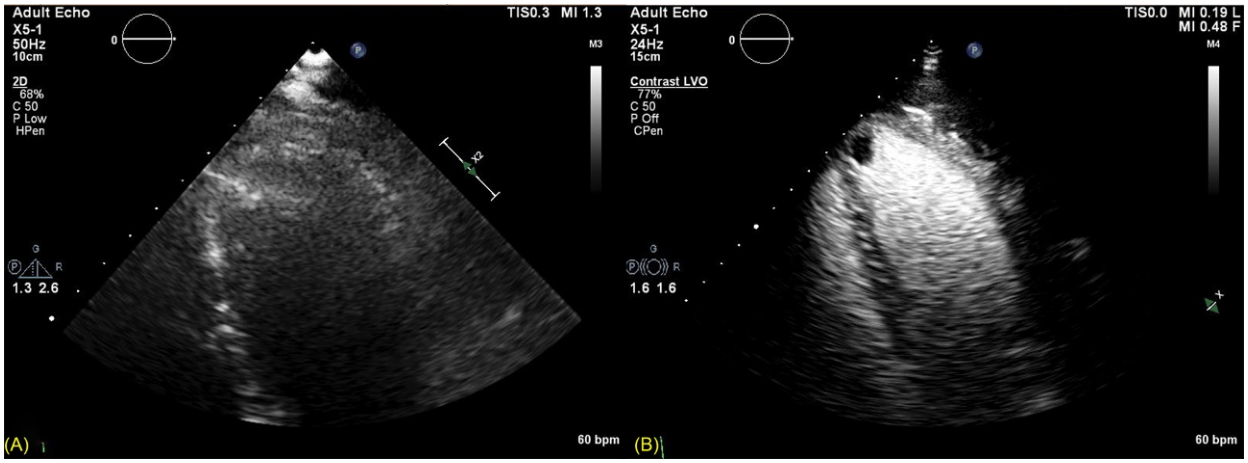

Fig. 8 Left ventricular thrombus in a patient with apical akinesis. (A) Poor endocardial definition without contrast enhancement limits the detection of mural thrombus formation. (B) Opacification of the LV cavity with contrast greatly improves endocardial definition and reveals a filling defect at the apex likely representing a thrombus. (See also **Video 8**.).

diminishes wall thickening in the affected territory during physiologic stress, which can be induced by exercise or dobutamine infusion. Regional wall motion abnormalities can be qualitatively visualized by 2D echocardiography and semiquantitated by strain imaging. As myocardial infarction develops, regional wall motion abnormalities become apparent at rest. Dobutamine stress echocardiography can identify hibernating myocardium with contractile reserve that may recover in function following coronary revascularization and lead to improved survival (Afridi et al., 1995, 1998). In areas of transmural infarction, replacement fibrosis causes the myocardial wall to become akinetic and appear thinned and bright by echocardiography over time (**Videos 5–7**). Nonischemic etiologies of cardiomyopathy can also cause fibrotic changes resulting in a similar echocardiographic appearance, though usually in a noncoronary distribution. Aneurysms can occur in areas of scarred myocardium and have a propensity for LV thrombus formation, which carries a high risk of systemic embolization (van Dantzig et al., 1996). Presence of an LV thrombus can be detected by echocardiography, particularly with the aid of contrast for chamber opacification (**Fig. 8** and **Video 8**).

Functional Mitral Regurgitation

Left ventricular remodeling associated with heart failure leads to mitral regurgitation (MR) via the alteration of the opposing tethering and closing forces involved in mitral valve function. Spherical LV dilatation causes apical and lateral displacement of the papillary muscles leading to leaflet tethering as well as flattening of the saddle-shaped mitral annulus (Ray, 2010). Focal scarring due to ischemic disease may also cause papillary muscle displacement. Annular dilatation further perpetuates MR, as does impairment of the force of mitral valve closure by LV systolic dysfunction.

Echocardiography plays an important role in both elucidating the mechanism of and quantifying the severity of MR. Visualization of the entire mitral valve apparatus and the left ventricle allows for assessing whether MR is due to primary leaflet abnormality or functional in nature. Conventional echocardiographic methods for quantifying severity are more difficult in functional MR due to the noncircular regurgitant orifice area as well as the dynamic nature of MR, which is highly dependent on loading conditions and timing in the cardiac cycle (Ray, 2010). Furthermore, functional MR is often eccentric or comprised of multiple regurgitant jets. 3D echocardiography allows for direct planimetry of the vena contracta (**Fig. 9**) without geometric assumptions and has been well validated (Thavendiranathan et al., 2013).

Thorough evaluation of functional MR by echocardiography is essential due to its significant prognostic implications. Functional MR has been associated with increased mortality and heart failure hospitalizations in patients with both ischemic and nonischemic cardiomyopathy, independent of LV systolic function or severity of heart failure (Trichon et al., 2003; Rossi et al., 2011; Bursi et al., 2010). Therapies for functional mitral regurgitation with the most clinical benefit have been those directed at reversal of ventricular remodeling, such as guideline-directed medical therapy of heart failure, coronary revascularization, and cardiac resynchronization therapy in certain situations. Surgical valve repair or replacement has not been demonstrated to improve survival in patients with severe, functional MR (Calafiore et al., 2013; Wu et al., 2005). However, mitral valve surgery may have a limited role in patients undergoing concomitant coronary artery bypass or other cardiac surgery (Mihaljevic et al., 2007; Chan et al., 2012). Transcatheter mitral valve repair, such as with the MitraClip device, has emerged as a feasible therapeutic option for severe functional MR, particularly in patients at high operative risk (Feldman et al., 2011; Mauri et al., 2013). Transesophageal echocardiography, often with 3D, is crucial for patient selection and procedural guidance of Mitraclip placement.

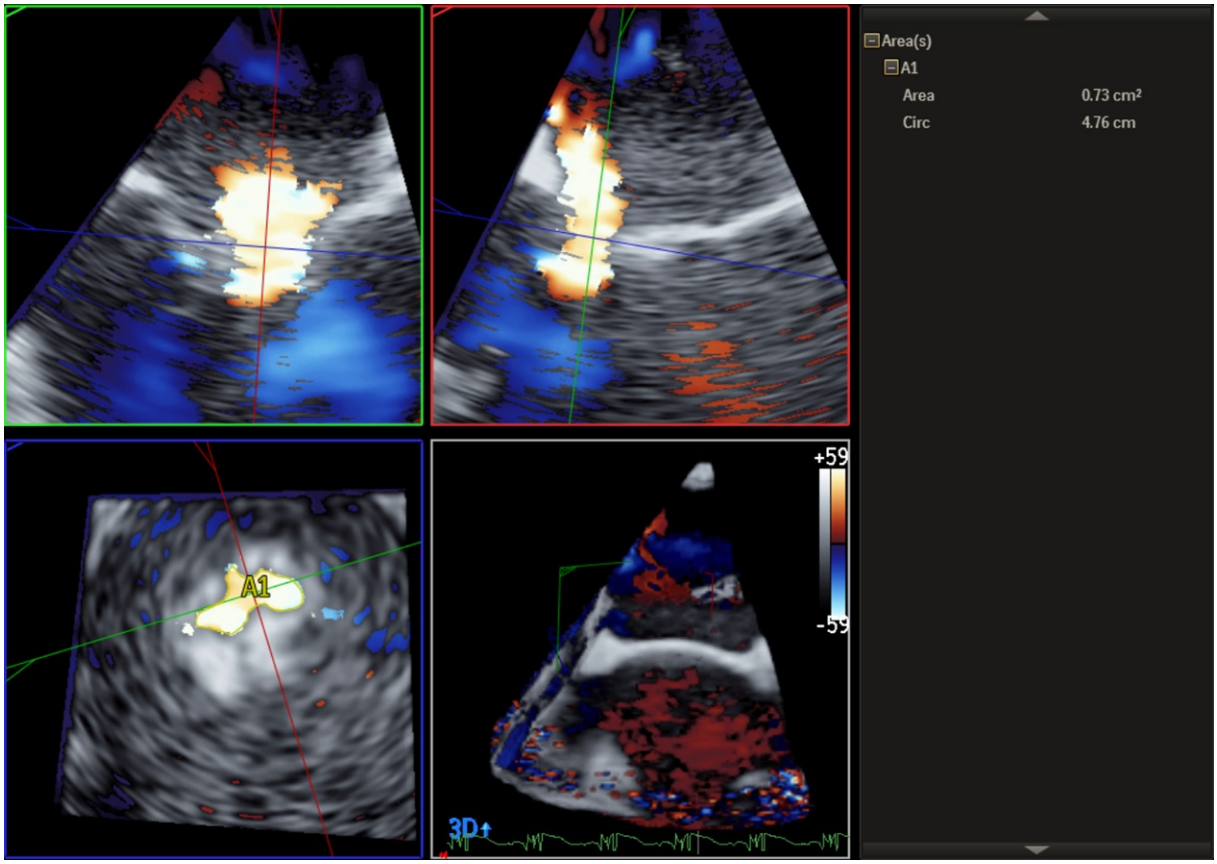

Fig. 9 3D echocardiography in severe functional mitral regurgitation. Multiplanar views of the mitral regurgitant jet by 3D color Doppler showing a noncircular vena contracta area, which measures 0.73 cm^2 by direct planimetry (*bottom left*), consistent with severe MR.

Guidance of HF Therapy

Medical Therapy

Echocardiography serves an important role in not only diagnosis and prognostication of heart failure but also in guidance of HF therapy. Evaluation of hemodynamics, ventricular function, and cardiac structure by echocardiography is essential in the management of acutely decompensated heart failure, particularly when the precipitant of clinical decompensation is unclear (American College of Cardiology Foundation Appropriate Use Criteria Task Force et al., 2011). Furthermore, evaluation of filling pressures and volume status by echocardiography is valuable in guiding diuresis in the acute setting. Medical therapies for chronic heart failure also often depend upon echocardiographic assessment of LV ejection fraction. Medications that mediate neurohormonal blockade such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), angiotensin receptor neprilysin inhibitors, beta-blockers, and aldosterone antagonists have demonstrated clinical benefit in terms of reduction in mortality only in heart failure with reduced LVEF (Anon, 1999; Packer et al., 2001; The Consensus Trial Study Group, 1987; SOLVD Investigators, 1991; Pfeffer et al., 1992, 2003; Cohn et al., 2001; Granger et al., 2003; Pitt et al., 1999, 2003; McMurray et al., 2014). Beta-blocker therapy has been associated with evidence of reverse remodeling, in terms of increase in LVEF and reduction in LV mass, end-diastolic volume, and end-systolic volumes (Lowes et al., 1999; Groenning et al., 2000). Several large echocardiographic studies have also shown similar reverse remodeling with ACE inhibitor and ARB therapy (St John Sutton et al., 1994; Solomon et al., 2005; Wong et al., 2002). Aldosterone antagonist therapy may also influence LV remodeling, though the evidence is less robust (Cicoira et al., 2002; Vizzardi et al., 2010). Monitoring clinical response with echocardiography allows for optimization of these neurohormonal and other adjunctive medical therapies in the longitudinal care of systolic HF patients.

Device-Based Therapy

In addition to its impact on medical therapy of heart failure, echocardiography also helps in identifying HF patients who would benefit from an implantable cardioverter–defibrillator (ICD) placement or cardiac resynchronization therapy (CRT). Current guidelines for ICD placement for primary prevention of sudden cardiac death from ventricular arrhythmia are based on LV systolic

function by echocardiography (Epstein et al., 2008). Mortality benefit of primary prevention ICD therapy has been shown for patients with an LVEF ≤35% despite optimal medical therapy and at more than 40 days following myocardial infarction (Moss et al., 2002; Bardy et al., 2005; Hohnloser et al., 2004). The benefit of prophylactic ICD implantation may be less in those with systolic HF due to nonischemic cardiomyopathy (Kober et al., 2016). Following ICD implantation, echocardiography allows for evaluation of potential late complications, including defibrillator lead infection or severe tricuspid regurgitation.

Mechanical dyssynchrony in patients with systolic HF causes inefficient ventricular contraction and further impairs systolic function. Cardiac resynchronization therapy utilizes biventricular pacing to reestablish intraventricular and interventricular synchrony. Echocardiographic evidence of LV reverse remodeling, reduction of functional MR, and improvement in ventricular performance have been shown to follow resynchronization therapy (Sutton et al., 2006; St John Sutton et al., 2015). Current guidelines recommend CRT for symptomatic patients with an LVEF ≤35% and a widened QRS duration, particularly in a left bundle branch block (LBBB) pattern, due to the mortality benefit in several clinical trials (Bristow et al., 2004; Moss et al., 2009; Cleland et al., 2005; Tracy et al., 2012). Despite these criteria, hemodynamic response to CRT is not achieved in all patients. Doppler echocardiographic parameters of dyssynchrony, such as septal-lateral wall delay (intraventricular delay) and the difference between LV and RV preejection intervals (interventricular delay), have yielded inconsistent results in predicting CRT response (Chung et al., 2008). However, speckle tracking measures, especially anteroseptal–posterior wall delay by radial strain, have demonstrated correlation with clinical and LVEF response to CRT (Gorcsan et al., 2010; Tanaka et al., 2010). LV lead positioning with the guidance of radial strain imaging has also been shown to optimize CRT response (Saba et al., 2013; Khan et al., 2012). Three-dimensional speckle tracking techniques may offer further insight into the relationship between mechanical dyssynchrony and CRT response. Although intraventricular synchrony has a greater hemodynamic impact than atrioventricular (AV) synchrony (Auricchio et al., 1999), optimization of the AV delay may be performed by echocardiographic assessment of diastolic filling patterns (Gorcsan et al., 2008).

Advanced Heart Failure Therapy

Several heart failure risk prediction models for determining the rate of adverse outcomes are based on LVEF derived from echocardiography in addition to clinical features and lab findings (Levy et al., 2006; Pocock et al., 2013). High-risk patients with end-stage heart failure despite optimal medical therapy and CRT, if indicated, often warrant consideration for advanced heart failure therapies (AHFT), such as a left ventricular assist device (LVAD) or orthotopic heart transplantation. Echocardiography serves an important role in AHFT screening and managing patients who have undergone LVAD implantation or cardiac transplantation.

Mechanical Circulatory Support

Mechanical circulatory support (MCS) devices consist of short-term, often percutaneously placed, support devices and long-term, durable ventricular assist devices (VADs) for either the left or the right ventricle. Percutaneous MCS devices offer temporary ventricular support as a bridge to recovery, transplantation, or durable VAD. Furthermore, temporary MCS devices provide periprocedural ventricular support for high-risk, complex percutaneous coronary interventions or arrhythmia ablations (Dangas et al., 2014). Durable MCS devices serve as either a bridge to transplantation or destination therapy for patients who are not transplant candidates.

Echocardiography plays a central role in patient selection and in monitoring of MCS device function. Criteria for LVAD implantation include the presence of severely depressed LV ejection fraction and LV cavity dilatation. Significant aortic regurgitation can render an LVAD ineffective and is a contraindication for the Impella, a percutaneous transaortic device used for temporary support. Careful assessment of RV function with echocardiography is also essential for the determination of whether mechanical RV support is necessary, given the prevalence of RV failure in the LVAD population (Kirklin et al., 2014; Kormos et al., 2010). Echocardiography guides positioning of temporary MCS devices for initial placement (e.g., transseptal puncture for the percutaneously-placed TandemHeart) and subsequent management, since these devices, particularly the Impella, tend to migrate (**Fig. 10** and **Video 1**).

In terms of routine surveillance of durable LVADs, echocardiography is utilized to monitor for subclinical LVAD dysfunction and to assess response to mechanical support. Current practice guidelines recommend obtaining surveillance echocardiograms at predetermined intervals in LVAD patients (Stainback et al., 2015). Furthermore, echocardiography can diagnose the cause of symptoms or device alarms that may result from complications such as inflow or outflow cannula obstruction (due to thrombosis or kinking), pump thrombosis, RV failure, and tamponade. These complications are associated with hemodynamic changes that cause overfilling or underfilling of the LV. Overfilling manifests as LV dilatation with bowing of the interventricular septum toward the RV and can result from LVAD pump failure (most commonly, pump thrombosis) or cannula obstruction, which can be evaluated by pulsed-wave Doppler interrogation of cannula flow (**Fig. 11B** and **C**). Underfilling from conditions of decreased preload (RV failure, tamponade, sepsis, or volume depletion) manifests as a smaller LV cavity and may cause suction of endocardial structures into the inflow cannula, resulting in reduced cardiac output and potentially ventricular arrhythmias.

Another application of echocardiography in LVAD management is in optimization of continuous-flow LVAD rotor speed for the patient's hemodynamics. The frequency and degree of aortic valve opening is a key measure for these speed-optimization studies, as it reflects the relative contributions to the cardiac output by the LVAD versus the contractile function of the ventricle. The frequency,

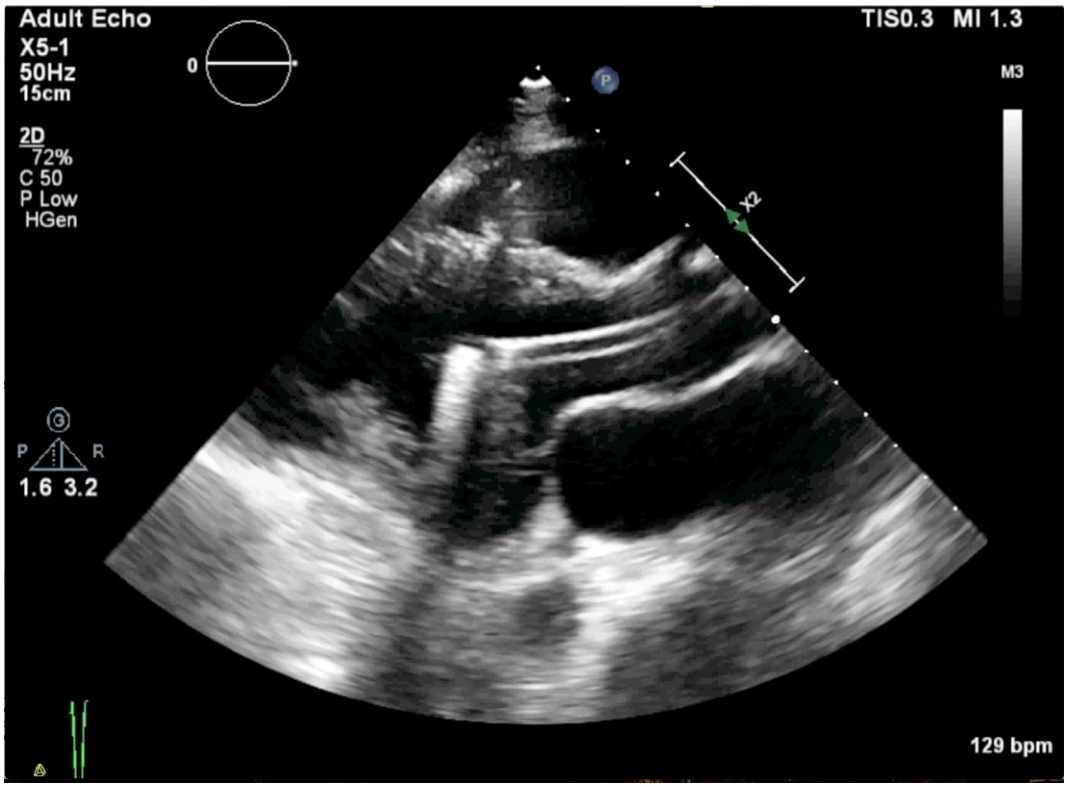

Fig. 10 Cannula positioning of an Impella percutaneous ventricular assist device. Parasternal long-axis view showing an Impella device positioned across the aortic valve with the inflow cannula in the LV cavity. The device should be angulated toward the LV apex with the inlet area located approximately 4–4.5 cm from the aortic valve. Transthoracic echocardiography provides real-time imaging for positioning the Impella device. (See also **Video 1**.).

duration, and extent of aortic valve opening may be assessed by M-mode echocardiography (**Fig. 11A**). Determination of the optimal LVAD speed is based on aortic valve opening as well as the degree of LV filling. High-speed settings result in LV underfilling and cessation of aortic valve opening, and the converse holds true for low speeds. In addition to hemodynamic optimization, echocardiographic imaging at varying LVAD speeds is also used in ramp studies to evaluate for pump thrombosis when the expected changes in terms of reduced LV filling and decreased aortic valve opening do not occur at increasing speeds. During weaning studies when LVAD speed is gradually decreased, improvement in LVEF, increased aortic valve opening, and lack of significant LV dilatation serve as indicators of myocardial recovery on which candidacy for LVAD explant is based.

Transplant Cardiology

In patients with advanced heart failure who are considered for heart transplantation, echocardiography is instrumental in the pretransplantation process. Candidacy for transplantation is based on numerous clinical factors, in addition to echocardiographic findings of severe left ventricular dysfunction. Pulmonary hypertension secondary to chronically elevated LV filling pressures can lead to irreversible pulmonary vascular remodeling and has been associated with increased mortality following cardiac transplantation, primarily due to right heart failure (Costard-Jäckle and Fowler, 1992). As a result, severe pulmonary hypertension unresponsive to vasodilator therapy may preclude transplantation. Although pulmonary pressures are typically evaluated by catheterization for transplant candidacy, echocardiography allows for noninvasive monitoring of right heart hemodynamics (**Fig. 6**). Another component of the pretransplantation process is evaluation of donor heart function, which involves echocardiographic assessment of biventricular function and screening for valvular or congenital abnormalities (Zaroff, 2004). Neurohormonally mediated LV systolic dysfunction, as well as regional wall motion abnormalities in the absence of coronary artery disease, is common in potential donors and may preclude use for transplantation (Dujardin et al., 2001).

Following cardiac transplantation, echocardiography continues to be an important tool for evaluation of graft function. In the early perioperative period, LV systolic dysfunction can be an indication of primary graft failure due to prolonged ischemic time, reperfusion injury, hyperacute rejection, or suboptimal donor heart. RV dilatation and dysfunction are common during this period due to the high afterload from residual pulmonary hypertension in the recipient (Bhatia et al., 1987; Hosenpud et al., 1987). Postsurgical pericardial effusions are associated with undersized donor hearts and raise the concern for infection (due to immunosuppression) or rejection (Hauptman et al., 1994). Tamponade physiology resulting from large effusions or focal loculations may be readily assessed by echocardiography.

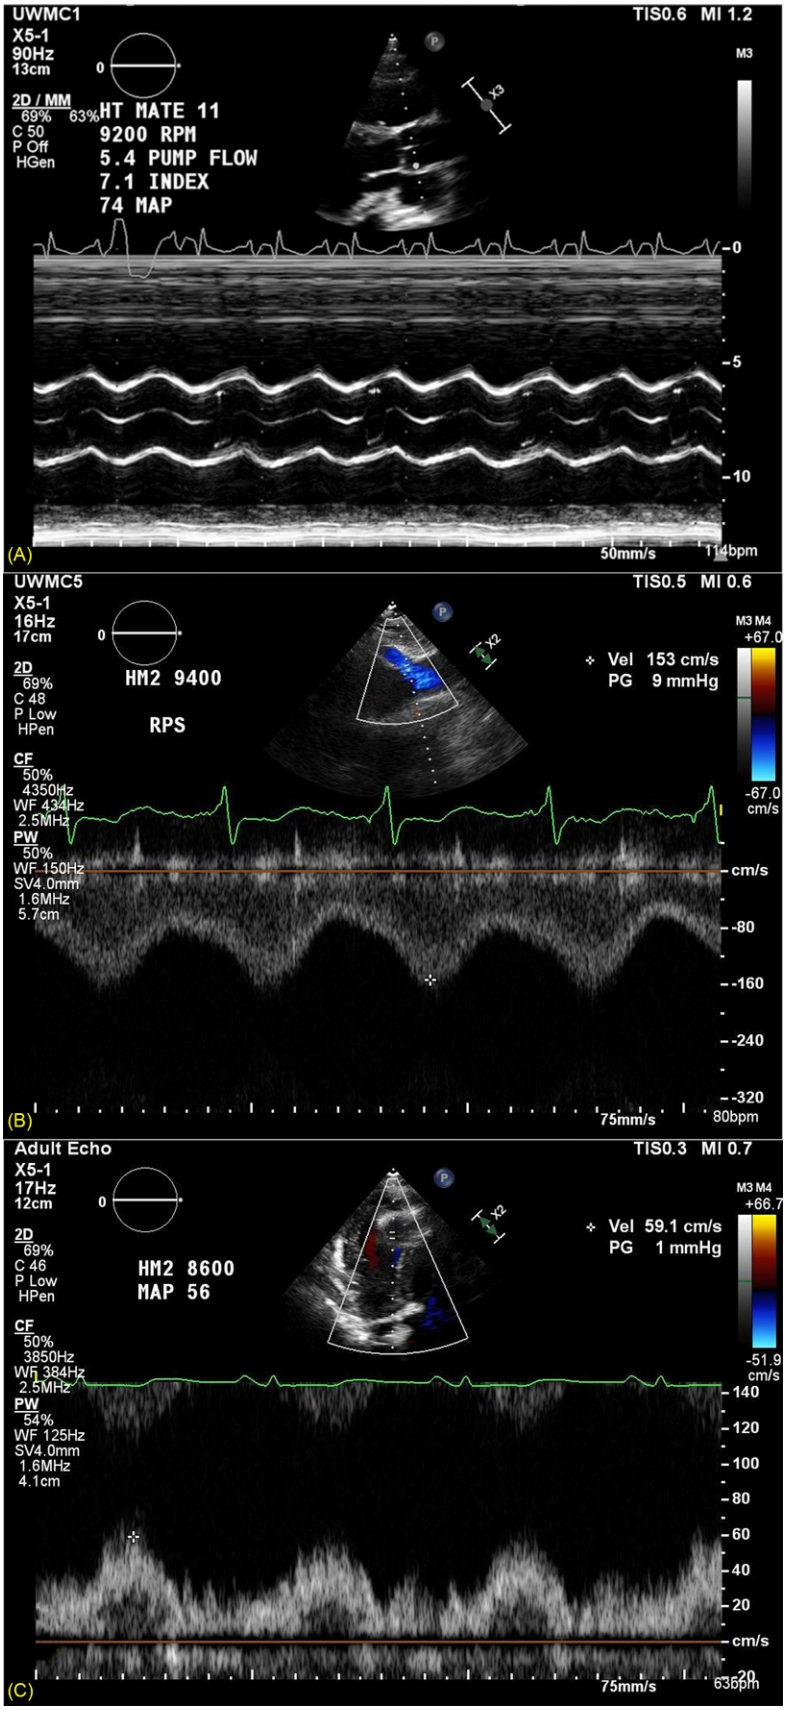

Fig. 11 Assessment of LVAD function in a Heartmate II continuous-flow device. (A) M-mode across the aortic valve shows intermittent, partial opening of the aortic valve. (B) Pulsed-wave Doppler interrogation of the outflow cannula showing laminar flow into the ascending aorta with normal velocities (<2 m/s). (C) Pulsed-wave Doppler interrogation of the inflow cannula showing laminar flow from the LV apex with normal velocities.

Current practice guidelines recommend routine surveillance for acute rejection, cellular or antibody-mediated, by endomyocardial biopsy in at least the first year posttransplantation (Costanzo et al., 2010). However, in patients presenting with symptoms concerning for acute rejection, echocardiography can assess graft function more rapidly and lead to earlier initiation of therapy. In acute rejection, systolic dysfunction presents later than diastolic dysfunction, which is not specific to rejection. There may be a role for strain imaging in the screening for acute rejection noninvasively (Kato et al., 2010). Late complications, occurring several years after transplant, are most commonly related to cardiac allograft vasculopathy (CAV), which is characterized intimal hyperplasia of the coronary arteries. CAV may be subclinical or present as heart failure, myocardial infarction, or sudden cardiac death. Screening for CAV by coronary angiography can be challenging due to the diffuse and concentric involvement. Intravascular ultrasound (IVUS) is more sensitive for detecting CAV and predicts adverse cardiac outcomes but still requires invasive catheterization (Tuzcu et al., 2005; Kobashigawa et al., 2005). Dobutamine stress echocardiography correlates well with the gold standard of IVUS in terms of detection of CAV and carries similar prognostic value (Spes et al., 1999). Furthermore, dobutamine stress echocardiography appears to have higher diagnostic accuracy than nuclear myocardial perfusion imaging for CAV, with the exception of quantification of myocardial blood flow with positron emission tomography (PET) (Bacal et al., 2004; Wu et al., 2010; Mc Ardle et al., 2014).

Introduction

Valvular heart disease is a significant cause of morbidity and mortality around the world (Nkomo et al., 2006). Echocardiography serves as the workhorse imaging modality in the diagnosis of valvular heart disease and in many cases, remains the gold standard. Advances in echocardiography (both due to widespread availability and technological improvements) have helped improve our understanding of valve structure and function and simplified the diagnosis of valve disease. Several major society guidelines have

been published which comprehensively (often using multiple modalities) address the identification and quantification of valve disease (Nishimura et al., 2014 Jul; Zoghbi et al., 2017; Baumgartner et al., 2009; Lancellotti et al., 2010a,b). In this article, we have outlined the role of echocardiography in understanding valve structure and function and reviewed various ultrasound principles and echocardiographic techniques in the diagnosis of valve disease encountered in adults.

Ultrasound Principles in the Assessment of Valve Structure and Function

Knowledge of the principles of ultrasonography is crucial to image heart valves and interpret valvular pathology. Otherwise, significant errors in the diagnosis and grading of severity of valve disease may occur.

Two-Dimensional Echocardiography

Two-dimensional B mode (2D) transthoracic echocardiography (TTE) is the first step in the assessment of valve structure and function. Visualization of valves depends on ultrasound penetration as well as careful probe manipulation in standard views to obtain orthogonal 2D images of three-dimensional valvular and subvalvular structures. Such imaging is influenced by the ultrasound principles underlying 2D image formation.

Fundamental versus harmonic imaging

Tissue harmonic imaging (THI) has greatly improved endocardial border delineation (improved lateral resolution) and reduced artifacts (such as near field clutter) which are common with fundamental imaging in TTE (Thomas and Rubin, 1998). Many echocardiographic laboratories now image exclusively with THI. It is important to note, however, that THI imaging leads to reduced axial resolution which makes cardiac structures appear thicker than when fundamental imaging is used (van Wijk and Thijssen, 2002). Although leading edge to leading edge measurement technique can resolve this to some extent in the assessment of chamber dimensions, there is limited data for such adjustment in measurement of valve thickness. With application of THI, many laboratories report an increase in diagnosis of increased valve thickness and sclerosis. For example, the mitral valve leaflets appear thicker with THI compared to fundamental imaging (**Fig. 1**) (Gorgulu et al., 2005). This can lead to false diagnosis of mitral valve pathology and can also alter therapeutic decisions. In the case of mitral stenosis, valvular and subvalvular thickness play an important role in the choice of percutaneous versus surgical therapies (Prior et al., 2000). In otherwise eligible patients, THI imaging may lead to a falsely high valve score precluding the option of balloon valvuloplasty. In such cases, fundamental imaging should be used judiciously to improve accuracy of diagnosis. Transesophageal echocardiography (TEE), by elimination of ultrasound tissue attenuation inherent to TTE, improves diagnosis of valve pathology by virtue of the ability to image at both fundamental and higher frequencies than TTE (see what follows). Despite these limitations, THI has improved our overall ability to diagnose valve disease simply by better visualization of the valve.

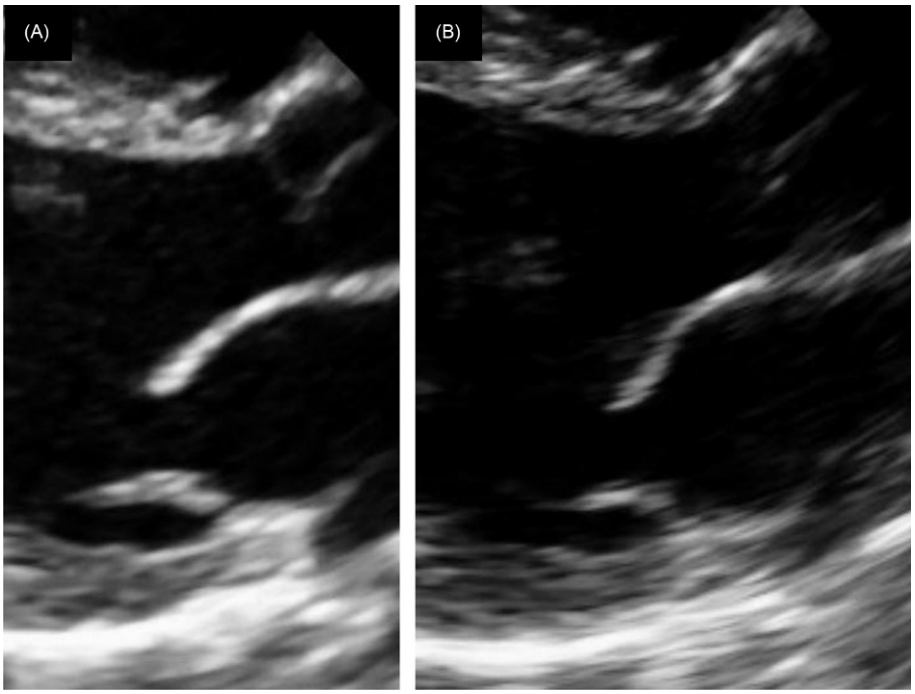

Fig. 1 Effect of harmonic imaging on assessment of valve structure. The anterior mitral valve leaflet appears thicker with harmonic imaging (transmit energy 1.5 MHz/receiving frequency 3 MHz, panel A) compared to fundamental imaging (transmit/receive at 3 MHz, panel B).

High frequency imaging

The higher the frequency of ultrasound, the better the axial resolution at the cost of reduced penetration. In patients with reasonable ultrasound penetration, high frequency TTE (3–4 MHz) imaging improves resolution of valve structures than lower frequency imaging. Though higher frequency, phased array TTE transducers are available (up to 12 MHz), diagnostic quality imaging is not feasible in many adult patients.

Depth of imaging and focal zone

Because valves are often far field in standard echocardiographic views, every attempt should be made to improve both spatial and temporal resolution. Reducing depth, matching sector size to the area of interest and/or zoomed-in views of the valve in question improve resolution and signal-to-noise ratios. Reducing sector size is the single most important step in increasing frame rate which in turn improves temporal resolution.

Doppler Echocardiography

Both color and spectral Doppler play a crucial role in the assessment of valvular function. Whereas color Doppler is essential to detect the presence of regurgitation, spectral Doppler is essential to quantify the extent of both regurgitation and stenosis.

Spectral Doppler

Pulse wave (PW) Doppler and continuous wave (CW) Doppler are critical modalities in quantifying flow across valves. Briefly, these techniques are based on the Doppler principle: the frequency of a waveform emitted by a moving object changes relative to the position of the observer. This change is called Doppler frequency shift and is summarized by the Doppler equation:

$$\mathbf{f_d = 2f_t V(\cos \theta)/c}$$

where f_d = Doppler shift frequency, f_t = transmit ultrasound frequency, v = velocity of blood flow, c = speed of ultrasound in medium (blood in case of echocardiography), and θ = angle of flow relative to ultrasound beam (angle of insonation).

When frequency shift information is available, velocity of blood flow is computed instantaneously on contemporary Doppler systems. A major limitation is the assumption that cosine angle is zero (=1). As the angle of insonation increases (cosine >0 degrees), the velocity is underestimated. Because blood flow in normal and abnormal valve function states varies three dimensionally, angle correction by estimating the angle of insonation is often inaccurate and should be avoided.

In PW Doppler, discrete pulses of ultrasound are transmitted and received by a single transducer element with specific time windows to listen to the reflected signal. By placing the sample volume at a location of interest, Doppler frequency shifts at that site are detected and processed to resolve velocity. Because the pulses are not simultaneously transmitted and received, this modality is limited by the sampling rate, that is, pulse repetition frequency (PRF). If the velocity of flow at the area of the Doppler sample volume is high, the higher frequencies shift and a higher pulse repletion frequency is needed to accurately detect such shift. The Nyquist limit refers to the maximum velocity that can be accurately quantified within the given sample volume and is determined by the formula:

$$\mathbf{Nyquist\ \ limit = PRF/2}$$

The longer the distance of the sample volume from the transducer, the lower the Nyquist limit because longer time is taken for the pulse to be transmitted and reduced. When the velocities exceed the Nyquist limit, aliasing occurs. In contrast, CW Doppler is continuously emitted from a dedicated transducer element while a separate element simultaneously and continuously receives returning signals (Fig. 2). While this mode is not constrained by the limitations posed by the Nyquist limit, the location of the signal cannot be specified. Thus, PW Doppler is used to localize flow disturbance and quantify lower velocities (usually less than 2 m/s), while CW Doppler resolves higher velocities without the ability to localize.

Assessment of valve function using spectral Doppler echocardiography is based on the assessment of flow and pressure gradients via the application of physical principles of fluid mechanics. The following pitfalls should be recognized while using spectral Doppler techniques in valve disease.

Measurement of pressure gradients

The Bernoulli equation is used to estimate the pressure gradient between two chambers separated by an orifice. A simplified form of the Bernoulli equation assesses convective acceleration while ignoring flow acceleration (which is almost nonexistent at flows being interrogated in clinical echocardiography) and viscous fraction (which is minimal for blood flow across even the most stenotic valves):

$$\mathbf{P_1 - P_2 = 1/2\rho\left(V_2^2 - V_1^2\right)}$$

where P_1 and P_2 are pressures proximal and distal to the orifice, V_1 and V_2 are velocities proximal and distal to the orifice, and ρ is the density of blood.

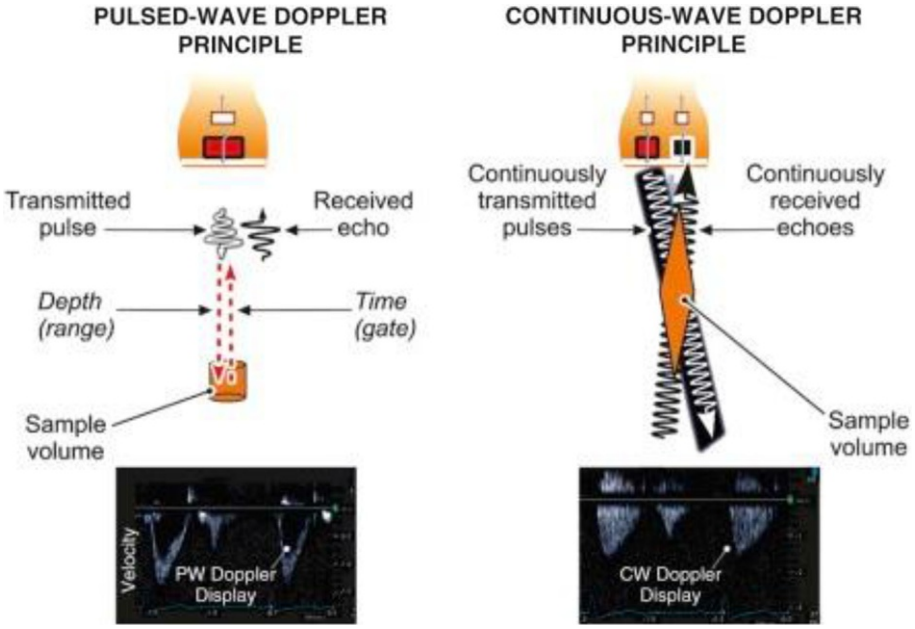

Fig. 2 Difference between pulse wave and continuous wave Doppler. Reproduced with permission from *Braunwald's Heart Disease*, 10th edn, 2015.

Because the velocity proximal to a stenotic orifice in the heart is often quite low compared to that distal to the orifice, they are often ignored. After solving for 1.06×10^3 kg/m^3 as ρ at room temperature, a very simple equation is derived:

$$\mathbf{P1 - P2 = 4(V_2)^2}$$

This simplified formula is sufficient in most cases but can overestimate the pressure gradient in cases where V_1 is not insignificant. An example is a case of aortic stenosis (AS) with increased left ventricular outflow tract (LVOT) velocity due to increased flow or LVOT obstruction. In these cases, V_1 should be included in the equation when the velocity is over 1.5 m/s (Baumgartner et al., 2009). In addition, pressure gradient is underestimated if the ultrasound beam is not aligned parallel with flow through the orifice which leads to underestimation of velocity (higher cosine angle of insonation, especially above 20 degrees). Of note, CW Doppler is employed to resolve the maximal velocity which is of interest in estimation of pressure gradients. When location of flow at a particular area is of interest in calculating volumes, PW Doppler is used.

Derivation of volume from Doppler echocardiography

Volume assessment is a two-step process. First, flow rate is calculated by integrating the velocities resolved throughout the relevant phase of the cardiac cycle at the site of interest (using PW Doppler) into a velocity time integral (VTI). Second, flow rate (VTI) is multiplied by the cross-sectional area (CSA) of the region of interest to calculate the magnitude of flow (volume):

$$\mathbf{Volume = VTI \times CSA}.$$

Because the diameter (D) of a given structure is easily measured by 2D echocardiography while CSA is not, the region of interest is assumed to be a circle and the CSA is derived by the formula:

$$\mathbf{CSA = \pi \times (D/2)^2}$$

This calculation can be applied to assess effective orifice area (EOA) of stenotic valves by the application of the continuity equation. The continuity equation is based on the principle of conservation of mass which states that flow in one region of the heart should be equal to flow in another region. When applied to stenotic valves, flow proximal to the stenosis is equal to flow distal to the stenosis provided there is no regurgitation or shunt. For example,

$$\mathbf{LVOT_{VTI} \times LVOT_{CSA} = Aortic\ Valve_{VTI} \times Aortic\ Valve_{EOA}}[11]$$

There are three significant pitfalls in this process. One, if the ultrasound beam is not aligned parallel with flow (angle of insonation >0 degrees), velocities are underestimated which in turn will underestimate flow and volume. Second, in estimating the flow proximal to the stenosis, the sample volume should be placed carefully at the area of laminar flow. For example, while calculating LVOT flow, the sample volume should be placed about 5–10 mm away from the aortic valve to avoid contamination of the PW Doppler signal by turbulence that occurs closer to a stenotic aortic valve. If flow turbulence is captured, LVOT velocity and thus flow is overestimated. Similarly, the modal velocity (densest portion) and not the outer edges of the PW Doppler signal should be traced. Third, CSA calculation depends both on accurate calculation of diameter and the region of interest confirming to the assumption of circular geometry. If the diameter is calculated incorrectly (such as in patients with poor ultrasound windows), the magnitude of the

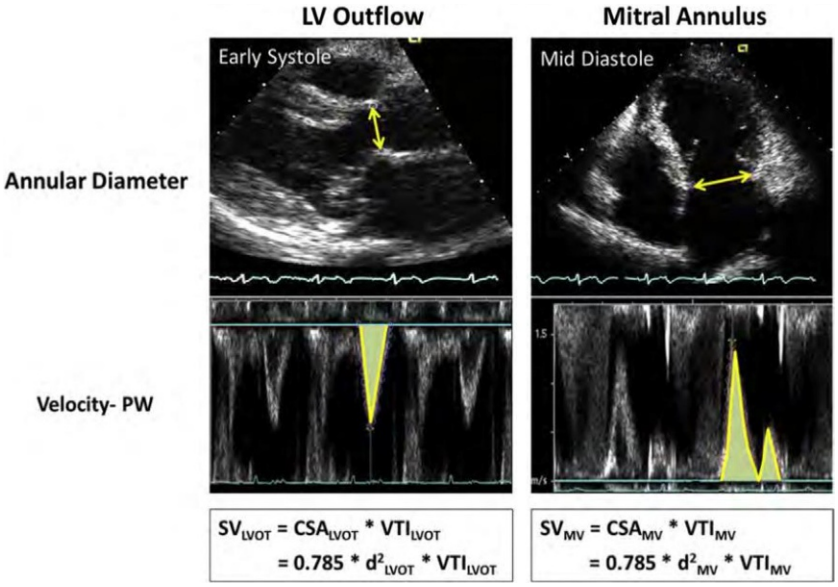

Fig. 3 Application of the principle of Doppler volumetric assessment in mitral and aortic regurgitation. The difference between the stroke volume across the regurgitant valve and the normal valve represents regurgitant volume. Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

error is squared. Similarly, CSA is underestimated if the anatomical structure (such as the LVOT, a crucial step in the derivation of aortic valve area in AS) is noncircular which leads to underestimation of EOA.

Spectral Doppler evaluation can also be used in quantification of regurgitant volumes by calculating the difference in flow across the regurgitant valve and stroke volume (Rokey et al., 1986). This is termed the Doppler volumetric method. For example, regurgitant volume of mitral regurgitation (MR) can be calculated as the difference between total transmitral stroke volume (VTI of transmitral flow at annulus × CSA of mitral annulus) and the stroke volume across the LVOT. Because several calculations are required and due to the multiple assumptions inherent to this calculation (that both mitral annulus and LVOT are circular), errors are common (Fig. 3).

An important method in estimating regurgitant volumes is the proximal isovelocity surface area (PISA method) which requires a combination of color and CW Doppler.

Color Doppler

Qualitative assessment by color Doppler is the most common echo parameter used for detection and assessment of severity of valvular regurgitation. Color flow Doppler imaging produces a color-coded map of Doppler frequency shifts detected using PW ultrasound. By convention, flow toward the transducer is coded red and flow away is coded blue. Because multiple areas within a color sector need to be interrogated for flow information, fewer pulses are used per scan line and the frequency shift between each area of measurement is color encoded and compared using a technique called autocorrelation. The transducer also switches rapidly between color Doppler and B mode imaging to produce a combined image (which is an illusion because scanning in these modalities does not occur simultaneously). Techniques such as a variance mapping (which compares the degree of difference between different velocities to the mean velocity in a given sample volume and encodes these differences with green providing a multitude of shades) are used to better depict turbulence within the regurgitant flow.

A well-defined regurgitant color Doppler jet consists of three parts—proximal flow convergence (representing the area where blood flow accelerates as it converges through the regurgitant orifice), vena contracta (VC, narrowest portion of the regurgitant jet which is just distal to the regurgitant orifice and is in essence the effective regurgitant orifice area, EROA), and the jet area (Fig. 4). The most important error in the assessment of color Doppler in valve regurgitation is overreliance on jet area and length. First, color Doppler does not measure actual regurgitant flow but rather provides an estimate of the change in velocities due to the regurgitation. A wall hugging eccentric jet may appear smaller because it loses momentum sooner and cannot entrain a larger pool of blood flow velocities compared with a central jet arising from similar regurgitant orifice area. Even indexing jet area to chamber size can also be misleading in the presence of severe chamber dilation.

Pitfalls in color Doppler imaging (Zoghbi et al., 2017; Thomas et al., 1990)

a. *Frame rate*: When frame rates are low, a coherent color Doppler jet cannot be realized and valve regurgitation can be missed or underestimated. Principles to improve frame rate in color Doppler include reducing depth and decreasing size of both color Doppler and 2D sectors.
b. Color Doppler settings (Fig. 5).

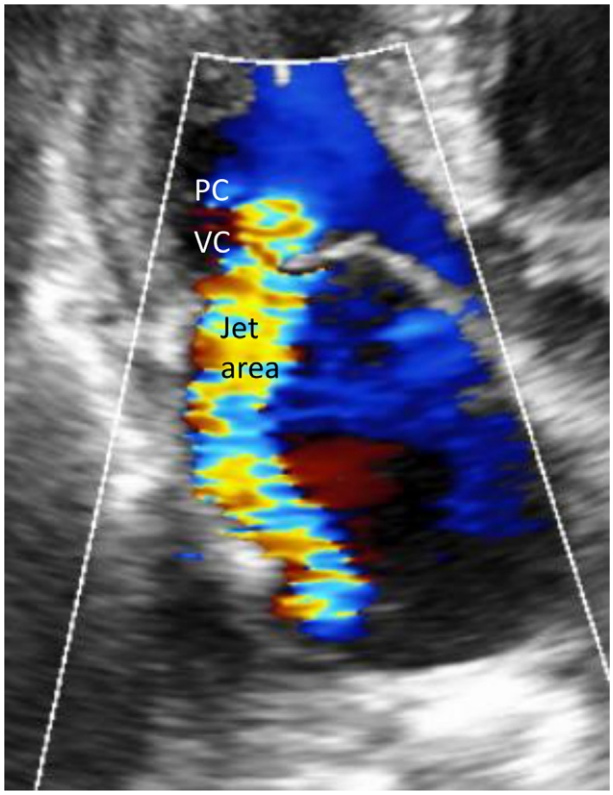

Fig. 4 The three areas of a regurgitant jet by color Doppler. *PC*, proximal flow convergence; *VC*, vena contracta.

Gain: Excess gain can overestimate color jet size by recruiting random noise while too low gain leads to underestimation. Gain should be high enough to avoid Doppler signal within the tissues.

Nyquist limit: As a special application of PW ultrasound, velocities resolved by color Doppler are subject to the Nyquist limit. Low Nyquist limit settings lead to overestimation by merging lower velocity blood flow in the chamber into the regurgitant jet. A Nyquist limit of at least 50–60 cm/s is recommended. Similarly, a high Nyquist limit may underestimate regurgitation by failing to detect lower velocity flow with the regurgitant jet.

High frequency imaging: While high-frequency imaging improves diagnosis of valve structure, it can make color Doppler jets appear larger due to increased detection of lower velocities. This effect needs to be considered especially in TEE imaging because many commercially available probes offer a range of imaging frequencies between 3.5 and 8 MHz.

c. *Temporality*: Color jet area is instantaneous while regurgitant volume is not. This principle is key in avoiding overestimation of severity of regurgitation. Assessment of regurgitation severity by color Doppler is based on jet area/dimension compared to the chamber into which the jet empties. Jet area/size is calculated at a maximum instantaneous time, while regurgitant volume depends on both flow rate and duration of flow. This is significant in cases of mitral valve prolapse where a mid to late systolic MR jet may appear significant by color Doppler but due to the shorter duration of regurgitation, the regurgitant volume is less impressive.

d. *Hemodynamics*: Color Doppler depiction of regurgitant jet depends on jet momentum which depends on both orifice area and jet velocity. Jet velocity in turn depends on the driving pressure across the regurgitant valve. Thus, elevation of LV systolic pressures (due to systolic hypertension) can make mitral regurgitant jet appear large and correction of blood pressure may reduce the jet area. Similarly, the color jet of MR may appear small when LV systolic pressures are low (such as with sedation in a dehydrated patient or intraoperatively). In acute severe regurgitation, the jet may appear laminar due to the lower driving pressure across the regurgitant orifice. This underscores the importance of integrating patient hemodynamics into color Doppler assessment.

e. *Image plane*: Deviation from standard imaging planes may be needed to clearly define the regurgitant jet. In eccentric jets, standard echocardiographic views to evaluate valve structure may not capture the full extent of Color jet area. In addition, the same view may not capture the flow convergence and jet area simultaneously. In these cases, individual components should be defined in separate optimized views.

Color Doppler can be used to quantitate regurgitant flow by assessment of proximal flow convergence and VC width.

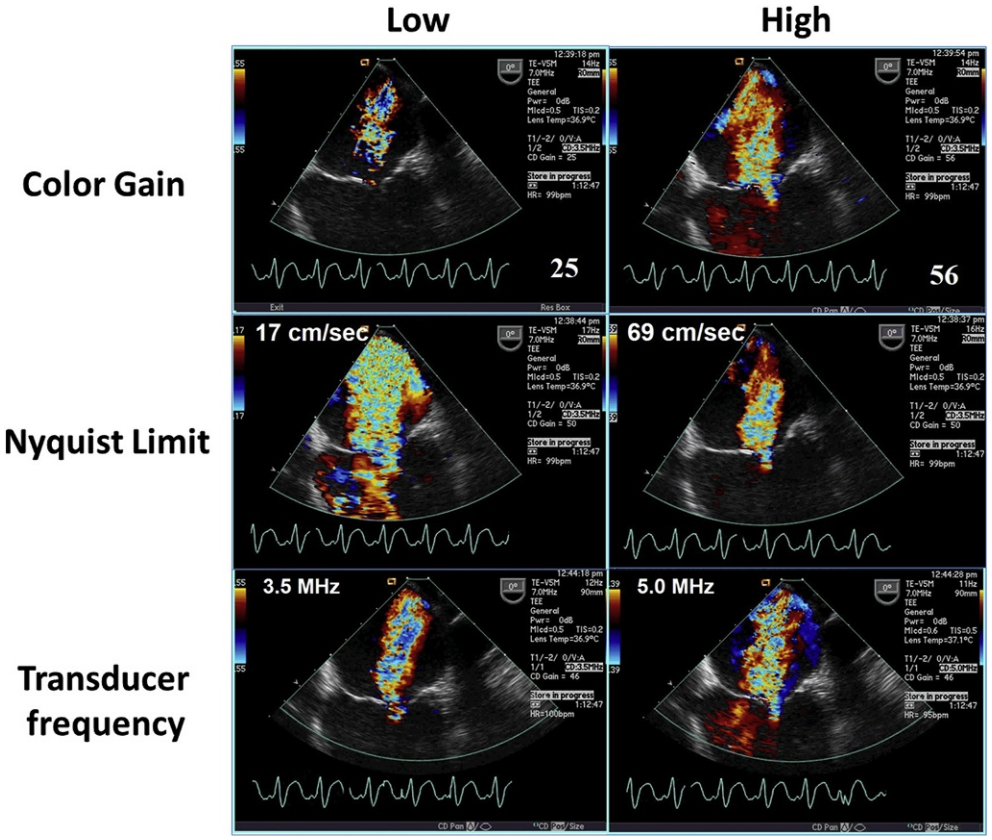

Fig. 5 Effect of gain, transducer frequency, and Nyquist limit on the color Doppler appearance of mitral regurgitation. Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

Vena contracta width

Measurement of VC dimension provides a semiquantitative measure of severity of regurgitant lesion (Baumgartner et al., 1991). By virtue of being the narrowest portion of the regurgitant jet, VC represents the EROA.

Pitfalls in measurement of vena contracta

a. *Shape and form*: 2D VC measurement provides a single measure of a three-dimensional EOA. Depending on the plane chosen, a single measurement may overestimate or underestimate true VC size. This is especially true when the VC is an ellipse (such as a case of secondary MR) rather than a circle. 3D assessment of VC provides accurate assessment of VC area but is limited by the poor temporal and spatial resolution of current generation 3D systems and not well validated.
b. *Measurement unit*: Because VC width quantified is in millimeters, even a small error in measurement can result in a misleading assessment of severity of valvular regurgitation. Axial resolution of ultrasound is better than its lateral resolution, therefore VC is best measured in the parasternal views in both mitral and aortic regurgitation (AR).
c. *Severity of regurgitation*: VC is best at identifying severe regurgitant lesions but lacks sufficient accuracy to distinguish less severe cases. Values in intermediate range require verification by another method of quantification.

Proximal isovelocity surface area

The proximal isovelocity surface area (PISA) method represents an application of the continuity principle and utilizes both color and spectral Doppler (Schwammenthal et al., 1994). As blood converges toward a regurgitant orifice, it accelerates and forms concentric hemispherical shells whose boundaries contain blood cells of similar velocity (isovelocity surfaces). As the blood gets closer to the orifice, the velocity increases and aliasing occurs and is depicted by a distinct red blue interface at the boundary of the shell. By adjusting the color Doppler baseline in the direction of the regurgitant flow (reducing the Nyquist limit) and turning off variance mapping, this interface is accentuated and radius of the shell can be measured. Assuming the shell is hemispheric, the surface area can be calculated ($2\pi r^2$) and finally the flow rate can be estimated by multiplying the surface area with the aliasing velocity (**Fig. 6**). Based on the continuity principle, the flow rate at isovelocity surface is similar to the flow rate through the regurgitant orifice (Flow rate at isovelocity shell = EROA × regurgitant jet velocity). By measuring the maximum velocity of the regurgitant jet by CW Doppler, the

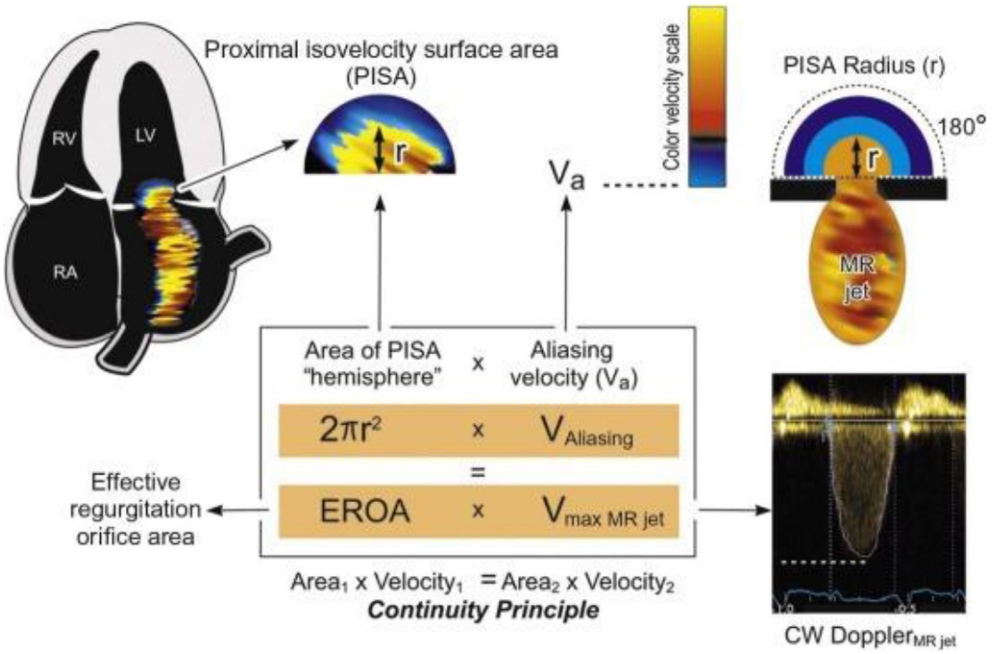

Fig. 6 Estimation of regurgitant volume and effective regurgitant orifice area (EROA) using the PISA method. This example shows the measurement of the PISA radius and the timing of the selection of the color frame for measurement (*solid yellow arrow*), corresponding to the maximal jet velocity by CWD (*dashed arrow*). *Reg*, regurgitation; *PKV*, peak velocity of regurgitant flow by CWD; *VTI*, velocity time integral of the regurgitant jet by CWD Reproduced with permission from *Braunwald's Heart Disease*, 10th edn, 2015.

EROA can be calculated. Regurgitant volume can then be derived by multiplying the EROA by VTI of the regurgitant jet (obtained by tracing CW velocity curve). Despite being technically challenging, accurate estimation of regurgitant volume and EROA is possible in many cases where the proximal flow convergence zone is clearly defined. In patients with multiple jets, volumes and EROA can be calculated for each individual jet and combined to provide an assessment of severity.

Pitfalls in the estimation of regurgitation by PISA

a. *Flow convergence*: It is difficult to obtain a clear flow convergence zone in all cases. Off-axis views are sometimes required. In some cases, valve thickening and calcification preclude accurate depiction of flow convergence. An additional pitfall is the challenge of identification of the orifice which is a critical component of estimation of radius.
b. *PISA shape, plane, and orifice geometry*: EROA estimation of the PISA method is based on three geometric assumptions which can introduce error into calculations. The first assumption is that the isovelocity shell is hemispheric which is not always true. Some shells appear flat and some assume a tear drop shape. The flow convergence zone may be constrained by a ventricular wall (especially in eccentric jets). Though angle correction can be used, this introduces another degree of complexity into an already complicated equation (Pu et al., 1995). It introduces a significant source of error. The second assumption is that the orifice lies in a flat plane which does not hold good in all cases, for example, the plane may be conical in secondary MR with leaflet tethering. The final assumption is that of a circular orifice geometry, the most noTable exception is that of an elliptical orifice in secondary MR.
c. *Timing and duration of measurements*: EROA by the PISA method is an instantaneous measure of an average EROA through a phase of the cardiac cycle. Thus, EROA can be overestimated in regurgitant jets limited to a small part of the cardiac cycle (late systolic MR due to mitral valve prolapse) or underestimated in jets with a dynamic variation of EROA (such as the bimodal secondary MR) (Topilsky et al., 2012). In addition, the measurement of PISA radius and the MR velocity should be timed to the same point of the cardiac cycle.
d. *Locating the regurgitant orifice*: The PISA radius is drawn from the location of the regurgitant orifice to the point of first Color Doppler aliasing. The location of the regurgitant orifice can sometimes be challenging to define. In practice, one of three methods are useful: (i) Location of VC can be used to draw the radius because it represents location of EROA; (ii) often, a horizontal Color Doppler flow occurs at the EROA can be a marker; and finally (iii) turning off the Color Doppler flow is possible in some PACS software (EchoPAC, GE) which allows for visualization of the anatomical orifice area.

In conclusion, Doppler echocardiographic quantification is useful in many cases of valvular regurgitation. In some cases, however, significant discrepancy can occur and multiple methods should be used to obtain the best possible estimate of severity. Accurate flow quantification and chamber volume assessment by cardiovascular magnetic resonance imaging (CMR) is helpful in such cases (Zoghbi et al., 2017).

Three-dimensional echocardiography

Current generation three-dimensional (3D) echocardiography is based on processing data obtained from a matrix-array transducer which simultaneously emits and receives ultrasound in multiple planes. Improvements in processing technologies allow for real-time rendering of 3D images as well as acquisition of full volume data sets that are suïTable for postprocessing (Lang et al., 2012). The ability to generate 3D images has helped improve our understanding of valve structure as well as facilitated easier identification of abnormalities such as mitral valve prolapse or flail leaflets. During postprocessing, multiplanar reconstruction can be performed to obtain in-plane measurements. This has especially been useful in cases such as rheumatic mitral stenosis. Integration of color Doppler to 3D echo has helped clarify several pitfalls and assumptions in standard 2D measurements such as PISA and VC. By virtue of the large amount of data that is generated and processed, currently available 3D suffers from poor spatial and temporal resolution compared with 2D echocardiography.

Currently, 3D echocardiography is superior to 2D in the following aspects of valvular heart disease: (a) accurate estimation of chamber size and volumes by eliminating the assumptions on which 2D volumetry is based as well as avoiding apical foreshortening (Mor-Avi et al., 2008); (b) assessment of 3D valve anatomy in some cases such as mitral valve disease (e.g., a surgeon's view with identification of leaflet segments in a single view), and (c) guiding catheter-based interventional procedures such as mitral clip implantation. The most important pitfall of 3D echocardiography relevant to valve disease is the failure to understand that a poor 2D image results in a worse 3D image. Time should be spent optimizing 2D TTE images first. In cases of poor ultrasound penetration, a 3D dataset rarely helps. With better resolution and less interference, 3D imaging is an invaluable resource in TEE imaging (Lang et al., 2012).

Stress echocardiography

Stress echocardiography plays an important role in three subsets of patients with valve disease: (a) to assess the hemodynamic effects of asymptomatic severe valve disease, (b) when resting echocardiography results are incongruent with exertional symptoms, and (c) when low flow states blur the distinction between true stenosis and failure of valve opening due to low flow itself (pseudo stenosis). Exercise testing with or without concomitant echocardiography is a valuable tool in an objective assessment of functional capacity in patients with apparently asymptomatic severe valve disease (Lancellotti et al., 2005). When noninvasive testing is performed to assess the impact of mechanical stress on myocardial and valve function, exercise is preferred over pharmacological stress because physical activity is more physiological. Exercise modalities that enable assessment at peak heart rate (semisupine exercise and bicycle ergometry) are preferred over those where assessment is performed post peak-stress (treadmill exercise). This is particularly important in some patients with seemingly moderate mitral stenosis at rest who have significant increases in mitral valve gradients and RV systolic pressure with exercise. When a low flow state (such as reduced LV systolic function) exists, increasing flow with a pharmacological agent such as dobutamine allows for distinction between true stenosis and pseudo-stenosis. This is applied commonly in AS in the setting of a low stroke volume (Takeda et al., 1999; Nishimura et al., 2002).

Contrast echocardiography

By utilizing the reflective properties of gas filled microspheres, endocardial border definition is improved by utilization of commercially available ultrasound opacification agents (Mulvagh et al., 2008). This allows accurate assessment of LV volumes and estimation of LV systolic function (Thomson et al., 2001). These agents also help enhance Doppler signals and can be used to better delineate the Doppler velocity trace across a valve. This has been mostly studied in the assessment of RV systolic pressure using the jet of TR and in enhancing the signal of AS (Himelman et al., 1989; Nakatani et al., 1992). Because dispersion of ultrasound increases artifact and causes blurring around CW Doppler signals, care should be taken to avoid measuring artifact which can result in overestimation of velocities.

Speckle tracking echocardiography

A wealth of information now exists that assessment of LV mechanics provides incrementally useful information in assessment of the myocardial effects of left-sided valve disease (Yingchoncharoen et al., 2012; Magne et al., 2012; Lancellotti et al., 2010c). In patients with asymptomatic severe valve disease with normal cardiac function, assessment of LV longitudinal strain by speckle tracking echocardiography can help diagnose early stages of myocardial dysfunction. This can be particularly useful in serial longitudinal follow-up. However, widespread clinical application of this technique in valve disease is in its infancy and requires validation in larger studies. The lack of intervendor compatibility also limits its use in routine clinical practice especially in multivendor labs where a patient may receive serial follow-up studies on different machines.

Transesophageal echocardiography

Transesophageal echocardiography (TEE) is a valuable tool in the assessment of valve anatomy because of the close proximity of the TEE probe to the heart, unhindered by structures such as adipose tissue, ribs, and lungs, and its ability to employ high-frequency imaging that enables better resolution (Hahn et al., 2013). However, a carefully performed TTE outperforms a TEE in some situations:

a. Interrogation of Velocities Across the Aortic Valve. Except for the deep transgastric apical view (which can be difficult to obtain in nonintubated patients), a spectral Doppler beam cannot be aligned parallel to transaortic flow during TEE.

b. Evaluation of Anterior Structures – Anterior structures such as the pulmonic valve are nearfield in TTE and far field in TEE. Similarly, though TEE enables an en face evaluation of the tricuspid valve, reverberation artifact from the aortic root can sometimes effect imaging of the tricuspid valve in the esophageal views.

Integrated approach to echocardiographic evaluation of valves

Echocardiographic evaluation often starts with a review of the clinical history and an assessment of overall health status of the patient. Evaluation performed on supine patient in a hospital bed may preclude accurate valve assessment by reducing available ultrasound windows and preventing parallel alignment of Doppler beam with the valve of interest. In such cases, a follow-up study after the patient recovers enough to be examined thoroughly is sometimes required. Heart rate and blood pressure recorded at the time of the study are essential in estimating the hemodynamic effects of valve disease. For example, the heart rate at which the mitral stenosis gradient is recorded should be part of all reports because the mean gradient across the valve is heavily dependent on flow (which, in turn, is affected by heart rate). Similarly, the blood pressure at the time of the exam can influence the assessment of severity of left-sided regurgitant valve lesions, especially MR.

Echocardiographic evaluation often starts with the assessment of overall chamber size and volumes and then 2D evaluation of valve structure. Multiple views should be used to assess valve structure. En face views of the aortic valve and mitral valve opening are easily obtained by TTE, while similar views are difficult to obtain for the tricuspid valve. When a valve abnormality is found, attention should be paid to the structure and function of the affected cardiac chamber. For example, left atrial size in mitral stenosis and MR, LV dimensions, volume, and systolic function in AR and MR and RV dimensions and function and IVC size in tricuspid regurgitation (TR) help assess the hemodynamic burden of valve disease. Color Doppler is used to detect valvular regurgitation and also to detect flow acceleration across stenotic valve. In stenotic valves, the presence of flow acceleration allows one to cross check the accuracy of CW Doppler measurement across stenotic valves. For example, flow acceleration during diastole across a mitral valve with calcified annulus should alert one to assess mitral valve gradients despite what appears to be adequate leaflet tip motion.

Spectral Doppler images are then assessed to evaluate gradients and effective orifice areas across stenosis and regurgitant volumes and effective regurgitant areas. Some commercially available PACS systems (EchoPAC, GE) allow the interpreter to manipulate raw image data to change gain and alter color Doppler scale (which is crucial in PISA assessment for regurgitant valves). Attention should be paid to the intercept angle between the ultrasound beam and the flow being interrogated. Discrepancies in degree of severity of valve disease (especially AS) are often related to his error. If such a discrepancy is detected, additional images should be obtained to correct the technical error or use additional nonstandard views (such as CW Doppler evaluation of AS from the right parasternal window). Similarly, assessment of flow in structures effected by regurgitant flow (PW Doppler of pulmonic veins in MR, descending aorta in AR, hepatic veins in TR) provides valuable information of its hemodynamic significance. In selected cases, 3D imaging is performed to better assess valve structure though poor ultrasound penetration may prevent diagnostic quality 3D TTE imaging.

TEE is often used in cases where TTE does not provide definitive information or in cases where surgical repair or transcatheter therapies are planned. Despite the higher resolution of TEE images, TTE is superior for assessment of gradients across stenotic valves (especially AS). Additionally, TEE is useful in surgical planning (such as mitral valve repair for primary MR) or assessing suitability for transcatheter valve therapies (mitral valve anatomy for MitraClip).

Aortic Valve

Anatomy of Aortic Valve

The aortic valve complex consists of valve leaflets, the aortic root, and a virtual annular ring formed by basal attachment of leaflets to the left ventricle (LV) (Piazza et al., 2008). A normal aortic valve has three leaflets or cusps which are designated by their relationship to the origin of the coronary arteries—right, left, and noncoronary. The area enclosed by each leaflet and the corresponding outpouching of the aortic root form the respective sinuses of Valsalva. The noncoronary leaflet adjoins the interatrial septum and the commissure of the right and noncoronary cusp lies over the membranous intraventricular septum and the cardiac conduction system; the commissure of the noncoronary and left coronary cusps point toward the mitral valve; and the commissure of the right and left cusps point toward the pulmonary leaflets. The leaflets are anatomically divided into free margins, body or "belly" of the leaflet, and the basal attachments. The leaflet margins are attached to the aortic root with their commissures forming the highest points of attachment at the sinotubular junction. The leaflet margins are mostly uniform except for a thickened node (nodule of Arantius) which facilitates optimal coaptation. During systole, the leaflet body and the margins fall backward onto the aortic root to allow free flow of blood from the ventricle and the aorta. During diastole, these leaflets bulge forward and coapt to prevent regurgitation.

The basal portions of the leaflets are semicircular; they attach all the way from the aortic root, cross the anatomic ventriculo-aortic junction, and attach to the LV myocardium at their lowest point of attachment (hinges). An imaginary line joining the hinges at the level of the ventricular myocardium forms the annulus. The aortic annulus is thus a virtual planar representation of a complex

three-dimensional structure and actually lies in the LV. The leaflets, their basal attachments, and the virtual annular ring thus form the shape of a coronet.

Echocardiographic Assessment of Aortic Valve Structure

Two-dimensional TTE is often sufficient in the identification of normal aortic leaflet anatomy. In a standard parasternal long-axis view, the right and noncoronary cusps are visualized (though a slight tilt to the left depicts right and left cusps), while the parasternal short axis provides an en face view. In the parasternal short-axis view at the level of the aortic valve, the noncoronary cusp is adjacent to the interatrial septum while the right cusp is adjacent to the RVOT (**Fig. 7**). In those with poor parasternal windows, a subcostal short axis en face view can be frequently obtained. The apical views are best suited for Doppler evaluation though care should be taken to align the ultrasound beam as co-axial with blood flow as possible. The corresponding views by TEE are: (a) mid-high esophageal 45–60 degrees short-axis en face view and (b) mid-esophageal 120 degrees long-axis view (corresponds to the parasternal long-axis TTE view). Doppler evaluation by TEE requires deep transgastric apical views to ensure coaxial alignment of the probe.

Aortic Stenosis

Echocardiography can be considered the de facto standard for the evaluation of AS in modern clinical practice. Direct measurement of transvalvular gradients by cardiac catheterization is rarely required (Baumgartner et al., 2009).

Assessment of valve structure in aortic stenosis

The most common causes of AS are calcific degenerative stenosis, bicuspid aortic valve disease, and rheumatic valve disease and echocardiography often helps delineate the etiology. When evaluating a case of suspected AS, the initial anatomic evaluation should include identification of the number of leaflets. The parasternal short-axis view at the level of the aortic valve is most helpful to identify the number of leaflets as well as assess leaflet mobility and degree of calcification. Bicuspid aortic valve disease is congenitally acquired and commonly results in fusion of the right and left coronary cusps (**Fig. 8**) (Siu and Silversides, 2010). In systole, an elliptical fish mouth-shaped systolic orifice is identified with two commissures. A raphe is often present on the larger of the bicuspid valve leaflets and can mimic a tri-leaflet valve. In the parasternal long-axis views, systolic doming and an asymmetric closure suggest a bicuspid aortic valve. The parasternal short-axis view also helps in the differentiation of calcific AS and rheumatic AS. In rheumatic AS, thickening and calcification are most prominent along the margins of the cusps. This is accompanied by commissural fusion which results in a triangular systolic orifice with blunted corners. In contrast, calcific AS of a tricuspid valve is prominent in the body of each cusp. Because the commissures are free and open, this results in a stellate orifice. The degree of calcification and restricted leaflet motion can also be assessed in this view. Degree of calcification is an important predictor of outcomes and should be described quantitatively as part of echocardiographic evaluation (Rosenhek et al., 2000). Unlike mitral stenosis where planimetry is useful for the assessment of valve area, it is less helpful in the evaluation of AS (Okura et al., 1997). Though it appears to correlate well with AVA by continuity equation in small studies, there are three major sources of error in measuring AVA by planimetry: (a) valve calcification and resultant reverberations may limit identification of the valve orifice, (b) planimetry should be performed at the area of the cusp tips; if measured more proximally, the valve area is overestimated, and (c) the effective orifice area (EOA) does not correspond with the location of geometric orifice area (GOA) (Gilon et al., 2002). The EOA is often distal to the GOA (aortic aspect) and smaller. Three-dimensional geometry of the stenotic valve plays an important role

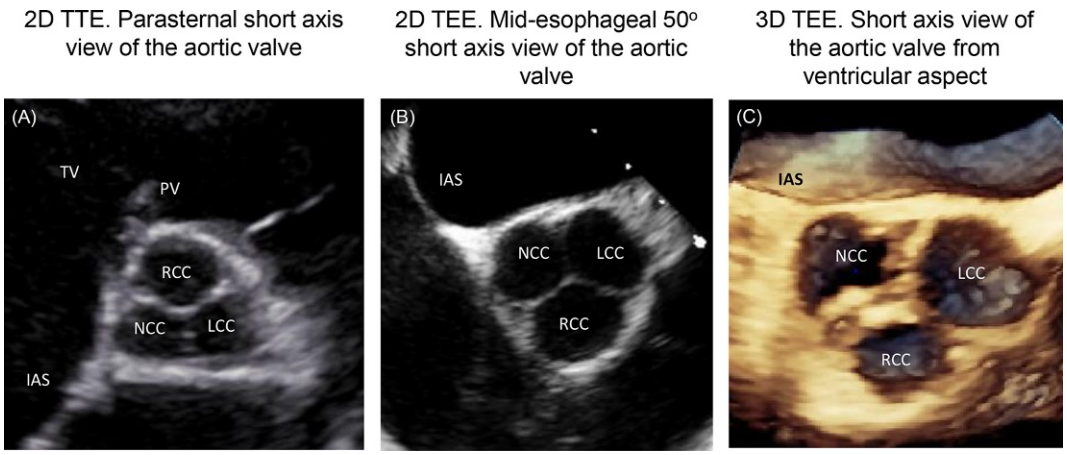

Fig. 7 Identification of aortic valve cusps by 2D TTE (panel A), 2D TEE (panel B), and 3D TEE (panel C). *IAS*, interatrial septum; *RCC*, right coronary cusp; *NCC*, noncoronary cusp; *LCC*, left coronary cusp; *PV*, pulmonic valve; *TV*, tricuspid valve.

with a smaller EOA for a flatter valve than a long tapering valve with the same GOA (Gilon et al., 2002). In addition, the primary predictor of outcome is EOA rather than GOA, because it better represents the hemodynamic burden on the LV. Finally, an old-fashioned axiom that has far outlived its usefulness is that "if the valve opens, it is not severely stenotic." Visual 2D estimation of valve severity is an insensitive method to assess severity and has high interobserver variability (Quader et al., 2015). This axiom should be modified for current day practice in the following manner "If the transaortic gradients are high but valve looks relatively disease free, look for subvalvular pathology (such as a subaortic membrane or LVOT obstruction)."

In the era of transcatheter aortic valve replacement, TEE (which is rarely useful in cases of AS except when the valve is not well-visualized by TTE) plays an important role in preoperative and intraoperative guidance of trans-valve replacement. Annular and LVOT dimensions can be accurately assessed using 3-D TEE and these correlate well with CT measurements (Altiok et al., 2011).

Assessment of valve function in aortic stenosis

After valve anatomy is established, the degree of aortic valve stenosis is assessed using Doppler ultrasound. The most important hemodynamic parameters are aortic valve peak velocity (AV Vmax), mean transaortic gradient, aortic valve area (AVA) by continuity equation, and dimensionless index (or Doppler velocity index) (Fig. 9).

Peak velocity and gradients across the aortic valve

The peak velocity and gradients across the aortic valve are measured using CW Doppler (Baumgartner et al., 2009). The five important principles in the accurate assessment of peak velocity and mean transaortic gradient are:

a. *Doppler beam alignment*. It is crucial to align Doppler beam in the direction of blood flow across the stenotic aortic valve. This is the most important source of error. In the standard echocardiographic views (apical five-chamber and three-chamber views), the jet flow may not be aligned well with CW Doppler beam despite appropriate patient positioning. This is especially true in elderly patients with aortic ectasia where the aorta arises at an angle with the LVOT. It is important to interrogate the aortic valve using multiple acoustic windows such as the right parasternal or suprasternal windows and using a nonimaging, dedicated CW

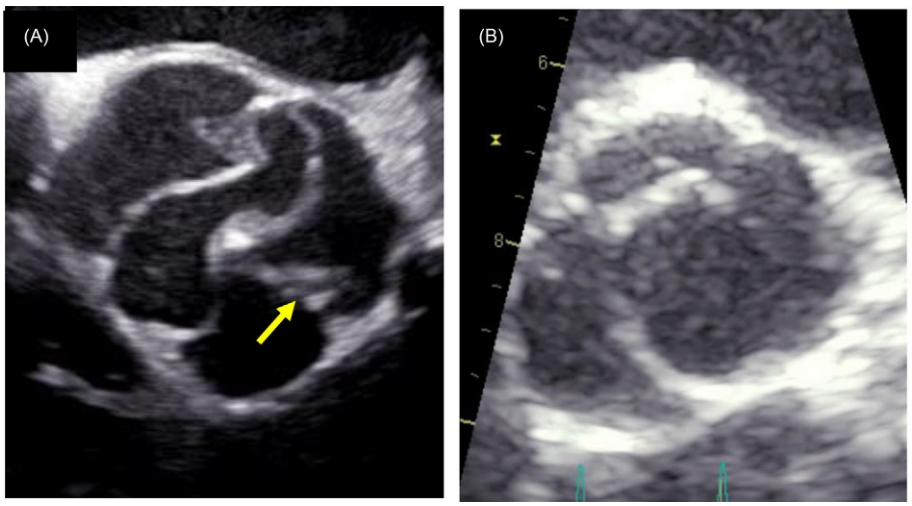

Fig. 8 Echocardiographic appearance of congenitally bicuspid (panel A) and unicuspid aortic valves (panel B). Yellow arrow denotes raphe.

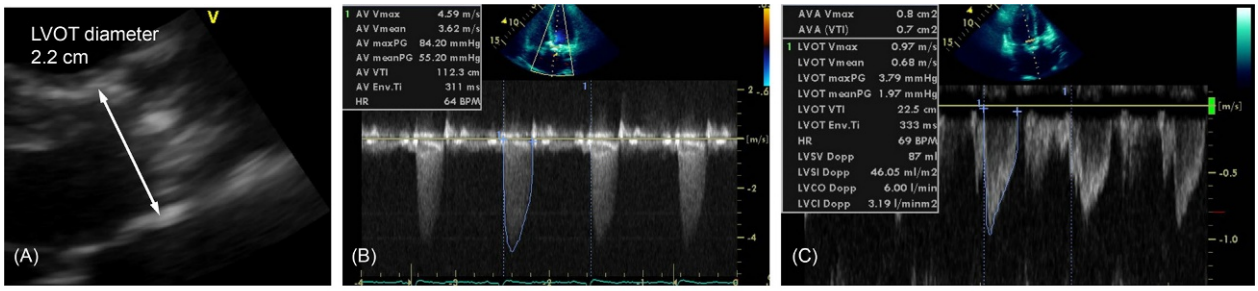

Doppler Velocity Index = $AV_{VTI}/LVOT_{VTI}$= 22.5/112.3 = 0.20

Fig. 9 Doppler assessment of severe aortic valve stenosis. (Panel A) Thickened and calcified aortic valve in parasternal long-axis view by TTE. (Panel B) Significantly increased transvalvular velocity and gradient. (Panel C) Determination of valve area by continuity equation by measurement of LVOT velocity and flow.

Doppler transducer (PEDOF probe). This probe has the advantage of allowing better transducer positioning and angulation as well as a better signal-to-noise ratio.

b. *Avoid cosine error*. The intercept angle between blood flow and the ultrasound beam should be kept within 20 degrees. Because the three-dimensional direction of the jet is unpredictable, angle correction which is commonly used in vascular ultrasound should not be used.
c. *Avoid measuring Doppler artifact*. Due to transit time effects, CW Doppler curves often demonstrate Doppler blur toward the tip of the velocity curve. Care should be used in recording only the dense portions of the outer edge in measuring peak velocity and mean trans-aortic gradient.
d. *Avoid recording other sources of increased flow*. Velocity curves from two other cardiac pathologies can be mistaken for trans-aortic flow. The jet of MR (especially eccentric jets) can be distinguished by its onset soon after mitral valve closure (during isovolumetric contraction time) as well as the shape of the signal (rounded compared with the peaked appearance of severe AS). In patients with dynamic outflow obstruction (such as hypertrophic cardiomyopathy), the velocity curve is late peaking with a concave upward curve during the early part of systole (dagger-shaped).
e. *Average measurements*. Conditions such as atrial fibrillation and frequent premature atrial and ventricular contractions can alter flow across the aortic valve due to changes in stroke volume resulting from variable LV filling times. In atrial fibrillation, avoid cardiac cycles with very small filling times. In the presence of ectopy, avoid post-extrasystolic beats. In general, three or more cardiac cycles are averaged in sinus rhythm, while at least five consecutive beats should be averaged in atrial fibrillation.

In addition to quantification of gradients, a marker of severity that can be derived from CW Doppler signal is the time to peak velocity. A delay in time to peak velocity (analogous to the late peaking murmur by auscultation) is positively correlated with severity of AS (Kamimura et al., 2016).

Aortic valve area by continuity equation

Calculation of AVA by applying the Continuity equation is the standard method of assessment of severity of AS (Kamimura et al., 2016; Zoghbi et al., 1986; Baumgartner et al., 1990). It is based on the concept that flow across the LVOT tract is equal to flow across the aortic valve. While jet velocity and mean transaortic gradient depend on flow, the valve area is relatively independent of flow rate except in cases of low-flow low-gradient AS with the degree of valve opening is impaired by the low-flow itself. Some sources of error are:

a. Measurement of LVOT Diameter. The most significant error that can be introduced into the measurement of aortic valve area by continuity equation is in the assessment of the LVOT diameter. The LVOT diameter is measured in the parasternal long-axis zoomed-in view, within a centimeter of the valve orifice (corresponding to where the laminar LVOT flow velocity signal is obtained in the apical views) and parallel to the aortic valve plane. In some cases, averaging for several beats is appropriate. Despite careful measurement of the LVOT diameter, a significant error in the assessment of LVOT area results from the presumption that the LVOT is circular in shape. 3D echo studies reveal that the shape of the LVOT is highly variable and is often oval (Altiok et al., 2011). This results in underestimation of the area of the LVOT which eventually leads to underestimation of aortic valve area (falsely severe).
b. Assessment of LVOT VTI. The LVOT velocity is recorded using PW Doppler from an apical five-chamber or three-chamber view. Sample volume is usually placed about 5–10 mm proximal to the aortic valve to obtain a smooth laminar velocity curve with a narrow band of velocities (modal) throughout systole. The VTI is measured by tracing the dense modal velocity throughout systole while avoiding the blur at the peak of velocity curve.
c. Pressure Recovery. A source of discrepancy between Doppler-derived AVA by continuity equation and that AVA derived from cardiac catheterization is the phenomenon of pressure recovery (Oh et al., 1988). In general, peak velocity and gradients obtained by CW Doppler are often higher than that measured by cardiac catheterization. CW Doppler resolves highest velocity across the stenotic valve (at the region of VC where velocity is highest and pressure is lower due to conversion of kinetic energy to potential energy) while a double lumen catheter placed during cardiac catheterization often measures the difference in gradient between the LV and a point distal to the VC in the aorta (where potential energy is converted back to kinetic energy and pressure has recovered). The impact of this is usually small but can be significant when the ascending aorta is small (Baumgartner et al., 1999).

Dimensionless Doppler velocity index

Because calculation of the LVOT area introduces a significant error in the measurement of the aortic valve area, the dimensionless Doppler Velocity Index (DVI) which is independent of the LVOT area has simplified the assessment of severity of AS (Niederberger et al., 1996):

$$\mathbf{DVI} = \mathbf{LVOT}_{\mathbf{Vmax\ or\ VTI}} / \mathbf{AV}_{\mathbf{Vmax\ or\ VTI}})$$

Although peak velocity or VTI can be used to calculate DVI, we prefer VTI because small errors in calculating peak velocity (e.g., measuring Doppler blur) are amplified when Vmax is used instead of VTI. A DVI of less than 0.25 correlates well with severe AS. In addition to being a useful diagnostic marker, a low dimensionless index has prognostic significance (Otto et al., 1986).

Table 1 shows the echo parameters for grading severity of aortic stenosis.

In routine practice, cases which do not meet all criteria for a given severity of AS are often encountered. Some of the reasons for noncongruence between gradients and AVA have already been discussed earlier (Rusinaru et al., 2015) and a stepwise approach to

resolution is depicted in Fig. 10. A final important factor is that the guideline criteria for severity are inherently inconsistent with a mean AV gradient below 40 mmHg in a significant number of patients with an AVA <1 cm^2, by both Doppler echocardiography and cardiac catheterization (Michelena et al., 2013; Minners et al., 2008). An AVA cutoff of 0.8 cm^2 has been proposed for severe AS because that area correlates better with a mean gradient >40 mmHg. Indexing for body surface can be helpful but can overestimate severity in larger patients. Reduced flow obviously reduces gradients across the aortic valve and two different low-flow, low-gradient (LF-LG) states are well characterized—LF-LG AS with reduced LV ejection fraction and LF-LG AS with preserved LV ejection fraction (reduced LV stroke volume index <35 mL/m^2) (Minners et al., 2010). A detailed discussion is beyond the scope of this article but detection of true severity often requires additional testing such as dobutamine echocardiography and multimodality imaging (Pibarot and Dumesnil, 2012).

In conclusion, an important consideration in incorporating echo parameters in clinical practice is to correlate the echo findings with the clinical status of the patient. There is no echocardiographic holy grail that precludes such careful patient individualization (Clavel et al., 2017).

Effect on cardiac chambers in aortic stenosis

The LV bears the hemodynamic burden of AS. Severe AS causes concentric LV hypertrophy due to pressure overload. The thickened walls with a small ventricular cavity lead to diastolic dysfunction which can cause symptoms by itself. In addition, it leads to a low stroke volume which can affect the assessment of valve stenosis (LF-LG AS with preserved ejection fraction). Presence of severe LV hypertrophy can be used as a marker to guide clinical decision making especially in a patient with asymptomatic severe stenosis. This is supported by the observation that despite reversal of LV hypertrophy with valve replacement, maladaptive changes persist at an ultrastructural level (Michelena et al., 2014).

Table 1 Echocardiographic grading of aortic stenosis

	Aortic sclerosis	*Mild*	*Moderate*	*Severe*
Aortic jet velocity (m/s)	<2.5 m/s	2.6–2.9	3.0–4.0	>4.0
Mean gradient (mmHg)		<20	20–40	>40
AVA (cm^2)		>1.5	1.0–1.5	<1.0
Indexed AVA (cm^2/m^2)		>0.85	0.60–0.85	<0.6
Dimensionless index (peak velocity or VTI)		>0.50	0.25–0.50	<0.25

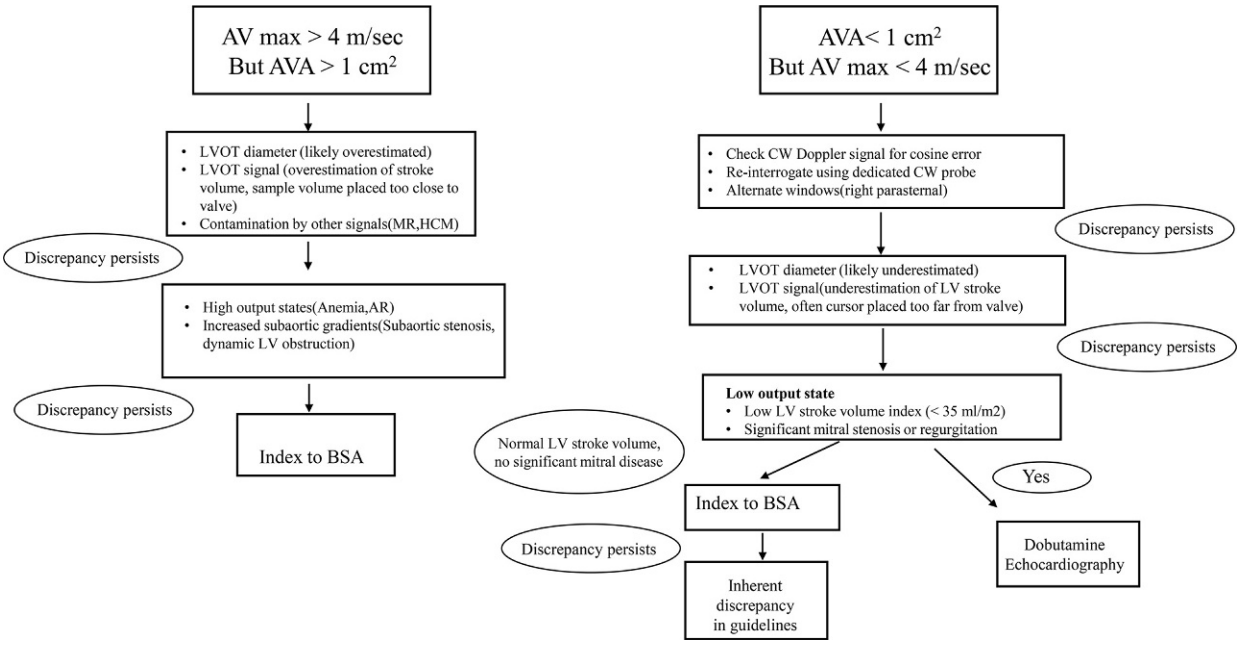

Fig. 10 Approach to resolving discrepancy between Doppler valve area and trans-aortic velocities in suspected severe aortic stenosis.

Stress echocardiography in aortic stenosis

Stress echocardiography is useful in the clinical management of AS. Exercise testing is an accepted measure for the assessment of functional status in a patient with asymptomatic severe AS. This is often performed without the use of echocardiography, though limited data suggests that the increase in mean pressure gradient with exercise predicts outcome. Dobutamine stress echocardiography is invaluable in the assessment of LF-LG AS. In patients with LF-LG severe AS (AVA less than 1 cm^2 with a peak velocity less than 4 m/s and mean gradient less than 40 mmHg), graded infusion of dobutamine can be used to distinguish between true severe stenosis versus pseudo severe stenosis (reduced valve opening due to low-flow itself) (Takeda et al., 1999; Nishimura et al., 2002). In addition, the absence of contractile reserve (failure to increase stroke volume by more than 20%) is a predictor of poor outcomes though its presence should not preclude valve replacement (Minners et al., 2010). In the era of transcatheter valve replacement, patients who are previously considered to be too high risk for surgical aortic valve replacement can now benefit from a less invasive option.

Effect of concomitant valve disease in aortic stenosis

Mixed aortic valve disease

The estimation of AS severity can be affected when more than moderate AR is present. AR leads to high transaortic flow with resultant higher than expected AV maximum and mean gradient for the calculated AVA (**Fig. 11**). These high transaortic gradients (irrespective of the dominant valve lesion) have independent prognostic value and should be used to drive decision making in addition to symptom status (Yarbrough et al., 2012). In general, a combination of moderate AS and moderate AR can be considered to represent severe mixed aortic valve disease.

Effect of concomitant mitral stenosis

Mitral stenosis can co-exist in patients with rheumatic as well as calcific AS. Due to impaired LV filling, mitral stenosis causes low cardiac output. This can lead to a LF-LG AS state despite normal LV function and lead to underestimation of severity of AS.

Effect of concomitant mitral regurgitation

In patients with AS, both primary (concomitant mitral valve disease) and secondary MR (due to LV pressure overload) can occur. Transesophageal echocardiography should be performed before surgical or transcatheter therapies in patients with suspected primary MR to establish etiology and severity of mitral valve disease. Secondary MR due to LV pressure overload often improves after correction of AS while more than moderate primary MR likely needs to be addressed along with the aortic valve intervention. In the presence of severe MR (both primary and secondary), a LF-LG AS can occur due to reduced LV forward stroke volume.

Aortic Regurgitation

Assessment of valve structure in aortic regurgitation

During echocardiographic assessment of AR, all portions of the aortic valve complex should be evaluated. The number of cusps should be carefully evaluated by identification of the commissures. Dilation of the aortic root and the ascending aorta should be assessed. The mechanism of AR can be classified based on etiology (primary or secondary) to chronicity (acute or chronic). A useful classification method for the mechanism of AR is based on leaflet motion and is an adaptation of the Carpentier classification for mitral valve disease (Zoghbi et al., 2017) (**Fig. 12**). Type I is associated with normal leaflet motion and is subdivided into: type IA due to dilatation of the ascending aorta and sinuses of Valsalva; type IB due to dilatation of the sinuses and the sinotubular junction alone; type IC due to annular dilatation and type ID due to cusp perforation or fenestration of the leaflets. Type II is associated with excessive leaflet motion from leaflet prolapse. Type III is associated with restrictive leaflet motion from causes such as degenerative calcification or rheumatic heart disease. In cases of new onset or acute AR, presence of oscillating echodensities such as vegetations should be carefully investigated which can cause acute severe regurgitation.

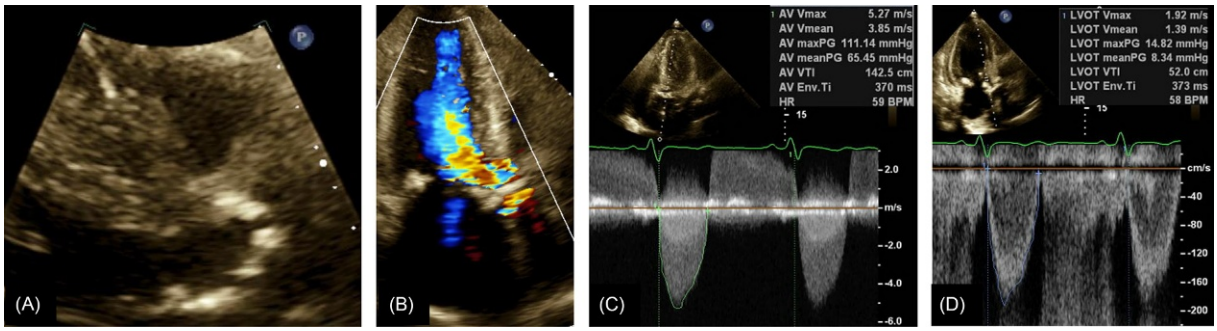

Fig. 11 Mixed aortic valve disease. In this example, TTE shows thickened aortic valve and restricted valve opening (panel A, mid systole) with significant regurgitant jet occupying the entire LVOT (panel B). The transvalvular gradient was significantly increased due to stenosis (panel C) and increased stroke volume (panel D). The mean gradient across the severely diseased aortic valve thus reflects the combined effect of stenosis and regurgitation.

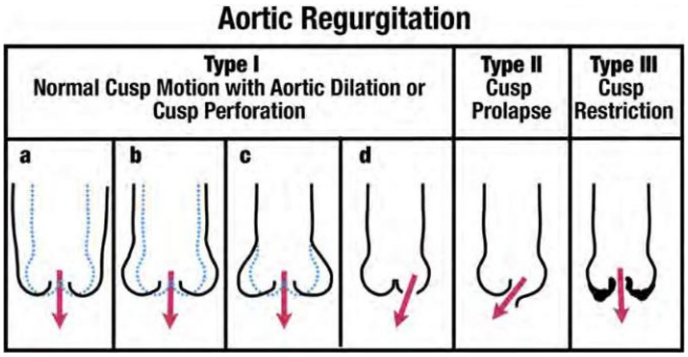

Fig. 12 Depiction of mechanisms of aortic regurgitation using the Carpentier classification. Type Ia shows sinotubular junction enlargement and dilatation of the ascending aorta. Type Ib shows dilatation of the sinuses of Valsalva and sinotubular junction. Type Ic shows dilatation of the ventriculo-arterial junction (annulus). Type Id shows aortic cusp perforation. *Assessment of valve function in aortic regurgitation (*Table 2*)*

Color Doppler imaging

Color-flow Doppler imaging forms the basis of the detection of AR by echocardiography. The three components of the jet of regurgitation with (flow convergence, VC, and jet area) are best visualized in the TTE parasternal long-axis view. The origin of the jet is sometimes best visualized in the parasternal short-axis view. The width of the jet in the LV outflow tract is a key component of the assessment of AR. The length of the jet is an unreliable parameter for severity because it is dependent on the difference of pressure between the aorta and the LV. In a centrally directed jet, the ratio of the width of the AR jet to the LVOT diameter provides a semiquantitative measure of the severity of regurgitation. The ratio is obtained in the parasternal long-axis view and the ratio more than 65% indicates severe AR, while less than 25% indicates mild AR (Egbe et al., 2016) (**Fig. 13**). Apical views should not be used for calculation of jet width because the regurgitation jets often appear wider due to poor lateral resolution of ultrasound. The ratio can be misleading in eccentric jets or in patients with multiple jets.

Vena contracta width

Width of the VC can be measured in a carefully optimized zoomed-in, parasternal long-axis view (at a Nyquist limit of 50–60 cm/s). VC >6 mm indicates severe AR, while <3 mm indicates mild AR (Perry et al., 1987). An advantage of the VC of method is that it can be useful even in eccentric jets.

PISA method

The PISA method can be used to calculate regurgitant volume (RVol) and EROA can be accomplished, typically in zoomed-in, parasternal, or apical long-axis view (Tribouilloy et al., 2000a). The radius of the proximal isovelocity shell is measured after defining the shell in a standard fashion (zoomed in view, baseline shift of the Nyquist limit in the direction of the flow). By calculating the radius of the shell and measuring AR peak velocity and VTI by CW Doppler, the EROA and regurgitant volume can be measured. Severe AR is defined by EROA ≥ 0.3 cm^2 and RVol >60 mm. Unlike MR, PISA quantification of AR is more challenging because flow convergence is often masked by aortic valve thickening and calcification.

Doppler volumetry

Doppler volumetric assessment is occasionally used in measurement of regurgitant volume. Using PW Doppler, the stroke volume at the LVOT and the stroke volume at the mitral valve annulus are measured. RVol is the difference between these volumes. This method is laborious and the area calculation is based on the assumption that both the LVOT and the mitral annulus are circular structures. It is not valid in the presence of more than mild MR.

Density of the Doppler signal

The density of the CW Doppler signal of AR compared with forward aortic flow is sometimes used as a qualitative measure of severity. A dense jet indicates significant regurgitation. A caveat is that CW Doppler interrogation should be in plane with the regurgitant jet or even a severe, eccentric jet can produce a faint or incomplete Doppler signal. Pressure halftime (PHT) of the AR signal provides an indication of the equalization of pressures between the aorta and the LV and thus AR severity. PHT is defined as the time interval in milliseconds between the peak AR gradient in early diastole to the time point where the gradient is half the maximum. PHT <200 ms suggests severe AR (especially in acute AR), whereas PHT >500 ms suggests mild AR. PHT is less useful in chronic severe AR, where compensatory LV remodeling can produce PHT between 200 and 500 ms. By virtue of its dependence on the aorto-ventricular gradient, PHT is unreliable in the presence of severe LV systolic or diastolic dysfunction due to another cause (in these cases, even mild AR may produce short PHT) or during treatment of systemic hypertension (high diastolic pressure can produce short PHT and treatment of hypertension lengthens PHT) (Tribouilloy et al., 1998).

Table 2 Echocardiographic assessment of aortic regurgitation

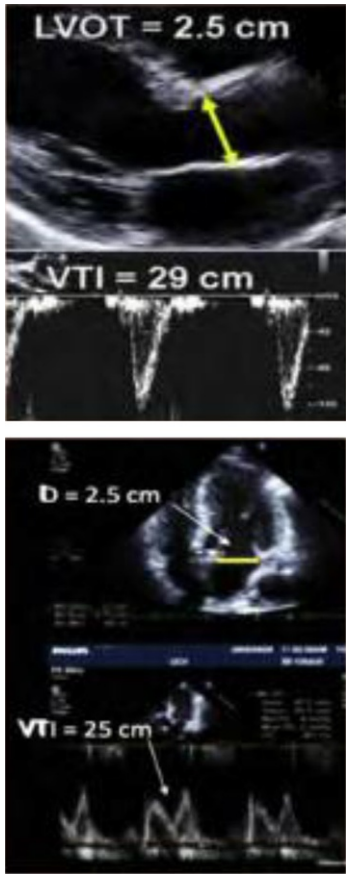
Modality	*Optimization*	*Example*	*Advantages*	*Pitfalls*
Color flow Doppler 3D: 3D VC	• Color flow sector should be narrow • Align orthogonal cropping planes along the axis of the jet • Choose a middiastolic cycle • Noncoaxial jets or aliased flow may appear "laminar" but still represent regurgitant flow		• Multiple jets of differing directions may be measured	• Dynamic jets may be over- or underestimated
Pulsed wave Doppler: Flow reversal in proximal descending aorta	• Align insonation beam with the flow in the proximal descending or abdominal aorta		• Simple supportive sign of severe AR • More specific sign if seen in abdominal aorta • Can be obtained with both TTE and TEE	• Depends on compliance of the aorta; less reliable in older patients • Brief velocity reversal is normal • Can be present in arteriovenous fistula in upper extremity, ruptured sinus of Valsalva • May not be holodiastolic in acute AR
CWD Density of regurgitant jet	• Align insonation beam with the flow • Adjust overall gain		• Simple • Density is proportional to the number of red blood cells reflecting the signal • Faint or incomplete jet is compatible with mild or trace AR	• Qualitative • Perfectly central jets may appear denser than eccentric jets of higher severity • Overlap between moderate and severe AR

(*Continued*)

Table 2 (Continued)

Modality	*Optimization*	*Example*	*Advantages*	*Pitfalls*
Jet deceleration rate (pressure half-time)	• Align insonation beam with the flow • Usually best from apical windows • In eccentric jets, may be best from parasternal window, helped by color Doppler		• Simple • Specific sign of pressure relation between aorta and LV • If long, excludes severe AR	• Qualitative • Poor alignment of Doppler beam may result in lower pressure half-time • Affected by changes that modify LV-aorta pressure gradient (if short, implies significant AR or high LV filling pressure)
Quantitative Doppler: EROA, regurgitation volume, and fraction				
	• Align insonation beam with the flow • Lower the color Doppler baseline in the direction of the jet • Look for the hemispheric shape to guide the best lower Nyquist limit • CWD of regurgitant jet for peak velocity and VTI	 	• Rapid quantitative assessment of lesion severity (EROA) and volume overload (RVol)	• Feasibility is limited by aortic valve calcifications • Not valid for multiple jets, less accurate in eccentric jets • Limited experience • Small errors in radius measurement can lead to substantial errors in EROA due to squaring of error.
SV method  RVol = $SV_{LVOT} - SV_{MV}$	• LVOT diameter measured at the annulus in systole and pulsed Doppler from apical views at same site • Mitral annulus measured at middiastole; pulsed Doppler at the annulus level in diastole • Total LV SV can also be measured by the difference between LV end-diastolic volume and end-systolic volume		• Quantitative, valid with multiple jets and eccentric jets. Provides both lesion severity (EROA, RF) and volume overload (RVol) • Verily results using LV end-diastolic volume and LV end-systolic volume	• Difficulties measuring mitral annulus diameter, particularly with annular calcification • Not valid for combined MR and AR, unless pulmonic site is used

- LV volumes are best measured by 3D. Contrast may be needed to better trace endocardial borders. If 3D not feasible, use 2D method of disks



Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

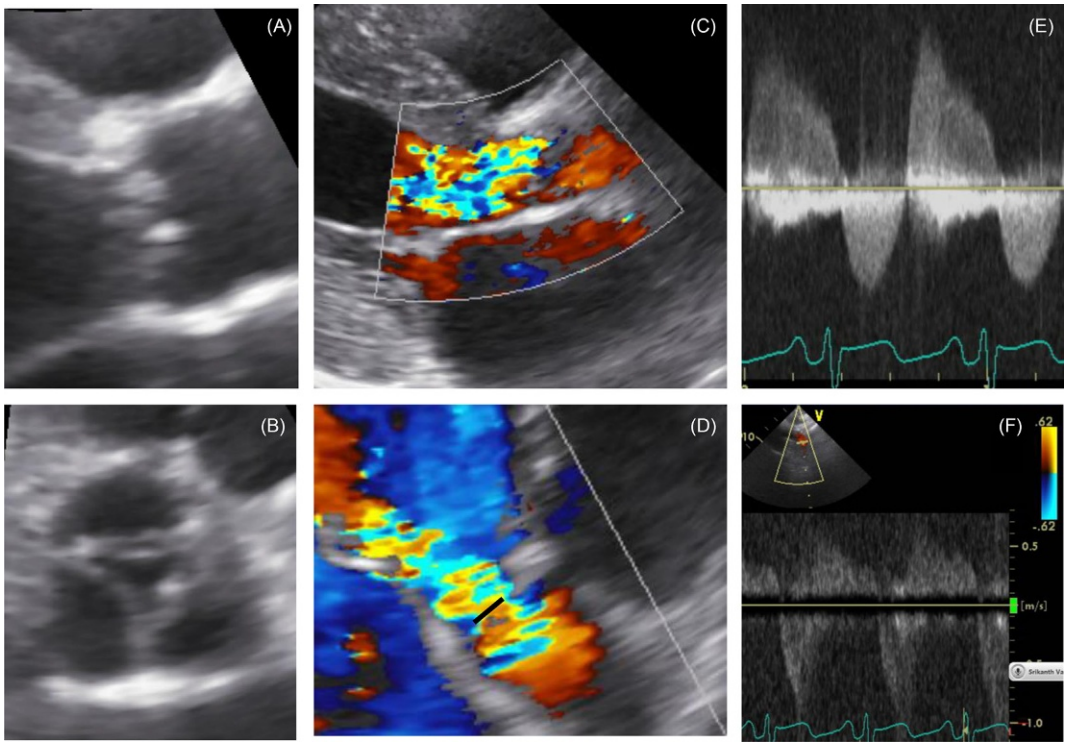


Fig. 13 Echocardiographic evaluation of a patient with severe aortic regurgitation. 2D TTE shows thickened leaflets with cusp eversion causing a significant coaptation defect during diastole (panels A and B). Color Doppler imaging shows the AR jet occupying most of the LVOT (panel C) with a vena contracta width of 9 mm (panel D). The CW Doppler profile of AR is as dense as forward flow profile (panel E). Holodiastolic flow reversal was present in proximal descending aorta (panel F).

Holodiastolic flow reversal in descending aorta

A useful sign of severe AR is the presence of holodiastolic flow reversal in the descending aorta. This is best accomplished by interrogating the proximal descending aorta from the suprasternal window and the abdominal aorta from subcostal views by PW Doppler. Presence of holodiastolic flow reversal in the abdominal aorta is specific for severe AR, while its presence in the proximal descending aorta indicates that the AR is at least moderate. Two useful semiquantitative measures that can be derived from the PW Doppler signals are: (a) an end-diastolic velocity more than 20 cm/s is often present in severe AR (Griffin et al., 1991); (b) a rough assessment of regurgitant fraction by the ratio of the VTI of reversed flow to forward flow.

Conditions that produce holodiastolic flow reversal in the absence of severe AR include a calcified noncompliant aorta in the elderly, presence of arteriovenous fistula in the upper extremity in patients with kidney disease, and rarely the presence of a patent ductus arteriosus or aortic dissection. Flow reversal may only occupy a small part of diastole despite severe AR in acute severe AR and with low heart rates.

Table 3 summarizes the echo parameters for grading severity of AR. Quantification of AR using these parameters has been validated prospectively and has good diagnostic and prognostic validity (Tribouilloy et al., 1991).

Effect on cardiac chambers in aortic regurgitation

Severe AR produces LV volume overload and ultimately reduced LV systolic function. Assessment of LV volume and function is thus crucial especially in the follow-up of AR. Left ventricular ejection fraction <55% or an LV end-systolic dimension >55 mm are predictors of outcomes and are useful in surgical decision making (Nishimura et al., 2014 Jul). Presence of normal LV volume and function almost rule out chronic severe AR. 3-D echocardiography allows more accurate assessment of LV volumes by eliminating the assumptions inherent to 2-D assessment and avoiding apical foreshortening. An additional supportive sign of severe AR (particularly acute) is its effect on the mitral valve. Due to the rapid rise of pressure in the LV during diastole in severe AR, the mitral valve closes prematurely. Presence of premature mitral valve closure provides a very valuable supportive sign of severe AR and surgical correction is recommended. By virtue of its excellent temporal resolution, M mode echocardiography is a valuable tool in detecting premature mitral valve closure.

Other modalities in aortic regurgitation

3-D echocardiography especially during TEE can be useful in the assessment of valve anatomy and measurement of annular dimensions. Integration of color flow with 3-D imaging can provide 3-D assessment of VC assessment. Exercise echocardiography can be useful in the assessment of functional status and LV function in patients with asymptomatic chronic severe AR and can be used to predict LV function recovery after valve replacement (Detaint et al., 2008).

Table 3 Echocardiographic grading of severity of chronic aortic regurgitation

Structural parameters	*Mild*	*Moderate*	*Severe*
Aortic leaflets	Normal or abnormal	Normal or abnormal	Abnormal/flail, or wide coaptation defect
LV size	Normal	Normal or dilated	Usually dilated
Qualitative Doppler			
Jet width in LVOT, color flow	Small in central jets	Intermediate	Large in central jets; variable in eccentric jets
Flow convergence, color flow	None or very small	Intermediate	Large
Jet density, CW	Incomplete or faint	Dense	Dense
Jet deceleration rate, CW (PHT, ms)	Incomplete or faint slow, >500	Medium, 500–200	Steep, <200
Diastolic flow reversal in descending aorta, PW	Brief, early diastolic reversal	Intermediate	Prominent holodiastolic reversal
Semiquantitative parameters			
VCW (cm)	<0.3	0.3–0.6	>0.6
Jet width/LVOT width, central jets (%)	<25	25–45 46–64	≥65
Jet CSA/LVOT CSA, central jets (%)	<5	5–20 21–59	≥60
Quantitative parameters			
RVol (mL/beat)	<30	30–44 45–59	≥60
RF (%)	<30	30–39 40–49	≥50
EROA (cm^2)	<0.10	0.10–0.19 0.20–0.29	≥0.30

LV, left ventricle; *CW*, continuous wave Doppler; *PW*, pulse wave Doppler; *PHT*, pressure half time. *LVOT*, left ventricular outflow tract; *VCW*, vena contracta width EROA denotes effective regurgitant orifice area. *RVol*, regurgitant volume; *RF*, regurgitant fraction.

Effect of other valve disease in aortic regurgitation

As described earlier, the presence of mixed AS and AR can affect the assessment of either valve lesion. The presence of MR affects the Doppler volumetric assessment of AR. Co-existing MR makes Doppler volumetric assessment of RVol unreliable and subjects the LV to the excess hemodynamic burden.

Mitral Valve

Anatomy of Mitral Valve

The mitral valve complex consists of two mitral leaflets, the mitral annulus and a subvalvular (chordae tendineae, and papillary muscles) apparatus interacting with the LV (Wahi et al., 2000; Ho, 2002). The mitral leaflets are commonly called anterior and posterior, though aortic and mural are probably more appropriate terms based on their anatomic orientation (Fig. 14). The anterior or aortic leaflet is trapezoid shaped and is larger and thicker than the posterior or mural leaflet. It is anchored to the fibrous portion of the mitral annulus (intravalvular fibrosa) and is adjacent to commissure between the left and noncoronary cusps of the aortic valve. The posterior leaflet is crescent shaped and smaller but occupies a longer circumferential area of the mitral annulus. The posterior leaflet often has indentations which demarcate it into three scallops (lateral P1, central P2, and medial P3). Though these indentations are not well developed in the aortic leaflet, the corresponding sections are labeled A1, A2, and A3. The two commissures of the mitral valve are anterolateral (A1–P1) and posteromedial (P3–A3). The normal mitral valve orifice area is 4–6 cm^2.

The mitral annulus is a dynamic, D-shaped fibromuscular structure which three-dimensionally resembles a nonplanar saddle. The straight edge of the D is formed by the anterior leaflet and is fibrous, while the circular portion is formed by the posterior leaflet and is muscular. This explains why the posterior annulus enlarges preferentially in cases of annular dilation. The normal annular orifice area is anywhere between 6 and 10 cm^2 in healthy adults. In secondary MR, flattening of the mitral annulus and absence of dynamic motion in addition to annular dilation contribute to valvular dysfunction.

The valve leaflets are anchored to the LV via fibrous structures called chordae tendineae which originate from papillary muscles (a few tertiary chordae arise directly from the ventricular myocardium). The chordae are fan-like and are inserted into the ventricular aspects of the leaflets. Primary or marginal chordae attached to the leaflet tips, while secondary or basal chordae attached to the body of the leaflets. A pair of thick secondary chordae called the strut chordae are commonly seen inserted into the anterior leaflet and are often preserved during mitral valve replacement. A normal mitral valve complex consists of two papillary muscles, anterolateral and posteromedial. The anterolateral papillary muscle has a single head and receives dual blood supply from the obtuse marginal branch of the left circumflex and the diagonal branch of the left anterior descending artery. The posteromedial papillary muscle commonly has two heads and is supplied either by the right coronary artery or the circumflex coronary artery (thus

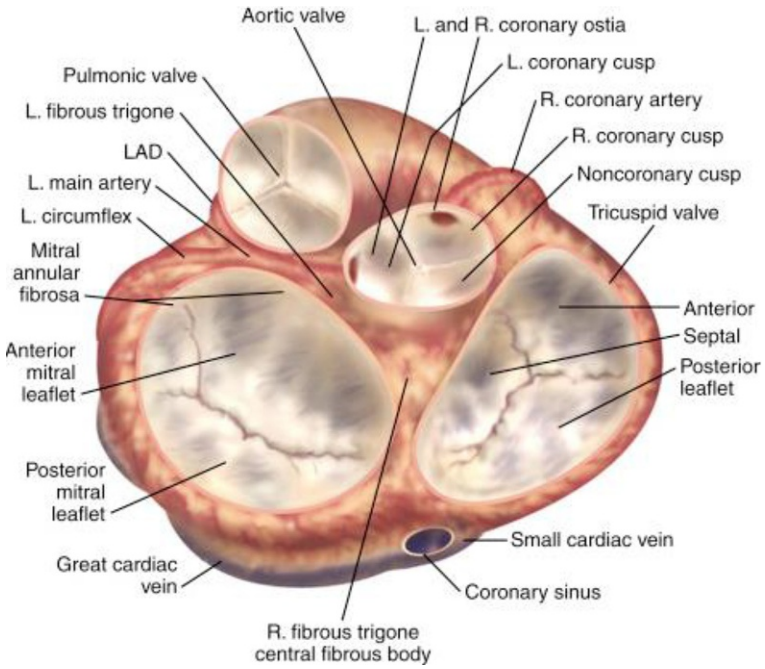

Fig. 14 Anatomical relationship of the mitral valve segments to surrounding structures. Reproduced with permission from Otto, C. M. et al. (2013). *Textbook of Clinical Echocardiography*, 5th edn, 2013.

making it more prone to ischemia). Contraction of the papillary muscles maintains the relationship between the LV and the mitral valve annulus and promotes normal coaptation. In patients with cardiomyopathy, remodeling of the ventricle disrupts this balance and produces malcoaptation.

Echocardiographic Assessment of Mitral Valve Structure (Fig. 15)

The mitral valve complex is evaluated in various orthogonal views by TTE. Leaflet segments can be identified in standard TTE views (marker to the right of the screen): A2-P2 in parasternal long-axis view; A2/A3 and P1/P2 in the apical four-chamber view, P1-A2-P3 in the apical two-chamber (commissural view); and finally an en face view in the parasternal short-axis view. In the parasternal short axis, A1-P1 are lateral most while A3-P3 form medial segments. Chordae and papillary muscles are assessed in parasternal long-axis or apical views (especially the apical two-chamber view). Apical views allow co-axial Doppler interrogation of the mitral valve. The papillary muscles can be identified in the parasternal short axis at approximately 4 o'clock (anterolateral) and 8 o'clock (posteromedial) positions.

Leaflet segment can be precisely identified by TEE examination from standard mid esophageal (ME) position by manipulating the probe at various angles and degrees of flexion: (A) ME 0 degrees—A2 and P2; at this angle, slight withdrawal—A1–P1 and slight advancement—A3–P3; (B) ME 45–60 degrees—commissural view, P1–A2–P3; (C) ME 90 degrees—two-chamber view—A2,3–P3; and (D) ME 120 degrees—long-axis view—A2–P2. An en face view of the valve is obtained in a transgastric 0 degree short-axis view of the mitral valve, this requires anteflexion of the probe. 3D TEE can help identify segments and pathology in a single frame and image can be manipulated to view the valve from either the left atrial (surgeons view) or the LV perspective.

Mitral Stenosis

Assessment of valve structure in mitral stenosis

Even in industrialized nations, the most common cause of mitral stenosis (MS) is rheumatic heart disease (RHD) (McCarthy et al., 2010). Rheumatic MS is characterized by commissural fusion, chordal fusion, and shortening, leaflet thickening (mostly at the tips) and calcification; this combination which finally lead to restriction of leaflet motion and stenosis (**Fig. 16A**). Common 2-D echocardiographic signs include a "hockey-stick appearance" of the mitral valve in the parasternal long-axis view due to restriction of leaflet motion and commissural fusion in the parasternal short-axis view resulting in a "fishmouth" appearance.

The second common cause is degenerative or calcific mitral stenosis which results from mitral annular calcification and its extension into the leaflets (**Fig. 16B**). Restriction of leaflet motion occurs at the bases (relatively free leaflet tips) and commissural fusion is absent. Rarer causes include radiation (**Fig. 16C**), carcinoid disease, and drug-induced valvulopathy.

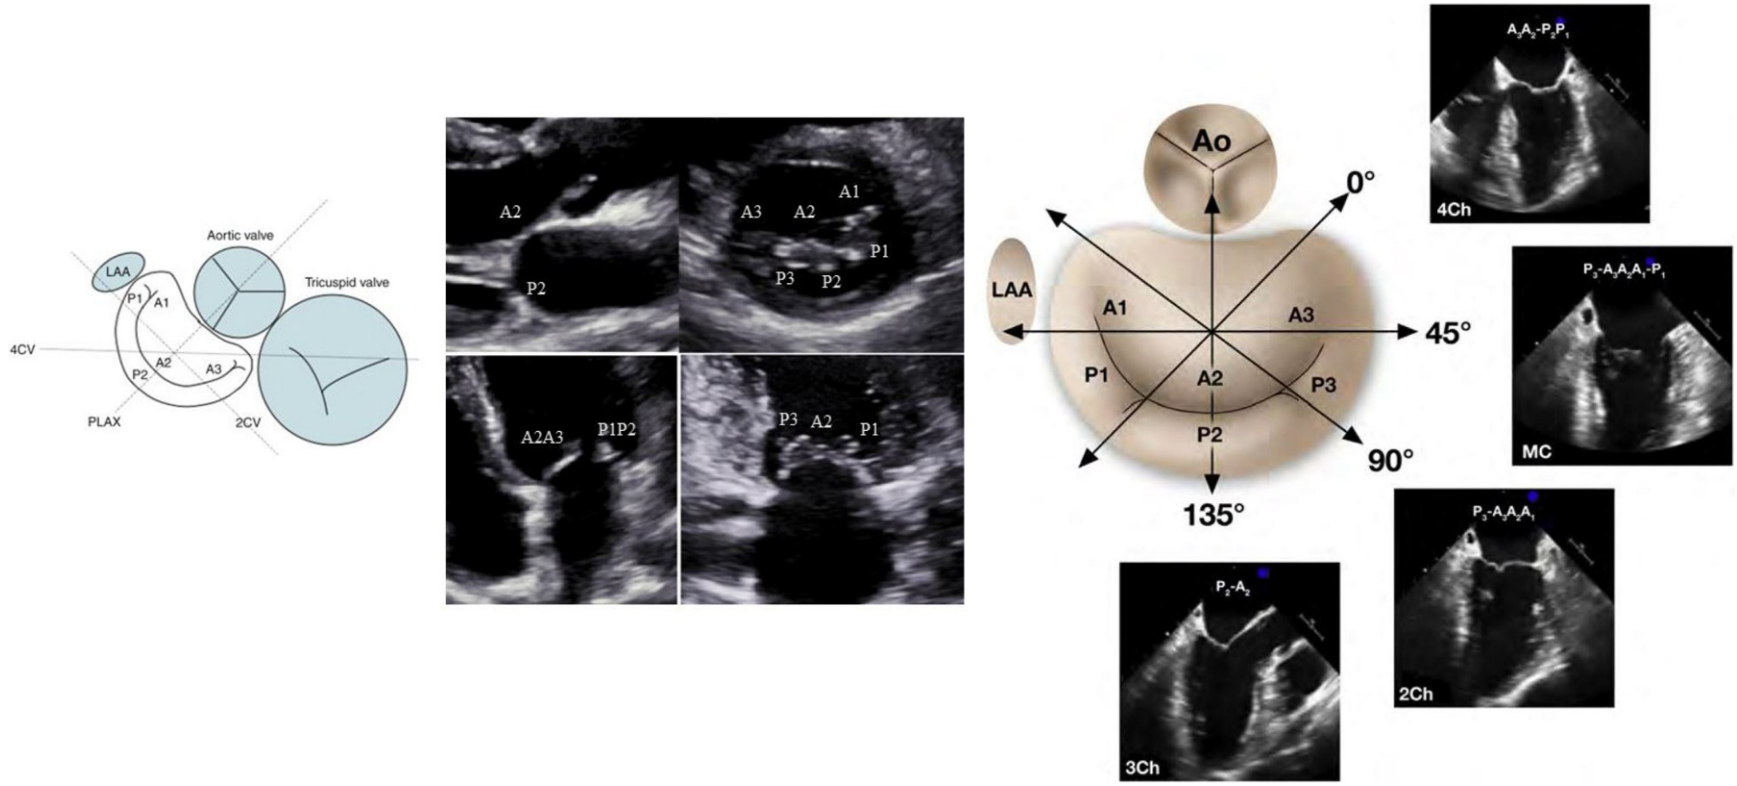

Fig. 15 Identification of mitral valve leaflet segments by 2D TTE and 2D TEE. Adapted with permission from Hahn, R. T. et al. (2013). *Journal of the American Society of Echocardiography*, **26** (9), 921–964 and Hutchinson, S. J. *Principles of Echocardiography*.

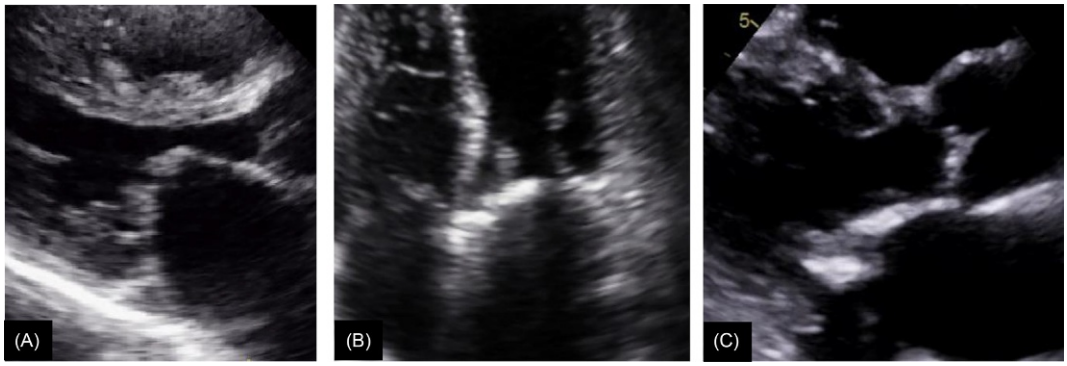

Fig. 16 Mitral valve structure in rheumatic mitral stenosis (leaflet tip restriction is the hallmark with relatively free bases) (panel A, mid diastole), calcific mitral stenosis in a patient with end stage renal disease (basal leaflet calcification with relatively free tips) (panel B) and mixed (radiation induced and mitral annular calcification) mitral stenosis (calcified anterior leaflet which was affected by mediastinal radiation to treat lymphoma) (panel C).

Evaluation of valve structure and MS is crucial both to establish diagnosis, define severity, as well as guide therapy. Mitral valve planimetry is the gold standard for the assessment of mitral valve area (MVA). It is obtained by direct tracing of the mitral orifice on the parasternal short-axis view at the tips of leaflets. Measurement distal or proximal to the leaflet tips can lead to under- or overestimation of the valve area. Planimetry is more accurate in patients with noncalcified leaflets and is best measured in middiastole (Baumgartner et al., 2009). Averaging of several measurements is recommended especially in patients with concomitant atrial fibrillation. It is important to note that planimetry was validated in patients with rheumatic MS and MVA by planimetry of leaflet tips may underestimate severity in MS due to causes such as calcific MS which predominantly affects the bases. 3-D guided measurement of mitral valve orifice area can improve the accuracy of planimetry measurement (Iung et al., 2003; Faletra et al., 1996; Sebag et al., 2005).

Percutaneous balloon mitral valvuloplasty (BMV) is a very effective method of alleviating symptoms severe MS. This method works by splitting of the commissures and thus suited for rheumatic MS (can cause acute severe MR if used in calcific MS with free leaflet tips and open commissures). It should be avoided in patients with extremely calcified leaflets and chordae. Several scores are available to assess suitability for BMV. These scores depend on thorough assessment of leaflet and chordal anatomy and of these, the Wilkins score is often used (Zamorano et al., 2004). Here, TEE is often useful in patients with poor TTE windows. Presence of moderate or more severe MR makes BMV a less desirable option.

Assessment of valve function in mitral stenosis

Doppler assessment of MS severity depends on assessment of valve gradients and estimation of MVA.

Peak velocity and gradients across the mitral valve

The mean gradient across the stenotic mitral valve is derived by tracing the transmitral diastolic velocity curve obtained by CW Doppler (Wilkins et al., 1988). This is best assessed in apical views to allow for parallel alignment of the ultrasound beam with the flow. The transmitral gradient is dependent on heart rate and flow (co-existing high flow states or MR) in all patients with MS and cycle length in those in atrial fibrillation. In patients with AF, at least five measurements should be averaged and extremes of cycle lengths should be excluded. Transmitral gradient of more than 10 mmHg (at a heart rate of about 70 bpm) suggests severe stenosis. Peak velocity is not used to assess severity.

Mitral valve area by pressure halftime

Mitral valve area (MVA) can be derived using the empirical formula:

$$\mathbf{MVA = 220/PHT}$$

where the pressure halftime (PHT) is defined as the time interval in milliseconds between the peak mitral gradient in early diastole in the time point where the gradient is half the maximum (Nishimura et al., 1994). Similar to measurement of mitral gradient, pressure halftime is best measured using CW Doppler and should be averaged in cases of atrial fibrillation. In cases of bimodal pattern (ski slope), the deceleration slope in mid-diastole should be traced (Thomas and Weyman, 1987) (**Fig. 17**). Despite its ease of performance, PHT depends on left atrial compliance and LV lusitropy and compliance (Gonzalez et al., 1987). In patients with LV diastolic function such as the elderly, PHT may be unreliable. It is best avoided in calcific MS where PHT has not been validated and often overestimates MVA (Karp et al., 1989a).

Other methods to assess mitral valve area

The MVA can be calculated similar to the estimation of aortic valve area using continuity equation and often correlates well with other methods (**Fig. 18**) (Akram et al., 2009). This is a useful additional parameter to assess MVA. MVA is calculated by dividing flow across the LVOT by VTI of the mitral flow at leaflet tips:

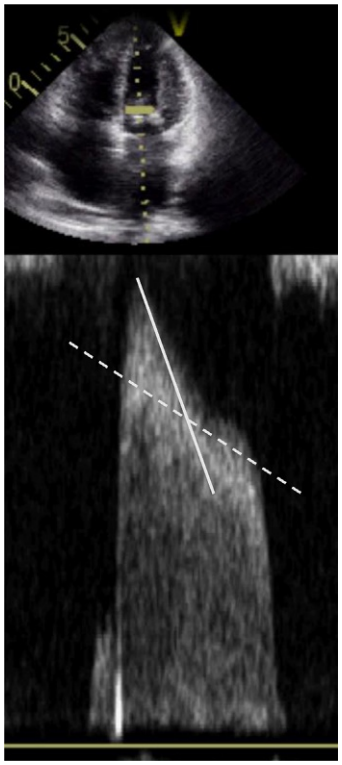

Fig. 17 Estimation of pressure half time (PHT) in a patient with a bimodal transmitral flow pattern. The dashed line represents the appropriate method for estimation of mitral valve area by PHT. The mitral valve area is overestimated by tracing PHT using the initial slope (*solid line*).

$$\mathrm{MVA} = \mathrm{LVOT}_{\mathrm{VTI}} \times \mathrm{LVOT}_{\mathrm{CSA}}/\mathrm{MV}_{\mathrm{VTI}}).$$

The proximal isovelocity surface area method can also be used but it is technically demanding and requires multiple measurements and angle correction because the orifice is quite obviously not flat.

Effect on cardiac chambers

The predominant effect of MS is on the left atrium (LA), pulmonary venous pressures, and thus the right ventricle (RV). With worsening MS, the LA size and pressure increase with two significant consequences: (a) increased LA remodeling and fibrosis which can result in atrial fibrillation. This is often poorly tolerated by patients with MS whose cardiac output (preload) is dependent on atrial contraction and (b) increased LA pressure is transmitted to the pulmonary circulation resulting in pulmonary venous hypertension and resultant RV dysfunction. The presence of RV dilation and dysfunction as well as concomitant TR should thus be carefully assessed during echocardiography. Tricuspid valve repair should be considered in patients with a dilated annulus (>40 mm or >21 mm/m^2) in patients being considered for mitral valve surgery (Nishimura et al., 2014).

The LV has traditionally been considered protected from the hemodynamics of MS. However, abnormalities in LV longitudinal and circumferential strain can be detected in many patients with severe MS. (Bonow et al., 2006) These abnormalities resolve soon after balloon mitral valvuloplasty, suggesting that abnormal loading conditions cause LV dysfunction rather than an intrinsic myocardial abnormality.

Echo parameters used to diagnose severe MS are depicted in **Table 4**.

Stress echocardiography in mitral stenosis

Exercise echocardiography is very useful in the assessment of the symptomatic patient with less than severe MS on resting echocardiogram. This is not an uncommon clinical scenario and reflects how a given MVA causes less than severe obstruction to flow at resting conditions but severe obstruction at higher flow rates. Measurement of transmitral gradient and pulmonary artery systolic pressure at peak exercise is necessary for accurate assessment of the hemodynamic significance of stenosis. Due to its ability to obtain gradients at peak exercise, semisupine exercise echocardiography is preferred to upright treadmill stress echocardiography. An elevation of RV systolic pressure (>60 mmHg) and transmitral gradients (often >15 mm) suggests exercise limiting MS. (Nakatani et al., 1988) Dobutamine stress echocardiography is rarely used because increase in flow created by dobutamine is not physiological.

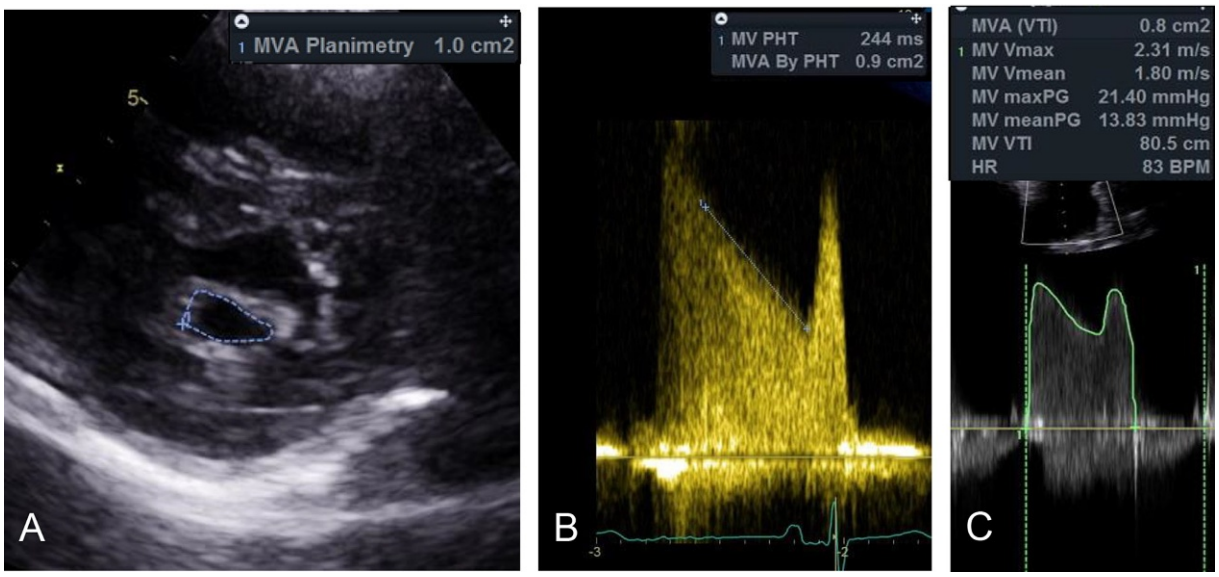

Fig. 18 Mitral valve area calculation in a patient with severe rheumatic mitral stenosis. There is good agreement between all three methods used: planimetry (panel A), pressure halftime (panel B), and continuity equation (panel C).

Table 4 Echocardiographic criteria for severe mitral stenosis

	Severe mitral stenosis
Specific findings	
Valve area (cm^2)	<1.5
Supportive findings	
Mean gradient (mmHg)	>5–10
Pulmonary artery pressure (mmHg)	>30 (2009 ASE guidelines [Ref 4])
	>50 (2014 ACC guidelines [Ref 2])

Effect of concomitant valve disease in mitral stenosis

Mixed mitral valve disease

Similar to mixed aortic valve disease, the presence of MR affects both the assessment and treatment of mitral stenosis. The increased flow from MR increases transmitral flow and gradients. Though PHT has traditionally been considered independent of MR, available data is conflicting and this method is best avoided. Presence of moderate MS and moderate MR can be labeled severe mixed mitral valve disease. Presence of MR also effects calculation of MVA by continuity equation.

Effect of concomitant aortic stenosis

As noted earlier, severity of AR may be underestimated due to the reduced stroke volume from MS.

Effect of concomitant aortic regurgitation

The PHT method for calculation of MVA is not valid in cases of severe AR (which effects LV compliance).

Mitral Regurgitation

Assessment of valve structure in mitral regurgitation

Echocardiography is useful in defining the mechanism of MR which can broadly be divided into two categories: Primary MR due to an intrinsic leaflet abnormality and secondary MR due to left heart remodeling in the presence of a normal and intact mitral valve apparatus (McCarthy et al., 2010). Within primary MR, the Carpentier classification based on leaflet motion provides a method of classification and helps planning of surgical repair (Fig. 19). Leaflet motion is normal in type I (e.g., leaflet perforation and annular dilation due to secondary MR), excessive in type II (e.g., degenerative mitral valve disease such as mitral valve prolapse or presence of flail leaflet), and restrictive in type III, which can be further divided into type IIIa where leaflet motion is restricted during both

diastole and systole (e.g., rheumatic valve disease, radiation-induced valve disease) and type IIIb where leaflet motion is restricted during systole alone (e.g., leaflet tethering due to LV dilatation in secondary MR) (Zoghbi et al., 2017).

The most common cause of primary MR is myxomatous degenerative valve disease such as mitral valve prolapse (MVP). In MVP, leaflets are thick and redundant and the coaptation point moves beyond the mitral annulus into the LA during systole (see online **Videos 1** and **2**). Echocardiography is useful in detecting MVP and distinguishing between two major causes—Barlow's disease and fibroelastic deficiency. In Barlow's disease, the mitral valve leaflets are diffusely thickened and redundant while redundancy and prolapse are limited to few leaflet segments in fibroelastic deficiency. The diagnosis of MVP is usually made in the parasternal long-axis view where the coaptation point of the mitral valve is displaced at least 5 mm posterior to the mitral annular plane. A key pitfall in the 2-D echo diagnosis of MVP is diagnosing it based purely on apical four-chamber or two-chamber views. In these views, the mitral valve leaflets are imaged along the low points of the saddle-shaped mitral valve annulus; this makes the leaflets appear to be displaced into the left atrium even in normal subjects (Sengupta et al., 2014). However, in patients with significant MR and poor parasternal windows, apical views can provide visual assessment of thickening of leaflets and leaflet motion though not being diagnostic of MVP except in severe cases.

MR due to MVP is usually limited to the mid-to-late systole. When chordal rupture appears, the prolapsed leaflet becomes flail (see online **Video 3**). Flail leaflet is defined by the presence of mobile leaflet edge with its tip pointing into the LA. In these cases, MR is usually severe and is holosystolic. Identification of a flail leaflet is crucial because its presence usually indicates significant MR and predicts adverse outcomes if left unrepaired. In secondary MR, distortion of the mitral valve apparatus by left heart remodeling (both LA and LV) occurs in the presence of usually normal leaflets. In the presence of adverse LV remodeling, leaflet mild coaptation occurs either due to regional or global LV systolic dysfunction. A common cause of secondary MR due to regional LV systolic dysfunction is hypokinesis of the inferior wall after a myocardial infarction. This results in tethering of the posterior leaflet and increased distance of the posterior papillary muscle from the intravalvular fibrosa. The direction of the MR jet in these cases is usually posterior. In contrast, global LV dysfunction results in several changes. The mitral annulus is frequently dilated, becomes flat-shaped, and is nondynamic (Zoghbi et al., 2017). Due to LV dilation, there is increased distance between the papillary muscles. This combination results in symmetric tethering of both leaflets resulting in apical displacement and malcoaptation. Because the posterior portion of the mitral annulus is muscular, it dilates more than the fibrous anterior annulus. The MR jet is frequently central.

In the era of trans-catheter mitral valve therapies, it is important to understand a few caveats in the distinction between primary and secondary MR. Mild leaflet thickening can occur in secondary MR as a reaction to the abnormal tethering forces on the displaced mitral leaflets (Levine et al., 1988). Chordal rupture and a flail leaflet can occur in patients with secondary MR. Similarly, LV dysfunction due to either ischemic or nonischemic cardiomyopathy can develop in a patient with known primary MR and leaflet anatomy may reflect characteristics of both types. In this condition, LV chamber size and function may reflect the underlying

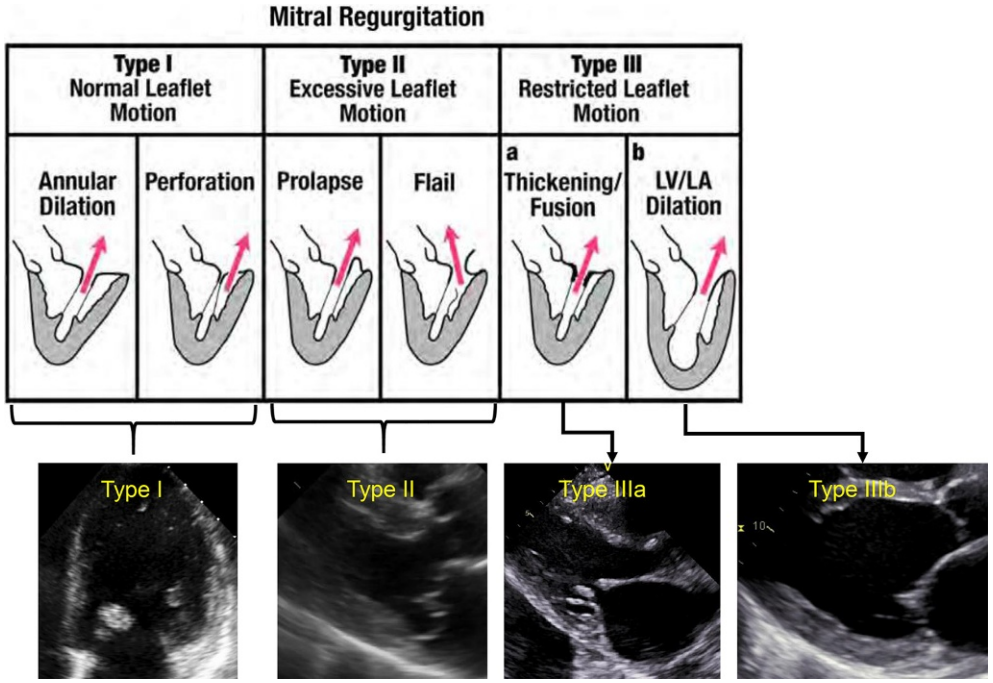

Fig. 19 Mechanism of mitral regurgitation according to Carpentier classification and examples of their representative TTE appearance. Endocarditis exemplifies type I; mitral valve prolapse illustrates type II; rheumatic mitral regurgitation with leaflet tip restriction and malcoaptation represents type IIIa; and leaflet malcoaptation due to LV enlargement is an example of type IIIb. Adapted with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

cardiomyopathy rather than the hemodynamic burden of MR alone. These types of mixed mitral valve disease (by etiology) should be clearly defined to enable accurate diagnosis, guide effective therapies, and avoid regulatory scrutiny (e.g., the Mitraclip device is currently approved only for primary MR in the United States and etiology should be clearly defined prior to this intervention).

Based on chronicity, MR can either present acutely or chronically. Echocardiography plays a crucial role in the timely identification and management of acute MR which often results in hemodynamic compromise. 2-D echo helps identify the pathology such as the flail leaflet due to a ruptured cord, leaflet destruction due to endocarditis, or ruptured papillary muscle due to acute myocardial infarction. Due to its sudden onset, the left atrial pressure increases rapidly and the stroke volume is reduced because of the lack of compensatory LV remodeling. Due to this low LV- LA gradient, color Doppler imaging can be unimpressive and may display little turbulence. TEE is often helpful in precise identification of valve pathology.

*Assessment of valve function in mitral regurgitation (*Table 5*)*

Color Doppler imaging

Color Doppler imaging is the primary modality for the detection of MR. Trivial MR is a common finding in normal subjects. When an MR jet is identified, effort should be made to display all three components of the jet—flow convergence, VC, and jet area. This may require slightly off axis views especially in cases of eccentric regurgitation and sometimes multiple views to define each component. Though the jet area and length are often used clinically for grading MR severity (Dal-Bianco et al., 2009), they can be very misleading.] An eccentric jet (such as in the presence of a flail leaflet) may appear small as part of the jet is constrained by the left atrial wall and loses kinetic energy quickly which prevents it from recruiting surrounding blood. Volume and loading conditions such as hypertension also affect jet area and explain the discrepancy when echocardiography is performed at different times (Zoghbi et al., 2017). Though the jet area would be similar in different echocardiographic views when the ERO is central, it can appear markedly different in the presence of elliptical or slit-like orifice. For example, in secondary MR where origin of the jet is slit-like along the region of malcoaptation, imaging in the commissural view (apical two-chamber view) produces a large jet area even in the presence of a small EROA. VC width provides a semiquantitative method of assessment of severity of MR. (Chaliki et al., 1998)VC $\geq$7 mm is consistent with severe MR, while VC $<$3 mm usually denotes mild MR. Additional methods of quantification should be used in case of intermediate values of VC (3–6 mm) due to substantial overlap between MR grades. Multiplanar reconstruction using 3-D echocardiography may provide more accurate assessment of VC with and allows direct calculation of the VC area (which corresponds to EROA) (see online **Video 4**). A 3D-derived VC area $>$0.41 cm^2 can differentiate between moderate and severe MR. (Tribouilloy et al., 1992) Due to the challenges posed by the lower spatial and temporal resolution of 3D echo and the lack of outcome data, this method is not widely used.

Spectral Doppler

The flow convergence or PISA method is the most reliable echocardiographic method for the determination of regurgitant volume (RVol) and EROA. The proximal isovelocity shell is optimized in a standard fashion (apical zoomed-in view of the mitral leaflet, lowering the Nyquist limit in the direction of the flow to define the boundary of the shell) and the radius calculated. Using the maximal velocity and VTI of the CW jet of MR, RVol and EROA can be estimated (**Fig. 20**). The pitfalls in PISA assessment have been described earlier (Section 2.2.2.3.1). In part, they are related to the assumption that the shell is hemispheric and the orifice is circular. The shell may not be well delineated in eccentric jets with the flow convergence are can be constrained by the LV wall. Similarly, severity of MR can be underestimated in patients with noncircular EROA geometry (such as secondary MR). Finally, both the PISA method and VC are performed on single frame images and can be misleading when the MR is limited to part of systole (such as MVP).

A simplified PISA method

By shifting the aliasing velocity to 40 cm/s and assuming an MR velocity of 5 m/s, the PISA equation can be simplified to:

$$\mathbf{EROA} = \mathbf{r^2/2} \ldots .. [\mathbf{80}]$$

This method may not hold good in patients with extremes of blood pressures or in severe LV systolic dysfunction.

Doppler volumetry

Doppler volumetric assessment can be used to calculate the RVol by estimating the difference between the stroke volume at the LVOT and the mitral valve annulus. PW Doppler is used to calculate the VTI of flow in the LVOT and at the level of the mitral annulus. The calculation of the area of the LVOT and the mitral annulus assumes that both of these structures are circular in shape. When this assumption is not true, this introduces significant error in calculation. In addition, the calculation is often laborious and is uncommonly used in clinical practice.

Supportive Doppler signs

There are some supportive signs for severity of MR on PW and CW Doppler assessment of mitral valve. The most important supportive PW Doppler sign of the severity of MR is PW evaluation of pulmonary venous flow. Presence of systolic flow reversal correlates well with an EROA $>$0.3 cm^2 and thus is often present in severe MR. (Pu et al., 2001) Flow reversal in two or more pulmonary veins (which is better demonstrated by TEE) is more specific because a less than severe eccentric jet can selectively enter a single pulmonary vein and display reversal. Reduced or blunted systolic velocity is less useful because coexisting LV diastolic or systolic dysfunction cause increased LA pressure and reduce systolic flow from the pulmonic veins (S wave $<$D wave).

Table 5 Echocardiographic evaluation of mitral regurgitation

Modality	*Optimization*	*Example*	*Advantages*	*Pitfalls*
Color flow Doppler 2D: Proximal flow convergence	• Align direction of flow with insonation beam to avoid distortion of hemisphere from noncoaxial imaging • Zoomed view • Variance off • Change baseline of Nyquist limit in the direction of the jet • Adjust lower Nyquist limit to obtain the most hemispheric flow convergence (typically 30–40 cm/s) • Measure the radius from the point of color aliasing to the VC		• Rapid qualitative assessment • Absence of proximal flow convergence usually a sign of mild MR	• Multiple jets • Eccentric jets • Constrained jet (LV wall) • Nonhemispheric shape, particularly functional MR • Overestimation when MR not holosystolic
VCW	• Parasternal long-axis view • Zoomed view • Imaging plane for optimal VC • Best measured when proximal flow convergence, VC, and MR jet aligned in same plane		• Surrogate for regurgitant orifice size • Independent of flow rate and driving pressure for a fixed orifice • Can be applied in eccentric jets • Less dependent on technical factors • Good at separating mild ($<$0.3 cm) from severe MR ($\geq$0.7 cm)	• Problematic in the presence of multiple jets • Convergence zone needs to be visualized for adequate measurement • Overestimation when MR not holosystolic
Jet area or jet area/LA area ratio	• Apical view • Zoom view • Measure largest jet alone or as ratio to LA area in same view	 	• Easy to measure	• Shown to be imprecise in multiple studies, particularly in eccentric, wall-impinging jets • Dependent on hemodynamic (especially LV systolic pressure) and technical variables • Overestimation when MR not holosystolic

(*Continued*)

Table 5 (Continued)

Modality	*Optimization*	*Example*	*Advantages*	*Pitfalls*
Color flow Doppler 3D: 3D VCA	● Color flow sector should be as narrow as possible to improve volume rates and line density ● Align orthogonal cropping planes along the axis of the jet ● Planimeter the high velocity aliased signal of VC, avoiding low velocity (dark color) signals		● Multiple jets of differing directions may be measured ● Can identify severe functional MR in some cases where PISA underestimates EROA	● Subject to color Doppler blooming ● Limited temporal and spatial resolution ● Overestimation when MR not holosystolic ● Multiple jets may be in different planes, must be analyzed separately and then added ● Cumbersome, often requires offline analysis
Pulsed wave Doppler Mitral inflow velocity	Align insonation beam with the flow across the MV at leaflet tips in apical four- chamber view		● E velocity $\geq$1.2 m/s a simple supportive sign of severe MR (volume load) ● Dominant A-wave inflow pattern virtually excludes severe MR ● Can be obtained with both TTE and TEE	● Depends on LV relaxation and filling pressures ● High E velocity not specific for severe MR in secondary MR, atrial fibrillation, and mitral inflow stenosis
Pulmonary vein flow pattern	Use small sample volume (3–5 mm) placed 1 cm into pulmonary vein		● Systolic flow reversal in more than one pulmonary vein is specific for severe MR ● Normal pulmonary vein pattern suggests low LA pressure and hence nonsevere MR	● Eccentric MR of mild or moderate severity directed into a pulmonary vein alters flow pattern ● Systolic blunting is not specific for significant MR (common in secondary MR and present in elevated LA pressure, atrial fibrillation) ● Not valid for combined MR and AR, unless pulmonic site is used

Table 5 (Continued)

Modality	*Optimization*	*Example*	*Advantages*	*Pitfalls*
SV method  $RVol = SV_{MV} - SV_{LVO}$	• LVOT diameter measured at the annulus in systole and pulsed Doppler from apical views at same site • Mitral annulus measured at middiastole; pulsed Doppler at the annulus level in diastole • Total LV SV can be measured by pulsed Doppler technique at mitral annulus or by the difference between LV end-diastolic volume and end-systolic volume • LV volumes are best measured by 3D. Contrast may be needed to better trace endocardial borders. If 3D not feasible, use 2D method of disks	Mitral annulus  LVOT 	• Quantitative, valid with multiple jets and eccentric jets • Provides both lesion severity (EROA, RF) and volume overload (RVol) • Validated against CMR in isolated MR	• Cumbersome, needs training; small errors in each different measurement can combine to magnify error in final results • Pulsed Doppler method (mitral SV) and LV volume method may give different results

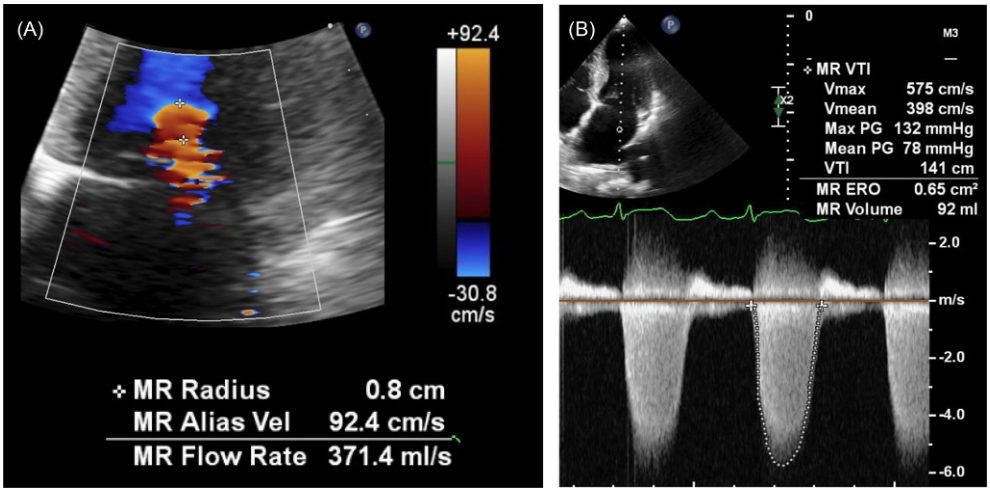

Fig. 20 Assessment of regurgitant volume and EROA in a patient with severe primary MR.

In patients with severe primary MR, the E velocity of transmitral flow pattern is usually high due to increased diastolic flow. In fact, severe MR can be almost excluded in the presence of an A wave-dominant impaired relaxation pattern. This may not be reliable in several conditions such as young age (where the mitral flow is E-wave dominant), secondary MR (where increased E velocity may be due to elevated LA pressure), and mitral annular calcification or MS (where flow is accelerated due to obstruction).

A simple nongeometric method relies on the principle that degree of regurgitant flow is reflected by the ratio of MV_{VTI} and $LVOT_{VTI}$ (Pu et al., 1999). This ratio is less than 1 in normal individuals because the mitral valve area is greater than the LVOT area. A ratio of >1.3 supports severe MR. This finding is however dependent on LV function and should only be used in conjunction with other parameters.

The shape and density of the CW Doppler MR jet can provide qualitative insight into the severity of MR. Compared to forward flow, significant MR causes echodense MR jet signal; lesser degrees of MR produce fainter signals. Similarly, the jet appears triangular and truncated in cases of severe MR with elevated LA pressure due to early peaking of MR jet signal with rapid decrease due to elevated LA pressure.

Echo parameters for grading severity of MR are depicted in **Table 6**. Echo variables for quantification of MR have been tested prospectively and have good prognostic validity (Tribouilloy et al., 1994).

A significant area of confusion in recent times has been the differing indices of severity for primary and secondary MR. (Nishimura et al., 2014 Jul) This was based on several studies showing that an EROA >0.2 cm^2 was associated with worse prognosis in secondary MR. This led to its inclusion as a cut-off for severity for severe secondary MR in the 2014 ACC/AHA valve guidelines (Nishimura et al., 2014 Jul). However, there is no data that valve interventions at that cut-off improve outcomes. In addition, patients with secondary MR are at a high risk of perioperative morbidity and mortality by virtue of their LV disease and valve surgery does not cure the underlying problem. This has led to a recent focused update which now aligns markers of severity equally between primary and secondary MR. (Enriquez-Sarano et al., 2005).

Effect on cardiac chambers in mitral regurgitation

The primary hemodynamic effect of MR is borne by the LV; hence, accurate assessment of LV volume and function is crucial in the assessment of severity. An LV end-systolic diameter >40 mm (>22 mm/m2 when indexed to BSA) and/or LV ejection fraction less than 60% justify surgical intervention. 3-D echocardiography provides a better assessment of LV volumes. LV dimensions and volumes should be indexed to body surface area especially in patients with smaller body surface areas to avoid underestimation of the hemodynamic burden. LA volume provides insight into the severity of MR especially in patients in sinus rhythm and who have no history of hypertension. Assessment of RV size and function is crucial in assessing the impact of elevated pulmonary venous pressures due to MR. The RV systolic pressure should be estimated by CW Doppler interrogation of the TR jet. Measurement of the tricuspid annulus and detection of the severity of TR is useful especially in patients undergoing mitral valve surgery so concomitant tricuspid valve repair can be planned (Nishimura et al., 2017).

Other modalities in mitral regurgitation

TEE, especially 3-D TEE places a very important role in the assessment of mitral valve anatomy especially in patients being considered for mitral valve repair. Accurate assessment of segments involved in prolapse or flail as well as accurate measurement of mitral annular size help surgical planning. Exercise echocardiography plays an important role in evaluation. In addition to assessment of functional capacity in patients with asymptomatic severe MR, response of LV function and the magnitude of increase in PA pressure with exercise provide useful diagnostic and prognostic information (Dreyfus et al., 2005; Leung et al., 1997).

Table 6 Echocardiographic grading of severity of mitral regurgitation

	MR severity[a]			
	Mild	*Moderate*		*Severe*
Structural				
MV morphology	**None or mild leaflet abnormality** (e.g., mild thickening, calcifications or prolapse, mild tenting)	Moderate leaflet abnormality or moderate tenting		**Severe valve lesions** (primary: flail leaflet, ruptured papillary muscle, severe retraction, large perforation; secondary: severe tenting, poor leaflet coaptation)
LV and LA size[b]	Usually normal	Normal or mild dilated		Dilated[c]
Qualitative Doppler				
Color flow jet area[d]	**Small, central, narrow, often brief**	Variable		Large central jet (>50% of LA) or eccentric wall-impinging jet of variable size
Flow convergence[e]	**Not visible, transient or small**	Intermediate in size and duration		**Large throughout systole**
CWD jet	Faint/partial/parabolic	Dense but partial or parabolic		Holosystolic/dense/**triangular**
Semiquantitative				
VCW (cm)	<0.3	Intermediate		≥0.7 (>0.8 for biplane)[f]
Pulmonary vein flow[g]	**Systolic dominance** (may be blunted in LV dysfunction or AF)	Normal or systolic blunting[g]		Minimal to no systolic flow/**systolic flow reversal**
Mitral inflow[a]	**A-wave dominant**	Variable		E-wave dominant (>1.2 m/s)
Quantitative[h,i]				
EROA, 2D PISA (cm^2)	<0.20	0.20–0.29	0.30–0.39	≥0.40 (may be lower in secondary MR with elliptical ROA)
RVol (mL)	<30	30–44	45–59[h]	≥60 (may be lower in low flow conditions)
RF (%)	<30	30–39	40–49	≥50

ROA, Regurgitant orifice area.

Bolded qualitative and semiquantitative signs are considered specific for their MR grade.

Most valid in patients >50 years old and is influenced by other causes of elevated LA pressure.

[a]All parameters have limitations, and an integrated approach must be used that weighs the strength of each echocardiographic measurement. All signs and measures should be interpreted in an individualized manner that accounts for body size, sex, and all other patient characteristics.

[b]This pertains mostly to patients with primary MR.

[c]LV and LA can be within the "normal" range for patients with acute severe MR or with chronic severe MR who have small body size, particularly women, or with small LV size preceding the occurrence of MR.

[d]With Nyquist limit 50–70 cm/s.

[e]Small flow convergence is usually <0.3 cm, and large is ≥1 cm at a Nyquist limit of 30–40 cm/s.

[f]For average between apical two- and four-chamber views.

[g]Influenced by many other factors (LV diastolic function, atrial fibrillation, LA pressure).

[h]Discrepancies among EROA, RF, and RVol may arise in the setting of low or high flow states.

[i]Quantitative parameters can help subclassify the moderate regurgitation group.

Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

Effect of other valvular disease in mitral regurgitation

The presence of mixed mitral valve disease (MS and MR) complicates the assessment of either stenosis or regurgitation. In general, the guiding principle remains that moderate stenosis and moderate regurgitation signify severe mixed valve disease. The mitral valve diastolic gradient is a useful parameter because it signifies the combined hemodynamic flow burden of both lesions.

Effect of aortic valve disease

In patients with AS, both primary (concomitant mitral valve disease) and secondary MR (due to LV pressure overload) can occur. TEE should be performed before surgical or transcatheter therapies in patients with suspected primary MR to establish etiology and severity of mitral valve disease. Secondary MR due to LV pressure overload often improves after correction of AS while more than moderate primary MR likely needs to be addressed along with the aortic valve intervention. In the presence of severe MR, a LF-LG AS can occur due to reduced LV forward stroke volume. The presence of more than mild AR complicates the measurement of regurgitant volumes by the Doppler volumetric method. In addition, the combined hemodynamic burden of coexisting MR and AR can lead to LV dilation and dysfunction disproportionate to the severity of each lesion.

Patients with significant MR should be screened for coexisting tricuspid valve disease. In patients with mitral valve prolapse, tricuspid valve prolapse can also occur. Due to RV dilation from severe MR, secondary TR often occurs. They should be carefully assessed prior to mitral valve surgery because uncorrected significant TR causes worse postoperative outcomes.

Tricuspid Valve

Anatomy of Tricuspid Valve

The normal tricuspid valve has an area of 4–6 cm^2 oriented nearly vertical (highest anteriorly) (Lancellotti et al., 2003). The three cusps are labeled anterior (antero-superior or infundibular), posterior (marginal) and septal. The anterior cusp is the largest while the septal is the smallest. The annulus is nonplanar and fibromuscular (fibrous portion corresponding to the septal leaflet). Thus, in cases of annular dilation, the septal leaflet is often unaffected and dilation occurs in the AP plane. The tricuspid subvalvular apparatus consists of three muscles–anterior, posterior, and septal papillary muscles and their true chordae tendinae. The anatomy and chordal distribution of papillary muscles is varied. The anterior papillary muscle is the largest and supplies chordae to the anterior only or the anterior and septal leaflet. The posterior PM is often bifid or trifid and provides chordae to the posterior and septal leaflets. The septal PM is the smallest and provides chordae to the septal and anterior leaflets. In addition, the septal leaflet is also supported by chordae that arise from the ventricular septum.

Echocardiographic Assessment of Tricuspid Valve Structure (Fig. 21)

By 2D TTE, the tricuspid valve is viewed from the parasternal RV inflow view, parasternal short-axis view at aortic valve level, apical four-chamber, and subcostal views. Identification of individual tricuspid valve leaflets in the 2-D views is controversial. 3D analysis as well as pathological examination of valves have demonstrated how leaflet identification by 2D TTE can be erroneous. In the 2-D parasternal long-axis (right ventricular inflow) view, the anterior leaflet is consistently visualized as the more proximal leaflet arising from the anterior free wall. The leaflet furthest from the probe is usually the septal leaflet, though the posterior leaflet can sometimes occupy this position. Identification of septal leaflet is facilitated by probe rotation to the interventricular septum into view. In the parasternal short-axis view at the level of the aortic valve, the posterior leaflet lies adjacent to the RV free wall and either the septal or anterior leaflet is adjacent to the aortic root. In the apical four-chamber view, the septal leaflet is consistently visualized adjacent to the septum, and the anterior leaflet is usually visualized along the RV free wall (occasionally the posterior leaflet is seen). The subcostal view usually displays the anterior and septal leaflets.

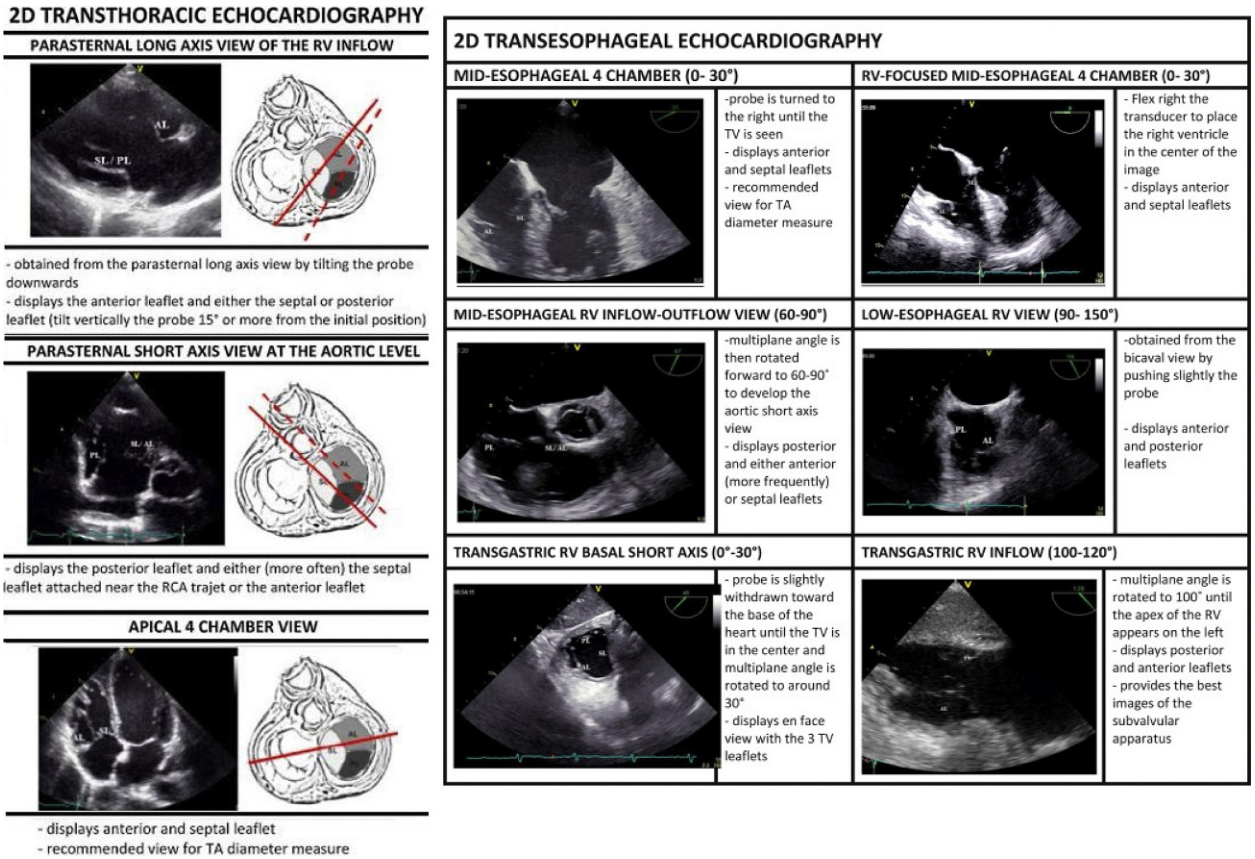

Fig. 21 Tricuspid valve leaflet identification using 2D TTE and 2D TEE. Adapted with permission from Huttin, O et al. (2016). *Archives of Cardiovascular Diseases*, **109** (1), 67–80.

3-D imaging of the tricuspid valve enables both en face visualization of the three leaflets as well as accurate identification of each leaflet in a corresponding 2 D view. The tricuspid valve annulus is slightly apically displaced compared with the mitral valve annulus.

By virtue of its location, the tricuspid valve is anterior and thus far field from the TEE transducer. The tricuspid valve is best visualized in ME 0 degrees (anterior and septal leaflets) and by clockwise rotation from ME level at 30 and 60 degrees; mid-high esophageal level 45 degrees, and clockwise rotation from the transgastric 0 and 90 degree views. TR jet velocity is best measured in a view in which the ultrasound beam and the regurgitant jet are most parallel, often between 30 and 90 degrees in the ME level.

Tricuspid Stenosis

TS is the least common valvular stenosis and is commonly caused by rheumatic heart disease. Other causes include carcinoid syndrome, mechanical obstruction due to tumors and endocarditis, and rarely pacemaker lead induced adhesions (**Fig. 22**, see online **Video 5**).

Assessment of valve structure in tricuspid stenosis

Anatomical assessment of the tricuspid valve is best accomplished through the parasternal RV inflow view as well as an apically focused four-chamber view. The presence of valve thickening and calcification, reduced leaflet opening and RA size can be assessed. An en face view of the valve is best obtained using 3D echo.

Assessment of valve function in tricuspid stenosis

CW Doppler evaluation of the valve provides assessment of trans-tricuspid gradient (Rogers and Bolling, 2009). Unlike the mitral valve, tricuspid flow is affected by respiration, thus Doppler flow measurements are best made at end expiration or should be averaged. As in MS, measurement should be averaged for at least five cardiac cycles in the presence of atrial fibrillation. The mean pressure gradient >5 mmHg has been considered to indicate hemodynamically significant TS. Similar to MS, PHT can be useful. Despite not being well validated, PHT $\geq$ 190 ms corresponds to a valve area $\leq$1 cm^2 (**Table 7**) (Fawzy et al., 1989; Pearlman, 1991; Yousof et al., 1985).

Effect on cardiac chambers in tricuspid stenosis

The right atrium bears the brunt of the hemodynamic consequences of TS. Severely enlarged right atrium and a dilated inferior vena cava are supportive criteria to suggest hemodynamically significant TS.

Stress echocardiography

Owing to its rarity, the role of stress echocardiography in tricuspid stenosis is unknown.

Effect of concomitant valve disease in tricuspid stenosis

The presence of TS should be meticulously investigated in all patients with rheumatic MS. Significant TS reduces RV cardiac output and this could theoretically underestimate severity of MS.

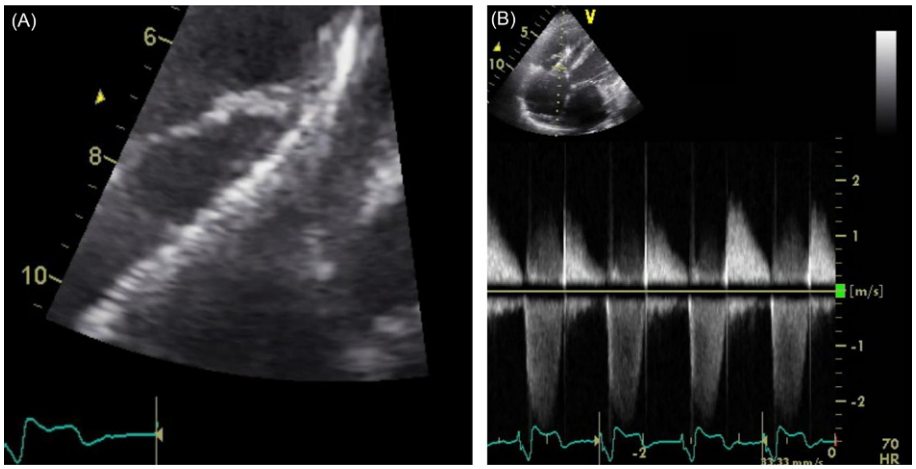

Fig. 22 Severe tricuspid stenosis due to defibrillator lead adhesions. Mean gradient across the valve was 8 mmHg.

Table 7 Echocardiographic findings suggestive of severe tricuspid stenosis

Specific findings	
Mean pressure gradient	>5 mmHg
Inflow time-velocity integral	>60 cm
Pressure halftime	>190 ms
Valve area by continuity equation	<1 cm^2
Supportive findings	
Enlarged right atrium, > moderate	
Dilated inferior vena cava	

Reproduced with permission from Baumgartner et al. (2009) *Journal of the American Society of Echocardiography*, **22** (1), 1–23.

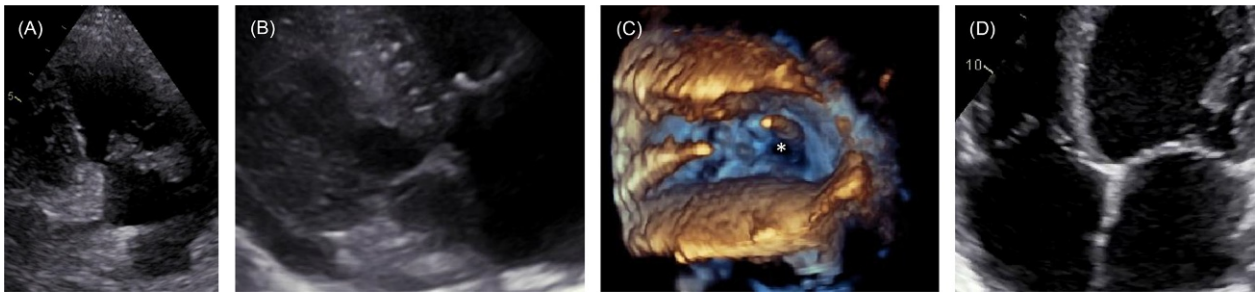

Fig. 23 Tricuspid valve appearance in significant TR due to endocarditis (panel A), carcinoid syndrome (panel B), pacemaker lead with restricted posterior leaflet causing malcoaptation (panel C), and secondary TR resulting from leaflet malcoaptation in dilated cardiomyopathy (panel D, mid systole).

Tricuspid Regurgitation

Though long ignored and considered a "forgotten valve disease," the prognostic importance of both primary and secondary TR is being increasingly recognized (Karp et al., 1989b; Topilsky et al., 2014).

Assessment of valve structure in tricuspid regurgitation

The tricuspid valve is best visualized in the standard and RV focused apical four-chamber view; parasternal right ventricular inflow view; parasternal short-axis view at the aortic level, and subcostal four-chamber views. Mechanism of TR can be divided into primary (rheumatic valve disease, degenerative valve disease, endocarditis, trauma and rarer causes such as congenital heart disease, carcinoid or drug induced valvulopathy) and secondary (RV and RA remodeling). (**Fig. 23**) Leaflets and chordae are thickened and retracted in rheumatic TR and leaflet motion is restricted. Tricuspid valve prolapse and flail can co-exist in patients with MVP. Carcinoid involvement of the tricuspid valve often results in thickening and immobility of the entire length of the leaflet with restricted motion and wide open TR (see online **Videos 6** and **7**). Secondary or functional TR is the result of tricuspid annulus dilatation, with structurally normal leaflets that are tethered and tented. These features are best demonstrated in apical four-chamber view. The normal tricuspid diastolic annulus diameter is 28 ± 5 mm in apical four-chamber view and a diameter >35 mm is considered abnormal.

Assessment of valve function in tricuspid regurgitation

Color flow Doppler

Trivial TR can be seen during echocardiographic exam in 65%–75% of normal individuals and facilitates the measurement of RV systolic pressure. Color flow imaging is the first step in TR diagnosis and provides an estimate of TR severity (Nath et al., 2004). TR can be graded based on the jet area: <5 cm^2 (mild), 5–10 cm^2 (moderate), and >10 cm^2 (severe). As with other regurgitant lesions, color jet area is influenced by hemodynamic (RA pressure, volume) and technical factors (gain) and tends to underestimate the severity of eccentric jets. VC width is a semiquantitative method for TR severity estimation. A VC width ≥ 7 mm is quite sensitive and specific for severe TR (Gonzalez-Vilchez et al., 1994). Similar to MR, 3D assessment provides an accurate assessment of VC area. (Tribouilloy et al., 2000b) Unlike MR however, there is no clear cut off between mild and moderate TR.

Spectral Doppler

EROA and RVol can be assessed by the PISA method but is seldom used in clinical practice. When a clear isovelocity shell is defined, the PISA radius, aliasing velocity and Vmax and VTI of CW TR jet can be used to calculate EROA and RVol. An EROA ≥ 40 mm^2 and

RVol ≥45 mL characterize severe TR. The contrast in RVol between MR and TR despite similar EROA reflects the smaller difference in RV-RA (smaller TR velocity) compared with LV–LA pressures.

The shape and density of CW Doppler TR jet signal provides a means for qualitative assessment of TR severity. The denser the envelope compared to the forward flow, the more severe the TR. In severe TR (especially acute) rapid equalization of RA and RV pressure causes a triangular truncated envelope (V cut off sign) (**Fig. 24**). While RV systolic pressure can be measured in lesser grades of TR, caution should be exercised in patients with wide open TR where the velocity of the TR jet is low due to the small pressure difference between the RA and RV. An E wave >1 m/s by PW Doppler at leaflet tips is an indirect marker of severe TR by providing an estimate of early transtricuspid flow.

The most important PW Doppler indicator of TR severity is systolic flow reversal in the hepatic veins. In the subcostal view, the right superior hepatic vein (1–2 cm proximal to the junction with the inferior vena cava) is interrogated. In severe TR, flow is directed toward the right atrium and reflected back into the hepatic veins; this causes systolic flow reversal and provides a specific marker of severe TR (Egbe et al., 2016). Caution should be exercised in interpreting hepatic vein flows in patients with atrial fibrillation or flutter. Echo parameters for grading severity of TR are depicted in **Table 8**.

Effect on cardiac chambers in tricuspid regurgitation

Severe chronic TR is associated with RA, RV, and IVC dilation which are important supportive signs. In fact, normal right heart volumes and IVC dimension rule out significant chronic TR.

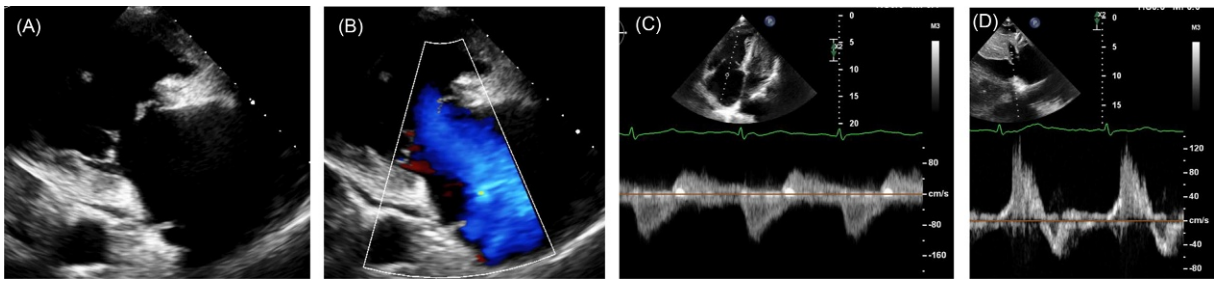

Fig. 24 Echocardiographic evaluation in a patient with severe, wide open TR due to a flail anterior leaflet (panel A). Due to the very high RA pressure, normal RV pressure and large EROA, rapid equalization of pressures between RA and RV occurs and is depicted by laminar color Doppler flow (panel B) and a low velocity CW Doppler TR signal (panel C). Systolic flow reversal is present in the hepatic veins (panel D).

Table 8 Grading the severity of chronic tricuspid regurgitation by echocardiography

Parameters	*Mild*	*Moderate*	*Severe*
Structural			
TV morphology	Normal or mildly abnormal leaflets	Moderately abnormal leaflets	Severe valve lesions (e.g., flail leaflet, severe retraction, large perforation)
RV and RA size	Normal	Mild dilation	Usually dilated
Inferior vena cava diameter	Normal <2 cm	Normal or mildly dilated 2.1–2.5 cm	Dilated >2.5 cm
Qualitative Doppler color			
Flow jet area	Small, narrow, central	Moderate central	central jet or eccentric wall impinging jet of variable size
Flow convergence zone	Not visible—transient or small	Intermediate in size and duration	Large throughout systole
CWD jet	Faint/partial/parabolic	Dense, parabolic, or triangular	Dense, often triangular
Semiquantitative			
Color flow jet area (cm^2)	Not defined	Not defined	>10
VCW	<0.3	0.3–0.69	≥0.7
PISA radius	≤0.5	0.6–0.9	>0.9
Hepatic vein flow	Systolic dominance	Systolic blunting	Systolic flow reversal
Tricuspid inflow	A-wave dominant	Variable	E-wave >1.0 m/s
Quantitative			
EROA	<0.20	0.20–0.39	≥0.40
R Vol	<30	30–44k	≥45

TV, tricuspid valve; *RV*, right ventricle; *RA*, right atrium; *CWD*, continuous wave Doppler; *VCW*, vena contracta width; *PISA*, proximal isovelocity surface area; *EROA*, effective regurgitant orifice area; *R Vol*, regurgitant volume.

Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

Other modalities in tricuspid regurgitation

The role of exercise echocardiography in TR is unclear. 3D imaging allows to accurate identification of leaflets and associated pathology.

Effect of concomitant valve disease in tricuspid regurgitation

Presence of significant primary TR complicates the assessment of RV function from left-sided valve disease (such as MS and MR).

Pulmonic Valve

Anatomy of Pulmonic Valve

Anatomically, the pulmonic valve is located anterior, superior, and to the left of the aortic valve. Normal pulmonic valve has three cusps—right, left, and anterior.

Echocardiographic Assessment of Pulmonic Valve Structure (Fig. 25)

Pulmonic valve is best visualized in the parasternal short-axis view the aortic level (**Fig. 25A**). In the parasternal long-axis view, tilting the probe cranially (sometimes moving up an intercostal space) also provides an excellent view of the pulmonic valve and the pulmonary artery including its bifurcation (**Fig. 25B**). Color Doppler and spectral Doppler interrogation of the valve can be accomplished. In some patients with poor transthoracic echo windows, subcostal views can sometimes be useful. 3-D echocardiography is useful in cases with good quality 2-D imaging and is useful in defining valvular anatomy. By virtue of its anterior location, the pulmonic valve is best seen by TTE. By TEE, the best views to visualize the pulmonic valve are aortic short-axis view with an (between 40 and 60 degrees) and mid-to-high esophageal long-axis view (between 110 and 130 degrees).

Pulmonic Stenosis

Assessment of valve structure in pulmonic stenosis

Valvular PS results from thickening and the fusion of the leaflets and can be either congenital or acquired. Congenital PS is by far the most common cause. The leaflets are often thickened and dysplastic and can be bicuspid. Thickened leaflets with systolic bowing can be seen (**Fig. 26**, see online **Video 8**). Post stenotic pulmonary artery dilatation can sometimes be visualized.

Assessment of valve function in pulmonic stenosis

Increased flow velocity and gradient across the stenotic valve can be assessed by CW Doppler (Chen et al., 2013). Unlike left-sided valve stenosis, measurement of gradients forms the predominant method to assess severity of stenosis. Severe stenosis is defined by a peak jet velocity more than 4 m/s and a corresponding peak gradient >64 mmHg (**Table 9**). Compared to other valve stenosis, peak gradients have been traditionally used to define severity due to good correlation with catheterization-derived gradients (Lima et al., 1983; Silvilairat et al., 2005). Pulmonic valve area can be calculated using the continuity equation:

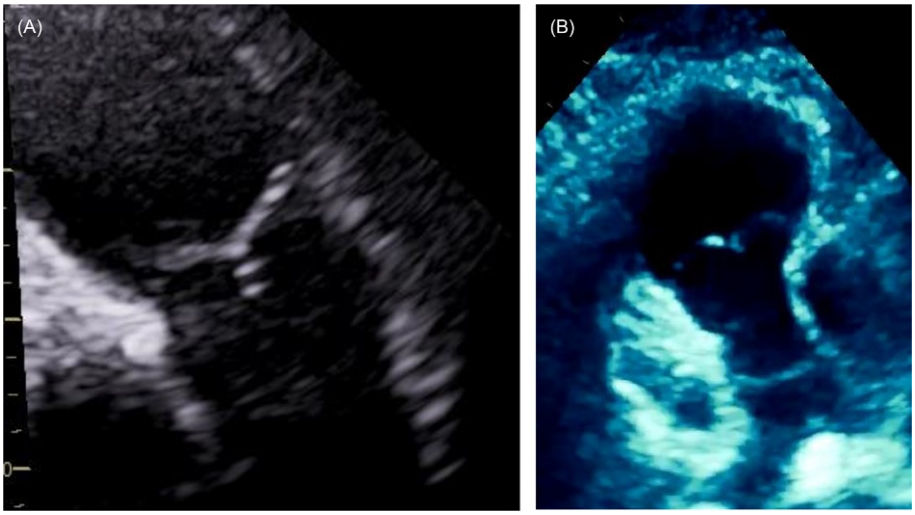

Fig. 25 2D TTE imaging of pulmonic valve. Zoomed-in parasternal short-axis view at aortic level (panel A). A cranial tilt to the probe in the parasternal long-axis position provides a dedicated view of the RVOT, pulmonic valve, and proximal pulmonary artery (panel B).

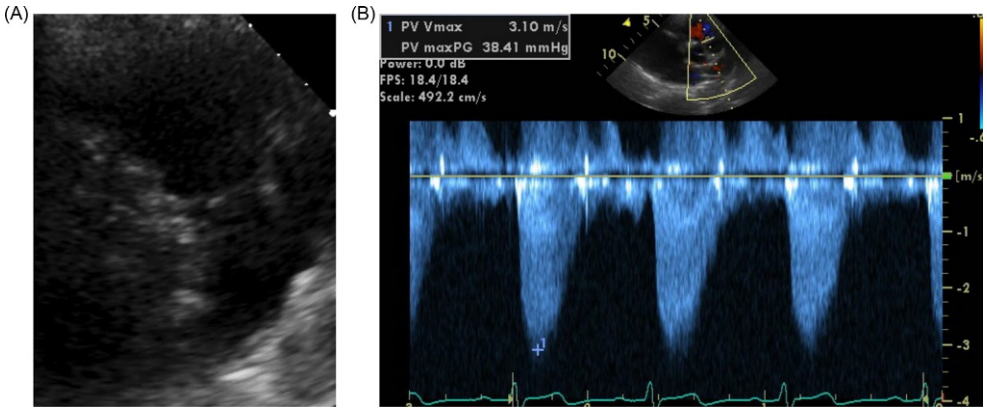

Fig. 26 Echocardiographic evaluation of a patient with pulmonic stenosis. Panel A shows the doming appearance of pulmonic valve (see online **Video 8**); CW Doppler evaluation in panel B quantifies gradient across the stenotic valve (mild stenosis).

Table 9 Echocardiographic grading of pulmonary stenosis

	Mild	*Moderate*	*Severe*
Peak velocity (m/s)	<3	3–4	>4
Peak gradient (mm Hg)	<36	36–64	>64

Reproduced with permission from Baumgartner et al. (2009). *Journal of the American Society of Echocardiography*, **22** (1), 1–23.

$$\mathrm{PVA} = \mathrm{CSA_{RVOT}}^{*}\ \mathrm{VTI_{RVOT}})/\ \mathrm{VTI_{PV}}$$

However, due to the difficulty in imaging the RVOT and the inability to obtain coaxial Doppler interrogation, this is rarely used in clinical practice. Color Doppler mapping and PW Doppler can be used to rule out other levels of obstruction at the sub- or supravalvular level.

Effect on cardiac chambers in pulmonic stenosis

Severe PS causes RV pressure overload and right ventricular hypertrophy. RV free wall thickness >5 mm (measured a few centimeters below the tricuspid annulus in the subcostal view) is used to define increased RV wall thickness. 3-D echocardiography and CMR provide better assessment of RV volume and function than 2D echo.

Other modalities in pulmonic stenosis

As noted earlier, TEE is used in patients with poor transthoracic window or in planning and guiding transcatheter pulmonic valve therapies. When possible, 3D echo provides en face views of the valve. The role of stress echocardiography is limited to functional capacity assessment and largely unstudied.

Effect of concomitant valve disease in pulmonic stenosis

In cases of congenital PS, careful evaluation is required to rule out co-existing abnormalities. When hemodynamically significant PS is present, it complicates the evaluation of other valve structures on the right heart. Similar to other valve diseases, severity of mixed pulmonic stenosis and regurgitation can be tough to assess.

Pulmonic Regurgitation

A majority of normal individuals have mild, functional, PR which are small, central jets by color Doppler.

Assessment of valve anatomy in pulmonic regurgitation

Valve pathology such as a flail leaflet and right heart size and function should be assessed. TTE is the preferred modality.

Assessment of valve function in pulmonic regurgitation

Unlike other valvular regurgitation, the quantification of degree of PR is not supported by robust data (Table 10).

Color Doppler imaging is useful in evaluating the spatial location of the jet (central, eccentric) and assessing its severity (Williams et al., 2002). A ratio of the jet diameter to the width of the RVOT just below the valve provides a semiquantitative measure

of severity (severe PR >65% of the RVOT) (Fig. 27, see online Video 9). Unlike other valves, VC width is often estimated as a ratio of the annular diameter and a cutoff >0.5 suggests severe PR (Williams et al., 2002). A PHT <100 ms is a good indicator of significant PR but is unreliable in the setting of high RV end-diastolic pressures (Renella et al., 2010). Though EROA by PISA can be calculated, this approach has not been well validated. By CW Doppler, signal density may provide a qualitative measurement of the regurgitation while a steep deceleration of the Doppler spectrum or an early termination of diastolic regurgitant flow might be a sign of severe PR. A PR index (ratio of PR time to total diastolic time traced using CW Doppler) <0.77 provides a quantitative

Table 10 Echocardiographic and Doppler parameters useful in grading severity of pulmonic regurgitation

Parameter	*Mild*	*Moderate*	*Serve*
Pulmonic valve	Normal	Normal or abnormal	Abnormal and may not be visible
RV size	Normal	Normal or dilated	Dilated
Jet size, color Doppler	Thin (usually <10 mm in length) with a narrow origin	Intermediate	Broad origin; variable depth of penetration
Ratio of PR jet width/pulmonary annulus			>0.7
Jet density and contour (CW)	Soft	dense	Dense; early termination of diastolic flow
Deceleration time of the PR spectral Doppler signal			Short, <260 ms
Pressure half-time of PR jet			<100 ms
PR index		<0.77	<0.77
Diastolic flow reversal in the main or branch PAs (PW)			Prominent
Pulmonic systolic flow (VTI) compared to systemic flow (LVOT VTI) by PW	Slightly increased	Intermediate	Greatly increased
RF	<20%	20%-40%	>40%

RV, right ventricle; *CW*, continuous wave Doppler; *PW*, pulse wave Doppler; *PR*, pulmonic regurgitation; *LVOT*, left ventricular outflow tract; *EROA*, effective regurgitant orifice area; *RF*, regurgitant fraction.

Reproduced with permission from Zoghbi et al. (2017). *Journal of the American Society of Echocardiography*, **30** (4), 303–371.

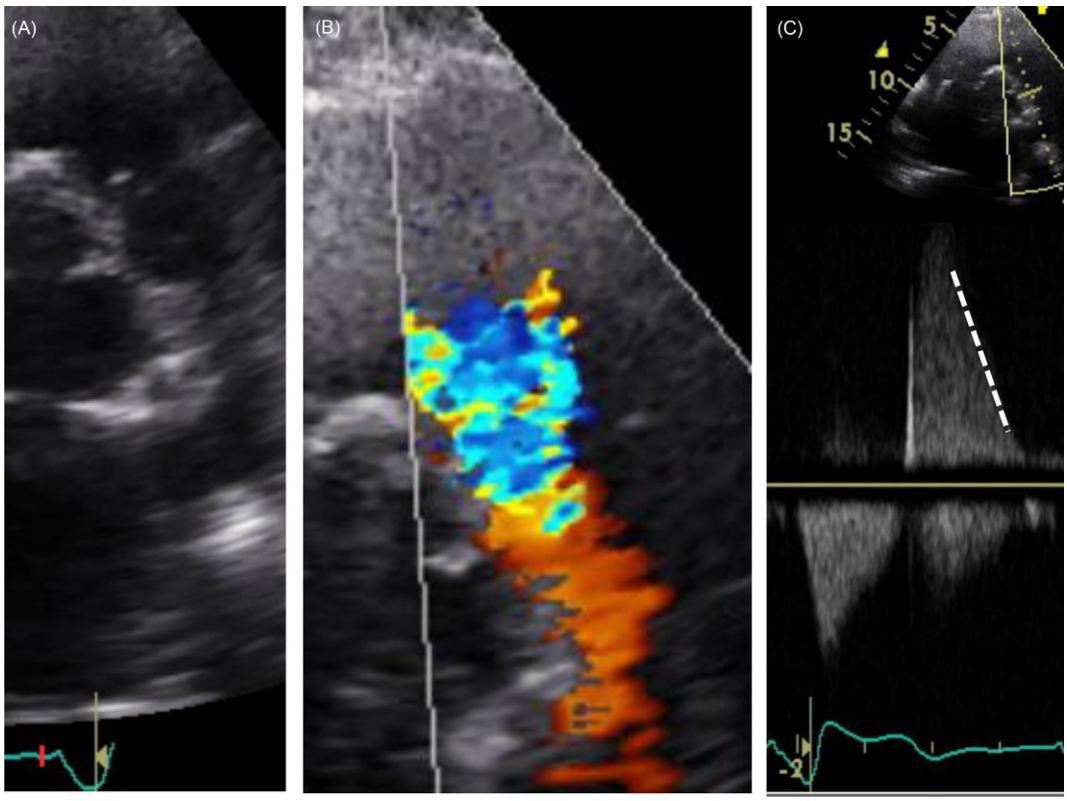

Fig. 27 Echocardiographic evaluation of a patient with severe pulmonic regurgitation due to flail leaflet (panel A, Video 9). Color Doppler shows a significant jet of PR occupying the entire RVOT (panel B). CW Doppler shows dense PR jet with a short pressure half time (*dashed line*, PHT = 60 ms).

measure of this phenomenon and suggests severe PR (Silversides et al., 2003). Analogous to AR, holodiastolic flow reversal in the branch pulmonary arteries is a useful parameter that suggests severe PR.

Effect on cardiac chambers in pulmonic regurgitation

The dominant hemodynamic effect of PR is on the RV. While commonly ignored in the past, RV size and function provide valuable prognostic information and guide decision making. The presence of a dilated RV is not specific for severe PR especially in patients without concomitant pulmonary hypertension or in complex congenital heart disease. Serial follow-up studies are often more valuable in assessing worsening hemodynamic burden of PR.

Other modalities in pulmonic regurgitation

3D echo (and CMR) are superior in the assessment of RV size and function which play an important role in timing of surgical intervention.

Effect of concomitant valve disease in pulmonic regurgitation

Presence of significant PR complicates assessment of the effect of other valve lesions on RV size and function.

Conclusions

This article provides an overview of the importance of echocardiography in the evaluation of valve structure and function. Despite advances in 3D technology and rapid growth of alternative modalities of imaging such as CMR, 2D, and Doppler echocardiography provide a rapid, easily available, and cost effective method to evaluate and manage valve disease.

Economic Aspects of Heart Failure

The syndrome of heart failure (HF) is one of the most prevalent cardiovascular conditions worldwide, with the number of cases rising as the population progressively ages in many parts of the globe (Khatibzadeh et al., 2013). Overall, it is estimated that 26 million people across the globe are affected at any given time (Ambrosy et al., 2014). In the United States alone, HF is estimated to affect 5.7 million people aged 20 years or more with an incidence approaching 10 cases per 1000 per annum in those aged 65 years or more (Mozaffarian et al., 2016). From a health-care service perspective, in North America and Europe combined, HF contributes to >1 million hospitalizations per annum (Ambrosy et al., 2014). Reports from Asia (Shimokawa et al., 2015), Australia (Chan et al., 2016), and even Africa (Keates et al., 2017) indicate an equivalent or at least emerging (with respect to sub-Saharan Africa) burden of disease associated with the syndrome. Consequently, HF-related health-care expenditure (direct costs) accounts for ~2% of the total health-care budget in the US, with equivalent or even higher proportional expenditure in many other high-income countries around the world (Cook et al., 2014).

Iterative guidelines (Ponikowski et al., 2016) for the gold-standard diagnosis and treatment of acute and chronic forms of HF reflect an expanding armory of therapeutic options with the potential to substantially increase HF-related health-care costs, from the introduction of new biomarkers to detect the syndrome at an earlier clinical stage, to device-based therapies to treat more advanced clinical cases. Isolated HF is rare (<10% of cases). In the majority of the cases, beyond the common antecedents of hypertension and coronary artery disease, HF often occurs in the setting of multimorbidity; concurrent management of these comorbidities adding to the plethora of health-care costs already associated with the syndrome (Stewart et al., 2016). As such, HF commonly copresents with other high-cost conditions such as respiratory disease, renal dysfunction, diabetes, and atrial fibrillation (AF) that both complicate its management and prolong hospitalization (Wiley et al., 2017).

Key Components of Heart Failure Costs

Given the diversity of health-care systems (with different cost-dynamics imposed by a variety of funding models) around the world, there is no definitive source of health-care costs associated with HF. Therefore, in this chapter, health-care expenditure relating to HF is expressed in US dollars and the lowest cost price is listed (unless specified otherwise). Specific costs were obtained from the Healthcare Bluebook (2017).

Direct Costs

The direct costs of HF include those activities specifically arising from a patient's diagnosis, medications, device-based and surgical treatment, HF management, and, at the end-of-life, palliative care. A primary hospital admission for HF (where it is listed as the principal diagnosis) is usually the most expensive direct cost associated with the syndrome, with initial high-level care, investigations of cardiac function (such as transthoracic echo and brain-type natriuretic peptide (NP) levels) and high cost pharmacological (e.g., IV inotropic support) and device-based therapies (e.g., insertion of a cardiac pacemaker with the capacity for internal defibrillation) now becoming increasingly common. Chronic pharmacological treatment, requiring ongoing specialist HF surveillance in the community, also contributes to the direct cost of managing the syndrome. It is estimated that costs directly associated with HF in the US will have increased from $21 billion in 2012 to $53 billion by 2030 (Heidenreich et al., 2013). However, as already noted, estimates of total HF-related expenditure from a whole health service and societal perspective vary widely from country to country, with US-based estimates, at least from an absolute cost perspective, being substantially higher than many other countries (Nicholson et al., 2016).

Initial screening and diagnosis

Due to the relatively low cost (>$550), ease, lack of contraindications, and critical details obtained, echocardiography (typically using the least expensive option of a transthoracic approach as opposed to the more expensive transesophageal approach (>$594)) is generally the preferred modality for diagnosing underlying cardiomyopathy and associated cardiac dysfunction, whether it be in the form of HF with reduced (HFrEF) or preserved ejection fraction (HFpEF). Accordingly, echocardiography represents the cornerstone for the diagnosis (and ongoing management) of HF (Ponikowski et al., 2016; Yancy et al., 2013).

As per contemporary expert guidelines (Ponikowski et al., 2016; Yancy et al., 2013), initial HF investigations may involve determining the plasma concentration of NPs (>$89), especially in the cases where echocardiography is not immediately available. While relatively inexpensive, NP testing cannot be used to definitively establish a diagnosis of HF, and is only recommended to rule out HF. This is also the case for a 12-lead electrocardiogram (ECG) (>$41), which cannot be used to definitively diagnose HF due to the low specificity of the test. However, the 12-lead ECG is relatively inexpensive, often available in situations in which an echocardiogram is not, and can be used to determine which patients require echocardiography. Regardless of the combination of diagnostic tests applied, they require trained technicians to perform the test(s), and expert cardiology review to diagnose the presence of HF and, if confirmed, the extent, nature, and underlying cause of associated cardiac dysfunction, further adding to the costs involved. A range of common diagnostic tests (most notably a chest x-ray (>$68)) is also typically undertaken during the diagnostic phase of management. If, after echocardiography, the diagnosis or causality of HF requires further elucidation, additional imaging options of varied costs include cardiac magnetic resonance (>$1,154), positron emission tomography (>$2,809), coronary angiogram (>$8,911), and coronary computed tomographic angiography (>$918).

Pharmacological treatment

Initial pharmacological treatment of the most common form of HF, HFrEF secondary to ischemic cardiomyopathy, generally entails a combination of angiotensin converting enzyme inhibitors (>$9 per 30 day supply) and beta-blockers (>$7 per 30 day supply), with mineralocorticoid receptor antagonists (>$9 per 30 day supply), ivabradine (>$209 per 30 day supply), digoxin (>$21 per 30 day supply), hydralazine and isosorbide dinitrate (>$97 per 30 day supply), and/or loop-diuretics (>$6 per 30 day supply) considered on an individual basis. The replacement of angiotensin converting enzyme inhibitors with angiotensin receptor neprilysin inhibitors (>$215 per 30 day supply) may also be indicated (Ponikowski et al., 2016). The total pharmacological treatment cost per patient per annum is estimated to be between $750 and $1626 (Voigt et al., 2014). While the evidence-based management of HFpEF (an increasingly more common form of HF within the aging populations of high-income countries) is less clear, the cost (per annum) of treating such patients is likely to be equivalent given the typical presentation with hypertension and/or AF. For example, in combination with typical signs and symptoms of congestion associated with the syndrome, active treatment is mandated (Ponikowski et al., 2016; Yancy et al., 2013).

Device-based therapies

There are currently two nonsurgical device based therapies routinely recommended for the treatment of HFrEF: implantable cardioverter-defibrillators (ICDs) (>$64,560) and cardiac resynchronization therapy (CRT) (Ponikowski et al., 2016; Yancy et al., 2013). While US costing for CRT is not made widely available, a Belgian assessment has placed the price at >$23,000 for the device alone (Van Brabandt et al., 2010). Costs for these devices are extremely high, and both require ongoing monitoring and maintenance by cardiologists and highly trained technicians once implanted, with the prospect of replacement in younger individuals with prolonged survival. There is a broad variability in both device cost, and the cost of remotely monitoring devices within and between countries. Analysis of cardiac implantable device usage within the Asia-Pacific region revealed that the cost of remote monitoring can vary from as low as an additional 5% of the device cost (in Japan), to as high as an additional 20% in expenditure (in China, Hong Kong, and South East Asia) (Lau and Zhang, 2013).

Surgical procedures

Many surgical procedures can be used to treat HF depending on the underlying causes and consequences of the syndrome. Current guidelines recommend the application of coronary artery bypass grafting (CABG) (>$51,072), percutaneous coronary intervention

(PCI) (>$21,694), surgical aortic valve replacement (>$60,609), transcatheter aortic valve implantation (TAVI) (>$78,415), and mitral valve surgery (>$62,364) on a case-by-case basis (Ponikowski et al., 2016; Yancy et al., 2013). More rarely, heart transplantation may be considered (>$196,774). The insertion of an intraaortic balloon pump (IABP) (>$181,340) or a left ventricular assist device (LVAD) (>$187,535) is most commonly used as bridging strategies until patients can undergo a more permanent procedure. However, LVADs are increasingly being used as a permanent solution for patients not eligible for heart transplantation (Kilic, 2015). It is worthwhile to note that these costs represent only the surgical procedure, and not the cost of hospitalization pre and postprocedure monitoring, and specialist management and treatment in the longer-term. These costs are substantive.

HF-specific management: Hospital and community-based care

As noted, hospitalization (particularly in the form of recurrent, unplanned admissions denoting ongoing clinical instability in a subset of high cost patients) represents a substantive component of the overall economic burden of HF, as demonstrated in **Fig. 1** using data collected from a recently completed, large, multicenter trial of HF management in Australia where the primary outcome was health-care costs during 12 months follow-up (Scuffham et al., 2017). Typically, those admitted with acute HF require management (noting a substantive burden imposed by those who receive Emergency Department management without subsequent admission) in high-cost facilities. Moreover, the short- and longer-term rate of recurrent hospitalization is extremely high; in the United States, as in many parts of the world, all-cause readmission is as high as 20%–25% within 30-days of an HF admission (Jencks et al., 2009; Wiley et al., 2017). A recent estimate has placed the median hospital cost for HF hospitalization in the US at $23,051 (Bress et al., 2016) and hospitalization costs are projected to rise 154% between 2012 and 2030 (Heidenreich et al., 2013). While the majority of people admitted to hospital for HF for the first time are discharged home, 21% are discharged to a long-term care facility/residential care. Significantly, the proportion of those requiring such long-term care increases with age and each subsequent HF-related admission, denoting the progressive and debilitating nature of the syndrome in affected individuals (Chan et al., 2016).

Community-based care (often specialist in nature) is critical to the ongoing management of HF, particularly for those recently admitted with acute HF and/or treated with specialist pharmacotherapy requiring routine monitoring (e.g., electrolyte levels and renal function) or devices (e.g., routine pacemaker and ICD checks to ensure optimal function). This component of health-care includes primary care physician visits (>$176 per 15 min visit), medical specialist (>$505 per visit), allied health outpatient appointments (>$195 per visit), and ongoing surveillance costs (Voigt et al., 2014). For high-risk hospitalized patients, post-discharge multidisciplinary management (typically HF nurse-led) is also recommended to reduce the risk of rehospitalization and to prolong survival. The cost of applying these multifaceted programs will vary according to the level of specialist outpatient, community/home visits, remote monitoring (from structured telephone support and remote monitoring techniques), and referrals to other services (from pharmacological reviews to exercise programs) applied. In the recently completed WHICH? II Trial undertaken in the subsidized health-care system of Australia, the median cost of applying an intensive form of HF management was $285 per month per patient (Scuffham et al., 2017).

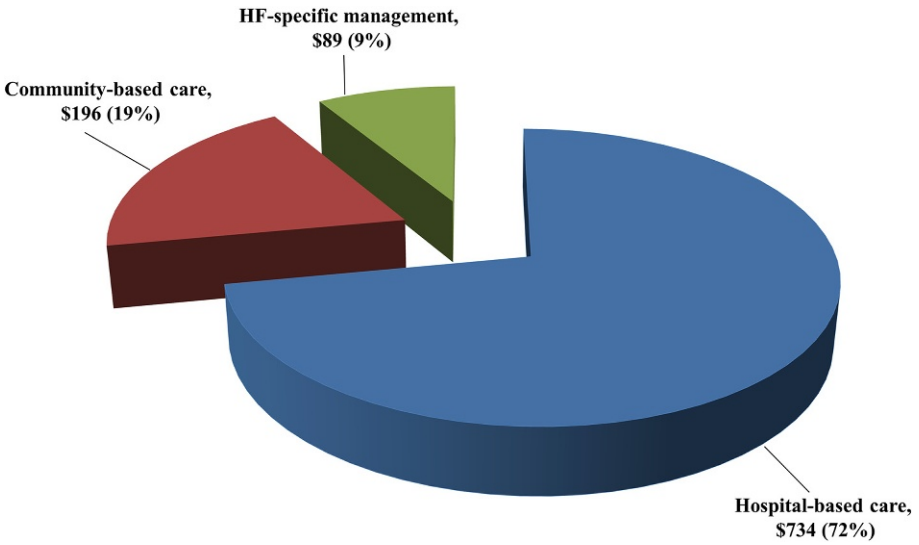

Fig. 1 Breakdown of HF costs (per person, per month). Data obtained from Scuffham, P. A., Ball, J., Horowitz, J. D., et al. (2017). Standard vs. intensified management of heart failure to reduce healthcare costs: results of a multicentre, randomized controlled trial. *European Heart Journal*. https://doi.org/10.1093/eurheartj/ehx259 [Epub ahead of print].

Palliative care

Within an aging HF patient population in whom survival rates have improved (Mamas et al., 2017), the need for palliative care is becoming increasingly more common. It is suggested that patients with advanced and intractable forms of HF now represent the second most common reason for hospice admission (after cancer patients) (Heidenreich et al., 2013). However, compared to patients with the common forms of malignancy, their end-of-life trajectory is quite unclear and unpredictable, broadly differing between patients. Perhaps due to the difficulty in predicting the life expectancy of patients with HF, they are more likely to be either discharged alive or to remain in hospice for more than 6 months (Heidenreich et al., 2013). Accordingly, costs accumulated by HF patients during the last 6 months of life are high, and continue to rise (Unroe et al., 2011), with recent estimates placing this figure at an average of $23,606 (Nicholson et al., 2016).

Indirect Costs

The indirect costs associated with HF (particularly in the setting of multimorbidity) are often difficult to define. However, they can be broken down into two broad categories: microeconomic versus macroeconomic costs (as detailed below). As described by Stewart and colleagues (2002), it is critical to consider the indirect cost of HF through its contribution to hospital admissions where the syndrome is listed as a secondary diagnosis. Reflective of the complicated nature of HF (as a syndrome that complicates more clearly defined clinical conditions), the ratio of primary versus secondary HF admissions is often 1:1.5–2.0. Consequently, when considered in economic analyses, these admissions almost double estimated HF-related expenditure (Chan et al., 2016).

Microeconomic costs

Microeconomic costs can be defined as out-of-pocket expenses associated with HF treatment and management. These costs typically infer negative, downstream economic consequences such as the loss of monetary savings or the sale of a house to cover health-care expenses (Braunwald and Bonow, 2012). Microeconomic costs may vary depending on the health-care system and are influenced by the age and broader socioeconomic profile of the affected individual, the cost and comprehensiveness of health insurance, transport to health-care appointments, pharmacological costs, and potential loss of employment/income due to illness.

Macroeconomic costs

Macroeconomic costs relate to the loss of worker productivity and economic growth when individuals with HF and their carers reduce work hours or drop out of the workforce entirely as a result of illness (Braunwald and Bonow, 2012). Macroeconomic costs are difficult to quantify. However, whole population data from Sweden suggest that the wider societal impact of HF is larger than the most common forms of cancer for both men and women in respect to total life-years and quality-adjusted life-years lost (Stewart et al., 2010).

The Cost Dynamics of HF: A Case Study

As outlined above, management and treatment of HF can be associated with significant direct and indirect costs. **Fig. 2** details the sequence of events relating to a patient's diagnosis of HF and the associated costs. The key economic aspects of their case are outlined below.

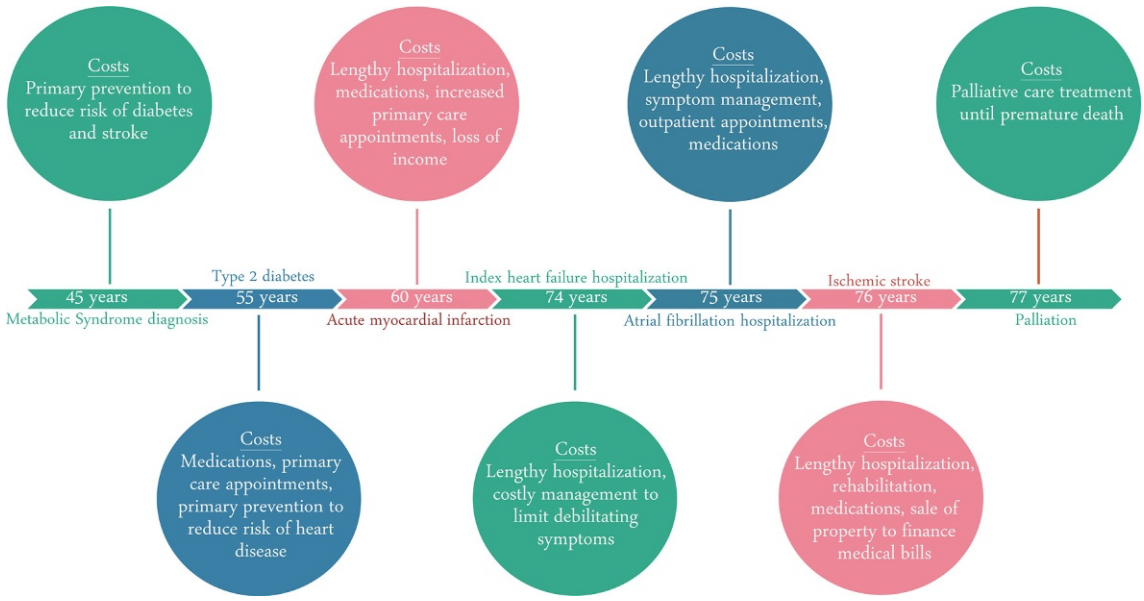

Fig. 2 Sequence of events relating to the patient's diagnosis of heart failure.

Primary and Secondary Care

The patient had regular visits with his primary care personnel, who were essential for early detection of disease and management of symptoms to prevent (or at least delay) subsequent HF-related morbidity and mortality that would be costly for an individual to societal perspective. His primary care personnel were involved in both pharmacological and nonpharmacological management of his symptoms. Secondary care commenced when the patient's primary care physician referred him immediately for an acute hospital admission with specialist cardiology treatment and management.

Treatment and Management

The patient's diagnosis of HFrEF (characterized by progressive cardiac dysfunction and multimorbidity—including type 2 diabetes and renal disease) required costly inpatient and outpatient management. Due to the typical natural history of the syndrome, this management was aimed at providing clinical stability, rather than a cure, in order to reduce costly hospitalizations and prolong his life (Ponikowski et al., 2016).

Palliative Care

As the patient's HF symptoms worsened, his ability to perform daily self-care activities declined markedly and, despite the support of his wife, he was placed into a nursing home for long-term, high-level care. His subsequent advanced-stage HF was treated with palliative management until he died at the age of 77 years, 3 years following his de novo acute HF presentation.

The Impact of HF and Multimorbidity

As shown in Fig. 2, those affected by HF have health issues that are both complicated and not confined to the syndrome. As is often the case in HF (Stewart et al., 2016), in the presented case study, HF contributed to subsequent hospitalizations for the management of chronic AF and an ischemic stroke, these conditions contributed to his clinical instability and decline. The 12 most common comorbidities in HF are hypertension, coronary artery disease, anemia, arrhythmias (predominantly AF), cognitive dysfunction, depression, diabetes, musculoskeletal disorders, renal dysfunction, respiratory disease, sleep disorders, and thyroid disease (Stewart et al., 2016). The close link between multimorbidity and incremental health-care costs in patients affected by HF is now well established (Glynn et al., 2011; Picco et al., 2016) with a recent study finding that multimorbid HF patients have an increased risk of 30-day all cause readmission upon discharge compared to those with lone HF (Wiley et al., 2017). This economic effect is well demonstrated in the recently reported WHICH? II Trial of HF management (Scuffham et al., 2017). Figs. 3 and 4 show a breakdown of length of stay and hospitalization costs accumulated over a 12-month follow-up of the WHICH? II Trial cohort. These data demonstrate that of $7,489,876 total health-care expenditure due to hospitalization during 12-month follow-up, only $1,944,461 (26%) was HF-related, meaning the residual portion of expenditure ($5,545,415 or 74% was attributable to HF-related multimorbidity).

The annual global economic burden of heart failure. *International Journal of Cardiology* 3, 368–376. The World Bank (2017). GNI per capita, Atlas method (current US$). http://data.worldbank.org/indicator/NY.GNP.PCAP.CD (accessed 1 May 2017); Population Reference Bureau. (2012). 2012 world population data sheet. [online] Washington: PRB, pp. 6–9. http://www.prb.org/Publications/Datasheets/2012/world-population-data-sheet.aspx (accessed 0505.17).

Global Economic Burden of Heart Failure

As noted previously, it is now estimated that HF affects more than 26 million people globally, with figures on the rise as many populations progressively age (Ambrosy et al., 2014; Bui et al., 2011). Increasing HF prevalence places a varied burden on the global economy (as shown in Fig. 5). However, the economics of HF is difficult to calculate and compare between countries due to the complexity of the syndrome, variability in definitions, and the differing characteristics of health-care and insurance systems

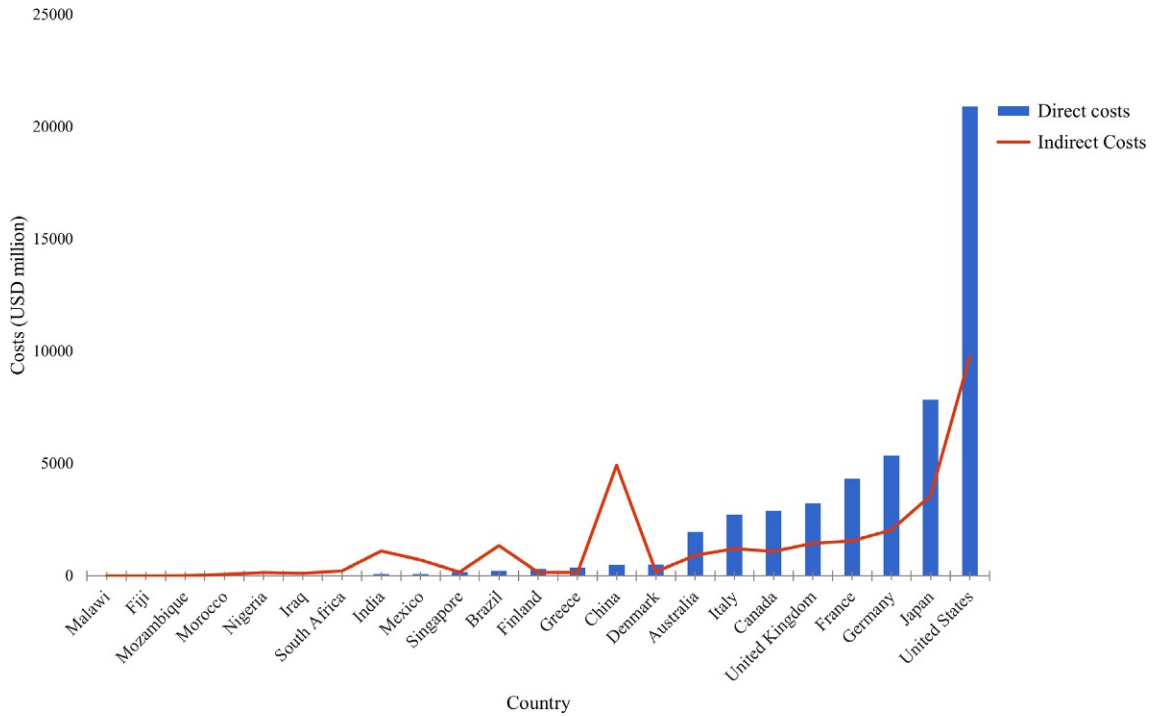

Fig. 6 Direct and indirect HF costs per country. Data obtained from Cook, C., Cole, G., Asaria, P., Jabbour, R. & Francis, D. P. (2014). The annual global economic burden of heart failure. *International Journal of Cardiology* 3, 368–376.

(Voigt et al., 2014). Despite these caveats, Cook and colleagues (2014) estimated that in 2012, the annual economic cost of HF was $108 billion globally (comprising $65 direct and $43 billion indirect expenditure). The cost dynamics of HF-related expenditure varied greatly between high-income and low- and middle-income countries (LMICs), the former spending a larger proportion of direct costs, while the pattern was reversed in LMICs (Fig. 6).

A Low- and Middle-Income Country Perspective

When compared to high-income countries, the cost of HF in LMICs differs for a variety of reasons. For example, the average age of HF patients in sub-Saharan Africa is markedly lower than many other regions of the world. This places a burden on the economy through loss of income and productivity, and through needing to care for those who may normally be caregivers themselves. For example, direct HF costs are substantially lower in Nigeria (approximately 50% of the total cost of HF) as compared to high-income countries (Ogah et al., 2014). The mean cost of care per HF patient per annum in Nigeria is approximately $2000: while this is far lower than the approximate cost of $20,000 in the US, this represents a far higher proportion of the gross national income (GNI) per capita, at 72% and 36%, respectively (Voigt et al., 2014; The World Bank, 2017). However, the approximate mean cost of care per annum (for patients with HFrEF) in Turkey was $608, representing only 6% of their per capita GNI (Aras et al., 2016). In China, the per annum HF cost was $4204, representing 53% of their per capita GNI (Huang et al., 2017), demonstrating a large variation in the relative economic burden of HF among LMICs.

Cost Pressures in Heart Failure

As the prevalence of HF is predicted to increase in the foreseeable future, so too will the economic burden. An aging population will contribute to a greater proportion of men and women at higher risk of HF (Cook et al., 2014). The US-based data has indicated that HF prevalence will increase by 46% during the period 2012–2030 (Heidenreich et al., 2013). Concurrently, improved health-care and expanded treatment options are contributing to increased longevity following an initial diagnosis of HF, which in turn increases its economic impact. As highlighted previously, while this is occurring globally, there may be a greater and more adverse economic impact of HF in LMICs. Additionally, more people are being diagnosed with HF than ever before. This reflects both increased awareness and an expansion of the syndrome definition, recent European guidelines defining HFpEF and HF with midrange ejection fraction (HFmrEF) in addition to the more traditionally recognized HFrEF (Ponikowski et al., 2016). As surveillance efforts and definitions have broadened, so too have HF risk factors. Globally, there are currently historically high levels of obesity and

physical inactivity. As noted, there is also an alarming trend in the growing burden of multimorbidity, contributing to increased rates of hospitalization, and more complicated treatment patterns (Stewart et al., 2016).

Cost Evaluation in Heart Failure

It is worth noting that much of the early (and cheapest) treatment modalities in HF were (and still remain) untested from a robust scientific and subsequent health economic perspective, loop-diuretics being the most obvious example. However, with an evolving armory of more expensive pharmacological agents and devices, in particular, there is increasing need to evaluate the cost of different diagnostic and treatment modalities in HF, from an individual to societal perspective. Either in the form of cost-effectiveness estimates (e.g., quality adjusted life-years gains per health-care expense) or cost–benefit analyses (e.g., potential cost-savings relative to an old treatment), most new therapeutic modalities in HF are formally assessed before being subject to subsidized funding by governments or health insurance agencies. Rarely is one therapeutic option [one recent example being the superiority of home-based versus clinic-based management of HF in Australia (Maru et al., 2015)] proven to be "dominant" over another in terms of both health benefits and cost-savings. For example, in the UK, the National Institute for Health and Care Excellence established a cost-effective threshold (relative to optimal pharmacotherapy) of up to £30,000 per quality adjusted life-year gained to support a recommendation of implanting a device with cardiac resynchronization and internal defibrillator capacities in a subset of patients with HF (National Institute for Health and Excellence, 2014). Increasingly, in the setting of limited financial resources and an expanding patient population with HF, thresholds for subsidizing therapeutic strategies (when individuals cannot pay directly) will undoubtedly become more stringent.

Reducing the Economic Burden of Heart Failure

Having provided an overview of the nature of the economic burden of HF, how then do we reduce its adverse impact? Around half of all US HF-related hospitalizations (the greatest component of HF expenditure) are potentially preventable (Braustein et al., 2003). Recent Australian data placed the median cost per month of hospital-based care for patients with HF at $734, compared to only $196 per patient per month for community-based care, and $89 per patient per month for HF-specific management (Scuffham et al., 2017). Any strategy that reduces hospital stay by even a modest amount, therefore, is likely to have a favorable economic profile.

Accordingly, reducing readmission rates in those patients with clinical instability could lead to a substantial lowering of HF-related expenditure. While some factors leading to high readmission rates are largely beyond the scope of the direct health-care system (such as severity of illness and socioeconomic factors) potentially modifiable factors include:

- *Increased communication between health-care providers*: As highlighted previously, multimorbidity and HF is common, being the primary cause of hospitalization for those with HFpEF (Stewart et al., 2016). As such, it is necessary for HF patients to see a variety of specialists in addition to their primary care physician. Increasing communication levels between these practitioners may lead to a clearer understanding of the patient's health-care plan to all involved (practitioners, patient, and other carers), which may, in turn, lead to greater adherence and reduced likelihood of rehospitalization. This is especially apparent in patients in long-term care facilities, who often have a large amount of personnel, with a broad range of skill- and knowledge-levels involved in their care (Heckman et al., 2016).
- *Providing clear and high-quality discharge instructions to patients*: Along the same lines, ensuring that this information is then provided to patients in a manner which is clear, easily understood, and remembered, is important. For all but the sickest HF patients, the majority of time is spent at home, and if the patient does not understand or cannot remember their health-care instructions, they are at increased risk of not following them.
- *Implementing early outpatient appointments*: Beginning HF-related outpatient appointments soon after discharge may lead to a reduction in hospital readmission rates (Soundarraj et al., 2017). A recent study revealed that follow-up appointments were only organized for 50% of patients discharged home post HF-related hospitalization, and that appointments were less likely to have been organized for patients aged over 65 years, and for patients with HFpEF (vs HFrEF) (Goyal et al., 2016).
- *Reducing initial hospital stay*: A fine balance needs to be found between ensuring a hospitalization stay is not unnecessarily long and ensuring that a patient is not discharged prematurely, increasing the likelihood of recurrent instability and readmission or death.
- *Specialist management*: Recent American research has suggested that intensive care unit (ICU) admission, while significantly more expensive than general medicine stays, was not significantly associated with differences in 30-day mortality for HF. As such, being more selective with those patients admitted to ICU may lead to a reduction in hospitalization costs without compromising the care of the patient (Valley et al., 2017).

Specialist HF management programs, particularly in the form of outreach models of care have the potential to markedly reduce rehospitalization and prolong survival (Maru et al., 2015), although implementing more intensive management may not necessarily deliver cost-savings (Scuffham et al., 2017).

The cost of new device-based therapies and pharmaceutical treatments for HF continue to exert an increasing economic burden. As previously discussed, while necessary, both of these treatment techniques can be quite expensive. There is a variety of potential cost saving mechanisms associated with HF-related devices. Improving the battery life of devices has been highlighted as of potential benefit—recent studies have shown that longer device battery life could save 60.4 million Swedish Krona (USD6.83 million) over a 6-year period in Sweden, and reduced device-related costs by 29%–34% over 15 years in Europe (Gadler et al., 2016; Boriani et al., 2013). Additionally, reducing the variability of cardiac device costs between and within countries may reduce costs. The price of cardiac devices is often established via confidential agreements between hospitals and/or insurance companies, and device companies—a method which may work to inflate prices. Similarly, there is broad variability in pharmaceutical pricing.

Summary

The economic footprint of HF, from the individual to societal level in nearly all part of the globe is substantial. In the US alone it is estimated that costs directly associated with the management of HF will rise from a current level of >$21 billion per annum to >$53 billion per annum by 2030 (Heidenreich et al., 2013). Indirect costs attributable to HF are likely to double these figures. Hospital costs and an increasing armory of expensive pharmacological and device-based therapies in an increasing number of older patients with complex clinical needs will be instrumental in driving the future cost burden imposed by the syndrome. Beyond preventing progression to HF, key targets to limit its economic impact include reducing the number of preventable hospital admissions (often recurrent in the same individual) and reducing the inflationary costs of new therapeutic strategies.

Introduction

The understanding and application of the electrocardiogram (ECG) has evolved immensely since 1912, when Einthoven first described his equilateral triangle to the Chelsea Clinical Society in London, and coined the term "EKG" in his landmark paper published in the Lancet (Barold, 2003). Advancements in the ECG continued in the early 1900s when Emanuel Goldberger created the augmented leads, which led to the modern-day 12-lead ECG (Burch, 1978). The ability to monitor patients remotely is largely attributed to the work of Norman Holter, who developed the first "Holter Monitor" in the 1940s. It allowed for a single ECG to be recorded for several hours, giving physicians the ability to monitor their patients ECG outside of the hospital setting (Roberts and Silver, 1983; Holter, 1961; Holter and Generelli, 1949). The original Holter monitor was a 75-pound backpack that utilized analog electronics and large batteries (Holter, 1961). Although it lacked practicality in its design, the Holter monitor revolutionized our ability to record and analyze ambulatory ECG data of patients not in hospital (Roberts and Silver, 1983) (**Fig. 1**).

Since the original Holter monitor, substantial technological advancements provide the ability to monitor patients continuously from days to years, and as a result, our diagnostic capabilities have dramatically improved. Clinical trials examining the role of implantable cardiac monitors (ICMs) have validated their role in patients with unexplained syncope. Furthermore, they have shown increased utility in patients with vasovagal syncope and postmyocardial infarction arrhythmia detection. The era of smartphones has brought with it the potential for cardiac-monitoring technology integrated into our daily activities. This can offer real-time feedback to patients and couple ECG monitoring to other physiological parameters (blood pressure, oxygen saturation, etc.).

This article will focus on summarizing the different modalities of electrocardiographic monitoring used in the context of common cardiac scenarios.

Clinical Scenarios Necessitating Cardiac Monitoring

Cardiac monitoring aids clinicians in obtaining a rhythm profile and helps to establish a symptom–rhythm correlation. Various monitoring modalities are utilized in patients with palpitations, syncope, postmyocardial infarction arrhythmia detection, atrial fibrillation management, and detection of atrial fibrillation in patients with cryptogenic stroke. With the continued advances in monitoring technology, the scope of clinical application continues to expand.

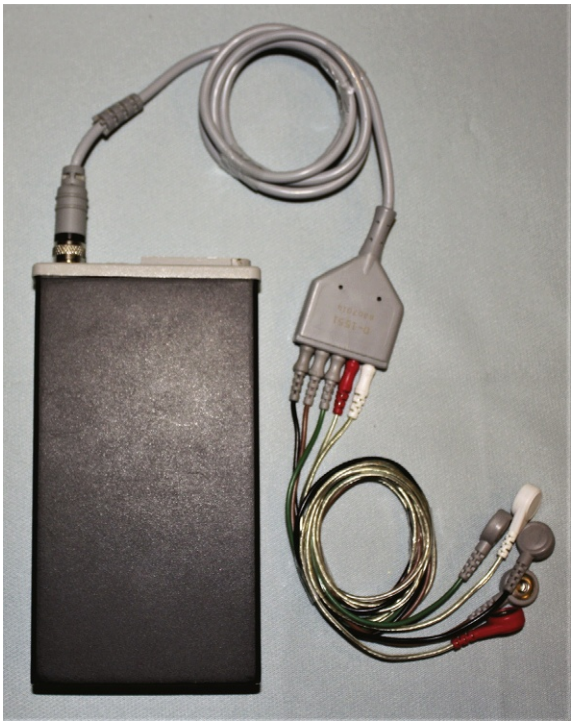

Fig. 1 Holter monitor device. The patient wears the device using a shoulder strap or belt loop, attached to 3–5 skin electrodes for continuous monitoring. An event button (not shown) at the *top* of the housing of the device is pressed in the event of symptoms to mark the recording.

Palpitations

Palpitations represent one of the most commonly encountered symptoms by general practitioners and emergency department (ED) physicians, and frequently prompt referral to a cardiologist (Zimetbaum and Goldman, 2010). Palpitations can be completely benign or abnormal depending on the clinical scenario; therefore, a careful history needs to be elicited (Zimetbaum and Goldman, 2010; Weber and Kapoor, 1996). In patients with palpitations that remain unexplained after initial evaluation with routine ECG, cardiac monitoring is often considered. Monitoring can help establish symptom–rhythm correlation and detect asymptomatic arrhythmias that are inferred to be relevant, which can help to establish a diagnosis. Typically, the interval between palpitations can be lengthy and therefore, the type of continuous monitoring strategy chosen needs to be carefully considered (Zimetbaum and Goldman, 2010). Multiple studies have compared the diagnostic yield of the different monitoring devices, an important consideration for choosing the appropriate device based on symptom frequency.

Syncope

Syncope is a common presentation encountered by primary care and ED physicians. It accounts for 1%–3% of ED visits and 0.6%–1% of all hospitalizations (Olde Nordkamp et al., 2009). It is estimated that the lifetime cumulative incidence of syncope in the general population is between 35% and 39%, with the majority of patients having their first syncopal episode before the age of 30 (Sud et al., 2009). Despite its prevalence, the management of syncope remains a challenge for many physicians. Obstacles in the diagnosis of syncope include the high spontaneous remission rates as well as the episodic and unpredictable frequency of events. Syncope falls under the broad definition of "transient loss of consciousness" and therefore the differential diagnosis for patients presenting with syncope can be extensive in some cases (Olde Nordkamp et al., 2009; Anon, 2016). The differential can include a number of life-threatening causes, which often leads to physicians feeling compelled to complete an extensive diagnostic work-up. Monitoring is often considered when the syncope likely attributed to a cardiac etiology. However, despite a full diagnostic evaluation, the etiology of the syncope is not found in approximately one-third of patients. Therefore, monitoring strategies are utilized to help record or exclude an arrhythmia as a contributing cause of syncope (Zimetbaum and Goldman, 2010; Subbiah et al., 2013). Extended monitoring is typically necessary to record the ECG during a spontaneous episode of syncope, but asymptomatic arrhythmias may have compelling inferential use (Krahn et al., 2004).

Atrial Fibrillation

With an increasingly aging population, the prevalence of atrial fibrillation (AF) continues to rise (Colilla et al., 2013). It is estimated that by 2030, 12.1 million individuals will be living with AF in the United States (Colilla et al., 2013). Many of the adverse events

associated with AF can be correlated with episode duration, frequency, and overall arrhythmia burden. Therefore, there is a great deal of interest in AF monitoring to help guide anticoagulation therapy, rate control, rhythm control efficacy, and burden in patients with heart failure (Botto et al., 2009). Multiple studies have examined the role and utility of different monitoring strategies, and there is evidence that longer duration ECG monitoring enhances arrhythmia detection rates (Boriani et al., 2014; Andrade and Krahn, 2013; Brachmann et al., 2016; Korompoki et al., 2016; Sposato et al., 2015).

Postmyocardial Infarction Arrhythmia

Individuals who survive an acute myocardial infarction (AMI) that are left with left ventricular dysfunction (ejection fraction $\leq$40%) are at high risk of sudden death due to cardiac arrhythmias (Solomon et al., 2005; Huikuri et al., 2001). There is evidence to support that prophylactic implantation of an implantable cardioverter-defibrillator (ICD) late after an AMI reduces all cause mortality (Hohnloser et al., 2004). This benefit is lessened when the ICD is implanted early after an AMI. In addition, use of left ventricular function alone selects high-risk individuals for ICD implantation, but has a modest effect on population sudden death risk, because the majority of sudden deaths occur in apparently low-risk patients (Adabag et al., 2010; Myerburg et al., 1992) Prolonged ECG monitoring is an area of interest to identify improved noninvasive risk stratifiers that may help identify which patients post AMI may find the most benefit from ICD implantation. The Cardiac Arrhythmias and Risk Stratification after AMI (CARISMA) trial was the first large-scale prospective trial that utilized a prolonged ECG monitoring strategy to help identify invasive and noninvasive risk markers that may predict the occurrence of arrhythmias in patients post AMI (Huikuri et al., 2009). Overall, evidence to support prolonged ECG monitoring in these patients is limited by low positive predictive value, and more studies will be necessary to make definitive recommendations.

Atrial Fibrillation and Embolic Stroke of Undetermined Source

As many as 25% of patients presenting with an ischemic stroke have no probable cause identified after a thorough evaluation, which includes an ECG, echocardiogram, in-patient telemetry, magnetic resonance imaging (MRI), or computed tomographic (CT) imaging of the brain. These patients are ultimately diagnosed as having a cryptogenic stroke or more recently termed as an embolic stroke of undetermined source (ESUS) (Sanna et al., 2014; Saver, 2016; Seet et al., 2011). Some of these strokes are attributed to embolism of venous thrombi through a patent foramen ovale (PFO) (Meier et al., 2013; Calvert et al., 2011). Several randomized clinical trials have demonstrated that closure of PFO failed to yield significant benefit (Carroll et al., 2013), suggesting that ischemic strokes through paradoxical embolism of venous thrombi are very rare. More recently, studies have focused on better understanding the extent to which AF contributes to ESUS. AF increases risk of thromboembolic strike as much as fivefold (Boriani et al., 2014). In the evaluation of patients with ischemic strokes, the incidence of either persistent or paroxysmal AF predating the stroke is approximately 15% (Joundi et al., 2016; Liao et al., 2007). Following their stroke, an additional 8% and 5% of patients presenting with sinus rhythm are identified as having AF through inpatient cardiac telemetry or 24-h monitoring, respectively (Brachmann et al., 2016). Clinical trials using longer duration monitoring strategies have shown an even greater yield in the identification of AF in this patient population and will be discussed further.

Electrocardiographic Monitoring Modalities

Short-Term Recording

Inpatient telemetry

Classically, hospital electrocardiographic monitoring allowed for basic heart rate and rhythm monitoring. Advancements in technology now allow for evaluation of more complex rhythm disturbances, including myocardial ischemia, extent and nature of bradycardia, ectopy, ventricular arrhythmia burden/morphology, and QT interval prolongation. The challenge lies in which patients warrant inpatient monitoring. Logistical and economic constraints limit the number of patients that can be monitored at any given time. In the case of syncope, inpatient ECG monitoring is recommended for patients deemed to be at high risk for an arrhythmic cause, such as those with known structural heart disease (Subbiah et al., 2008; Simpson et al., 1999). The European Society of Cardiology (ESC) and Canadian Cardiovascular Society (CCS) have outlined characteristics, which necessitate urgent hospitalization (**Table 1**). Despite these recommendations, the overall yield for 72-h inpatient monitoring is only 16%; nonetheless, in select patients, this modality of monitoring is appropriate and justified for risk stratification.

Holter monitoring

Holter monitoring is the most commonly utilized diagnostic tool for ambulatory monitoring and consists of a portable recording device attached to cutaneous electrodes on the chest wall (Roberts and Silver, 1983; Galli et al., 2016). Holter monitors can provide 2, 3, or 12 electrodes and typically provide recordings for 24–48 h; however, newer monitors now have the capability of offering up to 2 weeks of monitoring (Galli et al., 2016). The data is stored in the device using digital media, analyzed with software by a technologist, and subsequently edited and reported by the physician.

Table 1 ESC and CCC guidelines for inpatient telemetry

Canadian cardiovascular society	*European society of cardiology*
● Major risk factors (should have urgent cardiac assessment) ○ Abnormal ECG (any bradyarrhythmia, tachyarrhythmia, or conduction disease; new ischemia or old infarct) ○ History of cardiac disease (ischemic, arrhythmic, obstructive, valvular) ○ Hypotension (systolic BP $<$90 mm Hg) ○ Heart failure (either past or present) ● Minor risk factors (could consider urgent cardiac assessment) ○ Age $>$60 ○ Dyspnea ○ Anemia (hematocrit $<$0.30) ○ Hypertension ○ Cerebrovascular disease ○ Family history of SCD ○ Syncope while supine, during exercise or with no prodrome	● Severe structural or coronary artery disease (CHF, low LVEF, or previous MI) ● Clinical or ECG features of arrhythmic syncope: ○ Exertional or supine syncope ○ Palpitations at time of syncope ○ Family history SCD ○ Nonsustained VT ○ Bifascicular block or other intraventricular conduction abnormalities (QRS $\geq$120 ms) ○ Inadequate sinus bradycardia ($<$50 bpm) or sinoatrial block without negative chronotropic medication or physical training ○ Preexcited QRS complex ○ Prolonged or shortened QT interval ○ Brugada pattern ○ Negative T waves right precordial leads, epsilon waves, and ventricular late potentials (suggestive of ARVC)

Abbreviations: *BP*, blood pressure; *SCD*, sudden cardiac death; *CHF*, congestive heart failure; *LVEF*, left ventricular ejection fraction; *MI*, myocardial infarction; *VT*, ventricular tachycardia; *ARVC*, arrhythmogenic right ventricular cardiomyopathy.

Table adapted from Sheldon, R. S., Morillo, C. A., Krahn, A. D., O'Neill, B., Thiruganasambandamoorthy, V., Parkash, R., et al. (2011). Society position statement standardized approaches to the investigation of syncope: Canadian cardiovascular society position paper. *Canadian Journal of Cardiology* **27**(2), 246–253 and Moya, A., Sutton, R., Ammirati, F., Blanc, J. J., Brignole, M., Dahm, J. B., et al. (2009). Guidelines for the diagnosis and management of syncope (version 2009). *European Heart Journal* **30**(21), 2631–2671.

Fig. 2 Evidence for arrhythmic etiology for syncope on Holter monitor. Rhythm strip demonstrating a greater than three second pause in a patient with documented syncope while wearing a 24-h Holter monitor.

The advantages of Holter monitoring lie in its widespread accessibility, low cost, and easy application. Most importantly, it offers continuous electrocardiographic monitoring and requires minimal patient participation for data acquisition. Patients are asked to maintain a diary of symptoms and activity during the monitoring period to help establish a symptom–rhythm correlation. This form of monitoring is most beneficial in clinical scenarios where there is a suspected arrhythmic cause of the syncope and the symptoms occur frequently (Fig. 2). In reality, the majority of patients with syncope experience weeks, months, or years between episodes, which limits the diagnostic yield of Holter monitoring. This has been demonstrated in several large studies, in which only 4% of patients had symptoms during the monitoring period. In studies where patients were not carefully selected, the yield of detecting an arrhythmic cause of syncope was as low as 1%. In patients with palpitations, Holter monitors are frequently used despite evidence that the diagnostic yield is only 35% unless symptoms occur with daily frequency. In one study comparing Holter monitors to event recorders (see below) in patients with uninvestigated palpitations, a symptom–rhythm correlation was obtained in 67% of patients with event monitors compared with 35% of patients with Holter monitoring (Kinlay et al., 1996). It was also demonstrated that event monitors proved to be a more cost-effective approach in these patients.

While they are frequently utilized, Holter monitors have a number of notable limitations. The physical size of these monitors creates a significant burden for patients. This ultimately results in limiting their ability to maneuver throughout their daily activities, which may precipitate their symptoms. The brief duration of monitoring, as discussed above, results in low diagnostic yield in patients experiencing infrequent symptoms. The lack of real-time data transmission requires close interaction between the patient and ordering physician. Noncompliance in maintaining a log of symptoms and using event markers can further limit the diagnostic value.

Prolonged Recording

External cardiac event recorders

Event recorders are newer-generation devices, which allow for prolonged monitoring. These devices can be divided into two categories: loop recorders and event recorders. The loop recorders can further be divided into external loop recorders (ELRs) and implantable loop recorders (ILRs).

Event recorders, sometimes referred to as nonlooping recorders, are a form of noncontinuous ambulatory ECG monitors that can be used for 14–30 days (Fogel et al., 1997; Sciaraffia et al., 2014). The event recorder is a portable handheld or wrist-based device that is activated when symptoms occur (**Fig. 3**). Patients activate the device, which will then record an ECG rhythm strip. The duration of ECG recording depends on the device model, but averages 1–2 min. This event then must be directly transmitted to the receiving center, which will convert the information into a single lead rhythm strip (Wu et al., 2003). Nonlooping event recorders are suitable devices for investigating symptoms that are sustained long enough to record the rhythm with the application of a recorder (Saarel et al., 2004).

The major advantage to these devices is that they are small and easily worn by patients and avoid the skin irritation associated with the fixed recording electrodes that are required for loop recorders. However, these devices present with a few disadvantages, including the required technical skills to transmit the data to the central monitoring station and the coherency of the patient to activate the device during times of symptoms. Additionally, the mode of recording does not allow rhythm to be captured during the onset of symptoms and therefore, brief arrhythmias may be missed before the device is activated (Bhandari et al., 1992). These limitations often result in low diagnostic yield, especially during episodes that result in disabling symptoms that prevent activation of the device (Kus et al., 1995). Patients are now using smartphone-based applications to record either heart rate or an actual ECG during symptoms, leading to patients bringing their own recordings to medical attention. This enabling technology clearly has merit for improving access to monitoring, but requires context to prevent medical information overload.

Loop-recorders

ELRs are attached to the patient through 1–3 chest electrodes or a single-patch electrode, which are only removed for bathing and showering. The transmitter of most ELRs is the size of a pager or small mobile phone and can be worn on a belt or within nine meters of the patient to enable transmission (**Fig. 4**) (Sciaraffia et al., 2014). Rhythm recording is either initiated by patient activation or automatically triggered by inputted programmable criteria. The recorder will register the ECG data for a few seconds to minutes before and after the recorder has been activated (according to preprogrammed durations). The memory "loop" or buffer allows the patient to answer both "what just happened?" as well as "what is happening?" Given that loop recorders can be activated when symptoms are present, it allows for accurate symptom–rhythm correlation and ultimately can help exclude or diagnose a causative role for rhythm disturbances as the etiology of patients' syncope or palpitations (**Fig. 5**) (Farwell et al., 2004; Lombardi

Fig. 3 Cardiac event recorder device. Four electrodes are present on the back of the device to permit single lead rhythm capture. A record button (*top left*) is pressed at the onset of symptoms, and the recorded event is transmitted to a base station over an analog phone line.

Fig. 4 ELR device. The record button is pressed in the event of symptoms to store a predetermined time (up to 9 min) of rhythm data prior to the onset of symptoms along with the ensuing minute. The phone receiver is also placed over this button to transmit data over an analog phone line.

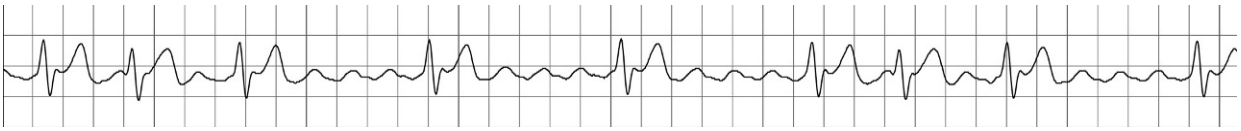

Fig. 5 ELR tracing during symptoms of palpitations. Sample tracing of atrial flutter in a patient experiencing palpitations.

et al., 2005). These devices can theoretically be used indefinitely as long as weekly battery changes are performed. However, because of practical limitations, they are typically worn for several weeks to a month.

ILRs, or more recently known as ICMs, have become the primary investigative tool in patients with recurrent unexplained syncope who have had negative initial investigations (Farwell et al., 2004, 2006). Several manufacturers make devices, with a widening scope of capabilities and form factors. They are increasingly smaller devices (Medtronic's Reveal LINQ, one-third the size of an AAA battery) that are designed for subcutaneous implantation in the chest wall using a minimally invasive technique (**Fig. 6**) (Krahn et al., 1999). The evolution and development of smaller form factors in ICMs has allowed for the creation of these less invasive devices (Krahn et al., 2014). The projected battery life of most ICMs is in the order of 36 months.

Prior to implantation, external ECG mapping is typically used to help determine the site of insertion that will provide optimal R-wave amplitude (Krahn et al., 1997). These leadless devices record a single-lead ECG signal through two electrodes within the device. The typical position of the ICM usually lies in the left parasternal region, with an adequate signal usually obtained with implantation anywhere in the left hemithorax (Krahn et al., 1998). The device is anchored to the muscular plane to avoid mechanical instability, displacement, or migration, all of which may create artifact and reduce R-wave amplitude. In patients concerned with the aesthetic impact of an anterior chest surgical scar, there is the option for anterior axillary implantation, which recently has been shown to be as effective as the standard approach in achieving adequate R- and P-wave amplitudes (Miracapillo et al., 2010, 2016). Thus far, implantation of ICMs has been shown to be safe and associated with very low infection rates, with emerging data to support feasibility of in-office implantation with semisterile precautions (Rogers et al., 2017).

Similar to other external event recorders, ICMs have been developed to correlate symptoms with recorded cardiac rhythms. They are especially useful in noncompliant patients as there are no external parts or batteries to manage. At the time of implantation, the patient and their family members are instructed on how to activate the device (Sciaraffia et al., 2014). Once symptoms occur, a handheld activator is used to record the episode. The data can be transmitted over a standard phone line or via transtelephonic monitoring. Remote monitoring can allow for prompt intervention and therapy if a relevant arrhythmia is detected. Most devices have the capability to store 40–60 min of a single lead ECG. Therefore, if arrhythmias are very frequent, they may be missed, because either the memory is full or the device is programmed to stop storing new data, or old episodes are overwritten by the new data (Hoefman et al., 2007). Therefore, timely data transmission is essential, especially for patients living in remote areas where access to specialized clinics is both difficult and costly. Remote monitoring has the ability to virtually eliminate concern regarding memory capacity, since any recorded events are transmitted daily. This has however led to information overload at the receiving end, where many monitored patients generate immense workloads for device clinics.

Fig. 6 ICM. Examples of two different ICMs from Medtronic, (A) Reveal LINQ and (B) Reveal XT. The two devices are placed next to an AAA battery to provide size perspective.

ICMs have been shown to be effective in patients with infrequent palpitations. In patients without severe heart disease and infrequent ($\leq$1 episode/month), sustained ($>$1 min) palpitations, conventional testing with a 24-h Holter monitor led to diagnosis (with symptom–rhythm correlation) in only 21% of patients versus 73% in patients tested with an ICM (Galli et al., 2016).

To date large-scale studies of ICMs have focused on their utility in patients with recurrent syncope with an uncertain diagnosis. The ESC has given a Class I recommendation for the use of ICMs in the early phase of evaluation of patients with recurrent syncope (Task Force for the Diagnosis and Management of Syncope et al., 2009). Three studies from the International Study on Syncope of Uncertain Etiology (ISSUE) investigators examined different groups of patients with unexplained syncope after they had undergone initial conventional testing (Moya et al., 2001; Brignole et al., 2001; Menozzi et al., 2002). The first of the studies examined 111 patients with unexplained syncope who had undergone tilt table testing. These patients received an ICM irrespective of their tilt table result. In 34% of these patients, syncope recurred irrespective of their tilt table response, the most common rhythm during the episodes were marked bradycardia or asystole (Moya et al., 2001). The second study examined patients with underlying bundle branch block and negative electrophysiological testing. Syncope recurred in 22 of the 52 patients in the study wherein the most common rhythm finding was again marked bradycardia, mainly attributed to complete AV block (Brignole et al., 2001). The third study included 35 patients with syncope, overt heart disease, and negative electrophysiological testing (Menozzi et al., 2002). Of these patients, 54% (19/35) had recurrent symptoms, with bradycardia in four, supraventricular tachyarrhythmias in five, and ventricular tachycardia in one. This third study by the ISSUE investigators was the first to demonstrate an ongoing risk for cardiac arrhythmias despite negative electrophysiological testing in this patient population, and further strengthened the evidence for the use of ICMs in this patient cohort.

The follow-up ISSUE-2 was a nonrandomized, multicenter observational study that investigated the efficacy of therapies based on ICM diagnosis in patients with recurrent suspected neurocardiogenic syncope (Brignole et al., 2006). This demonstrated that diagnostic information obtained from early ICM implantation allowed for safe and effective therapy in patients with neurocardiogenic syncope. Based on these promising results, the ISSUE-3 study was initiated, which examined 511 patients over the age of 40 with recurrent vasovagal syncope, who were all implanted with an ICM (Brignole et al., 2012). In the 17% with asystolic recurrence, dual chamber pacemaker therapy was superior to those whose pacemaker was turned off in the overall prevention of recurrent syncope. This study further strengthened the evidence that prolonged monitoring with an ICM is useful in patients with recurrent vasovagal syncope who would be considered for a permanent pacemaker if marked bradycardia was detected (the minority).

The PICTURE study (Place of reveal In the Care pathway and Treatment of patients with Unexplained Recurrent Syncope) was a large prospective, multicenter study that evaluated the usage and diagnostic effectiveness of ICMs for the everyday evaluation of patients with unexplained syncope (Edvardsson et al., 2011). Overall, the results demonstrated that implantation with an ICM resulted in high diagnostic yield (78%) and should be considered early on in the workup of patients with unexplained syncope to reduce the overall number of tests required to lead to a diagnosis. Specific rhythms diagnosed were not reported by the investigators, but historically bradycardia outweighs tachycardia in most case series.

To date, there have been only a few randomized trials that directly compared ICMs with conventional testing strategy for syncope. The first trial was the Randomized Assessment of Syncope Trial, which clearly demonstrated the superiority of prolonged monitoring strategy with ICM over conventional testing in the diagnosis of syncope (55% vs. 19%) (Krahn et al., 2001, 2003). This was followed by the Eastbourne Syncope Assessment Study (EaSyAS), which examined 201 patients with recurrent unexplained syncope (Farwell et al., 2004). The population was randomized to receive the ICM (Reveal plus, Medtronic) compared to conventional testing. The results demonstrated that after 17 months of follow-up, 43% of patients with an ICM versus 6% with conventional testing received an electrocardiographic diagnosis for their syncope (Farwell et al., 2006). As a result, they had more rapid access to tailored therapy, which led to a longer time to a second syncopal episode. ICM was also shown to be a more cost-effective strategy compared to conventional testing. The FRESH study from France examined 78 patients with recurrent or severe syncope who were randomized to ICM or conventional testing (Podoleanu et al., 2014). This population consisted of low-risk patients with syncope, which did not include any subject with cardiac disease. After 14 months of follow-up, the results clearly favored ICMs over conventional testing in establishing a diagnosis of syncope. Finally, the most recent trial EaSyAS II followed 246 patients for 20 months after randomization into different arms: conventional strategy versus syncope clinic, versus ICM and syncope clinic versus an ICM alone. Finally, the most recent EaSyAS II trial followed 246 patients for 20 months after they were randomized to one of four arms: 1) conventional management, 2) syncope clinic alone, 3) ICM alone or 4) ICM and syncope clinic. Patients randomized to the ICM arm had an overall significantly shorter time to diagnosis, compared to conventional management (Sulke et al., 2016).

There is growing evidence for the utility of ICMs for the detection of AF, and not surprisingly, several studies have demonstrated that longer monitoring strategies improve detection rates (Giada et al., 2012). It has been estimated that serial 7-day Holter monitors or event recorders may miss up to 30% of AF episodes (Kirchhof et al., 2007). Guidelines have not yet adopted ICMs as the gold standard for AF detection in clinical trials evaluating the efficacy of interventions such as ablation or cardioversion. Prolonged rhythm monitoring with ICMs in assessing AF burden is currently being examined in large clinical trials to assess the role of oral anticoagulation in subclinical AF.

The hypothesis that loop recorders improve the detection of AF in patients with ESUS has been examined by a number of large-scale studies (Brachmann et al., 2016; Saver, 2016; Yong et al., 2016). The Cryptogenic Stroke and Underlying AF (CRYSTAL AF) trial examined 441 patients over the age of 40 with a diagnosis of cryptogenic stroke or transient ischemic attack (TIA) of undetermined cause and randomized them to receive an ILR or conventional ECG testing (Sanna et al., 2014; Thijs et al., 2016). The study reported the detection of AF to be 8.9% at 6 months, 12.4% at 1 year, and 30% at 3 years with ICM monitoring, compared to 1.4%, 2.0%, and 3.0% at 6 months, 1 year, and 3 years, respectively, for the control group (Brachmann et al., 2016; Thijs et al., 2016). The 30-day Cardiac Event Monitor Belt for Recording AF after a Cerebral Ischemic Event (EMBRACE) trial examined a total of 572 patients, who were randomized to receive an ELR or 24-h Holter monitor (Gladstone et al., 2014). This patient population included those over the age of 55 without known AF and a diagnosis of ESUS or TIA of undetermined cause. The results showed that testing with an ELR was superior to Holter monitoring in detecting AF in this population. AF that lasted 30 sec or longer was detected in 16.1% of patients with an ELR, versus 3.2% in the patients with Holter monitoring after 30 days. A meta-analysis examining 50 studies and over 10,000 patients with recent stroke found that 23.7% of the patients were diagnosed with AF after their hospital admission (Sposato et al., 2015; Joundi et al., 2016). Currently, there is no clear consensus on the type of extended monitoring that should be utilized in patients with a diagnosis of cryptogenic stroke to detect low-burden or silent AF. Overall, these studies provide convincing evidence that a prolonged monitoring strategy with either an ELR or ILR is a reasonable approach in the work-up of patients with cryptogenic stroke and negative findings on conventional testing.

The aforementioned experiment clearly demonstrates the role and superiority of extended monitoring in the detection of subclinical AF (SCAF) in patients with ESUS. The Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial (ASSERT) demonstrated that SCAF was associated with a 2.5-fold increased risk of stroke or systemic embolism (Healey et al., 2012). Despite the evidence of SCAF in patients with thromboembolic strokes, the causal and temporal relationships between SCAF and embolism are not entirely clear, since timing of AF did not correspond to subsequent stroke or TIA, and most stroke patients did not have recent AF. SCAF may be associated with embolic stroke without direct causality.

The TRENDS study evaluated the relationship between long-term atrial tachycardia (AT)/AF burden and thromboembolism in patients that had stroke risk factors and were scheduled to receive a pacemaker or ICD for a class I/II indication (Glotzer et al., 2009; Ziegler et al., 2010). A subgroup analysis of this study was conducted, which examined 40 patients who suffered a stroke, systemic embolism, or a TIA. It was demonstrated that of the 20 subjects with AF prior to the embolic event, only 30% had AF within the 1 month prior to the embolic event and the timing for the most recent AF episode was an average of 166 ± 189 days prior to the embolic event (Daoud et al., 2011). The ASSERT study demonstrated that only 15% of patients with a SCAF-associated embolic event had evidence of SCAF, which was >6 min in duration 1 month prior to the event (Healey et al., 2012). More importantly, most of the SCAF occurring before these embolic events were less than 48 h, which has previously been felt to be the minimum duration necessary for thrombus formation in the left atrial appendage (Healey et al., 2012; Weigner et al., 1997). Patients in the ASSERT trial had an absolute stroke risk of 1.7% per year, which is lower than previously published reports. The initial results of the ASSERT trial were followed up by a posthoc analysis, which focused on the duration of device-detected subclinical AF and the occurrence of stroke (Van Gelder et al., 2017). In this substudy, patients with SCAF ≤6 min were excluded from the study. The 2455 patients that were included in the post-hoc analysis were stratified based on the longest single episode of SCAF. They defined four categories of SCAF: (1) no SCAF, (2) SCAF with a duration of >6 min–6 h, (3) SCAF between >6 h–24 h, and (4) SCAF >24 h. The

post-hoc analysis revealed that SCAF lasting >6–24 h occurred in 7% of patients and episodes lasting >24 h occurred in 11% of patients. Importantly, they reported a significantly higher absolute risk (3.1%) of ischemic stroke or systemic embolism compared to patients with no SCAF. This absolute risk is similar to patients with clinical AF and higher than that reported in the primary ASSERT study. In patients with SCAF <24 h, their risk of stroke or systemic embolism was not significantly different from those that did not have SCAF. Overall, the more robust analysis of the data from the ASSERT study highlights the importance of SCAF duration on overall stroke risk, a topic that remains controversial. Collectively, these results highlight the importance for careful interpretation of SCAF that is identified during prolonged ECG monitoring. Currently, there is no consensus regarding the role of anticoagulation in patients with SCAF. There is a need for randomized trials to help better understand the temporal relationship of SCAF and embolic events, several of which are underway.

Mobile cardiac outpatient telemetry

Real-time continuous attended cardiac monitoring has emerged over the past decade with the aim of overcoming some of the limitations of Holter monitors and ELRs. These systems are commonly referred to as mobile cardiac outpatient telemetry (MCOT); these systems were developed to overcome some of the limitations associated with Holter and ELR monitoring systems (Joshi et al., 2005). MCOT systems are similar in size to the ELR and consist of three chest electrode leads attached to a small sensor, which is similar to a pager clipped onto a belt. For patients not able to tolerate adhesive electrodes, there is the option for a chest belt with three built-in nonadhesive electrodes. A key distinguishing characteristic of the MCOT is the associated monitoring device, which is in constant communication with the sensor and records the cardiac rhythm independent of any patient participation. While in the home, the monitor transmits events and pertinent rhythm strips transtelephonically to a service center that is staffed with monitoring specialists (Olson et al., 2007). While outside of their home, patients carry their monitor and the events are transmitted through cellular signals. In the event no signal is available, most MCOT systems are equipped to store 24 h of ECG data, which can then be transmitted to the monitoring center once a signal has been restored. Patients are also able to record symptoms and activity directly into the monitoring device. Monitoring specialists provide detailed reports to the ordering physicians on a daily basis, which include heart rate trends, representative ECG events of predetermined cardiac rhythms, and urgent reports based on the ordering physicians' criteria.

Thus far, there have been very few RCTs comparing the MCOT system to other forms of external monitoring devices. In one RCT, 266 patients with symptoms of syncope, presyncope, or severe palpitations with a negative 24-h Holter monitor were randomized to an MCOT device or ELR for up to a period of 30 days (Rothman et al., 2007). A diagnosis was made in 88% of patients with an MCOT compared to 75% in those with an ELR. In a subgroup analysis examining those patients with presyncope or syncope, a diagnosis was made in 89% versus 69% for MCOT and ELR devices, respectively. Overall, MCOT devices were also found to be superior in identifying clinically significant arrhythmias (41% vs. 15% in MCOT vs. ELR devices, respectively). In one study investigating the diagnostic yield of MCOT systems in patients with a diagnosis of cryptogenic stroke, a monitoring period of 30 days was not sufficient to identify occult AF in a significant proportion of these patients who were later found to have AF.

Patch ECG monitors

Holter monitors have a number of limitations, including their bulk, which creates a significant inconvenience for patients. This often leads to patient noncompliance or results in limited maneuverability, which lowers diagnostic yield (Diemberger et al., 2015). While there are now 2-week Holter monitors available, the desire to create long-term monitoring devices with ease of use for patients has led to the development of patch ECG Monitors (PEMs) (**Fig. 7**) (Lobodzinski and Laks, 2012). PEMs are wearable ECG

Fig. 7 Patch ECG monitor device. Examples of two different patch ECG monitors, (A) Zio XT cardiac monitor from iRhythm technologies, (B) CardioSTAT cardiac monitor. These devices are water-resistant, wire-free, single-use devices that allow for prolonged (up to 7 days) ECG monitoring. Each patch has a centrally placed button that can be activated by the patient to mark their symptoms.

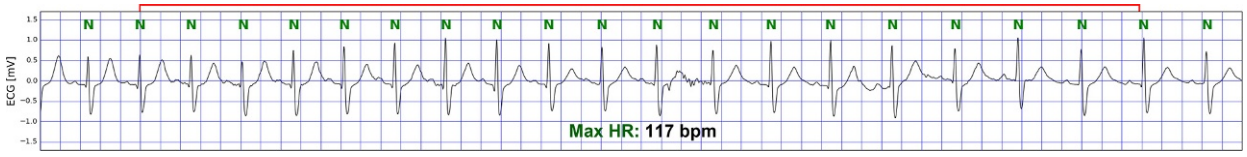

Fig. 8 Example tracing from PEM. Sample tracing of sinus rhythm from a patient wearing a CardioSTAT cardiac monitor.

monitors capable of continuously recording ECG data for up to 14 days (Barrett et al., 2014; Cheung et al., 2014). PEMs can record data without visible electrodes or lead wires and fall into two main categories, those that function as recording devices only and those that can record and transmit. The Zio Patch (iRhythm technologies) is a single-channel, single-use, waterproof PEM device that is capable of continuous recording for up to 14 days (Fig. 8). The patch is placed in the left pectoral region and does not require any patient activation. There is a single button on the device that allows the patient to mark a symptomatic episode. At the end of the recording period, the patient simply mails the device in a prepaid envelope to the monitoring center, and within 3 days, a finalized report is provided to the ordering physician. In a direct comparison to 24-h Holter monitors, 146 patients that were referred for cardiac arrhythmia evaluation underwent simultaneous ambulatory ECG monitoring with a Holter monitor worn for 24 h and the Zio Patch worn for a goal of 14 days (Barrett et al., 2014; Cheung et al., 2014). The mean wear-time in days for the Holter monitor and PEM was 1.0 (range, 0.9–1.0) and 11.1 (range, 0.9–14.0), respectively. The primary outcome was the detection of arrhythmias during the wear-time of each device. In this study, the PEM detected 96 arrhythmias compared to 61 events with the Holter monitor. Of these recorded events, both the Holter monitor and PEM detected 60 of the same events. The results of this study demonstrated a clear increased diagnostic yield with the PEM and strong patient preference for the PEM over the Holter monitor, with 81% preferring the PEM. Clinician satisfaction was also higher, with 90% feeling a definitive diagnosis was made with the PEM versus 64% with the Holter monitor. Multiple manufacturers are emerging in this space. It is clear that PEMs will change the face of ambulatory ECG monitoring.

Future Directions

With recent advances in ICM design and the presence of many different manufacturers, it is clear that long-term electrocardiographic monitoring will continue to be area of growth and development in the field of cardiology. The focus will be directed toward the design of products that are minimally invasive, utilize modern technology, and integrate seamlessly into the daily lives of patients. Increasingly, there is a great deal interest and research dedicated to smartphone ECG monitoring.

Smartphone monitoring

It is estimated that by 2020, there will be 6.1 billion smartphone users, approximately 70% of the world's population. With this expansion in smartphone usage, there have been a large number of medical applications and ancillary products being designed to utilize this technology. These applications provide a unique opportunity to implement monitoring strategies that integrate seamlessly into the daily lives of patients (Konecny and Saxon, 2016). Thus far, there is little data on the effectiveness of mobile health technology in detecting arrhythmias. The Smartphone Pediatric ElectrocARdiogram (SPEAR) trial examined pediatric patients with documented paroxysmal arrhythmia using the AliveCor® heart monitor (AHM) and found the device was able to generate tracings of diagnostic and therapeutic qualities in children with diagnoses of AF and SVT (Nguyen et al., 2015). Patient satisfaction was very high, with 98% indicating ease in obtaining tracings and 93% reporting ease in transmitting the recorded tracings. This study was followed by the iTransmit study, which enrolled 60 patients and directly compared the AHM to TTM. Patients were then asked to record their rhythms using both monitors simultaneously whenever they had symptoms, at least once a week (Tarakji et al., 2015). The AHM had 100% sensitivity and 97% specificity for the detection of AF and atrial flutter, and the vast majority of patients (92%) preferred using the AHM for detection of their AF as opposed to the TTM.

Smartphone-based applications that have been designed to analyze the pulsatile signals by illuminating the fingertip using the smartphone camera have been shown to be successful in distinguishing AF from sinus rhythm (McManus et al., 2013). The first study using this technology conducted by McManus and colleagues utilized an iPhone 4S camera to analyze 76 patients with AF scheduled to undergo elective cardioversion (McManus et al., 2016). Pre- and post-ECGs were recorded along with pulse signal recordings using the iPhone 4S camera. The novel algorithm used in this study, which was previously validated, demonstrated 100% and 96.05% accuracy in identifying AF and normal sinus rhythm, respectively. Subsequent follow-up study using the same PULSE-SMART technology demonstrated the successful discrimination in pulse recordings during AF, sinus rhythm, premature atrial contractions, and premature ventricular contractions (McManus et al., 2016). While the technology and software behind the pulse-sensing algorithm provides the promising possibility for ECG monitoring in every person with a smartphone, a number of important issues still need to be considered, including the management of previously healthy patients who are identified with AF using this technology. Should they be further investigated? Is there a need for anticoagulation in those with patients identified as having significant risk of stroke based on the $CHADS_2$ scoring system? More data will be needed to properly address these questions.

Table 2 Comparison of ambulatory electrocardiographic monitoring devices

Device	*Advantages*	*Limitations*	*Indications*
Holter monitor	• Low cost • Continuous monitoring • Record and then analyze data (not real time)	• Short duration of monitoring and low diagnostic yield • Size of device limits daily activities, which may precipitate symptoms	• Patient with very frequent symptoms ($\geq$1 week)
Event recorder	• Low cost • Easily portable • Record and then analyze data (not real time)	• Poor patient compliance with device application • Technical experience required to transmit data • Onset of arrhythmia is not captured • Patient coherence needed during arrhythmia to activate device • Short-lasting arrhythmias may not be recorded	• Compliant patients with intersymptom interval $\leq$4 weeks
ELR	• Prospective and retrospective recording capabilities • Ability to record asymptomatic arrhythmias based on inputted programmable criteria • Record and then analyze data (not real time)	• Poor patient compliance to wearing device • Must be removed for bathing, swimming • May lose electrode contact during sweating/physical activity • Poor electrocardiographic recordings • Continuous device maintenance with weekly battery replacement	• Compliant patients with intersymptom interval $\leq$4 weeks • Syncope and presyncope where preceding/onset of symptoms or arrhythmia is important
ICM (or ILR)	• Prolonged monitoring without any external electrodes or other parts to manage • Highest diagnostic yield of all monitoring devices • Record and then analyze data (not real time) • Use of remote monitoring to access stored data, extends memory capacity dramatically, and allows next day notification of events	• Invasive implantation with risk of local complications • High cost	• Early-phase evaluation of patients with recurrent syncope and absence of high-risk features • Growing role in atrial fibrillation monitoring for burden, symptom–rhythm correlation, potential role in influencing antithrombotic therapy decisions (being assessed in clinical trials)
Mobile outpatient cardiac telemetry	• Continuous monitoring • Real-time data transmission • Patient activation to report symptoms	• High cost • Not widely available • Poor patient compliance to wearing device • Continuous device maintenance	• Compliant patients with intersymptom interval $\leq$4 weeks

To date, there has not been a randomized controlled trial comparing smartphone ECG monitoring to conventional monitoring strategies. The iHEART study is a single-center, prospective randomized controlled trial currently underway (NCT02731326). The trial will randomize 300 participants 1:1 to receive iHEART intervention, which included a smartphone equipped with an AliveCor® Mobile ECG and accompanying Kardia application or standard cardiac care for 6 months. The investigative arm will receive behavior-altering motivational text messages throughout the study period. The standard arm will receive guideline-based care at the discretion of their clinical provider based on ACC/AHA/HRS guidelines for management of patients with AF. This study has the potential to provide robust data on rhythm recording quality, diagnostic yield, and ultimately on the potential of smartphone ECG monitoring in the ambulatory setting.

Conclusion

Electrocardiographic monitoring has evolved dramatically since the development of the Holter monitor. Devices with progressively longer recording capabilities have significantly enhanced the ability of clinicians to obtain silent or symptomatic physiological data. With the development of ICMs, we have an enhanced ability to diagnose intermittent arrhythmias in a number of different clinical settings. **Table 2** summarizes the comparative advantages, limitations and indications for the different modes of ambulatory electrocardiographic monitoring. The continued development of novel, less invasive, and user-friendlier devices will undoubtedly advance the field of electrocardiographic monitoring even further. Ongoing clinical trials will be needed to determine the suitability of these devices in helping clinicians investigate and diagnosis a variety of clinical conditions.

Introduction

Ventricular tachycardia (VT) and fibrillation (VF) are the most common cause of cardiac arrest and sudden death. Hence, the presence of ventricular arrhythmia warrants careful assessment to determine risk for arrhythmic death and its prevention. In the absence of structural or genetic abnormalities, these arrhythmias are termed idiopathic. While idiopathic VF is a rare life-threatening condition, idiopathic monomorphic VT usually originates from a single focus or may be due to interfascicular reentry. Idiopathic VT is usually considered benign and infrequently associated with sudden death. Occasionally, ventricular arrhythmias such as frequent Premature ventricular contractions (PVCs), repetitive VT, or slow incessant VT can initiate systolic LV dysfunction or worsen preexisting heart failure.

Types of VT

Nonsustained VT refers to episodes that last less than 30 s. Episodes of VT that persist for longer than 30 s cause syncope or cardiac arrest or require an intervention such as cardioversion or overdrive pacing for termination is commonly designated *sustained VT*. VT at a rate less than a 100 bpm is usually due to an *accelerated idioventricular rhythm* but occasionally it may be due to a slow reentrant tachycardia involving a scar.

Monomorphic VT has the same QRS configuration from beat to beat, indicating a stable VT origin from a focus or structural substrate. The ECG morphology suggests the ventricular origin (Josephson and Callan, 2005). A left bundle branch block-like configuration, defined by a dominant S wave in lead V1, suggests that the arrhythmia originates in the right ventricle or interventricular septum. A right bundle branch block-like configuration defined by a dominant R wave in V1 typically originates from the left ventricle (**Fig. 1**). VT that originates from the base of the heart usually has an inferiorly directed frontal plane axis with positive QRS in the inferior limbs leads and prominent R waves in the apical precordial leads (V5 and V6). Inferior wall origin is suggested by superiorly directed frontal plane axis with predominantly negative QRS complexes in the inferior limb leads (**Fig. 1**).

Polymorphic VT has a continually changing QRS axis indicating a varying ventricular activation sequence. A fixed anatomic substrate is not required. Acute myocardial ischemia, genetic arrhythmia syndromes, or electrolyte disturbances are the causes. Polymorphic VT associated with QT prolongation often has a characteristic waxing and waning QRS amplitude referred to as "torsade de pointes (TdP) (Roden, 2008)."

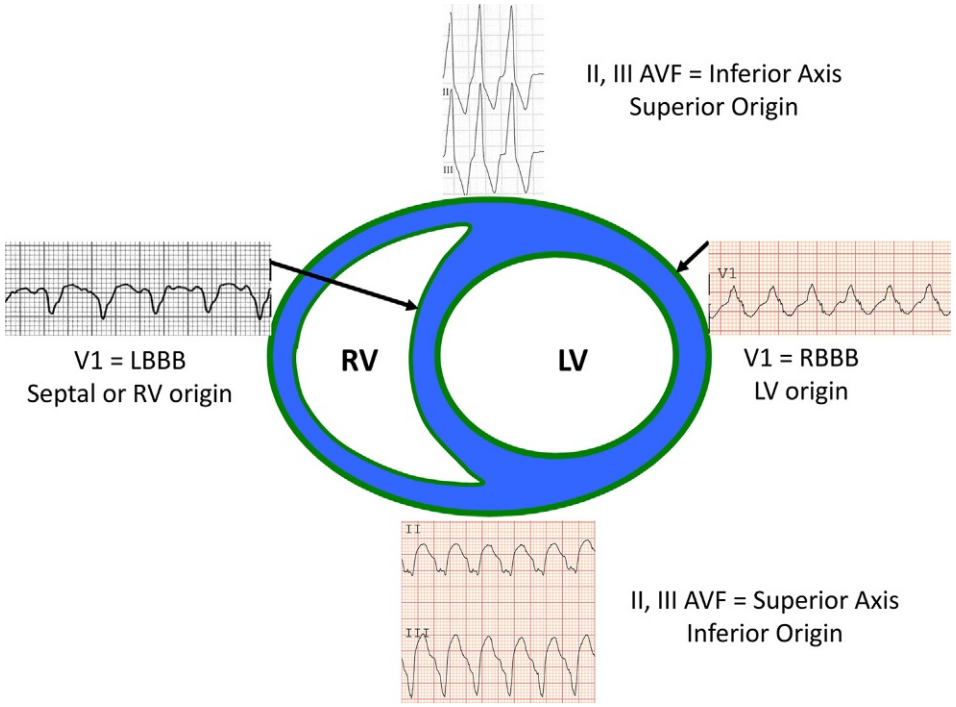

Fig. 1 Morphology and frontal plane axis of a monomorphic suggests site of origin (see text for details). Reproduced from John, R.M. and Stevenson, W.G. (2014). Ventricular arrhythmias. In: Kasper, D.L., Fauci, A.S., Hauser, S.L., Longo, D.L., Jameson, J.L. and Loscalzo, J. (eds.) Harrison's principles of internal medicine (19th edn.). New York: McGraw Hill. Chapter 277.

Diagnosis

Because ventricular arrhythmias originate below the His bundle, the QRS duration is typically wider than 120 ms. However, VT that originates from the Purkinje fibers or the high septum can be relatively narrow and mimic supraventricular arrhythmias. The main differential diagnoses of wide complex tachycardia include VT, supraventricular tachycardia (SVT) with aberration, or preexcited tachycardias. SVTs with preexisting wide QRS, arrhythmias associated with drug toxicity, and pacemaker-mediated tachycardia may also present with wide complex tachycardia. Clinically, the most common cause of a wide complex tachycardia is VT, accounting for 80% of cases (Miller and Das, 2009). A history of structural heart disease increases the probability of VT with a positive predictive value of >95% (Alzand and Crijns, 2011). Patients with VT tend to be older. Age below 35 years and recurrent events over >3 years support SVT with aberration. Hemodynamic stability is not a good marker for VT diagnosis as VT can present with stable hemodynamics.

Several ECG criteria have been published to distinguish monomorphic VT from SVT with aberration. In general, SVT with aberration tend to follow typical bundle branch block of fascicular block patterns, whereas VT that originates outside of the bundle branches or Purkinje system tend to have atypical patterns. Scar-related reentrant VT exit into ventricular myocytes. Hence, initial ventricular activation is usually slower compared with terminal activation. Lead aVR yields a negative QRS during SVT as the ventricular activation wavefront is conducted away from this lead. The presence of an initial R in aVR is thus supportive of VT (Alzand and Crijns, 2011; Vereckei et al., 2008). In addition, the direction of ventricular activation from supraventricular stimulation gives rise to an R wave in at least one or several precordial leads, therefore the absence of RS complex in the precordial leads indicates VT (**Fig. 2**) (Vereckei et al., 2008). None of these criteria are perfect. Because a definitive diagnosis is mandatory for assessing risk and guiding therapy, an electrophysiologic study maybe required if the diagnosis remains in doubt. ECG artifacts can mimic VT, particularly polymorphic VT, and can lead to inappropriate treatments if not recognized.

Management of Ventricular Arrhythmias

VT frequently cause symptoms, but some are recognized on routine evaluation or present with progressive heart failure symptoms. The common presentation is with palpitations, syncope, or cardiac arrest. Initial management of an unstable arrhythmia should follow established advanced cardiac life support guidelines. History and physical examination should focus on identifying heart disease. Potential aggravating factors should be sought and addressed, including electrolyte imbalances, stimulants such as caffeine and amphetamine analogues, and other drugs. The electrocardiogram often provides the first indication of underlying heart disease or a genetic arrhythmia syndrome (see below). Coronary artery disease is the initial major consideration in adults. Ventricular

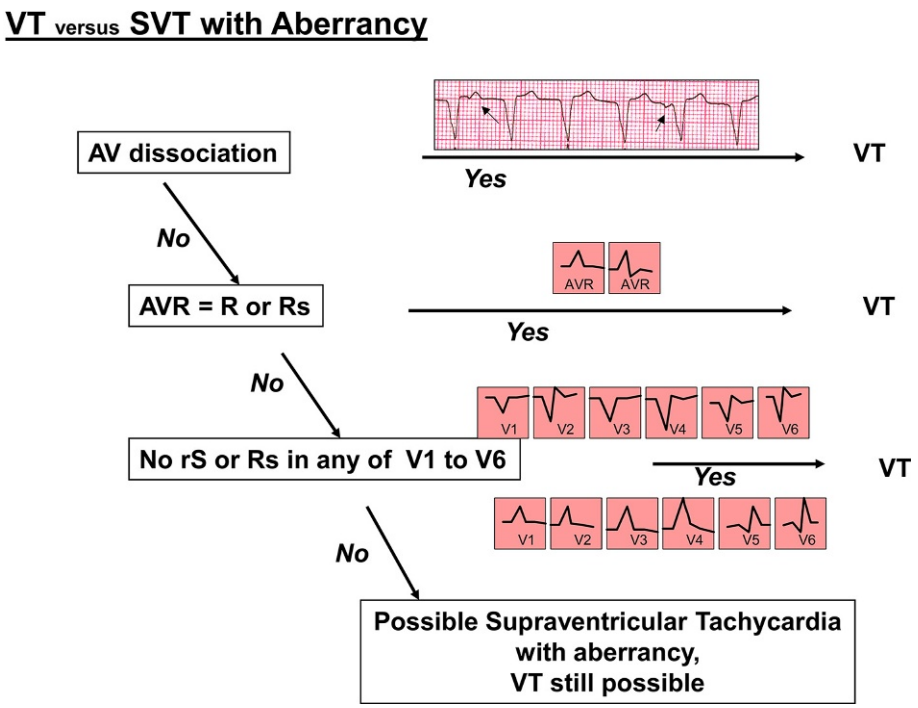

Fig. 2 Algorithm to differentiate ventricular tachycardia (VT) from supraventricular tachycardia (SVT) with aberration. Reproduced from John, R.M. and Stevenson, W.G. (2014). Ventricular arrhythmias. In: Kasper, D.L., Fauci, A.S., Hauser, S.L., Longo, D.L., Jameson, J.L. and Loscalzo, J. (eds.) Harrison's principles of internal medicine (19th edn.). New York: McGraw Hill. Chapter 277.

imaging, usually with echocardiography, is warranted to detect myopathies and assess ventricular function. Cardiac MR imaging and ^{18}F-fluoro-deoxy-glucose PET imaging with CT can be helpful in assessing the presence of scar, infiltration, and inflammation (Blankstein and Waller, 2016; MEMBERS WRITING COMMITTEE and MEMBERS ACCF TASK FORCE, 2010). Long-term management strategies for VT management are determined primarily by the nature of the underlying heart disease and the risk for sudden arrhythmic death. The specifics of the arrhythmia can often direct one to specific evaluation and management.

Premature Ventricular Contractions (PVCs) and Nonsustained VT

PVCs are common, and are observed in up to 27% of healthy individuals during exercise testing (Morshedi-Meibodi et al., 2004). Their prevalence increases with age and with the presence and severity of heart disease. Exercise-induced and recovery-phase PVCs or nonsustained VT (NSVT) are associated with increased mortality, likely because they are markers for underlying heart disease. In the absence of structural heart disease or an underlying genetic arrhythmia syndrome, prognosis is excellent. Specific therapy is rarely required; beta-blockers may be used for control of symptoms.

Very frequent PVCs, typically in excess of 20% of total heartbeats per 24 h, or incessant repetitive monomorphic VT (Figs. 3 and 4) can depress LV ejection fraction in a manner similar to tachycardia-induced cardiomyopathy from incessant SVT or rapid atrial fibrillation (Cha et al., 2012). However, accurate measurement of ventricular function can prove difficult due to frequent arrhythmia. In addition, an underlying cardiomyopathy may be present causing the PVCs. Reassessment of ventricular function after suppression of the arrhythmia with drugs or ablation is often required to clarify the initiating event.

Sustained Monomorphic VT

When structural heart disease is present, monomorphic VT is usually due to scar-related reentry and tends to be recurrent. Although myocardial ischemia can act as a trigger for such VT, revascularization therapies alone are unlikely to prevent recurrences. More than 40% of patients presenting with sustained monomorphic VT will have recurrent arrhythmia within 2 years and there is a risk of sudden death (Kuck et al., 2010). An implantable cardioverter defibrillator (ICD) should therefore be considered in such patients. ICDs terminate, but do not prevent VT episodes. Recurrent VT is common and is associated with increased mortality and hospitalizations and reduced quality of life if VT elicits ICD shocks (Aliot et al., 2009; Poole et al., 2008). Antiarrhythmic drugs or catheter ablation are used to reduce the frequency of recurrences and to control incessant VT. It is important to achieve adequate control of VT before implantation of an ICD to prevent recurrent ICD shocks. In experienced centers, ablation for VT should be considered early in such situations (see what follows) (Aliot et al., 2009).

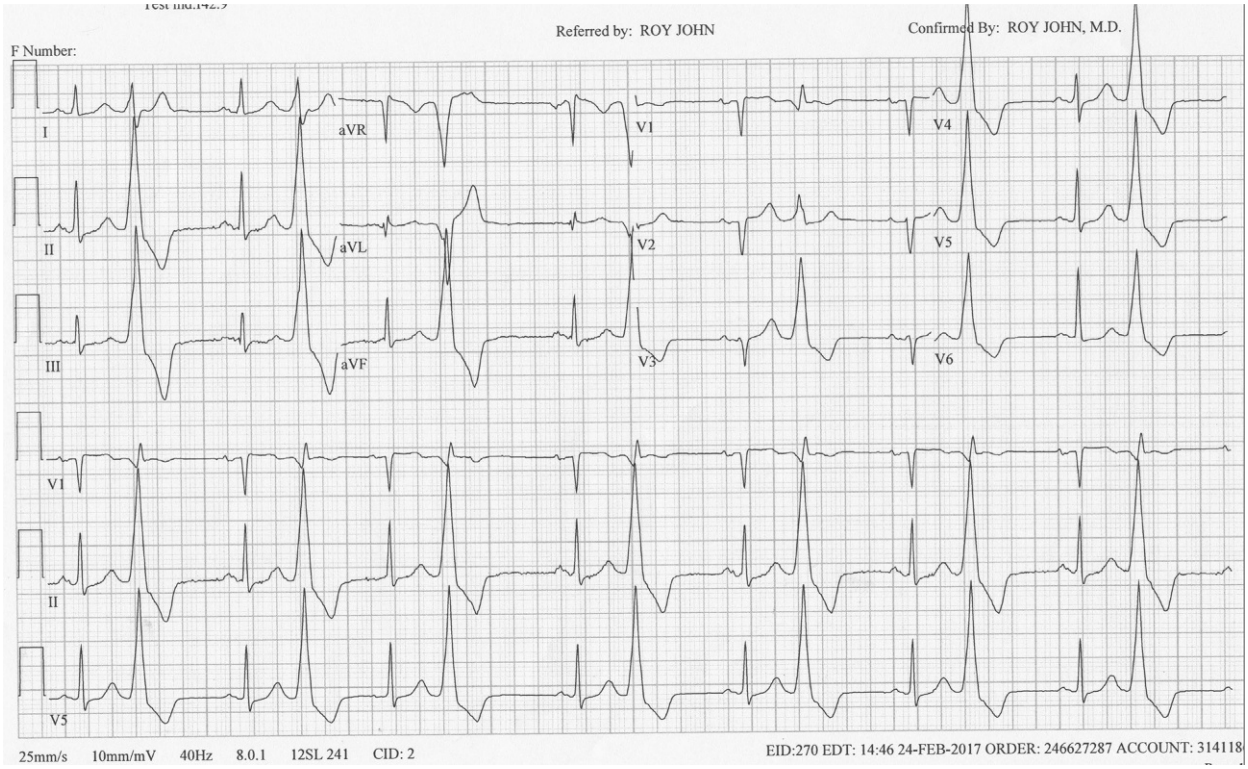

Fig. 3 Frequent MM PVC of LV outflow tract origin.

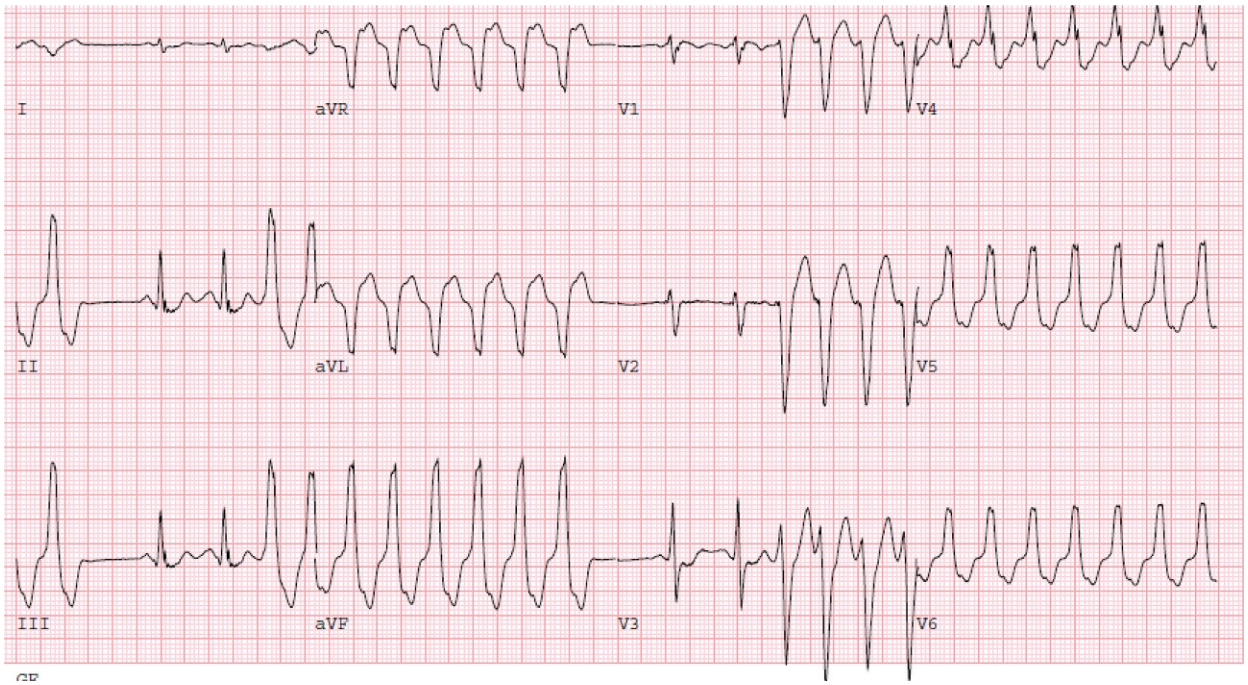

Fig. 4 A 50-year-old male with exercise-induced palpitation. During an ETT, single monomorphic PVCs were present. During recovery phase after 8 min of exercise, he developed repetitive monomorphic VT with morphology similar to PVCs at rest. The VT has a left bundle branch morphology with rightward inferior axis. Because of continued symptoms despite beta-blockers, he underwent ablation of a focus in the anterior septal aspect of the right ventricular outflow tract with suppression of the arrhythmia and no recurrence.

Idiopathic VTs are those that occur in the absence of structural heart disease. Most commonly, these are monomorphic and originate from the right ventricular outflow tract, although several other sites including the left ventricular outflow tract, papillary muscles, and perivalvular areas can give rise to these VTs. The diagnosis requires exclusion of underlying heart disease, and diseases such as ARVC and sarcoidosis that can cause VTs with similar characteristics to idiopathic VTs. Distinguishing idiopathic VT from VT with structural heart disease is of critical importance as the latter often warrants an ICD. Detection of ventricular scar on cardiac imaging can be helpful (MEMBERS WRITING COMMITTEE and MEMBERS ACCF TASK FORCE, 2010). Idiopathic monomorphic VT may be present with frequent PVCs that occur in clusters or as repetitive monomorphic VT usually during exercise (**Fig. 4**). Fascicular reentrant VT can similarly cause monomorphic VT that may respond to verapamil. Although idiopathic VTs occasionally cause syncope, sudden death is rare (Shimizu, 2009). Beta-blockers, calcium channel blockers, or catheter ablation (see what follows) are often effective in controlling symptoms.

Polymorphic VT and Resuscitated VF

Polymorphic VT generally indicates the presence of significant heart disease due to acute myocardial ischemia, cardiomyopathies, or a genetic arrhythmia syndrome (see what follows). Drugs causing QT prolongation and metabolic derangements are other causes (**Fig. 5**) (Roden, 2008). Unless a clear precipitant can be identified and corrected, an ICD is often warranted (Epstein et al., 2008). Polymorphic VT or VF complicating the first 48 h of acute myocardial infarction is associated with greater in-hospital mortality, but not greater long-term mortality for patients who survive to hospital discharge, and an ICD is not warranted (Mehta et al., 2009). Patients who are found in VF and resuscitated may have had sustained monomorphic VT or polymorphic VT as the initial arrhythmia, requiring a broader evaluation for specific diagnoses.

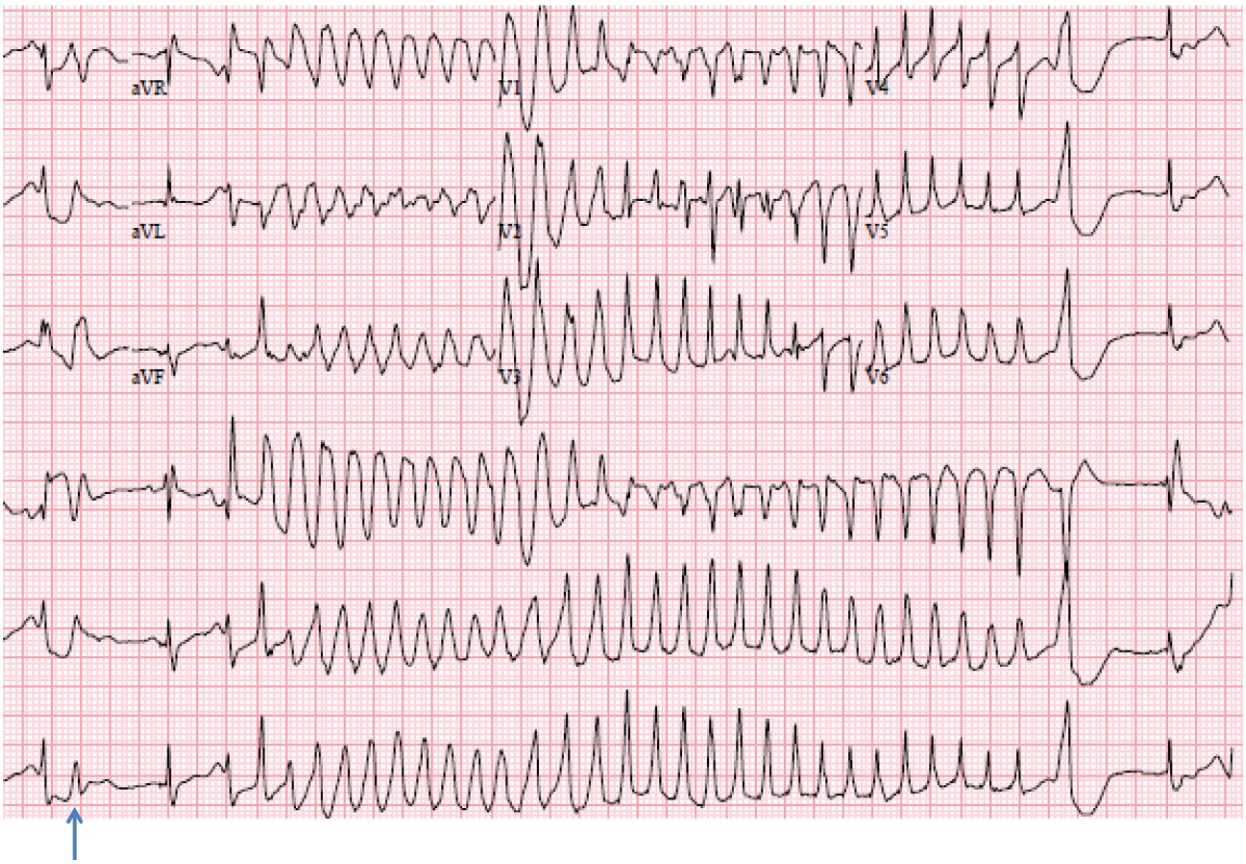

Fig. 5 A 40-year-old male developed recurrent VT following abdominal surgery. He was being treated with levofloxacin and haloperidol and had a resting ECG that showed QT prolongation at baseline. The 12-lead ECG trace in figure shows a closely coupled PVC (*arrow*) with a compensatory pause followed by a sinus beat with longer QT and PVC arising from the T wave that initiates polymorphic VT. This initiation with long short short coupling is typical of torsade de pointes VT associated with QT prolongation. In this particular case, the use of QT prolonging drugs (levafloxacin and haloperidol) on an underlying long-QT syndrome provoked the arrhythmia.

Structural Heart Disease Associated With VT

Coronary Artery Disease

Ischemic cardiomyopathy with infarct scar is the most common substrate for VT. Infarct-related monomorphic VT typically arises from regions of poorly coupled surviving myofibers within scar tissue that characteristically demonstrates slowed electrical conduction. These arrhythmia substrates related to ischemic cardiomyopathy are commonly located subendocardially but can also occur intramurally and subepicardially. A single area of infarct scar can give rise to multiple morphologies of VT (Aliot et al., 2009). Progressive fibrosis and ventricular remodeling can give rise to onset of VT late after a myocardial infarction. A small proportion (approximately 10%) of monomorphic VT in ischemic cardiomyopathy is due to automaticity or reentry involving the Purkinje system (Lopera et al., 2004).

Nonischemic Cardiomyopathy

Nonischemic cardiomyopathy (NICM) is a heterogeneous group of diseases including idiopathic cardiomyopathy, genetic LV cardiomyopathies, arrhythmogenic RV cardiomyopathy (ARVC), inflammatory disease (sarcoid heart disease, myocarditis, Chagas disease), and hypertrophic cardiomyopathy (HCM). Key differences in the VT substrate of NICM compared to ischemic cardiomyopathy include: (i) generally smaller scars with multiple reentrant VTs despite small scar; (ii) predilection for anatomical location around the valve annuli or septum; (iii) less frequent transmural scars; (iv) more frequent intramural scars; (v) extensive epicardial scarring that may occur in the presence of normal endocardium or extend beyond the region of endocardial scarring (Piers et al., 2013; Desjardins et al., 2013). Because the replacement scar of NICM is smaller and diffusely distributed especially during its early stages, patients may present with polymorphic VT or VF. As the disease progresses, scarring becomes more confluent. Sustained monomorphic VT is due to scar-mediated reentry in over 80% of patients with the remainder being focal in origin or due to bundle branch reentry.

Inherited cardiomyopathies

Genetic, familial cardiomyopathies account for 30%–40% of cases originally diagnosed as idiopathic or nonischemic dilated cardiomyopathy (Jacoby and McKenna, 2012). Some are associated with skeletal muscular dystrophy. Autosomal dominant, recessive, X-linked, and mitochondrial inheritance patterns are recognized. Mutations in genes coding for structural proteins of the nuclear lamina (lamins A and C) and the SCN5A gene are particularly associated with conduction system disease and ventricular arrhythmias in association with a cardiomyopathy (Van Tintelen et al., 2007). One study suggested that defects in the giant molecule titin maybe one of the most common causes of inherited dilated cardiomyopathy (Herman et al., 2012).

HCM is the most common genetic cardiovascular disorder occurring in 1 in 500 individuals and is a prominent cause of sudden death before the age of 35 years (Gersh et al., 2011). Most cases are due to mutations in sarcomeric proteins, but once the diagnosis is made, genotyping has a limited role in assessing sudden death risk. Sudden death can be due to polymorphic VT/VF. Risk factors include young age, nonsustained VT, failure of blood pressure to increase during exercise, recent (within 6 months) syncope, ventricular wall thickness >3 cm, and possibly the severity of LV outflow obstruction (Christiaans et al., 2011). Cardiac MRI demonstrating scar has been suggested as a high-risk profile (Chan et al., 2014). An ICD is recommended for high-risk subjects, but the specific risk profile warranting an ICD continues to be debated. Surgical myectomy is effective for relief of symptoms from outflow obstruction and has been associated with a sudden death rate of less than 1% per year (Gersh et al., 2011). The reported annual rate of sustained VT or sudden death after transcoronary ethanol septal ablation has been reported to range between 1% and 5% (Gersh et al., 2011).

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a group of genetic disorders characterized by VT arising in regions of fibrosis and/or fatty replacement of ventricular myocardium (Corrado et al., 2017). Most are due to mutations in genes involved in cell to cell adhesion proteins in desmosomes, such as plakoglobin and plakophilin. Approximately 50% has a familial transmission with an autosomal dominant inheritance. Left ventricular involvement occurs in approximately a third of cases and can predominate. The sinus rhythm ECG displays inverted T-waves in the anterior precordial leads in over 75% of patients. Sudden death and ventricular arrhythmias are often the initial presentation and frequently provoked by exercise (Corrado et al., 2017). Right ventricular monomorphic VT may be the initial manifestation of ARVC and care must be taken to differentiate it from idiopathic RV outflow VT. If a diagnosis of ARVC is confirmed, an ICD is usually warranted. Autosomal recessive forms result in cardiocutaneous syndromes such as Naxos disease and Carvajal syndromes associated with plantar and palmar hyperkeratosis.

Genetic Arrhythmia Syndromes

An increasing number of single gene mutations are being defined that cause arrhythmias and sudden death by disrupting cardiac ion channel function (channelopathies) or causing cardiomyopathy. Most are uncommon, or rare, but the first point of medical contact is often the primary care physician when an otherwise healthy individual develops arrhythmia symptoms or is seen after the sudden death of a relative. The electrocardiogram is an important screening tool, but abnormalities can be subtle and can vary from day to day in some disorders (Juntilla et al., 2012; Narayanan and Chugh, 2015). Family screening is further complicated by substantial

variability in penetrance, such that the same mutation can cause frequent arrhythmias in one individual and be asymptomatic in another. Genotyping is playing an increasing role in confirming the type of disorder, identifying other affected family members, and in some, but not all disorders, helping to assess risk of sudden death.

Abnormalities of Repolarization and the QT Interval

The *congenital long-QT syndrome* (LQTS) is due to mutations in genes encoding cardiac ion channels or their supporting proteins. The corrected QT (QTc) interval is typically prolonged to greater than 440 ms in men and 460 ms in women. Syncope or cardiac arrest due to TdP VT is the presenting symptom (**Fig. 5**). Depending on the mutation, other clinical features can include bradycardia, dysmorphic features, and deafness. Several different forms of congenital LQTS have been identified, but three groups of mutations that lead to LQT-1, LQT-2, or LQT-3 syndromes account for 90% of cases (Cerrone and Priori, 2011; Ackerman et al., 2011). The most common form, LQT-1, is due to a loss-of-function mutation in the gene encoding the alpha subunit for the slow inward rectifier potassium channel (KvLQT1). Symptoms typically occur during exertion, notably swimming. LQT2 is due to a loss-of-function mutation of the hERG gene that reduces rapid component of the delayed rectifier potassium current I_{Kr}. Arrhythmias are often triggered by surprise, such as a sudden loud noise. LQT3 is due to a mutation that increases the cardiac sodium current. Sudden death during sleep is a notable feature. Most patients with LQT-1 and LQT-2 respond to beta-blocker therapy especially of symptoms are provoked by adrenergic stimulation (Goldenberg et al., 2012). Markers of increased risk include longer QT intervals (particularly >0.5 s), female gender, and a history of syncope or cardiac arrest. Recurrent syncope despite beta-blocker therapy or high-risk profiles merit consideration of an ICD (Epstein et al., 2008). Left cardiac sympathetic denervation is effective when beta-blockers are not tolerated or when arrhythmias occur despite adequate beta blockade (Schwartz et al., 2004). Avoidance of QT prolonging drugs is critical for all patients with the LQTS including those who are genotype positive, but have normal QT intervals.

Acquired LQTS is common due to electrolyte disturbances and drugs blocking the I_{Kr} currents mediated via the KCNH2 potassium channel, the primary mechanism of action of drugs such as sotalol and dofetilide. QT prolongation with associated risk factors of hypokalemia, hypomagnesemia, bradycardia, older age, and female sex increases the risk for TdP VT. Common nonantiarrhythmic drugs include haloperidol, macrolide, and quinolone antibiotics, but a number of drugs have been implicated. Mutations affecting LQTS genes may be present in 5% of patients with drug-induced TdP and gene polymorphisms that contribute to the risk is present in another 5%–10% (Yang et al., 2002).

The *short QT syndrome* is very rare compared to the LQTS. The QTc is shorter than 0.36, and usually less than 0.3 s. The genetic abnormality causes a gain of function of the potassium channel (I_{Kr}) or reduced inward depolarizing currents. The abnormality is associated with atrial fibrillation, polymorphic VT, and sudden death (Patel et al., 2010).

The *Brugada syndrome* is diagnosed by characteristic electrocardiographic appearance with ST segment elevation in at least two of leads V1–V3 with a typical coved morphology (referred to as Type I Brugada ECG) either spontaneously or induced by administration of a sodium channel blocking drug, combined with syncope, resuscitated cardiac arrest, or a family history of the disorder (Priori et al., 2013). Syncope and sudden death are due to polymorphic VT with a predilection during sleep or acute illnesses associated with fever. There is male predilection. Gene mutations are identified in fewer than 30% of patients, and most have involved the cardiac sodium channel gene SCN5A with an autosomal dominant inheritance pattern. Abnormal conduction and fibrosis in the RV outflow tract and overlap with ARVC have been described, suggesting that the syndrome may have multiple causes (Priori et al., 2013). An ICD is indicated for individuals who have had unexplained syncope or been resuscitated from cardiac arrest. Quinidine has been shown to be effective for the prevention of recurrent ventricular arrhythmias.

Catecholaminergic Polymorphic VT

Catecholaminergic polymorphic VT (CPVT) is due to mutations in the ryanodine receptor or the sarcoplasmic calcium binding protein calsequestrin 2. These mutations result in abnormal calcium handling, and polymorphic ventricular arrhythmias that can resemble those of digitalis toxicity, for example, bi-directional VT. Patients typically present with syncope or cardiac arrest during exertion or emotional upset (Priori et al., 2013). ICD, restriction of physical activity, and beta-adrenergic blocker are the mainstays of therapy. The antiarrhythmic drugs flecainide and propafenone are effective for arrhythmia suppression (van der Werf et al., 2011). Left cardiac sympathectomy can be helpful in refractory cases (Wilde et al., 2008).

Drug Therapy for Ventricular Arrhythmias

Drugs have an important role in reducing the frequency of recurrent symptomatic arrhythmias. Beta-adrenergic blockers are the most commonly used drugs because many arrhythmias are provoked by sympathetic stimulation, and they have a favorable safety profile. However, they have limited efficacy for suppressing reentrant arrhythmias associated with structural heart disease.

Membrane active antiarrhythmic drugs that block cardiac ion channels have little role in preventing sudden death in patients with structural heart disease, but are useful for reducing symptomatic arrhythmias. The sodium channel blocking drugs such as flecainide and propafenone are occasionally considered for idiopathic VTs, but these agents should be avoided in patients with heart disease. They have negative inotropic effects, and flecainide increased mortality when given to survivors of myocardial infarction (Zipes et al., 2006). Quinidine is better tolerated hemodynamically due to its effect on action potential duration and its vasodilatory

properties that tend to offset any negative inotropy from sodium channel blockade. However, all these drugs have significant proarrhythmic effects such that use of sodium channel blockers in patients with structural heart disease is largely limited to those with an ICD. Drugs that predominantly block potassium channels (sotalol, dofetilide) prolong repolarization and are better tolerated in heart failure. However, these drugs can cause TdP VT, and the risk is likely increased in heart failure due to electrophysiologic changes that accompany myocardial hypertrophy, impaired excretion of many drugs, and diuretic-induced hypokalemia. Careful monitoring for excessive QT prolongation during initiation is required.

Both oral amiodarone and sotalol reduce ventricular and atrial arrhythmias that can lead to ICD shocks (Connolly et al., 2006). Amiodarone is most effective for control of ventricular arrhythmias but extra-cardiac toxicities (prominently thyroid, lung, liver, and neurologic) prevent long-term use in more than 20% of patients. In a recent trial in patients with LVEF $\leq$35%, amiodarone had no effect on mortality in NYHA class II heart failure, but was associated with increased mortality in class III heart failure (Bardy et al., 2005). Nevertheless, amiodarone is a reasonable consideration for patients who have had spontaneous sustained VT or VF, but who have a contraindication to or refuse to have an ICD (Zipes et al., 2006). In patients who are refractory of combination of drugs, addition of ranolazine, a slow sodium channel blocker, has shown promise in case series and small studies (Bunch et al., 2011).

Implantable Cardioverter Defibrillators

ICDs are highly effective for termination of VF or tachycardia and have been shown to improve mortality in cardiac arrest survivors and in patients at risk for sudden death due to structural heart diseases (Epstein et al., 2008). ICDs are recommended only if there is also expectation for survival of at least a year with acceptable functional capacity. The exception is in cases of patients with end-stage heart disease who are awaiting cardiac transplantation outside the hospital, or who have left bundle branch block QRS prolongation such that they are likely to have improvement in ventricular function with cardiac resynchronization therapy from a biventricular ICD.

Despite their high efficacy for termination of ventricular arrhythmias, there is considerable morbidity associated with their use. ICD shocks are painful, associated with increased mortality, mostly from deteriorating heart failure and may result in post traumatic stress disorder. With improved programming parameters and early detection of lead malfunction, the annual rate of inappropriate or unnecessary shocks due to sinus tachycardia, atrial fibrillation, nonsustained VT, or lead malfunction has dropped to approximately 2.5% (Moss et al., 2012). Dual-chamber ICDs are better than single-chamber devices in reducing inappropriate shocks (Kolb et al., 2014). ICD implantation has a 3% risk of complications, including pneumothorax, perforation, bleeding, and heart failure decompensation, but the procedure-related mortality is less than 1% (Lee et al., 2010). ICD infections require device and lead removal, with a 0.25% procedural mortality in experienced centers. Patients receiving ICDs require careful follow-up to detect arrhythmias that are predictive of heart failure deterioration and monitoring for device malfunction, and assessment of battery life. Remote-monitoring systems that allow automated and patient-triggered transmissions of ICD recordings have simplified follow-up, and enhanced early detection of arrhythmias and device malfunction. A recent meta-analysis of three randomized trials suggests reduced mortality with remote monitoring of ICD patients (Hindricks et al., 2017).

Catheter Ablation for VT

Catheter ablation is a reasonable first-line therapy for many symptomatic idiopathic VTs (Aliot et al., 2009). Most idiopathic VTs originate from a focus in the right ventricular outflow tract and ablation in this location has 80%–90% success rate for prevention of recurrence. Success rates are less well defined, but likely lower for those arising in less common locations such as the left ventricular outflow tract, aortic root, along the AV valve annuli, and from the papillary muscles. Failure of ablation is often due to inability to induce the arrhythmia for precise localization, or VT origin in a location that is inaccessible or in close proximity to a coronary artery that precludes safe ablation.

In patients with structural heart disease, catheter ablation of VT is used to reduce the frequency of symptomatic VT that triggers ICD therapies, or to control VT storms that are life-threatening (see what follows) (Aliot et al., 2009). For arrhythmias that hemodynamically stable, mapping and ablation is performed during induced VT in an attempt to terminate VT. For hemodynamically unstable VTs, the likely arrhythmia substrate is sought by identifying areas of scar and abnormal conduction. These regions are indicated by low voltage and abnormal electrograms during stable sinus or paced rhythm. In this "substrate mapping" approach, regions within the scar likely to contain the reentry circuits can then be targeted for ablation without inducing VT. Substrate mapping can also be combined with limited mapping during VT for more focal targeting of the reentry circuit. Hemodynamic support with intraaortic counterpulsation or temporary ventricular assist devices has also been used to improve the ability to map during VT.

Catheter ablation reports are largely limited to experienced centers. Procedural complications occur in approximately 3% of patients with idiopathic VT, and 6% of patients with structural heart disease, including tamponade, stroke, heart block, and, most frequently, vascular access complications (Aliot et al., 2009). Procedural mortality is rare in idiopathic VT, but ranges from 1% to 3% for patients with structural heart disease, usually due to uncontrollable ventricular arrhythmias when the procedure fails. Risks

are greater with percutaneous epicardial access and ablation, which has a 5% risk of major complications, including coronary artery injury and pericardial bleeding, that is usually self-limited, but deaths have been reported.

When antiarrhythmic drug therapy and catheter ablation fails, or is not an option, surgical cryoablation, often combined with aneurysmectomy, can be effective therapy for recurrent VT due to prior myocardial infarction and has also been used successfully in a few patients with nonischemic heart disease (Anter et al., 2011). Few centers now maintain the expertise for this therapy. Transcoronary ethanol ablation has also been used, in a small number of patients who have failed catheter ablation and drugs, with modest success (Tokuda et al., 2011).

Management of VT Storm

An electrical or ventricular arrhythmia storm is increasingly being recognized as a distinct syndrome because of specific management issues and prognostic consequences that differ from a single episode of VT. An electrical storm refers to three or more episodes of VT or VF or ICD shocks within a period of 24 h and is associated with a high mortality (Sesselberg et al., 2007). In the long-term follow-up of AVID study participants who received a secondary prevention ICD, mortality was 5.6-fold higher compared to patients who had ventricular arrhythmia unrelated to a storm (Exner et al., 2001). Scar-related VT accounts for over 80% of VT storms (Nayyar et al., 2013). Acutely administration of beta-blockers, amiodarone, and sedation combined with general anesthesia is required to suppress sympathetic tone. Reversible causes such as ischemic and electrolyte disturbance should be sought and corrected. In the event of hemodynamic deterioration, ventricular support with assist devices, or extracorporeal membrane oxygenation might be required. Catheter ablation can be life saving and effective for suppression of a storm in 70% of patients (Nayyar et al., 2013). Failure of catheter ablation is associated with a high mortality. Left cardiac sympathetic denervation and thoracic epidural anesthesia have been reported with variable success for suppressing VT storms (Bourke et al., 2010). Patients with an electrical storm should be considered for transfer to a high volume, tertiary center for expert management.

Summary

The significance of ventricular arrhythmias relate to symptoms, associated structural or genetic heart disease and the risk of sudden cardiac death. The primary focus in assessment is the determination of the risk of arrhythmic death and its prevention. In the absence of a risk of sudden death, management is primarily aimed at symptom relief. The less common role of ventricular arrhythmias as a primary initiator of ventricular dysfunction is increasingly being recognized, but prospective clinical trials are just getting under way to determine if suppression of arrhythmia will improve outcome. Although management strategies for ventricular arrhythmias have been defined for several forms of heart disease, prevention of VT-related sudden death in the rare genetic arrhythmia syndromes remain a challenge. Data from multicenter registries and rapidly accumulating genetic database will continue to provide important insights to guide managements of these uncommon but important causes of sudden arrhythmic death.

Introduction

A multidisciplinary team made up of emergency physicians, surgeons, nurses, and ancillary staff is optimal to promptly and efficiently manage severely traumatized patients throughout the continuum of care. However, as this level of resources may not be available, it is critical that a formal process of planning for all stages of care occur to best understand and utilize the resources available. This planning should lead to a structure where each member of the care team will understand their well-defined role in the management of the trauma patient.

Preparation for the Patient

Prior to arrival at the hospital, emergency medical service (EMS) providers will typically inform the receiving emergency department (ED) regarding the arrival of a significant trauma patient. While there are expectations for ACS level one trauma centers regarding specific resource requirements on selected patients, trauma centers often use a combination of physiological and mechanistic criteria in deriving their formal activation process (Markovchick and Moore, 2007). Criteria based on mechanism alone, such as pedestrian struck, motor vehicle collision with intrusion, or prolonged extrication, have mixed results and relatively poor specificity, but when used in combination with anatomical or physiological criteria, the accuracy increases (Kohn et al., 2004). Generally it is felt that some reasonable level of over triage is preferred to under triage in assembling a bedside trauma response.

Evaluation of the Patient in the Emergency Department

The ED care of the trauma patient begins with an assessment of potentially life-threatening injuries. Although every patient should have a complete and thorough evaluation, the rapidity, extent, and amount of testing are related to the mechanism, initial findings, chief complaints, age, and co-morbidities of the patient. In the primary survey, a rapid assessment of the airway, breathing, and circulation is completed. In principle, as major injuries are identified, they are treated before moving to the next part of the primary survey. In reality, however, there are often multiple concurrent interventions. The ability to perform simultaneous interventions, however, often depends on both the number and makeup of the team. What is critical is that there is a team leader who is prioritizing interventions through a systematic, clear, and consistent approach. Specific injuries that must be immediately addressed include the loss of airway integrity, inability to oxygenate or ventilate, tension pneumo- or hemo- thorax, massive external hemorrhage, and cardiac tamponade. Geriatric trauma patients present an additional challenge. Patients >60 years of age have higher mortality and complication rates in comparison with younger patients with similar injuries. Special awareness must be given to this patient population (Campbell-Furtick et al., 2016; Kuhne et al., 2005).

Airway Management

Inadequate oxygenation or ventilation can be life-threatening but is often easily reversible. The airway assessment should include patency and ability to protect the airway both at the time of evaluation and in the near future. General indications for intubation include inability to protect the airway, inability to successfully oxygenate or ventilate, airway obstruction, and Glasgow Coma score <8. Oral intubation using rapid sequence intubation (RSI) is generally the optimal approach in the ED (Mayglothling et al., 2012). While the best induction agent to use is a source of ongoing discussion, common medications currently used include propofol, ketamine, and etomidate. Succinylcholine remains the most common agent for paralysis (Brown et al., 2015). All patients undergoing RSI should have a backup plan in place in the event of a failed intubation. While rare, in cases of severe maxillofacial trauma or direct tracheal injury, cricothyrotomy may be the initial step.

Breathing

This step focuses on rapid identification of chest injuries that may impair ventilation or oxygenation. As a general rule, all significantly traumatized patients should initially be placed on supplemental oxygen while the primary survey is occurring. The examination consists of visualization for signs of splinting, disordered or paradoxical breathing or obvious deformity followed by palpation for tenderness, subcutaneous air, evidence of fractures, and finally auscultation. While clinical decision rules exist to decrease the utilization of chest radiography in the trauma patient, significantly traumatized patients, unstable patients, or patients with evidence of chest trauma should undergo radiography (Rodriguez et al., 2013). In stable patients, a chest radiograph is essential to help aid in the diagnosis of suspected chest trauma, but should not delay a needle decompression or chest tube in the unstable patient. While a supine radiograph is the initial choice at the bedside, the use of bedside ultrasound have been repeatedly shown to has higher sensitivity than plain X-ray for a pneumothorax (Alrajhi et al., 2012).

Circulation

Initial management of circulatory status begins with immediate control of any large volume of external hemorrhage. Bleeding is often controlled by compression and elevation alone. Next, initial steps include rapid assessment of pressure, pulse, and perfusion. This includes, in addition to vital signs, an evaluation of mental status, skin tone and temperature, and respiratory rate. Clinically, differences in compensation occur for different types of injuries, ages, and blunted physiological responses in the elderly. Additionally, comorbidities and medications might alter or conceal shock. On the other hand, patients who have evidence of hypotension in the prehospital setting or ED, generally defined by a systolic pressure <90mmHg, have been shown to have a greater likelihood of severe injury and mortality, and this finding must be taken extremely seriously.

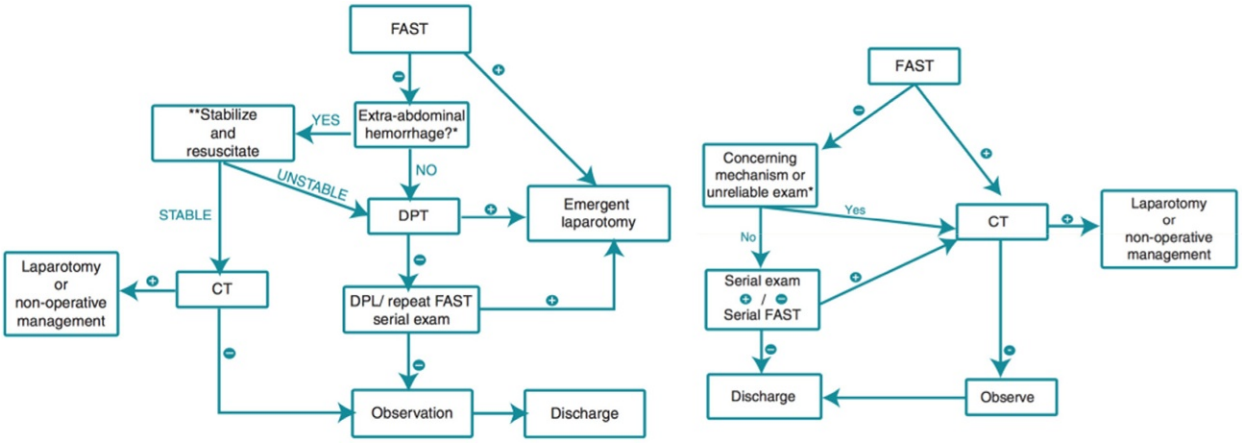
Concern for internal bleeding should lead to the establishment of intravenous access. All significantly traumatized patients should have two 14 or 16 gauge IVs placed, preferably in the antecubital fossa. If there is an inability to obtain access peripherally, it may be obtained via ultrasound guidance or central or intraosseous catheter.

The choice of fluids for resuscitation in the ED includes crystalloid and blood products (Perel et al., 2013). The goals of resuscitation are to rapidly diagnosing bleeding and critical injuries, prevent an uncompensated anaerobic state and rapidly attain definitive care for the injuries. Traditional teaching has been to initiate crystalloid resuscitation in a 20 mL/kg or 2 L bolus followed by blood products if persistent hypotension. However, there has been an ongoing trend toward less crystalloid fluid and greater use of blood products. This is consistent with an approach known as damage control resuscitation that includes avoidance of hypothermia and acidosis, permissive hypotension, hemostatic resuscitation with balanced blood products, damage control surgery, and eventual definitive care of the injury (Driessen et al., 2016). Concepts that are more germane to ED resuscitation include permissive hypotension (or limited resuscitation) and hemostatic resuscitation with balanced blood products. Permissive hypotension may be indicated in the patient who has not had definitive management or control of their bleeding. Rather than aggressive fluid or blood resuscitation to normotension, treatment goals in the nonhead-injured patient are systolic blood pressures around 90mmHg, although some studies have aimed lower. While animal trials clearly showed benefit to this approach, human studies have been more limited and less definitive (Mapstone et al., 2003). Although one large randomized controlled trial has shown this to be an effective and improved approach, some methodological concerns with the paper and other studies inability to find real benefit from the approach (although no worse outcomes) keep this from becoming a clear standard (Bickell et al., 1994; Dutton et al., 2002). Massive transfusion protocols that provide hemostatic resuscitation with balanced products may ameliorate some of coagulopathies associated with trauma, provide an improved method of resuscitation and ultimately lead to better patient outcomes. When massive transfusions are used, they should generally be adopted by a formal hospital policy agreed upon with department of surgery, blood bank, and the emergency department (Borgman et al., 2007; Hallet et al., 2013; Holcomb et al., 2011, 2015).

A focused abdominal sonography in trauma (FAST) examination should be performed on patients as an adjunct to the assessment of circulation. A FAST is a four view, directed ultrasound (US) examination to identify fluid within the abdomen and pericardial sac. The presence or absence of free intra-abdominal, intrathoracic, or intrapelvic hemorrhage diagnosed by ultrasound may direct the immediate management of trauma patients. Pericardial effusions or tamponade can be readily identified. The major limitation of US is that it shows fluid in the abdomen, but does not identify the degree of bleeding.

A FAST is primarily used in blunt trauma, however, a finding of free intraperitoneal fluid in penetrating trauma has an extremely high positive predictive value for an operative lesion, and should prompt strong consideration of an urgent laparotomy or

laparoscopy. A negative FAST, on the other hand, cannot rule out an intra-abdominal injury (Quinn and Sinert, 2011). An algorithm in the succeeding text shows one common way that ultrasound is incorporated into early clinical decision-making.



FAST for stable and unstable abdominal penetrating trauma patients. From Legome and Shockley, *Trauma a comprehensive emergency medicine approach.*2011 Chapter 13. Cambridge University Press.

Disability

The next step in the evaluation is an assessment of their neurological status. A rapid and focused examination should be performed with specific concentration on the Glasgow Coma score (see **Table 1**), pupillary examination and gross motor function.

While the initial score is important in planning treatment decisions and prioritizations, serial examinations are critical in following the course of the patient. Since many traumatized patients may have injuries or intoxicants that may make scoring difficult, emphasis on the motor score, with or without the pupillary examination has been found to have similar sensitivity in diagnosing intracranial injury (Brown et al., 2014; Chou et al., 2017; Kupas et al., 2016). The motor evaluation generally involves making sure the patient has no obvious focal weakness or evidence of spinal cord injury

Secondary Survey

After assessment and securing of the airway, breathing, and circulation, a complete head to toe physical exam should be performed.

Traumatic Head Injuries

Head trauma includes the full spectrum of injury, from superficial contusions, abrasions, and lacerations of the soft tissues, to injuries deep within the skull. The vast majority of patients who present to the ED with head trauma have blunt or closed head injury. Most injured patients fall into a category of mild traumatic brain injury category, with a GCS of 13–15 (CDC, 2016). Approximately 5%–10% of patients with mild traumatic brain injury will have an abnormal head CT scan, but only 0.5%–1.0% will require acute neurosurgical intervention for intracranial injury (Bazarian et al., 2003; Jagoda et al., 2009).

There are five distinct injuries frequently described: epidural hematomas, subdural hematoma, subarachnoid hemorrhages, diffuse axonal injury, and intraparenchymal hemorrhage. They may be seen in isolation or as a combination of injuries. An epidural hematoma is the result of an arterial injury, most commonly the middle meningeal artery secondary to direct force. Classically, it is thought that individuals might have a rapid deterioration following a "lucid interval," although this is neither specific nor highly sensitive. On CT imaging, a hyperdense lens-shaped or lenticular lesion is seen adjacent to the cranium. Frequently, emergent neurosurgical evacuation of the hematoma is indicated. Rarely, in exigent circumstance in underresourced areas, a burr hole in the emergency department may be performed. A subdural hematoma occurs when the bridging veins become disrupted. This typically

Table 1 Glasgow coma scoring

	2 = extension	1 = none
	1 = none	

causes a slow progressive bleed. Nevertheless, these types of bleeds can still cause severe neurological deterioration and often may have greater parenchymal injury and require neurosurgical intervention. On CT imaging, this hematoma is seen as a crescent-shaped hyperdense lesion. A subarachnoid hemorrhage (SAH) consists of bleeding in the subarachnoid space and can occur either in isolation or in combination with other intracranial bleeds. Intraparenchymal hemorrhages are caused by the disruption of the small intraparenchymal vessels secondary to shearing forces and management will vary based on size and location. Any type of intracranial bleed that causes increased intracranial pressure (ICP) can lead to cerebral herniation. Physical exam signs of herniation, include fixation and or dilation of one or both pupils, low GCS, and posturing (**Figs 1–4**).

Head-injured patients can exhibit significant agitation and combativeness, which can be dangerous and increase ICP. Additionally, they often have taken intoxicants that may obscure or worsen the injury (Easter et al., 2013). Clinical judgment must be used in

Fig. 1 Subarachnoid hemorrhage.

Fig. 2 Subdural hemorrhage.

Fig. 3 Epidural hemorrhage.

Fig. 4 Intraparenchymal hemorrhage.

deciding whether to chemically restrain these patients, especially prior to CT, or perform intubation and airway management due to a high concern for intracranial injury. One must also consider other reversible non traumatic causes of agitation, e.g., hypoglycemia, hypoxemia, hypotension, hypothermia, toxicology, and infection.

Despite many attempts, no specific medical treatments have been shown to improve outcome in severe brain injury. Although the full benefits are unclear, one very reasonable option is to follow the precepts of the National Brain Trauma Foundation (BrainTrauma.org), which appears to show benefit in mortality and morbidity of severely injured patients (Gupta et al., 2016). Much of the benefit, however, may be due to inpatient management including appropriate invasive monitoring and surgery. Much of the ED options are level 2 or 3, centered on the discussion of what remains unproved, e.g., hypothermia and hyperosmolar

Table 2 CT clinical decision rules

	Canadian CT head rule	*New Orleans criteria*

Risk factors identified	GCS <15 at 2 h post injury Suspected skull fracture ≥2 episodes of vomiting Age ≥65	Headache Vomiting Age >60 Persistent amnesia Visible trauma above the clavicles seizure
Exclusion criteria	Age <16 years Blood thinners Seizure after injury	
Sensitivity for injuries requiring neurosurgical intervention	100%	100%

therapy, or what to avoid, e.g., prolonged hyperventilation. In the ED, appropriate steps for the patient may include avoiding hypotension and hypoxia and consideration of antiepileptic drugs to avoid early post traumatic seizure and include basic maneuvers to decrease ICP such as raising the head of the bed to 30 degrees, providing adequate sedation and analgesia and treating fever. Early neurosurgical consultation is important to assist with decision making for surgical decompression, fluid drainage or intracranial monitoring.

One of the most common types of injuries to manage is the patient with a mild traumatic brain injury and a GCS of 15. Several clinical decision instruments have been created to help the clinician (Bouida et al., 2013; Haydel et al., 2000; Servadei et al., 2001; Stiell et al., 2001). A comparison of the two decision rules can be seen in **Table 2**. Performing advanced imaging on all patients in order to diagnose the few critical injuries is expensive and time-consuming and may cause eventual harm from the delayed effects of radiation. The authors recommend familiarity with a validated CT head injury rule or the American College of Emergency Physician head injury guidelines when caring for patients with a GCS of 13–15 with the loss of consciousness or posttraumatic amnesia.

Approximately one-third of adults older than 65 years of age will experience a fall each year (Hausdorff et al., 2001). Frequently, these individuals are on anticoagulant or antiplatelet agents. No well-validated decision rules comprehensively target patients with mild traumatic brain injury who are on these medications. The authors recommend that if resources are available, ED patients on an anticoagulant or antiplatelet agent, excluding aspirin, with more than minimal traumatic head injury should receive a CT scan of the brain to evaluate for an intracranial injury (Nishijima et al., 2012; Reddy et al., 2014; van den Brand et al., 2017). Trauma centers should create some protocol by which these individuals with evidence of intracranial injury have reversal of their agent rapidly to prevent further intracranial bleeding.

Neck Injuries

Penetrating and blunt trauma to the neck can cause a variety of injuries to vascular, respiratory, gastrointestinal, and neurological structures. The emergency physician must carefully assess for respiratory distress, stridor, bleeding, subcutaneous emphysema, expanding hematoma, or tracheal shift. Hard signs of significant vascular injury include a pulsatile hematoma, hemorrhagic shock, carotid bruit, absent pulse, or focal neurological deficit and generally are indications for early operative intervention. Early rapid sequence intubation should be strongly considered in someone with any acute airway concern or respiratory distress. In evaluating penetrating trauma, the neck has been divided into three anatomical zones not only to help clinicians both identify structures in each region, but also to help guide management. Zone one initiates at the clavicles and extends to the cricoid cartilage and includes all vital structures in this region. Injury to this area has been found to have the highest rate of mortality secondary to the difficulty in gaining access to these structures during surgical exploration (Kendall et al., 1998). Zone two is identified by the cricoid cartilage to the angle of the mandible. The platysma muscle covers most vital structures, and if intact, local wound care is all that is needed for patient management. Penetrating injuries deep to the platysma in zone two used to be routinely explored in the OR; however, currently, a stable patient may undergo CT imaging first, which may obviate further surgical intervention. Bronchoscopy and endoscopy are occasional needed if there is a high clinical suspicion for an aerodigestive injury. Zone three begins at the angle of the mandible and extends to the base of the skull. Vascular injuries are usually visualized clinically or by CT imaging, aerodigestive and neurological injuries can be more difficult to diagnose as CT imaging may appear normal.

Musculoskeletal Disorders of the Spine

The spine is a complex bony structure providing stability and protection. Injuries to the spine range from minor soft tissue contusions without structural abnormality to bony fractures, severed ligaments, and nerve damage. In a cooperative patient immobilized in a cervical collar, it should be loosened momentarily to evaluate for midline tenderness. With assistance, the patient

should be logrolled and the back should be examined for bruising, penetrating trauma, bony deformities, or bony step-offs. In an effort to maintain sensitivity for serious injury and reduce unnecessary imaging, two decision rules, NEXUS low-risk criteria (NLC) and the Canadian cervical spine rule (CCR) have been developed and should be a part of every emergency of physician's practice (Hoffman et al., 2000). Imaging the spine with CT is becoming the preferred modality to evaluate for bony pathology after blunt trauma. The benefits of improved sensitivity and specificity and better resolution should be balanced by greater radiation exposure and very small but real risk of radiation induced head and neck cancers.

Chest Trauma

Rapid evaluation and management is critical for the patient with significant chest trauma. The most severe and early life-threatening chest injury is blunt aortic injury, which is typically associated with frontal or nearside high-speed motor vehicle crashes with the lack of restraints and significant intrusion (Demetriades et al., 2008; LoCicero and Mattox, 1989). Other immediate life-threatening injuries of the chest include upper airway obstruction, tension pneumothorax, large hemothorax, flail chest, open chest wound, and cardiac tamponade. A tension pneumothorax occurs when air in the pleural space pushes the heart and mediastinal structures to the opposite side, compressing the contralateral lung and impeding venous return to the heart. Clinically, there will be absent breath sounds on the affected side and deviation of the trachea away from the side of injury. The treatment is immediate decompression of the affected side using a large bore, 14–16 gauge needle. Based on recent literature, the fourth or fifth intercostal space in the mid or anterior axillary line is probably the most effective area to insert the catheter. In order to ensure success, the needle and catheter must be appropriately long enough to penetrate into the pleural space (Akoglu et al., 2013; Inaba et al., 2015; Laan et al., 2016). With a successful decompression, one should hear a rush of air. While a needle thoracostomy will relieve a tension pneumothorax, a chest tube must still be placed afterward to evacuate air from the pleural space. Mechanisms of tension or pneumothorax without tension include laceration of the pleura or lung by a fractured rib, alveolar rupture from the compression of the chest against a closed glottis, or penetrating wound in the thorax. As noted earlier, a bedside ultrasound has very high accuracy for diagnosing pneumothorax (Soldati et al., 2008). The management of a significant pneumothorax includes tube thoracostomy placed to water seal. A small pneumothorax or one seen on CT alone may sometimes be managed expectantly. A hemothorax is the accumulation of blood in the pleural space. Bleeding can be from lacerations of the lung parenchyma or injuries from the intercostal vessels. The amount and rapidity of bleeding that occurs determines the management of such an injury. With a large hemothorax, patients will likely have diminished breath sounds and are often hypoxic and hemodynamically unstable. The treatment for a hemothorax includes evacuating the blood from the chest via a chest tube. In large or ongoing hemothoraxes, repletion of blood to restore intravascular volume may be required. This can be done using blood transfusions, but if available, an autotransfuser can be used to collect blood from the chest injury, filter it, and then reinfuse it back to the patient (Rhee et al., 2015). General indications for thoracotomy include an initial output of more than 1500 cc of blood from the chest tube or continued bleeding of greater than 200 cc/h over 4 h with hemodynamic instability; however, the decision may be altered by other injuries or co-morbidities and must ultimately be made by the surgeon who will be operating on the patient.

A flail chest occurs when there are three or more adjacent ribs fractured in more than one location. There is usually an associated pulmonary contusion. Physiologically, when a patient inspires, the flail portion may cave in. On expiration, the positive pleural pressure will cause the segment to flail out, causing a paradoxical motion of the chest and irregular respirations. This leads to significant pain during breathing and may result in both hypoxia and tachypnea. Management includes appropriate analgesia the including consideration of intercostal nerve blocks. In severe cases, intubation and mechanical ventilation may be required.

Traumatic cardiac tamponade is caused by the accumulation of blood in the pericardial sac from blunt or penetrating trauma. This accumulation of blood leads to decreased filling of the heart during diastole and decreased cardiac output. The classic signs and symptoms include muffled heart sounds, hypotension, and distended neck veins. Rarely are all three findings present (Stolz et al., 2017). The most sensitive test for pericardial effusion is by evaluating for pericardial blood using bedside ultrasound. Immediate treatment is fluid loading with a plan for needle decompression, a pericardial window or an emergent thoracotomy depending on both etiology and stability.

One of the most challenging situations for an emergency physician is the decision to perform a ED resuscitative thoracotomy for a trauma patient who presents in cardiac arrest or periarrest. In the appropriate setting, this procedure can be lifesaving by releasing of pericardial tamponade, controlling cardiac and great vessel wounds and cross clamping the aorta to limit hemorrhage and improve central perfusion. There are few scenarios where an ED thoracotomy for blunt thoracic injury is indicated. Time to loss of vital signs, surgery capabilities, and comorbidities all play a role in the decision. Patients with penetrating thoracic trauma, however, should receive a resuscitative thoracotomy if they had documented the loss of vital signs within 5–10 min of ED arrival, lose vital signs in the ED, or are hemodynamically unstable and found to have pericardial tamponade on ultrasound. In a study published in 2004, it was found that resuscitative thoracotomy to be futile in blunt trauma with prehospital CPR longer than 5 min and in patients with penetrating trauma with prehospital CPR duration greater than 15 min (Capote et al., 2013; Dennis et al., 2016; Powell et al., 2004; Slessor and Hunter, 2015).

Other potential serious but not immediately life-threatening injuries to the chest include fractures to the ribs and sternum. Fractures occur at the site of direct blows or at their posterior weak point as a result of compressive forces. Thoracic cage injuries usually result in significant pleuritic pain, localized tenderness and splinting, crepitus, ecchymosis, atelectasis, and increased risk for pneumonia. Multiple rib fractures interfere directly with the mechanics of ventilation. Fracture fragments may penetrate the pleura and lungs and result in pneumothorax and hemothorax. Adequate pain control should be provided, and patients should be instructed to perform incentive spirometry or take regular deep breaths throughout the day.

Sternal fractures are not particularly dangerous per se, but should be taken seriously and a search for underlying cardiac and pulmonary trauma should be undertaken. Generally, an isolated nondisplaced sternal fracture without associated findings requires analgesia alone (Sadaba et al., 2000).

Abdominal Trauma

Abdominal trauma, both blunt and penetrating, is a common cause of traumatic morbidity and mortality. Concerning findings for a patient with abdominal trauma include pain or tenderness and ecchymoses and abrasions on the abdominal wall. Increasing abdominal distention may be a marker of ongoing intraperitoneal bleeding. Physical examination is limited in its ability to identify the presence or absence of intraabdominal injury. Further diagnostic testing if frequently indicated despite minimal clinical findings in the patient with multiple or distracting injuries or limited examination due to comorbidities, age, or mental status.

The management of a patient with intra-abdominal trauma can be divided into the stable and unstable patient. The unstable patient should generally proceed immediately to the operating room without further diagnostic testing if any of the following are present: evisceration, gross blood per rectum, hematemesis, diaphragmatic injury, peritonitis, and hemodynamic instability with evidence of intraperitoneal injury on bedside ultrasound FAST examination or diagnostic peritoneal lavage (Stengel et al., 2001, 2005). For stable patient, there is further discrimination based on etiology. In the stable blunt trauma patient, diagnostic imaging is the mainstay of evaluation. FAST is recommended for all blunt trauma patients with a significant mechanism and is a may be a useful, if not well proved, screening tool (Stengel et al., 2001; Dammers et al., 2017). The FAST technique includes obtaining images of four standard views: right upper quadrant (Morrison pouch), subxiphoid, left upper quadrant, and suprapubic (pouch of Douglas) (**Figs 5** and **6**).

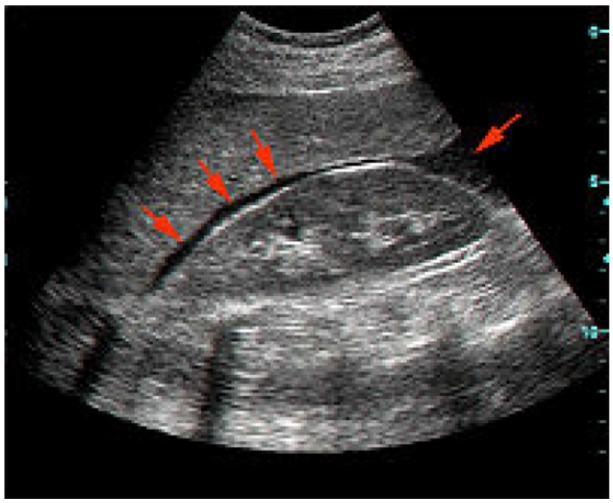

Fig. 5 Fluid in Morrisons pouch.

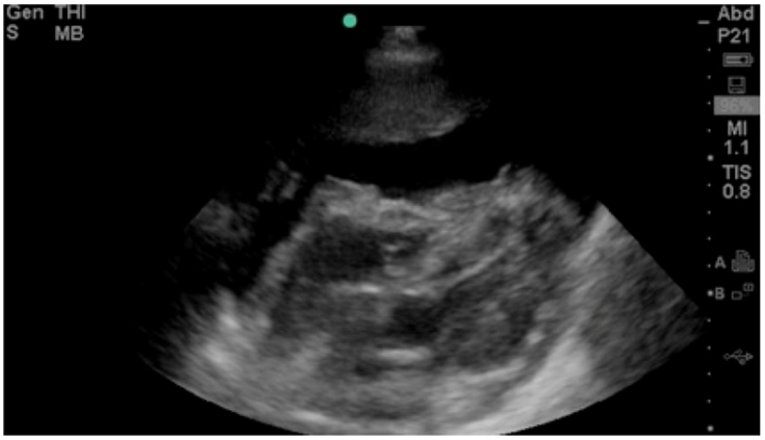

Fig. 6 Pericardial effusion.

Abdominal and pelvic CT is the standard diagnostic imaging modality for a blunt stable patient with concern for intraabdominal injury. CT provides excellent detail of solid organ and retroperitoneal injuries. Its performance in diagnosing hollow viscus injuries continues to improve. Because of the accuracy and detail of CT images, nonoperative management of solid organ injury is commonly and safely performed.

The initial treatment of patients with blunt abdominal trauma and finding of intr-abdominal injury includes fluid resuscitation, blood and product transfusion, and surgical consultation for possible operative repair. Indications for operative intervention include hemodynamic instability, diaphragmatic injury, and hollow viscus injury. Although high-grade spleen and liver injuries once routinely underwent surgery, the use of angiography with embolization has become more common (Schimmer et al., 2016).

In penetrating abdominal trauma, the most common mechanism is from knives and guns. In either case, hollow viscous injuries are more common than solid organ. Stab wounds, as opposed to gunshot wounds, tend to follow the track of the wound and have more predictability. In addition to wounds involving the abdominal cavity, injuries to the thoracic cavity must also be considered in patients with thoracoabdominal stab wounds or any gunshot wound. A FAST examination can be used in penetrating trauma as a diagnostic tool; specificity and positive predictive values are in the 90th percentile range for therapeutic laparotomy if ultrasound reveals free fluid. However, if the US is negative, further observation or testing is required (Quinn and Sinert, 2011).

Treatment options for penetrating abdominal trauma include observation, serial examinations, CT scanning, local wound exploration, laparoscopy, laparotomy, or combination of the aforementioned. Specific benefits and risks are dependent on multiple factors including comorbidities and associated injuries, mental status, and local resources.

Conclusion

The care of the severely injured trauma patient is complex. A multidisciplinary team made up of individuals familiar with the care of trauma patients is essential to promptly evaluate and treat these patients. Trauma patients may have suffered significant injuries despite normal vital signs and an initially benign physical examination. The appropriate use of imaging studies can promptly diagnose injuries and guide management and disposition. The placement of patients where they can receive definitive care, whether in the operating room, the ICU, or another facility, is a high priority in trauma care.

Introduction

Environmental medicine is a new field of practice and research (Reis and Roman, 2007; Calderón-Gareidueñas et al., 2016) dedicated to a worldwide, comprehensive and translational study of the effects of the environment on humans.

Environmental medicine uses four approaches in the study of environmental factors affecting people: by agents (such as chemicals), by milieu (such as water, air), by population (in children, in elderly), and by pathology (Calderón-Gareidueñas et al., 2016).

The World Health Organization defines air pollution as the "contamination of the indoor or outdoor environment by any chemical, physical, or biological agent that modifies the natural characteristics of the atmosphere" (Calderón-Gareidueñas et al., 2016).

Atmospheric pollution is a major problem of environmental health with an increasing concern for populations (Brunekreef and Holgate, 2002). It is well known that exposure to ambient air pollution increases mortality and morbidity, and shortens life expectancy (Feigin et al., 2016a; Murray and Lopez, 2013; Feigin et al., 2015). Moreover, cardiovascular disease, stroke, and cancer are the leading causes of death worldwide (Lozano et al., 2012) while their association with environmental air pollution increases (Henrotin et al., 2010; Mostafic et al., 2012; Danaei et al., 2005).

Previous studies observed a tight temporal association between exposure to air pollutants, stroke onset, and death induced by stroke (Feigin et al., 2016a; Shah et al., 2015). Results in the literature indicate controversies due to several factors as well as heterogeneous mechanisms, causes and stroke subtypes, various vascular risk factors, stroke triggers (Feigin et al., 2016a; Guiraud et al., 2010), and numerous air pollutants.

The present review focuses on the relationship between air pollution and stroke onset.

Toxicity of Air Pollutants

With the Industrial Revolution starting in the late 18th century, regional air pollution increased dramatically. The combustion of fossil fuels (coal, coke, gasoline, and diesel) needed to power industries, transportation, and housing, became responsible for the release of several contaminants into the atmosphere. However, the mix of air pollutants changed in the 20th century: oil and diesel replaced coal, and became the major energy sources used in expanding cities in Western countries. By the 1960s and 1970s, two major types of pollution were recognized: the London-type smog, linked to fossil fuel combustion and emissions of particulate matter (PM), and the Los Angeles-type smog, or photochemical oxidant pollution, the main compounds of which are ozone and secondary aerosols (sulfates and nitric oxides) (Calderón-Gareidueñas et al., 2016; Zhang and Samet, 2015).

Air pollution is a complex mixture of gases and particles whose composition varies geographically and temporally. Population-weighted annual average concentrations of particle mass with aerodynamic diameter less than 2.5 μm ($PM_{2.5}$) and ozone are the two indicators used to quantify exposure to air pollution. $PM_{2.5}$ is the most consistent and robust predictor of mortality in studies of long-term exposure (Platt et al., 2014; Suissa et al., 2013).

Nowadays, only some atmospheric air pollutants are monitored, depending on their health effects and the regulations in place in different countries; these include ozone, sulfur dioxide, carbon monoxide, nitrogen dioxide, lead, and PM (**Fig. 1**). However, other air contaminants should also be measured because they include highly neurotoxic chemicals, such as volatile organic compounds, benzene, formaldehyde, tri- and tetrachloroethylene, toluene and polycyclic aromatic hydrocarbons, and metals such as lead, manganese, iron, mercury, arsenic, cadmium, and cobalt (Calderón-Gareidueñas et al., 2016; Kyle et al., 2001).

Airborne PM varies in its physical and chemical composition, source and particle size, and includes PM_{10} (particles >2.5 μm but <10 μm), $PM_{2.5}$ (fine particles >100 nm but <2.5 μm), and ultrafine PM (UFPM < 100 nm) and their components, the key pollutants found in European cities (Calderón-Gareidueñas et al., 2016).

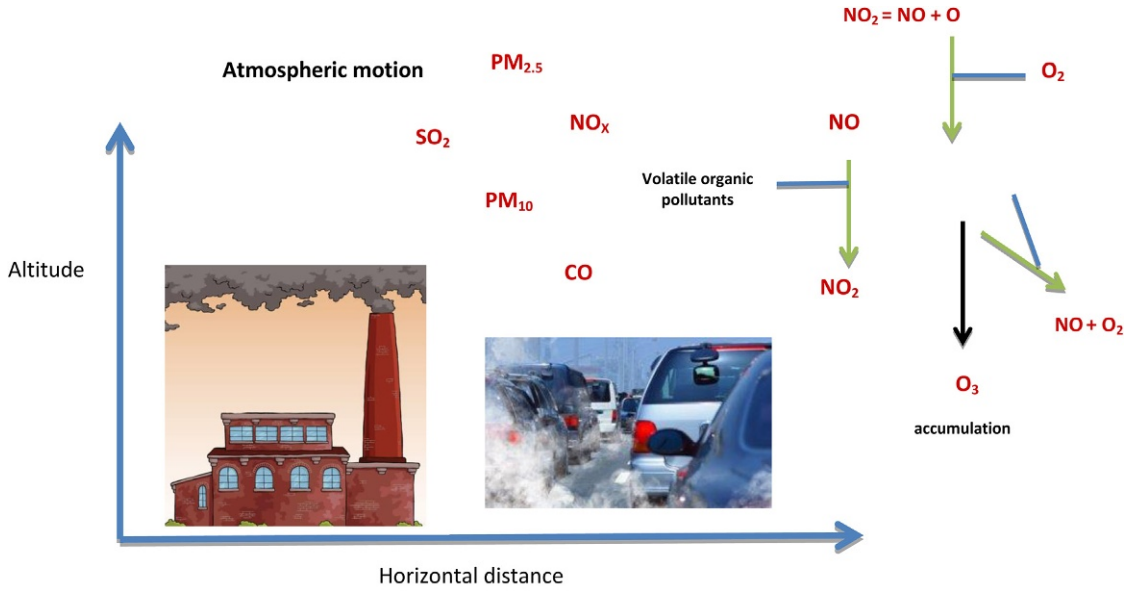

Fig. 1 The most toxic of atmospheric pollutants.

The neurological effects associated with sustained exposures to concentrations of outdoor air pollutants above the current international air quality standards are now an important issue for the millions of people living in megacities around the world. Moreover, the increasing worldwide warming is modifying all these conditions (Feigin et al., 2016a; Murray and Lopez, 2013; Feigin et al., 2015; Lozano et al., 2012).

Air Pollutants and Stroke Onset

Consequences have been clearly described first in terms of cardiovascular mortality and morbidity (Stafoggia et al., 2014; Samet et al., 2000; Katsouyanni et al., 1997; Pönkä and Virtanen, 1996; Hong et al., 2002; Maheswaran and Elliott, 2003; Kan et al., 2003).

With time, the association was confirmed mainly from long-term population-based studies. One of the first to evaluate stroke subtypes was conducted in the population-based stroke registry of Dijon, France, between March 1994 and December 2004 (Henrotin et al., 2007). The register recorded all first-ever strokes among residents of the medium-size town of Dijon (150 000 inhabitants), using standard stroke diagnostic criteria. Pollutant concentrations as sulfur dioxide (SO_2), carbon monoxide (CO), nitrogen oxides (NO_2), ozone (O_3), and PM_{10} were measured by three meteorological stations every hour.

A bi-directional case-crossover design was used to examine the association between air pollutant and stroke onset. The conditional logistic regression model included the meteorological parameters (temperature, relative humidity), influenza epidemics and holidays. The authors collected 493 large artery infarcts, 397 small artery infarcts, 530 cardioembolic infarcts, 67 indeterminate infarcts, 371 transient ischemic attacks, and 220 hemorrhagic strokes. For single-pollutant and for a 10 $\mu g/m^3$ increase of O_3 exposure, a positive associations was observed only in men, over 40 years of age, between ischemic stroke occurrence and O_3 levels with a 1-day lag. No significant association was observed for hemorrhagic stroke. In two-pollutant models, the effects of O_3 remained significant after each of the other pollutants was included in the model, in particular for PM_{10}. A significant association was observed for ischemic strokes of large arteries and for transient ischemic attacks (**Table 1**).

Moreover, the authors found an exposure-response relation between O_3 exposure and ischemic stroke. An increase in association in men with several cardiovascular risk factors (smoker, diabetes, dyslipidemia, and hypertension) was also observed (**Fig. 2**).

This work was associated with a second one adding stroke and myocardial ischemia (Henrotin et al., 2010). This work (Henrotin et al., 2010) evaluated the effects of short-term exposure to O_3 on ischemic heart and cerebrovascular disease, downtown the city of Dijon (150 000 inhabitants) for a long period from 2001 to 2007.

Table 1 Odds ratios describing the relationship between ischemic stroke subtypes (TOAST classification) and pollutant concentrations from 1-day lag, Dijon stroke registry (France), (Henrotin et al., 2007) from 1994 to 2004

	Ischemic stroke: large arteries (n = 262)[†]		*Ischemic stroke: lacunar (n = 193)*[‡]		*Ischemic stroke: cardioembolic (n = 208)*[§]		*Ischemic stroke: transient ischemic attacks (n = 172)*[¶]

ORa: adjusted odds ratio for minimum temperature (1-day lag), maximum relative humidity (1-day lag), holidays (0-day lag), influenza epidemics (0-day lag), and for an increase of 10 μg/m^3 of pollutant.

*PM_{10}: data from 1999 to 2004:

[†]$n = 145$;

[‡]$n = 93$;

[§]$n = 92$;

[¶]$n = 80$

Daily levels of urban O_3 pollution, the incidence of first-ever, recurrent, fatal and nonfatal ischemic cerebrovascular events (ICVE) and myocardial infarction (MI), were correlated using a case-crossover design. The authors analyzed 1574 ICVE and 913 MI that occurred in Dijon, France from 2001 to 2007. SO_2, NO_2, Co, and PM_{10} were used to create bi-pollutant models. Using the adjusted OR, the effects of O_3 exposure were calculated for every 10 μg/m^3 increase in pollutants in multivariate logistic models adjusted for temperature, humidity, flu outbreaks and holidays.

The authors found a significant association between exposure to O_3 and recurrent ICVE with a 3-day lag (OR = 1.115; 95% CI 1.027 to 1.209). The direction and magnitude of the association between exposure to O_3 and recurrent MI were similar but not statistically significant. For incident events, the authors detected only a nonsignificant association for ICVE with a 2-day lag (OR = 1.041; 95% CI 0.996 to 1.089). In the subgroup analysis for ICVE, the authors observed an increased association with cardiovascular risk factors (OR = 1.523; 95% CI 1.149 to 2.018). For MI, the authors found an association with O_3 when hypercholesterolemia was present (OR = 1.111; 95% CI 1.020 to 1.211) and the association became stronger with the number of cardiovascular risk factors. The authors found a marked dose-response relationship.

The authors concluded that recurrent ICVE and MI could be triggered by short-term exposure to even low levels of O_3, especially among subjects with severe vascular risk factors, defining the population at risk, information useful for practitioners.

Recent metaanalyses suggest a tight temporal association between exposure to air pollution and admission to hospital for stroke or death induced by stroke (Shah et al., 2015).

Recent and worldwide data: three recent metaanalyses explored long-term exposure to air pollution and stroke events and found suggestive evidence of an association between long-term exposure to fine particles and stroke incidence. Stafoggia et al. (2014) found suggestive evidence of an association between $PM_{2,5}$ exposure and stroke incidence in European countries, although the main estimate did not reach statistical significance. A 5-μg/m^3 increase in annual $PM_{2,5}$ exposure was associated with 19% increased risk of incident stroke [hazard ratio (HR) = 1.19, 95% CI: 0.88 to 1.62]. Similar findings were obtained for PM_{10}. The results were robust to adjustment for an extensive list of cardiovascular risk factors and noise coexposure. The association with $PM_{2,5}$ was apparent in subgroups, among those ≥60 years of age (HR = 1.40, 95% CI: 1.05 to 1.87), among never-smokers (HR = 1.74, 95% CI: 1.06 to 2.88), and among participants with $PM_{2,5}$ exposure <25 μg/m^3 (HR = 1.33, 95% CI: 1.01 to 1.77).

Scheers et al. (2015) published a metaanalysis including 20 studies from three different continents. The authors found a pooled HR for each 10-μg/m^3 increment in PM_{10} at 1.061 (95% CI: 1.018 to 1.105) and 1.080 (95% CI: 0.992 to 1.177) for overall stroke events and stroke mortality, respectively. A stratified analysis by continent revealed that the association between stroke and long-term PM_{10} exposure was positive in North America (HR = 1.062 [95% CI: 1.015 to 1.110] and Europe (HR = 1.057 [95% CI: 0.973 to 1148]), but studies in Asia (HR = 1.010 [95% CI: 0.885 to 1.153]) showed a high degree of heterogeneity. In regard to exposure to $PM_{2,5}$ (Europe and North America combined), the HR for a 5-μg/m^3 increment was 1.064 (95% CI: 1.021 to 1.109) and 1.125 (95% CI: 1.007 to 1.256) for stroke events and mortality, respectively.

Environmental air pollution emerges as a leading risk factor for stroke worldwide (Feigin et al., 2016a).

Feigin et al. (2016a) used data from the Global Burden of Disease Study 2013 to estimate the population-attributable fraction (PAF) of stroke-related disability-adjusted life-years (DALYs) associated with potentially modifiable environmental, occupational, behavioral, physiological, and metabolic risk factors in different age and sex groups worldwide and in high-income countries and low-income and middle-income countries, from 1990 to 2013.

They evaluated attributable DALYs for 17 risk factors (air pollution and environmental, dietary, physical activity, tobacco smoke, and physiological) and six clusters of risk factors by use of three inputs: risk factor exposure, relative risks and the theoretical minimum risk exposure level. For most risk factors, they synthesized data for exposure with a Bayesian metaregression method or spatial-temporal Gaussian process regression.

Globally, 29.2% (95% UI 28.2–29.6) of the burden of stroke was attributed to air pollution.

In consequence, air pollution has emerged as a significant contributor to global stroke burden, especially in low-income and middle-income countries, and therefore reducing exposure to air pollution should be one of the main priorities to reduce stroke burden in these countries (Feigin et al., 2016a).

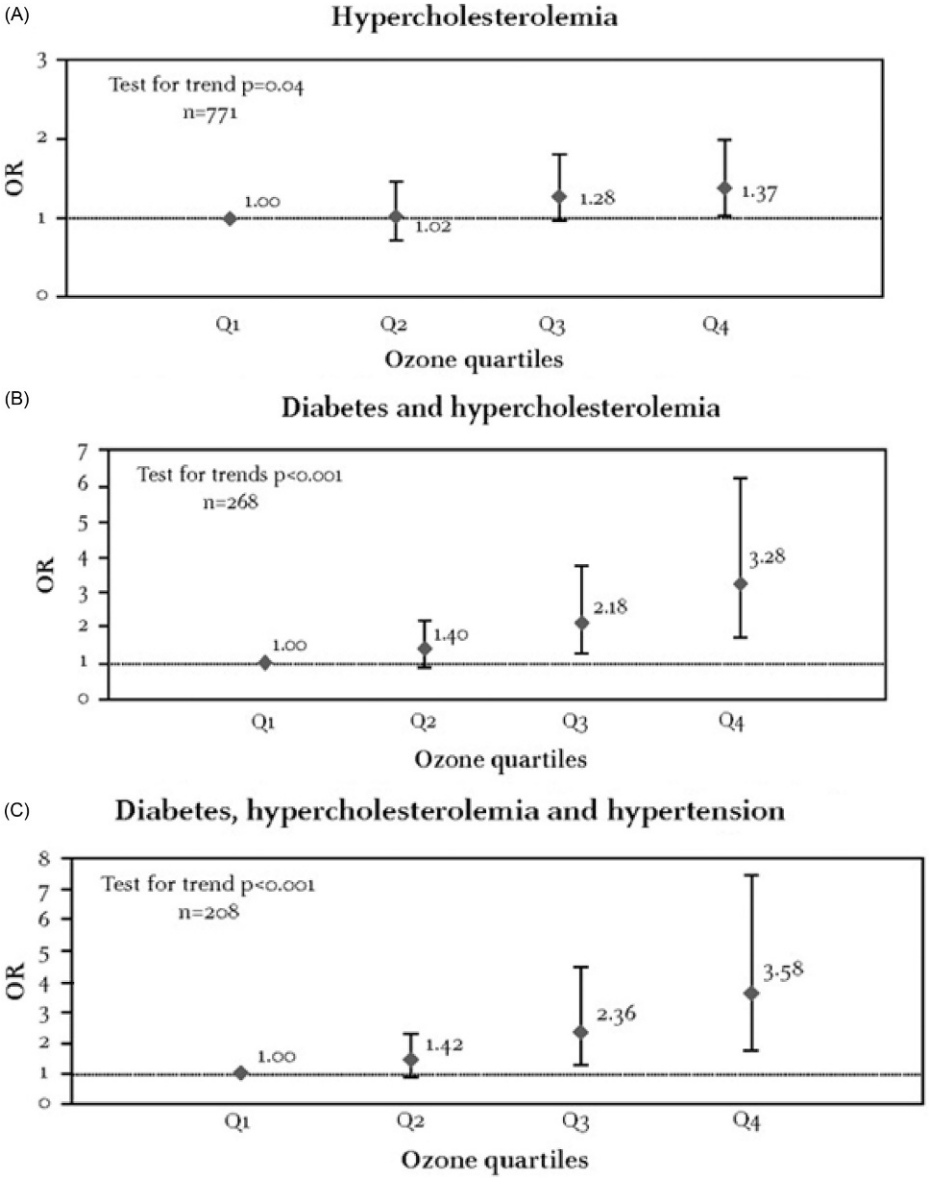

Fig. 2 Dose-response relationship (with 1-day lag) between O_3 quartiles and ischemic events according to the number of vascular risk factors (Henrotin et al., 2007).

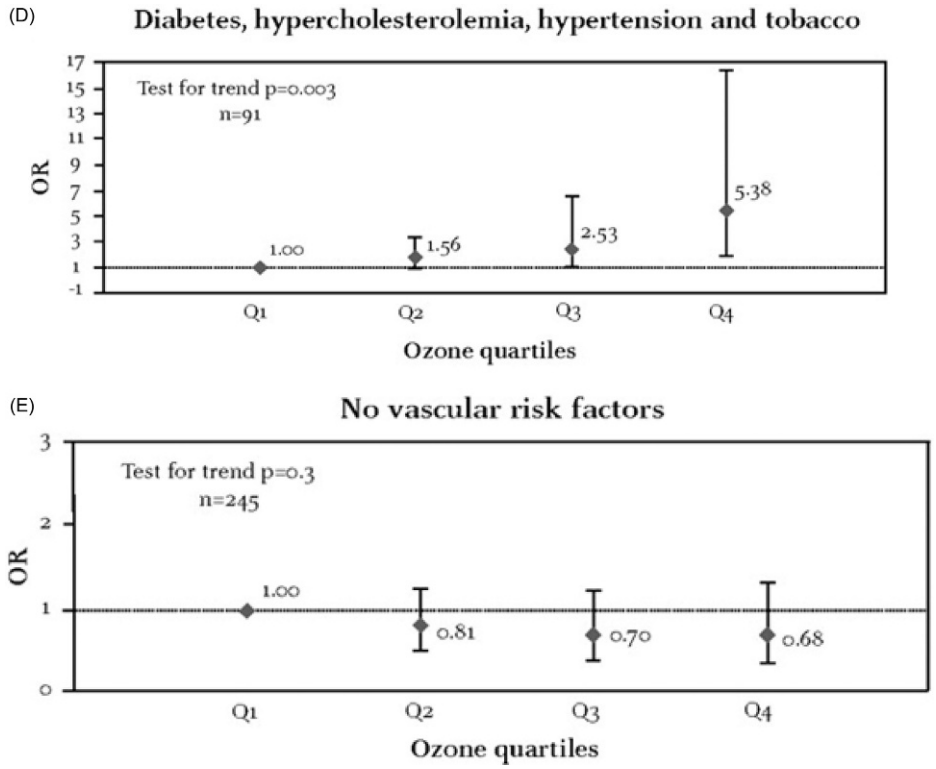

Fig. 2, Cont'd

Mechanisms of Stroke Induced by Air Pollutants

The mechanisms by which air pollution has multiple systemic effects in human, in particularly on the cardiovascular system and the brain, are not fully elucidated.

The penetration routes of the air pollutants into the body are questioned (Peters et al., 2006). Although pulmonary inhalation is the obvious exposure route, the nose-to-brain way has become of great interest. Translocation to the brain of very small particles via the olfactory epithelium in the nose has been demonstrated through experimental rodent studies with engineered nanoparticles (carbon nanoparticle, copper oxide nanoparticles, silver nanoparticles) and metals (e.g., radiolabeled isotope Mn, manganese oxide and chloride) (Heusinkveld et al., 2016; Brenneman et al., 2000).

Evidence of brain inflammatory processes and increase of biomarkers of inflammation come from laboratory studies in the brain of mice (Calderón-Gareidueñas et al., 2016; Campbell et al., 2005; Gerlofs-Nijland et al., 2010) and rats (Gerlofs-Nijland et al., 2010; Patchin et al., 2016). Levels of pro-inflammatory cytokines (IL-1a, TNF-a) and immune-related transcription factor NF-kB were increased in the brain tissue of mice exposed to small particles (Particulate Matter) compared with control animals. Using a nose-only exposure in rats, diesel engine exhaust and silver nanoparticles were able to induce inflammation in different brain regions (Patchin et al., 2016) or microglial activation (Patchin et al., 2016).

Inhalation of ozone has led to the lung-brain axis hypothesis: experimental data showed that cerebral microglia remains activated 24 h after an ozone exposure in rats, suggesting an on-going signal from lung to brain. Circulating cytokine-independent signals present in serum, that elevate the brain pro-inflammatory background, would be involved. Do these signals also act on the vascular endothelium? The release of vasoactive factors into the systemic circulation after pollutant inhalation (notably ozone), has been assessed in mice; these factors are capable of impairing vaso-relaxation to ACh via a CD36-dependent signaling mechanism. The presence of circulating factors appears to be independent of CD36 and inflammatory responses (Robertson et al., 2013). PM pulmonary inhalation also provokes a release locally and into the systemic circulation of bioactive species, pro-oxidative (i.e., reactive oxygen species) or inflammatory (i.e., cytokines such as IL-6 and TNF), and endothelins (vasoactive hormones) (Franchini and Mannuci, 2011).

Other pathophysiological hypotheses have been suggested to explain the increased risk of cardiovascular diseases including effects on: blood coagulation, endothelial dysfunction, systemic inflammatory responses, acute arterial vasoconstriction (Wellenius et al., 2013; Newman et al., 2015), or a propensity for arrhythmia (Link et al., 2013; Newby et al., 2015).

More recent works demonstrate that increase of air pollutant concentrations are significantly associated with methylation on tissue factors, interferon-gamma and interleukin 6 hypermethylation, toll-like receptor 2 hypomethylation and intercellular adhesion molecule 1.

A possible consequence is that changes in methylation may affect some genes (Bind et al., 2016). DNA methylation may be a consequence of air pollution.

Secondly, DNA methylation may be modulated by temperature and relative humidity. Therefore, temperature and relative humidity may also interact with air pollution and produce stronger adverse events (Bind et al., 2016).

Third, air pollution is associated with a shortening of telomere length. Telomere can be considered as the cell memory of exposure to oxidative stress and inflammation, and environmental air pollution is an important determinant of telomere length; these facts might provide new ways to understand the relationship between air pollution and cerebral vascular disease and will help to promote new preventive strategies (Haycock et al., 2014).

Conclusion

Ambient air pollution contributes substantially to the global burden of disease. (Calderón-Gareidueñas et al., 2016; Feigin et al., 2016a). This reflects both demographic and epidemiologic trends and increasing levels of air pollution in low- and middle-income countries, portending increasing burdens absent major reductions in level of ambient $PM_{2.5}$ (Feigin et al., 2016a). The challenges for future reductions in the burden of disease attributable to air pollution are considerable. Exposure to ambient air pollution and its associated burden of disease can potentially be lowered for entire populations via policy action at the national and subnational levels without the need to modify individual behaviors (Feigin et al., 2016a; Feigin et al., 2016b).

For the first time, Feigin et al. (2016a) showed that air pollution has emerged as one of the leading contributors to stroke burden worldwide, accounting for almost 30% of stroke-related disability-adjusted life-years. Moreover, global warming is modifying the impact of air pollution on stroke. Together, these considerations provide a global imperative for action to control and reduce air pollution (Feigin et al., 2016b).

Introduction

The environmental neurology approach to diseases is systematic, holistic, and translational. This approach exists practically as long as the field of medicine itself; indeed, Hippocrates (460-370 BC) emphasized environmental factors in his "*Treaty of Water, Air, and Places*" (Hippocrates et al., 2003; Le Moal and Reis, 2011). To define the environment, we adopt words of Albert Einstein "*The environment is everything that isn't me.*" To this notion, we introduce the concept of environmental risk factors. A systematic approach should explore the multiple dimensions of these factors: their nature, sources, carriers, spatiotemporal characteristics, interactions (multicausality), and finally, health impacts (protective/harmless/noxious) (Reis and Roman, 2007).

In the case of stroke, for example, environmental risk factors can be classified in three categories depending on the nature of the risk (or agent), the milieu conveying the agent (e.g., air, water, soil, food), and the affected population (with a special interest for vulnerable population like children, pregnant women, and seniors). Environmental risk factors also have a geographical or spatial dimension (e.g., altitude, climate). In the previous chapter, we investigated the association of air pollution and stroke, as a well-recognized example of the role of the milieu. Here, we will study environmental factors from another point of view: their nature, be it physical, chemical, or biological. The impact of sociopsychological factors like stress and human interaction is considered elsewhere in this book.

Stroke, as a leading cause of mortality and morbidity around the world, is a major issue in the public health field. Neuroepidemiological studies currently underway are exploring all possible causes and risk factors for stroke. Among them, "new" environmental risk factors are being studied, taking into account the famous Hill's criteria (Hill, 1965). Nowadays, "biologically plausible" mechanisms have gained in importance and should be investigated extensively (Causality Meeting, 2016). In this chapter, we focus on some of the major targets and mechanisms underlying the risk factors involved in stroke: the heart, the vascular endothelium (container), and the blood (content).

Physical Environmental Risk Factors for Stroke

Environmental and Occupational Noise

The concern of the biomedical community and regulatory bodies about the cardiovascular impact of noise developed slowly in the 1980s. The health effects on adults of exposure to transport noise (road, air, and rail) were demonstrated first for hypertension and ischemic heart disease (Babisch, 2006). Addressing the impact of noise in stroke is quite recent; the first relevant publications appeared in 2010. Now, several years later, there is an agreement to consider that traffic noise is the second most important environmental risk factor for stroke in urban societies, after air pollution (Münzel et al., 2017). Comparative burden of disease studies have shown that environmental noise is ranked second in terms of disability-adjusted life years lost (DALYs) in Europe (Stansfeld, 2015). Several recent reviews have addressed the epidemiological evidences (Belojević and Paunović, 2016; Basner et al., 2015; Münzel et al., 2014) and the various potential mechanisms involved (Stokholm et al., 2013).

The impact of occupational noise exposure is controversial. No association has been shown between occupational noise exposure and stroke; risk has largely been attributed to lifestyle (Stokholm et al., 2013). However, in 2015 the Swedish Council

 https://doi.org/10.1016/B978-0-12-809657-4.64111-X

on Health Technology Assessment stated that people who are exposed to noise at work "*more often develop stroke over time than people who are not subjected to noise at work*" (Swedish Council on Health Technology Assessment, 2015).

The sources of environmental noise include trains, road traffic, and aircraft. The impact of noise depends on the nature of the source (rail < road < air) (Münzel et al., 2014), its time of occurrence (daytime versus night), its physical characteristics (e.g., intensity, chronic versus acute), and the exposed population (vulnerability related to age).

Epidemiological studies about the relation between noise and stroke are sometimes contradictory. Long-term air pollution increases stroke risk, regardless of concomitant noise pollution (Hoffmann et al., 2015). Moreover, some epidemiological studies have found no associations; for instance, a study in a Danish cohort of individuals aged 50–64 and another in the Swiss national cohort (Huss et al., 2010) found no association between aircraft noise and stroke mortality (cited in Floud et al., 2013). However, in a Danish cohort of 57,053 people, residential road traffic noise exposure was associated with a higher risk (HR) for ischemic stroke: 14% HR per 10 dB higher exposure to noise for all participants and 27% HR per 10 dB higher exposure to noise for participants above 64.5 years. Stroke risk increased in a dose-dependent manner at exposure levels of 60 dB among the oldest participants (Sørensen et al., 2011). A cross-sectional study from six European countries used data from the Hypertension and Environmental Noise near Airports study including 4712 participants with 276 stroke cases. Members of the study population lived near the major airports in London, Amsterdam, Stockholm, Milan, Berlin, and Athens. An association between nighttime average aircraft noise and heart disease/stroke was found (after adjustment for sociodemographic confounders) for participants who had lived in the same place for ≥20 years (odds ratio: 1.25 per 10 dB). The association between 24-h average road traffic noise level and heart disease/stroke was also significant although the association was not adjusted for air pollution (Floud et al., 2013). In a population of 3.6 million people living near Heathrow airport, a study based on hospital admissions and mortality showed a significant excess risk of stroke and CVD. The noise intensity was investigated by grouping daytime aircraft noise and road noise into six categories from ≤51 to >63 dB in increments of 3 dB and nighttime aircraft noise into 5 dB categories (≤50, >50–55, and >55 dB). In multiple adjustment models, the relative risk (RR) for stroke was 1.24 for daytime aircraft noise (>63 dB v ≤51 dB) and 1.29 for nighttime noise (>55 dB v ≤50 dB). The RR of mortality was similar to those for hospital admissions at the higher noise levels. Thus the RR is the highest with high daytime noise levels and nighttime aircraft noise (Hansell et al., 2013). An 2009 U.S. study, recruited 6 million seniors (>65 years) living near one of the 89 largest airports to evaluate the association between airport-related noise and the risk of hospital admission for CVD and heart failure. Despite the study's methodological limitations, a statistically significant association between exposure to aircraft noise and risk of hospitalization for CVDs was shown (Correia et al., 2013).

One explanation of these contradictory results is related to the difficulty to deal with two major confounders, "indoor noise" produced by the neighborhood in a residential area (Tenaillon et al., 2015) and environmental (ambiant) air pollution, as this pollution shares many common sources with environmental noise (Tétreault et al., 2013).

The pathological effects of noise involve many functions: sleep disruption, disautonomic perturbations (e.g., increases of blood pressure and heart rate), stress reactions (release of stress hormone), and increase of oxidative stress, which in turn may result in vascular endothelial dysfunction and arterial hypertension (Münzel et al., 2014).

Altitude, Air Planes, and Erythropoietin

Altitude is a geophysiological condition which impacts all living organisms. Physical and climatological characteristics, decrease of available oxygen, lower atmospheric pressure and lower temperature, more frequent winds, and a larger exposure to solar radiation are determining Life. These conditions vary according to the altitude, low (<2000 m), moderate (2000–2999 m), high (3000–4999 m), and extreme (>5000 m) and also to the latitude.

Adaptation to high-altitude challenges the brain. As hypoxemia can be deleterious for cellular adaptation and survival, the regulatory homeostasis favors all mechanisms related to convective oxygen transport (cardiovascular, respiratory, and hematopoietic functions) that will counteract a possible cellular hypoxia (Petousi and Robbins, 2014). The first adaptative mechanism is hyperventilation which has the quickest effect. An increase in cerebral blood flow up to 31% of values measured at sea level can occur in few days (3–7) of a subject's transition to high altitudes. The return to sea-level base values follows, depending on the degree of the hypoxic stimulus and on the cerebrovascular sensitivity to hypoxia and carbon dioxide (Bor-Seng-Shu et al., 2012). The heart function is modified typically with tachycardia and no change in stroke volume but a slight temporary blood pressure increase. After a few days of adaptation, cardiac output returns to normal (Naeije, 2010). Supply of oxygen is favored by an adaptative release at the tissue level and an increase of the red blood cells (RBC) production. The direct effect of production is an increase of the hematocrit and the blood viscosity. Other factors contribute also to increased coagulability: namely, increases in platelets (mean platelet volume), erythrocyte aggregability, and plasma viscosity (Bor-Seng-Shu et al., 2012; Alper et al., 2009). Protection of the cellular metabolism involves hypoxia-inducible factor(s) (HIFs) (capable of inducing protective metabolites and proteins) (Kumar and Choi, 2015) as well as chemical agents such as nitric oxide (NO), carbon monoxide (CO), eicosanoid products, oxygen-derived free radicals, endothelins, K^+, H^+, and adenosine (Bor-Seng-Shu et al., 2012), and an control of key enzymes (Na-, K-ATPase). Oxygen-derived free radicals and H_2O_2, NO, and oxidized glutathione are the signaling messengers that make Na-, K-ATPase systems "oxygen-sensitive" (Bogdanova et al., 2016).

The number of exposed people varies; thus, more than 140 million people around the globe reside at high altitude (≥3000 m) in Africa (Ethiopian Highlands; Kilimanjaro), Asia (Himalaya Mountains and Tibet), and the American continents (Rocky Mountains and Andes Mountain Range) (Ronen et al., 2014). Two types of population must be distinguished, the native

mountain-born and the sea-level-born people who need to adapt. In fact, altitude stress and its neuro-cardiovascular consequences differ markedly depending on the cerebrovascular regulation and on the capability to adapt.

Impairment of the cerebral autoregulation is the major risk for travelers who rapidly reach altitudes above 2500 m. They may manifest several syndromes: altitude headache (HAH), acute mountain sickness (AMS), high-altitude cerebral oedema (HACO/HACE), and high-altitude pulmonary oedema (HAPO/HAPE) (Wilson et al., 2009; Yanamandra et al., 2014). Although rarely reported, acute stroke is possible during short-term visits to high-altitude regions (Chan et al., 2012). Thus, stroke or stroke-like episodes have been described in association with high altitude for the first time in 1895 (Szawarski et al., 2012). Differential diagnosis must consider cerebral venous thrombosis (Chan et al., 2012) and HACO, which can mimic stroke and provoke deficits; those resolve with the resolution of cerebral oedema (Yanamandra et al., 2014). In case of stroke, an asymptomatic patent foramen ovale should be excluded (Szawarski et al., 2012; Murdoch, 2015).

High-altitude impact during long-term stays (e.g., several months) has been investigated notably among soldiers stationed in the Himalaya Mountains. The relative risk for stroke above altitudes of 3000 m is significantly increased (Jha et al., 2002) by a factor as high as 10-fold (Niaz and Nayyar, 2003); extreme altitudes (over 5000 m) are associated with a 30-fold risk of spontaneous vascular thrombosis (Anand et al., 2001). Polycythaemia is clearly a major risk factor.

The effect of altitude on native populations is a different issue. Several publications (USA, Kashmir, South America, India) have shown that the incident stroke is lower in these populations compared to populations living at sea-level and lower altitudes (Mahajan et al., 2004), to the contrary of a Saudi Arabian study (al Tahan et al., 1998). A study in Cuzco (Peru), located at 3380 m above sea level, showed a crude prevalence ratio of 6.47 per 1000 (cohort of 3246 individuals). The prevalence risk was related to age, polycythemia, high alcohol consumption, residence's area (down-town versus suburban), blood pressure, and increased hematocrit. These two last parameters may vary following altitude (Jaillard et al., 1995). In the large Swiss National Cohort, a clear dose–response relationship between lifetime altitude exposure and mortality was demonstrated: mortality from coronary heart disease and stroke decreased with increases of altitude (22% per 1000 m and 12% per 1000 m, respectively). Switzerland has specific characteristics: altitude of residence between 200 and 2000 m and minimal changes in geographic latitude. However, this study has several limitations related to the methodology and the impossibility of collecting data on individual risk factors (e.g., atherosclerosis). The conclusion, that being born at higher altitude (although the range is not clear) has a protective effect, needs a clear confirmation. Possible physiological explanations could be found: solar radiation and Vit D, less air pollution, genetics, etc. (Faeh et al., 2009). In any case, these studies point to acclimatization, which differs from adaptation, as it is a long-term population-based process, involving both genetic and gene-environmental mechanisms (Petousi and Robbins, 2014). All populations living at high altitude do not show the same acclimatization. For example, at similar high altitudes, Tibetans have significantly lower hemoglobin concentrations than their Andean or Han Chinese immigrants counterparts (Petousi and Robbins, 2014); they also suffer less from chronic mountain sickness (CMS). Stroke risks should likewise be different.

The stroke's risk related to altitude during airplane travel (potentially associated with hypobaric and hypoxic conditions) is low even in patients with symptomatic carotid occlusion (Reynolds et al., 2014). Recently, the incidental risk has been reevaluated; it is now estimated to be 1 stroke in 35,000 flights (Álvarez-Velasco et al., 2016), or less than one in a million passengers (Humaidan et al., 2016). There is no difference between short-haul (<2 h) and long-haul flights (>2 h) for healthy individuals (Reynolds et al., 2014).

The role of blood erythropoietin (Epo) in the adaptation to high-altitude hypoxic exposure in humans led to its use as medicine and doping in competitive sports (Robinson et al., 2006). Epo causes a rise in red cell mass accompanied by elevated hemoglobin concentrations and hematocrit. Its side effects have been documented (Pope et al., 2014).

Climatic and Meteorological Variables: Seasonality and Temperature

In the context of an increasing interest in the health effects of climate change, climate and weather characteristics are now scrutinized as possible risk factors for stroke.

When considering the admission to a hospital or the mortality, the incidence of ischemic stroke seems to be cyclic during the year. Seasonality has been observed worldwide (Chen et al., 2013a) although some studies have reported no seasonality; for instance, a study in Taiwan (Lee et al., 2008). Furthermore, the peak season differs for different countries. In Japan (Takashima stroke register), an excess of ischemic stroke fatality occurs in spring followed by winter (after adjusting for age, gender); the rates are more when compared to during summer (Turin et al., 2009). In the United States, an epidemiological study conducted in the VA hospitals showed that the peak occurrence for ischemic stroke was mid-May, with the lowest occurrence in early December. The authors emphasized that, "Neither the region (i.e., climate) nor the race of the patient substantially modified the seasonal trend" (Oberg et al., 2000). In Melbourne, Australia, ischemic stroke occurrence was significantly higher during spring than summer (incidence rate ratio (IRR) 1.14) (Mao et al., 2015). Peak season was in winter in Hong Kong (Goggins et al., 2012) and in August in Eastern Turkey, with the lowest occurrence in spring (Anlar et al., 2002). Diverse explanations for these patterns have been proposed, including lunar patterns (Mao et al., 2015), rainfalls related to the El Niño Southern Pacific Oscillation (ENSO) (Kintoki Mbala et al., 2016), and in the case of global mortality, relations to air pollution, and meteorological variables (Qian et al., 2010).

The question addressed in a 2010 paper, "What is it with weather and stroke?" (McArthur et al., 2010), remains crucial. Most evidences suggest that cold and hot apparent temperatures (which consider both air temperature and humidity) are associated with stroke mortality, as shown by the eight Large Chinese Cities Study (Chen et al., 2013a). The results show a U-shaped relationship,

with increased risk at extreme high or low temperatures. The potential effect of cold temperature might last more than 2 weeks in contrast to the more immediate effect of hot temperature. However, the burden of stroke mortality is different. In the six large Chinese cities (2007–2013) the stroke burden was caused by cold temperature and was higher in males and seniors (Yang et al., 2016). The same patterns are known for mortality by all causes (Gasparrini et al., 2015; Medina-Ramón et al., 2006). Several subpopulations are particularly susceptible to temperature extremes, for example, patients with atrial fibrillation (Medina-Ramón et al., 2006). The relationship between heat waves and stroke has been addressed by several articles. Heat waves have a strong adverse effect on stroke mortality with an excess mortality of 6%–52% (Chen et al., 2015). A multicity case-only analysis of 50 U.S. cities showed that extremely high-temperature days posed a higher relative stroke mortality risk compared to pneumonia and CVD (Medina-Ramón et al., 2006). Heat wave (with a 2-day lag) is significantly associated with the risk of hospitalization for stroke (odds ratio [OR] 1.173) with more significance for men and over 80 years, in a study conducted in Pennsylvania (Ha et al., 2014). A Chinese study pointed to a clear spatial pattern of stroke mortality during heat waves; the risk was higher in rural areas (Luhe district) compared to the urban area of Nanjing, probably because of a higher vulnerability of the populations; this vulnerability seems to be linked to the socioeconomic level, the air condition availability, the population's age, and the medical facilities' access (Chen et al., 2015). Obviously, further works are needed to assess the real impact of weather (characterized by temperature, humidity, sunshine duration, etc.) on stroke subtypes and pathogenesis (hemorrhagic/stroke, lacunar/atherothrombotic/cardioembolic).

Biological explanations involve complex interactions between endothelium function, vasomotricity, blood pressure, brain demand for oxygen, and change of the quality of blood components (thrombogenic factors) and blood properties (viscosity). For example, cold induces vasoconstriction while heat promotes dilation (Chen et al., 2013a).

Geomagnetic Storms Can Trigger Stroke: A New Environmental Risk Factor

The term "geomagnetic activity" concerns natural variations in the geomagnetic field (Feigin et al., 2014). A geomagnetic storm is a temporary disturbance of the Earth's magnetosphere caused by a solar wind shock wave and/or cloud of magnetic field which interacts with the Earth's magnetic field; these are prominent during the solar maximum phase of the solar cycle. The sun has a solar cycle which averages 11 years in length; at the end of each cycle, the polar magnetic field of the sun reverses. During these cycles, there is an increased solar activity, which generally has a peak in the middle of the solar cycle. During the solar maximun, the increase of sunspots and the solar storms produce the emission of large quantities of electromagnetic and particle radiation. Theses events are known to disrupt technology such as power grids, magnetic compasses, damage satellite microchips and disturb radio and radar transmissions. The solar minimum refers to a relatively low solar activity. This takes place 5–6 years after the solar maximum.

Levels of geomagnetic activity are commonly measured by the Ap Index. Of all locales, Auckland (Feigin et al., 2014) had the most data collected during the solar maximum years, and even had high levels of geomagnetic activity including during 2003, a solar minimum year. Oxfordshire and Melbourne (Feigin et al., 2014) had data collected during solar minimum years only. However, the solar minimum that Oxfordshire data was collected for had high levels of geomagnetic activity. Melbourne (Feigin et al., 2014) data were collected during times of very low geomagnetic activity. The remaining Northern hemisphere cities had more data collected during solar minimum years: Dijon (8 out of the 11 years) and Northern Sweden (12 of the 20 years). Perth had data collected equally over solar maxima and solar minima. It is important to note that data collection for the four cities overlapped during very low levels of geomagnetic activity (1996–1997).

Overall, geomagnetic storms (Ap Index 60+) were associated with a 19% increase in the risk of stroke occurrence (95% CI, 11%–27%). The triggering effect of geomagnetic storms was most evident across the combined group of all strokes in those aged <65 years, increasing stroke risk by $>50\%$: moderate geomagnetic storms (60–99 Ap Index) were associated with a 27% (95% CI, 8%–48%) increased risk of stroke occurrence, strong geomagnetic storms (100–149 Ap Index) with a 52% (95% CI, 19%–92%) increased risk, and severe/extreme geomagnetic storms (Ap Index 150+) with a 52% (95% CI, 19%–94%) increased risk (test for trend, $P<2\times10-16$) (Feigin et al., 2014). It will be necessary to evaluate the impact of geomagnetic storm on air pollutants, as some researchers have suggested that they may act together on the brain and cardiovascular system (Stoupel, 2016).

Ionizing Radiations

Ionizing radiation has been assessed as a risk factor for cardiovascular diseases and sometimes for stroke in different exposure's conditions: military usage, occupational settings (miners), medical treatment (radiotherapy), and rarely in usual environmental exposures. Epidemiological studies have confirmed the radiation-related risks of noncancer outcomes. The stroke risk is related to the conditions of the exposure and the dose of the irradiation.

High doses of radiation for specific solid tumors and/or blood cancers (lymphoma and leukemia), involving specific targets (brain, neck, heart) are associated with an excess of deaths (heart disease or stroke) and an increased risk of stroke (Shimizu et al., 2010). The same risk has been shown among atomic bomb survivors in the Japanese survivors cohort. Radiation exposure has been associated with some CVDs, hypertension (Ozasa et al., 2017), and the risk of atherosclerotic disorders (Ozasa et al., 2016).

The cardiovascular effect of lower-radiation doses has recently been assessed. A systematic review and meta-analysis dedicated to moderate- and low-level whole-body ionizing radiation exposure found an excess population risks (mortality) and for all circulatory diseases. The risk ranged from 2.5%/Sv for France to 8.5%/Sv for Russia (Little et al., 2012). Between 1950 and 2003,

the Life Span Study registered about 9600 deaths related to stroke and 8400 related to heart failure in the Japanese cohort of atomic bomb survivors (86,611 members). For stroke, the estimated excess relative risk (ERR) per gray was 9% on the basis of a linear dose–response model. Individual radiation doses have been estimated and ranged from 0 to >3 Gy (86% received <0.2 Gy). The authors concluded that radiation may increase the rates of stroke and heart disease at moderate dose levels (mainly 0.5–2 Gy) although the results below 0.5 Gy were not statistically significant (Shimizu et al., 2010).

Two cohorts of miners bring precise data about occupational irradiation and notably radon. The Wismut cohort uranium mining company in Eastern Germany included 58,987 men from 1946 to 1989; 5141 deaths from heart diseases, and 1742 deaths from CVDs were observed. There was no evidence for mortality from CVDs when the ERR per unit of cumulative exposure to radon in working level months was analyzed (Kreuzer et al., 2010). Canadian authors came to the same conclusion in the Newfoundland fluorspar miners' cohort (2070 miners followed from 1950 to 2001) (Villeneuve et al., 2007). However, there are some data and clues that point to a relation between radiation and premature development of atherosclerosis (Villeneuve and Morrison, 1997; Xu and Cao, 2014; Simonetti et al., 2014).

Chemical Environmental Risk Factors for Stroke

The millennium years (1995–2005) were accompanied by a huge change of the dominant paradigm; environmental risk factors for CVDs had become a new field of research. The purpose was to better analyze and understand the behind-the-scene agents, notably the effects of various metals, chemicals, and obviously air pollution (Navas-Acien et al., 2005). These chemical compounds have been investigated as they are conveyed by multiple milieus, food, air, and water and related to multiple environmental sources and occupational exposures.

Arsenic, a common metal acting as poison and carcinogen, is nowadays considered as a risk factor for CDVs. In a systematic review of the epidemiologic evidence, in general populations, Navas-Acien et al. (2005) showed a significant increase of the RR for stroke which ranged from 0.69 to 1.53. In an occupational population the RR for stroke mortality ranged from 0.30 to 1.33. However, the best evidence has come from Taiwan; arsenic levels in drinking water were found to be associated with CVDs, in particular with stroke, despite methodological limitations. The RR between the highest and the lowest arsenic exposure's categories ranges from 1.19 to 2.69 for stroke. This is consistent with a role for high arsenic exposure in atherosclerosis. This review and a later one (Moon et al., 2012) pointed to the inconclusiveness of the chronic low-dose exposure to arsenic. Risk assessment, based on epidemiological studies (cohort, case-control cross-sectional, and ecological studies) from the United States, Taiwan, Bangladesh, and China, proposes a no-observed-adverse-effect level of 100 μg/L for arsenic in water, equivalent to an iAs dose of 0.009 mg/kg-day (Tsuji et al., 2014).

Cadmium is the second metal studied as risk factor for CVDs. In their 2013 review of cadmium studies, the team of Navas-Acien gave a pooled RR for stroke at 1.18 although the number of studies with stroke outcome was small (Tellez-Plaza et al., 2013a). The mechanisms of cadmium toxicity (data from animals and experimental) involve atherosclerosis (initiation and progression), increased blood pressure, and kidney damage (Tellez-Plaza et al., 2013b).

The third metal considered as a risk factor is lead. With a comparable methodology as that used for arsenic, Navas-Acien et al. (2007) have identified a positive association of lead exposure with the cardiovascular outcomes (included stroke) and obviously hypertension in general and occupational populations. Stroke mortality was higher among workers with the highest number of employment's years, under lead-exposure conditions (Navas-Acien et al., 2007).

For antimony, barium, chromium, nickel, tungsten, uranium, and vanadium, the scarcity of studies and data is insufficient to establish a role (Nigra et al., 2016).

Some organic compounds should also be considered as potential risk factors for stroke, even if reviews or meta-analyses are lacking. The use of pesticides increased significantly the risk of stroke mortality (RR = 1,91) among aerial applicator pilots versus flight instructors (Cantor and Silberman, 1999). Persistent organic pollutants (POPs) such as chlorinated organic compounds (polychlorinated biphenyls, (PCBs), dioxins, and chlorinated pesticides) were shown to increase the CVDs' risk; dioxin exposure is associated with higher risk and mortality for CVD (Chang et al., 2011; Humblet et al., 2008). The RR for stroke was 1.17 among patients discharged from the hospital after stroke (in New York State) and living near a POPs' source (e.g., waste sites) (Shcherbatykh et al., 2005). A hospitalization population-based study from the same team (Sergeev and Carpenter, 2011) confirmed this risk: the RR for stroke with hypertension was 13.4% higher in populations residing in zip codes containing or abutting POPs' environmental sources (RR = 1.134). The Prospective Investigation of Vasculature in Uppsala Seniors (PIVUS) studied background exposure to POPs. Plasma concentrations of 21 POPs (16 PCB congeners 3 organochlorine (OC) pesticides, 1 brominated diphenyl ether (BDE), and octachlorodibenzo-*p*-dioxin) were measured. During the 5-year of follow-up, 35 participants (among the cohort of 898, aged at baseline over 70) developed hospital-treated stroke. After adjusting for known stroke risk factors, the PIVUS showed that POPs' plasma concentrations significantly predicted the future risk of stroke (Lee et al., 2012).

Biological Environmental Risk Factors for Stroke

Infections and stroke

Although knowledge about the relation between infections and stroke goes back to the 19th century, with the discovery of the major infections' role in stroke (i.e., bacterial meningitis, sepsis, endocarditis), there has been an increasing interest in this topic over the last 25 years (Lindsberg and Grau, 2003). Besides the "classical" tropical infections, pediatric and adult strokes related to "minor" infections gain a greater attention.

In the tropics, the common central nervous system infections associated with stroke are cerebral malaria, Chagas' disease (which is an independent risk factor for stroke in South America), and neurocysticercosis (causing transient ischemic attacks as well as ischemic strokes). Other pathogens can be involved: bacteria (tuberculosis, syphilis, and brucellosis), viruses (hemorrhagic fevers due to arenavirus and flavivirus, Dengue fever, Japanese encephalitis, Nipah virus), HIV (in young Africans), fungi, and parasites. For example, gnathostomiasis is a cause of subarachnoid hemorrhage in south-east Asia (Sanchetee, 2009; Moghtaderi and Alavi-Naini, 2012). There have been several recent reports of clinical stroke cases linked to emerging viruses, such as Ebola and coronaviruses, including severe acute respiratory syndrome and Middle East respiratory syndrome (Bang et al., 2015). The reported frequency of cerebral infarction cases of neurocysticercosis has ranged from 2% to 12%. Extensive reviews are not available and epidemiological data are lacking. One estimation has been proposed but without a proper methodological support; the assertion is that "*Several diseases that are endemic in the tropics, can be responsible for up to 10% of the cases of strokes in adults.*" (Carod-Artal, 2007).

Although the first cases' reports of arterial ischemic stroke (AIS)/acute infantile hemiplegia related to infections issued in the seventies (Roden et al., 1975; Janaki et al., 1975) and though child infections are common, the interest in infectious pediatric strokes had developed recently, probably due to the AIS scarcity (2,4/100,000 US Children per year) (Fullerton et al., 2015). The Vascular Effects of Infection in Pediatric Stroke (VIPS) case control study demonstrated that childhood infections, including varicella zoster virus (VZV), are associated with an increased risk of AIS. Thirty-nine percent of the cases had a parental report of infection in the prior 4 weeks and the adjusted odds ratio (OR) between infection and childhood AIS was 6.5 (95% CI 3.3–13, for infection in the prior week). Based on serological evidences, the VIPS study also showed that recent herpesvirus infections (VZV, Herpes Simplex Virus HSV1, HSV2, EBV, CMV) are associated with an increased risk of AIS among children (29 days to 18 years old). Acute HSV infection (serologies suggestive of *primary* HSV infection) was present in 40% of AIS cases. Neither subjects with past infection nor reactivated cases with latent infection serological evidence were found to be at risk (Elkind et al., 2016). Although the biologic plausibility of a cerebral arteritis induced by VZV infection appears high, the plausibility of the HSV infection's role needs further investigation (Grose, 2016).

The relationship between herpesviruses and stroke has become an important issue because herpesviruses infect a large population: more than 95% of the world's population is infected by the VZV (Nagel and Gilden, 2014). Zoster can be complicated by a VZV vasculopathy (Nagel and Gilden, 2015). A recent systematic review and meta-analysis (Marra et al., 2017) pooled nine studies, published between 2009 and 2016, and found that the relative risk for stroke after a VZV infection was the highest at one postinfection month (RR of 1.78) and decreased progressively to 1.20 after one year. The RR was higher for a herpes zoster ophthalmic episode (RR: 2.05) and remain elevated for one year. The questioning of Borbinha et al. "*Should We Pay More Attention to Varicella Zoster Infection?*" should be probably, answered positively as more than 50% of strokes in young adults are cryptogenic (Borbinha et al., 2016).

Another recent review (Guiraud et al., 2010) has examined the stroke risk related to a large panel of infections in 11 case-controlled and 1 self-controlled case–series studies. The risk of stroke doubled or tripled within the first week after the infection. Thereafter, it decreased slowly, remaining still significant after 3 months. This increased risk exists regardless of the infection site (OR 2.4 for respiratory and OR 1.6 for urinary tract infection) or the agent type (OR 4.4 for bacterial and OR 2.6 for viral infection) when ORs are calculated during the first week.

Since then, new data have been issued. A meta-analysis analyzed the risk of cerebrovascular disease in the presence of IgG for *Chlamydia* pneumonia, showing that *C. pneumoniae* is strongly associated with stroke among patients with large artery atherosclerosis. However, the results (association or not) depended on the serological methods and infection's biomarkers (Chen et al., 2013b). The limits of meta-analyses are illustrated by the opposite results obtained in the case of *Helicobacter pylori*; one study showed that *H. pylori* infection contributes to the risk of ischemic stroke (Wang et al., 2012), the following study refuted it (Yu et al., 2014).

The mechanisms underlying the effects of infection on the cerebral vascular system are complex; there are several interactions and targets are numerous. The vessels can be damaged by the germs (vasculitis-angiitis), or the arterial vessel walls may develop atherosclerotic vascular lesions with inflammatory and prothrombotic alterations leading to thrombosis; embolic mechanisms can be related to infectious heart failure or directly to plasmatic circulating parasites (microembols). The outcomes are ischemic strokes (cerebral infarction) and/or hemorrhages (intracranial, subarachnoid) (Lindsberg and Grau, 2003; Sanchetee, 2009). The mechanisms of immune reactions involved in atherogenesis and the pathogenesis of stroke have also been investigated. An association of increased serum immune complexes (ICs) with stroke incidence was demonstrated. These ICs are the immune response to an acute infection preceding the stroke. *C. pneumoniae* or *Cytomegalovirus* could trigger such an immune response (Tarnacka et al., 2002).

Venomous bites and stings

"*Snake and spider bites, as well as scorpion stings envenoming are neglected diseases affecting millions of people all over the world*". This introductory sentence of Oscar H Del Brutto's article (Del Brutto, 2013) summarizes well the important burden of these issues despite the scarcity of published case reports and the absence of epidemiological studies about the neurological morbidity and mortality (including stroke) of venom exposure. Venoms are concentrates of complex mixtures of toxins targeting the central nervous system, the neuromuscular transmission, the cardiovascular system, and/or the coagulation cascade. Depending on the toxin, intracranial hemorrhage (Indian red scorpion) or ischemic strokes (snake) may occur (Del Brutto and Del Brutto, 2012).

Although the common occurrence of hymenopteran (wasp, bee) stings, primary neurologic manifestations including stroke, are rare. Around a dozen of cases have been published (Kulhari et al., 2016; Rajendiran et al., 2012; Bilir et al., 2013; Schiffman et al., 2004). No pathogenic hypotheses have been proposed.

Conclusions

Besides individual risk factors (nutrition, physical activity, behavior), we have shown that new and well-recognized, environmental risk factors are also related to stroke. Epidemiological investigations are needed to assess their importance. That is the question raised by Hankey in his 2006 publication's title: "*Potential New Risk Factors for Ischemic Stroke: What is Their Potential?*" (Hankey, 2006) although the impacts of air pollution was ignored at that moment. Nowadays, air pollution has become a major "new" environmental risk factor (Feigin et al., 2016). Should we expect the emergence of other new potent environmental risk factors? The environmental health approach is modifying our understanding of the causes of stroke (Boehme et al., 2017). Consequently the classical recommendations and strategies for prevention (Goldstein et al., 2011) have to be improved. Based on these new issues, physicians should better inform their communities and the policy makers about their respective roles and responsibilities. Together, we should act to reduce the impact of amenable environmental risk factors related to human activities, such as air pollution, noise, and chemical exposures.

LLMICs	Low-, lower-middle-, and upper-middle-income countries
LMICs	Lower-middle-income countries
MI	Myocardial infarction
NCDs	Noncommunicable diseases
PAD	Peripheral arterial/artery disease
PVD	Peripheral vascular disease
TIA	Transient ischemic attack
UMICs	Upper-middle-income countries
WHO	World Health Organization
YLL	Years of life lost

Atherosclerotic Cardiovascular Diseases

Atherosclerosis, which is characterized by inflammation and dysfunction of the lining of blood vessels and the buildup of cholesterol, lipids, and cellular debris, can result in the formation of a plaque, which leads to the obstruction of blood flow and diminished oxygen supply to target organs (Anderson, 1999). Although atherosclerosis is widespread, the degree of it varies throughout the body with it more prevalent in certain areas. It is most common in the coronary arteries, cerebral arteries, and arteries supplying the lower limbs, in that order, with the resulting cardiovascular disease (CVD) caused by atherosclerosis differing depending on where it occurs (Davies and Woolf, 1993).

Atherosclerosis of the coronary arteries results in reduced coronary blood flow due to partial or complete occlusion, leading to insufficient oxygen reaching the heart muscle, particularly in the case of rupture or plaque formation (Arbustini et al., 1999). This results in ischemic heart disease (IHD), most commonly angina or myocardial ischemia through heart tissue necrosis. Atherosclerosis of the cerebral arteries can lead to cerebrovascular disease through a diminution of blood supply to the cerebral tissue. Momentary ischemia can result in transient ischemic attack (TIA), whereas more prolonged ischemia results in necrosis of the cerebral tissue due to occlusion of a cerebral artery (cerebral infarction), commonly referred to as ischemic stroke. Hemorrhagic

 https://doi.org/10.1016/B978-0-12-809657-4.99735-7

strokes (cerebral hemorrhage), resulting from the rupture of an intracranial artery, are most commonly caused by cerebral aneurysms with evidence that the prevalence of these are also associated with atherosclerosis (Rinkel et al., 1998). Narrowing and progressive occlusion of the arteries supplying the limbs, through atherosclerosis, results in peripheral vascular disease (PVD), also referred to as peripheral arterial (or artery) disease (PAD). This is most commonly found in the lower limbs but on occasions does occur in the proximal arteries of the upper limbs (Welling et al., 1981).

Mortality

The most obvious burden from atherosclerosis comes from the deaths that result from it. ASCVDs make up the majority of all CVDs, which are the most common cause of death globally. Total CVDs accounted for around 18 million deaths in 2015, the equivalent of 32% of all deaths (31% for men and 34% for women). In the decade preceding 2015, there was an increase of around 10% in the number of people dying from CVD globally. Much of this change has occurred due to an increasing population and progressive aging (Nowbar et al., 2014), demonstrated by the decrease in age-standardized mortality rates (ASMRs) over the same period of time, from 384 deaths from CVD per 100,000 individuals in men in 2005 to 334/100,000 in 2015. Over the same period of time, ASMRs in women decreased from 298/100,000 to 233/100,000 (GBD, 2016).

Age standardization controls for changes in the age structure of the population and accounts for increasing longevity, which is important as ASCVDs are more common at older ages. This is reflected in the much lower global ASMRs in women (115.0/100,000) than men (172.8/100,000) for ischemic heart disease (IHD), despite smaller differences in the absolute number of deaths (men = 4.9 million IHD deaths and women = 4.0 million), as age standardization adjusts for the greater longevity in women. These 8.9 million global IHD deaths in 2015 make IHD the single leading cause of death worldwide, accounting for 16% of total deaths in both sexes. IHD also accounts for 52% of CVD deaths in men and 47% of CVD deaths in women (Wang et al., 2016). Stroke is the second most common single cause of death globally, accounting for more than 3 million deaths in both sexes in 2015, 35% of total CVD deaths. Of these stroke deaths, those from hemorrhagic stroke were slightly more common, making up 56% of all stroke deaths. This is largely due to greater mortality from hemorrhagic stroke in men, with ischemic and hemorrhagic stroke accounting for roughly equal number of deaths in women. In comparison with stroke and IHD, there are comparatively low numbers of deaths from PVD, making up less than 0.5% of CVD deaths in both sexes (GBD, 2016).

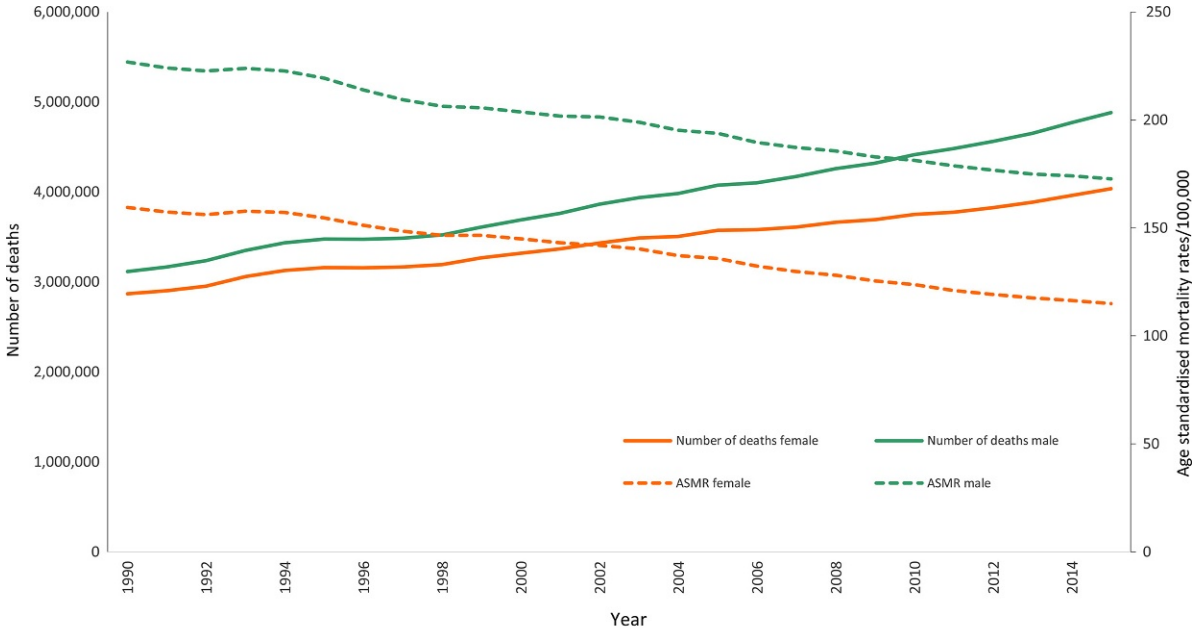
Although there has been little change in the number of deaths and ASMRs from PVD, the number of individuals dying from both IHD and stroke increased in the decade between 2005 and 2015. This has led to these two ASCVDs becoming the two most common causes of death globally, a result of changes in the causes of death in the last 30 years. In 1990, stroke was ranked the fifth most common cause of global deaths, rising to third in 2005 where it was behind lower respiratory disease and IHD; it is now second behind IHD, which has been consistently ranked the leading cause of death since 2005. In 1990, IHD was the fourth leading cause behind diarrheal disease, neonatal preterm birth complications, and lower respiratory infections (Wang et al., 2016). Population aging is one cause of this change, with shifts in population age structures estimated to account for more than 23% of increased mortality due to IHD and stroke. Although this population aging has led to increasing mortality for most causes, its relative contribution differs by disease. With a range in its influence from less than 4% for interpersonal violence and diarrheal diseases to 30% for Alzheimer's disease and other dementias (Wang et al., 2016) (**Fig. 1**).

Premature Mortality

To some people, deaths at older ages from diseases such as ASCVDs, along with other noncommunicable disease (NCDs), are inevitable as prevention and treatment of infectious disease and other causes improve. Deaths at younger ages may therefore be a greater demonstration of its burden, as these are deaths that many consider preventable. The number of CVD deaths in those under the age of 70 years, otherwise defined as premature mortality (GBD, 2013 Mortality and Causes of Death Collaborators, 2015, p. 13; Wang et al., 2016), has risen slightly from 2005, with 4.2 million men and 2.3 million women dying prematurely from CVD in 2015. Premature mortality from other causes has declined over the same period of time meaning that the percentage of premature deaths that arise due to CVD has risen, with CVD now accounting for 20% of all premature deaths in women and 23% in men (GBD, 2016). The World Health Organization (WHO) has declared that these current rates of premature deaths are unacceptable, as cost-effective interventions to prevent CVD are available (WHO, 2014a).

Around 2.2 million IHD deaths occur in men under the age of 70, equivalent to around 45% of all IHD deaths in this population. This compares to just under 1 million premature deaths in women, equivalent to less than 25% of all IHD deaths in females (Wang et al., 2016). These sex differences are also true for stroke, for which although it accounts for a greater percentage of the total premature deaths in women (38%) than men (33%), 43% of all stroke deaths in men occur in individuals aged under 70 years, compared with 29% of all stroke deaths in women. Of these premature stroke deaths, 70% are due to hemorrhagic stroke in both sexes. However, the number of premature deaths for both type of stroke has increased slightly in men since 2005 and decreased slightly in women over the same period. As with total deaths, PVD mortality is very rare, with one quarter of all PVD deaths in men occurring in those under 70 years of age, compared with around 10% in women (Wang et al., 2016).

Years of life lost (YLL) is a metric that takes into account the age at which deaths occur, by relating age at death to a standard life expectancy, thereby giving greater weight to deaths at younger ages.



Source: GBD, 2016. Burden of Disease Study 2015 Results. Institute for Health Metrics and Evaluation (IHME), Seattle, United States. http://ghdx.healthdata.org/gbd-results-tool

Fig. 1 Global trends in age-standardized mortality rates and number of deaths from ischemic heart disease, by sex, 1990–2015.

CVD accounts for 321 million years of life lost, just under 20% of all YLLs. IHD is the greatest individual cause of YLL globally with estimates that 99 million years of life were lost on account of IHD in men and 57 million lost in women. Increases in YLLs due to IHD were found for both sexes, with a 14% increase in YLL from IHD in men since 2005 and a 5% increase in women. This saw IHD move up from the fourth greatest cause of YLL in 1990, when it was ranked behind preterm birth, diarrheal diseases, and lower respiratory infections (GBD, 2013 Mortality and Causes of Death Collaborators, 2015, p. 13; Wang et al., 2016). In comparison, there is a slight decrease in overall YLLs from stroke, as a result of an 8% decrease in YLL due to stroke in women, contrasting a 5% increase among men. This pattern is the same for both types of stroke, ischemic and hemorrhagic. As with mortality figures, however, YLL due to hemorrhagic stroke is greater than for ischemic stroke. Although the largest increases in YLL over the last decade for ASCVDs come from PVD (a 28% increase in men and 30% increase in women), the absolute burden from PVD remains small, accounting for less than 0.2% of all YLLs due to CVD (GBD, 2013 Mortality and Causes of Death Collaborators, 2015, p. 13; Wang et al., 2016).

Morbidity

The burden of ASCVDs does not just come from the deaths caused by them. There are a number of people surviving with these diseases who are still affected by them. Disability-adjusted life years (DALYs) are a health gap measure that extends the concept of potential years of life lost due to premature death, to include equivalent years of "healthy" life lost by virtue of being in states of poor health or disability (Kassebaum et al., 2016). Globally, 347 million DALYs are lost due to CVD, with increases in these in men but not women in the last decade. IHD was the leading single cause of DALYs in 2015. However, despite an 11% increase in global DALYs due to IHD, from 147.8 million in 2005 to 164.0 million (men = 103.2 million and women = 60.8 million) in 2015, there was a 14.2% decrease in age-standardized DALYs over the same period of time (GBD, 2016; Kassebaum et al., 2016).

Although DALYs from stroke, the second leading single cause of DALYs, have shown little change since 2005 for all individuals, this conceals differences between the sexes, with a 6% increase in men and a 7% decrease in women. Hemorrhagic stroke accounts for more than three-fifths of all stroke DALYs in all ages (62%) and 72% for those aged under 70 years. Although DALYs due to PVD remain a relatively small burden, they have shown a greater risk than the other ASCVDs, with a 31% increase in the last decade and little change in age-standardized rates, compared with decreases in standardized rates for IHD and stroke (GBD, 2016; Kassebaum et al., 2016).

Prevalence

These increases in DALYs have occurred, in part, due to the rising global prevalence of CVD. The prevalence of a disease describes the number of people in a population who are currently living with the disease or, in the case of some ASCVDs, such as myocardial

infarction (MI) and stroke, the number of people living today who have ever suffered (and survived) an event. There have been increases of around 25% in the number of people living with CVD between 2005 and 2015, aligning with slight decreases in age-standardized rates, which demonstrate the impact of the growing population size and increasing longevity. Age-standardized prevalence rates in IHD decreased by around 3.4% in the 10 years leading up to 2015, but the number of people living with IHD increased from 87.5 million people in 2005 to 110.6 million in 2015 (64.4 million men and 46.1 million women) (Vos et al., 2016). Of this IHD prevalence, 65% comes from angina, 20% from heart failure, and 14% due to MI. IHD has shown the largest decreases in age-standardized prevalence rates of the three ASCVDs described here. Stroke has demonstrated 4% decreases in age-standardized rates, despite 21% more people living with the disease since 2005. PVD is the only ASCVD to show increases in age-standardized rates, albeit low ones, and accounts for around 40% of all prevalent CVD cases in men and women (GBD, 2016).

Changes in prevalence arise due to changes in incidence (the number of new cases that develop within a population over a specified period of time) and case fatality (the proportion of people dying from the disease over the course of it). Forty-five percent of total CVD incidence occurs due to IHD, close to 24 million individuals, with around half of these occurring in those under 70 years of age. PVD makes up 31% of all CVD incident cases in women and 26% in men with around 14.9 million incident cases of PVD in 2015. There were just under 9 million incident cases of stroke occurring in 2015. As with prevalence, PVD was the only ASCVD to demonstrate increases in age-standardized rates (GBD, 2016).

Global Inequalities

These global figures demonstrate the overall burden of ASCVDs, but they hide enormous inequalities that exist throughout the world, continents, and countries. Around 80% of CVD deaths occur in those countries classified as low-, lower-middle-, and upper-middle-income (LLMICs), often referred to as "developing countries." Although the greatest number of deaths from ASCVDs is found in upper-middle-income (UMI) countries, in which 90% of premature CVD occur deaths, absolute numbers do not account for differences in population size. ASMRs are greatest in lower-middle-income (LMI) countries for men and low-income (LI) countries for women. LI countries have also shown the smallest decreases in ASMRs and the largest relative increases in absolute number of deaths since 2005 (GBD, 2016).

High-income countries (HICs), also referred to as developed countries, have the lowest IHD ASMRs for both sexes, with ASMRs among men in HICs (87.9/100,000) lower than those found for women in all developing countries. Around 22% of global IHD deaths occur in HICs with this disparity greater for premature deaths, 88% of which occur in developing countries. There is also great variation between individual counties in the probability of dying from IHD, despite it being the most common single cause of death globally, with this ranging from 0.8% for women in Japan to more than 24% for men in Belarus (GBD, 2013 Mortality and Causes of Death Collaborators, 2015; Wang et al., 2016). Similar inequalities are found for stroke, with 87% of stroke deaths in men and 82% in women occurring in developing countries, along with 90% of all premature stroke deaths. There have, however, been decreases in stroke ASMRs in all country types, with these ASMRs lowest in HI countries for both ischemic and hemorrhagic stroke. PVD is the only ASCVD for which a greater number of deaths are found in developed than developing countries (61% of global deaths for men and 67% for women). However, HICs are also the only ones to show decreases in ASMRs in PVD, with all other countries demonstrating an increase. Rates and numbers of deaths of PVD remain low in comparison with the other disease types (GBD, 2016).

Similar inequalities are found for DALYs and YLLs from ASCVD. There have been small decreases in the number of DALYs and YLLs from IHD in the last 10 years in HI countries but increases in all developing country classifications, with the largest relative increases found in LICs. Similarly, decreases in DALYs and YLLs in HICs for stroke are compared with increases in LMICs and LICs. For both diseases, however, DALYs and YLLs are lowest in LICs (GBD, 2016).

Although the burden of these ASCVDs is greatest in developing countries, the relative impact of them can differ due to the burden of other diseases. IHD and stroke are the top and second largest cause of YLLs globally, and this holds true for HICs and UMICs; however, IHD is only the fifth greatest cause of YLL and stroke the eighth in LMICs, with neither featuring in the top ten largest causes of YLL in LICs. Within developing countries, IHD and stroke feature in the top ten causes in all countries and regions except in sub-Saharan Africa in which neither feature (Wang et al., 2016) (**Fig. 2**).

Causes of ASCVDs

These global inequalities demonstrate inequalities between countries and regions in the treatment and the risk factors that cause atherosclerosis and its associated CVDs, with these causes often categorized as modifiable and nonmodifiable.

Nonmodifiable Risk Factors

Nonmodifiable risk factors include sex, age, and family history. As with all noncommunicable diseases (NCDs), ASCVDs take time to develop and are therefore more prevalent at older ages, with clinical manifestations seen mainly in the elderly. Although ASCVDs are very rare in those aged under 30 years, rising to become the main cause of death and disability in older age, the process of atherosclerosis that leads to these diseases actually begins in childhood with evidence of atherosclerosis found in teenagers (Berenson et al., 1992; Rose, 1982). The process of atherosclerosis develops in the different arteries at different ages, and it has

Fig. 2 Years of life lost (YLL) to stroke, by sex and World Bank country income group.

been reported to be present in the aorta of almost every child, regardless of age, sex, or environment, from the age of 10 years (Strong et al., 1992). Studies in western countries have found advanced plaque to be common by the third decade and then to be found with increasing frequency in adult life, with clinical features and associated disease usually beginning after the fifth decade of life (Insull, 2009).

As demonstrated earlier in the article, when considering mortality and mortality from ASCVD, the burden of ASCVDs is greater for men, once greater longevity in women is controlled for. This is understood to be due to both behavioral and physiological factors. The behavioral risk factors that lead to atherosclerosis are commonly more prevalent in men, but it is also thought that the female sex hormones have a protective effect in the development of ASCVDs in women, with this protection lost after menopause (Rosano and Panina, 1998).

Having close relatives who have suffered ASCVDs has been found to be a strong predictor for developing these conditions (Holdt and Teupser, 2015). Diseases such as ASCVDs arise due to a large number of genes, with evidence that the risk of atherosclerosis is modulated through interaction between genetic factors and the environment (Holdt and Teupser, 2015). The major medical risk factors also arise in part due to complex genetic determination, and this complexity can detract from the use of genetic predisposition in targeting population and individual level interventions. This can limit the use of genetic prediction in clinical practice (Holdt and Teupser, 2015; Perk et al., 2012).

Modifiable Risk Factors

The WHO identifies eight key modifiable risk factors linked to ASCVDs. These include behavioral risk factors, alcohol use, tobacco use, diet, and physical inactivity, and intermediate (medical/physiological) risk factors, high blood pressure, high adiposity, high cholesterol, and high blood glucose (WHO, 2005, 2009). It is estimated that together, these risk factors account for the majority of deaths from these diseases (WHO, 2009) with evidence that exposure to these risk factors at all ages is linked with the development of ASCVDs over the life course (Labarthe et al., 2009; O'Flaherty et al., 2015).

Of these intermediate risk factors, hyperlipidemia (Scandinavian Simvastatin Survival Study Group, 1994; Shepherd et al., 1995) and hypertension both play an important role in the development of ASCVDs by causing damage to the lining of the blood vessels, which can result in the formation of atheromatous plaques (Munro and Cotran, 1988; Susic, 1997). Diabetes mellitus is closely linked to atherosclerosis, leading to dysfunction of the blood vessels and abnormalities of blood coagulation (Steiner, 1996). Adipose tissue, often measured in individuals through proxies such as body mass index (BMI) and waist circumference, is metabolically active, releasing a number of mediators that not only affect both the other ASCVD medical risk factors but also influence inflammation and thrombotic pathways, leading to endothelial dysfunction and atherosclerosis (O'Flaherty et al., 2015; Van Gaal et al., 2006). Due to the close interaction of all these conditions, many now consider the clustering of a number of these

risk factors within individuals as metabolic syndrome (Reaven, 2004; Townsend and Scriven, 2014). Also referred to as syndrome X, this is linked to increased risk of all ASCVDs (Gami et al., 2007).

These medical risk factors are closely associated to the behavioral risk factors, which lead to their development. Cigarette smoking is considered the major behavioral risk factor for ASCVDs at an individual level, with smoking damaging the blood vessel wall lining and causing an increased tendency for blood to clot (Ambrose and Barua, 2004). Diet is currently the greatest determinant of ASCVDs at a population level, due to the low population prevalence of smoking in comparison with unhealthy dietary intake. Dietary saturated fats are the main determinants of blood lipid levels, particularly total cholesterol (Clarke et al., 1997), while salt consumption is considered to be the single most important factor determining blood pressure levels (O'Flaherty et al., 2015), with diet also very closely linked to blood glucose levels and adiposity (Townsend and Scriven, 2014). Conversely, diets that are higher in healthy foods such as fiber, healthy fatty acids (e.g., omega-3), vitamins, potassium, and other minerals have been seen to have a protective effect (Brahmkshatriya et al., 2006; Connor and Connor, 1989; Harris et al., 1983; Nestel et al., 2002). Physical activity can lead to improvements in these medical risk factors (Kelley et al., 2005) with sedentary behavior, which is not only the absence of physical activity but also the engagement in activities that involve little movement and low energy expenditure (Reilly et al., 2008), seen as an independent risk factor to activity (Katzmarzyk et al., 2009; O'Flaherty et al., 2015). The WHO recommends that adults take at least 150 min of moderate-intensity aerobic physical activity throughout the week or at least 75 min of vigorous-intensity aerobic activity. Children and young people aged 5–17 years old should accumulate at least 60 min of moderate-to-vigorous-intensity physical activity daily (WHO, 2010a). The guidance on alcohol intake is less clear, with some types of alcohol thought to have a protective effect at low levels of consumption (Bell et al., 2017; Brahmkshatriya et al., 2006). Excess alcohol intake, however, has an impact on hyperlipidemia, liver disease, diabetes, and hypertension (Da Luz and Coimbra, 2004), leading to concerns over recommending the intake of even low levels of alcohol (Brahmkshatriya et al., 2006; Thun et al., 1997).

A Combined Approach to Reduce the Population Burden of ASCVDs

In order to prevent the development and impact of ASCVDs, the WHO recommends comprehensive prevention strategies that blend together two types of approaches: public health interventions aimed at reducing population-level risk factor levels and medical interventions targeted specifically at high-risk individuals, with the importance of risk factor and disease surveillance and monitoring also emphasized.

They recommend adopting a life-course approach to ensure prevention of risk factor exposure from early life, alongside interventions for adults at older ages, who are more likely to suffer ASCVDs (WHO, 2013). This advice reflects the success of countries that have achieved major declines in cardiovascular deaths, through reduced incidence and improved case fatality of ASCVD events (Smolina et al., 2012), as a result of population-wide primary prevention and individual health-care interventions (WHO, 2011a). The multinational monitoring of trends and determinants of cardiovascular disease (MONICA) project, coordinated by the WHO, attributed 75% of the decline in IHD mortality in men and 66% in women, to reduced incidence, with the resulting improvements attributed to improved survival after an event (Kuulasmaa et al., 2000; Tunstall-Pedoe et al., 1999, 2000), demonstrating the importance of this coordinated approach. Similarly, around one-third of the decline in stroke mortality was estimated to be due to reduced incidence, with the remaining two-thirds a result of improved case fatality (Thorvaldsen et al., 1995, 1997).

These findings support the view that population-wide primary prevention and individual health-care approaches go hand in hand in reducing the population burden of ASCVDs with the WHO integrating both into the voluntary global targets they have set for NCDs (WHO, 2013). In these targets, they include a 25% relative reduction in the risk of premature mortality from CVDs, reductions or containment in the prevalence of raised blood pressure, and a halting in the rise of diabetes and obesity. They also include targets for improved health treatment equality, with at least 50% of eligible people receiving drug therapy and counseling (including glycemic control) to prevent heart attacks and strokes, along with an 80% availability of affordable basic drug therapy (WHO, 2013, 2014b). Behavioral risk factor goals are also included, recommending 10% relative reductions in the harmful use of alcohol and the prevalence of insufficient physical activity and 30% relative reductions in the mean population intake of salt and the prevalence of current tobacco use in adults (WHO, 2013).

In order to help countries achieve these targets, the WHO recommends a package of interventions termed "best buys" that they say should be implemented to produce accelerated results in terms of lives saved, diseases prevented, and heavy costs avoided, by addressing the diseases and their key underlying risk factors. These best buy interventions were chosen with consideration to four key criteria: (i) health impact, (ii) cost-effectiveness, (iii) cost of implementation, and (iv) feasibility of scale-up, with a particular focus on resource constrained settings (Bloom et al., 2011; WHO, 2011b). These best buy interventions include those for both the treatment and prevention of ASCVDs, reflecting the combined approach they recommend.

Treatment

A major challenge in tackling ASCVDs, particularly in LMICs, is the hidden burden of disease (Gakidou et al., 2011). This comes from the number of people in the population who are suffering from ASCVDs but either who remain undiagnosed or who are diagnosed late (WHO, 2013, 2014a). These late diagnoses are more likely to result in expensive, more invasive intervention and death or disability (Deshpande et al., 2008). This arises due to a focus on treatment for ASCVDs, along with all NCDs, currently residing in hospital-centered acute care. This is particularly the case in many developing countries in which ASCVD patients

generally present themselves in hospitals at a point of acute events or long-term complications (WHO, 2013, 2014a). Treating late-stage disease requires expensive high-technology interventions. Early detection of disease is therefore recommended so that primary prevention strategies can be targeted to those at high risk of ASCVD (WHO, 2010b) with this approach feasible even in low-resource settings (WHO, 2010b, 2013, 2014a), with the WHO recommending that this improved treatment should be integrated into health systems alongside a focus on prevention (WHO, 2013, 2014a).

Within the best buys, the WHO promotes the treatment of high-risk individuals of IHD and stroke with a multidrug approach, recommending that a regimen of aspirin, statin, and blood-pressure-lowering agents could significantly reduce vascular events in people at high cardiovascular risk (WHO, 2013, 2014a). They also recommend the provision of aspirin to people following a heart attack and the use of drug therapy for blood sugar control for diabetes mellitus (Bloom et al., 2011; WHO, 2011b, 2013, 2014a).

As well as having a health impact, estimates suggest that these interventions will have an economic impact, with these health improvements leading to a restored or continued ability of individuals to lead flourishing lives and to participate actively in the workplace. A 10% reduction in the mortality rate due to IHD and stroke is predicted to reduce economic losses in developing countries by an estimated US$ 377 billion over the period 2011–25, approximately three times the yearly cost of scaling up "best buy" interventions for CVD (Bloom et al., 2011).

Prevention

Alongside these treatment recommendations, the WHO best buys include a number of interventions to encourage prevention through the targeting of behavioral risk factors. These include a raise of taxes on tobacco and alcohol, enforcing bans on the advertising of both, and bans on smoking in public places. They also recommend the provision of information on the harms of smoking on tobacco packaging, the mass-media campaigns on physical activity and diet, and the reformulation and labeling of foods with a focus on reducing salt and trans fat intake (Bloom et al., 2011; WHO, 2011b, 2013, 2014a). Although not included in the best buys, the WHO recommends a number of other cost-effective and low-cost population-wide interventions focusing on these behavioral risk factors, such as nicotine dependence treatment; restrictions on marketing of foods and beverages high in salt, fats, and sugar, especially to children; and food taxes and subsidies to promote healthy diets (WHO, 2011a).

Both the United Nations and the WHO recognize that decisions made outside of the health sector have a major bearing on factors that influence ASCVD-related risk, in particular to these behavioral determinants. They recommend, therefore, that prevention gains may be achieved by influencing public policies outside of health sectors, in domains such as trade, food and pharmaceutical production, agriculture, urban development, pricing, advertising, information and communication technology, and taxation policies (WHO, 2011a, 2013). Such a multisectoral approach recognizes that the determinants of ASCVDs, as with all NCDs, lie beyond these behavioral risk factors onto the factors that determine them. These include the social, or wider, determinants of health that come from economic transition, rapid urbanization, and 21st-century lifestyles (WHO, 2011a, 2013). As the responsibility for much of these issues lies outside of the health sector, multisectoral approaches with a public or population health perspective should be developed for effective prevention on a population level (O'Flaherty et al., 2015) (**Fig. 3**).

Multisectoral Action

Multisectoral action recognizes that combating the burden of ASCVDs requires firm commitments of resources and capabilities from a number of government sectors along with civil society, development agencies, private sector, and academia (Mamudu et al., 2011; WHO, 2011a, 2013). This health in all policies approach describes the integration of health focus in policies from all government sectors, allowing government and international organizations to provide leadership, establish necessary frameworks, create infrastructure, and create health policies. Within these approaches, other sectors can play key roles. For example, academia can contribute expertise; NGOs and civil society can lead in advocacy and support implementation, while the private sector can offer business skills, networks, and funds (Bloom et al., 2011; Mamudu et al., 2011; WHO, 2011a, 2013). Collaboration among these partners will allow societies to capitalize on individual strengths and realize benefits beyond the reach of any single entity to ensure that communities have the necessary resources to manage the growing burden of NCDs (Bloom et al., 2011; Mamudu et al., 2011; WHO, 2011a, 2013).

Such approaches also recognize the importance of all settings in which individuals live their lives to be a part of promoting a healthy lifestyle that may aid in the prevention of ASCVDs. There is strong evidence that healthy nutrition and physical environments in schools, workplaces, and communities; nutrition information and counseling in health care; and designing the built environment to promote physical activity can be effective (WHO, 2011a). However, these settings, while being considered part of the health environment, need help in recognizing and developing their place within it. Integration in multisectoral action, therefore, can aid in the implementation of health promotion approaches within them.

Surveillance and Monitoring

The WHO recommends the development of surveillance and monitoring programs, to support treatment and prevention efforts. Most countries have little usable mortality data and weak surveillance systems, but accurate data are vital for problem definition, to understand the distribution of the burden from ASCVDs, to target interventions, to predict future trends, and to provide impetus for action (WHO, 2011a, 2013).

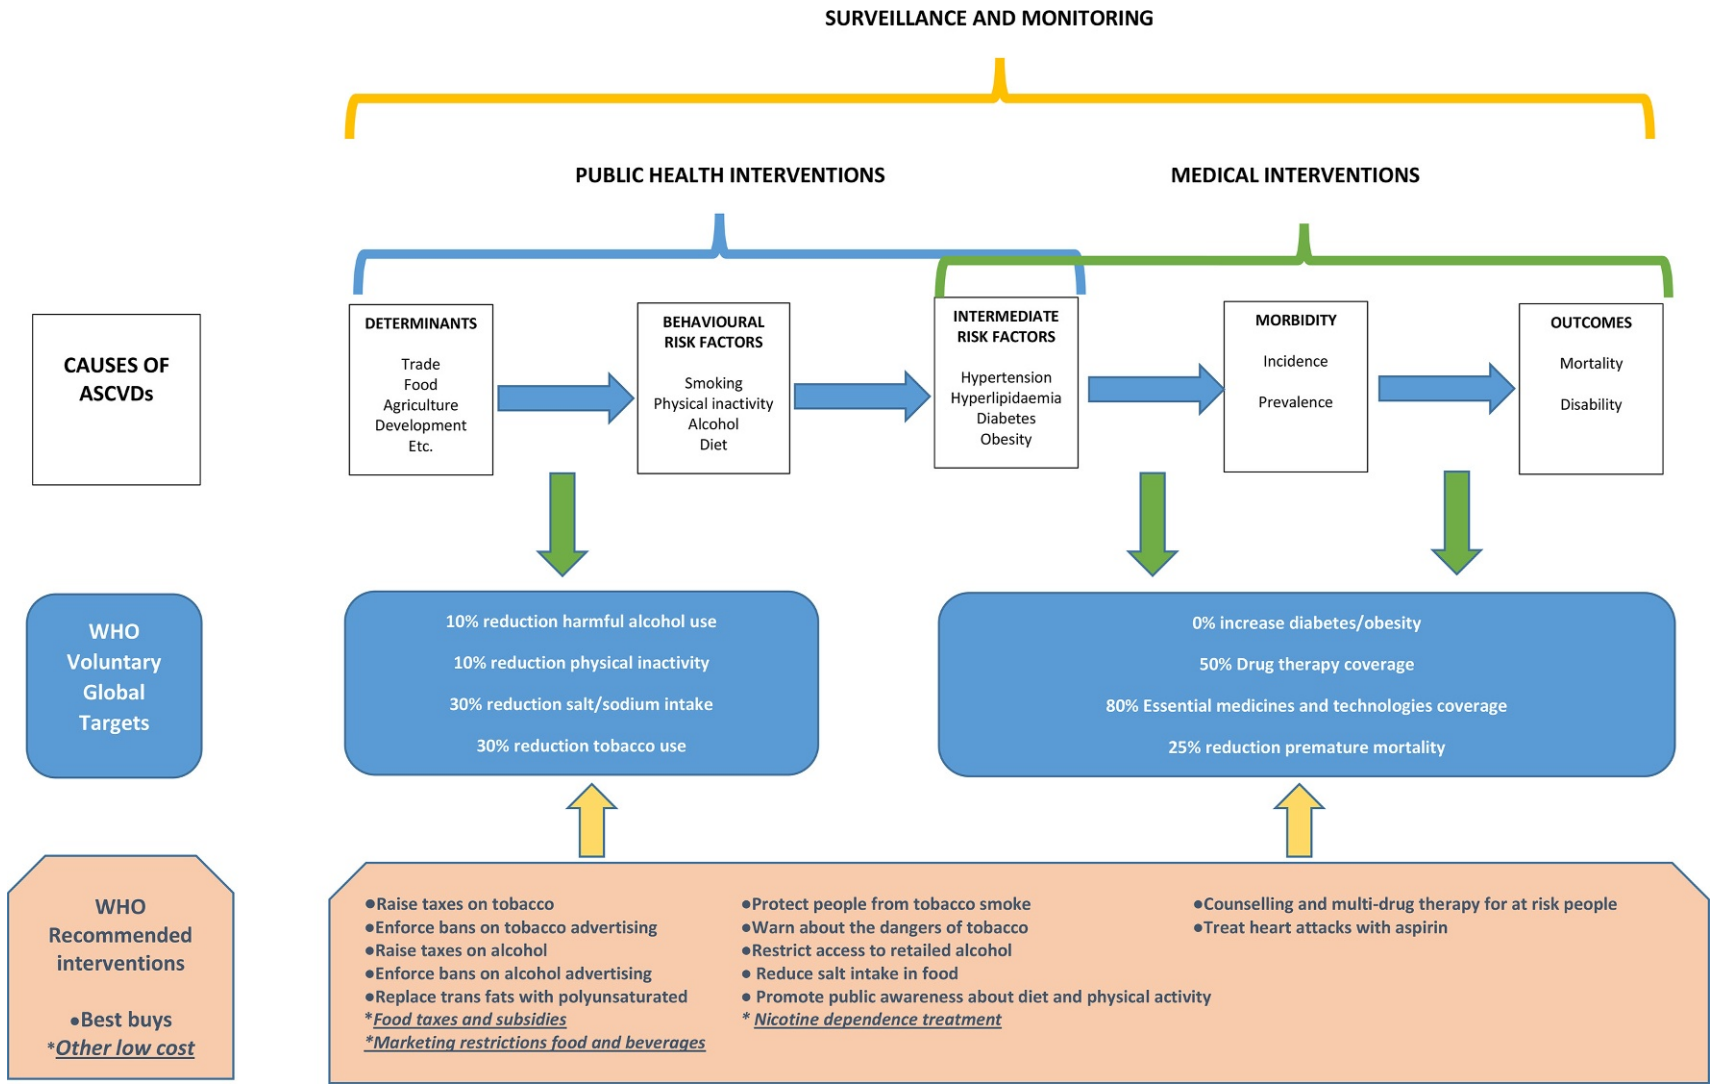

Fig. 3 A combined approach for the prevention of atherosclerotic cardiovascular disease.

Because of this, the WHO identifies improvements in country-level surveillance and monitoring as a priority in programs to prevent and treat ASCVDs, suggesting simple sustainable systems can be implemented in low-resource settings and still produce valuable data. The monitoring of ASCVDs is seen to be essential to the development of policies and program to prevent them, with three key areas of surveillance identified by the WHO:

1. Exposure to determinants and risk factors
2. Outcomes in the form of morbidity and mortality
3. Assessment of health-system capacity and response to prevent ASCVDs (WHO, 2011a, 2013, 2014a)

Although the WHO recommends that strengthening surveillance is a priority at the national and global levels, they acknowledge that this requires long-term funding to be effective, identifying surveillance of behavioral and metabolic risk factors in low-resource settings as the top priority (WHO, 2011a, 2013, 2014a).

Discussion

Atherosclerotic CVDs are the largest cause of death and disability in the world placing a greater burden on developing countries. A combination of public health and medical intervention is recommended to prevent and treat ASCVDs, in order to reduce both their incidence and case fatality. Early detection and intervention must be achieved alongside population-level prevention strategies that target the wider determinants of the ASCVD risk factors. This requires the collaboration of a number of sectors, such that responsibility in changing the environments in which individuals live our lives does not fall solely on health sectors and services. A coordinated approach to surveillance and monitoring will enable interventions to be targeted and evaluated and for health-system capacity to be improved.

Introduction

Cardiovascular diseases (CVD) are a general term for conditions affecting the heart and blood vessels. CVD are the main cause of death and disability in the western world and a growing problem also in developing countries. The incidence of CVD has rapidly increased in several countries, and since human genetic code does not evolve much in a few decades through classical mutations, epigenetic effects are likely to be involved. Genome-wide association studies (GWAS) have been performed in different CVD conditions in order to identify genetic variants associated with disease probability. For example, the CARDIoGRAMplusC4D Consortium studied 63,746 coronary artery disease (CAD) cases and compared them to healthy population (130,681 cases), identifying multiple genetic risk locations and associated single nucleotide polymorphisms (SNPs) related to CAD (Doney et al., 2012). However, this study also observed that these variations explain only 10.6% of the heritability of CVD. It is becoming clear that the variations in the gene sequence alone are not enough to explain all differences, but factors affecting the readability of this sequence are equally important. Thus, epigenetic studies are needed to characterize the state of DNA methylation, histone modifications and non-coding RNA (ncRNA) expression, to generate more complete picture of the variability lying behind gene expression. This effort is now on the move, and at least one publication studying the chromatin organization behind the risk alleles and SNP variants, utilizing the data generated by consortiums such as CARDIoGRAM and METASTROKE, is already out (Haitjema et al., 2017). This article aims to offer the basic information about different epigenetic modifications and modifiers, as well as to introduce the current methodology for epigenetic studies.

Epigenetics

In eukaryotes, DNA is wrapped around a histone protein core thus allowing the tight packaging of chromatin in the nucleus. The nucleosome core consists of two of each of the histones H2A, H2B, H3 and H4 and approximately 147 bp of DNA that is wrapped around the histone octamer (Hayes and Hansen, 2001). The cores are connected by around 80 bp DNA stretch and histones H1 and H5 act as a linker to enable further chromatin compaction. The N-terminal tails of histones H3 and H4 extend from the core and their amino acid residues are subjected to a wide range of posttranslational modifications that affect chromatin structure and gene expression. Epigenetics as a term is used to refer to gene regulation mechanisms that are not affecting the DNA sequence itself but act 'above' (greek '*epi-*') it. This epigenetic information can also be heritable and involves modifications of DNA and the proteins attached to it. The most common epigenetic modifications include DNA methylation and posttranslational modifications of histones. In addition, RNA-mediated mechanisms contribute to the epigenetic regulation. These classes of epigenetic regulation are introduced in **Table 1**. Epigenetic regulation, the epigenome, helps to explain processes such as the maintenance of cellular identity in multicellular organisms and the ability to adapt to rapid environmental changes, since the epigenetic marks can be written, removed and rewritten in the genome by distinct enzymes (e.g., histone acetylases and histone deacetylases). The study of epigenome is referred to as epigenomics and it aims to identify the epigenetic factors and understand their function. The field has moved forward fast during the last decade together with the development of global epigenomics analysis tools such as different deep sequencing methods.

DNA Methylation

The cytosine residues on DNA can be covalently modified by addition of a methyl group. The methylation of DNA is catalyzed by DNA methyltransferase enzymes (DNMTs). In mammalian cells, there are three DNMTs: DNMT3a and DNMT3b act as de novo

 https://doi.org/10.1016/B978-0-12-809657-4.99575-9

Table 1 Epigenetic modifications

Epigenetic class	*Modification*	*Function; effect for chromatin activity*	*References*
DNA methylation	Methylation of cytosine residue of DNA (5mC)	Silencing	(Li and Zhang, 2014)
	Hydroxymethylation of cytosine residue of DNA (5hmC)	Intermediate step for removal of 5mC to "erase" DNA methylation	(Kriukienė et al., 2012)
Histone modification	Acetylation	Mostly associates with active chromatin region	(Wu and Grunstein, 2000)
	Methylation	Both active and repressed chromatin state, depending on the modified residue and the level of methylation (mono-, di-, tri-)	(Barski et al., 2007)
	Phosphorylation	Transcriptional activation	(Rossetto et al., 2012)
	Ubiquitinylation	Transcriptional activation	(Zhang, 2003)
	Sumoylation	Transcriptional repression	(Cubeñas-Potts and Matunis, 2013)
RNA	miRNA	Posttranscriptional gene silencing; however, some studies suggest activation of genes	(Almeida et al., 2011)
	siRNA	Posttranscriptional gene silencing; transcriptional regulation both activating and repressing chromatin	(Turner and Morris, 2010)
	piRNA	Silencing of genome (transposons)	(Huang et al., 2013)
	lncRNA	Genomic imprinting; also fine-tuning of gene expression	(Kaikkonen et al., 2011)

DNA methyltransferases, establishing the DNA methylation patterns during development, while DNMT1 functions in the maintenance of the marks during DNA replication (Turek-Plewa and Jagodzinski, 2005). The biological function of the fourth DNA methyltransferase, DNMT2, is still uncertain but it has been shown to methylate transfer RNAs (tRNA) (Goll et al., 2006). Interestingly, DNMT3a and DNMT3b have also been linked to the demethylation pathway in a Ca^{2+}-ion dependent manner, and might therefore play a dual role in the regulation of DNA methylation and demethylation (Chen et al., 2013; van der Wijst et al., 2015). DNA methylation can also be reversed by an active process whereby 10–11 translocation (TET) enzymes hydroxylate the methyl groups (Tahiliani et al., 2009).

DNA methylation is typically considered a mark of transcriptionally repressed genes or genomic areas. Methyl-binding domain (MBD) family of proteins recognizes and binds methylated DNA and mediates the transcriptional state of the chromatin (Du et al., 2015). These proteins can act in conveying the multilayered epigenetic signal of DNA methylation and histone modifications. DNA methylation is considered to be a fairly stable silencing modification which plays a role in processes such as genomic imprinting and transposon silencing.

Several studies have been done to elucidate the role of DNA methylation in cardiovascular diseases (Laukkanen et al., 1999; Aavik et al., 2015; Turunen et al., 2009). Sharma et al. found 72 hypermethylated differentially methylated regions (DMR) from blood in CAD patients. 12 of these regions were further analyzed by bisulfite sequencing and 6 regions were found to be associated with CAD (Sharma et al., 2014). Mice with global reduction in DNA methylation have been shown to develop fatty streaks in aorta (Chen et al., 2001). Furthermore, knockout $ApoE^{-/-}$ mice show alterations in global DNA methylation in peripheral blood mononuclear cells and aorta even before typical vascular lesion formation occurred (Lund et al., 2004). In humans, a correlation between increased DNA methylation and lesion severity has been observed (Valencia-Morales et al., 2015). Recent genome-wide association study (GWAS) described associations between blood lipid levels and DNA methylation (Hedman et al., 2017).

Histone Modifications

Another well-known factor in the epigenome is modification of the histones. Histones consist of approximately 130 amino acid residues and have highly positive charge, which enables their strong association with negatively charged DNA. Histone "tails", 10–30 amino acid N-terminal domains protruding from the nucleosome, are subjected to posttranslational modifications and also act as platforms for nucleosome binding proteins (Luger et al., 1997; McGinty et al., 2014). Outside of the four core histones there are "linker" histones, H1 and H5, which interact with linker DNA that joins the nucleosomal structures, further condensing the chromatin (Bednar et al., 1998; Fan and Roberts, 2006). Nucleosome complex is modified by several different methods, including posttranslational modification of histones by histone modifying enzymes, replacement of the common histone proteins with special variants, and by altering the nucleosome position and composition by ATP-dependent chromatin modeling enzymes (Swygert and Peterson, 2014; Talbert and Henikoff, 2010; Hargreaves and Crabtree, 2011).

Currently several different histone modifications have been characterized: acetylation, methylation, phosphorylation, ubiquitinylation, sumoylation, ADP ribosylation, deimination, proline isomerization, citrullination, formylation, succinylation, butyrylation, propionylation and crotonylation (Tessarz and Kouzarides, 2014; Kouzarides, 2007). These may take place on over

60 different histone residues, and the methylation can occur in two or three different layers (mono- or di-, and mono-, di- or trimethylation) for arginine and lysine residues, respectively, thus creating a wide and complex landscape of regulation. This has been sometimes described as the histone code, where all the histone modifications and their interactions produce a code for the enzymes that are able to recognize and bind the specific modifications, and then recruit other proteins such as transcription factors (TFs) to modulate gene activity. Whether the histones form a unified 'code' is still unclear, but some patterns for histone modification occurrence have been observed (Wang et al., 2008). However, it is clear that some specific histone modifications are typically associated with either repressed or activated states of gene expression on specified genetic areas. These include histone H3 lysine K4 trimethylation and H3K27 acetylation on active promoters, H3K4 monomethylation on active enhancers, and H3K27 trimethylation and H3K9 dimethylation on repressed promoters (Heintzman et al., 2007; Stewart et al., 2005; Tie et al., 2009). Promoter-associated acetylation of lysines neutralizes the charge of lysine, weakening the bond between nucleosomal chromatin and histones, thus making the DNA more accessible for the transcriptional machinery (Zentner and Henikoff, 2013). Also, the interplay between different modifications has been detected, for example, phosphorylation of H3 serine S10 seems to be inhibitory for the methylation of H3K9 but instead promotes the acetylation of H3K14 (Rea et al., 2000). Extensive reviews are available for a more detailed description of histone modifications and modifying enzymes (Kouzarides, 2007; Lawrence et al., 2016; DesJarlais and Tummino, 2016).

Histones are modified by a variety of enzymes. The so-called *writers* are enzymes that establish modifications, such as histone lysine methyltransferases (KMTs) or histone acetyl transferases (HATs) that add the methyl or acetyl group, respectively, to their target histone residues. *Eraser enzymes* are able to remove these marks, histone lysine demethylases (KDMs) remove the methylation, and histone deacetylases (HDACs) the acetylation of the histones. Histone acetylation is usually associated with active genes and therefore the transcriptional coactivators, such as p300/CBP or SRC-1, often contain HAT activity (Ogryzko et al., 1996; Spencer et al., 1997). Correspondingly, the global transcriptional repressor complexes often associate with HDACs, for example, the complex of NCoR, mSin3, and RPD3 (Heinzel et al., 1997). KMTs and KDMs act more specifically, sometimes even mediating the methylation or demethylation of only one specific residue, such as is the case with KMT SUV39H1, which only methylates H3K9 (Rea et al., 2000). The same histone residue can be modified by different enzymes, such as in the case of H3K4 methylation where Jarid1B (also known as KDM5B) seems to demethylate di- and trimethylated H3K4, whereas LSD1 (also known as KDM1A) instead modifies the mono- and dimethylated forms of the same residue (Seward et al., 2007; Shi et al., 2004). *Reader enzymes* are transcription factors and enzymes that can bind DNA only when certain histone modifications are set on place. For example, HP1 proteins require the methylation of H3K9 by the associated KMT SUV39H1 for the generation of a favorable chromatin structure that it then binds and regulates transcriptional activity of the loci (Lachner et al., 2001). Review by Swygert and Peterson describes enzymes taking part in chromatin and histone remodeling in more detail (Swygert and Peterson, 2014).

Histone modifications and changes in their function have relevance for CVD as well. HDACs seem to have both pro- and antiangiogenic properties: HDAC inhibitors decrease the VEGF-induced migration and branching of human umbilical cord endothelial cells (HUVEC) (Deroanne et al., 2002). Opposing results were shown in the study by Jin et al., where HDAC inhibition in HUVECs resulted in enhanced sprout formation and upregulation of acetylated H3 levels (Jin et al., 2011). In vivo, HDAC3 expression in $ApoE^{-/-}$ mice aortas is increased, and *Hdac3* knock-down mice show more severe atherosclerotic phenotype (Zampetaki et al., 2010). HDAC9 gene region 7p21.1 has been identified as a strong risk locus for CAD and large artery stroke, a subtype of ischemic stroke (Dichgans et al., 2014). Azghandi et al. showed, that $Hdac9^{-/-}ApoE^{-/-}$ mice have less severe and fewer plaques when compared to $Hdac9^{+/+}ApoE^{-/-}$. Furthermore, healthy human subjects with HDAC9 risk allele rs2107595 showed higher mRNA expression of HDAC9 in their peripheral blood mononuclear cells. However, expression of the same risk allele did not have an effect on plaque morphology in human carotid artery plaques (Azghandi et al., 2015). In the study by Yang et al., increased expression of SUV39H was observed in mice after myocardial infarction. SUV39H is a methyltransferase responsible for H3K9Me3, a transcription repressive mark leading to formation of heterochromatin. Transgenic mice lacking SUV39H were noticed to have better survival when compared with wild-type animals (Yang et al., 2017).

RNA Transcripts

Even though only less than 3% of the genome encodes protein sequences, over 85% of the DNA is still transcribed to RNA (Hangauer et al., 2013). These RNA transcripts that are not translated into protein are called non-coding RNAs (ncRNAs) and include some functional RNAs, such as ribosomal RNAs (rRNAs) and tRNAs, that have been already well characterized with functions in protein synthesis. Recently the substantial role of other RNA transcripts has emerged with increasing number of publications reporting new functions for these 'junk RNAs'. The novel action of ncRNAs is in the regulation of gene expression, turning them into epigenetic actors. Different ncRNAs regulate gene expression at multiple levels: transcriptional, posttranscriptional, and translational levels. The ncRNAs are usually classified based on their size, long ncRNAs (lncRNAs) with the length of over 200 nt and small ncRNAs with the length less than that. Especially small RNAs are then categorized into subclasses, such as the best-studied examples of miRNAs, siRNAs, and piwi-interacting RNAs (piRNAs).

The best-known example of ncRNAs in gene regulation is the miRNAs that act in posttranscriptional gene silencing (PTGS). miRNAs target the 3′ UTR of mRNAs with complimentary sequence and upon binding to mRNA, can induce PTGS by inhibition of translation or resulting in degradation of the mRNA (Kim, 2005). Endogenous siRNAs expressed as long double-stranded RNAs from the genome, or exogenously administered siRNAs in research or therapeutic applications act in the same PTGS pathway.

Some ncRNAs play a role in establishing epigenetic modifications in the chromatin. For example, originally found from the centromeric regions, siRNAs were observed to form a nuclear RITS complex and thereby induce histone H3 lysine K9 methylation and chromatin condensation (Volep et al., 2002). In a study in *Schizosaccharomyces pombe*, an lncRNA termed BORDERLINE, which is further processed into siRNAs by Dicer, prevented histone H3 lysine K9 methylation outside the pericentromeric region (Keller et al., 2013). This ncRNA acts as a boundary for the HP1 protein that binds the H3K9 methylation and promotes the spreading of heterochromatin. The small RNAs generated from this lncRNA are not bound by Ago1 unlike the centromeric siRNAs, and they act in a locus-dependent manner independent of their sequence.

X-inactive specific transcript (XIST) is the best-known example of an lncRNA regulating epigenetic silencing. The X chromosome contains more genetic information than the gene-poor male Y chromosome and in female cells, one X chromosome must be silenced in order to prevent possible toxic effects of "double-dose" of gene expression. The inactive X chromosome transcribes an lncRNA XIST that is retained in the nucleus and localizes to the chromatin where it was produced. It also recruits chromatin modifying enzyme complexes such as PRC2 that increases methylation of H3K27 residues (da Rocha et al., 2014). The inactivation of the X chromosome also requires other ncRNAs such as TSIX, an antisense transcript for XIST, that represses XIST expression by a mechanism involving H3K36me3 on the XIST promoter (Ohhata et al., 2015). The interplay between the various ncRNAs and chromatin modifying enzymes in the regulation of X chromosome inactivation has not yet been fully resolved.

Recent study has shown that miRNAs are capable of binding to double-stranded DNA (Paugh et al., 2016). Some miRNAs have already been shown to have non-canonical functions and target promoters of genes, regulating their expression at the transcriptional level. In some studies, this has been associated with changes in epigenetic modifications, such as increase in H3K9me2 (Younger and Corey, 2011). piRNAs have been shown to mediate epigenetic modifications as well. Similarly to miRNAs, piRNAs were localized to their complementary sequences and recruit Piwi, HP1, and SUV-family KMTs that increase H3K9 methylation and reduce Pol II activity on the target sites (Huang et al., 2013). In this genome-wide study, Piwi and piRNA were shown to colocalize on both euchromatic and heterochromatic regions, preferably at pericentromeric and subtelomeric loci.

The biogenesis and action of ncRNAs have been studied extensively during the recent years. These findings are comprehensively described in many good reviews (Khorkova et al., 2015; Mattick and Makunin, 2006; Roberts, 2014). In addition, the association of ncRNAs with different diseases, including CVD, has been studied and reviewed (e.g., Almeida et al., 2011; Greco et al., 2015; Uchida and Dimmeler, 2015).

Tools for Studying Epigenetics

The tools for studying epigenetic phenomena have developed during the recent years toward more global analysis of epigenetic status of the cells and tissues. The first studies of, for example, DNA methylation were focused on specific genes of interest and/or total amount of DNA methylation in the cell, but with first microarray techniques and more recently the next-generation sequencing methods, the interest is moving towards mapping the whole genome at single residue level. Genomic high-throughput assays provide large amounts of data and the interpretation of the data may be challenging. Methods for epigenomics analysis are described briefly here and summarized in **Fig. 1**.

The basic tools for analysis of DNA methylation in the cell are digestion assays and bisulfite sequencing of DNA. In digestion assays, methylation-sensitive and -insensitive restriction enzymes are used to digest genomic DNA (Hatada et al., 1991). Methylation-sensitive endonucleases can only cleave unmethylated DNA and leave methylated DNA targets undigested. The digested DNA can be analyzed by sequencing or microarray, and that way the sites of methylation are mapped. The limitation of this method is that it only characterizes the sequences near the targets of chosen restriction enzymes, and is usually used to characterize only global levels of DNA methylation instead of identifying methylated DNA at the single residue level. Resolution is improved by using bisulfite sequencing method. In strand-specific bisulfite sequencing described first in 1992, bisulfite treatment is used to convert cytosines to uracil, whereas methylated cytosine residues remain unaffected (Frommer et al., 1992). The resulting DNA can be analyzed using various methods, often by sequencing after PCR of the regions of interest. The analysis can also be done using MALDI-TOF mass spectrometry or microarrays.

DNA methylation can also be studied using affinity-enrichment based methods. Methyl-binding domain (MBD) of MeCP2-protein has been bound to, for example, column resin to create affinity columns against methylated DNA (Zou et al., 2007). Fragmented DNA samples can be loaded to the columns and methylated DNA fractions eluted out for analysis with genome-wide techniques (such as MBDCap-seq/MethylCap-seq). Immunoprecipitation of methylated DNA (MeDIP) utilizes antibodies recognizing the methylated cytosine (5mC) in DNA (Mohn et al., 2009). DNA sample is fragmented and antibody used for immunoprecipitating those fragments that contain 5mC. This method is also used for the analysis of hydroxylated methylcytosine (5hmC). Purified fragments are analyzed by PCR, sequencing or microarray. When using these methods, the analysis resolution is restricted to the DNA fragment level of often 100–300 bp instead of identifying single-base modifications. However, depending on the research question, this can often be sufficient.

For histone modifications, chromatin immunoprecipitation (ChIP) is a widely used technique to identify local posttranslational modifications of the histone tails and to monitor changes in the modifications in response to different stimuli. The protocol was first described in 1984 when it was used for identifying RNA pol II occupancy on E. coli genes (Gilmour and Lis, 1984). Shortly, antibodies against specific histone modifications (such as trimethylation of histone H3 lysine K27) are used for immunoprecipitation and pulldown of the chromatin regions that have these modifications. ChIP can also be used to analyze the binding of

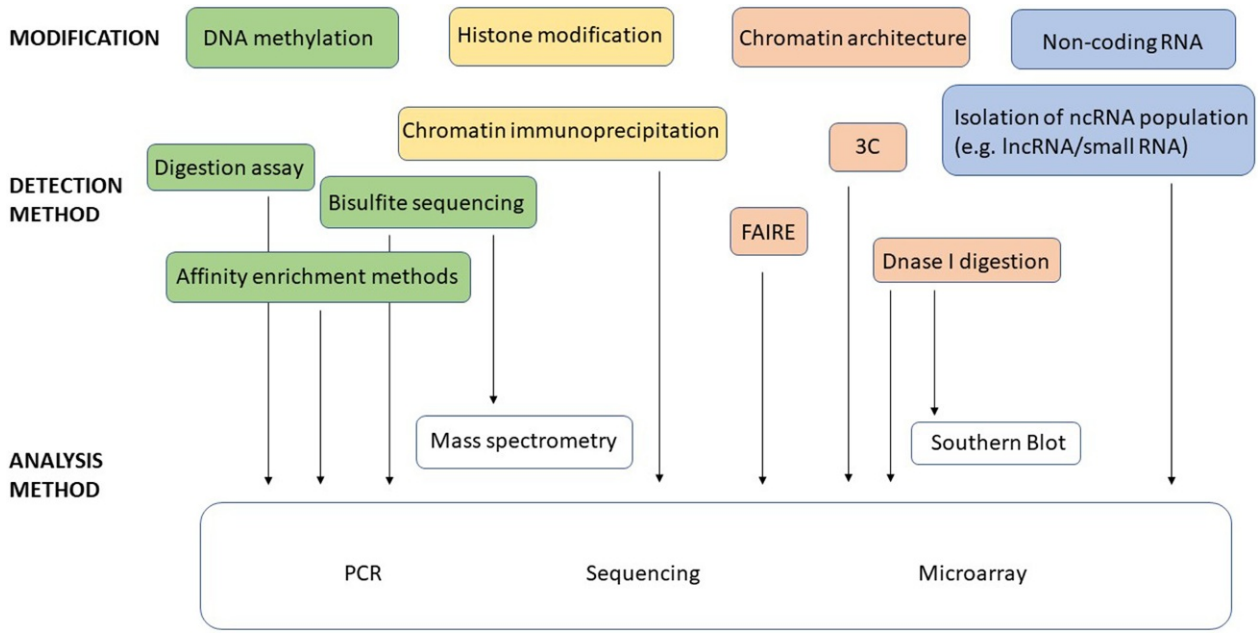

Fig. 1 Tools for studying epigenomics. Epigenetic modification (DNA methylation, histone modifications, chromatin architecture and non-coding RNA) can be studied using versatile detection methods. These methods are specific to each modification, such as antibody-based affinity methods in detection of DNA methylation or histone modification. Nevertheless, the final outcome of these methods is often analyzed with common analysis technologies: PCR, sequencing and microarray.

transcription factors and enzymes to the chromatin, using a specific antibody against the factor of interest. Usually, using either PCR to detect specific loci or deep sequencing for a more global view, the associated chromatin regions can be identified. ChIP experiments can also be analyzed using microarray (ChIP-chip), but the resolution of data is weaker compared to sequencing. The ChIP approach has been used, for example, for the identification of histone mark signatures of different chromatin elements, such as promoters or enhancers (Heintzman et al., 2007). Furthermore, during the last decade, the basic ChIP method has been developed to more specifically answer different research questions and to utilize more recent analysis technologies, so diverse ChIP methods have been described in the literature. Such are the μChIP-seq for low, micro-scale sample amount analysis, and the modern single-molecule real-time sequencing (SMRT; "third generation sequencing") of ChIP-samples (Dahl and Collas, 2008; Wu et al., 2016).

Epigenetic landscape can also be studied by chromatin accessibility methods. These studies can identify the active regions of chromatin, for example by using DNAse I—digestion of DNA. In the DNase-seq, DNase I—treatment digests the DNA that is not protected by nucleosome structure, so the regions that are sensitive to DNase are associated with active genes (Song and Crawford, 2010). Sequencing results in a more precise characterization, but also microarray or Southern Blot analysis can be used if single-base pair resolution is not necessary. Another method for the detection of open chromatin is the formaldehyde-assisted isolation of regulatory elements (FAIRE) that also result in the isolation of open, nucleosome-depleted chromatin regions (Giresi et al., 2007). In FAIRE, DNA and histones and other proteins associated with it are cross-linked with formaldehyde, sonicated to fragment the DNA, and DNA isolated with phenol-chloroform extraction. Only DNA that is not bound by nucleosomes and associated proteins remains in the aqueous phase in the extraction, thus resulting in the isolation of the open and active regions of the genome. The isolated fragments can be analyzed again with different methods, such as PCR, microarray, and sequencing. Chromatin architecture can also be studied using chromatin conformation capture (3C) technique that identifies the chromatin regions that are physically associated together, such as promoters with enhancers. 3C is often analyzed by PCR, but nowadays also by deep sequencing of the interactions globally (Hi-C) (van Berkum et al., 2010).

The RNA component of epigenetics is nowadays most often analyzed on a genome-wide scale using next-generation sequencing methods (Fernandez-Moya and Ehses, 2017). Deep sequencing can be performed for different populations of RNA to characterize the changes in both ncRNA and mRNA populations. mRNAs can be sequenced by isolating them based on their poly-A tails, still resulting in sequencing of some polyadenylated lncRNAs as well. Small RNAs and miRNAs can be sequenced separately based on their smaller length by using size exclusion. The role and function of miRNAs and other ncRNAs are mainly studied by cell line models, where it is easy to interfere with normal signaling using either overexpression or inhibition of the ncRNA of interest. Mostly, this is done using mimic or inhibitor oligonucleotides, respectively, that are transfected into the cells. Besides global sequencing methods, the expression of RNAs can be analyzed with qPCR. Modern techniques can detect low copy number transcripts and their expression differences, even on a single-cell level (Ziegenhain et al., 2017).

The methods described here only briefly scratch the surface of the numerous applications of these techniques. Detailed reviews are available that describe the progress of the technology and the use of these methods with different starting materials, such as when the starting cell number is fairly limited (Yong et al., 2016; Callinan and Feinberg, 2006; Khyzha et al., 2017).

Summary

Epidemiological studies have shown correlation between environment and epigenetics that can also be inherited to next generations. An example is from the Dutch Famine (1944–45), where families have been followed for decades after they were exposed to severe famine during the wartime. These studies have found that the region of insulin-like growth factor II (IGF2) gene was less methylated in individuals who were prenatally exposed to famine, compared with their other siblings (Heijmans et al., 2008). The DNA methylation status of the gene persisted for the lifetime of these individuals, showing the far-reaching consequences of environmental exposure.

With advances in technology, the single-base resolution mapping of epigenetic status (both DNA methylation and histone modifications) has become reality even at a single-cell level. Determining the genomic sequence may not be enough but the landscape needs more detailed characterization in the form of epigenetic studies. These studies will be necessary in the era of personalized medicine, to treat the individual patients with right drugs. Detailed characterization of epigenetic status in CVD, cancer and other diseases increases our understanding of the mechanisms of those diseases and will facilitate the development of epigenetic drugs in the future.

Introduction

The cardinal symptom of heart failure is exercise intolerance secondary to fatigue and dyspnea. Exercise intolerance leads to significant reductions in patients' quality of life and functional level, estimated by the New York Heart Association (NYHA) classification. The aim of exercise training is to increase patients' exercise capacity and improve their functional level, quality of life, frequency of admission, and mortality.

Cardiac rehabilitation is a prescribed program of exercise training that has evolved into a multidisciplinary approach that may also include patient education, disease management, self-care counseling, and behavioral change coaching. Cardiac rehabilitation is defined by the Centers of Medicare and Medicaid Services (CMS) as a "program that furnishes physician-prescribed exercise, cardiac risk factor modification, psychosocial assessment, and outcomes assessment" (CMS, 2009).

Historical Perspective

Prior to the 2000s, the efficacy and safety of exercise training in heart failure were unestablished. Decades earlier, studies of exercise training first began in the care of patients with acute myocardial infarction (MI).

A patient suffering an MI in the first half of the 20th century would have been prescribed weeks of strict bed rest during which moving, let alone exercise, was verboten. After being established in a landmark paper by (Herrick et al., 1912), bed rest remained standard for decades until the early 1950s, when Levine and Lown (1952) began allowing patients to sit in armchairs and noticed shortened recovery times. With some controversy, physicians began to incorporate exercise earlier, and noted not just reduction in clots and bed sores but also decreased angina, increased exercise capacity, and decreased mortality.

Exercise training in heart failure has followed a similar arc from controversy to acceptance though decades after its adoption in MI. In the past, patients with heart failure were prescribed bed rest in an attempt to minimize symptoms and over concern that exercise would worsen left ventricular dysfunction (McDonald et al., 1972). Skepticism around the safety of exercise in heart failure persisted for logical reasons. In comparison to coronary heart disease patients, patients with heart failure are generally older, frailer, have more comorbidities, and are more prone to arrhythmia and fluid overload. In its 2005 guidelines on heart failure, the American College of Cardiology and American Heart Association (ACC/AHA) stopped short of providing a recommendation citing a lack of studies on long-term effects (Hunt et al., 2005).

In 2007, the National Institute of Health helped address this uncertainty by funding HF-ACTION, a large trial studying the efficacy and safety of exercise training in stable systolic heart failure. Based largely on results of the trial, the 2013 ACC/AHA guidelines provided a I–A recommendation for exercise training and a IIa–B recommendation for cardiac rehabilitation in stable patients with heart failure. CMS followed in 2014 with a National Coverage Decision approving cardiac rehabilitation in patients with stable, chronic heart failure defined as patients with left ventricular ejection fraction of 35% or less and NYHA class II–IV symptoms despite being on optimal heart failure therapy for at least six weeks, and who have not had recent ($\leq$6 weeks) or planned ($\leq$6 months) major cardiovascular hospitalizations or procedures (CMS, 2014).

Despite the approval of cardiac rehabilitation in stable heart failure, physician referrals and patient adherence to cardiac rehabilitation remain low. Also, patients with heart failure with preserved ejection fraction (HFpEF) and patients who have had admissions within six weeks remain ineligible. Cardiac rehabilitation has the potential to confer additional benefits in survival and

 https://doi.org/10.1016/B978-0-12-809657-4.99674-1

quality of life in heart failure patients. To achieve its full potential, additional work is needed to improve referral and adherence rates and to study populations which lack robust evidence of benefit and safety.

Physiologic Basis for Exercise Training in Heart Failure

Measures of Exercise Capacity

Heart failure is characterized by exercise intolerance due to fatigue and dyspnea. In physiologic terms, this intolerance is due to reduced exercise capacity, which is often estimated by screening tools like the NYHA classification or by tests at submaximal effort such as the 6-min walk test. A more accurate estimate of exercise capacity is peak oxygen consumption, also known as maximal aerobic capacity (peak VO_2), which is the amount of oxygen consumed by the body at maximal effort. It can be measured during cardiopulmonary exercise testing (CPX), a standard first step after referral to cardiac rehabilitation. It is defined by the Fick equation as the product of cardiac output and the arteriovenous oxygen difference at peak exercise:

$$\text{peak } VO_2 = (HR^{*}SV)^{*}[C(a-v)O_2]$$

HR = heart rate; SV = stroke volume; C(a − v) is the difference in arterial and venous oxygen concentration. Peak VO_2 is often reported in mL/kg/min to allow for comparisons between people of different weight.

Another measure estimating exercise capacity is the ventilatory threshold (VT), which provides a better measure of exercise capacity at submaximal workloads. VT is based on the work of Wasserman and is thought to reflect the anaerobic threshold, or the point at which oxygen demand by muscle exceeds oxygen delivery (Wasserman, 1987). At low and moderate rates of exercise, expired gas (VE) rises linearly with VO_2. At a threshold work load, called VT, VE begins rising faster than VO_2 (see **Fig. 1B**). This divergence is thought to be due to the release of CO_2 from the conversion of lactic acid to lactate after the beginning of anaerobic respiration. Some dispute the accuracy and physiologic basis of VT as a marker for lactic acidosis and anaerobic respiration (Myers and Ashley, 1997; Hopker et al., 2011); however, given the increase in respiratory rate and dyspnea at VT, it remains a useful and conveniently measured surrogate for maximal sustained submaximal work rate. Other physiologic measures recorded during cardiopulmonary testing can be found in **Table 1**.

Reduced Exercise Tolerance in Heart Failure

In heart failure with reduced ejection (HFrEF), cardiac output is reduced by a lower stroke volume and lower heart rate reserve. Since VO_2 is the product of cardiac output and arteriovenous oxygen difference, it might be inferred that a decrease in stroke volume is the main driver behind reduced exercise capacity in HFrEF. Oddly, studies demonstrate a poor correlation between measures of resting ventricular function and exercise capacity suggesting other pathologies contribute (Franciosa et al., 1981). Studies comparing patients with heart failure to age and activity-matched controls show further defects in ventilation, skeletal muscle, endothelial function, and neurohormonal regulation (see **Table 2**) (Downing and Balady, 2011).

In heart failure with preserved ejection fraction (HFpEF), the left ventricle is not able to increase compliance to accommodate the greater diastolic filling rate needed during exercise. Dyspnea occurs due to a rise in left ventricular diastolic pressure and pulmonary capillary wedge pressure.

Physiologic Effects of Exercise Training

Peak VO_2 and VT have been shown to rise with exercise training in both healthy individuals and in patients with heart failure.

Interestingly, most studies have not shown increases in LVEF after exercise training. Much of the gain in exercise capacity is thought to be due to improvements in peripheral fitness. Studies have shown increases in mitochondrial density and type 1 oxidative fibers, and a decrease in sympathetic tone (see **Table 3**) (Downing and Balady, 2011). Cardiac adaptations, however, such as improvement in diastolic function have been documented.

Support for Cardiac Rehabilitation in Heart Failure

Prior to HF-ACTION, small trials had shown mixed data for the benefit of cardiac rehabilitation in heart failure, though meta-analyses supported a benefit in exercise capacity and quality of life and a decrease in hospitalizations. HF-ACTION was designed to definitively measure the safety and efficacy of exercise training in stable patients with systolic heart failure (LVEF <35%). Patients had to be medically optimized on ACEI/ARB and beta blocker. The study enrolled 2331 patients, NYHA Class II–IV (63% class II, 36% class III), of whom 40% had implantable defibrillators and 18% had biventricular pacing. The composite primary endpoint was all-cause mortality or hospitalization. Patients were randomized to either 36 sessions of supervised, moderate-intensity training (60%–70% of heart rate reserve) followed by home-based training or usual care. Subjects in the control arm were recommended to exercise 30 min per day at moderate intensity per ACC/AHA recommendations at that time. Halfway through the period, subjects in the experimental arm were given a treadmill or stationary bike and advised to exercise at moderate intensity for 40 min five times

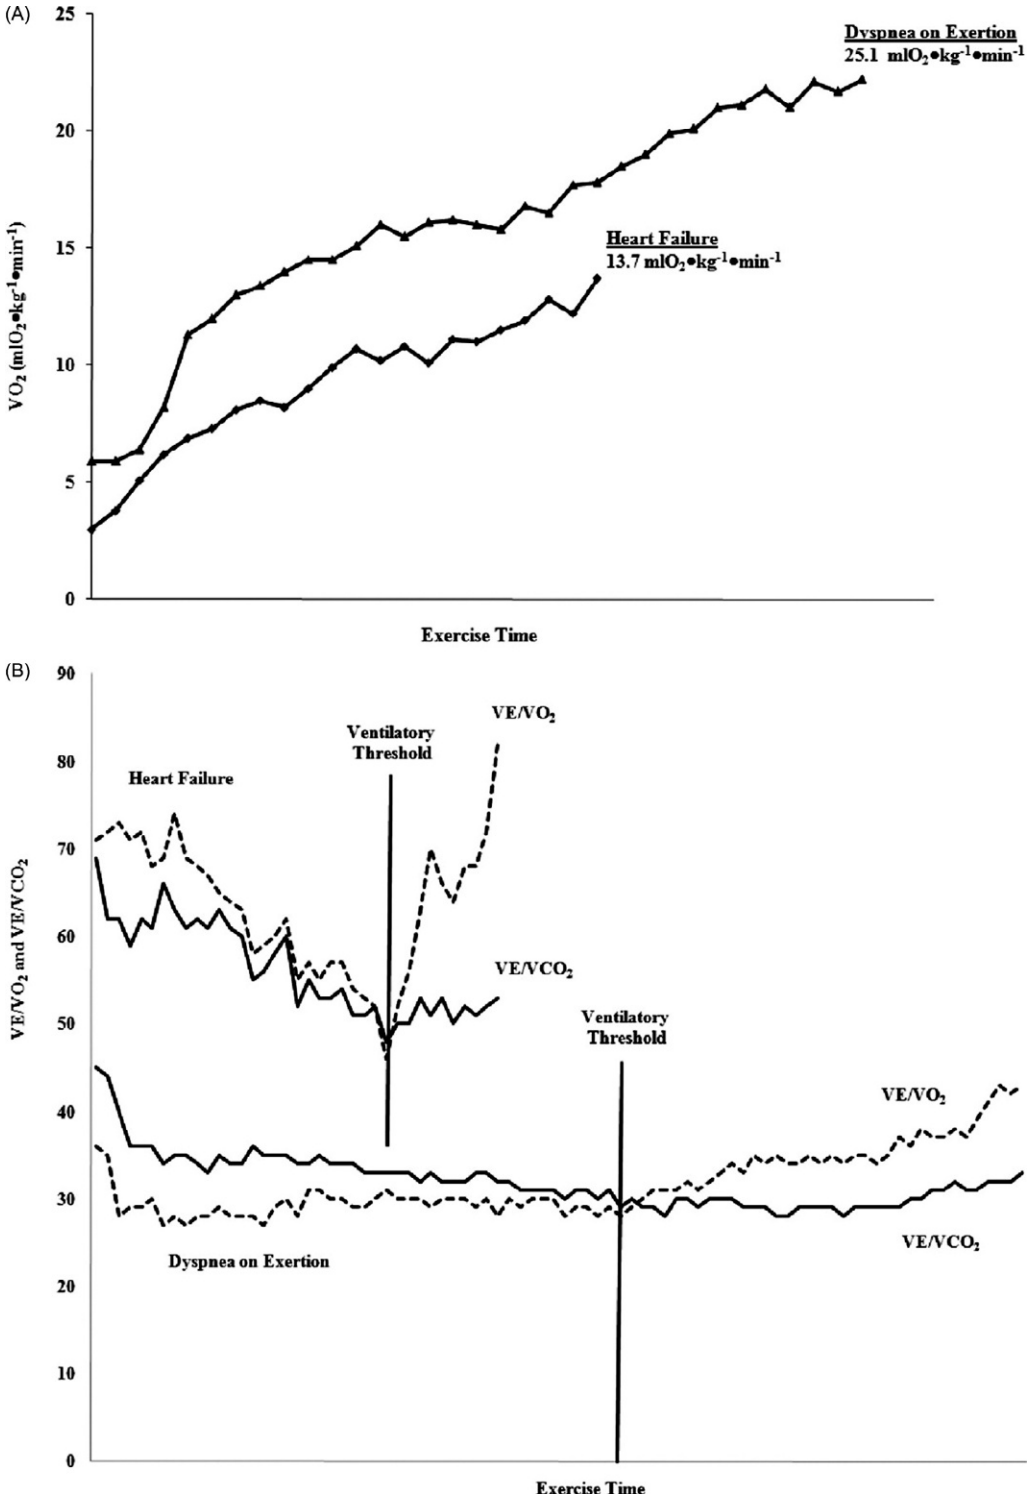

Fig. 1 (A) Peak VO_2, a measure of aerobic capacity, is reduced in heart failure. (B) determination of ventilatory threshold during cardiopulmonary exercise testing at point of increase in slope of VE/VO_2.

weekly. After a median follow-up of 30 months, the study found a nonsignificant 7% reduction in the primary combined endpoint ($P=0.13$). After adjusting for prespecified predictors of clinical outcome (baseline exercise duration, LVEF, Beck Depression Inventory II, history of atrial fibrillation, or flutter), investigators found a significant 11% reduction in the primary combined endpoint ($P=0.03$) (see Fig. 2). The secondary endpoint of cardiovascular mortality or heart failure hospitalization was also significantly reduced after adjustment (0.85, $P=0.03$). There was no significant difference in mortality (0.96, $P=0.7$). The study also established the safety of exercise training as adverse events were similar between the two groups.

Table 1 Comparison of physiologic parameters of heart failure and dyspnea on exertion

Reason for test	*Heart failure*	*Dyspnea on exertion*
Baseline characteristics	35-year-old female	35-year-old female
	Normal body weight	Normal body weight
Relevant past medical history	3-year history of idiopathic heart failure	2-year history of unexplained dyspnea on exertion
	Resting left ventricular ejection fraction 15%	Normal cardiac and pulmonary function
Aerobic capacity	Peak $\dot{V}_{O_2}$: 13.7 mL O_2 kg^{-1} min^{-1}	Peak $\dot{V}_{O_2}$: 25.1 mL O_2 kg^{-1} min^{-1}
	45% of predicted for age/sex	83% of predicted for age/sex
Peak RER	1.14	1.18
Submaximal exercise tolerance	$\dot{V}_{O_2}$ at VT: 8.5 mL O_2 kg^{-1} min^{-1}	$\dot{V}_{O_2}$ at VT: 14.0 mL O_2 kg^{-1} min^{-1}
Ventilatory efficiency	Abnormally elevated $\dot{V}E/CO_2$ slope	Normal $\dot{V}E/CO_2$ slope
Additional pulmonary function testing	No change in PEF after exercise compared with baseline	30% reduction in PEF after exercise compared with baseline
Breathing reserve	$(1 - \dot{V}E/MVV) > 20\%$ and within normal limits	$(1 - \dot{V}E/MVV) < 20\%$ and abnormally reduced
Electrocardiography	Occasional ventricular ectopy	No abnormalities detected
	Maximal heart rate = 122 bpm (66% of predicted) on a β-blocker	Maximal heart rate = 176 bpm (95% of predicted)
Hemodynamics	Blood pressure at rest: 110/60 mmHg	Blood pressure at rest: 118/72 mmHg
	Blood pressure at maximal exercise: 140/68 mmHg	Blood pressure at maximal exercise: 180/66 mmHg
Subjective symptoms	Maximal perceived exertion: 16/20	Maximal perceived exertion: 16/20
	Maximal dyspnea: 3/4	Maximal dyspnea: 4/4
	Reason for stopping: dyspnea	Reason for stopping: dyspnea
Interpretation	Severely diminished aerobic capacity and abnormal ventilatory efficiency: consistent with moderate to severe heart failure pathophysiology	Mildly diminished aerobic capacity; changes in pulmonary function after exercise and abnormally reduced breathing reserve are consistent with exercise-induced bronchospasm

PEF indicates peak expiratory flow rate; *bpm*, beats per minute.

Table 2 Pathophysiological mechanisms of exercise intolerance in heart failure (Downing and Balady, 2011)

Cardiac
Systolic and/or diastolic dysfunction
Reduced stroke volume
Elevated filling pressures
Secondary pulmonary hypertension and RV dysfunction
Mitral regurgitation
Reduced chronotropic reserve
Ventilatory system
Exaggerated minute ventilation relative to CO_2 production
Pulmonary hypertension and resulting pulmonary vascular damage and fibrosis
Ventilation/perfusion mismatch
Alveolar edema
Skeletal muscle
Reduced muscle mass
Reduced Type IIa fibers relative to Type IIb fibers
Reduced enzymes for oxidative metabolism and generation of ATP
Delayed resynthesis of high-energy compounds
Endothelial function
Reduced nitric oxide
Increased reactive oxygen species
Reduced vasodilatory response to shear stress
Neurohumoral system
Increased sympathetic activity
Low vagal activity
Increased levels of pro-inflammatory cytokines

Table 3 Beneficial effects of exercise in chronic heart failure (Downing and Balady, 2011)

Aerobic training
Increased exercise capacity
Lower heart rate response to submaximal exercise
Improved diastolic function
Improved endothelial function
Increased skeletal muscle oxidative capacity
Enhanced vagal tone and lower sympathetic tone
Reduced inflammatory cytokines
Lower all-cause mortality or hospitalization
Improved quality of life
Resistance training
Increased muscle strength and endurance

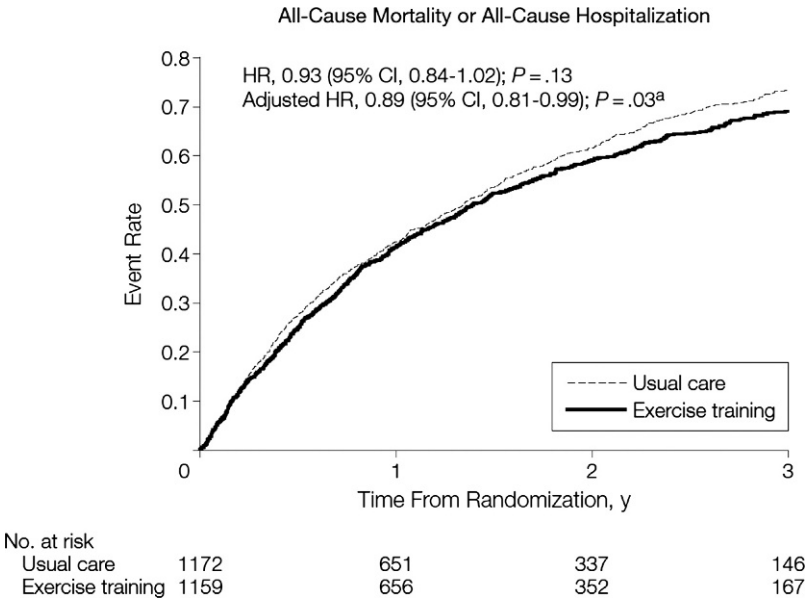

Fig. 2 Reduction in all cause mortality or hospitalization over the study period after adjustment for predictors.

The study was seen as disappointing to some for requiring statistical adjustment to achieve a significant result and for achieving a lower than expected effect size. The median improvement in peak VO_2 in the experimental group was 4%, much lower than the 10%–15% expected increase seen in previous studies. The results may have been affected by low adherence in the experimental group, as only 30% of patients in the experimental arm exercised at or above the target number of minutes per week. A subsequent analysis by Keteyian et al. (2011) investigated the relationship between volume of exercise and events and found that patients who achieved the prescribed exercise target had a 30% reduction in mortality and hospitalizations.

The importance of adherence was further demonstrated by a trial in Italy of 123 patients with stable heart failure randomized to a 10-year supervised exercise training program or control group. The trial was able to achieve 88% adherence to the exercise training program in the experimental group, which showed an increase in peak VO_2 of 14.7% compared to −2.5% for the control group ($P<0.01$) at 12 months (see **Fig. 3**). At 10 years, the experimental group had significantly fewer readmissions (0.64, $P<0.001$) and cardiac deaths (0.68, $P<0.001$) (Belardinelli et al., 2012). Unfortunately, a ten-year supervised exercise program is likely unfeasible, and it is unclear if these results could be replicated in an unsupervised program.

A 2014 Cochrane review of 33 trials of exercise-based rehabilitation in heart failure found no effect of exercise training on one-year mortality (0.93, 95% CI: 0.69–1.27) but a trend toward a reduction in mortality in trials with more than one year of follow-up (0.88, 95% CI: 0.75–1.02). Exercise training reduced overall hospitalization (0.75, 95% CI: 0.62–0.92) and heart failure-specific hospitalization (0.61, 95% CI: 0.46–0.80) and showed improved quality of life on the Minnesota Living with Heart Failure questionnaire (−5.8 points, 95% CI: −9.2 to −2.4). These benefits were independent of patients' age, gender, and severity of heart failure. The review highlights the need for further studies on cardiac rehabilitation in heart failure with preserved ejection fraction.

The safety and efficacy of cardiac rehabilitation has also been evaluated in specific populations. Rehab-VAD was a small trial ($n=26$) of patients with left ventricular assist devices that showed significant improvements in treadmill time, six-minute walk test,

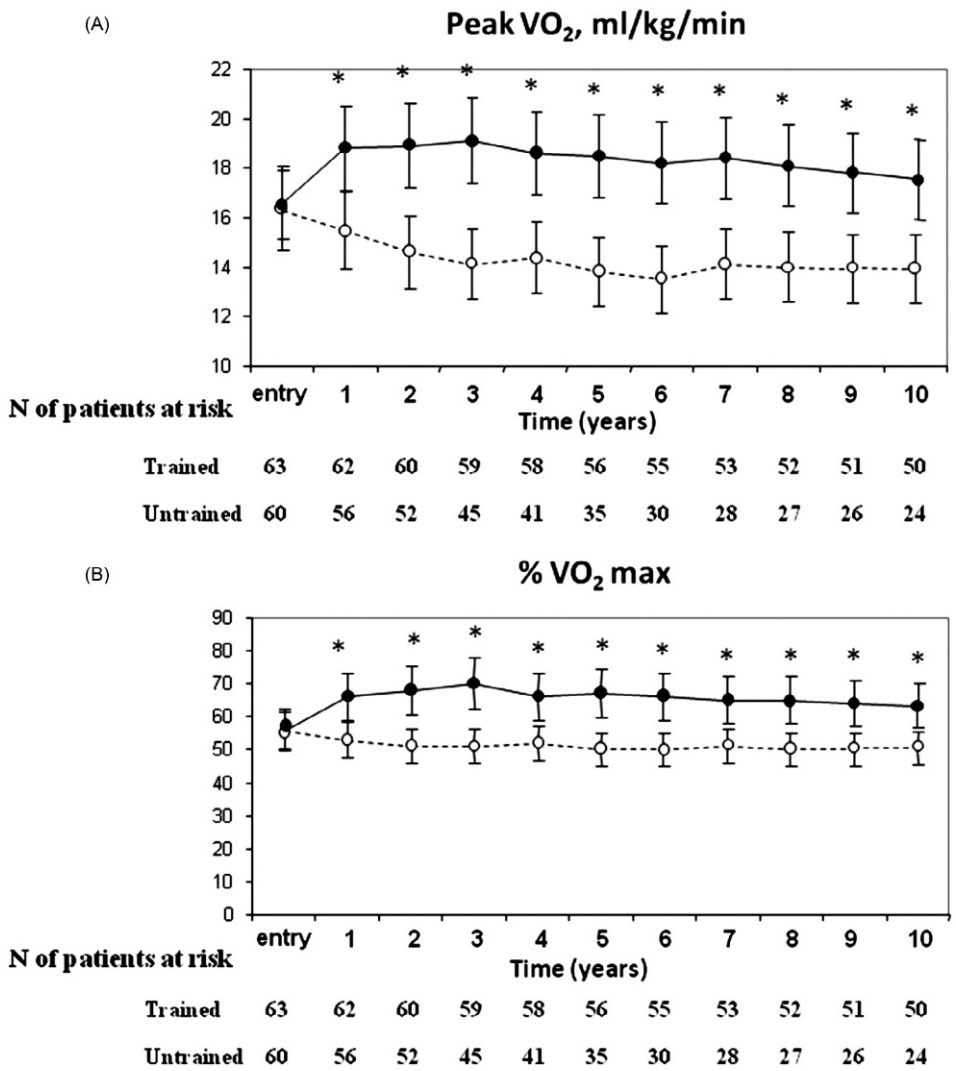

Fig. 3 Effect on aerobic capacity (peak VO_2) of a ten-year supervised exercise training program (Belardinelli et al., 2012).

and leg strength without significant improvement in peak VO_2 (Kerrigan et al., 2014). Sub-analysis of HF-ACTION by Luo et al. (2017) showed similar benefits from exercise for patients with atrial fibrillation (AF) as those in sinus rhythm even though patients with AF were older and had worse outcomes. REHAB-HF is currently in process and will evaluate the efficacy of cardiac rehab for 360 patients with acute decompensated heart failure over age 60 (Reeves et al., 2017).

Cardiac Rehabilitation in Practice

Cardiac rehabilitation, as developed in the treatment of acute MI, traditionally consists of three phases defined by setting and time. Phase I is inpatient rehabilitation occurring in the hospital after an acute event. It plays a smaller role today due to decreases in hospital admission lengths. Phase II occurs after discharge or upon referral. In the case of heart failure in the United States, it must begin at least six weeks removed from an acute cardiovascular hospitalization. It is commonly composed of 36 sessions over 3–4 months. Phase III refers to indefinite training occurring after the termination of Phase II and is not often covered by insurance in the United States.

The individual structure of cardiac rehabilitation programs can vary widely along a number of attributes (see **Table 4**). The optimal approach for different types of patients with heart failure has yet to be elucidated. Generally, resistance and inspiratory training is added as a complement to aerobic training, but respiratory training may be useful as a standalone therapy or a bridge for patients who are too frail or have a disability preventing use of an exercise machine. Aerobic exercise training is designed to increase exercise capacity; resistance training increases muscle strength and bone mass, and respiratory training can increase exercise capacity and ventilatory efficiency. Resistance training should be dynamic (isotonic) rather than static (isometric), which can increase blood pressure and lower stroke volume (Labate and Guazzi, 2015).

Table 4 Attributes of cardiac rehabilitation

Approach	*Examples*
Modality	Endurance aerobics
	Resistance training
	Respiratory training
Intensity level	Light
	Moderate
	High
Method	Continuous
	Interval
Application	Systemic muscle
	Regional muscle
	Respiratory muscle
Mode	Bicycle
	Treadmill
Setting	Hospital
	Center
	Home

Adapted from Labate, V. and Guazzi, M. (2015) Past, present, and future rehabilitation practice patterns for patients with heart failure. *Heart Failure Clinics* **11** (1), 105–115.

Several studies of high-intensity interval training (HIIT) have shown larger gains in peak VO_2 over moderate continuous training (MCT) (Wisloff et al., 2007). However, the SMARTEX trial, which randomized 261 patients with stable systolic heart failure to HIIT (90%–95% peak HR), MCT (60%–70% peak HR), or regular exercise found no significant difference between the improvement in aerobic capacity of HIIT and MCT. Additionally, 80% of MCT patients exercised above their target while 51% of HIIT patients exercised below their target, calling into question the general feasibility of HIIT in a heart failure population (Ellingsen et al., 2017).

Several studies have compared center and home-based therapies. A 2015 Cochrane Review on home-based versus center-based cardiac rehabilitation supports home-based cardiac rehabilitation as equally effective as center-based rehabilitation in short-term studies. The authors did not see a consistent difference in costs between center and home-based cardiac rehabilitation and recommend patient's needs and preferences drive decision (Taylor et al, 2015). The European Association on Cardiovascular Prevention and Rehabilitation has recommended center-based cardiac rehabilitation for patients with recent clinical stabilization or multiple comorbidities (Vanhees et al., 2012).

Challenges Facing Cardiac Rehabilitation

Increasing Utilization

Referral rates in the United States, which were at 13.3% of heart failure patients prior to Medicare approval, remain low (Golwala et al., 2015). One factor is certainly lack of cardiac rehabilitation services in certain geographic areas and a lack of capacity for all eligible patients in areas it exists (McNeely et al., 2016; Pack et al., 2014). Low provider referral rates in areas that do offer cardiac rehabilitation also play a role and vary largely at the hospital level, with bottom quartile hospitals referring less than 20% of eligible patients and top quartile hospitals referring over 80% (Aragam et al., 2015). Strategies shown to increase referral rates include the adoption of automatic referral systems in standard order sets and staff liaisons who help with the enrollment process (Mueller et al., 2009). Physicians must still play a role, however, as direct, in-person recommendations and discussion of potential barriers are a powerful predictor of cardiac rehabilitation participation.

Improving Adherence

A large challenge for cardiac rehabilitation programs is poor adherence and participation. HF-ACTION reported just 30% of patients achieved target exercise levels, a factor many cited as cause for the lower than expected increase in peak VO_2 of the experimental group. Many strategies can be used to improve adherence. Home-based cardiac rehabilitation has been shown to be as effective as center-based rehabilitation and can be more feasible for certain patients. Telehealth and mobile care plans have also been used to increase patient engagement and can assist in behavioral change. Consistent communication and reinforcement from all members of the rehabilitation team including case managers, liaisons, physical therapists, exercise physiologists, and physician can help drive participation. In addition, psychosocial and barrier assessment remains crucial as lower participation is found in low socioeconomic groups and depressive symptoms are found in nearly 30% of patients with heart failure (Kato et al., 2012).

Expanding Populations

Since 2014, Medicare only covers cardiac rehabilitation for patients with stable HFrEF on optimal therapy. Currently, the REHAB-HF trial is evaluating cardiac rehabilitation after acute exacerbation in elderly patients and including patients with HFpEF. More trials need to be performed to establish the long-term benefits of cardiac rehabilitation in patients with HFpEF, who comprise just over 50% of the population with heart failure. After CMS updated eligibility for cardiac rehabilitation in 2014, the percentage of patients with heart failure eligible for cardiac rehabilitation rose from 14% to 41%. This added just 27% of the heart failure population and left 59% ineligible mostly due to EF >35%. In analysis by Kelly et al. (2016), both HFpEF and HFrEF groups had one year mortality greater than 30% and readmission rates >65% suggesting an equal need for interventions that may reduce admissions and mortality. Given the lack of success of pharmaceutical trials in HFpEF, the potential for benefit from cardiac rehabilitation is intriguing and deserves greater study.

Introduction: Physical Activity, Exercise, and Heart Disease

For six decades, researchers have explored the cardiovascular benefits of exercise and physical activity, and documented consistent protective and therapeutic benefits for being physically active. This article reviews some of this evidence, with a focus on cardiovascular disease (CVD), defined here particularly as coronary heart disease (CHD).

Exercise is defined as planned and structured large muscle activity with the aim of improving maintaining physical fitness, performance, and health (Boden et al., 2013). It is a subset of "physical activity" which is more broadly defined as any movement involving large skeletal muscles leading to energy expenditure (Caspersen et al., 1985; Boden, 2013). Physical activity includes all large muscle movement throughout the day, at work, in travel to or from places, at home and in recreation or leisure time.

We review the primary prevention evidence for physical activity in reducing the risks of developing CVD among populations initially free of disease. We consider the new evidence on sedentary behavior (prolonged sitting time) and CVD. Then we consider the roles of physical activity and exercise for people with heart disease, and for common forms of heart disease: people with atrial fibrillation (AF) and patients with heart failure (HF), as exemplars of common cardiac conditions related to, or treated by physical activity and exercise. (Note that strictly this is tertiary prevention (as secondary prevention is screening for disease), but the term secondary prevention is widely used in cardiovascular health to mean patient-related prevention, so that this terminology is used here.)

The evidence for primary prevention comes from population-based epidemiological studies; the evidence for exercise and physical activity and potential benefits for people with cardiac disease comes from epidemiological, clinical, and basic science research. Hence, the perspectives in this chapter are multidisciplinary, emanating from both population and clinical sciences.

The Cardiovascular Health Benefits of Physical Activity: A Primary Prevention Approach

This section reviews the evidence for physical activity in the primary prevention of CVD, and is based on the epidemiological and population health research evidence accumulated over several decades. Primary prevention implies that in physical activity is beneficial in reducing the risk of developing CVD in populations of healthy individuals who are free of CVD. Much of this research emanates from epidemiological studies, starting in the 1950s with the observation that London bus drivers had higher CVD event rates than bus conductors, with the latter group being more active throughout the working day (Morris et al., 1953). Many studies followed, with consistent evidence provided for occupational and leisure time physical activity. Up until the 1990s, physical activity for health was usually defined as vigorous intensity "aerobic exercise," at least three times per week for at least 20 min each time (Kravitz et al., 2011). By 1990, there was a meta-analysis (Berlin and Colditz, 1990) and a systematic review (Powell et al., 1987) that clearly identified the risks of physical inactivity; on average, those who were least active were 1.9 times as likely to develop heart disease compared to the most active in the population.

A decade later, the US Surgeon General's report on the health benefits of physical activity was released (USSG, 1996) that redefined the minimal quantum of physical activity required to realize most cardiovascular and health benefits. This was a minimum recommendation of 30 min of at least moderate-intensity physical activity on most days of the week, a guideline that emphasized a new and more achievable level of physical activity for population health (USSG, 1996). The rationale for this was that most mortality risk and cardiovascular risk occurs in those who were completely inactive, and that maximum population benefit occurs if these inactive individuals start doing some activity, ideally half an hour a day (Powell et al., 2011). Benefit continued to accrue up to an hour a day of moderate-vigorous physical activity (MVPA), but beyond an hour a day, little additional benefit was noted (Arem et al., 2015). These benefits focused on all causes of mortality, but included risks of cardiovascular deaths, and risks of incident CVD events.

These cardiovascular benefits are now well established. Li and Siegrist (2012) conducted a meta-analysis of 21 epidemiological cohort studies, and compared to low active males, the men who met the recommended levels of activity had a 24% reduction in

CVD events; the same analysis showed a 27% risk reduction for women. These recent studies mostly focused on leisure time physical activity, with the role of occupational activity less clear (Li et al., 2013). The dose-response relationship was further verified by a 2011 meta-analysis of 33 cohorts (Sattelmair et al., 2011) which showed greater risk reduction for 300 min/week (an hour a day) compared to the minimum recommended level of 150 min/week of MVPA. The cardioprotective relationship was greater for women than men. Earlier meta-analyses had reached similar conclusions (Nocon et al., 2008; Oguma and Shinoda-Tagawa, 2004; Gebel et al., 2015), with even regular walking providing clear cardioprotection (Oguma and Shinoda-Tagawa, 2004). A consistent observation was that there was a stronger relationship for objective measures of fitness or movement, compared to self-report physical activity, indicating that the many self-report studies may underestimate the association (LaMonte and Blair, 2006; Nocon et al., 2008). Although moderate activity does, by itself, confer much of the preventive benefit, adding some vigorous activity further increases the benefit (Gebel et al., 2015).

One additional concept is the notion of the burden of disease, or the attributable fraction for disease; in other words, what proportion of diseases could be prevented if the risk factor was reduced or eliminated. According to the World Health Organization (2009), 57% of cardiovascular deaths can be traced back to one of the lifestyle risk factors and conditions (physical inactivity, smoking, unhealthy diet, hazardous alcohol use, and the resultant hypertension, obesity, and hypercholesterolemia). Physical inactivity is responsible for 3–5 million preventable deaths per year, and is the fourth ranked of these risk factors, ranking ahead of overweight and obesity (especially for CVD risk, WHO, 2009). These physical inactivity-related deaths and cardiovascular events occur in high and middle income countries, and especially in middle income countries may lead to premature mortality of people of middle age, which has national economic and productivity implications in many countries.

Given the strong evidence base, many Government and non-Government organizations have developed and adopted physical activity guidelines for preventing heart disease. The recent guidelines by the American Heart Association point to the benefits of at least half an hour of moderate-vigorous intensity physical activity on most days of the week (Haskell et al., 2007); the World Health Organization has a similar recommendation, of 150–300 min MVPA per week. For most patients with heart disease, the same recommendation, 30–60 min of activity on most days of the week remains current. In addition, sedentary behavior guidelines, to reduce prolonged and uninterrupted sitting time, are being developed, although the exact cut-points and nature of sitting-related risk remains uncertain (Young et al., 2016).

The Role of Exercise as a Secondary Prevention in Managing CVD

Exercise and physical activity are evidence-based approaches to the management of CVD, and in particular to cardiac rehabilitation following a cardiac event (Anderson et al., 2016). The physiological mechanisms underlying the beneficial effects of exercise in the secondary prevention for patients with CHD are well established. Exercise remains an important component of recovery from cardiac events, because it protects against cardiac ischemia/reperfusion injury (Boden et al., 2013). A number of reviews showed that regular moderate or vigorous-intensity exercise benefits people who have CHD by: (i) preventing the coronary arteries from further narrowing (antiatherosclerotic), (ii) inhibiting blood clotting (antithrombotic), (iii) promoting perfusion (antiischaemic), (iv) maintaining a normal heart rhythm (antiarrhythmic), (v) positively impacting on established cardiovascular risk factors (antiatherogenic), (vi) lowering inflammatory markers (antiinflammatory), and (vii) improving autonomic and vascular endothelial function (Boden et al., 2013; Fletcher et al., 2013; Leon et al., 2005). To exemplify this, exercise evokes antithrombotic effects by increasing fibrinolysis and decreasing platelet adhesiveness, fibrinogen, and blood viscosity (Fletcher et al., 2013). Moreover, the antiarrhythmic effect of exercise is stimulated through reduced adrenergic activity and increasing both vagal tone and heart rate variability (Fletcher et al., 2013). These changes help to decrease the load on the heart at rest and during exercise, which diminishes some of the symptoms of CHD (Fletcher et al., 2013).

It is well documented that people diagnosed with CHD who engage in aerobic exercise generate cardiac and peripheral adaptations including improvements in peak oxygen uptake, cardiac output, myocardial oxygen demand, and autonomic function (Fletcher et al., 2013; Mezzani et al., 2013). Regular, long-term exercise generates a range of morphological and phenotypic alterations in the myocardium such as resting bradycardia, left ventricle hypertrophy, cellular growth/adaptations in cardiac myocytes, and modified coronary vascular function (Brown et al., 2003; Fletcher et al., 2013). Moreover, participants diagnosed with heart disease who engaged in aerobic exercise frequently demonstrate an increase in cardiorespiratory fitness (VO_2 max levels, Mezzani et al., 2013). In addition, exercise may increase cardiac output which leads to improved vasomotor function (e.g., coronary dilatation) resulting in improved myocardial oxygen delivery to the myocardium leading to increased stroke volume (Leon et al., 2005). People with CHD who exercise at high-intensity levels show improvements in their cardiac function such as increased ejection fraction, stroke volume, diastolic function, and wall motion parameters (Fletcher et al., 2013). Exercise also promotes lowered myocardial oxygen demand after training for participants with CHD, leading to lower heart rate, systolic blood pressure, and circulating catecholamines (Fletcher et al., 2013; Leon et al., 2005). In summary, a plethora of evidence confirms a dose-response relationship between exercise and cardiovascular-related physiology and risk (Varghese et al., 2016).

When CHD is established, exercise and physical activity play a beneficial and significant role in the disease management. This is primarily because increased physical activity levels and cardiorespiratory fitness appear to mitigate CHD progression (Boden et al., 2013; Leon et al., 2005). Exercise also favorably influences some CHD risk factors, including insulin resistance, glycaemic control, blood pressure, lipid profile, fibrinolysis, endothelial function, inflammatory defense systems, and hemostatic factors

(Fletcher et al., 2013; Varghese et al., 2016). Exercise improves cardiorespiratory fitness, muscle strength, body composition, and flexibility—which ultimately lead to enhanced functional capacity and improvements in the functionality of the cardiovascular and endocrine systems (Varghese et al., 2016). Recent meta-analyses reported a 26% reduction in the risk of cardiac mortality (Anderson et al., 2016), a 13% reduction in all-cause mortality (Heran et al., 2011), and an 18% reduction in hospital admissions (Anderson et al., 2016), at 12 months in participants who undertook exercise-based cardiac rehabilitation compared to those who did not undertake cardiac rehabilitation. The meta-analyses demonstrated improvements in CHD risk factors, a greater increase in functional capacity, and enhanced health-related quality of life (Anderson et al., 2016; Taylor et al., 2015). Structured exercise for 12 months in patients with stable angina may even produce better outcomes than the standard therapy of percutaneous coronary intervention as measured by greater event-free survival, reduced hospitalization, and repeated vascularization procedures (Hambrecht et al., 2004). These findings reinforce the importance of exercise and physical activity as a therapeutic approach in the management of people diagnosed with CHD.

Given the numerous benefits of exercise-based cardiac rehabilitation, it forms part of national health policy recommendations (Achttien et al., 2013; Anderson et al., 2016). Most programs include supervised exercise sessions with an exercise physiologist and education on physical activity recommendations (Achttien et al., 2013). Guidelines for cardiac rehabilitation recommend that during phase II of the program, exercise sessions should be offered twice weekly for a minimum of 6 weeks (Achttien et al., 2013). The guidelines suggest that cardiac rehabilitation should be individualized and include a review of progress at each contact, plus follow-up telephone contact to facilitate long-term exercise behavior change (Piepoli et al., 2016). Guidelines also recommend counseling interventions for patients that promote setting specific and short-term goals; offer feedback on progress; advocate behavioral self-monitoring; and use tailored and personalized interventions, built on readiness to change, motivational interviewing, and enhanced patient self-efficacy (Piepoli et al., 2016; Varghese et al., 2016). Physical activity should comprise at least 150 min of moderate-intensity per week (or for 30 min, 5 days/week, overall) or 75 min of vigorous-intensity per week or equivalent combinations of moderate and vigorous activity, along with 2–3 days per week of resistance and flexibility exercise (Piepoli et al., 2016).

Health care professionals are encouraged to evaluate patients' physical activity levels at every visit and prescribe exercise at suitable dosages along with the use of mobile wearable physical activity devices and use social media platforms to increase physical activity awareness and motivation, and to self-monitor exercise progress (Kaminsky et al., 2016). It is also important to note that when cardiac rehabilitation is completed, exercise should be promoted as a lifetime habit (Achttien et al., 2013).

Exercise and Heart Failure

Exercise reduces the risk of HF, but the type and intensity of exercise have different effects on risk, and the effects persist into later life. For example, walking pace and leisure activity reduce the risk of developing HF, but the intensity of exercise does not. Reduced risk for HF occurs when walking at a moderate pace, versus a slow pace (>3 vs. 2 miles/hour, hazard ratio (HR): 0.74, 0.63–0.86). Higher total leisure time physical activity also reduces the risk of developing HF in comparison to lower physical activity levels (>845 vs. <845 kcal/week, HR 0.78; 0.69–0.87) (Del Gobbo et al., 2015). The risk of HF is reduced by exercise through multiple pathways; both direct, in terms of improved cardiac endothelial cell function and nitric oxide availability for example, and indirect, through the prevention of hypertension, left ventricular hypertrophy, CHD, and type 2 diabetes, all major risk factors for HF (Schuler et al., 2013). Even among older people (>65 years) exercise can have benefits for reducing the risk of HF. The mechanisms for the benefit of exercise in primarily through decreasing arterial stiffening and left ventricular changes commonly associated with aging, although there are no effects on cardiac stiffening (Fujimoto et al., 2010).

When HF occurs, there are marked effects on exercise tolerance leading to reduced capacity to complete normal daily activities and reduced health-related quality of life, and in the longer-term HF results in admissions to hospital and mortality. Reduction in exercise capacity occurs regardless of whether ejection fraction is preserved or reduced. Exercise training improves exercise intolerance and is recommended globally for HF patients as an effective and safe component of HF management (McMurray et al., 2012; O'Gara et al., 2013; National Clinical Guideline, 2014). Exercise training is usually delivered as a component of comprehensive cardiac rehabilitation programs. While exercise-based cardiac rehabilitation does not reduce mortality in HF patients, there are significant benefits for patients in terms of risk of hospital admission for any cause (RR 0.75; 0.62–0.92) and HF-specific cause (RR 0.61, 0.46–0.80), as well as clinical improvements in HF-specific health-related quality of life (mean difference −5.8 points, −9.2 to −2.4) (Sagar et al., 2015). The specific quantum or type of exercise training required to achieve these effects was not identified, as the programs varied greatly. The effects noted were found to be independent of the type of exercise (aerobic or resistance) and the dose of exercise, as well as the length of follow-up. However, post hoc analyses of the HF-ACTION trial indicated that 3–7 metabolic-equivalent hours/week is needed to achieve a clinical benefit in HF (Keteyian et al., 2012).

The mechanism of the effects of exercise training in HF patients is through improved oxygen extraction by skeletal muscle rather than by improving cardiac compliance or ventriculo-arterial coupling, both hallmarks of HF (Haykowsky et al., 2012). Further, the evidence for the effects of exercise in HF patients applies best to chronic, stable HF patients as patients with comorbid conditions and/frailty are excluded from trials. Given the greater prevalence and severity of comorbid conditions, such as diabetes, musculoskeletal disorders and cerebrovascular disease, in HF, this is an important limitation (Fleg et al., 2015).

Exercise and Atrial Fibrillation

The relationship between physical activity and risk of incident AF is complex: it appears a U-shaped risk-curve exists in men, and a dose-response association among women (Mohanty et al., 2016). Sedentary lifestyles are associated with an increased risk of incident AF, odds ratio (OR) 2.47 (Mohanty et al., 2016). Moderate physical activity lowers AF risk for both women (OR 0.91) and men (OR 0.81) (Mohanty et al., 2016); with a graded reduction in cardiac arrhythmias of 4.8% for every metabolic equivalent (MET)h/day run or walked (Williams and Franklin, 2013). Physical activity is thought to protect against AF through lowering systemic inflammation, lowering resting heart rate, blood pressure, and improving lipoprotein profiles (Aizer et al., 2009).

Some associations are not necessarily protective. Previous meta-analyses associated high-intensity exercise with increased AF risk in endurance athletes (OR 5.29, Abdulla and Nielsen, 2009), but recent analyses suggest this increased risk is only for males (OR 3.30). Excess risk is highest in men aged 30–50 years performing >5 sessions/week, with risk reducing with increasing age (Aizer et al., 2009; Abdulla and Nielsen, 2009; Drca et al., 2014). Endurance exercise is thought to increase AF risk through left atrial enlargement, longer p-wave duration, increased vagal tone affecting the atrial refractory period, increased atrial ectopy, and chronic systemic inflammation (Wilhelm et al., 2011; Swanson, 2006).

Improving cardiorespiratory fitness is likely to reduce AF risk. For each additional 1 MET achieved on baseline-exercise testing, AF risk reduces by 7% (Qureshi et al., 2015); and each 1 MET increase is associated with a decreased risk of AF recurrence (HR 0.87) (Pathak et al., 2015a,b). Recent evidence suggests possible reversal of AF, and significant improvement in AF recurrence, symptom burden, and arrhythmia-free survival, through both weight reduction (Abed et al., 2013; Pathak et al., 2015a) and increasing cardiorespiratory fitness >2 METs from baseline (Pathak et al., 2015a,b), in patients with paroxysmal and persistent AF. Structured exercise, ranging from aerobic exercise to walking and yoga, are demonstrated to be safe for people with AF, and can improve exercise capacity, resting heart rate, quality of life (Lowres et al., 2012; Wahlstrom et al., 2017), management and treatment of AF, and may even reduce the incidence of AF (Giacomantonio et al., 2013).

Sedentary Behavior and CVD: Current Evidence Overview

Sedentary behavior SB is defined as a low-energy expenditure rate (<1.5 MET) in a sitting or reclining posture (SBRN, 2012). In general, research on the health risks of SB is mostly concerned with prolonged "sitting time". Despite the substantial research progress in the last decade, our understanding of the links between SB and cardiovascular health is not fully developed. Multiple methodological issues, such as poor measurement and considerable heterogeneity between studies hinder a confident translation of the evidence into quantitative sedentary behavior guidelines. For example, international multicountry studies using questionnaires have estimated a sitting median time of around 5 h in adults (Bauman et al., 2011; Bennie et al., 2013), which is a substantially less than that international estimates using objective assessment of sitting time, that reported medians of 8–9 h of sitting time per day (Matthews et al., 2008; Stamatakis et al., 2012; van der Berg et al., 2016; Clark et al., 2015).

In children and adolescents the overwhelming majority of the evidence examining the links between objectively assessed sedentary behavior and surrogate CVD markers is cross-sectional; the results of the few available prospective studies point toward weak or limited associations (Ekelund et al., 2012; Stamatakis et al., 2015). In adults, a meta-analysis of nine prospective cohort studies ($n = 720{,}425$) examining the dose-response association between self-reported sitting and CVD risk, and found a nonlinear association; only very high amounts of daily sitting in excess of 10 h/day were linked to increased risk (Pandey et al., 2016).

The supposition that SB is associated with adverse cardiovascular outcomes independently of physical activity has been widely proposed in recent years (Hamilton et al., 2008; Young et al., 2016). However, a substantial meta-analysis in a pooled sample with greater than 849,000 adults (Ekelund et al., 2016) found that among those who reported >35 MET-hours of physical activity per week (just over 1 h of moderate intensity physical activity per day) eliminated the association between sitting time and CVD mortality. Although these results are encouraging in highlighting that the risks of prolonged sitting can be offset by being more active, it is worth noting that this amount of physical activity is achieved only by a minority of adult populations in developed countries. Smaller previous prospective studies also found that average daily amounts of physical activity roughly equivalent to (Petersen et al., 2014) or greater than (Chomistek et al., 2013) meeting the public health recommendations attenuate the CVD risk associated with sitting.

The introduction of frequent and regular interruptions of continuous bouts of sitting (termed as "sedentary breaks") has been proposed as a promising intervention to counteract the cardiometabolic risks of prolonged sitting (Healy et al., 2008). Currently there are no prospective epidemiological studies examining the association between sedentary breaks and cardiovascular biomarkers (Chastin et al., 2015) and even cross-sectional studies showed inconsistent or no associations (Healy et al., 2011; van der Berg et al., 2016). Some laboratory trials in type 2 diabetic patients have showed beneficial effects of frequently interrupting sitting time with simple resistance activities (Dempsey et al., 2016) or light intensity walking on resting blood pressure and nonesterified fatty acids (Dempsey et al., 2016; Henson et al., 2015).

In summary, sedentary behavior is associated with CVD risk in adults who report relatively large amounts of sitting per day (>10 h/day) and do not report relatively high amounts of physical activity (approx. 1 h/day). To date, all prospective studies in this area estimated sitting times using questionnaires that appear to be subject to underreporting; it is therefore important that future studies using objective measures of sitting and physical activity revisit these thresholds and associations, as self-report sitting time

might underestimate the epidemiological risk. The concept of sedentary breaks for CVD risk reduction is promising but needs further evidence through large prospective studies with objective measures of sitting and physical activity.

Conclusion

Physical activity, and its more structured form, exercise, are useful in the treatment of people with heart disease, through cardiac rehabilitation programs. New forms of telehealth and remote contact cardiac rehabilitation are required, such that more people can access physical activity programs after cardiac events (Huang et al., 2015). The role of exercise in HF is also well established, with increasing interest in the role of activity in AF.

Other forms of CVD are outside the scope of this review, but may be strongly related to physical activity, such as the prevention of stroke (McDonnell et al., 2013; Diep et al., 2010), and the clinical treatment of stroke and maintenance of functional capacity (Billinger et al., 2014). There are a subset of cardiac diseases where excessive exercise may pose hazards, for example, extreme exercise in athletes (La Gerche, 2016; Merghani et al., 2016). Further, a small number of young people with inherited cardiac disease may be susceptible to sudden cardiac death, and need early identification and special provision made for participation in physical activity (Diller and Baumgartner, 2016; Hammond-Haley et al., 2016).

In summary, physical activity and exercise remain substantial risk factors for the development of heart disease, and substantial elements of managing many people with CVDs. In terms of primary prevention, maintaining lifelong regular and active lifestyles has consistent and strong associations with reduced CHD morbidity and mortality. It is still somewhat neglected in clinical practice, as many professionals focus on clinical prevention, biomarker-improving pharmacotherapy, and the main areas of advice are around tobacco cessation. Physical activity is as important in global health as either tobacco control or obesity control (Lee et al., 2012), especially in the prevention and management of CVD.

Introduction

Extracorporeal membrane oxygenation (ECMO) has its roots with the development and idea of supporting the cardiopulmonary system by way of an artificial oxygenator and ventilator as well as a perfusion circuit to provide circulatory support. This became a reality in the 1950s through the work of Gibbon and his heart–lung machine and the development of a bubble oxygenator following early experience with cross circulation by Lillehei (Gibbon, 1954; Lillehei, 1982). These were designed to provide cardiopulmonary support for the performance of cardiac surgery and not as a temporary support. The ability to use ECMO as a standalone tool to provide cardiopulmonary support for recovery was first successfully performed in 1972 for an adult suffering from respiratory failure (Lewandowski, 2000). In the 1970s, a government-funded randomized trial to evaluate ECMO efficacy in adults with respiratory failure versus traditional mechanical ventilatory support failed to show a benefit of ECMO (Zapol et al., 1979). However, there was evidence of success with ECMO in neonates with the first successful therapy being instituted in 1975 (Bartlett et al., 1976). Building upon Bartlett and his colleagues' early success, the Extracorporeal Life Support Organization (ELSO) was founded in 1989 as an international, multiinstitutional effort in pushing the field forward. More recently with improvements in technology, advancements in critical care medicine, and understanding of physiology combined with success with its use for the H1N1 epidemic in late 2000s, ECMO has been thrusted into the mainstream of therapeutic consideration for patients with cardiopulmonary collapse (Peek et al., 2009).

Indications

ECMO is the tool by which to provide extracorporeal life support (ECLS) in those patients suffering from cardiopulmonary collapse. The three main indications for ECLS are for patients suffering from cardiac failure, respiratory failure, and a combination needing extracorporeal cardiopulmonary resuscitation (ECPR).

Patients requiring ECMO for strictly respiratory failure by definition have an intact cardiovascular system and the mode for delivering ECMO is via veno-venous cannulation (VV-ECMO). This provides only the ability to oxygenate and ventilate a patient with hemodynamic support and circulation to the body remaining by way of the patients own cardiovascular system. The main indications for this therapy are worsening hypoxia and/or hypercarbia refractory to maximal medical and ventilator therapy secondary to a reversible etiology. The most common causes of this are patients with pneumonia, vasculitis, acute or chronic graft failure following lung transplantation, chemical pneuomonitis, pulmonary hemorrhage or contusion, pancreatitis, and massive pulmonary embolism. The advantage of VV-ECMO for these patients is the avoidance of instrumentation of a large cannula into a systemic artery, thereby preventing systemic thromboembolic phenomenon as well as ischemia to the peripheral arterial system where the cannula is placed. In this article, we will not discuss VV-ECMO further, but concentrate on the use of ECMO for patients with primary cardiogenic shock and/or failure requiring ECLS.

Venoarterial ECMO (VA-ECMO) is required for patients suffering from either cardiopulmonary failure or primarily cardiac failure. Patients with cardiopulmonary failure are those patients with witnessed in-hospital cardiac arrest whose indication for ECMO is for ECPR. Although not universal, the generalized indications for institution of VA-ECMO in these patients are for adults who are in cardiac or respiratory arrest following a witnessed, in-hospital arrest where effective, uninterrupted, and ongoing CPR without evidence of hypoxia and/or anoxic brain injury have occurred. Additionally, patients should be immediately evaluated for initiation of ECPR as best results are obtained in patients for whom VA-ECMO is instituted within 10–15 min of cardiopulmonary arrest.

Primary cardiovascular collapse can be an immediate phenomenon or may take several days to develop. Those patients with evidence of hypotension that is medically refractory and does not respond to inotropes, vasopressors, or mechanical circulatory support (intraaortic balloon pump, percutaneous ventricular offloading device, etc.) to maintain appropriate perfusion to end organs warrants screening for VA-ECMO. Decreased organ perfusion can be seen in patients with persisting lactic acidosis >3.2 mmol/L, decreasing urine output, cool and diaphoretic extremities, altered mental status, rise of creatinine of >1 mg/dL in 24 h, elevation in transaminases or development of pulmonary edema or hypoxia should raise concern, and profound cardiogenic

shock should be diagnosed in patients requiring high dose of one or more inotropes, persistent cardiac index <1.8 L/min/kg with concomitant hypotension despite fluid resuscitation. The etiology for cardiogenic shock may include acute on chronic decompensated heart failure, acute decompensated heart failure, acute coronary syndrome, peripartum cardiomyopathy, fulminant myocarditis, or cardiac allograft failure. Other less common indications include refractory ventricular tachycardia or ventricular fibrillation unresponsive to conventional therapy, hypothermia, acute anaphylaxis, pulmonary embolism, sepsis-related cardiac dysfunction, and drug overdose.

The modified vasoactive-inotropic score (VIS), a calculation utilizing dosage of vasopressors and inotropes calculated into a score, is an objective measure that can guide the need for ECMO (Gaies et al., 2014). As the indications for VA-ECMO are quite varied with multiple disciplines involved, there are no standardized, absolute contraindications to VA-ECLS. It is important though to consider the futility of therapy in those patients who have advanced age (>75 years), life expectancy from end-stage/active malignancy with less than 1 year, severe peripheral vascular disease, end-stage renal disease on dialysis, advanced liver disease, current intracranial hemorrhage or other contraindication to systemic anticoagulation, unwitnessed cardiopulmonary arrest with ongoing cardiopulmonary resuscitation, and witnessed cardiopulmonary arrest with prolonged cardiopulmonary resuscitation (>30 min) without return of spontaneous circulation.

Components of ECMO

The VA-ECMO circuit consists of a pump, a membrane oxygenator, a controller, cannulas for venous return from patient to circuit, and arterial outflow from pump to patient as well as tubing (**Fig. 1**) (Rodriguez-Cruz et al., n.d.). The pump is usually a centrifugal pump that can generate up to 4000 rotations per minute and flow up to 8 L per minute. The oxygenator functions not only to oxygenate blood but also to eliminate carbon dioxide. The controller for the oxygenator has the ability to alter the fraction of inspired oxygen into the system as well as the sweep in liters per minute for the purpose of carbon dioxide removal. The controller displays information to the clinician and allows for adjustments to pump speed in rotations per minute and ultimately flow through the entire system.

In determining the best method for cannulation in the initiation of VA-ECMO, it is imperative to consider the indications, patient baseline characteristics, and anatomic pitfalls. In the most simplistic terms, there is a drainage cannula that takes blood from the patient to the circuit and a return cannula that takes blood from the circuit back to the patient. Dual lumen, single cannulas can be employed for veno-venous support, but is beyond the scope of this article. The drainage cannula is inserted into the venous system of the patient and is typically a large diameter (21–25 French) and longer (up to 60 cm) than its arterial counterpart.

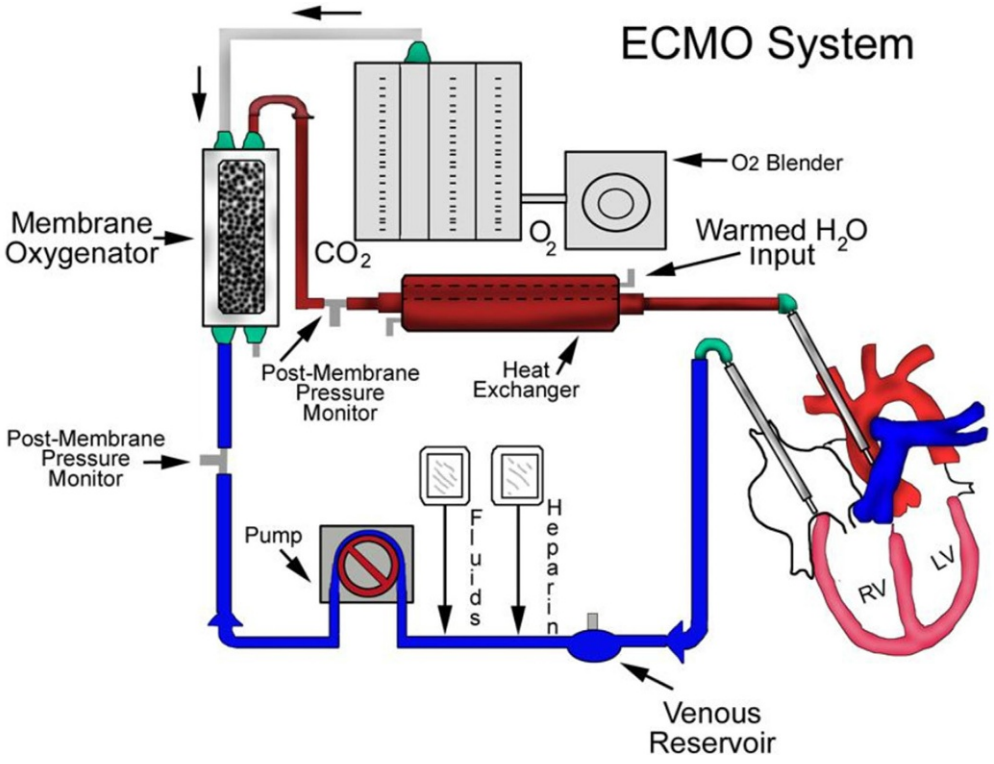

Fig. 1 The extracorporeal membrane oxygenation circuit. Courtesy of *EMedicine.com*.

The venous drainage cannula can be either single or multistage to facilitate drainage and hence inflow into the ECMO circuit. The return cannula is inserted into the arterial system, is typically 15–19 French in diameter, and is shorter with lengths of 20–25 cm when inserted peripherally.

The initiation of VA-ECMO in patients suffering from postcardiotomy shock, inability to wean from cardiopulmonary bypass, or in cases of emergent reentry sternotomy in a recent cardiac surgery patient represents arguably the most straightforward cannulation decision. Central cannulation with a drainage (venous) cannula inserted directly into the right atrium and a return (arterial) cannula directly into the ascending aorta are the most efficient and least problematic cannulation strategy. This is how cardiopulmonary bypass during routine cardiac surgery is performed and should be second nature to the cardiothoracic surgeon. For most patients, the chest is left open with packing material and cannulas tunneled away from the midline wound. In certain instances where aortic insufficiency may be present and/or left ventricular distension is seen on echocardiography, a left ventricular vent can be directly inserted into the left atrium and "y-ed" into the drainage cannula to facilitate left ventricular offloading and stagnation.

In the patient who is not status post recent cardiac surgery, peripheral VA-ECMO is the most common cannulation strategy. Peripheral cannulation requires vessels that can accommodate appropriate diameter cannulas for both drainage and perfusion. For these reasons and ease of access, the femoral artery and vein are the most frequently utilized vessels. Although there can be multiple configurations of VA-ECMO that can be employed, the most common indication and clinical scenario is one where emergent VA-ECMO is required during active cardiopulmonary resuscitation. As this is a hectic time and no adequate pulsatility and/or oxygenation exists, it is unreliable to use the usual measures to delineate venous versus arterial entry such as palpation of pulses, color of blood return, and presence of pulsatile flow. In this setting, the optimal configuration for cannulation is the ipsilateral femoral venous and femoral arterial access as the first cannula can act as the anatomic landmark for the second cannula. If an intraaortic balloon pump is already in place, one can utilize the ipsilateral femoral venous access based on relative anatomy and the contralateral side for femoral arterial access.

Other, less expeditious methods for return (arterial) cannulation include placement of a 8 mm graft (woven double velour vascular graft, polyester, or polytetrafluorethylene) sewn to the axillary artery or femoral artery. The advantage is to prevent distal limb ischemia and prevent high line pressures, and the disadvantage is the time necessary to dissect out the appropriate vessel and make a hemostatic anastomosis. Important considerations are to ensure systemic anticoagulation immediately once access is obtained and commencement of VA-ECMO.

This is often the time to pause and ensure appropriate circuit function. An activated clotting time (ACT) >220 s or an activated partial thromboplastin time (aPTT) >70 (depending on local laboratory normalization values) will ensure appropriate thinness of the blood for the circuit. The patient should be maintained on intravenous heparin infusion to prevent thrombus formation in the oxygenator and the need for an urgent circuit replacement.

Cannula position should be immediately evaluated using an array of diagnostics. Arterial line pressures >200 mm Hg can signal vascular injury, dissection, malpositioning, as well as an impending retroperitoneal hematoma. To further reduce the chance of vascular ischemia to the lower extremity of the femoral artery used, a 7 French armored (wire wound) catheter in the superficial femoral artery placed in an antegrade manner after the patient has been initiated on VA-ECMO support. Lack of venous return can signal hemorrhage, inadequate volume resuscitation, vasoplegia, or malpositioned venous cannula. In peripherally inserted cases, the tip of the venous cannula should be in the distal inferior vena cava by the cavoatrial junction. This position can be confirmed by echocardiography or chest X-ray postprocedure. Other methods of providing venous drainage access have been via internal jugular vein in cases of inferior vena cava thrombosis or inferior vena cava filters. It is imperative to ensure that cannulas are secure as to prevent migration and dislodgement. This should be done by a pursestring suture at the entrance site, multiple heavy sutures along the skin exit site, as well as course of cannulas to prevent any tension in addition to securing all tubing connection sites.

In some cases, where left ventricular distension is occurring either via intracardiac shunt, inappropriate venous drainage, or intracardiac shunt, adjunctive measures can be taken to decompress the left ventricle. These include left atrial or ventricular vents, intraaortic balloon pumps, and percutaneous ventricular offloading devices. The central idea is to allow reduction of myocardial wall stress and oxygen demand and ultimately improving the chance of ventricular recovery.

Outcomes

Along with the increased use of ECMO in the last decade, there has been an increase in the scrutiny of outcomes, definition of success or futility, and the cost to benefit ratio of this technology (Shah, 2016). Secondary to the inherit differences for the indication for ECMO initiation, center-specific guidelines on utilization of the technology, and definition of success, there are quite varied reports of outcomes following ECMO. Outcomes, as defined by ELSO, can be reported as survival to decannulation or survival to discharge. According to the ELSO database for those patients supported with ECMO in the registry between 1990 and 2015, 66% and 58% survived to decannulation and survival for respiratory indication for support ($n=9102$), 56% and 41% for patients supported for cardiac reason ($n=7850$), respectively, and 40% and 30% for patients with ECPR ($n=2374$), respectively. When compared with conventional CPR rates of 17% survival, these outcomes are encouraging as are the outcomes for respiratory and cardiac reasons for initiation (Extracorporeal Life Support Organization Registry Report, n.d.). Even in patients supported for cardiac reasons alone, there are variances in outcomes reported. In patients where there exists a reversible insult such as acute fulminant myocarditis, a multicenter analysis demonstrated cardiac recovery and weaning from VA-ECMO in up to 76% of cases with survival to hospital discharge of 72% (Lorusso et al., 2016). In cases of ECMO institution following the postcardiac surgery

phase, a single institution series of 233 patients demonstrated a much lower survival rate to hospital discharge of only 36% (Elsharkawy et al., 2010).

An equally important consideration in addition to survival to decannulation and/or discharge from the hospital is the absence of complications. In particular, ELSO definitions of quality measures include mechanical complications of ECMO (cannula, oxygenator clots), hemorrhagic complications, neurologic complications, renal failure, metabolic complications, infectious complications, and cardiopulmonary complications. Aside from nonrecovery of cardiac function and multiorgan failure, vascular complications are the most frequent cause of death with utilization of VA-ECMO. The rate of hemorrhagic complications can be as high as 40%, malperfusion with critical lib ischemia can occur in 15%–20% (10% fasciotomy requirement, 5% amputation rate), acute kidney injury in 55% (45% with need for renal replacement therapy), neurologic complications in 10%–15%, and infection in 30% of patients supported with ECMO (Cheng et al., 2014).

Discussion

In patients suffering from witnessed in-hospital cardiopulmonary arrest, respiratory failure refractory to mechanical ventilation with advanced maneuvers, and those in cardiogenic shock, ECMO can be a life-saving intervention. The moribund nature of these patients has to be remembered when trying to determine the success or futility of this therapy. In fact, ELSO recommendation for the consideration for ECMO is the presence of a 50% mortality with initiation of therapy when 80% mortality risk exists in appropriate patients. ECMO has become an increasingly prominent treatment modality in the armamentarium of clinicians who treat patients with acute, medically refractory circulatory failure. Although general guidelines and techniques exist for this therapy, there are no large randomized, controlled studies that can serve as unbiased studies in cardiogenic shock. Indeed, this form of therapy is a last resort in patients who are in desperate need of cardiopulmonary support.

It is crucial to develop a multidisciplinary institutional team in the management and selection of patients that will benefit from this therapy. It is the hope in all cases that there exists a reversible cause for patient deterioration, but a realistic time frame (i.e., 14 days) for support of these patients needs to be made in conjunction with patient and their families. Any steps to aid in recovery or escalate therapy such as suitability for decannulation, more permanent mechanical support, an ablation procedure, a revascularization procedure, or transplantation should be considered on an ongoing and daily basis. Undoubtedly, there will always exist a significant risk of mortality and morbidity in these patients. Clear goals of care with constant communication with patient and their family in conjunction with help from palliative care medicine can stress the importance of not just treating a pathology but the patient.

A healthy understanding of the indications and management will be essential in continuing to optimize survival while reducing the complication rates of this technology. Furthermore, suprainstitutional networks of early referral and transfer of patients to tertiary care centers for consideration for ECMO can improve outcomes in patients prior to the onset of multiorgan failure (Aubin et al., 2016). In cases of ECPR, the education of first line respondents such as emergency room, critical care, and interventional cardiology physicians are paramount to increase survival from patients in shock. Despite the ongoing challenges of ECMO, there is no doubt that it has already saved thousands of critically ill patients' lives and will continue to do so in the foreseeable future.

Introduction

Autosomal dominant hypercholesterolemia (ADH) is a genetic disorder affecting low-density lipoprotein cholesterol (LDL-C) metabolism, characterized by very high levels of circulating LDL-C and premature cardiovascular disease, myocardial infarction or death early in the life, especially in untreated subjects (Nordestgaard et al., 2013; Cuchel et al., 2014; Wiegman et al., 2015; Krogh et al., 2016). Despite the current availability of several cholesterol-lowering drugs, which appear to be very effective also in the treatment of genetically determined hypercholesterolemia, a main gap in the management of this disease to prevent its cardiovascular complications is the detection of familial hypercholesterolemia (FH) subjects. In fact, while the most severe forms are generally characterized by the presence of unequivocal physical features, the less severe forms may remain undetected until the first cardiovascular event occurs. Due to the high burden of cholesterol exposure from the birth, the early detection of such subjects is essential so that they can be treated from childhood to reduce their cardiovascular risk and gain decades of life free of cardiovascular events. In this chapter, we will describe the features of FH disease and present the results of clinical trials of currently available drugs approved for the treatment of FH patients.

Genetics of Familial Hypercholesterolemia

Several genetic defects cause ADH; FH (or ADH1) is the most common form of ADH and is due to mutations in the *LDLR* gene, encoding for the LDL receptor (LDLR), responsible for the binding and uptake of LDL particles in the liver (**Fig. 1**) (Sniderman et al., 2014). Mutations in the *APOB* gene, which block the association of the LDL particle to LDLR, are the cause of familial defective apolipoprotein B100 (FDB, or ADH2) (**Fig. 1**; Whitfield et al., 2004; Andersen et al., 2016); gain-of-function (GOF) mutations in *PCSK9* gene reduce LDLR recycling and accelerate its lysosomal degradation, causing a condition referred to as ADH3 (**Fig. 1**; Sniderman et al., 2014). Finally, a rare recessive form of hypercholesterolemia (autosomal recessive hypercholesterolemia, ARH), caused by the loss-of-function (LOF) mutations in the *LDLRAP1* gene (encoding for a protein promoting the hepatic internalization

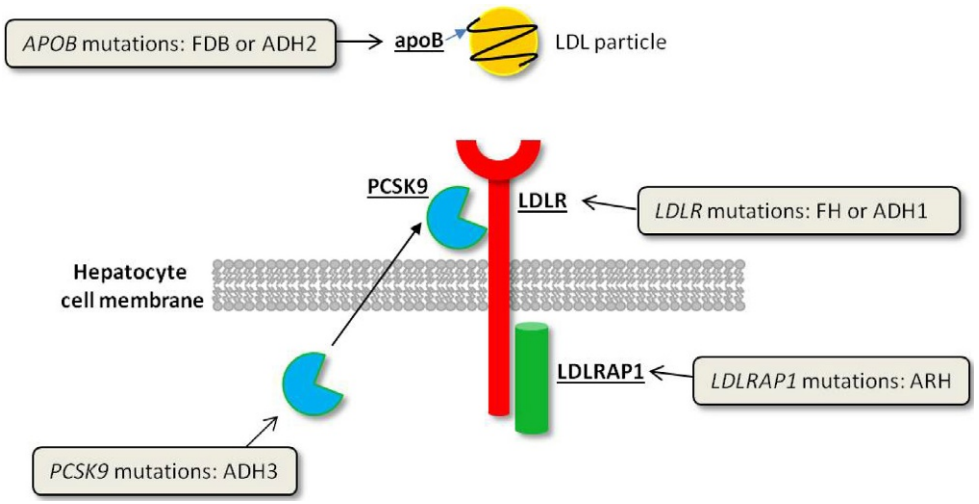

Fig. 1 Genetic causes of autosomal dominant hypercholesterolemia or autosomal recessive hypercholesterolemia.

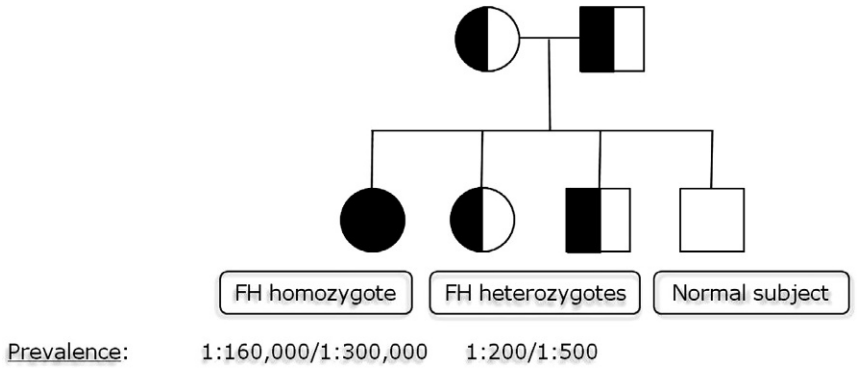

Fig. 2 Inheritance of homozygous or heterozygous familial hypercholesterolemia in a pedigree and prevalence in the general population.

of LDLR/LDL complex), has also been described (**Fig. 1**; Garcia et al., 2001; Fellin et al., 2015). All these conditions are commonly referred to as FH.

Being a genetic disorder, FH can present either in the less severe heterozygous form (HeFH) or in the rarer homozygous form (HoFH) (**Fig. 2**; Cuchel et al., 2014; Singh and Bittner, 2015). HeFH has a prevalence of ~1/500–1/200 in the general population and is characterized by a reduced LDLR activity (~50%) which translates into a two- to threefold increase of LDL-C levels and the occurrence of coronary heart disease (CHD) before the age of 55 (60 for women) (Nordestgaard et al., 2013). HoFH includes the true homozygotes, carrying the same mutation in both gene alleles, compound heterozygotes, carrying two distinct mutations in the two alleles of the same gene, and the rare form of double heterozygosity, due to the presence of mutations in two different genes (Nordestgaard et al., 2013; Cuchel et al., 2014). HoFH, with a prevalence of ~1/160,000–1/300,000, is characterized by a significantly reduced LDLR activity and includes either receptor-defective subjects (2%–30% residual LDLR activity) or receptor-negative subjects (<2% LDLR activity) having more severe cardiovascular conditions compared with subjects with receptor deficiency (Cuchel et al., 2014). Being exposed to very high levels of LDL-C (>500 mg/dL) from birth, receptor-negative HoFH may present clinical signs of heart disease very early and may experience myocardial infarction before the age of 20 if untreated (Cuchel et al., 2014; Sniderman et al., 2014). Subjects with FDB present a less severe hypercholesterolemia, lower occurrences of tendon xanthoma, and a lower incidence of coronary artery disease compared with FH (Whitfield et al., 2004). Heterozygous and homozygous FH determined by *PCSK9* mutations exhibit a milder phenotype compared with FH caused by *LDLR* mutations (Mabuchi et al., 2014).

Other Lipid Abnormalities in FH: Focus on Lipoprotein(a) Levels

Lipoprotein(a) (Lp(a)) is an LDL-like particle to which apolipoprotein(a) is linked to apoB via a disulfide bond; several epidemiological studies have suggested that elevated plasma levels of Lp(a) represent a cardiovascular risk factor independently of LDL-C levels (Nordestgaard et al., 2010). It has been shown that FH patients, particularly those with cardiovascular disease, exhibit

significantly higher plasma levels of Lp(a) compared with their nonaffected relatives (Alonso et al., 2014), although no difference was observed between FH patients carrying *PCSK9* GOF mutations and FH patients carrying *LDLR* mutations (Tada et al., 2016). Furthermore, Lp(a) represents an independent predictor of CVD in these subjects (Alonso et al., 2014). Lp(a) levels are higher in FH subjects with early CHD events than in FH subjects with late or no CHD (Nenseter et al., 2011). Finally, although statin therapy has significantly improved the prognosis of FH patients, a considerable degree of CAD in asymptomatic FH under long-term statin treatment has been observed, suggesting that additional risk factors independent of LDL-C levels may contribute to the residual CVD risk in treated FH patients, and Lp(a) may play a role. Experimental and clinical evidence indicate a desirable Lp(a) levels below 50 mg/dL (Nordestgaard et al., 2010).

An association between Lp(a) levels and c-IMT has been observed both in the general population and in hypercholesterolemic subjects (Baldassarre et al., 1996; Schreiner et al., 1993). Surprisingly, when analyzed in FH, patients with high or low Lp(a) levels (>30 mg/dL and ≤30 mg/dL, respectively) had the same plaque prevalence and similar c-IMT values (Bos et al., 2015). A possible explanation for this finding is that patients were relatively young (mean age 48 years) and treated with aggressive statin therapy. On the other hand, another study reported an association between Lp(a) plasma levels and aortic valve calcification (which is a significant risk factor for aortic valve stenosis and cardiovascular disease), but not with coronary artery calcification (Vongpromek et al., 2015). Although statin therapy attenuates the progression of CAC, as a result of LDL-C lowering, it does not appear sufficient to provide better clinical outcomes in patients with aortic valve calcification, possibly because it does not reduce Lp(a) levels (Vongpromek et al., 2015).

In fact, while it is possible that LDLR is involved in Lp(a) uptake and degradation, the observations that non-FH subjects have lower levels of Lp(a) compared with FH patients, that carriers of null LDLR mutations have higher Lp(a) levels compared with those with defective mutations (Alonso et al., 2014), and that HoFH have higher Lp(a) levels compared with HeFH suggest a gene-dosage effect (Kraft et al., 2000). However the effect of statins (which upregulate LDLR) on Lp(a) levels is inconsistent (Tziomalos et al., 2009). On the contrary, PCSK9 inhibitors, which act also on LDLR expression, seem to reduce significantly also Lp(a) levels.

Altogether these observations suggest that Lp(a) levels should be assessed in FH patients to identify those who could benefit from more aggressive lipid-lowering treatments.

Diagnosis of Familial Hypercholesterolemia

The diagnosis of FH can be based on either clinical criteria or genetic tests. The last provide a definitive diagnosis of FH, although some patients presenting with clinical characteristics of FH may have a negative genetic test, suggesting the possible involvement of unknown genes. Several criteria exist for the diagnosis of FH, including the Simon Broome register (Scientific Steering Committee on behalf of the Simon Broome Register Group, 1991), the WHO criteria (World Health Organization, 1999), and the Dutch Lipid Clinic Network (DLCN), the latter being the most commonly used. DLCN criteria establish a score that gives the probability that a subject has FH (**Table 1**). The score is calculated based on family history of premature CHD or hypercholesterolemia, on patient history of premature CHD or presence of high levels of LDL-C, on the presence of physical signs such as tendon xanthomas or corneal arcus (**Table 1**). HoFH can be diagnosed based on the clinical conditions of the patient, including very high levels of untreated LDL-C (>13 mmol/L or >500 mg/dL) or treated LDL-C ≥8 mmol/L or ≥300 mg/dL, the presence of cutaneous or

Table 1 Dutch Lipid Clinic Network (DLCN) criteria for the diagnosis of FH

Criteria	*Score*
Family history	
First degree relative with known premature (<55 years for men, <60 years for women) coronary heart disease	1
OR	
First degree relative with known LDL-C >95th percentile by age and gender for country	
First degree relative with tendon xanthomas and/or corneal arcus	2
OR	
Children <18 yeards with LDL-C >95th percentile by age and gender for country	
Clinical history	
Subject with premature (<55 years for men, <60 years for women) coronary heart disease	2
Subject with premature (<55 years for men, <60 years for women) cerebral or peripheral vascular disease	1
Physical examination	
Tendon xanthomas	6
Corneal arcus in a subject <45 years	4
Untreated LDL-C levels	
>8.5 mmol/L (>325 mg/dL)	8
6.5–8.4 mmol/L (251–325 mg/dL)	5
5.0–6.4 mmol/L (191–250 mg/dL)	3
4.0–4.9 mmol/L (155–190 mg/dL)	1
Genetic test	
Causative mutation in *LDLR*, *APOB*, or *PCSK9* genes	8

tendon xanthomas before the age of 10, or the presence of high levels of LDL-C in both parents, or the genetic confirmation of two mutants alleles in *LDLR*, *apoB*, *PCSK9*, or *LDLRAP1* genes (Cuchel et al., 2014). However, the discrimination between HeFH and HoFH may be not always simple, particularly if based only on LDL-C plasma levels, as a high phenotypic heterogeneity has been observed due to the high heterogeneity of underlying genetic defects.

Cardiovascular Risk and Complications in Patients With FH

Due to the exposure to high levels of circulating LDL-C from birth, patients with FH are at high risk for cardiovascular disease; HeFH have a 3.5–16-fold higher risk of CAD compared with non-FH subjects (Hovingh and Kastelein, 2016), and homozygous have a further increased risk (Cuchel et al., 2014). HoFH patients have an accelerated atherosclerosis that impairs not only coronary arteries and the aortic root, but also carotid, descending aorta, and peripheral arteries (Raal and Santos, 2012). Clinically diagnosed HoFH commonly present their first cardiovascular event, including angina pectoris and myocardial infarction, during adolescence, but may also occur in early childhood when the genetic defect leads to an LDLR-negative phenotype (Cuchel et al., 2014). If untreated, they usually die before the age of 20; LDLR-defective HoFH have a better prognosis, as they manifest their first cardiovascular event by the age of 30 (Cuchel et al., 2014). The underlying genetic defects determine the severity of the disease; thus, the phenotype of a severe HeFH condition may be similar to a HoFH phenotype (Snozek et al., 2009).

A major limitation in the management of FH patients is that, while HoFH often present with unequivocal physical symptoms, HeFH may be undetected until they present with their first coronary event. Furthermore, due to the overall "milder" phenotype compared with HoFH, they may present with LDL-C levels unnecessarily extremely high and thus may be confounded with "normal" hypercholesterolemic subjects. However, the presence of genetic defects per se increases the cardiovascular risk, as it implies a life-long exposure to elevated LDL-C levels; thus, FH subjects with LDL-C $\geq$190 mg/dL have a threefold increased risk compared with non-FH subjects with the same LDL-C plasma level (Khera et al., 2016). This reinforces the idea that the genetic testing may provide risk information beyond the LDL-C levels.

FH in Childhood

Due to the high risk of early cardiovascular events in FH subjects, the identification of children and adolescents with FH, followed by lifestyle changes and lipid-lowering therapy, represents an important step in the prevention of premature coronary complications. In fact, increased c-IMT can be observed as early as 7 years in FH children, as well as endothelial dysfunction and thickening of the arterial vessel wall (Wiegman et al., 2004a; de Jongh et al., 2002; Narverud et al., 2014); if untreated, they may experience their heart attack very early in the life (Kusters et al., 2014). As for adults, FH may be diagnosed either based on phenotypic criteria or by positive genetic testing; plasma Lp(a) levels may add prognostic value (Stock, 2015).

The management of young FH patients includes lifestyle changes and cholesterol-lowering therapy, that should be started at the lowest dose, with possible titration based on individual response, and a rigorous monitoring (Stock, 2015). Lifestyle changes include a low saturated fat diet devoid in trans-fat and high in fruits, vegetables, and fiber; the expected reduction in LDL-C levels is related to the baseline lifestyle behaviors and the adherence to the recommendations (de Ferranti, 2015). Lipid-lowering therapy has as first-line agent statins, but may also include bile acid binding resins or ezetimibe (de Ferranti, 2015); a major issue is the safety of these pharmacological therapies in children.

Children with FH are also characterized by a pro-inflammatory profile, with increased levels of TNFα and reduced levels of IL-10 (Narverud et al., 2011). It can be hypothesized that the early vascular lesions present in these subjects may contribute to a low-grade inflammation; this may further activate inflammatory pathways, leading to a persistent inflammation that contributes to accelerate the atherosclerotic process. In agreement with this observation, FH children with reduced HDL-C levels ($<$1.3 mmol/L, $<$50 mg/dL) exhibited monocytosis and a shift in the monocyte subpopulations, characterized by increased pro-inflammatory, nonclassical monocytes, and reduced levels of classical monocytes (Christensen et al., 2016; Tolani et al., 2013), suggesting a very early activation of monocytes.

A selective screening of children with family history of early atherosclerotic events and/or high LDL-C levels is recommended; a child of an FH subject has a 50% probability of inheriting FH and thus the cascade screening of families allows the early identification of these children. If the mutation in the family member has been identified, the molecular testing is the best method for the definite classification; in alternative, a phenotypic strategy should be used, including the measurement of LDL-C levels (Wiegman et al., 2015). An universal screening of children for hypercholesterolemia might be also proposed, thinking to perform it during routine health visits, so that the early identification and the optimal management may provide them decades of healthy life (Wiegman et al., 2015; Wald et al., 2016).

Guidelines for the Management of Familial Hypercholesterolemia

Clinical complications in FH subjects are related not only to the type and severity of the mutation causing the disease but also to the effectiveness of pharmacological treatments and the time of therapy initiation (Kolansky et al., 2008; Al-Shaikh et al., 2002). Based

Table 2 Recommended LDL-C targets in FH subjects

Category	*LDL-C levels*
Adults	<100 mg/dL (<2.5 mmol/L)
Adults with known CHD/diabetes	<70 mg/dL (<1.8 mmol/L)
Children	<135 mg/dL (<3.5 mmol/L)

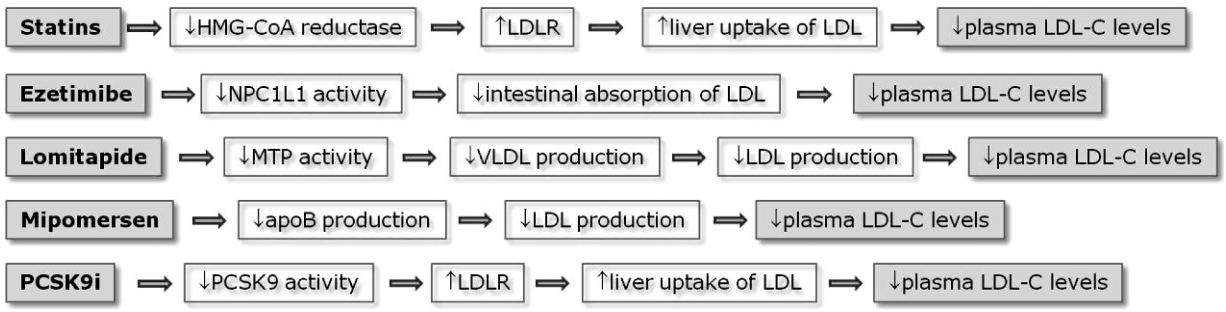

Fig. 3 Mechanisms of action of available drugs approved for the treatment of familial hypercholesterolemia.

on these observations, current guidelines suggest to lower LDL-C as early as possible, to reduce the cumulative burden of high levels of LDL-C, and to delay the onset of cardiovascular events (Cuchel et al., 2014; Kolansky et al., 2008; Raal et al., 2011). Recommended LDL-C goals for FH patients are <100 mg/dL (<2.5 mmol/L) for adults, or <70 mg/dL (<1.8 mmol/L) for adults with CHD or diabetes, and <135 mg/dL (<3.5 mmol/L) for children (**Table 2**; Nordestgaard et al., 2013).

Lifestyle interventions are recommended, but a strong reduction of LDL-C levels may be achieved only with pharmacological treatments associated with LDL apheresis, especially in HoFH or in nonresponders to therapy. Several cholesterol-lowering drugs are available; statins are the first choice not only in adults but also in children, in whom only those proven to be relatively safe should be used (Nordestgaard et al., 2013; McCrindle et al., 2003; Wiegman et al., 2004b). FH patients, in particular HoFH, usually cannot reach the recommended LDL-C level goals with statin monotherapy, thus requiring combination therapies in which statins are associated with ezetimibe or more recent cholesterol-lowering drugs such as mipomersen and lomitapide, or with anti-PCSK9 inhibitors. The combination of these drugs allows a greater LDL-C level reduction, taking advantage of distinct mechanisms of action (**Fig. 3**).

Current Treatments of Familial Hypercholesterolemia

Liver Transplantation

As 80% of total LDLR is localized in hepatic cells, liver transplantation represents the only definitive option for HoFH, resulting in the almost complete replacement of dysfunctional LDLR (Alim et al., 2016; Mansoorian et al., 2015). Liver transplantation determines an almost immediate massive improvement of lipid profile, with a significant decrease of LDL-C levels (Page et al., 2014); however, if this translates into a long-term cardiovascular benefit remains unclear, due to the low number of cases and short follow-up available. A 20-year follow-up of a case of combined heart and liver transplantation in a HoFH woman who presented with severe heart failure and advanced atherosclerotic disease showed that LDL-C levels were dramatically decreased 10 days posttransplantation (from 13 to 2.1 mmol/L) (Ibrahim et al., 2012); 20 years later LDL-C levels (with the support of lipid-lowering therapy) were only modestly abnormal (4.3 mmol/L), and tendon xanthomata were extensively reduced (Ibrahim et al., 2012). No signs of cardiovascular disease were observed (Ibrahim et al., 2012).

Due to the significant challenges regarding transplantation (limited availability of donors, high postoperative complication risk, and the need of life-long treatment with immunosuppressants), it remains an option only for patients with very severe phenotypes and refractory to existing cholesterol-lowering therapies.

LDL Apheresis

Lipoprotein apheresis is the physical removal of cholesterol-rich lipoproteins from plasma and represents an important tool for the treatment of FH, in particular for patients with HoFH or severe HeFH who do not respond to statins. A single procedure of apheresis (usually repeated every 2 weeks) significantly decreases LDL-C levels (50%–70%), which however return to normal within 14 days. Several reports have observed a reduced mortality among FH subjects treated with LDL apheresis compared with those untreated (Keller, 2009; Thompson et al., 1985; Mabuchi et al., 1998; Thompson, 2013), with data suggesting that the earlier apheresis is started, the better the prognosis. LDL apheresis is usually well tolerated, with side effects including hypotension, nausea, and

vomiting; the major limit of this procedure is the rebound of LDL-C levels after apheresis that requires continuous treatments to maintain low LDL-C levels, raising issues regarding the impact on the patient life quality and cost and accessibility of the treatment (Wang et al., 2016). The current availability of new cholesterol-lowering drugs may allow FH patients to reduce the frequency or even delay apheresis treatments.

Statins

Statin therapy represents the first step in the management of hypercholesterolemia also in FH patients. Due to the mechanism of action of statins, which inhibit the endogenous cholesterol synthesis thus resulting in increased expression of LDLR and reduced LDL-C levels, it is expected that statins would not be effective in homozygous FH patients with null mutation on LDLR gene (receptor-negative). Despite this, also these patients are responsive, although to a lesser extent (Feher et al., 1993; Raal et al., 1997), which suggests alternative mechanisms of action of statins, such as a reduction of VLDL production, the major source of circulating LDL. Thus, atorvastatin reduced LDL-C levels in either HoFH with residual LDLR activity or LDLR-negative HoFH (Raal et al., 2000). The LDL-C reductions achieved in FH patients with statin therapy, although not massive (~20%, compared with 40%–60% achieved in nongenetically determined hypercholesterolemia (Hovingh et al., 2013)), may have a clinical relevance, particularly when statin therapy is started early in the life, as it may translate into a delayed occurrence of cardiovascular events and prolonged survival (Raal et al., 2011).

An important observation is a plateau effect observed in FH patients, with no further LDL-C reduction by increasing atorvastatin dose, which suggests a limit to the ability of statins to reduce LDL-C levels in FH patients and the need of combination therapies including drugs with different mechanisms of action (Raal et al., 2000).

The need to start as early as possible with a pharmacological therapy in FH children, especially if homozygous, raised a question regarding the safety of statins in children. Thus, a meta-analysis of six studies with 798 children showed that statins significantly reduced LDL-C, total cholesterol, and apoB, with an incidence of adverse events comparable to that observed in children receiving placebo (Avis et al., 2007). More recently, two studies have demonstrated the efficacy and safety of rosuvastatin and pitavastatin, not included in the previous meta-analysis, in FH children, and the lack of adverse effects on growth and sexual maturation (Braamskamp et al., 2015a,b).

Despite all these considerations, a very small number of FH patients achieve the recommended LDL-C level target with statin monotherapy, suggesting the need of adding other drugs able to reduce LDL-C levels by a different mechanism of action (Nordestgaard et al., 2013; Hovingh et al., 2013).

Ezetimibe

Ezetimibe is an inhibitor of the intestinal uptake transporter Niemann-Pick C1 Like 1 and is a useful cholesterol-lowering drug often given in combination with a statin for the management of FH patients; this results in an additional reduction of LDL-C levels of about 10%–15% (Pisciotta et al., 2007; Gagne et al., 2002; Kastelein et al., 2008), which may translate in a further decrease of cardiovascular event incidence. Despite the addition of ezetimibe to statin therapy further reduces LDL-C levels, contrasting results have been reported on the effect on intima-media thickness progression (Kastelein et al., 2008; Kalogirou et al., 2010; Avellone et al., 2010).

The combination ezetimibe/simvastatin has been tested also in adolescents with HeFH, showing a greater reduction of LDL-C levels compared with simvastatin alone (−49.5% vs. −34.4%, $P<0.01$) (van der Graaf et al., 2008). The combination was well tolerated throughout 53 weeks (van der Graaf et al., 2008).

Lomitapide

The microsomal triglyceride transfer protein (MTP) is a lipid transfer protein involved in the assembly and secretion of apolipoprotein-B-containing lipoproteins (Hooper et al., 2015); it transfers neutral lipids (triglycerides and cholesteryl esters) from the endoplasmic reticulum membrane to the nascent apoB (Hooper et al., 2015). Subjects carrying mutations in the gene encoding for MTP (*MTTP*) exhibit inadequate formation of VLDL and chylomicrons and increased apoB degradation, resulting in a significant reduction of circulating VLDL and LDL (Goldberg, 2013); this suggested MTP as a possible pharmacological target to treat hypercholesterolemia.

Lomitapide is an MTP inhibitor that binds to this protein and inhibits the MTP-mediated synthesis of both hepatic VLDL and intestinal chylomicrons, resulting in significant reductions of LDL-C levels (**Fig. 3**). Lomitapide is effective in HoFH patients, even those LDLR-negative, and reduces LDL-C levels dose-dependently, with a good tolerance and gastrointestinal disorders (that can be prevented by a low-fat diet) as the most common side effects (Cuchel et al., 2007; Raper et al., 2015; Averna et al., 2016); hepatic enzymes as well as liver fat content were however increased following the treatment (Cuchel et al., 2007; Averna et al., 2016). To assess the relevance of the observed hepatic fat accumulation, lomitapide has been evaluated in HoFH in single-arm, open-label, phase 3 study (Cuchel et al., 2013; **Table 3**). This study, that included a 26-week efficacy study and a 52-week safety study, showed a significant LDL-C reduction (−50%) at week 26, with some patients being able to discontinue or delay LDL apheresis (Cuchel et al., 2013). At week 78, LDL-C levels, although significantly lower compared with baseline, were slightly higher compared with the values at the end of efficacy study, probably due to changes in the concomitant lipid-lowering therapies or to the reduction of

Table 3 Effects of lomitapide and mipomersen in FH

Clinical trial (ref.)	*Subjects*	*Duration*	*LDL-C (% change from baseline)*	*Lp(a) (% change from baseline)*
Lomitapide				
Cuchel et al. (2007)	HoFH	4 weeks for each dose	−24.7% (0.3 mg) −50.9% (1.0 mg)	Unchanged
Cuchel et al. (2013)	HoFH	26 + 52 weeks	−50% at week 26 −38% at week 78	−15% at week 26 −0.5% at week 78

NCT02399852	HoFH	5 years	Ongoing	
Mipomersen				
Akdim et al. (2010b)	HeFH	13 weeks	−37% (300 mg)	−29% (300 mg)
Stein et al. (2012a)	HeFH with CAD on maximally tolerated statin, LDL-C ≥ 100 mg/dL	28 weeks	−28% (200 mg)	−21.1% (200 mg)
Raal et al. (2010)	HoFH	28 weeks	−24.7% (160 mg)	−31.1% (160 mg)
Santos et al. (2015)	FH or severe hypercholesterolemia	4.5 years	−28% at week 104	−14% at week 104
FOCUS FH (NCT01475825)	Severe HeFH	60 weeks	Completed	

lomitapide doses in patients reporting adverse effects (Cuchel et al., 2013). Other lipids were significantly decreased, including VLDL-C, non-HDL-C, and TG levels (Cuchel et al., 2013). Some patients experienced an increase of hepatic enzymes, but such changes were transient and did not associate with deterioration of liver function (Cuchel et al., 2013); mean hepatic fat increased during the efficacy phase (from 1.0% to 8.6% at week 26), but it remained stable throughout the study (8.3% at week 78) (Cuchel et al., 2013). The long-term clinical relevance of this increase of liver fat is still unclear, requiring further investigations to establish whether it can progress to hepatic fibrosis.

Overall, these studies support, in one hand, the importance of low-fat diet adherence to lessen the impact of gastrointestinal disorders, thus increasing the tolerability and success of lomitapide therapy, and the relevance of a close monitoring of the hepatic enzymes during the treatment to prevent the impairment of the hepatic function and discontinuation of the therapy (Roeters van Lennep et al., 2015). Longer follow-up with clinical outcomes is required to establish whether lomitapide therapy may translate into a reduced cardiovascular risk. In this context, LOWER (Lomitapide Observational Worldwide Evaluation Registry) is a noninterventional study aimed at evaluating the long-term safety and efficacy of lomitapide in clinical practice by following patients for at least 10 years (Blom et al., 2016). Furthermore, an ongoing study is evaluating the effect of lomitapide treatment on carotid and aortic atherosclerosis in HoFH patients (NCT02399852) and has as primary outcome the percent change from baseline in carotid vessel wall area at the 2-year evaluation and as secondary outcome the percent change from baseline in carotid aortic vessel wall area and thickness at 1- and 5-year intervals (Table 3).

Lomitapide can be given in combination with other drugs taking advantage of their different mechanisms of action to further decrease LDL-C levels, particularly in FH subjects. It is worth noting that lomitapide is a weak inhibitor of CYP3A4 and may thus increase the exposure to statins metabolized by this enzyme, including simvastatin and atorvastatin (Tuteja et al., 2014; Aegerion, n.d.); although rosuvastatin is mainly excreted unaltered and only a minor part (<10%) is metabolized through CYP2C9, a significant increase of rosuvastatin exposure (32%) has been reported (Tuteja et al., 2014). Furthermore, lomitapide is metabolized primarily via CYP3A4, thus if administered concomitantly with moderate or strong CYP3A4 inhibitors they may significantly increase lomitapide exposure, and a reduction of lomitapide dose may be required (Aegerion, n.d.).

Mipomersen

High plasma levels of apoB, the main apoprotein of atherogenic lipoproteins (LDL, VLDL, chylomicrons, and Lp(a)), represent an established risk factor in atherosclerosis (Sniderman et al., 2011). Thus, apoB inhibition may represent a valuable tool for the treatment of hypercholesterolemia.

Mipomersen is a second-generation antisense oligonucleotide targeting the coding region of human apoB mRNA; this results in the mRNA degradation and reduction of apoB production, with consequent reduction of LDL-C (**Fig. 3**) (and other apoB-containing lipoproteins) levels independent of LDLR function (Crooke and Geary, 2013). Mipomersen is not metabolized through the cytochrome system and it does not inhibit major CYP isoenzymes, resulting in a lack of relevant clinical interactions with statins or ezetimibe (Yu et al., 2009).

Several studies have shown the cholesterol-lowering efficacy of mipomersen both as monotherapy and in combination with other drugs (Akdim et al., 2010a; Akdim et al., 2010b; Kastelein et al., 2006; McGowan et al., 2012; Raal et al., 2010; Stein et al., 2012a; Akdim et al., 2011; Visser et al., 2012). In HeFH patients, mipomersen injection for up to 13 weeks resulted in a dose-dependent reduction of LDL-C (up to −37%, $P < 0.001$) and Lp(a) (up to −29%, $P < 0.05$) (Akdim et al., 2010b; **Table 3**); all the included patients were on conventional cholesterol-lowering therapies and the addition of mipomersen induced an further

reduction of LDL-C, due to the different mechanism of action. In phase 3 studies the efficacy of mipomersen was evaluated in either HoFH or HeFH patients. In HoFH on low-fat diet and maximal tolerated cholesterol-lowering therapy, mipomersen reduced LDL-C by 21.3% ($P=0.0003$) and Lp(a) by 23.2% ($P=0.0013$) compared with placebo (Raal et al., 2010; **Table 3**); concomitant significant reductions were observed also in other lipid parameters, including non-HDL-C and VLDL-C (Raal et al., 2010). The most common adverse events were injection-site reactions (Raal et al., 2010). HeFH patients with coronary artery disease and LDL-C $\geq$ 100 mg/dL despite aggressive cholesterol-lowering therapy were treated with mipomersen for 26 weeks (Stein et al., 2012a); LDL-C significantly decreased (−28% difference between mipomersen and placebo, $P<0.001$) and also Lp(a) was reduced (−21.1%, $P<0.001$) as well as other lipids, including VLDL-C (−13.8%, $P=0.023$), total cholesterol (−19.4%, $P<0.001$), and non-HDL-C (−25.0%, $P<0.001$) (Stein et al., 2012a; **Table 3**). Some patients experienced elevations in alanine aminotransferase, the clinical significance of which is still unclear (Stein et al., 2012a). This effect has been evidenced also by two meta-analyses which confirmed the beneficial effect of mipomersen on LDL-C levels and reported elevation of ALT (>3X ULN), hepatic steatosis and flu-like symptoms as major adverse events associated with mipomersen (besides the risk of injection-site reactions) (Li et al., 2014; Panta et al., 2015). Although short-term studies reported increased steatosis (whose clinical relevance was considered low) in mipomersen-treated subjects, long-term (up to 104 weeks) clinical trials have indicated a return to normal of hepatic TG levels (Sahebkar and Watts, 2013; Toth, 2013). Biopsies of liver from patients treated with mipomersen showed a histopathological feature of simple steatosis without signs of inflammation or fibrosis (Hashemi et al., 2014). An interim report of a long-term open-label extension trial with mipomersen on HeFH/HoFH patients who completed phase 3 studies has confirmed these results (Santos et al., 2015). In fact, the treatment for up to 2 years on top of maximally tolerated dose of lipid-lowering therapy resulted in sustained reduction of apoB (−31%), LDL-C (−28%), and Lp(a) (−14%) levels, being safety issues similar to those reported for 26-week treatment (Santos et al., 2015; **Table 3**). Data from the 4-year time point as well as results from the FOCUS FH study (NCT01475825) are awaited to substantiate these findings.

PCSK9 Inhibitors

Despite commonly used cholesterol-lowering drugs have significantly improved the management of FH patients, particularly when used in combination, a large proportion of FH patients still do not achieve the recommended LDL-C level target even with maximally tolerated doses of drugs. Thus, there is the need of additional drugs that can efficiently reduce LDL-C levels below those achievable with the common cholesterol-lowering drugs.

GOF mutations in the *PCSK9* gene have been identified as causes of FH (Abifadel et al., 2003) and increased cardiovascular risk (Davignon et al., 2010), while LOF mutations are associated with reduced LDL-C plasma levels and lower prevalence of coronary disease (Cohen et al., 2006; Benn et al., 2010). These observations have suggested PCSK9 as a possible pharmacological target, leading to the development of PCSK9 inhibitors in the attempt to increase residual LDLR activity. Such inhibitors are monoclonal antibodies which act by binding PCSK9, thus preventing its interaction with surface LDLR. Several clinical trials have evaluated the efficacy of these antibodies, named evolocumab and alirocumab, in special groups such as FH patients that should be the most sensitive for the treatment with these agents. The RUTHERFORD study evaluated the effect of evolocumab in HeFH patients who did not achieve the LDL-C target <100 mg/dL despite statin therapy with or without ezetimibe (Raal et al., 2012). Rapid and significant reductions of LDL-C were observed (−43.8% and −56.4% vs. placebo with two different doses of evolocumab) (Raal et al., 2012; **Table 4**); after 12-week treatment, a high percentage of patients (>70%) reached LDL-C levels <100 mg/dL (<2.6 mmol/L) and many of them reached LDL-C <70 mg/dL (<1.8 mmol/L) (Raal et al., 2012). Other lipid parameters were also significantly reduced, including TC, apoB, and Lp(a) (Raal et al., 2012). The phase 3 RUTHERFORD-2 trial showed similar reductions (Raal et al., 2015a; **Table 4**). After the genetic test, seven patients clinically defined as HeFH were reclassified as HoFH or compound heterozygous, but, unexpectedly, they responded to evolocumab similarly to HeFH, even when receptor-negative mutations were identified (Raal et al., 2015a). This finding suggests that LDLR-independent mechanisms might have a role in the regulation of LDL-C levels in these patients, as already suggested by the heterogeneous responses observed in patients carrying the same mutation. HoFH enrolled in the TESLA part A study had a mean reduction of LDL-C of 17%, but the two patients carrying LDLR-negative mutations did not respond to the treatment (Stein et al., 2013; **Table 4**). This finding was not confirmed in the TESLA part B (Raal et al., 2015b), in which HoFH patients not receiving apheresis were administered evolocumab for 12 weeks in addition to their current lipid-lowering therapy. LDL-C levels were overall reduced by 30.9%; the LDLR-negative patient and the patient with ARH did not respond to the treatment, and patients homozygous for the same LDLR mutation had a heterogeneous response to the treatment (−7.1% up to −56%) (Raal et al., 2015b). It appears that the response to evolocumab is determined by the genetic defects, ranging from 0% in LDLR negative patients up to 40.8% in more than half patients carrying one or two defective LDLR mutations. The ongoing open-label TAUSSIG study (NCT01624142) will evaluate the long-term (5 years) efficacy and safety of evolocumab in HoFH patients not controlled by current lipid-lowering therapy (statin with/without ezetimibe) and will be completed in March, 2020. The interim results show a significant reduction of LDL-C and Lp(a) and indicate a potential reduction of cardiovascular event incidence (Raal et al., 2016a; Stein et al., 2016).

The other monoclonal antibody under current clinical evaluation is alirocumab. The first phase 2 study showed a substantial decrease of LDL-C levels (−67.9%) in a group of HeFH patients having LDL-C baseline levels $\geq$2.6 mmol/L ($\geq$100 mg/dL) on stable diet and statin dose with or without ezetimibe (Stein et al., 2012b; **Table 4**). This translated into a very high percentage of patients reaching the prespecified goals of <2.6 mmol/L (<100 mg/dL) and 1.8 mmol/L (<70 mg/dL) (Stein et al., 2012b). A group of studies within the ODYSSEY program (FH I, FH II, and HIGH FH) have evaluated the effects of alirocumab

Table 4 Effects of PCSK9 inhibitors evolocumab and alirocumab in FH

Clinical trial (duration)	*Subjects*	*Background LLT*	*Intervention*	*LDL-C (% change from baseline)*
Evolocumab				
RUTHERFORD (Raal et al., 2012) 12 weeks	HeFH LDL-C $\geq$100 mg/dL	Statin $\pm$ ezetimibe	350 mg Q4W 420 mg Q4W	−43.8% −56.4%
RUTHERFORD-2 (Raal et al., 2015a) 12 weeks	HeFH LDL-C $\geq$100 mg/dL	Statin $\pm$ ezetimibe	140 mg Q2W 420 mg Q4W	−59.2% −61.3%
TESLA part A (Stein et al., 2013) 36 weeks	HoFH; LDL-C $\geq$130 mg/dL	Stable LLT for at least 4 weeks	420 mg Q4W for 24 weeks +420 mg Q2W for 12 weeks	Q4W: −16.5% Q2W: −13.9%
TESLA part B (Raal et al., 2015b) 12 weeks	HoFH; LDL-C $\geq$130 mg/dL	Stable LLT for at least 4 weeks	420 mg Q4W	−30.9%
TAUSSIG (Raal et al., 2016a) 5 years	Severe FH	Stable LLT	Evo Q2W or Q4W	Ongoing
Alirocumab				
ODYSSEY FH I and FH II (Kastelein et al., 2015) 78 weeks	HeFH, LDL-C $\geq$100 mg/dL (for primary prevention) or LDL-C $\geq$70 mg/dL (for secondary prevention)	Max tolerated statin $\pm$ other LLT	75 mg Q2W (increased at 150 mg Q2W if LDL-C $\geq$70 mg/dL at week 8)	FH I: −57.9% FH II: −51.4%
ODYSSEY HIGH FH (Ginsberg et al., 2016) 78 weeks	HeFH LDL-C $\geq$160	Stable LLT	150 mg Q2W	−39%
ODYSSEY LONG TERM (Robinson et al., 2015) 78 weeks	HeFH or established CHD or CHD equivalent LDL-C $\geq$70 mg/dL	Max tolerated statin $\pm$ other LLT	150 mg Q2w	−61.9%
ODYSSEY OLE 176 weeks	HeFH who have completed one of the four parent studies		Ongoing	

administration in HeFH patients (Kastelein et al., 2014). ODYSSEY FH I and FH II studies showed a great efficacy of alirocumab in patients who did not achieve their recommended LDL-C level target despite maximal tolerated dose of statin (Kastelein et al., 2015; **Table 4**). The ODYSSEY HIGH FH reported a reduction of about 50% in HeFH patients with LDL-C $\geq$ 4.1 mmol/L ($\geq$ 160 mg/dL) despite maximal tolerated lipid-lowering therapy, with 41% of patients reaching the prespecified LDL-C goals (Ginsberg et al., 2016; **Table 4**).

The ODYSSEY LONG TERM evaluated a 86-week treatment with alirocumab in HeFH patients not adequately controlled and reported a −63.2% reduction of LDL-C level (Robinson et al., 2015; **Table 4**), a reduction comparable to that observed in non-HeFH patients (Robinson et al., 2015). A post-hoc analysis observed a lower incidence of major cardiovascular events in patients treated with alirocumab than in placebo group (1.7% vs. 3.3%, HR 0.52, nominal $P = 0.02$) (Robinson et al., 2015). The ongoing ODYSSEY OLE (NCT01954394) is evaluating the long-term safety of alirocumab up to 176 weeks in HeFH patients.

PCSK9 Inhibition and Lp(a) Plasma Levels

In contrast to statins, PCSK9 inhibitors have been shown to reduce Lp(a) by as much as 30% (Raal et al., 2014; Gaudet et al., 2014), although the exact mechanism by which such reduction takes place is still unclear. Reductions of LDL-C and Lp(a) levels following administration of PCSK9 inhibitors occur concomitantly, and greater Lp(a) reductions have been observed in patients who achieved lower LDL-C levels (Raal et al., 2016b); furthermore, LDLR has been shown to mediate the effects of PCSK9 on Lp(a) internalization in vitro (Romagnuolo et al., 2015). The possibility that other receptors modulated by PCSK9 may be involved in Lp(a) uptake cannot be excluded, however, especially based on the observation that the effects of statins on Lp(a) levels are inconsistent, despite they increase LDLR expression.

Based on these observations, Lp(a) levels have been evaluated in FH patients treated with evolocumab or alirocumab. Both mAbs significantly reduced Lp(a) levels. The RUTHERFORD studies, in fact, reported reductions ranging from −23% up to −31.6% versus placebo (Raal et al., 2012; Raal et al., 2015a) and similar results were reported by the studies of the ODYSSEY program performed in FH subjects, with reductions ranging from −14.8% to −25.6% versus placebo (Kastelein et al., 2015; Ginsberg et al., 2016; Robinson et al., 2015). Significant reductions were observed also in HoFH, apparently independent of the genetic defect (defective LDLR: −20.0%; negative LDLR: −22.7%) (Stein et al., 2013; Raal et al., 2015b). The clinical relevance of Lp(a) reduction remains however to be addressed.

Conclusions

The diagnosis and therapy of FH has dramatically improved in the last few years; new diagnostic tools as well as number of therapeutic options are now available even for those patients with the most severe forms such as HoFH. In the field of lipidology FH patients have been the front runners in the study of innovative therapeutic approaches that are now being developed for other genetic and nongenetic conditions.

The scene is set now for clinicians to better identify and treat these patients.

Introduction

Frailty is relatively common in the general elderly population, and even more so in patients with heart failure. Identifying frailty is an important aspect of care for the heart failure patients, as it may be a result of the heart failure itself, or comorbid to heart failure. As with the general population, frailty correlates with poorer outcomes in advanced heart failure management.

In this article we will review the concept of frailty, approaches to assessment, and potential management strategies for both general frailty and frailty in the setting heart failure.

Definition

Frailty is defined as a clinical syndrome of increased vulnerability in older adults due to dysregulation of energetics balance and multiple physiologic systems causing subclinical organ dysfunction (Goldwater and Pinney, 2015). Frail older adults are at increased risk of hospitalization, falls, disability, and mortality. This physiological dysregulation is chronic and progressive until it reaches a critical threshold. Since there is a strong relationship between frailty and negative outcomes, routinely screening for risk stratification and prognosis discussion should be implemented as clinical practice. The risk of mortality is over 6–12 months on patients who have advanced frailty.

The intrinsic aging process is associated with frailty, where sarcopenia, or loss of lean body mass and strength are key predictors of primary frailty. Nonetheless, similar vulnerability is associated with advanced stages of diseases where inflammation and wasting are present such as cancer, heart failure, COPD, and HIV/AIDS. This is known as secondary frailty (Fried et al., 2001).

There is a higher incidence of frailty and cardiovascular disease even though it is already particularly high in the elderly population (twofold to threefold higher). Likewise, the incidence of cardiovascular disease such as congestive heart failure (CHF) increases up to sevenfold in frail patients (Jha et al., 2015).

Pathobiology

CHF and frailty may share some pathophysiologic mechanisms. They are both systemic syndromes. There are several emerging biomarkers for frailty, which include interleukin-6 levels, tumor necrosis factor alpha, increased C-reactive protein sensitivity, and low vitamin D levels (Walston et al., 2002). Likewise, proinflammatory cytokines can contribute to the progression and side effects of CHF and in turn can be associated with skeletal muscle loss, cardiac cachexia, and declining physical function, which are all important markers of frailty (Anker and von Haehling, 2004). Hormonal changes seen in frailty that are relevant to CHF include dysregulation of the growth hormone/insulin-like growth factor I pathway, low DHEA-s, increased cortisol, low testosterone, increased insulin resistance with appearance of a catabolic state, muscle loss and, specifically for heart failure, decrease in cardiopulmonary exercise testing (Cicoira et al., 2003). Sarcopenia and cachexia are both paramount in the definition of frailty and very frequently present in CHF. Similarities between the two processes from the biological standpoint also explain why they may coexist frequently in the clinical setting.

Frailty Phenotype and Assessment

There are no standardized measures of frailty in CHF patients. The most commonly used assessments are the FP (FP), developed and validated by Fried and colleagues in the cardiovascular health study (CHS). It identified five physical indicators: sarcopenia, slowed motor performance, poor nutritional status, decreased physical activity, and worsened exercise tolerance (Fried et al., 2001). When three or more attributes are present a patient is considered frail. However, patients could experience some of the indicators without fulfilling the full definition of frailty. The comprehensive geriatric assessment (CGA) has also been used to determine frailty in heart failure population. This evaluation includes several different additional measures that have a more holistic approach to the diagnosis of frailty as it includes assessment of autonomy, cognitive deterioration, and emotional well-being. One of the criticisms for CGA is the fact that it evaluates not only frailty but also disability which may be considered two distinct concepts that belong on a continuum. This is important as both instruments have been used to evaluate frailty in people with CHF but prevalence varies depending on the instrument used. In the previously mentioned CHS, where the FP was used, prevalence of 6.3% was reported (Walston et al., 2002). On the other hand, when using the CGA as a tool to screen for frailty, we see that prevalence has consistently been higher and raging between 40% and 42% (Altimir et al., 2005; Lupon et al., 2008). Independent of the tool used, there appears to be a strong relationship between age and frailty in patients with CHF. Likewise, female gender has also been identified as a variable associated with higher prevalence of frailty (Altimir et al., 2005; Lupon et al., 2008).

It is very important to identify frailty in the CHF population for several reasons. Frail patients with CHF have higher mortality (Cacciatore et al., 2005; Lupon et al., 2008; Pulignano et al., 2010) and a higher hospitalization rate (Pulignano et al., 2010). These observations are not necessarily different from the general elderly population making the use of a frailty index a more interesting measure in younger patients with heart failure. Another important aspect is the intricate relationship that frailty may have with prognosis and response to invasive measures aimed at treating CHF. Similar to the observation of higher morbidity and mortality in CHF, elderly patients who are frail also have worse outcomes after cardiac surgery (Lee et al., 2010). One especially interesting population is those patients considered for destination therapy left ventricular assist device treatment (DT LVAD). Most of them are elderly and have multiple comorbidities that make them poor candidates for heart transplantation. Measures to determine outcomes after DT LVAD remain limited (Cowger et al., 2013) but there is growing evidence that patients who are deemed to be frail at the time of LVAD implantation have increased risk of death as well as higher incidence of hospital readmission (Dunlay et al., 2014). One unique aspect about the relationship between frailty and cardiovascular diseases is the concept that it may be reversible with adequate therapy. Heart failure itself can result in a multitude of changes in the body, which in turn may increase frailty on individuals. Some studies looking at different frailty measures such as hand grip strength and sarcopenia have identified patients who may experience improvement of these measures that can also be associated with resolution of some metabolic abnormalities that are present in chronic heart failure patients (Chung et al., 2014; Khawaja et al., 2014).

Because of the close relationship between frailty and CHF, one attractive pathway is to intervene on modifiable risk factors contributing to frailty in order to achieve better outcomes in CHF. Even though this is a controversial concept (frailty reversal), a recent trial has shown that improvement of frailty parameters is possible on an early population with interventions directed to specific components of the frailty index.

Prevalence

Over the past 15 years, studies have found the prevalence of frailty to range from 4% to 16% in patients over 65 years of age (Fried et al., 2001; Woods et al., 2005; Bandeen-Roche et al., 2006; Cawthon et al., 2007; Kiely et al., 2009). These studies mostly utilized the FP criteria, though definitions of the five criteria varied somewhat from study to study. Frailty is even more common in patients with heart failure, with a prevalence ranging from 18% to 54% in the outpatient setting (Jha et al., 2015). In a separate set of studies focusing on advanced heart failure patients (generally classified as New York Heat Association III–IV and potentially undergoing interventional management), a fairly similar prevalence of 22%–34% was observed (Dunlay et al., 2014; Chung et al., 2014; Dominguez-Rodriguez et al., 2015; Jha et al., 2016). These populations were evaluated either with the FP or through measuring grip strength as a surrogate for the FP. Of note, a portion of the advanced heart failure studies included patients as young as 53 years old, whereas most prevalence studies in the general population have a cut off of 65 years or older.

Therapeutics

There are four proposed frailty interventions for the general population including exercise, nutritional support, vitamin D supplementation, and polypharmacy control. In cardiac patients, optimal control of cardiac cachexia has not been established but there are recommendations about nutritional interventions in frail patients (Turner et al., 2014). HF patient participation in cardiac rehabilitation reduced hospitalization and improved quality of life (Davies et al., 2010).

One of the primary therapies for frailty is exercise and caloric and protein supplementation. There is little available evidence for effective therapies for cardiac cachexia, but there is some support for nutritional supplementation (Uchmanowicz et al., 2014).

In addition to nutritional supplementation, exercise is a principal therapy for heart failure-related frailty. In a meta-analysis, cardiac rehabilitation has been shown to effectively reduce hospitalizations and improve quality of life in heart failure patients (Davies et al., 2010). Rehabilitation may increase mobility and help reduce caregiver burden. Both short- and long-term cardiac rehab programs have been found to be effective.

Evidence shows that 25-OH vitamin D levels and hsCRP levels are correlated with lower exercise capacity in frail patients with heart failure. Biophysical markers associated with frailty were correlated with 6 min walk, and 25OHD and hsCRP correlated with a lower 6 min walk distance and predicted frailty status as measured by FP (Boxer et al., 2008). Although there is no data specific to frailty, vitamin D supplementation has been shown to reduce falls, hip fractures, and mortality in elderly patients (Morley et al., 2013).

Polypharmacy is a growing concern for patients with heart failure. Frequent hospitalizations lead to frequent changes in medical plans and patients are at a high risk for polypharmacy. 90% of patients admitted to a hospital for heart failure are taking at least four medications. It is critical that clinicians review medication lists frequently and eliminate duplicate medications or medications that carry a negative side effect profile in the frail population (Uchmanowicz et al., 2014). Guidelines such as the Beers Criteria can be helpful in identifying potentially problematic medications (Panel, 2015).

Utilization of a multidisciplinary team is essential in providing these interventions as well as minimizing potential frailty related incidents by identifying environmental risks and level of social support. In addition to specific frailty interventions, potentially reversible or manageable conditions such as depression, visual or auditory impairment, neurologic disease, and endocrine disorders should be investigated and optimized as part of the overall management of frailty.

Reversibility in Heart Failure

Technology is changing rapidly in the field of heart failure. Many patients are now eligible for advance cardiac therapies which include ambulatory inotropic support, DT LVADs, and heart transplant. Frailty related to heart failure is unique from frailty in the elderly because it is due to single organ failure. Therefore, with adequate treatment of the underlying condition, there is the possibility that intervention with advance cardiac therapies may reverse the underlying frailty. The key to success is determining if the source of the underlying frailty is multifactorial or related to single organ failure and ultimately reversible.

Due to the overlap of heart failure-related frailty and general frailty, it is critical to determine if a patient has "LVAD Responsive" heart failure during the selection process. LVAD responsive frailty is associated with systolic and diastolic dysfunction, high pulmonary capillary wedge pressure, and low cardiac output leading to the cascade of proinflammatory cytokines and the FP. LVAD-independent frailty will not change with implantation of an LVAD and is usually related to aging, comorbid conditions, and multiorgan dysfunction. Clinicians should critically assess patients prior to LVAD implementation to determine if they have LVAD responsive frailty. These patients have low risk for complications and they can expect and improve in functional status. Patients with LVAD unresponsive frailty are at high risk for premature death and complications with low ability to rehab and regain a high functional status (Flint et al., 2012).

A study by Dunlay et al. assessed frailty with the Deficit Index in 99 patients receiving LVAD implementation. After a 1.9-year follow-up, 79% of patients were hospitalized and 45% had died. They grouped patients into subcategories of frail, intermediate frailty, and not frail. There was a statistically significant correlation with frailty and survival after LVAD implementation. Mean days of lives were 250, 266, and 293 in the respective categories (Dunlay et al., 2014).

Another group looked at the biophysical markers of frailty prior to LVAD implantation. They assessed psoas muscle area of 100 patients via CT scan. Patients with lowest tertile area by gender were labeled as sarcopenic, a primary phenotypic feature of frailty. Sarcopenia was present in 32% of the heart failure population and was associated with prolonged hospitalization and higher risk of post LVAD mortality (Heberton et al., 2016).

In summary, clinicians should consider frailty as a key predictor of hospitalizations and increased risk of mortality. As patients are considered for advanced cardiac therapies the underlying cause of the frailty should be evaluated. Patients who have frailty associated with heart failure should be optimized with exercise, nutrition, vitamin D supplementation, and reducing polypharmacy. For those who have single organ failure or heart failure with sources of frailty that are thought to be reversible are good candidates for advanced cardiac therapies. Patients with sarcopenia and high frailty scores will be at high risk for prolonged hospitalizations and higher risk of mortality.

Conclusion

Frailty is a common syndrome found in heart failure patients. Though standardization of the assessment of frailty in heart failure is currently lacking, it is already clear recognition and management of frailty in patients with heart failure will help and may be a useful marker in the future when assessing risk in patients considering advanced therapies.

Example Cases

Case A

John Smith is a 56-year-old male with a history of acute chronic systolic heart failure secondary to nonischemic cardiomyopathy. He was recently admitted to the cardiac service for heart failure exacerbation. His heart failure was first diagnosed 7 years ago and a

recent echo revealed a left ejection fraction of <20%. He reports weight loss of 12 lbs over the past 8 months and minimal physical activity in the last month due to frequent exhaustion. His BMI is now 24. Mr. Smith underwent right heart catheterization and was found to have a low cardiac index.

Mr. Smith was evaluated by a multidisciplinary team including a cardiologist, a cardiothoracic surgeon, a social worker, and the palliative care team. He was offered left ventricular assist device implantation and underwent a successful surgery. Post op the patient improved significantly, with improved appetite, weight gain, and ability to tolerate physical activity. He was fortunate and did not experience significant complications, allowing him four relatively symptom-free years prior to onset of right heart failure.

Case B

Mary Barton is a 73-year-old female with a history of heart failure with reduced ejection fraction, diabetes, chronic kidney disease, and cognitive decline who is followed for heart failure management. Her medications include Lisinopril, metoprolol, furosemide, pravastatin, and zolpidem. She lives alone and a neighbor assists her in getting to appointments. During a recent office visit, Ms. Barton's neighbor expressed concerns about Ms. Barton falling more frequently. She had also lost 13 lbs over the last year and states that she feels exhausted all the time.

The patient and neighbor report good compliance with mediations and she feels that her intermittent shortness of breath on exertion is stable. Noting that her frailty posed a large risk to the patient, her care team began to focus on interventions to reduce her risk of adverse events. Her 25-OH vitamin D level was found to be 10 ng/mL and she was started on vitamin D supplementation. Her zolpidem was also discontinued and sleep hygiene education was provided. She was also provided with a supplemental nutrition drink and referred to a dietician. Ms. Barton returned for a follow-up visit feeling improved, with the neighbor reporting no falls and weight gain of 2 lbs.

Introduction

As a bearer of significant morbidity and mortality, atrial fibrillation (AF) presents one of the major therapeutic dilemmas in modern clinical practice. Despite significant advances in catheter-based and surgical therapies for AF, failure to maintain sinus rhythm remains high at ~25% with significant divergence in response to therapy. Possible explanations for this include the heterogeneous nature of AF, limited understanding of the molecular mechanisms of the arrhythmia, and inadequacy of current available therapies. Despite these imperfections, advancements over the last decade have brought into light the genetic architecture of AF. Linkage analyses, candidate gene approaches, and next generation sequencing (NGS) have identified mutations encoding cardiac ion channels including transcription factors and signaling proteins linked to early-onset familial AF. Simultaneously, large population-based studies have exposed common single nucleotide polymorphisms (SNPs) that modulate AF risk with the strongest association at the chromosome (chr) 4q25 locus (Darbar and Roden, 2013).

Genetic approaches to AF have not only provided important insights into the underlying mechanisms of AF but also defined responses to therapy. Nonetheless, bedside application of these insights has so far not been fully realized. Promising data from proof-of-concept studies support the hypothesis that genotype-directed therapies for AF may target therapy to those most likely to benefit. In addition, continued advancement of more mechanism-based therapies for AF is a path to enhanced therapeutic effectiveness and reduction in adverse side effects.

Mechanisms of AF

In recent times, there has been a tremendous progress in understanding the underlying mechanisms of AF. However, attaining a unifying underlying mechanism for AF i.e. Moe's multiple wavelet hypothesis (Moe and Abildskov, 1959) has been challenging. This is in part related to the heterogeneity of the processes propagating and maintaining AF, often times occurring concomitantly in order to manifest the arrhythm. This is evidenced by the tendency of AF to occur as age and risk factors accrue, arguing that numerous independent processes must occur concurrently to trigger the arrhythmia- genetic and acquired.

Preceding AF initiation, tissue level changes are vital to maintain reentry or rapid focal ectopic firing. Abnormal impulse formation is driven by focal ectopic firing resulting from increased automaticity. This is likely secondary to decreased cardiac inward rectifier potassium current (I_{K1}), heightened activation of the cardiac pacemaker "funny" current (I_f), or triggered activity (Stillitano et al., 2008). Early after depolarizations may be the driving force behind this as they increase L-type Ca^{2+} current (I_{CaL}). Alternatively, the process could be set in motion by delayed after depolarizations (DADs) instigated by functionally defective ryanodine receptors (RyR) or Ca^{2+} excess in the sarcoplasmic reticulum (Yeh et al., 2008; Voigt et al., 2012).

Concerning catheter ablation for AF, inadequacies in the therapy have been created due to the unintentional formation of gaps in ablation lines, causing anatomical barriers that develop reentry circuits. This, in turn, leads to persistent macroreentrant atrial tachycardias and ultimately, AF. Scenarios in which action potential duration (APD) and atrial effective refractory period (ERP) are shortened, or conduction velocity (CV) is slowed, can lead to the initiation and maintenance of AF (Nattel, 2002). Destructive structural remodeling, which leads to the development of fibrosis, activation of inflammatory pathway, neural restructuring, and electrical modifications, have also been reported to promote further AF by means of a reentrant substrate which is needed to sustain the rhythm (Nattel et al., 2008; Shiroshita-Takeshita et al., 2009). The evolution of the atrial remodeling varies in its time course from patient to patient, and the goal of modern therapies is largely to dampen the progression of the various pathogenic processes that proliferate the disease.

Genetic Basis of AF

In AF, Mendelian inheritance patterns have been recognized since the 1940's (Wolff, 1943a,b) Brugada et al. reported three families with autosomal dominant AF in 1987, and subsequently identified a genetic locus (10q22-24) linked with AF in these kindreds. (Brugada et al., 1997) Although the gene responsible for AF has not been identified (Darbar et al., 2003a; Shah et al., 2002), the report had initially suggested that AF could be a heritable and a monogenic disorder. However, further observation of incomplete penetrance of the phenotype within family members would ultimately suggest AF to be rather a multigenic and genetically heterogeneous disorder.

Most cases of AF in the general population are sporadic, and the likelihood of developing AF increases with age, as well as the presence of other risk factors such as hypertension, diabetes, obesity, sleep apnea, heart failure, and metabolic syndrome (Darbar and Roden, 2013). Nevertheless, at least 15% of patients develop sporadic AF at a relatively early age without such risk factors, a condition previously referred to as 'lone' but now better defined as early-onset AF (Ellinor et al., 2005). Although analysis of rare disease-causing variants with high penetrance can be insightful, early-onset familial AF accounts for only a minority of the overall prevalence of the arrhythmia.

Family history of AF itself has been shown to be an independent risk factor for developing AF in the general population. As seen in the Framingham study, offspring of parents with AF had double the 4-year risk of developing de novo AF even after accounting for established AF risk factors.(Fox et al., 2004) Similarly, in Icelandic population studies, relatives of an affected individual were at increased risk of developing AF, but this risk diminished as the degree of relation increased (Arnar et al., 2006). In the Danish Twin Study, the risk of developing AF was nearly twice as high for monozygotic twins compared to dizygotic twins (Christophersen et al., 2009). Taken altogether, it is quite likely that an individual's genetic predisposition also plays a role in polygenic AF. This observation has driven research into understanding the link between genetics and AF.

Insights Into Genetics of AF

Given the clinical and genetic heterogeneity of AF, the arrhythmia should best be viewed as the common final phenotype of multiple diverse pathways (Darbar et al., 2003b). The pathophysiology of AF is highly complex and even in the absence of identifiable risk factors, multiple structural or ionic mechanisms may be operant in a single patient with AF. Organized propagation of electrical conduction across myocardial cells is dependent upon a balanced interplay between structural features and ionic components of the atrium, which are potentially determined by a combination of genetic, environmental, and acquired factors. Currently, most identified mutations appear to affect pathways involving cardiac development, generation and propagation of electrical impulses, inflammation signaling pathways, atrial remodeling, and development of fibrosis. Ultimately, conditions that slow CV, and shorten APD or atrial ERP favor development of AF (Schotten et al., 2011).

Modulation of APD

Data gathered from candidate genes as well as in vitro functional studies have strongly suggested that mutations altering APD in cardiac ion channel can increase susceptibility to AF. For instance, in persistent and permanent AF, cellular and electrophysiological studies have demonstrated marked reductions in the density of several channels, including ultra-rapid delayed rectifier potassium current (I_{Kur}), L-type voltage-gated ($I_{Ca,L}$), and muscarinic potassium current (I_{KACh}).(Van Wagoner, 2003).

In familial AF, the first mutation identified was a S140G mutation in *KCNQ1*, which encodes the pore forming α-subunit of the delayed rectifier potassium current (I_{Ks}). This gain-of-function mutation ultimately shortens APDs in the atrium (Darbar and Roden, 2013). The pathogenic role of APD shortening by mutations in I_{Ks} has been reinforced by the identification of additional

mutations, such as *KCNQ1* (Das et al., 2009) and R27C mutations of the *KCNE2* gene. These mutations encode the shared β-subunits of I_{Ks} and I_{Kr} (Yang et al., 2004).

In patients with nonfamilial AF, a missense L65F mutation in *KCNE5* has been identified. *KCNE5* is believed to downregulate I_{ks} activity by competing with the *KCNE1* β-subunit for the *KCNQ1* α-subunit. In vitro transfection of KCNE5-L65F into Chinese hamster ovary cells failed to suppress I_{ks} activity, suggesting shortening of APD is the underlying mechanism by which this mutation causes AF (Ravn et al., 2008).

The first nonion channel gene linked with familial AF was identified in 2008. It involved a frameshift mutation in the *NPPA* gene that resulted in encoding of a mutant atrial natriuretic peptide (ANP) that, when infused in a rat whole-heart Langendorff's preparation, shortened the monophasic APD and ERP (Hodgson-Zingman et al., 2008). *NPPA* may also be involved in inflammatory pathways and regulation of electrical and structural remodeling (Darbar and Roden, 2013).

Finally, mutations in sodium channel genes may also play an important role in the pathogenesis of AF. Screening for *SCN5A* variants in a large AF cohort found mutations in 5.9% of those with AF (Darbar et al., 2008). A recent metaanalysis of over 7000 African American patients across five cohorts found that the common *SCN5A* variant rs7629265 was associated with increased AF risk and shorter PR interval. Other variants, such as rs6795970 for *SCN10A*, which encodes the Nav1.8 channel, have also been found to be associated with AF. In particular the A1073 genetic variant, which confers gain-of-function to Nav1.8, prolongs APD, and thereby increases susceptibility to AF (Ilkhanoff et al., 2014).

Modulation of Gap Junction Expression

Aging, structural remodeling, and development of fibrosis are all known to increase the likelihood of developing AF as the disturbance of uniform impulse propagation from cell to cell and the variability in regional cardiac velocity creates a substrate for reentry (Jennings, 2013). Both germ-line and somatic mutations in the *GJA5* gene, which encodes connexin-40, and a common variant in the promotor region of this gene have been shown to be associated with early-onset lone AF (Gollob et al., 2006; Wirka et al., 2011). Further, mutations in *GJA5* have also been identified in patients with familial AF (Yang et al., 2010), as knock-out mouse models appear to exhibit increased vulnerability to atrial arrhythmias. Similar to acquired cases of AF, genetic variants for genes encoding gap junction proteins likely mediate increased risk for AF by reduced expression of gap junctions, leading to slower and less uniform atrial conduction.

Role in Atrial Fibrosis and Inflammatory Pathways

Histologic evidence linking myocarditis to early-onset AF and the high incidence of AF following cardiac surgery suggests that pathways involved with inflammation and fibrosis play a role in the pathogenesis of AF (Gallagher et al., 1997; Patti et al., 2006). In animal studies, induction of atrial fibrosis has been associated with increased risk for atrial arrhythmias, and in humans, the extent of atrial fibrosis has correlated with success of ablation therapy (Akoum et al., 2011). Although the role of many common AF risk alleles has not been fully elucidated, there is now increasing evidence that atrial fibrosis may be a key mediator for increased risk of developing AF.

Besides its role in the development of the pulmonary vein myocardium, evidence suggests PITX2 may play a role in structural and electrical remodeling of the atria. PITX2 encodes for the homeobox transcription factor PITX2c, which is expressed 100-fold higher in the left than the right atrium (Kirchhof et al., 2011). *Pitx2c*$^{-/-}$ knock-out mice develop four-chamber cardiac enlargement, histological evidence of atrial fibrosis, and upregulation of collagen precursor genes. In contrast, *Pitx2c*$^{+/-}$ heterozygous mice have no evidence of cardiac enlargement but have increased expression of genes regulating Wnt signaling, a key fibrosis pathway (Kirchhof et al., 2011). Common SNPs at the chr7q31 AF locus encode caveolin-1, which internalizes transforming growth factor (TGF)-β receptors leading to suppression of this signaling pathway and prevention of atrial fibrosis. Variants in *CAV1* have not only been associated with myocardial fibrosis but also pulmonary hypertension.

The zinc finger homeobox 3 transcription factor encoded by ZFHX3, also plays an important role when responding to TGF-β signaling (Berry et al., 2001). SYNP02L and SYNE2 encode cytoskeletal and nucleoproteins that link the nucleoskeleton to the nuclear membrane structures and may play an important role in cardiac development (Beqqali et al., 2010). SYNE2 and emerin interact with a-catenin regulating the Wnt signaling pathway. PRRX1 is a transcription factor that is thought to be important for normal lung development and has been associated with pulmonary fibrosis. Scleroderma fibroblasts stimulated with TGF-β show increased expression of C90RF3. Another possible mechanism by which *NPPA* variants may mediate increased risk for AF is by causing both electrical and structural remodeling of the atria with the development of atrial fibrosis. Although overexpression of the humanized *NPPA* variant in mice does not seem to cause atrial enlargement, a different *NPPA* mutation identified in four Italian families was associated with an atrial myopathy, massive biatrial enlargement, and atrial standstill (Disertori et al., 2013).

Genetic Approaches to AF

Linkage Analysis and Candidate Gene Studies

Positional cloning and linkage analysis have proven to be powerful tools for detecting the chromosomal location of disease-associated genes and is based on the assumption that nearby genes on a chromosome tend to remain linked during meiosis (**Fig. 1**).

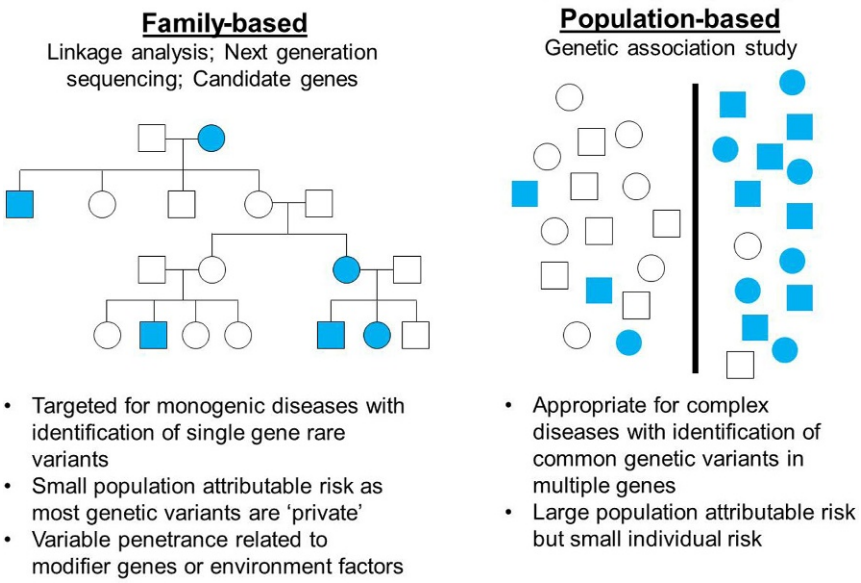

Fig. 1 Genetic approaches to defining the genetic architecture of atrial fibrillation (AF). Linkage analysis, next generation sequencing and candidate gene approaches have identified rare genetic variants in single genes in large familial kindreds with early-onset AF. Conversely, genetic association studies, that is, genome-wide association studies have uncovered common genetic variants associated with AF in many genes. (Filled in symbols indicate individuals with AF and unfilled symbols represent controls.)

While these disease-associated loci are expected to have stronger effect size than common genetic variants, a major limitation of this approach is the limited availability of large AF kindreds with multiple affected individuals. Regardless, positional cloning and linkage analysis have helped identify AF loci and genes with large effect size, including 11p15.5, 21q22, 17q, 7q35-36, 5p13, 6q14-16, and 10q22-24, although the responsible genes have not been identified.

The first gene to be linked to familial AF and to be validated in functional studies was *KCNQ1*, which encodes the -subunit of the delayed rectifier potassium channel (*KCNQ1*). Using a candidate gene approach, investigators have screened for other cardiac ion channel genes hypothesized to be mechanistically linked to AF including *KCNE2*, *KCNJ2*, *KCNE5*, *SCN5A*, and *SCN10A*. Otway et al.(Otway et al., 2007) examined 50 families with a history of AF and identified a single mutation (R14C) in *KCNQ1* in one family which did not have any direct effect on KCNQ1 and KCNE1 channels and corresponding current amplitudes in cultured cells. However, exposure to hypotonic solution led to swelling of atrial cells and mutant channels then exhibited a marked increase in current amplitude compared with wild-type channels. Further, only patients with dilated LA chambers carry the mutation developed AF. The concept that certain acquired or environmental conditions must be met before a genetic trait manifests itself, could perhaps explain why variable penetrance is observed in AF families carrying rare variants with large effect size (Darbar and Roden, 2013).

A significant limitation of the candidate gene approach is the low pretest probability due to the overall frequency of common polymorphisms within the genome and single variant associations are often difficult to replicate.

Genome-Wide Association Studies (GWAS)

Although many patients with non-familial AF have known risk modifiers (e.g., hypertension, diabetes, metabolic syndrome), most people in general population do not go on to develop AF despite carrying the same risk factors. A concept, known as the "two-hit hypothesis," has been proposed whereby common genetic variants are thought to increase susceptibility to AF in patients harboring other identifiable risk factors (Darbar and Roden, 2013). NGS has made it possible to sequence hundreds of thousands of SNPs across the human genome in a feasible manner to test for association between affected and unaffected subjects. Given that such a large number of genes are tested without a priori assumption regarding their potential disease association, the effect size of many disease-associated SNPs tend to be smaller and their association may be difficult to replicate, especially across different ethnic populations.

In the first GWAS performed in 2007, two noncoding SNPS on the chr4q25 locus were found to be independently associated with AF in an Icelandic population. This association was then replicated in Asian (Shi et al., 2009) and European populations (Gudbjartsson et al., 2007) and in patients after coronary artery bypass graft (CABG) surgery (Body et al., 2009). The nearest gene to this locus is the paired-like homeodomain transcription factor 2 (*PITX2*) gene, which encodes a transcription factor important for PV development (Mommersteeg et al., 2007a), determination of left and right atrial asymmetry during embryogenesis (Logan et al., 1998), and suppression of formation of the LA sinus node (Mommersteeg et al., 2007b). Nine additional AF loci and five novel AF genes were identified when a metaanalysis of AF GWAS was recently conducted (**Table 1**) (Ellinor et al., 2012; Sinner et al., 2014). Interestingly, the severity of cardiac developmental malformations appears correlated to the degree of PITX2 expression (Gage et al.,

Table 1 Common atrial fibrillation (AF) susceptibility loci identified by genome-wide association studies

SNP	Locus	Closest gene	Functional effect	Minor/ major allele	MAF (%)	RR (95% CI)	P value
rs2200733	4q25	*PITX2*	Development of pulmonary vein myocardial	T/C	25.8	1.71 (1.54–2.21)	6.1×10^{-41}

AF, Atrial fibrillation; *CI*, Confidence interval; *MAF*, Minor allele frequency; *RR*, Relative risk; *SNP*, Single nucleotide polymorphism;

1999) as complete absence of Pitx2 function in mice leads to embryonic lethality while homozygous null embryos exhibit severe cardiac defects (Kitamura et al., 1999). Heterozygous $Pitx2^{+/-}$ mice, which are fully viable, have higher rates of atrial arrhythmias with programmed stimulation. The role of *PITX2* in the development of the left atrial and pulmonary veins fits well with our understanding that in many cases of paroxysmal AF the arrhythmia is triggered by ectopic foci originating from pulmonary vein myocardial sleeves.

Clinical Applications of Genetic Discoveries

Current treatment paradigms for AF remain largely empiric given the lack of evidence-based data to support mechanism-based treatment approaches. The identification of rare and common susceptible variants through genetic approaches has unlocked new areas of investigation that involve specific biological pathways. These pathways are responsible for the pathophysiology of AF, including dysfunctional cardiac ion channels, signaling pathways, and gap junction proteins. Although in vivo and in vitro models offer opportunity for functional validation and potential pharmacological development, transition from the bench to meaningful outcomes in clinical practice has been limited.

GWAS studies have identified numerous common genetic variants associated with AF, however the effect size of many of these SNPs is small and the contribution to the pathophysiology of AF remains unclear for many of them. Given the overall breadth of the human genome, one difficulty has been distinguishing benign SNPs from pathogenic mutations. Numerous approaches have been proposed including examining the variant type and location, segregation of the variant with phenotype in affected family members, and analyzing the degree of conservation of encoded amino acids across species. Multiple "heuristic" prediction algorithms have also been developed to determine the likelihood of a rare variant being pathogenic.

While it has become clear that an individual's genetic background can influence the risk of developing AF (Everett et al., 2013; Tada et al., 2014) incorporation of genetic analysis into treatment strategies still remains limited. Our inability to readily identify specific mechanisms responsible for AF in an individual, difficulties determining response to therapies, and lack of genotype-directed prospective clinical trials, are all factors that prevent the integration of these genetic discoveries into our clinical practice.

Identification of Genetic Subtypes and Response to Therapy

Genetic studies have not only uncovered common and rare genetic variants associated with AF but have also identified AF subtypes with differential responses to therapy. One of the first studies assessing genotype influence on response to therapy involved the use of antiarrhythmic drugs (AADs). In a study published in 2012, Parvez et al. (Parvez et al., 2013) assessed whether the common AF risk loci on chr4q25 (near *PITX2*), 16q22 (in *ZFHX3*), and 1q21 (in *KCNN3*) modulated response to AADs in patients with symptomatic AF. The study determined that carriers of the chr4q25 SNP (rs10033464) were significantly associated with successful symptom control (odds ratio [OR], 2.97; 95% confidence interval, 1.42–6.21; $P = 0.003$). Further, individuals with the chr4q25 SNP responded better to class I versus class III antiarrhythmic drugs in both the discovery and validation cohorts.

Interestingly, it has been shown in multiple studies that carrying a chr4q25 SNP predicts poorer response to AF catheter ablation compared to the presence of the wild-type SNP (Benjamin Shoemaker et al., 2013; Husser et al., 2010). The chr4q25 SNPs have also been seen to be independent predictors of AF recurrence following restoration of sinus rhythm after electrical cardioversion (Parvez et al., 2013). Collectively, these data support the concept of selecting AF therapies based on a patient's genotype and predicted response. Also important is that although the effect size of common genetic susceptibility markers for AF have not been large (OR 1.1–1.7), in studies evaluating whether AF risk SNPs modulate response to therapy, the ORs were markedly higher than those used to determine predilection for AF itself.

While the possibility of tailoring AF therapy based on genotype rather than continuing current empiric approaches is exciting, prospective clinical trials are needed to validate the role of subtyping of AF by chr4q25 genotyping. Thus far, only a few centers have conducted such studies and replication in different ethnicities is essential as outcomes may be different among populations. In 2009, enrollment started for the CABANA Trial, which is the largest prospective international study yet to date comparing catheter ablation to pharmacologic rate/rhythm control. Along with the main trial, a substudy called CABANAgene will be performed concurrently and will provide a large multinational cohort in which replication studies can be performed.

Novel Approaches to Therapy

Although AF is a complex and multigenic disorder, insight into the genetic mechanisms of AF have resulted in proof-of-concept studies revealing novel pathways that may provide suitable targets for pharmacologic therapies. However, many promising new therapies have failed to show efficacy in prospective clinical studies (Podd et al., 2015), which can be discouraging considering the time and resources invested into the development of new drugs. Knowledge of a patient's genotype may potentially enhance selection of patients most likely to benefit from new mechanism-targeting therapies and aid in the execution of future clinical studies.

Pharmacologic agents targeting cardiac ion channels

Potassium channel antagonist

Research on familial AF-related mutations, especially WT-*KCNQ1* and *KCNQ1-S140G*, has reported that these two mutations possess distinct pharmacological properties that may enable inhibition of the I_{Ks}-selective blocker HMR-1556 (Campbell et al., 2013). Although a low concentration of the blocker had little effect on WT-I_{Ks}, it was capable of inhibiting the mutant channel. In cultured left atrial myocytes of adult rabbits, expression of S140G-I_{Ks} shortened APD; however, cells expressing WT-I_{Ks} did not. The familial *KCNQ1-S140G* gain-of-function mutation demonstrated increased sensitivity for the I_{Ks} blocker, suggesting the possibility of selective therapeutic targeting.

On the chr1q21 locus, AF risk SNPs have been identified in *KCNN3*, which encodes the SK channel, a member of the Ca^{2+}-activated potassium channel family. These channels are believed to contribute to the shortening of atrial APD. In large animal models, administration of the selective SK inhibitor, NS8593, led to termination of pacing-induced AF (>15 min of continuous AF), and decreased AF duration and vulnerability without affecting ventricular conduction and repolarization (Haugaard et al., 2015).

Ryanodine receptor antagonist

Mutations in the ryanodine receptor (*RyR2*) and sarcoplasmic reticulum Ca-binding protein, calsequestrin (*Casq2*), have been found to increase the risk for AF. Investigators at Vanderbilt examined the underlying mechanisms of AF associated with loss of Casq2, and tested a mechanism-based drug therapy for AF (Faggioni et al., 2014). Atrial burst pacing was used to quantify AF susceptibility in isolated hearts from *Casq2*$^{-/-}$ and *Casq2*$^{+/+}$ mice. AF was induced in 11/12 *Casq2*$^{-/-}$ mice hearts but not in *Casq2*$^{+/+}$ hearts.

The dual RyR2 and sodium channel blocker, R-propafenone, significantly reduced the frequency and amplitude of subthreshold diastolic calcium elevations, and DADs in atrial myocytes, and ultimately prevented induction of AF. In contrast, S-propafenone, an equipotent sodium channel blocker but much weaker RyR2 inhibitor, only partially reduced subthreshold diastolic calcium elevations and DADs, hence, failing to prevent AF.

These findings strongly suggest that targeting AF with R-propafenone may be a more mechanism-based approach to treating AF. A multisite, prospective human study using such a mechanism based approach for the treatment of paroxysmal AF is planned for the near future. Ranolazine, a late sodium channel blocker that blunts diastolic calcium accumulation in the cytosol, has been shown to have efficacy for prevention of postoperative AF, treatment of paroxysmal AF, and facilitation of electrical CV, both alone and in combination with amiodarone and dronaderone (Tsu and Lee, 2014; Murdock et al., 2012; Reiffel et al., 2015).

Gap junction modulators

Mutations in gene expressing connexin-40 and connexin-43 in familial and nonfamilial AF, as well as mice knock-out of GJA5 expression models, have been reported to increase vulnerability for atrial arrhythmias. Similarly, in canine models, extensive left and right atrial ablation is associated with lower acute recurrence of AF, but it is also associated with decreased connexin-43 near the ablation site. This suggests that worsened or irregular dispersion of CV may be proarrhythmic (Elvan et al., 1997).

Rotigaptide is a peptide that is believed to modulate gap-junction function by increasing PKC-dependent connexin-43 phosphorylation, which has been shown to reduce AF in chronic mitral regurgitation and acute ischemia models (Guerra et al., 2006; Shiroshita-Takeshita et al., 2007). Further, danegaptide, a dipeptide which behaves like rotigaptide, has also been shown to reduce AF inducibility in canine models (Dobrev et al., 2012).

Adenovirus-mediated gene transfer of connexin-40 and -43 was shown to reduce AF occurrence through normalization of connexin expression and CV pattern in swine models (Igarashi et al., 2012). While the clinical applicability of these approaches for AF in humans is still to be determined, genotype-based selection of patients with known mutations in connexin 40 and 43 genes may improve outcomes with these therapies compared to the general population.

Attenuation of the autonomic nervous system response

It is well known that autonomic nervous system is an important modulator of AF susceptibility. One clinical subtype, known as vagally-mediated AF, is thought to be caused by release of acetylcholine (Ach) from the vagus nerve and cardiac GP. This leads to enhanced I_{KACh} and heterogenous dispersion of APD shortening, potentially creating the electrical substrate for stabilizing reentrant rotors. I_{KACh} is composed of two homologous GIRK channel subunits: GIRK1 and GIRK4. In an animal model simulating sick sinus syndrome in $Ca_V1.3$ mice, inactivation of GIRK4 led to decreased inducibility of AF, suggesting that pharmacologic attenuation of I_{KACh} may be useful in vagally-mediated AF. Unfortunately, no human genetic variants associated with AF that affect I_{KACh} expression have been identified thus far.

Genetic variants in SCN10A encoding Nav1.8, which is expressed in peripheral nerve tissue, have been associated with early onset AF. In an animal study, administration of a Nav1.8 blocker resulted in blunting the effect of vagal nerve stimulation on CV and AF inducibility. This is presumably due to inhibition of neural activity of the cardiac GP. Further, in a small double-blinded clinical trial of 20 patients with paroxysmal AF and pacemakers, administration of BMS 914392 (a selective oral inhibitor of I_{KACh} current) did not reduce overall AF burden compared to controls (Podd et al., 2015). Identification of a pathologic genetic variant for I_{KACh} would potentially also allow tailoring of current AADs choices, such as disopyramide and dronaderone, which are potent inhibitors of I_{KACh}. Ultimately, suppression of autonomic signaling with pharmacologic therapy may also contribute to the efficacy of PV-directed ablation procedures for AF as the effect of GP-targeting ablation strategies depend on successful modification of autonomic innervation patterns.

Utilizing Genetics to Improve Catheter Ablation Outcomes

Outcomes following AF ablation remain modest despite advances in catheter technology and use of new mechanism-based approaches, with freedom from AF being only 20%–50% at 1 year. Investigators have sought to assess whether using common AF-susceptibility alleles can help identify genetic subtypes of AF with differential responses to ablation therapy. In 2010, Husser et al. evaluated whether the common AF-susceptibility SNPs on the chr4q25 locus modulated response to catheter ablation (Husser et al., 2010). While none of the clinical or echocardiographic parameters predicted the response to ablation, the presence of one of the 4q25 variant SNPs did positively associate with AF recurrence after catheter ablation (OR 4.1). This finding was replicated in a large cohort of patients with 'typical' AF (associated with known risk factors), where the overall recurrence rate was 53% over an 18-month period (Benjamin Shoemaker et al., 2013). Further, the presence of the 4q25 SNP risk allele predicted a 24% shorter recurrence-free time (survival time ratio 0.76) than did the presence of the WT SNP (Benjamin Shoemaker et al., 2013). For this, carrying one or two copies of the chr4q25 AF-risk alleles is one of the strongest predictors of 1-year recurrence of AF after catheter ablation (Fig. 2). It should be noted however, that a recently published study of patients of solely Asian descent did not demonstrate a significant correlation between AF-associated SNPs and AF recurrence following catheter ablation seen in other reports (Choi et al., 2015).

In a recent report, Mohanty et al. sought to examine the association between common AF risk SNPs, non-PV triggers, and prevalence of LA scar in 371 patients who underwent catheter ablation for AF (Mohanty et al., 2015). Of the common variants examined, only the chr16q22 (near *ZFHX3*) SNP rs7193343 was associated with a high risk for non-PV triggers and atrial scar formation. While the transcription factor zinc finger homeobox 3 (encoded by *ZFHX3*) is a tumor suppressor-suppressor gene, it associates with another transcription factor (runt-related transcription factor 3 [RUNX3]), and both translocate to the nucleus in response to transforming growth factor (TGF)–β signaling, an important mediator of fibrosis (Verheule et al., 2004; Mabuchi et al., 2010). Seven of the 16 SNPs examined in the study were associated with atrial fibrosis during endocardial scar mapping. It is increasingly appreciated that atrial fibrosis not only plays a prominent role in the pathogenesis of AF but may also be a plausible link between genetic variants and development of AF.

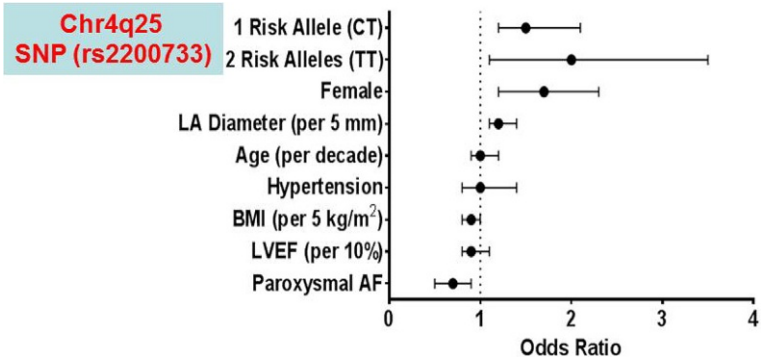

Fig. 2 Modulation of response to catheter ablation of AF by common genetic variants. Predictors of 1-year recurrence of AF after catheter ablation. *BMI*, Body mass index; *Chr*, Chromosome; *LA*, Left atrial; *LVEF*, Left ventricular ejection fraction; *SNP*, Single nucleotide polymorphism.

Risk Model Score

Ethnicity and AF

Although the risk of AF across different races has been addressed in a few studies, the focus is black versus white populations. However, there is paucity of data related to other races such as Asians, or Hispanic/Latinos. Reports suggest that black individuals have a lower prevalence and incidence of AF compared with white individuals. As seen in the Cardiovascular Health Study (CHS), the incidence is slightly lower in black participants than in white participants (12.0 vs 19.5 per 1000 person-years, respectively; $P>0.10$) (Psaty et al., 1997). Further, in a multivariate Cox proportional hazards model adjusted for age and traditional cardiovascular risk factors, black race/ethnicity was associated with lower risk of incident AF (HR: 0.47; 95% CI: 0.22–1.01) compared with white race/ethnicity.

Data regarding AF incidence in Hispanic/Latino and Asian populations is much more limited. A metaanalysis of data from seven randomized clinical trials reported that Asian race/ethnicity was associated with significantly lower rates of AF (OR: 0.65; 95% CI: 0.50–0.84; $P=0.001$) compared with white race/ethnicity. These findings are consistent with a previous report which demonstrated that AF is less common in patients of South Asian origin who were newly hospitalized for heart failure compared to white patients (15 vs. 31%; $P=0.0002$). In the Northern Manhattan Stroke Study, AF was more common in white patients (29%) than in either black (11%) or Hispanic (11%) patients. Similarly, in a large study of US Veterans, the prevalence of AF was 5.7% in White, 3.4% in Black, 3.0% in Hispanic, 5.4% in Native American/Alaskan, 3.6% in Asian, and 5.2% in Pacific Islander participants ($P<0.001$).

Conclusions

Advances in Next Generation Sequencing (NGS) have uncovered the genetic architecture of AF, provided important insights into the underlying mechanisms, defined response to pharmacologic and ablation therapy, and identified novel therapeutic targets. While the impact of these discoveries thus far has been limited, we envision a scenario in the near future where an individualized approach to the management of AF is a reality. Such an approach will not only improve efficacy but also minimize adverse events.

Introduction

Cardiovascular disease is the leading global cause of death and is responsible for one in three deaths in the United States (Benjamin et al., 2017). Valvular heart disease is one of the most common forms of cardiovascular disease and its prevalence increases with age. Using hospital admission and discharge data for 2010, valvular heart disease was identified as the cause of admission in 85,000 cases, and was associated with over 25,000 deaths in the United States. Based on prospective echocardiographic data from almost 12,000 participants, the prevalence of valvular disease has been suggested to be over 4.4% in individuals over the age of 65, and over 11% in those above the age of 75 (Benjamin et al., 2017). After adjustments for age and sex, this corresponds to a prevalence of 2.5% in the US population for any valve disease with no significant difference between males and females. To date, no effective medical therapies have been discovered to prevent or slow down the progression of valve deterioration. As a result, the only treatment for any type of valve disease is valve repair or replacement, a costly procedure that is associated with considerable morbidity and mortality. Despite clear evidence for the high burden of valvular disease, the pathophysiology and most importantly the genetic basis of many forms of valvular abnormalities remain poorly understood. In this article, we discuss the recent evidence surrounding valvular disease focusing on its epidemiology and genetic basis.

Aortic Valve Disease

The relationship between aortic valve structure and blood flow was first described in the 15th century Italy, by Leonardo Da Vinci. It has been reported that Da Vinci (1452–1519) used the motion of waterborne grass seeds flowing through glass models of aortas to describe this relationship (Dorn, 2013; Boon, 2009). Aortic stenosis (AS) has since been identified as the most common form of valvular heart disease in high-income countries of the Western world (Benjamin et al., 2017). Worldwide, rheumatic valve disease continues to be the most common cause of AS (Magnati et al., 2010). The prevalence of AS of any severity in the general US population is about 0.4%, corresponding to over 1.2 million Americans based on the 2016 US population data (Benjamin et al., 2017; Nkomo et al., 2006). The prevalence of AS rises from 1.3%–1.4% in those above the age of 65 to 2.6%–4.6% in individuals above the age of 75 (Nkomo et al., 2006; Lindroos et al., 1993; Stewart et al., 1997), and its associations with cardiovascular morbidity and death are well supported (Otto et al., 1999). In addition to age, male sex has also been reported as a risk factor for AS, but this has not been consistently noted (Stewart et al., 1997). Moreover, evidence suggests the presence of higher prevalence of

coronary artery disease (CAD), renal insufficiency, hypertension, smoking, and dyslipidemia among patients with AS (Nkomo et al., 2006; Stewart et al., 1997; Otto et al., 1999; Thanassoulis et al., 2010). However, it is unclear if the presence of these comorbidities is the result of a common pathophysiological process or not.

The causes of valvular AS include bicuspid valve (BAV), calcification, and rheumatic disease (which is often concomitantly associated with mitral valve disease), and less common processes such as alkaptonuria (Phornphutkul et al., 2002) or familial hypercholesterolemia (Rajamannan et al., 2003). AS requiring intervention is rare in those under the age of 70. In one study, more than two thirds of patients who underwent aortic valve replacement before the age of 70 were noted to have BAV (Roberts and Ko, 2005), suggesting that AS is fairly uncommon in the younger population in the absence of a congenital valve abnormality. Aortic sclerosis defined as aortic valve leaflet thickening, and aortic valve calcification, are the two processes that pave the way for AS and have a high prevalence among the elderly (Otto et al., 1999). These two clinically silent processes were previously thought to be benign, but new evidence suggests that they also increase the risk of cardiovascular death in patients (Otto et al., 1999).

Calcific Aortic Valve Disease

Clinical significance

Calcific aortic valve disease (CAVD), which includes aortic sclerosis and calcifications as well as clinical AS, is thought to be the most common cause of valve stenosis in the Western world (Benjamin et al., 2017). It is estimated to affect over five million individuals in North America (Bach et al., 2007), and has a huge burden on health care with direct health care costs exceeding $1 billion/year (Benjamin et al., 2017). Currently, it serves as the third most common cardiovascular disease after ischemic heart disease and hypertension (Thanassoulis, 2016). Data suggest that age serves as an important risk factor for aortic valve sclerosis/calcification with over 50% of patients above the age of 75 suffering from at least mild aortic valve sclerosis/calcification (Lindroos et al., 1993). Aortic sclerosis is currently a progressive and irreversible process that leads to AS (Owens et al., 2010).

Pathogenesis and current evidence

CAVD initially has a silent clinical phase that involves hardening and calcification of the aortic valve leaflets, known as sclerosis, with no hemodynamic compromise. This stage of the disease has a prevalence of 26% in those older than 65 years of age, and it increases to about 40% after the age of 75 (Lindroos et al., 1993). Previously, aortic valve sclerosis was thought to be benign. However, recent evidence suggests that patients with sclerosis have a 50% increased risk of cardiovascular death and myocardial infarction at five years (Otto et al., 1999; Taylor et al., 2005; Carabello, 1999). Sclerosis shares many of the risk factors with vascular atherosclerosis, such as elevated low-density lipoprotein cholesterol (LDL-C), lipoprotein(a) (Lp[a]), diabetes, smoking, and hypertension (Nkomo et al., 2006; Stewart et al., 1997; Otto et al., 1999; Thanassoulis et al., 2010). Despite similar risk factors, data suggests that aortic valve sclerosis and vascular atherosclerosis are two different disease states (Otto et al., 1994; Demer and Tintut, 2011; Kvidal et al., 2000; Chan et al., 2010; Cowell et al., 2005; Rossebo et al., 2008). A study by Otto and colleagues provided histologic and immunochemical evidence of the similarities and differences between aortic sclerosis and atherosclerosis, highlighting the presence of early mineralization phase and less smooth muscle cells in valve sclerosis compared to atherosclerosis (Otto et al., 1994). In valve sclerosis, calcification develops early and is thought to be independent of atherosclerosis (Demer and Tintut, 2011). In fact, of patients undergoing aortic valve replacement for noncongenital stenotic valve, only about 40% of the subjects required concomitant coronary bypass surgery again highlighting that although valve stenosis and vascular atherosclerosis share several risk factors, unique differences in pathophysiology must be at play (Kvidal et al., 2000). It is also important to note that trials using lipid-lowering agents (i.e., statins) have not shown any benefit in preventing aortic valve disease despite their established role in preventing the progression of atherosclerosis (Chan et al., 2010; Cowell et al., 2005; Rossebo et al., 2008).

The exact mechanism responsible for valvular calcification is not fully understood. Some suggest that cholesterol crystals, elastin fibers, and collagen may serve as locations that allow for mineralization (Towler, 2013; Laird et al., 2006; Fartasch et al., 1990). The process of valve calcification is thought to be similar to bone formation. Noncollagenous matrix proteins involved in bone formation, namely osteopontin, osteocalcin, and osteonectin, have been suggested to be expressed in cells that are in close proximity to valvular zones of calcification undergoing mineralization and could potentially serve as regulators of valvular calcification (Srivatsa et al., 1997). Moreover, early evidence pointed to coexpression of collagen and alkaline phosphatase (ALP) to be sufficient enough for promotion of mineralization (Murshed et al., 2005). Matrix vesicles that are involved in organization of mineral deposition associated with elastin and collagen shed ALP that can then inactivate osteopontin, and inorganic phosphates, which are putative natural inhibitors of calcification (Towler, 2013). Another matrix vesicle enzyme called Phospho1, has also been thought to be involved in biomineralization (Kiffer-Moreira et al., 2013). In addition to ALP and Phospho1, matrix vesicles also contain molecules that are able to bind calcium and promote mineralization even without ALP being active. These molecules are called annexins A5, annexins A6, and phosphatidyl serine (Kapustin et al., 2011). In addition, cells from the myeloid lineage and especially those expressing CD45 and type I collagen have also been suggested to be involved in calcification based on histopathologic studies that have noted their presence especially in the late stages of CAVD (Egan et al., 2011; Fadini et al., 2011). Despite extensive research, our understanding of the pathobiology of AS and CAVD remains incomplete. Ongoing research is currently looking into identifying novel genes that could shed light into molecular pathways that may be involved in this process, which could serve as potential therapeutic targets to prevent the progression of valvular calcification.

Genetics of calcific aortic valve disease

Heritability

With regard to the genetics of CAVD, evidence has highlighted familial clustering of this disease (Horne et al., 2004; Bella et al., 2007; Probst et al., 2006). Data from the Utah Population Database for cases of death attributable to nonrheumatic aortic and mitral valve disease initially suggested high degree of relatedness that extended beyond second-degree relatives among individuals with nonrheumatic valvular mortality (Horne et al., 2004). Researchers from the Hypertension Genetic Epidemiology Network (HyperGEN) Study, evaluated genotype and echocardiographic data from 1871 siblings and identified 142 affected siblings of which 78 sibships from 68 families suffered from at least two affected siblings with one or more types of valve calcification (Bella et al., 2007). The data from the HyperGEN study showed a modest degree of familial aggregation with sibling recurrence risk and sibling recurrence risk ratio for aortic valve sclerosis being 0.25 ($P=0.035$) and 2.31 (95% CI 1.72–3.11). Moreover, a study from France by Probst and colleagues detected specific regions in France with high rates of AS supporting the notion that CAVD may be heritable (Probst et al., 2006). The investigators identified 48 cases of severe AS, 13 of which were within the same family, and traced them all back to a single common ancestor born in 1650, 13 generations prior (Probst et al., 2006). None of the families analyzed had evidence of renal failure or familial hypercholesterolemia, which are considered confounding disorders for aortic valve disease. Moreover, there was no association between AS cases and carriage of Vitamin D receptor (VDR) or Apolipoprotein E variants. Based on their analysis, there was 33% first-degree recurrence rate, providing the most definitive evidence for heritability of CAVD.

Candidate gene studies

One of the main hypotheses surrounding the pathogenesis of aortic valve disease has been regarding the role of atherosclerosis and lipids in valve disease. Hence, there have been many genetic studies that have focused on the association between lipid genes and AS with conflicting results. Candidate gene studies for CAVD have been summarized in **Table 1**. Work by Avakian et al. using a case–control study design of apolipoprotein A1, B, and E polymorphisms in 122 subjects (62 controls and 62 cases with severe AS),

Table 1 Summary of candidate gene association studies for calcific aortic valve disease

Gene	*Polymorphism*	*Risk variant*	*Ethnicity*	P-*value*
Apolipoprotein B (*APOB*) (Avakian et al., 2001)	2p24.1 *Xbal* restriction enzyme	Xbal X+/X +	Brazilian	0.007
Apolipoprotein B (*APOB*) (Gaudreault et al., 2011)	2p24.1 E4181K, 3′ untranslated region	–	French Canadian	1.03×10^{-5}; 1.32×10^{-5}
Apolipoprotein E (*APOE*) (Avakian et al., 2001)	19q13.2 *HHa1* restriction enzyme	E2 allele	Brazilian	0.034
Apolipoprotein E (*APOE*) (Novaro et al., 2003)	19q13.2 *HHa1* restriction enzyme	E4 allele	Predominantly White European	0.046
Estrogen Receptor α (*ESR1*) (Nordstrom et al., 2003)	6q25.1 *Pvull* and *Xbal* restriction enzymes	p allele	Postmenopausal White European Women	0.03
VDR (Ortlepp et al., 2001)	12q13.11 *Bsml* restriction enzyme	B allele	–	0.001
Interleukin-10 (*IL10*) (Ortlepp et al., 2004)	1q31-32 G1082A, C819T, and C592A	A, T, and A alleles	–	0.026; 0.027; and 0.028
Interleukin-10 (*IL10*) (Gaudreault et al., 2011)	1q31-32 6 polymorphisms in 5′ region, introns, and 3′ region	–	French Canadian	$0.016–6.21\times10^{-11}$
Connective Tissue Growth Factor (*CTGF*) (Ortlepp et al., 2004)	6q23.1 G447C	GC	–	0.099 (0.037 in combination with CCR5 polymorphism)
Chemokine (C–C motif) Receptor 5 (*CCR5*) (Ortlepp et al., 2004)	3p21.31 Δ32 deletion	Deletion	–	0.213 (0.037 in combination with CTGC polymorphism)
Parathyroid Hormone (*PTH*) (Schmitz et al., 2009)	11p15.3-p15.1 rs6254	AA	–	0.007
Myosin VIIA (*MYO7A*) (Ellis et al., 2012)	11q13.5 rs2276288	AA	–	0.001
Angiotensin II Receptor, Type 1 (*AGTR1*) (Ellis et al., 2012)	3q24 rs5194	AA	–	0.004
Elastin (*ELN*) (Ellis et al., 2012)	7q11.23 rs2071307	AA	–	0.005
Lipoprotein(a) (*LPA*) (Thanassoulis et al., 2013)	6q26-27 rs10455872	G allele	White European	9.0×10^{-10}

Adapted from Mauer, A. C., Owens, D., O'Donnell, C. J., Post, W. S. and Thanassoulis, G. (2015). Genetics of valvular heart disease. In: Shah, S. J. and Arnett, D. K. (eds.) *Cardiovascular genetics and genomics in clinical practice*. New York: Demos Medical.

identified the apolipoprotein B XbaI restriction site polymorphism to be in excess among their AS cases along with the apolipoprotein E2 allele (Avakian et al., 2001). Novaro and colleagues evaluated the role of apolipoprotein E (*APOE*) gene in 802 individuals with 43 cases (Novaro et al., 2003). The investigators found that age and the APOE4 allele were independent predictors of AS, but not the E2 allele previously identified by Avakian and colleagues.

Given the previously demonstrated association of AS with age and atherosclerosis (Lindroos et al., 1993; Thanassoulis et al., 2010), Nordstrom and colleagues evaluated the role of postmenopausal hormone variations, such as polymorphisms in the estrogen receptor alpha (*ESR1*), and suggested an association with AS (Nordstrom et al., 2003). In addition, based on the suggested involvement of transforming growth factor beta1 (*TGFB1*) in fibrosis and atherosclerosis, Nordstrom et al. studied its effect in AS (Nordstrom et al., 2003). A mutation in the intron region of the estrogen receptor gene was identified in 41 women and was associated with increased risk of AS in their population. While a genotype resulting from the combination of this polymorphism and two additional *TGFB1* restriction sites was categorized as high-risk, no high-risk *TGFB1* polymorphisms were identified, ruling out a potential association between *TGFB1* and AS.

Based on recent evidence supporting the involvement of inflammatory pathways in the pathogenesis of CAD, Ortlepp and colleagues studied the effect of inflammation on AS (Ortlepp et al., 2004). The authors evaluated 187 patients undergoing surgical aortic valve replacement and surprisingly identified a haplotype made up of IL-10 gene polymorphisms that is associated with elevated IL-10 levels, an antiinflammatory cytokine, to be associated with AS (Ortlepp et al., 2004). This was however not replicated by a subsequent study that identified the alternate proinflammatory haplotype to be associated with AS (Gaudreault et al., 2011).

Given the suggested similarities between bone mineralization and valvular calcification, Ortlepp et al. studied a VDR gene polymorphism (BsmI polymorphism), that has been associated with bone mineral mass (Ortlepp et al., 2001). In their study, they reported that the BsmI B variant was present with a much higher frequency among the 100 patients with AS compared to controls. To investigate a similar hypothesis, Schmitz and colleagues studied *VDR* and the parathyroid hormone gene (*PTR*), however the *VDR* variant was only marginally significant, but an intronic *PTR* mutation was associated with aortic valve stenosis (Schmitz et al., 2009).

It is important to highlight that most of these candidate–gene associations have not been subsequently replicated, making the involvement of these genes in CAVD debatable. Gaudreault and colleagues tried to replicate the associations of several of these candidate genes with AS in 457 patients undergoing aortic valve replacement using more modern approaches and were only able to reproduce the association with two polymorphisms in the *APOB* gene (Gaudreault et al., 2011), which supports the LDL-C hypothesis in CAVD.

Ellis and colleagues were able to identify novel association between AS and *MYO7A* (a myosin variant), *ELN* (elastin), and interestingly *AGTR1* (angiotensin receptor II, type 1) genes by studying 660 single nucleotide polymorphisms (SNPs) in 265 cases of AS (Ellis et al., 2012). Of the genes identified in this study, the association with *AGTR1* is of most interest given the angiotensin may play a role in AS (Helske et al., 2004), as well as the early clinical evidence that has suggested improved survival in patients with AS who receive angiotensin-converting enzyme (ACE) inhibitors (Nadir et al., 2011).

Mutations in the *NOTCH1* gene at chromosome 9q34.3 that acts as a transcriptional regular and have been associated with familial forms of AS (including BAV) have also been linked to the development and progression of CAVD (Garg et al., 2005). As a result, Ducharme and colleagues genotyped *NOTCH1* in 457 patients with severe tricuspid aortic valve stenosis (Ducharme et al., 2013) and were able to identify one of the previously reported *NOTCH1* mutations. In addition, the authors were able to identify 32 other individuals who were heterozygous for two other polymorphisms. An association was initially found between AS and one polymorphism in intron 2, however this was not significant after correction for population stratification. *NOTCH1* represses the activation of *Runx2*, a transcription factor regulating the expression of osteoblast-specific genes that is thought to be upregulated in valvular calcification of animal models (Garg et al., 2005). In addition, *NOTCH1* was found to regulate the osteogenic pathways in murine aortic valves via bone morphogenic protein 2 (*BMP2*) (Nigam and Srivastava, 2009). Thus, there remains significant interest surrounding the potential involvement of the *NOTCH1* gene in CAVD.

Genome-wide association studies and Mendelian randomization

To date, the best evidence surrounding the genetics of aortic valve disease comes from only one genome-wide association study (GWAS) by Thanassoulis and colleagues (Thanassoulis et al., 2013). GWAS is a new technique in use since the early 2000s that was made possible with complete characterization of the human genome sequence. In their study, Thanassoulis et al. used genome-wide genotyping in almost 7000 individuals in three cohorts with computed tomographic (CT) evaluation of aortic valve calcium to identify variants associated with CAVD and subsequently replicated their results in several additional cohorts (Thanassoulis et al., 2013). Only one SNP that is located within intron 25 of the apolipoprotein(a) gene (*LPA*) reached genome-wide significance and was noted to double the odds of CAVD. This SNP was also validated prospectively in additional cohorts. This SNP is thought to lead to higher levels of Lp(a) because of its linkage disequilibrium with fewer Kringle IV- type 2 (KIV-2) repeats, which is an important regulator of *LPA* expression. Using Mendelian randomization, Thanassoulis et al. demonstrated that Lp(a) levels, which are genetically determined by the *LPA* genotype, are strongly associated with AS and increased risk by almost 70% per risk allele; providing robust evidence for a causal relationship between variation at the *LPA* gene and development of AS (Thanassoulis et al., 2013). These results have been replicated by several independent groups (Arsenault et al., 2014; Kamstrup et al., 2014; Cairns et al., 2017) demonstrating that the association between *LPA* variants, circulating Lp(a), and CAVD is robust and pointing to a novel therapeutic target for AS.

Subsequent work by Smith and the extracoronary calcium working group of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, used Mendelian randomization to investigate the effect of genetic elevations in

plasma lipids on aortic valve calcium and AS (Smith et al., 2014). The authors were able to demonstrate that genetic elevations in plasma LDL-C levels, but not high-density lipoprotein cholesterol (HDL-C) or triglycerides, was significantly associated with the presence of aortic valve calcium and incident AS, confirming prior evidence from observational studies that had suggested a causal association between LDL-C and AS (Smith et al., 2014).

Bicuspid Aortic Valve Disease

Clinical significance

Although Harvey was the first to describe blood circulation in the 16th century, Leonardo Da Vinci is credited as the first person to describe the mechanics of aortic valve and the effect of having a bicuspid versus a tricuspid valve on flow in the 15th century (Dorn, 2013). Later in the 1800s, Sir William Osler reported 18 cases of BAV in more than 800 autopsies (Osler, 1886). Since then, BAV has been identified as the most common congenital cardiac abnormality in the world, with the largest health burden of all congenital heart defects combined (Siu and Silversides, 2010). It affects about 1%–2% of the population, with a higher predominance of 3:1 in males versus females (Tutar et al., 2005; Movahed et al., 2006; Basso et al., 2004). It is the cause of AS in up to 85% of cases in the pediatric population and in about 50% of AS cases in adults (Schoen, 2008; Cripe et al., 2004). BAV is the result of the aortic valve developing with two leaflets rather than its normal trileaflet configuration. In over 60% of the cases, it is the result of congenital fusion of the right and left coronary cusps, identified as type A, with most of the remaining cases being the result of the fusion of the right coronary cusp with the noncoronary cusp, known as type B. The fusion of the left coronary cusp and noncoronary cusp, or type C BAV, is rarely seen (Fernandes et al., 2004; Sabet et al., 1999a; Russo et al., 2008; Schaefer et al., 2007, 2008; Ciotti et al., 2006).

Studies have suggested that patients with a BAV have the same life expectancy as those with a normal trileaflet aortic valve (Tzemos et al., 2008; Michelena et al., 2011). Despite this, more than 35% of those with bicuspid aortic valve develop severe complications that include aortic valve regurgitation, aortic valve stenosis, infective endocarditis, aortic coarctation, ascending aortic aneurysms, and aortic dissection (Michelena et al., 2011; Larson and Edwards, 1984; Roberts et al., 2012; Sabet et al., 1999b; LaHaye et al., 2014; Padang et al., 2012a). Moreover, having BAV increases the risk of premature valvular calcification. BAV has been shown to significantly increase the risk of aortic dissection by as much as eightfold, along with 26% increased risk of aortic aneurysm formation, and 53% risk of valve replacement over 25 years (Michelena et al., 2011). Although BAV can be present as an isolated abnormality, it has also been associated with a number of other diseases including coarctation of the aorta, ventricular septal defect (Duran et al., 1995), Turner syndrome (Hou et al., 1993; Sybert, 1998), Williams–Beuren syndrome (Hallidie-Smith and Karas, 1988; Del Pasqua et al., 2009; De Reubens et al., 2008), Rubinstein–Taybi syndrome (Stevens and Bhakta, 1995), Andersen syndrome (Andelfinger et al., 2002), Williams syndrome (Lopez-Rangel et al., 1992), and others.

Pathogenesis and current evidence

Studies since the 1970s have highlighted the familial clustering of BAV and point to the high likelihood of a genetic basis. In the first family study of BAV published in 1978, Emanuel and colleagues studied the families of 41 patients with surgically proven isolated BAV (Emanuel et al., 1978). They estimated a minimal familial incidence of 14%–32% in first-degree relatives of their patients and provided systemic evidence that BAV is a heritable disorder. Further evidence to support this theory was later obtained by reports of BAV in pairs of identical twins, and also families with multiple members in different generations affected (Godden et al., 1987; Brown et al., 2003; Clementi et al., 1996; Glick and Roberts, 1994). Current evidence suggests that the prevalence of BAV among first-degree relatives of patients with known disease is about 9%, and the prevalence increases to as much as 24% in families with more than one individual affected, and over 35% in families with at least two affected members (Padang et al., 2012a; Huntington et al., 1997). This is based on work by Huntington and colleagues who identified 30 patients with documented BAV on echocardiography and evaluated their relatives using echocardiography (Huntington et al., 1997). Of the 186 first-degree relatives that they evaluated, 17 had BAV. They also identified 11 families out of the initial 30 who had at least one additional member with BAV. In a more recent study of 100 families in a Mediterranean population, the prevalence of BAV in first-degree relatives was noted to be much lower at 4.6%, highlighting that the prevalence of BAV likely differs in different populations or geographic areas (Robledo-Carmona et al., 2013). Lastly, to estimate the heritability of BAV, Cripe et al. evaluated over 300 individuals from families of 50 patients with documented BAV using echocardiography (Cripe et al., 2004). They estimated the heritability of BAV at 89% with a prevalence of 24%. Furthermore, when BAV was present with another cardiac abnormality, they reported the combined prevalence of 31% with heritability of BAV with another malformation at 75%.

Despite knowledge of its existence since the 15th century, its high prevalence, heritability, and the large burden it imposes on healthcare systems around the world, little is known about the pathogenesis of BAV. Familial studies that highlighted the clustering of BAV in families suggest a pattern of autosomal dominant inheritance, but with reduced penetrance, an observation that was confirmed in linkage and candidate gene studies (Garg et al., 2005; Godden et al., 1987; Brown et al., 2003). Multiple genetic mutations including *GATA5* missense mutations in nonsyndromic BAV patients (Foffa et al., 2013; Padang et al., 2012b), *KCNJ2* mutation in those with Anderson syndrome (Andelfinger et al., 2002), *ACTA2* mutation in patients with ascending aortic aneurysm and dissection syndrome (Guo et al., 2007, 2009), fibrillin 1 mutation in Marfan patients (Faivre et al., 2007; Lemaire et al., 2011), elastin mutation in William–Beuren syndrome (Hallidie-Smith and Karas, 1988; Del Pasqua et al., 2009; De Reubens et al., 2008; Pober et al., 2008), and 45XO karyotype in Turner syndrome (Hou et al., 1993; Sybert, 1998; Bondy et al., 2013) are some of the genetic abnormalities that have been associated with BAV (Padang et al., 2012a).

However to date, the strongest genetic evidence comes from a study by Garg and colleagues in which they studied a family of European-American descent spanning five generations with six cases of isolated BAV out of nine cases of congenital aortic valve disease with an autosomal dominant pattern of inheritance (Garg et al., 2005). They used genome-wide linkage analysis and were able to identify a locus on chromosome 9q34-35, a region that includes the *NOTCH1* gene, to be associated with bicuspid aortic valve disease (Garg et al., 2005). Sequencing of the region revealed a mutation that resulted in a premature stop codon in the *NOTCH1* gene of affected family members. In the same study, the authors performed direct sequencing of *NOTCH1* in an unrelated Hispanic family with aortic valve disease and identified a second mutation that segregated with family members suffering from BAV. The authors then used murine models to demonstrate a role for *NOTCH1* gene in embryonic valve development (Garg et al., 2005). *NOTCH1* functions as a transcriptional regulator and is involved in cell differentiation during organogenesis including cardiac development (Artavanis-Tsakonas et al., 1999; De La Pompa and Epstein, 2012; High and Epstein, 2008). The NOTCH family of proteins are transmembrane proteins that once bound to their ligand proteins, become activated to modify gene expression (Artavanis-Tsakonas et al., 1999; De La Pompa and Epstein, 2012; High and Epstein, 2008). The transcripts of the *NOTCH1* gene have been found in the mesenchyme of the outflow tract and the developing aortic valve leaflets, highlighting its importance for aortic valve development (Garg et al., 2005; Krebs et al., 2000; Timmerman et al., 2004). Mutations in the *NOTCH1* gene cause dysregulation in this pathway and have been found in affected family members of those with BAV. Moreover, evidence suggests that *NOTCH1* mutations are not only involved in defective development of the aortic valve, but also can lead to rapid progression of aortic valve calcification discussed in the previous section of this article.

In contrast to CAVD, currently there are no GWAS studies reported for BAV. This is likely due to the low prevalence of BAV in the general population and the difficulty in clearly identifying the presence of a BAV when the valve is calcified and/or thickened, and the diversity of BAV phenotypes observed. Given these difficulties, Wooten and colleagues used a used gene network-based analysis techniques in 68 patients with BAV and identified a concentration of SNPs associated with BAV located at 16p13.3, a region encompassing two genes called *AXIN1* and *PDIA2* (Wooten et al., 2010). *AXIN1* (Axis Inhibitor 1) is a crucial member of signaling pathways involved in regulation of cardiac neural crest development (Niessen and Karsan, 2008) and heart valve formation (Armstrong and Bischoff, 2004). *PDIA2* (protein disulfide isomerase family A member 2), on the other hand, has no known involvement in cardiac valve formation. In the same study, they also identified a second gene, *ENG* (Endoglin), which is involved in neural crest differentiation of cells that inhabit the aorta (Mancini et al., 2007), and more importantly, defects in the *NOTCH* signaling pathway result in downregulation of this gene (Benedito et al., 2008). A summary of candidate gene studies for BAV can be found in **Table 2**.

Rare Forms of Aortic Valve Disease

Although some cases of aortic valve disease follow an autosomal dominant/reduced penetrance mode of inheritance, most cases do not follow a clear pattern. However, there are certain rare Mendelian syndromes that are an exception to this rule. These cases are extremely rare and have very little in common with the cases of AS that are encountered clinically.

Familial hypercholesterolemia

The association of familial hypercholesterolemia (FH) and AS has long been known, but the exact mechanisms are not well defined (Rajamannan et al., 2003; Barr et al., 1954). Phenotypes in FH differ from the typical presentation of AS. For example, FH patients often develop supravalvular, rather than valvular, aortic calcification (Brook et al., 1989).

Aortic insufficiency

Similar to AS, aortic insufficiency (AI) is also a characteristic of many connective tissue diseases including Marfans (Buntinx et al., 1991; Disabella et al., 2006), Loeys-Dietz (Attias et al., 2009), Ehlers-Danlos (Schwarze et al., 2004), and osteogenesis imperfecta (Hortop et al., 1986). Development of AI in these conditions appears to be a secondary consequence of primary aortic pathology.

Alkaptonuria

Alkaptonuria is a rare autosomal recessive disorder that is due to a mutation in the homogentisate 1,2 dioxygenase (*HGD*) gene, resulting in abnormalities of tyrosine catabolism and tissue deposition of homogentisic acid. The tissue deposition of this compound causes black pigmentation of collagenous tissues, in addition to arthritis, urolithiasis, vascular, and aortic valve mineralization that lead to premature AS (Phornphutkul et al., 2002; Hannoush et al., 2012).

Mitral Valve Disease

Mitral Valve Prolapse

Clinical significance

Mitral valve prolapse (MVP), also known as Barlow's disease, is a common valvular abnormality affecting approximately 2.4% of the population based on the most widely accepted definition of this disorder (Freed et al., 1999). There is some evidence for a higher prevalence in women compared to men (Freed et al., 1999). The mitral valve is composed of an anterior and a posterior leaflet. These leaflets are attached to the oval-shaped mitral annulus via their bases with their tips attached to the chordae that join the

papillary muscles. The anterior leaflet is described as long and narrow, while the posterior leaflet is short and wide. The posterior leaflet occupies a larger portion of the valvular area and based on Carpentier's description, it is divided into the anterolateral (P1), middle (P2), and postero-medial (P3) scallops. The anterior leaflet is divided into three segments (A1–A3) based on their corresponding posterior leaflet scallop (McCarthy et al., 2010).

The basic definition of MVP is the extension of its leaflet(s) beyond the mitral valve annulus and into the left atrium during ventricular systole when intracardiac pressures are elevated (Guy and Hill, 2012; Hayek et al., 2005; Delling and Vasan, 2014). This could then lead to disruption of the leaflet coaptation and result in mitral regurgitation, often starting in mid-to-late systole. Hence, MVP has been identified as the most common cause of mitral valve regurgitation requiring surgical repair. This valvular abnormality has also been shown to predispose patients to infective endocarditis, congestive heart failure, arrhythmia, and even sudden cardiac death (Freed et al., 1999; Guy and Hill, 2012; Hayek et al., 2005; Delling and Vasan, 2014). When isolated and in the absence of an identifiable connective tissue disease, MVP is classified as primary, which can be sporadic or familial. Secondary MVP is often associated with an identifiable connective tissue disease such Marfan, Ehlers–Danlos, osteogenesis imperfecta, pseudoxanthoma elasticum, Loeys–Dietz, or Williams syndromes (Hayek et al., 2005).

The exact echocardiographic diagnostic criteria for MVP have become more uniform in recent years based on results published from the Framingham Heart Study (Freed et al., 1999). Currently, MVP is diagnosed by abnormal displacement of one or more portions of the mitral valve leaflets ≥ 2 mm above the annular plane into the left atrium during systole, also called billowing, and best identified in a long axis view. This can occur with or without thickening of the leaflets, which is identified as having a thickness

of $\geq$5 mm or not. MVP with leaflet thickness is called classic MVP, where as a valve without thickened leaflets is identified as nonclassic MVP. Moreover, when MVP is present with extracardiac manifestations such as pectus excavatum (Bon Tempo et al., 1975), it is classified as syndromic. In this article, we will focus on familial and sporadic forms of MVP in nonsyndromic individuals. The prevalence of nonsyndromic MVP has been estimated as 2.4% in the general population (Freed et al., 1999).

Pathogenesis and current evidence

Histologically, distinct layers identified as atrialis, spongiosa, fibrosa, and ventricularis form normal mitral valve leaflets. These layers are comprised of fibroblasts, connective tissue fibers, and collagen. The atrialis and ventricularis layers are each covered by a layer of endothelial cells overlying them that is continuous with the luminal surface of the atrium and the ventricle. The diseased valve has been shown to have excessive proteoglycan deposition and expansion of the spongiosa layer (McCarthy et al., 2010). This along with other changes such as overexpression of proteolytic enzymes and diminished collagen fibers, results in pathologic remodeling of the valvular leaflet (Padang et al., 2012a).

The majority of our knowledge regarding the genetics of MVP comes from initial investigations into the various connective tissue disorders associated with MVP (Hayek et al., 2005). One example of such disorders is Marfan syndrome, which is secondary to a mutation in the Fibrillin 1 (*FBN1*) gene, a major component of the extracellular matrix microfibrils and a regulator of transforming growth factor-beta (TGF-β) (Ng et al., 2004). TGF-β has been suggested as a key player in valvular development during the embryonic period and remodeling in adult life seen in MVP (Coombs and Yutzey, 2009). Such mutations, however, have not been identified in isolated nonsyndromic MVP.

The identification of genetic factors in nonsyndromic MVP is the result of findings from familial studies. Evidence suggests that the most common method of transmission in familial primary MVP is autosomal dominant, but X-linked patterns of inheritance have also been described (Levine and Slaugenhaupt, 2007; Grau et al., 2007; Cooper and Abinader, 1981; Weiss et al., 1975; Shappell et al., 1973), with variable age and sex-dependent penetrance (Weiss et al., 1975; Devereux et al., 1982). Prior work estimated the prevalence of MVP in first-degree relatives to as much as 50% (Weiss et al., 1975; Devereux et al., 1982; Strahan et al., 1983). However, most of this work was done prior the adoption of clear and uniform diagnostic criteria and phenotyping. Further evidence supporting a genetic pattern of inheritance comes from twin studies, which suggested that the prevalence of MVP was higher among twins compared to controls (Rizzon et al., 1973; Girard and Girard, 1977). More recently, Delling and colleagues used a community-based sample in Framingham and identified parental MVP to be significantly associated with higher prevalence of MVP in offsprings. In addition, the authors highlighted the importance of nondiagnostic MVP morphologies by suggesting their association with increased prevalence of MVP in the offspring (Delling et al., 2015).

MVP with X-linked inheritance is a rare form of the disease that was first reported in 1960s by Monteleone and colleagues after they identified a family in which only male members in three generations had evidence of MVP (Monteleone and Fagan, 1969). More recent work by Kyndt et al. in a family with cosegregation of mild hemophilia A and MVP phenotype, allowed for mapping to the Xq28 locus (Kyndt et al., 1998). Later work identified a mutation in the filamin A (*FLNA*) gene at this locus to be responsible for this X-linked myxomatous valvular dystrophy (*XMVD*) (Kyndt et al., 1998; Lardeux et al., 2011). The Filamin A protein is involved in localization and activation of Smad proteins, including Smad2, and regulation of TGF-beta (Kyndt et al., 2007).

Family studies have been useful in identifying genes that are involved in familial forms of MVP. However, as stated previously, MVP can also occur sporadically. In nonsyndromic, sporadic MVP, association of disease with SNPs has been evaluated. Given that MVP is often present with connective tissue disease, particular attention has been given to genes involved in extracellular matrix remodeling, collagen metabolism, and the renin–angiotensin–aldosterone system (RAAS). Genome-wide linkage analysis in large families and recent diagnostic criteria for MVP have shed light on 3 potential loci called myxomatous mitral valve prolpase (*MMVP*) loci on chromosomes 16p11.2-p12.1 (*MMVP-1*), 11p15.4 (*MMVP-2*), and 13q31.3-32.1 (*MMVP-3*) (Disse et al., 1999; Freed et al., 2003; Nesta et al., 2005). Disse and colleagues identified the first of these loci in 1999 (Disse et al., 1999). They used four pedigrees of autosomal dominant, heritable MVP, of which, one pedigree involved 24 subjects over three different generations, with linkage to the region on chromosome 16, later called *MMVP-1* on locus 16p11.2-12.1. There were able to replicate this finding in a second pedigree, but not in the other two pedigrees likely due to genetic heterogeneity of MVP. Shortly after, Freed and colleagues identified the second locus (*MMVP-2*) located on chromosome 11p15.4, using a single large pedigree (Freed et al., 2003). In 2005, Nesta et al. used a pedigree of 46 subjects with living members in three generations and identified *MMVP-3* on the long arm of chromosome 13 (Nesta et al., 2005). It is worth highlighting that all three of these studies had a limited ethnic diversity and very small number of pedigrees. In addition, the causative genes on these loci have yet to be identified.

Based on evidence that *MMVP2*, a locus associated with nonsyndrome MVP was located on chromosome 11, Durst and colleagues identified four individuals from a large multigenerational family segregating a nonsyndromic MVP and performed capture sequencing of the linked interval on chromosome 11 (Durst et al., 2015). Their work identified a missense mutation in the *DCHS1* gene that segregated with MVP. Knockdown zebrafish models of this gene developed a cardiac atrioventricular canal defect that was only rescued with the wild-type human *DCHS1*, but not with the familial mutant form of the gene. Durst et al. were also able to identify a second mutation in *DCHS1* that segregates with MVP based on genetic data in two additional families. Both of the identified loss-of-function mutations in *DCHS1* are thought to reduce protein stability during valve morphogenesis (Durst et al., 2015). This work highlighted the potential involvement of *DCHS1* in MVP pathogenesis.

A recent meta-analysis of two independent French genome-wide association studies by Dina and colleagues with 1412 MVP cases and 2439 controls led to identification of few loci, which after replication in 1422 cases and 6779 controls provided genetic and functional evidence for two candidate genes called LIM and cysteine-rich domains 1 (*LMCD1*) on chromosome 3 and tensin 1

Mauer, A. C., Owens, D., O'Donnell, C. J., Post, W. S. and Thanassoulis, G. (2015). Genetics of valvular heart disease. In: Shah, S. J. and Arnett, D. K. (eds.) *Cardiovascular genetics and genomics in clinical practice*. New York, NY: Demos Medical.

(*TNS1*) on chromosome 2, both of which are involved in cell proliferation and migration possibly during valve development (Dina et al., 2015). The strongest overall association was observed at 3p13 for rs171408 that maps *LMCD1* (OR 1.32, $P = 1.29 \times 10e{-}11$). *LMCD1*, also known as dyxin, encodes a protein that belongs to the LIM-domain family of zinc-finger proteins and is involved in coregulation of transcription. This gene is highly expressed in mouse cardiac tissue and is a direct repressor of *GATA6*, an important regulator of cardiac development. In knockdown models of *LMCD1* in zebrafish, a significant increase in the incidence of atrioventricular valve regurgitation was noted (Rath et al., 2005). Another strong association was noted to be at 2q35 for rs12465515 that lies within the region for *TNS1* (OR 1.25, $P = 3.1 \times 10e{-}11$), a second candidate gene encoding a focal adhesion protein called tensin 1 involved in cytoskeleton organization. Similar to filamin A, tensin 1 interacts with actin and its variants can cause a rare X-linked form of MVP (Kyndt et al., 2007). The important work by Dina et al. also highlighted few other susceptibility loci including *IGFBP5*, *SMG6*, *PITPNB*, *PCNX*, *SIPA1L1*, *SETD4*, *CBR1*, and *MN1* in addition to the already discussed *LMCD1* and *TNS1* (Dina et al., 2015). A summary of these studies and other candidate gene association involving MVP can be found in **Table 3**.

Mitral Annular Calcification

Clinical significance

Mitral annular calcification (MAC) is defined by calcium deposition along the mitral annulus, valvular, and/or subvalvular structures. It is routinely identified by cardiac imaging among the elderly and is suggested to be independently associated with cardiovascular events (Fox et al., 2003, 2004; Barasch et al., 2006a). It has also been suggested to precede the development of clinically significant mitral valve regurgitation and stenosis (Labovitz et al., 1985; Movahed et al., 2007; Korn et al., 1962). Prevalence of MAC varies based on the modality used and ranges between 3% and 42%, and increases significantly with age (Fox et al., 2004; Savage et al., 1983; Barasch et al., 2006b). There are a number of clinical factors that have been associated with the presence and severity of MAC, including traditional cardiovascular risk factors (Thanassoulis et al., 2010; Abramowitz et al., 2015; Kanjanauthai et al., 2010; Elmariah et al., 2013), end-stage renal disease (Maher et al., 1987; Asselbergs et al., 2009), and chronic inflammatory conditions (Molad et al., 2006; Sherif, 2009).

Pathogenesis and current evidence

The development and progression of MAC is now recognized as a tightly regulated process involving complex biological pathways that cause progressive calcification. There is a shortage of studies investigating the heritability of MAC given that it has been presumed to be an age-related, degenerative disease. One of the best evidence for its heritability comes from the HyperGEN study, involving a total of 78 sibships in 68 families with at least 2 affected siblings, which suggested that despite the contribution of environmental factors to MAC, there likely is a significant genetic influence involved in the process (Bella et al., 2007). In another study, Novaro and colleagues evaluated the association between *APOE* alleles and MAC in over 800 participants, but were unable to identify any significant difference in genotype distributions between the cases and controls (Novaro et al., 2003).

Thanassoulis et al. used data from the CHARGE Consortium collaboration to better evaluate the associations of MAC (Thanassoulis et al., 2013). The authors identified MAC using CT scans among subjects of White European descent within the Multi-Ethnic Study of Atherosclerosis ($n = 2527$, 12%) and the Framingham Heart Study ($n = 1298$, 20%), and suggested an association between MAC and genetic variants near the *IL1F9* gene, which was also replicated among Hispanic Americans (Thanassoulis et al., 2013). Recently, the same group used Mendelian randomization to demonstrate that a genetically elevated triglyceride plasma level is strongly associated with the presence of MAC (Afshar et al., 2017). MAC was significantly associated with the triglyceride genetic risk score (GRS), a measure of the genetic predisposition to elevations in plasma triglyceride levels. Moreover, they did not find such an association between MAC and HDL-C or LDL-C. This work highlights the importance of genetic predisposition to elevated triglyceride level, and its association with the presence of MAC, suggesting a causal association between triglycerides and mitral valve disease (Afshar et al., 2017).

Conclusions and Future Directions

Valvular heart disease is a common cardiovascular condition and its prevalence appears to increase with age. Until recently, the genetic etiology of these disorders was poorly understood. However, recent advances have pointed to a variety of altered molecular and genetic mutations as a common pathway for familial and sporadic forms of valvular heart disease. The use of cardiac CT which provides excellent resolution of valve calcium and likely represents a "deep-phenotype", has been particularly useful in identifying new genomic insights for aortic valve and MAC. Using new imaging modalities, beyond echocardiography and CT, such as positron emission tomography (PET) may provide an opportunity to better evaluate valvular inflammation and osteoblast activity (Marincheva-Savecheva et al., 2011; Dweck et al., 2012), relevant biologic phenotypes that may be more amenable to genetic dissection. In addition, due to the relative rarity of valve disease in the community, the increasing availability of large cohorts derived from hospital-based electronic health records (where valve disease is enriched) as well as very large population cohorts with linkage to administrative data will provide the requisite sample size to identify new variants for valvular heart disease.

Finally, the discovery of *LPA* variants in AS has provided a highly robust pharmacological target to prevent disease progression and randomized trials for Lp(a) lowering are highly anticipated. The availability of larger sample sizes and new technologies for genetic analysis (including whole genome sequencing) as well as emerging integrative –omics approaches, will provide a deeper understanding of the molecular pathways involved in the genesis of valvular heart disease and will create unique opportunities for the development of novel pharmacotherapies to reduce the burden of valvular heart disease.

Introduction

The vascular system, which develops from a complex process of vasculogenesis and angiogenesis (Arboleda-Velasquez and D'Amore, 2014), represents an intricate network that serves a crucial role in the maintenance of life: the delivery of nutrients to

and the removal of waste products from our tissues (Sumpio and Chin, 2014). However, it has become abundantly clear that the vasculature is not merely a static conduit for blood flow but a dynamic system that responds to both physiologic and pathologic phenomena (Sumpio and Chin, 2014).

This dynamic system can be disrupted by genetic disorders that alter the different components of the vessel wall. While the relative size and the composition of the different layers of blood vessels may vary between arteries and veins, and among the different types of arteries (elastic and muscular), the basic organizational framework remains the same. This includes the tunica intima (composed of endothelial cells supported by an internal elastic lamellae), the tunica media (composed of smooth muscle cells (SMCs) and connective tissue), and the tunica adventitia (composed of connective tissue, vasa vasorum that supply nutrients to the media, and nerves) (Sumpio and Chin, 2014).

By altering endothelial cells, SMCs, and/or the extracellular matrix (ECM) of the vessel wall, the primary manifestations that result from underlying genetic disorders include arterial aneurysms and dissections, vascular malformations, and other vasculopathies that mainly lead to vessel rupture and/or downstream tissue ischemia. This article will focus on our current understanding of the genetics of arterial aneurysms and dissections, with a particular focus on thoracic aortic aneurysm and dissection (TAAD), abdominal aortic aneurysms (AAAs), and intracranial aneurysms (IAs), as well as the genetics of inherited vascular malformations and other inherited vasculopathies.

Genetics of Aneurysmal Disease

An aneurysm is defined as a focal pathologic dilatation of an artery to greater than 1.5 times its normal diameter (Norman and Powell, 2010). While TAAD, AAAs, and IAs may have differing underlying pathophysiology and risk factors (**Table 1**), the overall pathologic process that occurs with degenerative aneurysms, namely increased proteolysis, inflammation, and loss of arterial wall

Table 1 Epidemiologic characteristics and pathophysiology of TAAs, AAAs, and IAs

Characteristic	*TAAs*	*AAAs*	*IAs*
Mode of inheritance	20% of cases exhibit Mendelian inheritance (primarily autosomal dominant) (Biddinger et al., 1997; Coady et al., 1999)	Genetic heterogeneity (Kuivaniemi et al., 2015a; Ruigrok et al., 2008)	Genetic heterogeneity (Ruigrok et al., 2008)
Incidence/ prevalence	Incidence: 10.4/100,000 person-years (Ramanath et al., 2009)	Prevalence: 1.3%–8.9% in men, 1.0%–2.2% in women (Sakalihasan et al., 2005)	Prevalence: 2%–5% (Nasr and Brown, 2016; Etminan and Rinkel, 2017; Vlak et al., 2011)
% of individuals with a positive family history	20% (Biddinger et al., 1997; Coady et al., 1999)	Average = 12% (higher among brothers) (Kuivaniemi et al., 2015a)	9% (Ronkainen et al., 1997, 1998) (range from 7% to –20% (Thompson et al., 2015))
Major risk factors	HTN, BAV, FH/inherited mutation in TAAD-causing gene (Milewicz et al., 2016)	Smoking, FH/certain hereditary diseases, older age, male sex (Kuivaniemi et al., 2015a)	Smoking, HTN, female sex, FH/certain hereditary diseases, older age, multiple aneurysms (Etminan and Rinkel, 2017)
Male/female ratio	1.6:1 (Balistreri, 2015)	4–6:1 (Kent, 2014; Saratzis and Bown, 2014)	1:3 (Nasr and Brown, 2016)
Typical age of onset	>60 years (average = 69 years (Ramanath et al., 2009))	>50 for men, >60–70 for women (Kent, 2014) (average = 75 years (Balistreri, 2015)	40–60 years (Etminan and Rinkel, 2017)
Complication rates	Annual risk for rupture/dissection/death = 4.7%, 7.3%, and 12.1% for ascending aortas of 5, 6, and 7 cm, respectively (Elefteriades et al., 2015)	Annual rupture risk ≤1% for AAAs <5.5 cm and 32.5% for AAAs > 7.0 cm (Kent, 2014)	Overall rupture risk = 0.5–1.4%/year (Nasr and Brown, 2016)
Size for intervention	Standard: 5.0–5.5 cm ascending aorta (Hiratzka et al., 2010)	5.5 cm infrarenal aorta (Ahmed et al., 2016)	No definitive size; PHASES score estimates 5-year rupture risk (increased risk >0.7 cm (Nasr and Brown, 2016; Greving et al., 2014))
Typical shape	Fusiform (van 't Hof et al., 2016)	Fusiform (van 't Hof et al., 2016)	Saccular (van 't Hof et al., 2016)
Location	60% root/ascending, 10% arch, 40% descending, 10% thoracoabdominal (some involve >1 segment) (Isselbacher, 2005)	Primarily infrarenal (Kuivaniemi et al., 2015b)	90% anterior circulation (30%–35% ACA, 30% ICA + branches, 20% MCA), 10% posterior circulation (Fennell et al., 2016)
Pathophysiology/ histology	Cystic medial degeneration due to dysregulated TGF-β signaling and disruption of elastin-contractile unit, inflammation, cytokine activity (Karimi and Milewicz, 2016; Andelfinger et al., 2016; Elefteriades et al., 2011)	Inflammation, autoimmunity, ECM degradation, oxidative stress, VSMC apoptosis (Kuivaniemi et al., 2015b; Kent, 2014)	Degeneration of internal elastic lamina, disorganization of muscular media, intimal hyperplasia, irregularity of luminal surface, inflammation, hemodynamic stress (Etminan and Rinkel, 2017; Fennell et al., 2016)

AAA indicates abdominal aortic aneurysm; ACA, anterior communicating artery; BAV, bicuspid aortic valve; ECM, extracellular matrix; FH, family history; HTN, hypertension; IA, intracranial aneurysm; ICA, internal carotid artery; MCA, middle cerebral artery; TAA, thoracic aortic aneurysm; TAAD, thoracic aortic aneurysm and dissection.

matrix, has been observed with all three types of aneurysms (Norman and Powell, 2010). Whereas the most devastating complication associated with AAAs and IAs is rupture, an equally important complication with thoracic aortic aneurysms (TAAs) is aortic dissection, which primarily determines life expectancy in TAA-affected individuals (Gillis et al., 2013).

Since the original description of arterial aneurysms in the writings of ancient Egyptians in 2000 BC (Karimi and Milewicz, 2016), the familial nature of TAAD (Biddinger et al., 1997; Coady et al., 1999; Albornoz et al., 2006), AAAs (Clifton, 1977; Kuivaniemi et al., 2015a), and IAs (Ullrich, 1960; Nahed et al., 2007; Tromp et al., 2014) has now become well established. However, the familial clustering of aneurysms does not necessarily indicate that the observed phenotype is due to an underlying genetic etiology. For instance, Korja and Kaprio (Korja and Kaprio, 2016) argue that the observed clustering of IAs and subarachnoid hemorrhage (SAH) in families may be related to the familial aggregation of risk factors, particularly smoking and hypertension.

Nevertheless, research over the past two decades has led to an explosion in our understanding of the genetics of aneurysms. In particular, it has become clear that syndromic and familial TAAD have a strong monogenic component (Luyckx and Loeys, 2015; Milewicz et al., 2016), while AAAs and IAs are considered complex diseases with a genetic contribution (Kuivaniemi et al., 2015a; Nahed et al., 2007). Thus, while familial TAAD is primarily inherited via an autosomal dominant mechanism with reduced penetrance and variable expressivity (Albornoz et al., 2006; Milewicz et al., 2014), the inheritance pattern of AAAs and IAs is unclear, aside from the syndromic conditions that can manifest with AAAs or IAs or the familial cases of co-occurring aortic aneurysms and IAs. In fact, studies have described the phenotypes of individuals with likely autosomal dominant inherited TAAs with saccular IAs (Regalado et al., 2011a), as well as AAAs with saccular IAs (Kim et al., 2005). Furthermore, other studies have demonstrated the co-occurrence of TAAs and AAAs (Larsson et al., 2011; Svensjo et al., 1996), as well as AAAs with IAs (Miyazawa et al., 2007; Norrgard et al., 1987). A recent study of 1081 individuals with aortic aneurysms found that 11.8% had an associated IA with no significant difference in the rates of IAs observed between those with AAAs and TAAs (Rouchaud et al., 2016). These results provide evidence for a possible genetic overlap between these aneurysm conditions, which is further supported by a genome-wide association study (GWAS) mega-analysis that identified 4 chromosomal loci (9p21, 18q11, 15q21, and 2q33) significantly associated with all three aneurysm types (van 't Hof et al., 2016). Additionally, one genome-wide linkage analysis of 26 IA and TAA or AAA families found linkage peaks at chromosomal loci 6p23 and 11q24 (Worrall et al., 2009). A review of all whole genome linkage studies identified five chromosomal regions that are associated with at least two of the types of aneurysms, with the 11q24 region being associated with all three (Ruigrok et al., 2008). The differences in identified chromosomal loci between GWAS and DNA linkage studies can possibly be explained by the fact that there may only be a genetic overlap between all three aneurysm types in familial as opposed to sporadic cases (van 't Hof et al., 2016).

Furthermore, since the ascending aorta and intracranial arteries are both derived from neural crest cells (Weston and Thiery, 2015), several studies have evaluated aortic root diameters in individuals with IAs. Shin et al. found that aortic root dimensions were larger among individuals younger than 55 with at least one ruptured IA, an IA $\geq$7 mm in size, or multiple IAs than among those not meeting these criteria (Shin et al., 2014). Additionally, Can et al. found that individuals with ruptured fusiform IAs had larger aortic root diameters than those with ruptured saccular IAs (Can et al., 2015). Another study discovered that anterior circulation IAs were more common among patients with ascending aortic aneurysms, whereas internal carotid IAs were more common among patients with infrarenal AAAs (Shin et al., 2015). Perhaps ascending aortic aneurysms and anterior circulation IAs are linked genetically, which may partially explain the increased role that genetic risk factors play in the development of middle cerebral artery aneurysms (an anterior circulation IA) as compared to IAs at other sites (van 't Hof et al., 2014). While these results are intriguing, as Sattur et al. argue, it is premature to state that the observed link between IAs and aortic root diameters reflects an underlying genetic or developmental disease with diffuse vascular effects, as risk factors, such as hypertension, may confound the association (Sattur et al., 2016).

Genetics of TAAD

TAAs are typically asymptomatic yet potentially fatal, as their natural history is to progressively expand until rupture or dissection occurs. It is estimated that 10.4 per 100,000 people develop TAAs each year (Ramanath et al., 2009) and that the annual incidence of aortic dissection and rupture are each 3.5 per 100,000 patients (Clouse et al., 2004). However, this may underestimate the true burden of aortic disease, as patients with aortic dissection may be misdiagnosed up to 30% of the time (Ramanath et al., 2009). Treatment is targeted at preventing the complications of dissection or rupture via prophylactic surgery (Chau and Elefteriades, 2013). However, almost 60% of patients with type A dissections have aortic diameters $<$5.5 cm, the commonly used cutoff for surgical intervention, and 40% of patients have diameters $<$5 cm (Pape et al., 2007). Although size is a strong predictor of the complications of TAAs (Elefteriades et al., 2015), it is imperative that clinicians possess a better means of risk stratifying affected individuals to hopefully prevent these devastating complications. As this section of the article demonstrates, genetics plays a critical role in determining who is at risk of aortic dissection at aortic diameters $<$5.0 cm (Milewicz and Regalado, 2015).

Since the discovery of Marfan syndrome (MFS) in 1896 and the recognition that aortic disease is a chief characteristic of the disease in 1912 (Andelfinger et al., 2016), more than 30 heritable conditions have been described that can manifest with aortic or arterial aneurysms (Bradley et al., 2016a). However, the familial nature of non-syndromic TAAD was not elucidated until the late 1990s, when studies demonstrated that 21% of TAAD patients had an affected family member (Biddinger et al., 1997; Coady et al., 1999). This percentage most likely represents a marked underestimate though, since routine imaging of family members of affected patients would probably yield a higher percentage (Elefteriades and Farkas, 2010). Further studies determined that the primary

mode of inheritance of familial TAAD is autosomal dominant with reduced penetrance and variable expressivity (Albornoz et al., 2006; Milewicz et al., 1998), indicating that a single gene is most likely responsible for the disease (Milewicz et al., 2014).

TAAD can currently be classified into two categories: syndromic (associated with abnormalities of other organ systems) and non-syndromic (manifestations restricted to the aorta) (Pomianowski and Elefteriades, 2013; El-Hamamsy and Yacoub, 2009). Individuals with syndromic TAAD suffer from MFS, Ehlers–Danlos syndrome (EDS), Loeys–Dietz syndrome (LDS), arterial tortuosity syndrome (ATS), and Cutis laxa, among others (Bradley et al., 2016a; Pomianowski and Elefteriades, 2013; El-Hamamsy and Yacoub, 2009). These individuals tend to have abnormalities of the integumental, musculoskeletal, ocular, and/or craniofacial systems in addition to aortic and other cardiovascular disease (Isselbacher et al., 2016a). On the contrary, non-syndromic TAAD encompasses those with familial TAAD (more than one family member affected) and sporadic TAAD (no affected family members) (Pomianowski and Elefteriades, 2013). Albornoz et al. demonstrated that familial TAAD appears to be a more virulent disease than sporadic TAAD, as familial TAAD patients present at an earlier age (58.2 vs. 65.7) and have aneurysms that grow at faster rates (0.21 cm/year vs. 0.16 cm/year) (Albornoz et al., 2006). However, sporadic TAAD is estimated to account for 80% of all TAAD cases (Luyckx and Loeys, 2015). In a study of 760 individuals with either MFS, non-syndromic TAA (age <60 with cystic medial degeneration demonstrated on pathology or a positive family history), or bicuspid aortic valve (BAV), Sherrah et al. found that the calculated 10-year mortality rates for MFS (8.7%) and non-syndromic TAA (7.8%) were similar but significantly worse than for BAV patients (3.5%) (Sherrah et al., 2016). Sherrah et al. also demonstrated that aortic dissection is often the initial presentation for non-syndromic TAA and that the type of aortopathy, a family history of dissection, and age at presentation can be used to risk stratify patients (Sherrah et al., 2016).

Despite the categories presented above, there is significant overlap between syndromic and nonsyndromic familial TAAD, since the same gene can cause both forms of the disease (Bradley et al., 2016a). Furthermore, there is substantial variability in many of the syndromic causes of TAAD, which can lead to systemic features in certain family members that are absent in others (Bradley et al., 2016a). It is possible that unidentified genetic modifiers contribute to the wide variability in clinical presentation among individuals with the same mutation (Luyckx and Loeys, 2015).

There are at least 29 genes that have been associated with TAAD (**Table 2**), with the majority of them encoding proteins involved in the ECM, SMC contraction or metabolism, or the TGF-β signaling pathways. These identified genes will be presented according to this categorization, along with clinical implications specific for each gene (**Table 3** and **Fig. 1**).

ECM Genes

The hallmark pathologic change in the aortas of TAAD patients is medial degeneration, otherwise known as cystic medial necrosis, which is characterized by SMC loss, fragmentation and depletion of elastic fibers, and accumulation of proteoglycans and glycosaminoglycans within cell depleted areas of the aortic media (Wu et al., 2013). However, medial degeneration is not the root cause of an aortic dissection but is rather a pathologic consequence of a primary process (Gillis et al., 2013; Yuan and Jing, 2011).

Since the ECM of the aortic wall is a dynamic environment, mutations that alter its structure are predicted to disrupt the molecular pathways that govern aortic wall homeostasis (Wu et al., 2013).

The aortic media is composed of greater than 50 alternating layers of elastic lamellae and SMCs (Karimi and Milewicz, 2016). Elastin fibers are composed of elastin surrounded by microfibrils and associated proteins. These microfibrils attach to the surface of SMCs via focal adhesions, the same sites where components of the contractile unit within the SMC attach (Karimi and Milewicz, 2016). Disruption of this elastin-contractile unit, which is the structural and functional unit of the aortic media, is believed to underlie TAAD (Karimi and Milewicz, 2016).

FBN1

FBN1, the causative gene of MFS (OMIM 154700), encodes fibrillin-1, an important component of microfibrils (Karimi and Milewicz, 2016). MFS, which has an incidence of 2–3 cases per 10,000 individuals (Judge and Dietz, 2005), is a multisystem disease characterized by changes to the skeletal system (disproportionate overgrowth, joint laxity, vertebral column deformity), the ocular system (ectopia lentis), and the cardiovascular system (TAAD, mitral/aortic valve disease) (Gillis et al., 2013). The diagnosis of MFS is based on the revised Ghent nosology, which utilizes clinical criteria, family history, and genetic testing of the *FBN1* gene (Loeys et al., 2010) (**Table 4**). The primary cardiovascular manifestation of MFS is aneurysm of the aortic root (annuloaortic ectasia), which can extend to the ascending aorta (Isselbacher et al., 2016a). This places patients at increased risk for type A aortic dissection, as the two most important risk factors for dissection are aortic size and a family history of dissection (Judge and Dietz, 2005). Furthermore, MFS patients are also at increased risk for type B dissections even among those with prophylactic ascending aortic surgery and a normal or minimally dilated descending aorta ($\geq$2.7 cm) (den Hartog et al., 2015; Weinsaft et al., 2016) and for recurrent aortic dissections, which are more commonly type B, especially in MFS patients (Isselbacher et al., 2016b). Generally, aortic dissection or the requirement for prophylactic aortic root surgery does not occur until the third or fourth decade of life, although they can occur earlier (Bradley et al., 2016a).

MFS is primarily caused by heterozygous mutations in the *FBN1* gene, and to this date, approximately 1850 mutations have been identified within this gene (Collod-Beroud et al., 2003). While the majority of *FBN1* mutations are associated with MFS, Regalado et al. found that 3% of familial TAAD patients manifest mutations in the *FBN1* gene (Regalado et al., 2016). It is possible that wild

A "+" symbol in the syndromic TAAD column indicates that the gene is causative of syndromic TAAD (same for the non-syndromic TAAD column). A "−" symbol in the syndromic TAAD column indicates that the gene is not known to cause syndromic TAAD (same for the non-syndromic TAAD column).

AAT indicates aortic aneurysm, familial thoracic; AD, autosomal dominant; AOVD, aortic valve disease; AR, autosomal recessive; BAV, bicuspid aortic valve; CTD, connective tissue disease; FTAA, familial thoracic aortic aneurysm; FTAAD, familial thoracic aortic aneurysm and dissection; HHT, hereditary hemorrhagic telangiectasia; JP, juvenile polyposis; MYMY, moyamoya disease; OMIM, Online Mendelian Inheritance in Man; TGF, transforming growth factor; TAAD, thoracic aortic aneurysm and dissection; TGFBR, TGF-β receptor; XLD, X-linked dominant.

type *FBN1* expression levels contribute to the variability in intrafamilial clinical presentation (Aubart et al., 2015; Hutchinson et al., 2003; Verstraeten et al., 2016). The majority of mutations causing MFS are missense, though frameshift mutations, nonsense mutations, splicing errors, and complete deletion of the FBN1 gene have also been shown to lead to the disease (Karimi and Milewicz, 2016). Whereas MFS typically follows an autosomal dominant pattern of inheritance with high penetrance and variable inter/intrafamilial expressivity (Pomianowski and Elefteriades, 2013), 25% of cases arise de novo and rare cases of homozygous recessive or compound heterozygous mutations have been reported (Verstraeten et al., 2016; Hogue et al., 2013; Hilhorst-Hofstee et al., 2010; Van Dijk et al., 2009; de Vries et al., 2007; Karttunen et al., 1994). While initial reports indicated that homozygous and compound heterozygous individuals exhibited more severe phenotypes than their heterozygous relatives (Verstraeten et al., 2016), a recent study of four homozygotes and five compound heterozygotes found that their phenotypes were not more severe than those with only one mutated allele (Arnaud et al., 2017). It is thought that mutations in *FBN1* act via haploinsufficiency (by reducing the

Table 3 Associated vascular characteristics and size criteria for elective surgical intervention for each gene associated with thoracic aortic aneurysm and dissection

Gene	*Associated disease/syndrome*	*Associated clinical characteristics of the vasculature*	*Ascending aorta size (cm) for surgical intervention*

Table 3 (Continued)

Gene	*Associated disease/syndrome*	*Associated clinical characteristics of the vasculature*	*Ascending aorta size (cm) for surgical intervention*
TGFBR1	Loeys–Dietz syndrome type 1, AAT5	TAAD, early aortic dissection*, AAA, arterial tortuosity, other arterial aneurysms/dissection, IA, PDA, BAV (MacCarrick et al., 2014)	4.0–4.5[d] (Andelfinger et al., 2016; Hiratzka et al., 2010; Jondeau et al., 2016)
TGFBR2	Loeys–Dietz syndrome type 2, AAT3	TAAD, early aortic dissection*, AAA, arterial tortuosity, other arterial aneurysms/dissection, IA, PDA, BAV (MacCarrick et al., 2014)	4.0–4.5[d] (Andelfinger et al., 2016; Hiratzka et al., 2010; Jondeau et al., 2016)

It is important to note that since mutations in many of these genes are rare and have only recently been implicated in TAAD, there is a lack of adequate prospective clinical studies of individuals affected by mutations in the majority of these genes. Therefore, it is difficult to establish threshold diameters for intervention for TAAs. One must consider each individual on a case by case basis, taking into account the rate of change in aneurysm size (>0.5 cm per year is considered rapid) and any family history of aortic dissection.

A reference is provided for each of the associated vascular characteristics not reported in the OMIM entry for that gene.

AAA indicates abdominal aortic aneurysm; AAT, aortic aneurysm, familial thoracic; AD, autosomal dominant; AOVD, aortic valve disease; AR, autosomal recessive; ARD, aortic root dilatation; AVM, arteriovenous malformation; BAV, bicuspid aortic valve; CAD, coronary artery disease; CTD, connective tissue disease; FTAA, familial thoracic aortic aneurysm; HHT, hereditary hemorrhagic telangiectasia; IA, intracranial aneurysm; JP, juvenile polyposis; MYMY, moyamoya disease; PDA, patent ductus arteriosus; SVAS, supravalvular aortic stenosis; TAAD, thoracic aortic aneurysm and dissection; XLAS, X-linked Alport Syndrome.

Standard = surgical intervention at 5.0–5.5 cm.

Early aortic dissection* = dissection at aortic diameters < 5.0 cm.

[a]Individuals with MYLK and ACTA2 mutations have been shown to have aortic dissections at a diameter of 4.0 cm (Disabella et al., 2011; Wang et al., 2010).

[b]There *are* no data to set threshold diameters for surgical intervention for Ehlers–Danlos Syndrome type IV (Erbel et al., 2014). The Canadian guidelines recommend surgery for aortic root sizes of 4.0–5.0 cm and ascending aorta sizes of 4.2–5.0 cm for EDS type IV, though these patients are at high risk of surgical complications due to poor-quality vascular tissue (Boodhwani et al., 2014).

[c]There *are* limited data concerning the timing of surgical intervention for Loeys–Dietz Syndrome type 4. However, there has been a case of type A aortic dissection at an aortic diameter < 5.0 cm (Renard et al., 2013b), hence the recommended threshold range of 4.5–5.0 cm.

[d]According to the European guidelines, more clinical data *are* required to determine the appropriate threshold for surgical intervention for Loeys–Dietz syndrome (LDS) types 1 and 2 (Erbel et al., 2014). TGFBR2 mutation carriers have been shown to have similar outcomes to FBN1 mutation carriers once their disease is diagnosed (Attias et al., 2009), and the clinical course of LDS 1 and 2 does not appear to be as severe as originally reported (Tran-Fadulu et al., 2009; Jondeau et al., 2016; Teixido-Tura et al., 2016). Therefore, as Milewicz et al. assert, medically managed adult patients with LDS 1 or 2 may not require prophylactic surgery at ascending aortic diameters of 4.0–4.2 cm (Milewicz et al., 2016). Studies have demonstrated that individuals with TGFBR2 mutations are more likely to have aortic dissections at diameters < 5.0 cm than those with TGFBR1 mutations (Tran-Fadulu et al., 2009; Jondeau et al., 2016). Therefore, Jondeau et al. propose that utilizing the presence of TGFBR2 mutations (vs. TGFBR1 mutations), the co-occurrence of severe systemic features (arterial tortuosity, hypertelorism, wide scarring), female gender, low body surface area, and family history of dissection or rapid aortic root enlargement, which are all associated with an increased risk for aortic dissection, to determine the appropriate time for surgical intervention may be beneficial for LDS 1 and 2 patients to avoid unnecessary surgery at small aortic diameters (Jondeau et al., 2016). Therefore, in LDS 1 or 2 individuals without the above features, Jondeau et al. contend that 4.5 cm may be an appropriate threshold, but females with TGFBR2 mutations and severe systemic features may benefit from surgery at 4.0 cm (Jondeau et al., 2016).

amount of fibrillin-1) and/or a dominant negative mechanism (by altering the deposition of fibrillin-1 within microfibrils) (Verstraeten et al., 2016) and thereby disrupt the elastin-contractile unit (Karimi and Milewicz, 2016). Furthermore, fibrillin-1interacts with the latent TGF-β binding protein, which is a component of the large latent complex (LLC) along with the TGF-β ligand and the TGF-β propeptide (Verstraeten et al., 2016). By causing fibrillin-1 deficiency, mutations in *FBN1* alter ECM targeting of the LLC, which leads to an increase in the release of TGF-β (Verstraeten et al., 2016). It is now well established that upregulated TGF-β signaling is the inciting event for TAA formation in MFS and is a principal characteristic of syndromic and nonsyndromic TAAD (Andelfinger et al., 2016).

Studies of MFS patients have demonstrated that there are genotype–phenotype correlations that may have important clinical ramifications. Mutations in exons 24–32 have been linked to either neonatal MFS (Tiecke et al., 2001) or severe phenotypes, including increased probability of ascending aortic dilatation (Faivre et al., 2007). Additionally, truncating and splicing mutations in *FBN1* have been shown to be associated with higher rates of aortic events (dissection/surgery) that occur at younger ages (29 years vs. 51 years for missense mutations) among patients who satisfy the revised Ghent criteria (Baudhuin et al., 2015a). Although dominant negative mutations are generally more likely to result in severe pediatric presentations than haploinsufficient mutations (Dietz, 2015), a recent prospective study of 570 MFS patients found that individuals with haploinsufficient mutations had a 2.5-fold increased risk of cardiovascular death and a 2.4-fold increased risk of the combined endpoint of death or dissection than patients with dominant-negative mutations (Franken et al., 2016). Furthermore, Franken et al. report that over a period of 3 years, daily losartan significantly reduced the aortic dilatation rate only among MFS patients with haploinsufficient mutations but not among those with dominant negative mutations (Franken et al., 2015). However, as Dietz maintains, an increased baseline severity of aortic disease in the haploinsufficiency group in this study may have contributed to the observed differences in response to losartan therapy (Dietz, 2015).

Despite the 2010 revised Ghent nosology, Baudhuin et al. demonstrated that 27% of patients with a pathogenic or likely pathogenic variants did not fulfill the criteria (Baudhuin et al., 2015b). Given that these criteria are not completely sensitive or specific, the authors therefore suggest that utilizing genetic testing as opposed to purely clinical features for diagnosing MFS is important (Baudhuin et al., 2015b). Baudhuin et al. also observed a lower rate of missense mutations (41%) in those meeting the revised Ghent criteria as compared to prior studies using the old Ghent criteria, which conflicts with the belief that MFS patients with

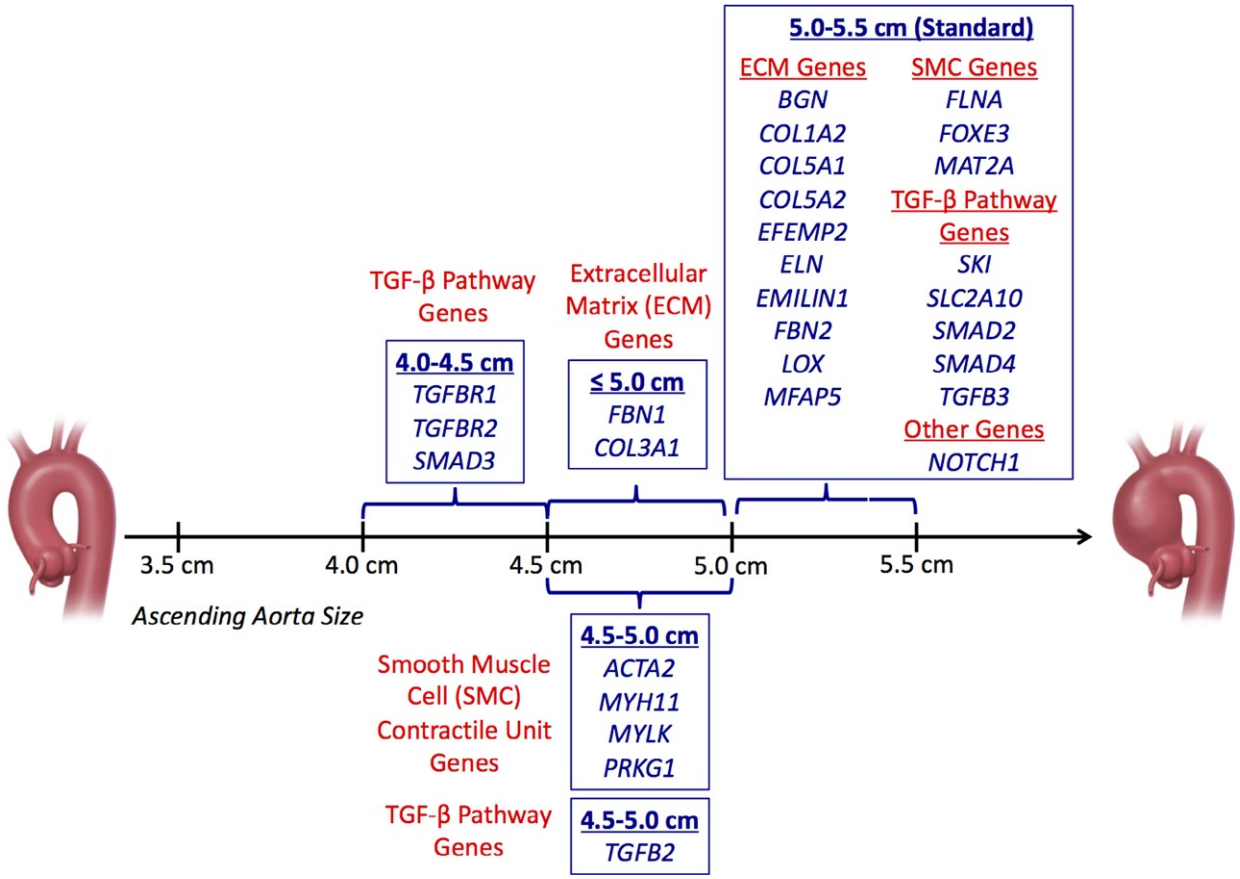

Fig. 1 Ascending aorta dimensions for prophylactic surgical intervention (Data derived from **Table 3**).

Table 4 2010 revised Ghent nosology for Marfan syndrome

In the absence of FHx:
- Ao ($Z \geq 2$) and EL = MFS
- Ao ($Z \geq 2$) and FBN1 mutation = MFS
- Ao ($Z \geq 2$) and Syst (≥ 7 pts) = MFS
- EL and FBN1 mutation with known Ao enlargement = MFS

In the presence of FHx
- EL and FH of MFS = MFS
- Syst (≥ 7 pts) and FHx of MFS = MFS
- Ao ($Z \geq 2$ above 20, ≥ 3 below 20 years) + FHx of MFS = MFS

Systemic score: 7 or higher is considered positive
- Wrist and thumb sign: 3 points
- Wrist or thumb sign: 1
- Pectus carinatum: 2
- Pectus excavatum: 1
- Hindfoot deformity: 2 (med rotation of med malleolus)
- Pes planus: 1
- Pneumothorax: 2
- Dural ectasia: 2
- Reduced upper/lower segment and increased armspan/height and no severe scolosis: 1
- Scoliosis or kyphosis: 1
- Reduced elbow extension: 1

- Skin striae: 1
- Myopia: 1
- Mitral valve prolapse: 1

Ao, aortic diameter at sinus of Valsalva; EL, ectopia lentis; FHx, family history; med, medial; MFS, Marfan syndrome; syst, systemic score; Z, *z*-score.

[a]Facial features: dolichocephaly, downward slanting palpebral fissures, enophthalmos, retrognathia, and malar hypoplasia.

Data derived from Loeys, B.L., Dietz, H.C., Braverman, A.C. et al. (2010). The revised Ghent nosology for the Marfan syndrome. *Journal of Medical Genetics* **47**, 476–485.

non-missense variants have a milder disease course (Baudhuin et al., 2015b). Once the diagnosis is established, an ascending aortic diameter threshold of 5.0 cm for prophylactic aortic surgery is adequate given the low rate of complications at smaller diameters (Andelfinger et al., 2016) unless the aorta dilates rapidly (>0.5 cm/year) (Hiratzka et al., 2010). However, since some MFS patients have been observed to dissect their aortas at diameters <5.0 cm (Gott et al., 1999), a family history of aortic dissection may justify prophylactic surgery at smaller aortic sizes (Andelfinger et al., 2016).

FBN2

FBN2, the causative gene in the autosomal dominant connective tissue syndrome congenital contractural arachnodactyly (OMIM 121050), otherwise known as Beals-Hecht syndrome (Putnam et al., 1995) encodes fibrillin-2, another component of microbils. The principal characteristics of this disease are external ear abnormalities, a marfanoid habitus with arachnodactyly, contractures, and progressive scoliosis (Callewaert et al., 2009), with aortic root dilatation occurring occasionally (Callewaert et al., 2009; Gupta et al., 2002). The majority of mutations in affected individuals occur between exons 24 and 35 of the gene (Frederic et al., 2009). A severe form has been described in a patient with a splicing mutation of exon 34, resulting in death during infancy from cardiovascular and gastrointestinal anomalies (Wang et al., 1996). While type A aortic dissection has been reported in a patient with a variant that led to deletion of exon 32 of the *FBN2* gene (Takeda et al., 2015), prospective studies are needed to assess the risk of aortic dissection among affected patients (Callewaert et al., 2009). It is recommended that patients with *FBN2* mutations be regularly screened for aortic dilatation via cardiac imaging (Bradley et al., 2016a).

COL3A1

COL3A1 is the causative gene of EDS type IV (EDS 4) (OMIM 130050), otherwise known as the vascular subtype of EDS. It is inherited in an autosomal dominant manner with penetrance close to 100% for missense and exon-skipping mutations (Pepin et al., 1993), though rare cases of biallelic disease causing variants leading to a more severe phenotype have been observed (Jorgensen et al., 2015). Taken together, all EDSs have an estimated prevalence of 1:10,000–1:25,000, with EDS 4 accounting for 5%–10% of all cases (Germain, 2007). The four major clinical diagnostic criteria are (1) thin, translucent skin, (2) extensive bruising, (3) characteristic facial appearance, (4) and arterial, digestive, or uterine fragility or rupture (Germain, 2007). The majority of initial clinical presentations are attributable to arterial or gastrointestinal complications, with approximately 80% of affected individuals having a complication by age 40 (Pepin et al., 2000). Arterial ruptures or dissections account for the majority of deaths (Germain, 2007), with the mean age of death being 48 years (Pepin et al., 2000). In a natural history study of over 1200 individuals (630 index cases and 601 relatives) with EDS 4, Pepin et al. found that disease of the aorta (aneurysm, dissection, and rupture), which occurred at a mean age of 35.7 years and was the leading vascular complication (22%), led to death in 68% of cases (Pepin et al., 2014).

COL3A1 encodes the pro-α1 chain of type III collagen (Smith et al., 2011), which is an essential component, along with type I collagen, of the aortic media (Karimi and Milewicz, 2016). It is thought that mutations in *COL3A1* alter the triple helix structure of type III collagen, thereby predisposing patients to arterial tears or dissections (Germain, 2007). The triple helix amino acid structure consists of repeated glycine-X-Y sequences (Germain, 2007), with the majority of mutations being missense mutations that lead to glycine substitutions (Shalhub et al., 2014). In fact, Pepin et al. found that over 90% of identified mutations in the *COL3A1* gene were missense or splice site variants (Pepin et al., 2014). More than 600 *COL3A1* mutations have been identified to cause EDS type IV, with 50% being de novo and 50% being inherited (Shalhub et al., 2014).

Just as with MFS, genotype–phenotype correlations have been described. Specifically, Pepin et al. demonstrated that the median survival rates for splice site acceptor, splice site donor, and glycine substitution mutations were 52, 37, and 51 years, respectively (Pepin et al., 2014). All three mutations types had a significantly higher hazard ratio compared to those with null mutations (patients with heterozygous mutations that caused loss of the stable mRNA transcript from one allele), with donor site mutations having the highest hazard ratio. Furthermore, among those with glycine substitution mutations, the specific amino that replaced glycine was important for survival, with valine substitutions having the highest hazard ratio. Null mutations have also been shown to be inherited with reduced penetrance compared to missense or exon-skipping mutations, and individuals with null mutations have a delayed onset of the first complication by almost 15 years (Leistritz et al., 2011). In another study, Shalhub et al. categorized patients into two groups based on mutations that led to the production of either 10%–15% (MIN), which included those with glycine substitution mutations, or 50% (haploinsufficiency) normal collagen (Shalhub et al., 2014). They found that patients in the haploinsufficiency group had significantly increased rates of aortic pathology, including dissection, though they presented at an older age than those in the MIN group (Shalhub et al., 2014). Similarly, Frank et al. demonstrated that patients with haploinsufficiency had higher rates of aortic complications compared to those with glycine substitutions and splice site mutations (Frank et al., 2015). Despite the higher rates of aortic complications in those with haploinsufficiency, these patients, along with those with variants in the N- or C-terminal region of the protein, were shown to have milder disease overall than those with glycine substitutions and splice site mutations (Frank et al., 2015).

Even with these observed genotype–phenotype correlations, it is challenging to counsel patients given the significant intra- and interfamilial variability in survival for the same disease causing variant (Pepin et al., 1993). Additionally, since aortic dissections have been shown to occur even without significant development of an aortic aneurysm in EDS type IV patients (Gillis et al., 2013), it is difficult to determine the appropriate time for prophylactic aortic surgery. This is further complicated by the fact that surgery can be quite dangerous in these patients as they have excess vessel fragility (Pomianowski and Elefteriades, 2013).

Other Collagen Genes

COL1A1 and *COL1A2*, the causative genes in EDS arthrochalasis type (OMIM 130060) and osteogenesis imperfecta, respectively, encode pro-α1 and 2 chains of type I collagen, the most abundant ECM protein in humans (Malfait et al., 2007, 2013). While the majority of mutations in *COL1A1* and *COL1A2* cause osteogenesis imperfecta (Malfait et al., 2007), a specific type of mutation that leads to partial or complete skipping of exon 6 is the cause of the EDS arthrochalasis type, leading to incomplete processing of the procollagen chains (Malfait et al., 2013). The syndrome is characterized by severe joint hypermobility with joint dislocations, muscular hypotonia, skin hyperextensibility, and mild dysmorphic features (Malfait et al., 2013; Klaassens et al., 2012). EDS arthrochalasis type can be inherited via an autosomal dominant or an autosomal recessive mechanism (Klaassens et al., 2012). Mutations in *COL1A1* have been associated with dissection of the infrarenal aorta as well as the iliac, femoral, and cervical arteries (Malfait et al., 2007; Mayer et al., 1996). Mutations in *COL1A2* are involved in the development of cardiac valvular disease and borderline aortic root enlargement (Bradley et al., 2016a; Schwarze et al., 2004).

Mutations in *COL5A1* and *COL5A2*, which encode components of type V collagen, cause the classical type of EDS (OMIM 130000) (De Paepe and Malfait, 2012). The major diagnostic criteria for the classical type of EDS are skin hyperextensibility, widened atrophic scars, joint hypermobility, and a positive family history (Malfait et al., 1993). Approximately 50% of individuals with the classical type of EDS have pathogenic variants within *COL5A1* and *COL5A2* (Malfait et al., 1993), with the majority being null mutations in *COL5A1* (Malfait et al., 2005). Aortic root dilation was diagnosed in classical EDS in 33% of patients at a mean age of 23.4 in one study (Wenstrup et al., 2002), but progression to aortic dissection is rare (Hiratzka et al., 2010). While mutations in *COL5A1* have been shown to cause similar clinical presentations to the vascular type of EDS caused by *COL3A1* mutations, including arterial rupture and dissection of medium-sized arteries (Mehta et al., 2012; Monroe et al., 2015), variants in *COL5A2* have not been associated with aortic dissection (Meienberg et al., 2010). However, one mutation that resulted in deletion of both the *COL3A1* and *COL5A2* genes causing haploinsufficiency of both genes was associated with aortic dissection (Meienberg et al., 2010). The authors attributed this clinical presentation primarily to deletion of the *COL3A1* gene. Despite the rarity of aortic and other arterial dissection/rupture in patients with mutations in collagen genes other than *COL3A1*, it may be prudent to consider screening these patients via baseline echocardiogram to assess for aortic dilatation.

EFEMP2

EFEMP2 (*FBLN4*), the causative gene of autosomal recessive cutis laxa type IB (ARCL1B) (OMIM 614437), encodes fibulin-4, an ECM protein that plays an important role in the assembly and function of elastic fibers (Renard et al., 2010). Homozygous or compound heterozygous mutations in *EFEMP2* lead to ascending aortic aneurysms, arterial tortuosity and stenosis, and cutis laxa (loose, redundant, and inelastic skin) (Renard et al., 2010; Hucthagowder et al., 2006; Hebson et al., 2014), and thus there is significant overlap with LDS and ATS (Renard et al., 2010). However, ARCL1B is highly variable in its clinical presentation, with some affected patients exhibiting perinatal cardiopulmonary failure while others have manifestations restricted to the vascular and craniofacial system and have minimal skin involvement (Loeys et al., 1993). Renard et al. reported for the first time survival beyond early childhood to ages 7 and 20 for two affected patients (Renard et al., 2010). Not only is fibulin-4 critical for elastogenesis but mouse studies have shown that it plays an important role in collagen maturation (Papke et al., 2015; Igoucheva et al., 2015). Additionally, mutations in *EFEMP2* have been associated with increased TGF-β signaling in aortic tissue of affected patients (Renard et al., 2010). There have been no reported cases of aortic dissection, though most patients present in infancy or at very young ages.

ELN

Heterozygous mutations in *ELN*, which encodes the protein tropoelastin, are the cause of autosomal dominant cutis laxa-1 (ADCL-1) (OMIM 123700) (Szabo et al., 2006), which is characterized by generalized lax skin folds (Callewaert et al., 2011). Although it was originally thought that affected patients did not exhibit systemic features (Loeys et al., 1993), several studies have shown that mutations within *ELN* are associated with dilatation of the aortic root and aneurysm formation, as well as pulmonary features, including emphysema (Szabo et al., 2006; Callewaert et al., 2011). In one of these studies, one of the probands' uncles suffered from an aortic dissection at age 26, though he did not exhibit skin laxity while alive (Szabo et al., 2006). Culturing of patients' fibroblasts by Callewaert et al. demonstrated increased TGF-β signaling, which the authors speculated is due to the inability of disorganized elastic fibers to sequester TGF-β (Callewaert et al., 2011). Interestingly, Callewaert et al. also observed a significant association of ADCL-1 with BAV (Callewaert et al., 2011). Additionally, one study involving patients with a 7q11.23 microduplication and another involving patients with a 7q11.23 triplication, a region of the chromosome that encompasses the *ELN* gene, found that almost all patients had aortic dilation or an ascending aortic aneurysm (Parrott et al., 2015; Guemann et al., 2015). Therefore, though longitudinal studies are lacking, regular aortic imaging in these patients is required to monitor for any development of aortic dilatation or aneurysm formation (Szabo et al., 2006).

Mutations in *ELN* can also lead to supravalvular aortic stenosis (SVAS) (OMIM 185500), an autosomal dominant systemic arteriopathy that leads to narrowing of the ascending aorta as well as other arteries (most commonly branches of the pulmonary and coronary arteries) due to intimal or medial thickening (Merla et al., 2012). While ADCL-1 is most commonly due to mutations at the 3′ end of the *ELN* gene, which are predicted to disrupt the C-terminal region of tropoelastin (a critical region for binding microfibril-associated glycoproteins and glycosaminoglycans), haploinsufficiency of the *ELN* gene due to premature stop codons is believed to lead to SVAS (Merla et al., 2012). A novel frameshift mutation leading to a stop codon was just recently described in a three-generation family with SVAS, in which two family members suffered from sudden death of unknown etiology and one

confirmed mutation carrier suffered from a ruptured IA (Jelsig et al., 2017). SVAS has also been described in an infant with autosomal recessive cutis laxa type IA (OMIM 219100), which is due to mutations in *FBLN5* (fibulin-5) (Loeys et al., 2002).

EMILIN1

The elastin microfibril interface 1 (*EMILIN1*) gene encodes an ECM protein that associates with microfibrils and elastic fibers and is involved in elastogenesis, vessel assembly, and regulation of TGF-β1 (Capuano et al., 2016). Capuano et al. identified a proband with one ascending and one descending aortic aneurysm, as well as bilateral lower leg and foot sensorimotor neuropathy, arthropathy, and increased skin elasticity (Capuano et al., 2016). He was found to have a variant in the signal peptide cleavage site of *EMILIN1*, which led to the abnormal accumulation of the protein in the endoplasmic reticulum and subsequent cellular apoptosis and altered ECM integrity (Capuano et al., 2016). The variant was found to segregate with disease in the family in an autosomal dominant manner, although there was marked intrafamilial variability since the patient's mother and son exhibited mild impairment with no history of aortic aneurysms (Capuano et al., 2016). Further studies are needed to confirm the role of *EMILIN1* in the formation of TAAs, as this is the first reported case involving this gene (Karimi and Milewicz, 2016).

MFAP5

MFAP5 (OMIM 616166) encodes microfibril-associated glycoprotein 2 (MAGP-2), a structural constituent of the ECM that has been shown to interact with other components of the ECM, including fibrillin-1 and tropoelastin, as well as to bind to both TGF-β1 and β2 (Barbier et al., 2014). Utilizing whole-exome sequencing, Barbier et al. identified two distinct mutations (one nonsense and one missense) within *MFAP5* that segregated with disease in two separate families, with one of the probands presenting with a type A aortic dissection at 58 years of age and other family members exhibiting aortic root dilatation (Barbier et al., 2014). Given that affected individuals only occasionally displayed mild skeletal features of MFS and LDS, mutations in *MFAP5* are believed to result in non-syndromic familial TAAD (Barbier et al., 2014). Consistent with what is seen with other TAAD causative genes, aortic tissue collected from the proband with aortic dissection showed enhanced TGF-β signaling (Barbier et al., 2014). Additionally, lone paroxysmal atrial fibrillation was present in multiple affected members of one of the two families studied. Given the clear possibility for aortic dissection in affected patients, regular cardiac imaging to monitor any aneurysmal growth would be prudent.

LOX

LOX (OMIM 617168) encodes a member of the lysyl oxidase protein family, a group of extracellular copper enzymes that cross-link collagens and elastin (Guo et al., 2016a). Two recent reports show that mutations in *LOX* resulted in familial TAAD, with one patient presenting at age 11 with an ascending aortic aneurysm and several patients presenting with aortic dissections in their 50s and 60s (Guo et al., 2016a; Lee et al., 2016). The identified mutations resulted in either haploinsufficiency or alteration of a highly conserved catalytic domain (Guo et al., 2016a). Since *LOX* encodes the enzyme primarily responsible for the cross-linking of collagen and elastin in the aorta, diminished enzymatic activity is thought to result in abnormal aortic development with decreased and fragmented elastic fibers (Guo et al., 2016a). Furthermore, *LOX* has been shown to bind to and inactivate free TGF-β via its amine oxidase activity (Atsawasuwan et al., 2008; Lindsay and Dietz, 2014). Since fibulin-4 is crucial for recruiting LOX to fibrillin microfibrils, decreased enzymatic inactivation of TGF-β by LOX as a result of fibulin-4 deficiency may also contribute to the predisposition toward aortic aneurysms in individuals with *FBLN4* (*EFEMP2*) mutations (Lindsay and Dietz, 2014). Interestingly, 3 of 20 *LOX* mutation carriers in one of the studies had BAVs (Guo et al., 2016a). More clinical data are needed to determine the risk of aortic dissection in *LOX*-mediated TAAD.

BGN

BGN, an X-linked gene, encodes the biglycan protein, which is a small leucine-rich proteoglycan involved in the maintenance and assembly of the ECM (Meester et al., 2017). Biglycan has been shown to interact with components of the ECM, including collagens and elastin, and with growth factors and cytokines, such as TGF-β (Meester et al., 2017). Meester et al. recently identified loss-of-function mutations in *BGN* in individuals with syndromic TAAD from five separate families (Meester et al., 2017). These individuals presented with TAAD at young ages (earliest cases of aortic aneurysm and aortic dissection were at age 1 and 15, respectively), along with several MFS and LDS-like extracardiovascular characteristics, including hypertelorism, pectus deformity, joint hypermobility, contractures, and mild skeletal dysplasia, among others (Meester et al., 2017). Furthermore, the aortic walls of affected individuals demonstrated increased TGF-β signaling, especially within the adventitia, which is the aortic wall layer where biglycan is mostly deposited (Meester et al., 2017; Heegaard et al., 2007). *BGN* and *FLNA* are the only genes shown thus far to lead to syndromic X-linked TAAD.

SMC Contractile Unit and Metabolism Genes

The SMC plays a critical role in the function and maintenance of the aortic media. The contractile unit of the SMC comprises actin thin filaments and myosin thick filaments, which interact to generate the force of contraction, as well as regulatory proteins including tropomyosin (Karimi and Milewicz, 2016). The components of the SMC contractile unit interact with the cytoskeleton

and the nuclear membrane, thereby allowing SMCs to convert mechanical stimuli into resultant biochemical activity (Karimi and Milewicz, 2016). It is thought that mutations in genes that disrupt these linkages lead to impaired sensation of mechanical stress in the aortic wall by SMCs, thereby diminishing their ability to adequately regulate and remodel the ECM (Karimi and Milewicz, 2016).

MYH11

MYH11 (OMIM 132900) encodes the smooth muscle myosin heavy chain, an essential contractile protein within SMCs (Zhu et al., 2006). In 2006, Zhu et al. found that two families with familial TAAD and patent ductus arteriosus (PDA) had mutations in *MYH11*, with one being a substitution at the splice donor site of intron 32 and the other being a missense mutation in exon 37 leading to substitution of glutamine for arginine (Zhu et al., 2006). These mutations are believed to affect the C-terminal coiled-coil region of the SMC myosin heavy chain (Zhu et al., 2006). Zhu et al. further demonstrated that *MYH11* mutation carriers had increased aortic stiffness compared to noncarriers, as evidenced by their decreased aortic compliance and increased pulse wave velocities (Zhu et al., 2006). In 2007, Pannu et al. identified novel missense mutations in two families affected by TAAD and PDA, though there was variable expressivity of both TAAD and PDA, as well as decreased penetrance of the mutation (Pannu et al., 2007). Interestingly, pathology from two affected patients revealed SMC disarray and focal hyperplasia of SMCs with evidence of dysregulation of insulin-like growth factor 1 and angiotensin II, as opposed to TGF-β (Pannu et al., 2007). This pathology is distinct from typical TAAD pathology and may contribute to the increased rates of vascular occlusive disease in these patients (Pannu et al., 2007).

In two further studies (Harakalova et al., 2013; Imai et al., 2015), the same deletion variant in *MYH11* was identified in a Dutch family and two Japanese families, though this variant only segregated with disease in the Japanese families. Additionally, a heterozygous missense variant identified in a Dutch family also did not segregate with disease entirely (Harakalova et al., 2013). Harakalova et al. therefore postulate that unidentified genetic modifiers may be contributing to the clinical phenotype observed in these Dutch families, which may explain the phenotypic variability and reduced penetrance observed (Harakalova et al., 2013). In addition to causing familial TAAD, it is possible that *MYH11* may contribute to sporadic TAAD, since a chromosomal duplication of 16p13.1, which contains *MYH11*, is estimated to impart an eightfold higher risk for development of TAAD (Luyckx and Loeys, 2015; Kuang et al., 2011). However, it is not established whether MYH11 is the culprit gene in this chromosomal duplication (Luyckx and Loeys, 2015).

For patients with familial TAAD with *MYH11* mutations, prophylactic aortic surgery is warranted at ascending aortic diameters of 4.5–5.0 cm (Andelfinger et al., 2016). Yet, Harakalova et al. maintain that family members of affected patients who do not carry the *MYH11* mutations should still participate in regular cardiac imaging given that the mutations they identified did not segregate with disease (Harakalova et al., 2013).

ACTA2

ACTA2 (OMIM 611788) encodes the smooth muscle α-actin, which polymerizes to form thin filaments that are crucial for SMC contraction (Karimi and Milewicz, 2016). Several studies have now shown that *ACTA2* mutations account for 12%–21% of FTAAD (Guo et al., 2007; Morisaki et al., 2009; Disabella et al., 2011). The majority of identified mutations are missense and result in a dominant negative mechanism that decreases actin filament assembly (Guo et al., 2007), though nonsense mutations have been identified as well (Renard et al., 2013a). Consistent with what is observed in syndromic TAAD, Renard et al. demonstrated increased TGF-β signaling in patients with an *ACTA2* mutation as well as those with an *MYH11* mutation (Renard et al., 2013a). Interestingly, this is in contrast to a prior study that did not observe increased TGF-β signaling in the aortas of *MYH11* mutation carriers (Pannu et al., 2007). Renard et al. postulate that enhanced TGF-β signaling may be a more prominent feature of *MYH11*-mediated TAAD than *ACTA2*-mediated TAAD, as not all biopsies from *ACTA2* mutation carriers showed increased TGF-β signaling, which was the case for *MYH11* mutation carriers (Renard et al., 2013a). Specific mutations in *ACTA2* have also been linked to early-onset coronary artery disease, stroke, iris flocculi, and livido reticularis (Disabella et al., 2011; Guo et al., 2009). Furthermore, one heterozygous de novo missense mutation, R179H, has been associated with severe multisystemic smooth muscle dysfunction (OMIM 613834), with all five patients in the study presenting with ascending aortic aneurysms at ages ranging from 11 to 26 years (Milewicz et al., 2010).

The most common presentation among family members with *ACTA2* mutations is thoracic aortic dissection, which has a penetrance of 50% (Luyckx and Loeys, 2015). One study of 277 patients with various *ACTA2* mutations found a lifetime cumulative risk of aortic events (dissection or repair) of 76% by age 85 (Regalado et al., 2015). The majority of patients presented with thoracic aortic dissections (88%) at a median age of 35 years with more type A than type B dissections (54% vs. 21%), though patients with type B dissections presented at significantly younger ages (27 vs. 36 years). Interestingly, the p.R179 and p.R258 substitution mutations were associated with increased risk for aortic events and at younger ages (100% by age 25 and 90% by age 63, respectively) (Regalado et al., 2015). On the contrary, p.R185Q and p.R118Q mutations were associated with a significantly decreased risk for aortic events relative to other *ACTA2* mutations. In fact, p.R185Q mutation carriers had a cumulative risk of aortic events of only 57% by age 77.

The specific *ACTA2* mutation also determines the presence and severity of extra-aortic vascular disease (Milewicz et al., 2016). In prior studies, the p.R179 and p.R258 mutations have been associated with increased severity of vascular disease, including PDA, early onset stroke, and tortuosity of small arteries of the retina (Guo et al., 2009; Munot et al., 2012; Moller et al., 2012). These more severe mutations have also been associated with dilatation of the pulmonary arteries and first-order branches of the thoracic aorta

(Milewicz et al., 2016). The Arg179 (primarily Arg179His) and Arg258 mutations produce a distinctive cerebrovascular phenotype (OMIM 614042), including dilatation of the proximal internal carotid artery, occlusive disease of the terminal internal carotid artery, a straight course of intracranial arteries, and no basal collaterals (unlike what is observed with Moyamoya disease) (Munot et al., 2012). Interestingly, this transition from a dilated to stenotic internal carotid artery occurs at the cavernous portion of the internal carotid artery, which is where the external elastic lamina disappears from the arterial wall (Munot et al., 2012). The Arg179Cys mutation has been observed to recapitulate this neurovascular pattern and has also been implicated in anomalies of brain development (de Grazia et al., 2017; Meuwissen et al., 2013). Despite the observed cerebrovascular anomalies in these patients, there is a relatively low frequency of IAs (1.8%) in those with *ACTA2* mutations (Milewicz et al., 2016). Additionally, Arg149 and Arg118 mutations have been linked to early onset coronary artery disease (Milewicz et al., 2016).

Importantly, Regalado et al. demonstrated that aortic dissection occurred at aortic diameters <5.0 cm in 1/3 of patients with *ACTA2* mutations who suffered from type A dissections (Regalado et al., 2015). Moreover, in another study, for three out of eight women with *ACTA2* mutations who had peripartum aortic dissections, their aortic diameters at the time of dissection ranged from 3.8 to 4.7 cm (Regalado et al., 2014). Therefore, patients with *ACTA2* mutations warrant surgical intervention at aortic diameters between 4.5 and 5.0 cm (Andelfinger et al., 2016) to hopefully mitigate their increased risk for dissection.

MYLK

MYLK (OMIM 613780) encodes myosin light chain kinase, a ubiquitously expressed kinase that phosphorylates regulatory light chain (RLC), thereby initiating SMC contraction (Wang et al., 2010). Through a candidate gene approach in 2010, two variants in *MYLK*, p.R1480X and p.S1759P, were found to segregate with aortic dissection in two families (Wang et al., 2010). Wang et al. found that these variants resulted in decreased kinase activity and therefore decreased SMC contraction (Wang et al., 2010). Importantly, affected patients were found to have aortic dissections at aortic diameters that were minimally dilated (even at 4.0 cm) (Wang et al., 2010). A recent study by Hannuksela et al., which identified a novel 2-bp deletion variant leading to a premature stop codon, also found that affected individuals suffered aortic dissections across a wide range of ages 23-77 and at diameters <5.0 cm (Hannuksela et al., 2016). Interestingly, Hannuksela et al. showed that carriers of this novel deletion variant did not differ from noncarriers in aortic diameter or aortic stiffness (Hannuksela et al., 2016). Although we recommend that patients with MYLK mutations should undergo prophylactic surgery at ascending aortic diameters between 4.5 and 5.0 cm (Andelfinger et al., 2016), it is likely that this criterion will not protect all patients, as individuals with this mutation can dissect at even smaller diameters.

PRKG1

PRKG1 (OMIM 615436) encodes type I cGMP-dependent protein kinase (PKG-1), which is activated upon binding of cGMP and leads to SMC relaxation via phosphorylation and activation of the phosphatase that dephosphorylates and thereby inactivates myosin RLC (Karimi and Milewicz, 2016). Only one variant (c.530G>A), which was identified in four families, has been shown to cause FTAAD (Guo et al., 2013). By altering the cGMP binding site of PKG-1, this gain of function mutation leads to constitutive activation of the kinase, leading to decreased phosphorylation of the myosin RLC, promoting SMC relaxation (Guo et al., 2013). Therefore, this gain of function mutation in *PRKG1* and loss of function mutations in *MYLK* both decrease phosphorylation of the RLC, thereby decreasing SMC contraction (Karimi and Milewicz, 2016). Guo et al. found that 63% of patients with this *PRKG1* mutation presented with aortic dissections at an average of 31 years, with the youngest being 17 years old (Guo et al., 2013). For the two aortic measurements available at the time of dissection, one patient had an ascending aortic diameter of 4.3 cm and the other had an aortic root diameter of 5.7 cm. Affected family members also exhibited other vascular abnormalities, including enlargement of the descending thoracic aorta, abdominal aorta, and other arteries, including the coronaries (Guo et al., 2013). Although there are limited data on *PRKG1* mutations, affected patients probably would benefit from prophylactic surgeries at the same aortic diameter as patients affected by mutations in other SMC genes, namely 4.5–5.0 cm.

FLNA

FLNA encodes filamin A, an important anchoring protein that links actin filaments in SMCs to transmembrane integrin molecules in focal adhesions of the cell membrane and thereby playing a prominent role in maintaining cell shape and cell signaling (Karimi and Milewicz, 2016). *FLNA* mutations are the cause of X-linked dominant periventricular heterotopia (XL-PH) (OMIM 300049), a neuronal migration disorder that primarily affects females and can lead to seizures, aortic aneurysms, PDA, and EDS-like features, including hyperextensible joints and skin laxity (Sheen et al., 2005). In a cohort of 47 affected individuals, Lange et al. found that the vast majority had truncating mutations and only 1 out of 34 patients had aortic dilation (Lange et al., 2015). However, other cohorts have described several patients with aortic dilation/aneurysms, so the estimated incidence of aortic dilation in XL-PH is unknown (Sheen et al., 2005; Reinstein et al., 2013). As far as we are aware, no cases of aortic dissection have been reported to date. In addition to causing aortic manifestations, XL-PH can also lead to dilatation/aneurysm of subclavian and pulmonary arteries (Reinstein et al., 2013). Interestingly, arterial tortuosity, which is a marker of adverse cardiovascular outcomes in MFS and LDS (Morris et al., 2011), was not present within a family of patients with XL-PH that manifested with an aortic aneurysm in one member and a subclavian artery aneurysm in another (Reinstein et al., 2014). Given the variable expressivity of vascular features, cardiac imaging in these patients is warranted to screen for aortic and pulmonary dilatation (Reinstein et al., 2013).

MAT2A

MAT2A encodes methionine adenosyltransferase II alpha (MAT-IIα), which catalyzes the production of *S*-adenosylmethionine (SAM), a critical enzyme involved in cellular metabolism (Guo et al., 2015). Guo et al. recently implicated two mutations in *MAT2A*, c.10131A>C (p.Glu344Ala) and c.1067G>A (p.Arg356His), in familial TAAD (Guo et al., 2015). While the exact mechanism by which *MAT2A* mutations lead to TAAD is unclear, it is thought that these mutations disrupt the enzyme activity of MAT-IIα, thereby altering SMC metabolism, perhaps by increasing oxidative stress or decreasing methylation activity within SMCs (Guo et al., 2015). In this study, 8 out of 18 (44%) of mutation carriers had dilatation of the ascending aorta and/or aortic root at a median age of 50 years. There were no reported cases of aortic dissection, though one obligate carrier died at the age of 32 suddenly from unknown causes (Guo et al., 2015). While there are limited data on the clinical phenotypes of *MAT2A* mutation carriers, the data suggest that affected patients may have a more benign presentation than other familial TAAD patients (i.e., no episodes of aortic dissection and youngest presentation with TAA at age 37). Therefore, Guo et al. postulate that it is possible a second environmental or genetic factor may be required for patients with *MAT2A* mutations to develop TAAD (Guo et al., 2015).

FOXE3

FOXE3, which encodes a forkhead transcription factor, was recently implicated in familial TAAD in a large family with eight identified cases of acute aortic dissection (Kuang et al., 2016). Seven out of eight family members presented with a type A aortic dissection at an average age of 45.6 years, with one family member having prior normal aortic imaging. Interestingly, decreased penetrance was observed in women, since only men were affected. Through exome and Sanger sequencing of this family and 564 unrelated familial TAAD probands, four likely pathogenic *FOXE3* variants were identified, which were all missense mutations that changed amino acids at the C-terminal end of the DNA-binding domain (Kuang et al., 2016). Through knockout mouse studies, Kuang et al. demonstrated that *FOXE3* is crucial for populating the ascending aorta with differentiated SMCs during development and for SMC response to aortic wall stress (Kuang et al., 2016). Further clinical studies are needed to determine the risk of aortic dissection in these patients and the timing of prophylactic aortic surgery to prevent such complications.

TGF-β Pathway Genes

Studies have consistently shown that increased TGF-β signaling is a feature of both syndromic and nonsyndromic TAAD (Andelfinger et al., 2016; Renard et al., 2013a; Loeys et al., 2005, 2006; Gomez et al., 2009). TGF-β acts via the canonical and noncanonical pathways (**Fig. 2**). The canonical pathway involves activation of the TGF-β receptor, phosphorylation of regulatory SMADs (SMAD2 and 3), recruitment of SMAD4 to form a SMAD2/3–SMAD4 complex, importation into the nucleus, and activation of gene transcription (Andelfinger et al., 2016; Wu et al., 2013). Several explanations have been proposed for why there is paradoxical upregulation of TGF-β signaling in the aortas of patients with TAAD despite their loss-of-function mutations in TGF-β pathway genes (Verstraeten et al., 2016). First, there is normally an autoregulatory feedback loop on TGF-β signaling provided by the canonical pathway (Lindsay and Dietz, 2011). However, it is believed that mutations in canonical TGF-β pathway genes lead to a loss of this feedback inhibition, thereby causing an upregulation of TGF-β signaling especially via the noncanonical pathways (Andelfinger et al., 2016; Lindsay and Dietz, 2011; Bolar et al., 2012). Second, the differential expression of TGF-β cytokines may play a role in the pathogenesis of TAAD, as increased *TGFB1* expression has been observed in LDS and Shprintzen–Goldberg syndrome (SGS) patients (Verstraeten et al., 2016; Doyle et al., 2012; Lindsay et al., 2012; van de Laar et al., 2011). Lastly, the interaction between second heart field-derived SMCs and neural crest cell-derived SMCs of the ascending aorta may play an important role (Lindsay and Dietz, 2011). Namely, it is thought that second heart field-derived SMCs are more susceptible to underlying TAAD-causing mutations than neural crest-derived SMCs and may therefore secrete excess TGF-β to compensate, which may have a paracrine effect on the surrounding neural crest-derived SMCs, leading to enhanced TGF-β signaling within these cells (Verstraeten et al., 2016; Lindsay and Dietz, 2011; Gallo et al., 2014). Regardless of the mechanism, the resulting upregulation of TGF-β signaling is thought to be a crucial element in the formation of TAAD.

TGFBR1 and *TGFBR2*

TGFBR1 and *2*, the causative genes in LDS type 1 (OMIM 609192) and 2 (OMIM 610168), respectively, encode the two major human TGF-β receptor subunits (Isselbacher et al., 2016a). LDS, which was originally described in 2005 (Loeys et al., 2005, 2006), is an autosomal dominant disorder with 3 characteristic features: (1) arterial tortuosity/aortic aneurysms, (2) bifid/broad uvula or cleft palate, and (3) hypertelorism (Loeys et al., 2005). Patients often exhibit features that overlap with MFS, including cardiovascular, craniofacial, and skeletal abnormalities (Gillis et al., 2013). Originally, LDS was classified based on the severity of craniofacial (type 1—typical dysmorphic features of hypertelorism, craniosynostoses, cleft palate) or cutaneous features (type 2—mild dysmorphic features with velvety, translucent skin and easy bruising) (MacCarrick et al., 2014). However, regardless of the severity of systemic features, LDS patients are at significantly increased risk of aortic dissection and aneurysm rupture at relatively young ages and small aortic diameters (MacCarrick et al., 2014). Therefore, a revised nosology has been proposed based on the causative gene: type 1 (*TGFBR1* mutations); type 2 (*TGFBR2* mutations); type 3 (*SMAD3* mutations)—previously known as Aneurysm

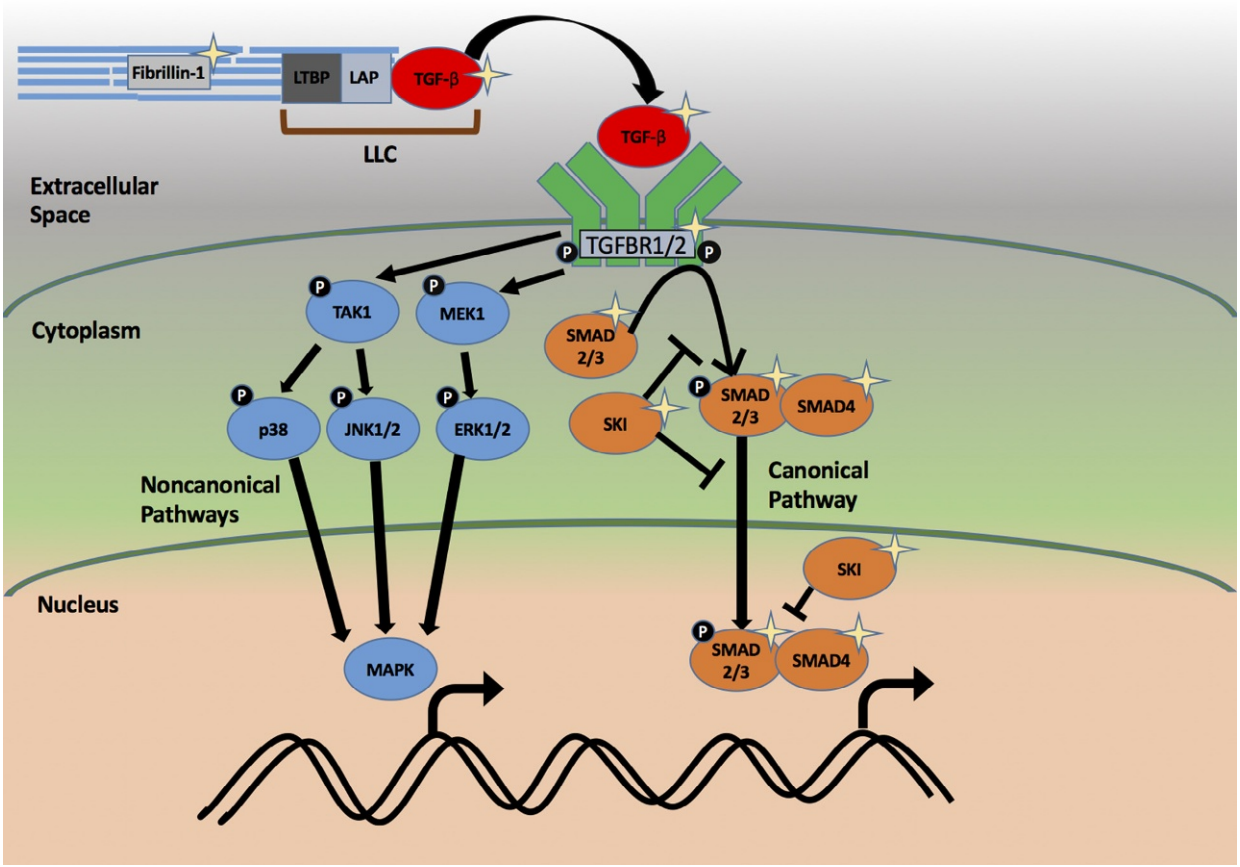

Fig. 2 Overview of canonical and noncanonical TGF-β signaling pathways. By interacting with the large latent complex (LLC) of TGF-β, comprised of the latent TGF-β binding protein (LTBP) and the latency-associated protein (LAP) (40), microfibrils composed of fibrillin-1 help sequester TGF-β, preventing it from acting upon cells. Once TGF-β is released, it can activate both the canonical (orange) and noncanonical (blue) pathways. The canonical pathway involves activation of the TGF-β receptor, phosphorylation of regulatory SMADs (SMAD2 and -3), recruitment of SMAD4 to form a SMAD2/3–SMAD4 complex, importation into the nucleus, and activation of gene transcription. SKI, a negative regulator of the canonical signaling pathway, acts by inhibiting many of these processes, including SMAD2/3 phosphorylation, importation into the nucleus, and activation of gene transcription (120). TGF-β receptors also activate noncanonical pathways, which involve multiple different SMAD-independent cascades (59). Upregulation of the noncanonical pathways is believed to play an important role in the development of aortic aneurysms (40). As depicted by the yellow stars, only mutations in the genes that encode components of the canonical signaling pathway have been shown to lead to thoracic aortic aneurysms and dissections.

Osteoarthritis Syndrome (AOS); type 4 (*TGFB2* mutations) (MacCarrick et al., 2014). This revised nosology indicates that a mutation in any of these genes plus presentation with an aortic aneurysm or dissection is sufficient for diagnosis regardless of the severity of systemic features (MacCarrick et al., 2014). Since this revised nosology was released, mutations in *TGFB3* are now considered to result in LDS type 5.

Mutations in *TGFBR1* and *TGFBR2* are almost exclusively missense and usually occur in the kinase domain of the receptors (Isselbacher et al., 2016a). Studies have demonstrated that mutations in both *TGFBR1* and *2* cause not only LDS but also nonsyndromic familial TAAD (Pannu et al., 2005; Tran-Fadulu et al., 2009), illustrating the wide range of clinical phenotypes seen with mutations in these genes (Luyckx and Loeys, 2015). In fact, identical *TGFBR2* mutations have been reported in familial TAAD patients and LDS patients displaying the typical characteristics of the syndrome (Luyckx and Loeys, 2015). LDS patients can also manifest with aneurysms of all portions of the aorta as well as different arterial branches of the aorta (MacCarrick et al., 2014). Additionally, type B dissections have been shown to occur at minimally or non-dilated aortic diameters of 3.7–4.2 cm, as has rapid expansion of aneurysms after a dissection in those with LDS 1–3 (MacCarrick et al., 2014).

Although initial reports did not show a difference in clinical presentation between LDS patients with *TGBR1* versus *TGFBR2* mutations (Loeys et al., 2006), one study of multigenerational TAAD families with *TGFBR1* ($n=30$ individuals) or *TGFBR2* ($n=77$ individuals) mutations did find differences in clinical presentations (Tran-Fadulu et al., 2009). In this study, the average age of presentation with vascular disease, including aortic aneurysms and dissections, was significantly younger in the *TGFBR1* cohort than in the *TGFBR2* cohort (31.4 vs. 45.6 years) (Tran-Fadulu et al., 2009). Interestingly, men with *TGFBR1* mutations presented primarily with ascending aortic disease, whereas women with *TGFBR1* mutations often presented with aneurysms and

dissections of other arteries. This led to lower rates of survival in men with *TGFBR1* mutations than women with *TGFBR1* mutations, which was not seen in the *TGFBR2* cohort. Finally, no individuals presented with aortic dissections at aortic diameters <5.0 cm with *TGFBR1* mutations, but three individuals did with *TGFBR2* mutations. Based on these results, Tran-Fadulu et al. suggest that individuals with *TGFBR1* mutations may not require prophylactic surgery for ascending aortic aneurysms at aortic diameters <5.0 cm due to their low risk of dissection at small diameters, though further data are required (Tran-Fadulu et al., 2009).

The recently published Montalcino Aortic Consortium (MAC) study of 441 *TGFBR1* or *2* mutation carriers further corroborated several of the findings by Tran-Fadulu et al., including no difference in overall survival between *TGFBR1* (median age of death 28.4) and *TGFBR2* (median age of death 34.8) mutation carriers but more aggressive disease in TGFBR2 mutation carriers (Jondeau et al., 2016). Among the seven patients who had aortic root diameters ≤4.5 cm within 1 year of dissection (only 22 patients had measurements available within 1 year or at time of dissection), all were women and six had *TGFBR2* mutations (average diameter 5.18 ± 1.34 cm for *TGFBR2* and 6.83 ± 2.30 cm for *TGFBR1*). Furthermore, as observed by Tran-Fadulu et al., the MAC study found that males with *TGFBR1* mutations had higher rates of type A dissection and aortic events than females with *TGFBR1* mutations, a differential which was not observed within the *TGFBR2* cohort. The MAC study also observed that type B dissections were a more frequent presenting feature of aortic disease in those with *TGFBR2* (6% of population) than in those with *TGFBR1* mutations (1.7% of population). Just as with MFS and vascular EDS, genotype–phenotype correlations were also observed in the MAC study, as the specific amino acid alteration in both *TGFBR1* and *TGFBR2* affected survival (Jondeau et al., 2016). In line with above studies demonstrating what appears to be a more severe disease phenotype in *TGFBR2* carriers, a recent cohort evaluating 33 genetically confirmed LDS adults over time found that those with *TGFBR2* mutations had a fivefold higher risk of requiring aortic surgery than those with *TGFBR1* mutations, with the surgeries tending to occur at younger ages (Teixido-Tura et al., 2016).

Initial reports indicated that the natural history of LDS involves early onset and rapid progression of TAAs with a mean age of death of 26.1 years, with aortic dissection being a major cause of death (Loeys et al., 2006; MacCarrick et al., 2014). However, other studies have challenged the concept that LDS patients always have a severe phenotype. In one study, Attias et al. found that when compared to patients with MFS, LDS two patients had similar rates of aortic dilatation (80%) and aortic dissection as well as similar rates of death once the disease had been diagnosed and medical care was provided (Attias et al., 2009). Furthermore, Texido-Tura et al. showed that the aortic dilation rate over a median period of 2 years among a cohort of 33 LDS adult patients was similar to previously calculated values for those with MFS (0.67 mm/year in LDS vs. 0.49 mm/year in MFS) (Teixido-Tura et al., 2016; Detaint et al., 2014). Texido-Tura et al. also observed a relatively milder aortic phenotype with a median age of first clinical presentation (surgery, death, dissection) of 50 as compared to the initial report describing a median age of 26 (Loeys et al., 2006). These differences may be explained by the inclusion of only adults in this recent study and the fact that the majority of patients had *TGFBR1* mutations (Teixido-Tura et al., 2016). The MAC study also confirms that survival is substantially better than originally thought, which may in part be explained by ascertainment bias (i.e., individuals with milder phenotypes were only reported after the initial description of patients with severe phenotypes and systemic features, which the MAC study demonstrates is associated with more severe aortic disease) and the implementation of better diagnostics and care (Jondeau et al., 2016). Nevertheless, these results indicate the remarkable heterogeneity in clinical severity among LDS patients, who exhibit considerable intra- and interfamilial variations (Teixido-Tura et al., 2016).

In sharp contrast to the increased risk of dissection in MFS patients at aortic diameters >5.0 cm, LDS 1–3 patients have been shown to dissect at aortic diameters of 3.9–4.0 cm (Loeys et al., 2006; MacCarrick et al., 2014). Therefore, current US guidelines indicate that those with LDS and mutations in *TGFBR1* or *TGFBR2* would benefit from prophylactic surgery at ascending aortic diameters between 4.0 and 4.2 cm (Andelfinger et al., 2016; Hiratzka et al., 2010; Boodhwani et al., 2014). However, as Milewicz et al. argue, these guidelines may be overly aggressive, particularly for medically treated adult patients (Milewicz et al., 2016). Jondeau et al. of the MAC study propose a more nuanced approach to prophylactic surgical repair for these patients based on gender, the mutated gene, family history of dissection, body surface area, and the presence of systemic features (Jondeau et al., 2016). In their analysis, Jondeau et al. found that systemic features, including arterial tortuosity, hypertelorism, and wide scars were significantly associated with a risk for aortic dissection after multivariate analysis and that females with *TGFBR2* mutations were at increased risk for aortic dissection at small aortic diameters. Therefore, they propose a threshold of 4.5 cm for LDS one and two patients, which can be lowered to 4.0 cm especially for women with *TGFBR2* mutations who have severe systemic features and a low body surface area (Jondeau et al., 2016). As the European guidelines state, more research is required to establish definitive criteria for surgical intervention (Erbel et al., 2014). Furthermore, Jondeau et al. recommend that patients who require prophylactic surgery should undergo complete ascending aorta replacement when possible, as 10% of individuals in the MAC study who underwent aortic root aneurysm surgery later presented with a type A dissection (Jondeau et al., 2016).

TGFB2 and *TGFB3*

TGFB2, the causative gene in LDS 4 (OMIM 614816), encodes the TGF-β2 ligand (MacCarrick et al., 2014). In 2012, Boileau et al. identified two mutations (frameshift mutation in exon 6 and nonsense mutation in exon 4) predicted to lead to haploinsufficiency in two large families with FTAAD, along with IAs and SAH (Boileau et al., 2012). They found that the youngest case of aortic dissection occurred at age 31 (mean of 35 years) and no dissections occurred at minimal levels of aortic enlargement (Boileau et al., 2012). Further heterozygous mutations or deletions were identified by Lindsay et al. in eight families with autosomal dominant TAAD and variable clinical expression (Lindsay et al., 2012). Boileau et al. and Lindsay et al. both demonstrated increased TGF-β signaling in the aortic walls of affected patients. In another cohort of 146 TAAD patients, four novel heterozygous loss-of-function

mutations in *TFGB2* were found among six patients, including two premature truncating mutations and a missense mutation (Renard et al., 2013b). There were two cases of type A aortic dissection, with one occurring at an aortic diameter <5.0 cm, and four cases of significant mitral valve disease (Renard et al., 2013b). Multiple other reports have found novel *TGFB2* mutations in patients affected by familial TAAD with variable expressivity of extra-cardiovascular manifestations, including skeletal and craniofacial abnormalities (Gago-Diaz et al., 2014; Leutermann et al., 2014; Ritelli et al., 2014a).

TFGB3, which encodes the TGF-β3 ligand, has recently been implicated in syndromic TAAD (known as LDS 5) (OMIM 615582) with associated craniofacial, skeletal, and cutaneous anomalies (Bertoli-Avella et al., 2015). Three truncating mutations and in-frame splice site mutations predicted to cause loss of function of *TGFB3* and *2* missense mutations in regions critical for TGF-β3 activation by integrins and TGF-β3 processing were identified (Bertoli-Avella et al., 2015). In this study of 43 affected individuals from 11 families, multiple mutation carriers had vascular abnormalities, including ascending aortic aneurysms and aneurysms of cerebral, iliac, and subclavian arteries. Four patients presented with type A and six patients presented with type B aortic dissections, occurring at median ages of 51 and 44.5, respectively, though no cases of aortic dissections at small diameters were found (Bertoli-Avella et al., 2015). Other cases of *TGFB3* mutations have been reported in pubertal age children presenting with characteristics of both MFS and LDS (Rienhoff et al., 2013; Kuechler et al., 2015), with one of the patients presenting with a mildly dilated aortic root (Matyas et al., 2014). Given the risk for aortic aneurysm and dissection, Bertoli-Avella et al. recommend that patients affected with *TGFB3* mutations undergo yearly echocardiograms to evaluate the aortic root as well the aorta and its side branches (Bertoli-Avella et al., 2015).

SMAD3 and other *SMAD* genes

SMAD3, the causative gene in LDS 3 (OMIM 613795), previously known as AOS, encodes a critical component of the canonical TGF-β signaling pathway (Regalado et al., 2011b). LDS 3 is characterized by arterial aneurysms, dissections, and tortuosity associated with mild craniofacial, skeletal, and cutaneous anomalies as well as early onset osteoarthritis and osteochondritis dissecans (van de Laar et al., 2011). The majority of the more than 20 pathogenic *SMAD3* mutations that have been identified (Zhang et al., 2015) involve the MH2 domain of the protein (Wischmeijer et al., 2013), a well-conserved region that is important for forming a complex with SMAD4 (van de Laar et al., 2011). This interaction is critical for translocation of the SMAD complex into the nucleus, where it can alter gene transcription (van de Laar et al., 2011). As these mutations cause a premature stop of translation through a frameshift or a substitution of highly conserved amino acids, it is believed this leads to a loss of function of *SMAD3* (Wischmeijer et al., 2013).

In the initial description of LDS 3, 60% of affected individuals had an aortic aneurysm or dissection, with some of the dissections occurring at minimally dilated ascending aortas (4.0–4.5 cm) (van de Laar et al., 2011). In another cohort of 45 patients described by van de Laar et al., cardiovascular abnormalities were found in 89% of affected individuals, including primarily TAAD as well as aneurysms of other arteries, left ventricular hypertrophy (in the absence of hypertension), atrial fibrillation, and congenital cardiac anomalies (van de Laar et al., 2012). Seventy-two percent of these patients had aortic aneurysms, mainly at the level of the sinuses of Valsalva, and 33% suffered from aortic dissections at aortic diameters ranging from 4.0 to 6.3 cm.

In a cohort of 44 patients with LDS 3 described by van der Linde et al., 71% of patients had an aortic root aneurysm and 15 deaths occurred at a mean age of 54 years (van der Linde et al., 2012), with aortic dissection accounting for 60% of deaths. Additionally, cerebrovascular abnormalities were diagnosed in 56% of patients and aneurysms of other arteries in the thorax and abdomen were diagnosed in 33% (van der Linde et al., 2012). Importantly, Wischmeijer et al. reported a patient with a *SMAD3* mutation who underwent prophylactic ascending aortic surgery for a progressively enlarging aorta at the age of only 12 months (Wischmeijer et al., 2013). Remarkably, the reported family exhibited a wide range of age of onset of TAAD (ranging from 1 to 54 years), variability which the authors attribute to unidentified genetic or environmental factors (Wischmeijer et al., 2013).

In addition to syndromic TAAD, Regalado et al. determined that *SMAD3* mutations account for 2% of familial TAAD (Regalado et al., 2011b). In this study of 42 affected individuals, 50% presented with TAAD, with several others presenting with IAs and AAAs. There is clearly a wide spectrum of clinical phenotypes, as some mutation carriers exhibited the characteristic extracardiovascular features of MFS and LDS (Regalado et al., 2011b). Individuals with *SMAD3* mutations warrant extensive cardiovascular imaging via echocardiogram plus imaging of the cerebral, abdominal, and thoracic vasculature, repeated regularly to monitor the growth of any identified aneurysms (van der Linde et al., 2012). Since cases of dissection have been reported at minimally enlarged aortic diameters, patients with *SMAD3* mutations would benefit from prophylactic surgery at diameters between 4.0 and 4.2 cm (Andelfinger et al., 2016).

In addition to *SMAD3*, *SMAD4*, which also encodes a key player in the canonical TGF-β signaling pathway, has been linked to TAAD (Teekakirikul et al., 2013). Two chart review studies of patients with both juvenile polyposis syndrome and hereditary hemorrhagic telangiectasia (JPS–HHT) (OMIM 175050), which are associated with heterozygous loss-of-function mutations in *SMAD4*, reported cases of aortic dissection in middle-aged individuals and several cases of aortic dilatation (Wain et al., 2014; Heald et al., 2015). Therefore, individuals with *SMAD4* mutations and JPS–HHT would benefit from screening for aortic aneurysms via echocardiography and computed tomography (Teekakirikul et al., 2013). On the other hand, gain-of-function mutations in *SMAD4* have not been associated with JPS–HHT but have been found to cause the rare autosomal dominant Myhre syndrome (OMIM 139210) (Lin et al., 2016). This syndrome has been shown to present with cardiovascular anomalies in 70% of patients, most commonly congenital heart disease, but also including juxtaductal aortic coarctation (15%), patent ductus arteriosus (20%), and diffuse descending aortic hypoplasia (6%) (Lin et al., 2016).

SMAD2, which encodes a SMAD protein that forms a complex with SMAD3 after its phosphorylation by the TGF-β receptor, has also been associated with TAAD (Micha et al., 2015). In this study, Micha et al. report four individuals from three families who were found to have *SMAD2* missense mutations located in the MH2 domain, the same evolutionarily conserved region where mutations are found to cause *SMAD3*-related TAAD (Micha et al., 2015). One of the probands, who developed a de novo *SMAD2* mutation, is a 17-year-old woman who was suspected of having MFS and presented with aortic root dilatation. Another affected individual presented with an ascending aortic aneurysm of 5.0 cm at age 46, while a third was found to have vertebral/carotid aneurysms and dissections; also, this patient's brother died from an abdominal aortic dissection at age 50 (Micha et al., 2015).

SKI

SKI is the causative gene in SGS (OMIM 182212), which is characterized by similar craniofacial, skin, skeletal, and cardiovascular features as MFS and LDS, along with intellectual disability and skeletal muscle hypotonia (Doyle et al., 2012; Shprintzen and Goldberg, 1982; Robinson et al., 2005). *SKI*, which encodes the Sloan Kettering proto-oncoprotein (SKI), serves as a negative regulator of the canonical TGF-β signaling pathway in several ways: by hindering SMAD2 and SMAD3 activation, preventing translocation of the activated SMAD2/3–SMAD4 complex into the nucleus, and by inhibiting transcription of TGF-β target genes (Doyle et al., 2012). To date, 17 different mutations in SGS patients have been identified, with all of them occurring in either the SMAD2/3 binding domain or the Dachshund-homology domain, which is crucial for binding to transcriptional corepressors (Schepers et al., 2015). Interestingly, all mutations occur in exon 1 and 73% of all affected patients have mutations affecting four adjacent SKI amino acid residues (Schepers et al., 2015). Though aneurysmal disease of the aortic root appears to be more benign (no cases of dissection) and less penetrant in SGS as compared to MFS and LDS, baseline echocardiography is recommended, with yearly screening in children followed by every 2–3 years in adult life (Schepers et al., 2015).

SLC2A10

SLC2A10, the causative gene in ATS (OMIM 208050), is a rare autosomal recessive disorder (approximately 100 affected individuals described to date) characterized by tortuosity of the aorta and medium-sized arteries with increased risk of aneurysm and dissection of the aorta and focal stenosis of the aorta and pulmonary artery (Bradley et al., 2016a; Coucke et al., 2006). ATS is also characterized by increased risk for ischemic vascular events, craniofacial abnormalities (high palate with dental crowding), musculoskeletal abnormalities (arachnodactyly, joint laxity, pectus excavatum, and hypotonia), hernias, and ocular involvement (Bradley et al., 2016a; Callewaert et al., 1993). Though early studies indicated severe disease with a mortality rate of 40% by 5 years of age (Wessels et al., 2004), more recent cohorts have demonstrated that patients live longer than previously thought (Callewaert et al., 2008; Ritelli et al., 2014b). One cohort of 3 families shows that 11 patients are alive with a mean age of 23 years (Ritelli et al., 2014b).

Mutations in *SLC2A10*, which encodes GLUT10, a facilitative glucose transporter, have been shown to lead to upregulation of TGF-β signaling (Coucke et al., 2006). Though the mechanism underlying this is not entirely understood, it is believed that loss-of-function mutations in *SLC2A10* lead to downregulation of decorin (its promoter contains a glucose response element), a natural inhibitor of TGF-β signaling, in VSMCs of ATS patients (Pomianowski and Elefteriades, 2013; Coucke et al., 2006). A total of 23 mutations have been identified to cause ATS, including 12 missense mutations, 5 nonsense mutations, 5 deletions leading to premature termination of translation, and 1 splice site mutation (Ritelli et al., 2014b). Ritelli at al. observed that 2 out of 12 patients had ascending/aortic root aneurysms (Ritelli et al., 2014b), while Callewaert et al. found that two adults (aged 23 and 35) out of 16 total patients had rapidly progressive aortic root dilation (Callewaert et al., 2008). However, given that the mean ages of these cohorts were 15 and 12.9 years, respectively, these patients may generally be too young to manifest with aortic root dilatation, which occurs more frequently in adulthood (Ritelli et al., 2014b). Affected patients require baseline full body vascular imaging with follow-up imaging depending on the results (and any family history of progressive aneurysmal disease); regular echocardiograms to determine aortic root diameters are also recommended (Callewaert et al., 2008; Castori et al., 2012).

Other Syndromes Associated With TAAD

In addition to the connective tissue disorders described above, several other syndromes have been associated with TAAD. First, Turner syndrome (TS), a sex aneuploidy syndrome due to loss of an X chromosome, can present with cardiovascular disease, including BAV, coarctation of the aorta, and TAAD (Halushka, 2014). One study found that 6.3% of TS patients had aortic dilatation or dissection (Lin et al., 1998), with many individuals presenting with TAAD at a young age (>50% of TS patients with aortic dissection were <30 years of age in another study (Carlson and Silberbach, 2007)). Second, Noonan syndrome (NS) (OMIM 163950), an autosomal dominant cardiofacial syndrome most commonly due to mutations in protein-tyrosine phosphatase, nonreceptor-type 11 (*PTPN11*), presents with cardiovascular involvement in 80%–90% of cases, most commonly pulmonary valve stenosis and hypertrophic cardiomyopathy (Halushka, 2014; Cornwall et al., 2014). In a cohort of 38 affected individuals, Cornwall et al. found that eight individuals (21.6%) had aortic root aneurysms, seven of which progressively dilated over an average follow-up interval of 6.8 years (Cornwall et al., 2014). Third, Alagille syndrome (OMIM 118450), an autosomal dominant disorder due to mutations in the NOTCH ligand jagged 1 (*JAG1*), can manifest with multiple cardiovascular abnormalities, including aortic

coarctation, pulmonary artery stenosis, large artery aneurysms, and moyamoya disease (Halushka, 2014). In a retrospective study of 268 affected patients, 16 had vascular abnormalities, including three with aortic aneurysms and several with IAs or intracranial artery anomalies (Kamath et al., 2004). Fourth, nonsense mutations in *COL4A5*, which encodes a component of type IV collagen and is the causative gene in X-linked Alport syndrome (XL-AS) (OMIM 301050), have been associated with aortic aneurysm and dissection (Kashtan et al., 2010; Earl et al., 2012). XL-AS primarily causes early-onset renal failure, sensorineural hearing loss, and ocular abnormalities (Halushka, 2014), although three of five patients in one study developed aneurysm and dissection of the thoracic aorta at ages ranging from 25 to 32 (Kashtan et al., 2010). Fifth, mutations in lysyl hydroxylase (*PLOD1*), the causative gene in EDS type VI (OMIM 225400), have been linked to aortic rupture and possibly aortic dissection, as well as rupture of other arteries (Wenstrup et al., 1989; Beighton, 1970). Last, autosomal dominant polycystic kidney disease (ADPKD), which is discussed more thoroughly in the IA section, has also been associated with TAAD.

BAV and TAAD

BAV, which affects 1%–2% of the general population, is the most common congenital heart defect (Luyckx and Loeys, 2015). It is estimated that BAV is associated with dilatation of the ascending aorta approximately 40%–50% of the time (Isselbacher et al., 2016a) and that 5% of individuals with a BAV will develop an aortic dissection (Elefteriades and Pomianowski, 2013). Therefore, BAV causes significantly more cases of aortic dissection than MFS (prevalence of 1/3–5000 people (Pyeritz, 2016)) despite the fact that there is a 40% risk of dissection in MFS patients (Elefteriades and Pomianowski, 2013). Aortic dissection associated with BAV typically occurs long before the aortic valve becomes significantly stenotic (Elefteriades and Pomianowski, 2013). The risk of aortic dissection in BAV patients is ninefold higher compared to patients with a normal tricuspid aortic valve, and 22% of aortic dissections in individuals younger than 40 are BAV related (Luyckx and Loeys, 2015).

Studies have clearly established the familial nature of BAV, which occurs in approximately 9% of first-degree relatives of affected patients (Huntington et al., 1997) and may have a heritability (an estimate of the genetic contribution to any phenotypic trait) as high as 89% (Andreassi and Della Corte, 2016; Cripe et al., 2004). It is believed that BAV is inherited via an autosomal dominant mechanism with decreased penetrance and variable expressivity, though the increased rates of BAV in individuals with TS provide evidence for a possible X-linked mechanism of inheritance as well (Andreassi and Della Corte, 2016). Unfortunately, however, the molecular genetics underlying BAV and associated TAAD remain unclear. While there are several monogenic causes of TAAD associated with BAV, including MFS (Nistri et al., 2012), LDS (Loeys et al., 2006; Girdauskas et al., 2011), *ELN*-related cutis laxa (Callewaert et al., 2011), *LOX*-related familial TAAD (Guo et al., 2016a), and *ACTA2*-related familial TAAD (Guo et al., 2007), these disorders collectively account for only a small percentage of all BAV cases (Isselbacher et al., 2016a). *NOTCH1* (Aortic valve disease 1 (AOVD1), OMIM 109730), which encodes a transmembrane receptor that functions as a transcriptional cofactor involved in cardiac embryogenesis and maintenance of the aorta, has been associated with BAV/TAAD (Garg et al., 2005; McKellar et al., 2007; Proost et al., 2015). Yet, mutations in *NOTCH1* are only estimated to contribute to 4% of BAV with or without TAAD (Andelfinger et al., 2016). Additionally, *NKX2.5* (Qu et al., 2014) and *GATA5* (Bonachea et al., 2014; Padang et al., 2012), which are both transcription factors critical for heart morphogenesis (Andreassi and Della Corte, 2016), have been implicated in BAV, though the same rare variants in *GATA5* have also been found in control patients (Foffa et al., 2013). *SMAD6* (AOVD2, OMIM 602931), which encodes an inhibitor of several important regulators of cardiogenesis that belong to the bone morphogenetic protein (BMP) family, has also been implicated in BAV (Tan et al., 2012). Several loci have been associated with BAV, including 18q, 5q, and 13q, though the specific genes within these chromosomal regions are yet to be identified (Andreassi and Della Corte, 2016; Martin et al., 2007) As Andelfinger et al. suggest, several factors may explain the difficulty with teasing out the genetic basis of BAV/TAAD, including its possible polygenic nature and its probable genetic heterogeneity, as well as the potential role for epigenetics and noncoding variants in contributing to the disease (Andelfinger et al., 2016).

Genomic Variation and TAAD

In addition to the established monogenic nature of TAAD, various single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) have been associated with an increased or decreased risk for TAAD. For instance, the rs2118181 SNP of the *FBN1* gene has been found to be highly associated with sporadic TAAD (LeMaire et al., 2011). Carriers of this SNP were shown to have a 76% increased risk of thoracic aortic dissection as compared to noncarriers (Iakoubova et al., 2014) (**Fig. 3**, panel A). Other SNPs of the *FBN1* gene have also been associated with increased risk for aortic dissection and increased risk for TAA formation (Lesauskaite et al., 2015). The Trp719Arg variant in the *KIF6* gene has also been linked to increased risk for aortic dissection. *KIF6* encodes a kinesin, which is a group of motor proteins that play a role in intracellular transport along microtubules (Iakoubova et al., 2008). This variant, which has also been found to be associated with myocardial infarctions and coronary artery disease, may alter the ability of KIF6 to transport its cargo by disrupting protein–protein interactions (Iakoubova et al., 2008). Carriers of this variant have a twofold higher risk of developing an aortic dissection than noncarriers (Iakoubova et al., 2016) (**Fig. 3**, panel B).

Moreover, Guo et al. discovered that the intronic SNP rs11172113 of the *LRP1* gene, which encodes low-density lipoprotein receptor-related protein 1, was associated with a decreased risk for sporadic thoracic aortic dissection (STAD) (Guo et al., 2016b). On the other hand, the same study found that the rs2272007 SNP of the *ULK4* gene, which encodes unc-51-like kinase 4, was

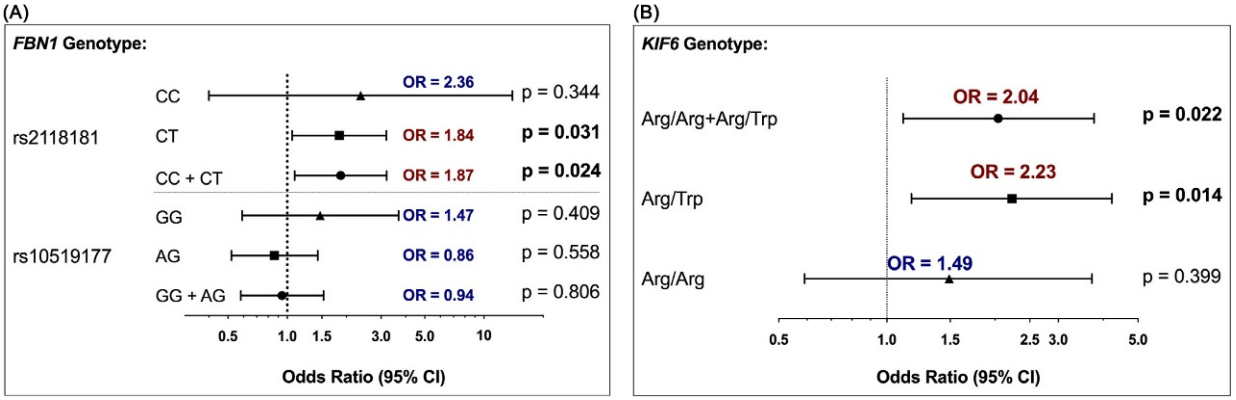

Fig. 3 Panel A—A substitution mutation at the rs2118181 locus on the *FBN1* gene predisposes twofold toward the development of aortic dissection; Panel B—The presence of the Arg/Trp and Arg/Arg + Arg/Trp alleles in the *KIF6* gene predispose toward the development of aortic dissection. associated with an increased risk for STAD and that *ULK4* genomic deletions were associated with TAAD (Guo et al., 2016b). Other studies have also identified SNPs or haplotypes within matrix metalloproteinase genes that are associated with an increased risk for TAAD (Liu et al., 2016a; Wang et al., 2014; Kato et al., 2012; Chen et al., 2006). Additionally, TAAD has been associated with SNPs on 9p21 (near CDKN2B gene) and within the tumor necrosis factor-alpha gene (Du et al., 2016; Liu et al., 2010).

Furthermore, one study found that individuals with familial TAAD had a higher percentage of CNVs containing genes involved in SMC adhesion or contractility than those with sporadic TAAD (Prakash et al., 2010). In another study, Prakash et al. discovered 47 CNV regions in those with early onset TAAD (mean age 20, 55% with BAV), familial TAAD, and sporadic TAAD that were not present or were extremely rare in controls (Prakash et al., 2016). Patients with early onset TAAD were also more likely to have these rare CNVs than those with familial or sporadic TAAD. Therefore, Prakash et al. argue that, since the percentage of deleterious CNVs in cardiac and vascular developmental genes is increased among those with early onset TAAD, testing for the presence of these CNVs may help predict who is at increased risk for TAAD (Prakash et al., 2016).

Genetic Testing for TAAD

Though studies have clearly demonstrated that at least 20% of TAAD individuals have a positive family history, only one-quarter to one-third of familial TAAD can be explained by our current genetic understanding (Luyckx and Loeys, 2015). It is currently estimated that syndromic genes, including *FBN1* and LDS genes (*TGFBR1*, *TGFBR2*, *SMAD3*, *TGFB2*), account for 10% of familial non-syndromic TAAD, *ACTA2* accounts for 12%–21%, and all other known genes collectively account for 1%–2% (Milewicz et al., 2016). Therefore, there is undoubtedly a substantial degree of genetic heterogeneity contributing to TAAD. There are many more genes yet to be discovered, including those in different chromosomal loci that have previously been linked to TAAD without identification of a specific causal genes (Luyckx and Loeys, 2015), such as 5q13–14 (OMIM 607087) (Kakko et al., 2003; Guo et al., 2001), 11q23–24 (OMIM 607086) (Vaughan et al., 2001), 15q24–26 (Pannu et al., 2006), and 12q13–14 (Guo et al., 2011).

Given the clear genetic etiology of TAAD, next-generation sequencing, including whole exome sequencing (WES) (DNA sequencing the exons (coding regions) of all genes in the genome (Biesecker and Green, 2014)), is being utilized more frequently to identify causative mutations and genes (Milewicz et al., 2014; Proost et al., 2015; Ziganshin et al., 2015). WES of patients with TAAD has multiple advantages: (1) WES is likely to identify pathogenic mutations, since approximately 85% of causative mutations for Mendelian disease are found in coding regions or canonical splice sites (Milewicz et al., 2014), (2) WES is comprehensive, (3) data can be reanalyzed as new genes are discovered to cause TAAD, (4) WES is becoming more cost-effective than conducting single gene tests, and (5) WES allows for the identification of new potential causative genes and variants.

To date, the Aortic Institute at Yale-New Haven has completed WES for 211 patients with TAAD (mean age 56.5 ± 14.2 years (range 15–83)). 23 specific genes associated with TAAD were analyzed: *ACTA2*, *ADAMTS10*, *COL1A1*, *COL1A2*, *COL3A1*, *COL5A1*, *COL5A2*, *ELN*, *FBLN4*, *FBN1*, *FBN2*, *FLNA*, *MAT2A*, *MYH11*, *MYLK*, *NOTCH1*, *PRKG1*, *SKI*, *SLC2A10*, *SMAD3*, *TGFBR1*, *TGFBR2*, *TGFB2*. Of the 211 patients, 150 (71.1%) were found to carry no mutations in this panel of genes. Among the remaining 61 individuals, 68 variants were identified as potentially causative of TAAD with 65 of these variants occurring in the panel of tested genes. Three deleterious variants occurred in other genes, namely *TGFB3* ($n = 1$) and *MIB1* ($n = 2$). Among the 65 variants in TAAD-related genes, seven were found to be deleterious (*FBN1* ($n = 3$), *TGFBR2* ($n = 2$), *FLNA* ($n = 1$), *MYLK* ($n = 1$)), while 58 were classified as variants of unknown significance. Variants in *FBN1*, *NOTCH1*, and *MYH11* were the most commonly seen (17%, 15%, and 14%, respectively) (Fig. 4). These findings differ from prior reports that identified ACTA2 as the most commonly affected gene in FTAAD.

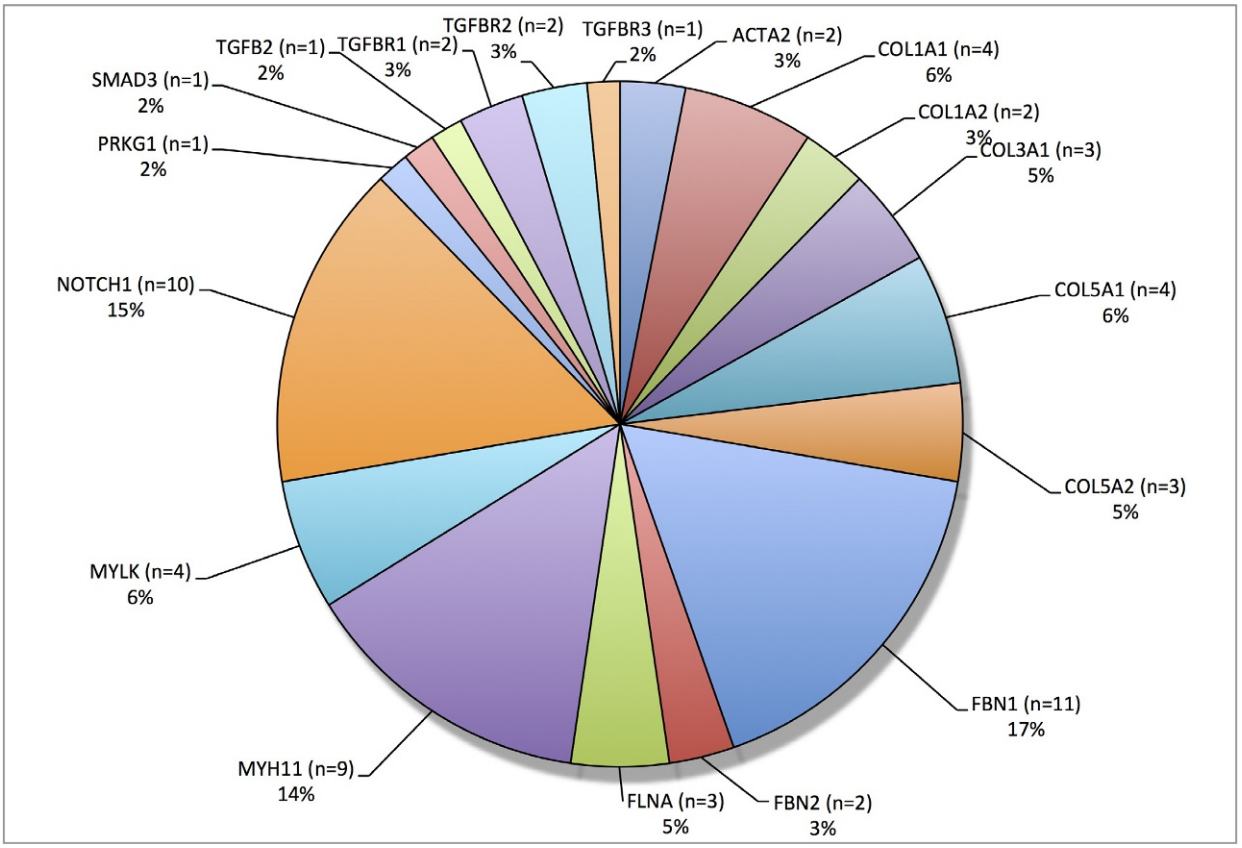

Fig. 4 Frequency distribution of genetic defects in TAAD-related genes based on the Yale Aortic Institute routine genetic testing program.

Genetics of TAAD: Conclusion

Since the identification of the *FBN1* gene as causative of MFS (Dietz et al., 1991), there has been a rapid advancement in our understanding of the genetics of TAAs and dissection. The familial nature of TAAD was a key turning point that led investigators to discover that multiple genes which alter the ECM, SMC contraction and metabolism, and TGF-β signaling pathways are involved in the pathogenesis of this disease. Studies have clearly demonstrated that the underlying causative gene in any given family can predict who is at risk for TAAD, how their aortic disease will manifest, and what is their risk for dissection at different aortic sizes (Milewicz et al., 2016). Therefore, we believe that personalized care based on the underlying mutation in any given individual is and will continue to be a critical component of effective and first-rate patient care. As genetic testing becomes more widely adopted, individuals at risk for TAAD will be identified earlier and thus provided with regular cardiovascular imaging, medical therapy, and timely prophylactic surgery to prevent the devastating complication of aortic dissection. Furthermore, WES will permit discovery of novel variants and genes, leading to construction of a comprehensive library of genetic variants linked to TAAD. Although, as surgeons, we emphasize the elegance and effectiveness of surgical therapies for TAAD, we recognize that the most important breakthrough in combating this fatal disease is currently, and will continue to be, on the genetic front.

Genetics of AAA

An AAA is defined as a permanent localized dilatation associated with an aortic diameter ≥ 3.0 cm (Kuivaniemi et al., 2015b). The natural history of AAAs is asymptomatic expansion until rupture occurs, which is the 16th leading cause of death in the United States (Go et al., 2014) and has an overall mortality rate of 85%–90% (Kent, 2014). The pathophysiology of AAAs involves inflammation, destruction of elastin and collagen in the media and adventitia, loss of SMCs, and neovascularization (Kent, 2014). It is also hypothesized that autoimmunity contributes to AAA formation and progression (Kuivaniemi et al., 2015b).

Studies have clearly demonstrated an overlap between AAAs and TAAs. While Larsson et al. found that 28% of individuals with AAAs had concomitant TAAs (Larsson et al., 2011), Chaer et al. observed that individuals with a AAA have a 10%–15% chance of

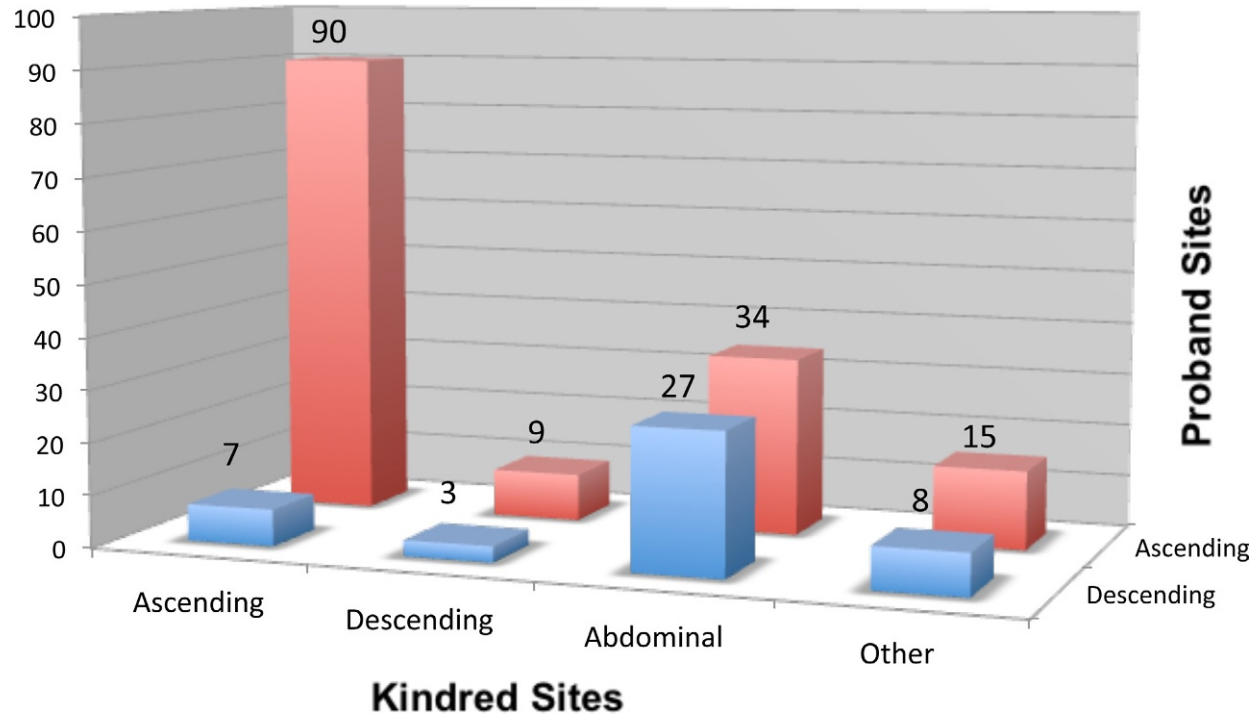

Fig. 5 Distribution of sites of arterial aneurysms and dissections in kindred of familial probands. (Modified with permission from Albornoz, G., Coady, M.A. and Roberts, M. et al. (2006) Familial thoracic aortic aneurysms and dissections—Incidence, modes of inheritance, and phenotypic patterns. *The Annals of Thoracic Surgery* **82**, 1400–1405).

having a synchronous (diagnosed within 2 years of AAA diagnosis) or metachronous (diagnosed >2 years after AAA diagnosis) TAA (Chaer et al., 2012). Despite these results, the vast majority of studies indicate that AAAs and TAAs independently segregate within families (Kuivaniemi et al., 2015b). In fact, Albornoz et al. demonstrated that individuals with ascending aortic disease were most likely to also have family members with ascending aortic disease, while individuals with descending aortic disease were most likely to have family members with AAAs (Albornoz et al., 2006) (**Fig. 5**). The fact that AAAs and TAAs appear to represent distinct disease processes may be related to the differing embryological origin of the ascending aorta (neural crest) versus the descending and abdominal aorta (mesoderm) (Liu et al., 2015; Cheung et al., 2012; Gittenberger-de Groot et al., 1999; Ruddy et al., 2013). While ascending aneurysms are highly familial, non-calcified, and non-atherosclerotic, descending and AAAs are highly associated with atherosclerosis and are often calcified and irregular with clot formation (Elefteriades and Pomianowski, 2013) (**Fig. 6**). Though there is significant overlap between the risk factors for AAA and for atherosclerosis (smoking, advanced age, male sex, and family history), there does not appear to be a strong common genetic background (Saratzis and Bown, 2014; Annambhotla et al., 2008).

Since the 1970s and 1980s, when the first studies of familial aggregation of AAAs were originally reported (Clifton, 1977; Tilson and Seashore, 1984a,b; Norrgard et al., 1984), it has become clear that family history, along with smoking, advanced age, and male sex, is a significant risk factor for AAA development (Kuivaniemi et al., 2015a). Though smoking is the most important risk factor for AAA development (Kuivaniemi et al., 2015b; Kent et al., 2010), having a family history increases an individual's risk for development of an AAA between 2- and 11-fold (Rolph et al., 2015). Two twin studies, one Swedish and one Danish, demonstrated higher concordance rates of AAAs between monozygotic twins than dizygotic twins (24% vs. 5% and 30% vs. 12%, respectively), with a calculated heritability of 70% and 77%, respectively (Wahlgren et al., 2010; Joergensen et al., 2016). While both interview studies and screening studies have observed a wide range estimating the familial nature of AAAs (average of 12%), Sakalihasan et al. found that approximately 10% of 618 AAA probands reported a positive family history in one study (Sakalihasan et al., 2014). In this analysis, ultrasound screening identified a prevalence of AAAs of 13% for all family members of AAA patients and a prevalence of 25% for brothers. Overall, the concordance rates between siblings varies between genders, as 20% of brothers and 5.8% of sisters of patients with AAA will develop one as well (Kuivaniemi et al., 2015a). Interestingly, in a cross-sectional analysis of a Danish population, Joergensen et al. found that first-degree relatives of a female patient with a AAA were greater than 2.5 times more likely to have a AAA than those with an affected male relative (OR = 2.65, 95% CI: 1.37–5.13) (Joergensen et al., 2014).

Furthermore, studies have demonstrated that familial AAAs may behave differently from sporadic AAAs. Individuals with familial AAAs are more likely to be female, present at a younger age, and manifest fewer cardiovascular risk factors and decreased carotid intima-media thickness (van de Luijtgaarden and Verhagen, 2015; van de Luijtgaarden et al., 2014a). Joergensen et al. demonstrated that individuals with familial AAAs have a significantly larger mean aortic diameter (20.5 mm) compared to those

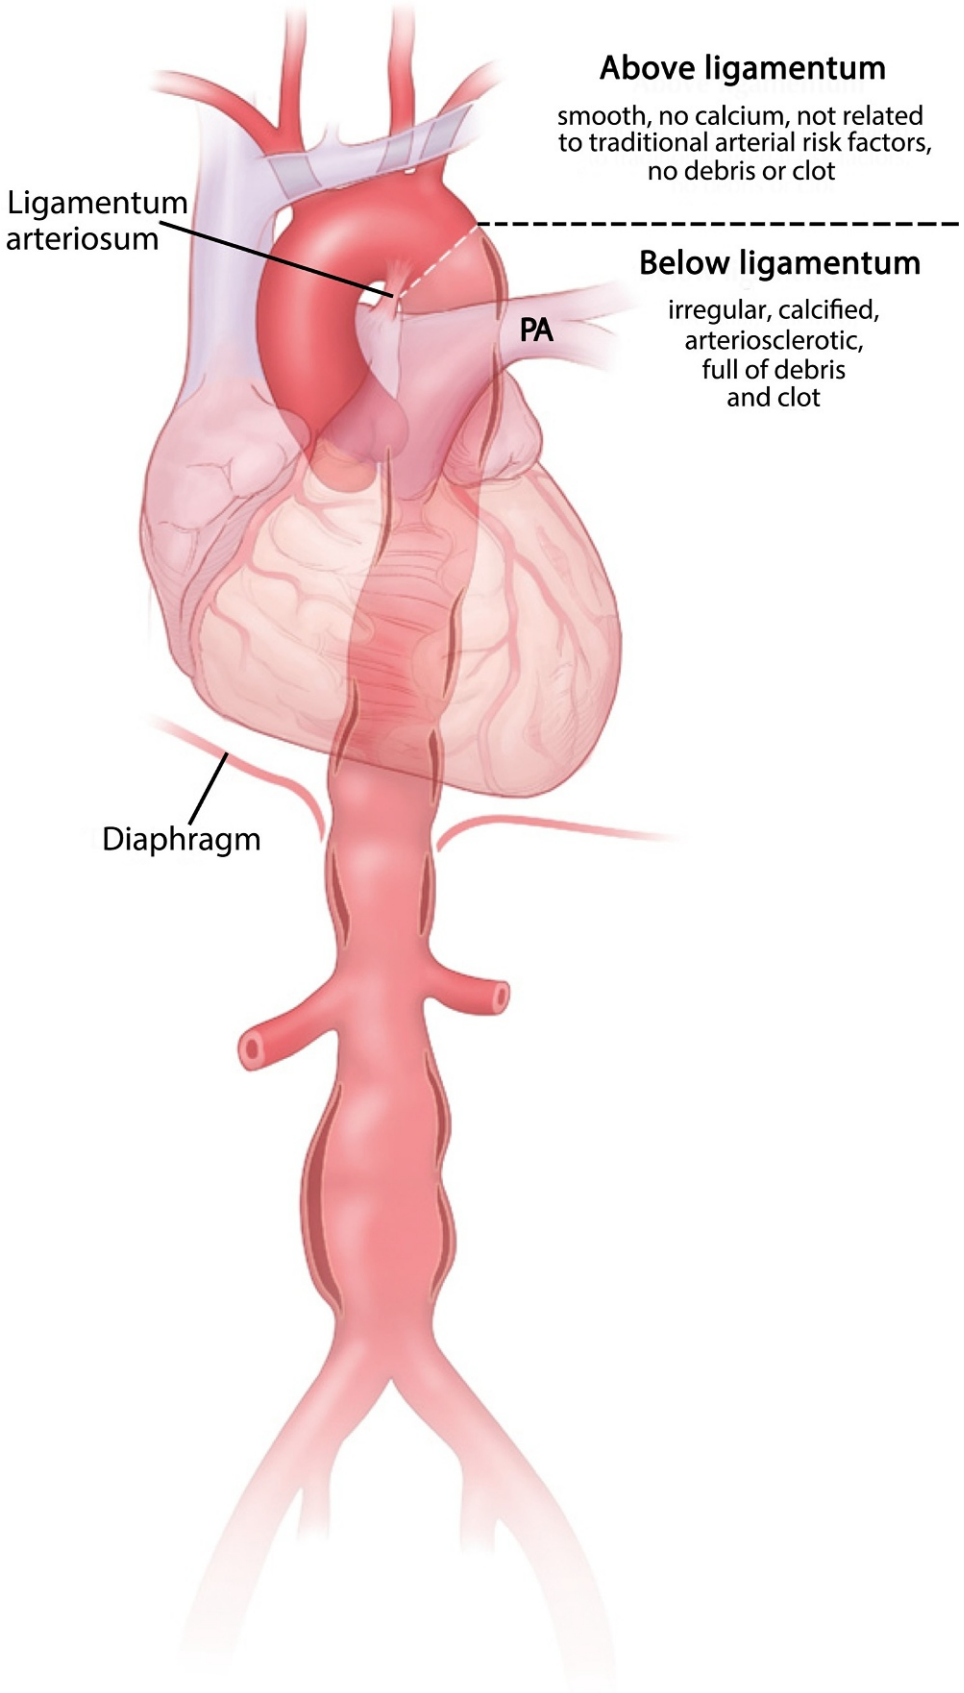

Fig. 6 Aortic aneurysm is really two diseases: ascending/arch disease differs markedly from descending/abdominal disease. (Reprinted with permission from Elefteriades, J.A. and Farkas, E.A. Thoracic aortic aneurysm clinically pertinent controversies and uncertainties. *Journal of the American College of Cardiology* **55**, 841–857).

with no family history (Joergensen et al., 2014), which, as van de Luijtgaarden et al. propose (van de Luijtgaarden and Verhagen, 2015), may explain the observed higher rate of AAA rupture in familial cases (Sakalihasan et al., 2014; Verloes et al., 1995). Moreover, Akai et al. found that the AAAs of those with a positive family history grew at more than two times the rate of those with a negative family history (4.2 mm/year vs. 2.0 mm/year, respectively; $P = .009$) (Akai et al., 2015). While Brewster et al. reported a trend toward increased aneurysm-related mortality after endovascular aneurysm repair (EVAR) in familial AAA patients (Brewster et al., 2006), other studies have identified increased rates of aneurysm-related complications, endoleaks, and secondary intervention following EVAR in familial AAA patients (van de Luijtgaarden et al., 2014b; Ryer et al., 2015). Similarly, Coscas et al. reported that having a family history of AAAs was significantly associated with an increased risk of late failure after open surgical aneurysm repair (Coscas et al., 2010). Therefore, as appears to be the case with TAAs, it is possible that familial AAAs represent a more virulent disease than sporadic AAAs.

Segregation analyses of affected families have demonstrated that AAAs appear to be genetically mediated and that familial AAAs exhibit either autosomal dominant or autosomal recessive modes of inheritance (Verloes et al., 1995; Majumder et al., 1991). In a study of 233 affected families, Kuivaniemi et al. demonstrated that 72% of families appeared to exhibit an autosomal recessive mode of inheritance, while 25% were consistent with an autosomal dominant mode of inheritance (Kuivaniemi et al., 2003). Despite these segregation studies, it has been challenging to identify causative genes of familial AAA given the late onset of this disease (van de Luijtgaarden and Verhagen, 2015). There are several monogenic connective tissue diseases, such as MFS, LDS, and EDS, that can be associated with AAA (Ahmed et al., 2016). Interestingly, a recent study investigating TAAD genes in familial and sporadic AAA patients found 47 rare heterozygous variants, including one pathogenic, segregating variant in *COL3A1* (p.Arg491X) in familial AAA, one likely pathogenic segregating variant in *MYH11* (p.Arg254Cys) in familial AAA, and one pathogenic variant in *TGFBR2* (c.1573delA) in sporadic AAA (van de Luijtgaarden et al., 2015). Therefore, while there may be monogenic causes of AAA, it is nevertheless considered a complex, multifactorial disease with a strong genetic component (Kuivaniemi et al., 2015a,b).

Over 100 genetic association studies have been conducted on AAAs using SNPs in biologically plausible genes, including genes involved in the ECM, cardiovascular system, immune system, and cellular signaling (Kuivaniemi et al., 2015b; Hinterseher et al., 2011). Genome-wide studies using family-based linkage analysis and GWAS have also been conducted to identify potential genes/loci involved in AAA pathogenesis (Kuivaniemi et al., 2015b). Linkage analysis has identified two chromosomal loci, 4q31 and 19q13 (Van Vlijmen-Van Keulen et al., 2005; Shibamura et al., 2004), demonstrating significant linkage, although the causative genes have not been identified (Kuivaniemi et al., 2015a). GWAS and candidate gene studies have identified a multitude of genes potentially linked to AAA, which are summarized in an extensive review by Hinterseher et al. (2011). However, a recent review by Bradley et al. illustrates that many of the observed associations of SNPs with AAAs are spurious due to biases, failed replication studies, or flawed methodology, including failure to correct for multiple testing, deviation from Hardy–Weinberg equilibrium, and flexible analysis (Bradley et al., 2016b). This article and others (Kuivaniemi et al., 2015a,b; Hinterseher et al., 2011) have extensively reviewed the most significant genetic associations for AAAs.

The identified genes with SNPs that are most significantly associated with AAAs encode either protein or RNA products involved in a wide variety of physiologic processes, such as cell growth, lipid metabolism, and inflammation (Kuivaniemi et al., 2015a,b). Two genes involved in cell growth have been significantly associated with AAAs. First, the rs10757278 SNP in *CDKN2BAS*, which encodes an antisense RNA that plays an important role in cell proliferation and apoptosis by regulating expression of cyclin-dependent kinase inhibitor 2A and 2B (Kuivaniemi et al., 2015a), was associated with both AAAs (OR = 1.31, $P = 1.2 \times 10^{-12}$) and IAs (OR = 1.29, $P = 2.5 \times 10^{-6}$) in a GWAS analysis (Helgadottir et al., 2008). Second, another GWAS identified a significant association of AAA with the rs7025486 SNP of *DAB2IP* (OR = 1.21, $P = 4.6 \times 10^{-10}$), which encodes DAB2-interacting protein, an inhibitor of cell proliferation and survival (Gretarsdottir et al., 2010). SNPs in five genes involved in lipid metabolism have also been significantly associated with AAAs, including *SORT1* (sortilin-1) (Jones et al., 2013), *LDLR* (low density lipoprotein receptor) (Bradley et al., 2013), *LRP1* (low density lipoprotein receptor-related protein 1) (Bown et al., 2011), *LPA* (apolipoprotein (a)) (Helgadottir et al., 2012), and *LRP5* (low density lipoprotein receptor-related protein 5) (Galora et al., 2013).Consistent with the role of inflammation in the pathogenesis of AAAs (Dale et al., 2015; Kuivaniemi et al., 2008), candidate gene studies have identified significant associations of a SNP in *IL6R* (Interleukin 6 receptor) (Harrison et al., 2013) and a SNP in *IL1RN* (Interleukin 1 receptor anatagonist) (Interleukin 1 Genetics C, 2015) with AAAs. Furthermore, a recent meta-analysis of 6 GWAS data sets verified the association of *SORT1*, *LDLR*, *IL6R*, *DAB2IP*, and *CDKN2BAS* with AAA and identified 4 novel loci significantly associated with AAA: 1q32.3 (*SMYD2*), 13q12.11 (*LINC00540*), 20q13.12 (near *PCIF1/MMP9/ZNF335*), and 21q22.2 (*ERG*) (Jones et al., 2017). Interestingly, these novel SNPs were not found to be associated with coronary artery disease, lipids, diabetes, or hypertension, indicating that while there is overlap between AAA and other cardiovascular diseases, as Jones et al. maintain, AAA nevertheless represents a distinct clinical phenotype (Jones et al., 2017). Though there have been multiple genes associated with AAAs, the causal relationship between many of these SNPs and AAA development needs to be investigated further (van de Luijtgaarden and Verhagen, 2015).

In a study of 3.1 million individuals, Kent et al. determined that more than 50% of persons predicted to have AAAs do not meet the established screening criteria set forth by the U.S. Preventative Services Task Force (men aged 65–75 ever smokers) (Kent et al., 2010). Given that more than 50% of AAA ruptures occur outside the target population stated above, scoring tools have been developed to detect large AAAs (>5.0 cm) in the general population (Greco et al., 2010). Currently, there are no risk scores or screening tests utilizing genetics that can be applied to clinical practice to help predict who will develop AAAs and which AAAs are more likely to rupture (Kuivaniemi et al., 2015a). Additionally, each allele in the genes described above may only increase an individual's risk of developing a AAA by 20% (van de Luijtgaarden and Verhagen, 2015). Since AAA is a disease with a complex

pathogenesis, however, the use of multiple polymorphisms in various genes may improve one's ability to risk stratify patients (Kuivaniemi et al., 2015b). For instance, Saracini et al. found that the presence of three or four polymorphisms in genes associated with AAA (*MMP2*, *MMP3*, *MMP13*, and *ELN*) was a strong and independent determinant of AAA disease (OR = 2.96, $P < .0001$) (Saracini et al., 2012). Furthermore, Ye et al. constructed a genetic risk score using SNPs in 4 genes significantly associated with AAA (*LRP1*, *DAB2IP*, *CDKN2A-2B*, and *SORT1*) and found that not only was the risk score associated with AAA independent of conventional risk factors and family history (OR = 1.06, $P < .001$) but also a higher risk score was associated with greater aneurysm growth rate (Ye et al., 2016).

Despite the well-established familial nature of AAAs (family history warrants early screening for men at age 55 and women at age 65 (Kuivaniemi et al., 2015a; Chaikof et al., 2009)), the complex nature of AAAs and the late onset of the disease have made it challenging to discover causative genes. More genetic studies are clearly required to improve our understanding of this potentially fatal disease, as the known genetic polymorphisms account for a small percentage of familial AAAs (Kuivaniemi et al., 2015a).

Genetics of IAs

Saccular IAs, which are estimated to affect 2%–5% of the adult population, are pathologic dilatations that commonly occur at proximal arterial bifurcations in the Circle of Willis (Nasr and Brown, 2016; Etminan and Rinkel, 2017; Vlak et al., 2011). IAs account for 80%–85% of non-traumatic SAH (Brown and Broderick, 2014; Kassell et al., 1990), which has a mortality rate of 42%–47% (Frosen, 2014; Karamanakos et al., 2012; Nieuwkamp et al., 2009). Though the pathogenesis of IAs is not entirely understood, it is thought that a combination of hemodynamic factors, including hemodynamic stress and vascular risk factors (hypertension, lipid accumulation, arteriosclerosis, and smoking), and genetic predisposition contribute to IA formation (Etminan and Rinkel, 2017). Therefore, IA is considered a complex disease with multiple modifiable and non-modifiable risk factors, including smoking (relative risk, 2.2–3.1), high blood pressure (relative risk, 2.5–2.6), heavy (>150 g/week) alcohol consumption (relative risk, 1.5–2.1), female gender (3:1 prevalence), older age (>50 years), ethnicity (increased risk among Finnish and Japanese descent), family history of IA or SAH, and the presence of certain hereditary diseases (Nasr and Brown, 2016; Bourcier et al., 2015).

Studies have clearly demonstrated that family history is an important risk factor for the development of IAs. In a study of 91 families with two or more affected family members without diagnosed heritable conditions, Ronkainen et al. found that the prevalence of IAs among first-degree relatives was 8.7% (Ronkainen et al., 1997). In a separate Finnish population study, the relative risk for unruptured IAs was 4.2 times higher in first-degree relatives of families with more than one IA case than in the general population (Ronkainen et al., 1998). In a cohort of patients in the familial intracranial aneurysm (FIA) study, among 303 individuals who were first-degree relatives of an individual with an IA, >30 years of age and had a history of smoking and/or hypertension, 19.1% were found to have an IA (Brown et al., 2008). Furthermore, in a long-term follow-up study of individuals with at least two first-degree relatives with SAH or unruptured IAs, family history was found to be a significant risk factor for IA at the first screening, when 11% were identified as having IAs (Bor et al., 2014). Although a personal history of IAs was the only risk factor for IA development at follow-up screening in this study, individuals with a positive family history are still at risk for development of IAs even after 10 years of follow-up (Bor et al., 2014). Consistent with these studies, the current guidelines recommend screening individuals with two or more first-degree relatives with SAH or unruptured IAs (Thompson et al., 2015).

Studies have also demonstrated that individuals with a family history of IAs are more likely to have multiple aneurysms and that the location of IAs are more likely to be shared among first-degree relatives (Mackey et al., 2012, 2013). Moreover, monozygotic twins from the FIA study exhibited higher rates of arterial location concordance than dizygotic twins, implying that genetics may influence IA location (Mackey et al., 2015). In addition to affecting the presence and possibly the location of IAs (familial IA occurs more commonly in the middle cerebral artery (Mackey et al., 2012)), family history of IAs is regarded as an important risk factor for IA rupture (Etminan and Rinkel, 2017). Broderick et al. demonstrated that individuals in the FIA study had IA rupture rates 17 times higher than comparative individuals with no family history of IAs (Broderick et al., 2009). Furthermore, the lifetime risk of SAH is increased 50-fold in those with ≥ 2 first-degree relatives with IAs compared to the general population (Etminan and Rinkel, 2017). Interestingly, geometric and morphologic characteristics associated with an increased risk for IA rupture (non-spherical shape, aspect ratio ≥ 1.6 (relation between length and neck of the IA), contact with or deformation by the perianeurysmal environment, and dominance of the posterior communicating artery in the case of IAs of that artery) cannot explain the increased rupture rates in familial IA patients (Mensing et al., 2016). Aneurysmal SAH patients with a positive family history have also been shown to present, at slightly younger ages (Bromberg et al., 1995a; Huttunen et al., 2010), to have poorer outcomes (Bromberg et al., 1995b) and to have larger aneurysms at the time of rupture (Ruigrok et al., 2004) than those with sporadic SAH. Despite these results, the largest twin study of SAH conducted to date estimated that the heritability of SAH is only 41%, implying that familial SAH is mostly attributable to environmental risk factors (Korja et al., 2010). Additionally, although Bor et al. found a strong relationship between the development of aneurysmal SAH and the presence of ≥ 2 affected relatives (odds ratio = 51 as compared to those with no affected relatives), only 0.2% of SAH patients had two or more affected relatives (Bor et al., 2008). Korja et al. therefore maintain that a positive family history only accounts for a small percentage of SAH and that the familial clustering of modifiable risk factors, including smoking and hypertension, may explain the increased rates of SAH seen in these individuals, as opposed to an underlying genetic etiology (Korja and Kaprio, 2016; Korja et al., 2010).

Nevertheless, it is currently thought that both genetic and environmental risk factors interact to contribute to the development of IAs (Etminan and Rinkel, 2017). Among affected individuals with a family history, autosomal dominant inheritance appears to be

the most common mode of transmission (Thompson et al., 2015), although one large study of 346 IA Finnish families found that autosomal recessive inheritance appeared to account for 57.2% of cases with the other cases being consistent with autosomal dominant inheritance (Wills et al., 2003). One study demonstrated that <10% of IA cases are associated with other conditions, such as BAV and aortic coarctation, or inherited syndromes, including ADPKD, EDS type 4, MFS, pseudoxanthoma elasticum (OMIM 264800), HHT, neurofibromatosis type 1 (OMIM 162200), alpha-1 antitrypsin deficiency (OMIM 613490), NS, alpha-glucosidase deficiency (OMIM 232300), and microcephalic osteodysplastic primordial dwarfism (OMIM 21072) (Thompson et al., 2015; Wiebers et al., 2003). ADPKD, EDS type 4, and microcephalic osteodysplastic primordial dwarfism are also associated with aneurysmal SAH (Thompson et al., 2015).

Autosomal dominant polycystic kidney disease (ADPKD), which is caused primarily by mutations in *PKD1* (OMIM 173900) or *PKD2* (OMIM 613095), is associated with aneurysms and dissections of almost every large artery, including the aorta and intracranial arteries (Perrone et al., 2015). IAs affect approximately 9%–12% of individuals with ADPKD (Perrone et al., 2015), and thus this disorder may increase the risk for IA formation 3- to 14-fold (Thompson et al., 2015). It appears that the risk of rupture of IAs in ADPKD patients is similar to that in the general population, although rupture tends to occur at younger ages (41 vs. 51 years, respectively) (Perrone et al., 2015). Interestingly, the same two base pair deletion variant in PKD1 was identified in two separate ADPKD + IA families (Rossetti et al., 2003; Watnick et al., 1999), suggesting that specific mutations may be associated with increased rates of IA formation among ADPKD patients (Perrone et al., 2015).

Among IA patients without an inherited syndrome, no genes have been identified yet that are strongly associated with IA development (Etminan and Rinkel, 2017). Multiple articles have reviewed the genes and chromosomal loci that have been associated IAs (Nahed et al., 2007; Tromp et al., 2014; Bourcier et al., 2015; Zhang and Claterbuck, 2008; Ruigrok and Rinkel, 2008; Caranci et al., 2013). Chromosomal loci identified via linkage studies, which have been replicated in different populations and are thus most strongly associated with IA formation (Bourcier et al., 2015), include 1p34.3–36.13 (Nahed et al., 2005), 7q11 (Onda et al., 2001), 19q13.13 (Mineharu et al., 2007), and Xp22 (Yamada et al., 2004). Though no specific genes at the 19q and Xp22 loci have been associated with IAs, a possible candidate gene at chromosomal locus 1p34.3–36.13 is *HSPG2* (Ruigrok and Rinkel, 2008). This gene encodes a heparin sulfate proteoglycan involved in arterial wall ECM maintenance, though only a moderate association was found (Bourcier et al., 2015; Ruigrok and Rinkel, 2008). Moderate associations were also identified at the chromosomal locus 7q11 for the *ELN* and *COL1A2* genes (Bourcier et al., 2015). A GWAS also identified the loci 12q22 and 20p12.1 as significantly associated with IAs (Yasuno et al., 2010).

In a meta-analysis of 61 GWAS and candidate gene association studies, Alg et al. identified 19 SNPs associated with IAs, with three chromosomal loci exhibiting the strongest associations: 9p21.3, 8q21.3, and 4q31.22 (Alg et al., 2013). The majority of genes implicated in this study are involved in vascular endothelial maintenance and ECM integrity (Alg et al., 2013). The chromosomal locus 9p21.3 contains the *CDKN2B/2A/2BAS* genes (Alg et al., 2013), which have also been associated with AAAs, TAAD, and coronary artery disease (Helgadottir et al., 2008). *CDKN2A* encodes a tumor suppressor protein that inhibits cyclin-dependent kinase 4, *CDKN2B* encodes a protein that prevents cell proliferation through induction by TGF-β, and *CDKN2BAS* is a noncoding RNA involved in transcriptional repression (Hussain et al., 2013). SNPs at the 9p21 locus have also been independently associated with IA rupture (Olsson et al., 2011). The 8q21.3 locus contains the *SOX17* gene, which plays a prominent role in the production and maintenance of vascular endothelial and hematopoietic stem cells (Alg et al., 2013). Through a meta-analysis, Foroud et al. further validated the association of the 9p21 and 8q21 chromosomal loci with IAs (Foroud et al., 2012). The 4q31 locus harbors *EDNRA*, which encodes a G-protein-coupled receptor for endothelins, which regulate vascular response after hemodynamic insult (Alg et al., 2013). Yasuno et al. also identified three chromosomal loci strongly associated with IA: 10q24.32, 13q13.1, and 18q11.2, which contain *CNNM2*, *STARD13*, and *RBBP8*, respectively (Yasuno et al., 2010). *CNNM2* encodes a protein involved in epithelial absorption of Mg^{2+} in the kidneys; *STARD13* is a tumor suppressor gene involved in endothelial cell migration and attachment; *RBBP8* encodes a protein that modulates cell cycle progression and DNA repair via interaction with retinoblastoma protein and P53 (Hussain et al., 2013).

Interestingly, one study of a genetic risk score calculated using 10 SNPs associated with IAs found that the risk score was only associated with the size of IAs as opposed to their presence in the general population (Peymani et al., 2015). The common variants in the above genes identified via GWAS only explain a fraction of the genetic risk for IAs (Farlow et al., 2015). In a recent WES study of 7 highly affected IA aneurysm families, 68 rare variants were identified in 68 genes segregating with disease, with only one gene being differentially expressed in aneurysmal tissue compared to control tissue: *TMEM132B* (Farlow et al., 2015). A heterozygous variant within this gene, which encodes a transmembrane protein of unknown function, was predicted to be pathogenic by altering a highly conserved amino acid (Farlow et al., 2015). Additionally, a recent study by Santiago-Sim et al. identified a nonsense mutation in Thrombospondin type 1 domain containing protein 1 (*THSD1*) that segregated with disease within a highly affected IA/SAH family as well as several missense *THSD1* mutations in 8 of 507 unrelated IA probands (Santiago-Sim et al., 2016). Functional analyses of *THSD1* demonstrated that disruption of the encoded protein leads to impaired endothelial cell adhesion to the basement membrane of cerebral arteries, which may explain the cerebral bleeding phenotype observed in the *Thsd1* loss-of-function animal models studied and possibly the development of IAs in affected patients (Santiago-Sim et al., 2016).

Further research is required to elucidate the complex genetics underlying IAs. Many of the SNPs associated with IAs occur in noncoding regions, indicating that studies are needed to address the regulatory function of noncoding SNPs and/or to identify the actual pathogenic variants within coding regions (Tromp et al., 2014). Further studies are required to replicate recent findings associating polymorphisms in multiple genes, including *RNF213* (Zhou et al., 2016), *ADAMTS* genes (Arning et al., 2016), *APOE* (Liu et al., 2016b), and *WWOX* (Fan et al., 2016) with IAs. According to Etminan et al., an unpublished systematic review by

Kleinloog et al. has identified 10 genetic factors associated with IA rupture (Etminan and Rinkel, 2017). Therefore, understanding the differential genetic risk between IA development and rupture through GWAS and next-generation sequencing approaches will hopefully permit the development of risk stratification tools based on underlying genetics. Furthermore, microarray expression data, which have strongly implicated immunologic genes in the pathogenesis of IA formation and rupture, can yield novel insights into the biology of IAs (Fennell et al., 2016).

Genetics of Vascular Anomalies

Vascular anomalies are localized defects in vascular development that are characterized by a focal increase in the number of vessels, which are abnormally tortuous and large (Boon et al., 2011). While the majority of vascular anomalies occur sporadically, there are a variety of inherited forms that most commonly exhibit autosomal dominant inheritance due to loss-of-function mutations (Nguyen et al., 2014). These disorders typically display incomplete penetrance and variable expressivity, which may be explained by Knudson's two-hit hypothesis: the combination of an inherited mutation and a post-zygotic somatic mutation leading to a localized loss of the gene is required for vascular anomaly development (Boon et al., 2011; Nguyen et al., 2014). This section will briefly describe the underlying genetics of inherited arteriovenous malformations (AVMs), capillary malformations (CMs), venous malformations (VMs), lymphatic malformations (LMs), and inherited complex syndromes manifesting with vascular anomalies.

Arteriovenous Malformations

AVMs are characterized by dilated vessels and arterialized veins due to a direct connection between arteries and veins that bypasses capillaries (Nguyen et al., 2014). Approximately 5% of AVMs occur as a result of inherited vascular disorders, primarily hereditary hemorrhagic telangiectasia (HHT) (Kim et al., 2016). HHT (incidence 1:5000–1:8000) is an autosomal dominant disorder that is diagnosed by satisfying three of the following four criteria: recurrent epistaxis, telangiectasias, visceral AVMs, and a positive family history (Shovlin et al., 2000). Six chromosomal loci have been linked to HHT, though only four genes, which all encode components of the TGF-β signaling pathway, have been identified as causative of the disease (Nguyen et al., 2014). Mutations in *ENG* (HHT1—OMIM 187300), which encodes the co-receptor endoglin, and *ACVRL1* (HHT2—OMIM 600376), which encodes the type I receptor activin kinase-like receptor-1 (ALK1), account for 80% of HHT cases (Nguyen et al., 2014; Shovlin, 2010). Interestingly, individuals with HHT1 suffer more commonly from cerebral and pulmonary AVMs, whereas HHT2 is more commonly associated with hepatic AVMs (Shovlin, 2010). As mentioned earlier, JPS–HHT is due to mutations in *SMAD4*, which accounts for 1%–2% of HHT cases (Shovlin, 2010). HHT5 (OMIM 615506) is caused by mutations in bone morphogenetic protein 9 (*BMP9*), which encodes a protein that exerts its effect on cells by binding to endoglin and ALK1 (Wooderchak-Donahue et al., 2013). No genes causative of HHT have been identified yet at chromosomal loci 5q31.3-q32 (HHT3—OMIM 601101) and 7p14 (HHT4—OMIM 610655) (Nguyen et al., 2014). Interestingly, in a recent WES study of one family with brain AVMs, Yilmaz et al. found a heterozygous mutation in *ACVRL1* in two siblings without any other HHT features, indicating the wide phenotypic variability with *ACVRL1* mutations (Yilmaz et al., 2017).

While approximately 10% of individuals with HHT have a brain AVM (Brinjikji et al., 2017), only 2% of brain AVMs are associated with HHT (Alvarez and Castillo, 2015). Given that there are reports of familial clustering of brain AVMs in those without HHT, there may be a genetic basis to the formation of brain AVMs outside of the HHT genes (van Beijnum et al., 2007, 2014). In a meta-analysis of six SNPs previously associated with sporadic brain AVMs (which constitute 95% of cases), only one SNP near the *ANGPTL4* gene was associated with AVM susceptibility (Kremer et al., 2016). *ANGPTL4* encodes the protein angiopoietin-like 4, which is thought to have both a proangiogenic and antiangiogenic effect via signaling independent of ACVRL1 and endoglin (Kremer et al., 2016). Additionally, the 9p21 locus, which has been linked with TAAs, AAAs, and IAs, has also been associated with sporadic brain AVMs (Sturiale et al., 2014). Currently, however, the role of genetic variants in sporadic brain AVMs is not well established (Yilmaz et al., 2017), and as Walcott et al. maintain, it is likely that underlying genetics, inflammation, and impaired blood–brain barrier integrity all contribute to brain AVM development (Walcott et al., 2016).

Capillary Malformations

CMs, which are commonly known as port-wine stains and are usually sporadic in occurrence, can be inherited via an autosomal dominant mechanism as part of the CM–AVM syndrome (Nguyen et al., 2014). CMs of CM–AVM are generally smaller than sporadic CMs, multifocal, and surrounded by a pale halo (Boon et al., 2011). These CMs, which can be associated with AVMs, AV fistulas, or Parkes Weber syndrome (OMIM 608355), are caused by mutations in *RASA1*, leading to loss of function of the encoded GTPase activating protein p120-RasGAP (Boon et al., 2011; Nguyen et al., 2014). Consequently, there is upregulation of the Ras/MAPK pathway, leading to abnormal cell growth, differentiation, and proliferation (Nguyen et al., 2014).

Cerebral cavernous malformations (CCMs), which are clusters of enlarged capillary caverns lined by a single layer of endothelial cells without normal intervening brain parenchyma (thus prone to rupture (346)), are inherited via an autosomal dominant mode in approximately 20% of cases (Nguyen et al., 2014). A double hit mechanism (inactivation of both alleles of a CCM gene) in one of

three discovered genes (*KRIT1*, *CCM2*, and *PDCD10*) linked to CCMs is required for their development (Nguyen et al., 2014; Pagenstecher et al., 2009; Akers et al., 2009). *KRIT1* (CCM1—OMIM 116860) encodes Krev Interaction Trapped-1, which plays a role in endothelial cell–cell junctions via the Delta-Notch pathway (Nguyen et al., 2014). *CCM2* (OMIM 60384) encodes the malcavernin protein, which serves as a scaffolding protein for mitogen-activated protein kinase kinase kinase and also interacts with KRIT1 (Nguyen et al., 2014; Kim et al., 2016). *PDCD10* (CCM3—OMIM 603285) encodes a protein involved in apoptosis that has been shown to interact with malcavernin (Kim et al., 2016). Though no gene has been discovered, a 4th CCM locus is possible at 3q26.3-q27.2 (Kim et al., 2016; Liquori et al., 2006). Interestingly, CCM1 patients may exhibit lower rates of hemorrhage than patients with CCM2 or 3 (Gault et al., 2006), while CCM3 patients may have a higher risk of cerebral hemorrhage (Denier et al., 2006).

Venous Malformations

VMs, which appear as dilated venous channels surrounded by thin, irregular layers of SMCs, are typically sporadic in nature but can be inherited in an autosomal dominant manner (Nguyen et al., 2014). The two forms that are inherited are cutaneomucosal venous malformations (VMCMs—OMIM 600195) and glomulovenous malformations (GVMs—OMIM 138000), which account for 1% and 5% of VMs, respectively (Nguyen et al., 2014). VMCMs are caused by mutations in *TIE2/TEK*, which is an extracellular receptor that binds angiopoietins and thus modulates angiogenesis and proliferation and maintains vessel wall stability (Nguyen et al., 2014). While 85% of mutations in sporadic VMs are attributable to the somatic L914F mutation in *TEK*, more than 50% of VMCMs are due to the R849W mutation (Nguyen et al., 2014). All mutations in *TEK* leading to VMCMs result in hyperphosphorylation of the receptor (Wouters et al., 2010), causing upregulation of PI3K/AKT signaling. This upregulation leads to decreased production of platelet-derived growth factor-beta, an important recruiter of SMCs (Nguyen et al., 2014).

GVMs, which are typically raised, nodular, multifocal, and hyperkeratotic, are histologically characterized by mural glomus cells in distended venous channels (Brouillard et al., 2013). GVMs are caused by loss-of-function mutations in glomulin (*GLMN*), which exhibit incomplete penetrance (90%) and variable expressivity, with no observed relationship between the specific mutation identified and the observed phenotype (Brouillard et al., 2013). It is thought that glomulin plays an important role in vascular SMC development (Nguyen et al., 2014). Brouillard et al. propose that the variable expressivity by family members with the same *GLMN* mutation may be related to the rate of somatic second-hit mutations that may vary among them (Brouillard et al., 2013).

Lymphatic Malformations

LMs, which consist of enlarged lymphatic vessels with fibrotic walls, only occur sporadically and are thus likely due to somatic mutations (Nguyen et al., 2014; Brouillard et al., 2014). However, lymphedema, which is characterized by the abnormal accumulation of interstitial fluid due to disruption of lymphatic vessels, can be primary (congenital) or secondary (acquired) (Nguyen et al., 2014). Primary lymphedema is most commonly sporadic, though 35% of cases are familial in nature and exhibit an autosomal dominant or recessive mode of inheritance (Nguyen et al., 2014; Brouillard et al., 2014). At least 21 genes have been linked to primary lymphedema, though only eight genes account for approximately 40% of familial lymphedema and 10% of sporadic lymphedema (Brouillard et al., 2014; Mendola et al., 2013). The other genes are known to cause rare syndromic diseases that manifest with lymphedema and thus only contribute to a small fraction of the cases of familial lymphedema (Brouillard et al., 2014). The majority of implicated genes encode proteins associated with the VEGFC/VEGFR-3 signaling pathway (Brouillard et al., 2014). Mutations can affect the function of this pathway at the level of the receptor/ligand (*VEGFR3*, OMIM 153100; *VEGFC*, OMIM 615907; *CCBE1*, OMIM 235510), modification of receptor activity (*PTPN14*, OMIM 613611), production of the receptor (*SOX18*, OMIM 607823 + 137940; *GATA2*, OMIM 614038), transcriptional regulation (*FOXC2*, OMIM 153400; *GATA2*), or a downstream target gene (*GJC2*, OMIM 613480; *VEGFR3*) (Mendola et al., 2013). *KIF11* (OMIM 152950), which encodes a protein involved in mitotic spindle assembly and has also been shown to be causative of primary lymphedema, has not been linked to the VEGFC/VEGFR-3 pathway, though inhibition of KIF11 activates the PI3K/AKT pathway (Brouillard et al., 2014; Mendola et al., 2013). Determining the underlying genetic etiology in familial primary lymphedema is crucial, as it helps clinicians predict the clinical prognosis of patients and their family members (Adamczyk et al., 2016).

Inherited Complex Syndromes

Vascular anomalies can also occur with several complex overgrowth syndromes, including Proteus syndrome (OMIM 176920), congenital lipomatous asymmetric overgrowth with vascular malformation, epidermal nevi, and skeletal anomalies (CLOVES—OMIM 612918), PTEN hamartoma tumor syndrome (PHTS), and Klippel–Trenaunay syndrome (KTS—OMIM 149000) (Nguyen et al., 2014). However, only PHTS, which is characterized by vascular anomalies, tissue overgrowth, gastrointestinal polyps, and macrocephaly, is an inherited condition (Nguyen et al., 2014). PHTS is caused by mutations in *PTEN*, a tumor suppressor gene that inhibits PI3K signaling (Nguyen et al., 2014). Rare chromosomal translocations have been associated with KTS, though this disorder, along with CLOVES, is most commonly due to somatic mutations in *PIK3CA*, whereas somatic mutations in *AKT1* are the cause of Proteus syndrome (Nguyen et al., 2014).

Other Vasculopathies

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH), which is characterized by intimal thickening, SMC hypertrophy, adventitial fibrosis, and occlusion of the pulmonary vasculature (Han et al., 2013; Humbert et al., 2004), can be inherited in an autosomal dominant manner with reduced penetrance (estimated at 27%) (Best et al., 2014) in approximately 6% of cases (Ma and Chung, 2017). Several genes belonging to the TGF-β superfamily have been implicated in hereditary PAH (HPAH), including *BMPR2* (PPH1, OMIM 178600), *SMAD9* (PPH2, OMIM 615342), and the HHT 1 and 2 genes (*ENG* and *ACVRL1*, respectively) (Ma and Chung, 2017). Loss-of-function mutations in *BMPR2* are discovered in approximately 70% of hereditary PAH (HPAH) cases and in 10%–40% of idiopathic PAH (IPAH) cases (Ma and Chung, 2017). Interestingly, *BMPR2* mutation carriers appear to have more severe disease at diagnosis and are less likely to respond to acute vasodilator testing than individuals without *BMPR2* mutations (Rosenzweig et al., 2008). *CAV1* (PPH3, OMIM 615343), which encodes a membrane protein that plays a role in TGF-β, G-protein, and nitric oxide signaling, and *KCNK3* (PPH4, OMIM 615344), which encodes an outwardly rectifying K+ channel, are implicated in rare cases of HPAH (Ma and Chung, 2017). Clinical genetic testing for mutations in the above stated genes, along with several others associated with PAH (*SMAD4*, *KCNA5*, *BMP9*, and *NOTCH3*), is warranted for HPAH, IPAH, and pediatric PAH and is helpful for risk stratification for family members (Ma and Chung, 2017).

Metabolic Vasculopathy

Metabolic myopathies, which are disorders of skeletal muscle due to impaired carbohydrate, fatty acid, or energy metabolism, have been associated with dilatation or aneurysm of various arteries (Finsterer, 2012). In particular, Pompe's disease (glycogen storage disease II, OMIM 232300), an autosomal recessive disorder due to mutations in acid alpha-1,4-glucosidase, has been shown to manifest with dilative arteriopathy, especially of the basilar artery (Finsterer, 2012). The most common complications associated with vascular manifestations of Pompe's disease are bleeding or arterial wall dissection, leading to ischemic or hemorrhagic stroke, including subarachnoid bleeding (Finsterer, 2012). The pathophysiology of this disease involves excess storage of glycogen in vascular SMCs, which most commonly affects the cerebral vessels (Finsterer, 2012).

Mitochondrial disorders, which typically have multisystem manifestations due to mutations in mitochondrial DNA (maternally inherited) or mitochondria-related nuclear DNA, can also manifest with vasculopathy (Finsterer and Zarrouk-Mahjoub, 2016; El-Hattab et al., 2015). These disorders, which have the highest incidence among congenital metabolic disorders, are caused by mutations in more than 250 genes (Kohda et al., 2016). Primary mitochondrial vasculopathy is due to a direct effect of the underlying metabolic defect on the components of the arterial wall (endothelium, muscularis, adventitia, pericytes), while secondary mitochondrial vasculopathy is attributed to atherosclerotic risk factors that commonly affect individuals with mitochondrial disorders (Finsterer and Mahjoub, 2012). The vascular manifestations of mitochondrial disorders include microangiopathy (leukoencephalopathy, migraine-like headaches, stroke-like episodes, and peripheral retinopathy) and macroangiopathy (atherosclerosis, arterial ectasia, aneurysms, dissection, and spontaneous arterial rupture) (Finsterer and Zarrouk-Mahjoub, 2016). Mitochondrial disorders have been associated with aortic root ectasia (Brunetti-Pierri et al., 2011), carotid artery dissection (Sakharova et al., 2012), spontaneous rupture of the aorta (Tay et al., 2006), and AVMs (Fujitake et al., 2002). Finsterer et al. maintain that individuals with mitochondrial disorders should be systematically screened for mitochondrial vasculopathy in order to establish an early diagnosis and hopefully prevent any complications (Finsterer and Zarrouk-Mahjoub, 2016).

Inherited Neurovascular Disease

Neurovascular disease, which is typically multifactorial in nature, can also be caused by rare inherited disorders that can manifest with stroke as the principal characteristic or as part of a systemic disease (Tan and Markus, 2015). A number of monogenic causes of stroke have been described and reviewed extensively (Tan and Markus, 2015; Sam et al., 2015; Southerland et al., 2013). Many of these monogenic disorders affect either endothelial cells or SMCs (Sam et al., 2015) and cause one stroke subtype (ischemic vs. hemorrhagic and small vessel vs. large arterial disease), though several of the disorders can cause more than one subtype (Tan and Markus, 2015). Cerebral arteriopathy, autosomal dominant, with subcortical infarcts and leukoencephalopathy, type 1 (CADASIL1, OMIM 125310), which is the most common monogenic cause of cerebral small vessel disease (Tan and Markus, 2015), results from mutations in *NOTCH3* that lead to aggregation of NOTCH3 around vascular SMCs and consequently vascular SMC degeneration and cerebral arterial stenosis (Sam et al., 2015). Mutations in high temperature requirement serine peptidase A1 (*HTRA1*) have been shown to be causative of both CADASIL2 (OMIM 616779) and cerebral arteriopathy, autosomal recessive, with subcortical infarcts and leukoencephalopathy (CARASIL), which is characterized by a much earlier age of onset of stroke and cognitive decline (20–30 years) than the autosomal dominant forms (Verdura et al., 2015; Hara et al., 2009). *TREX1* and *FOXC1* mutations have also been linked to autosomal dominant syndromes (OMIM 192315 and 602482, respectively) causative of cerebral small vessel disease and subcortical infarcts (Tan and Markus, 2015).

Mutations in *COL4A1* have been shown to cause a spectrum of small vessel diseases that can manifest with ischemic or hemorrhagic strokes (HANAC, OMIM 611773; BSVD, OMIM 607595, Porencephaly 1, OMIM 175780), while mutations in *COL4A2* been linked to Porencephaly 2 (OMIM 614483) (Tan and Markus, 2015). Heterozygous mutations in *COL4A1* and *COL4A2* have also been associated with sporadic adult-onset hemorrhagic stroke (OMIM 614519) (Weng et al., 2012; Jeanne et al., 2012). Through a

cohort of 183 index patients primarily with porencephaly or infantile hemorrhage as well as a literature review, Meuwissen et al. determined that 50% of *COL4A1* and *COL4A2* mutations were inherited, while 25% were de novo and 25% were of unknown origin (due to lack of parental testing) (Meuwissen et al., 2015). Autosomal dominant inherited forms of cerebral amyloid angiopathy (OMIM 605714) can also cause hemorrhagic cerebral small vessel disease via deposition of amyloid fibrils in blood vessel walls (Tan and Markus, 2015). Fabry disease (OMIM 301500), pseudoxanthoma elasticum, neurofibromatosis 1, and homocystinuria (OMIM 236200) are all monogenic disorders causative of small and large ischemic arterial disease due to mutations in *GLA* (galactosidase alpha), *ABCC6* (multidrug resistance-associated protein 6), *NF1* (neurofibromin 1), and *CBS* (cystathionine beta synthase), respectively (Tan and Markus, 2015). Additionally, mutations in *CER1*, which encodes adenosine deaminase 2, were found to cause early-onset ischemic and hemorrhagic stroke, as part of the autosomal recessive disease known as childhood-onset polyarteritis nodosa (OMIM 615688) (Zhou et al., 2014).

Furthermore, there are several relatively common cerebrovascular arteriopathies, including moyamoya disease, cervical artery dissection, and fibromuscular dysplasia (FMD), that have a genetic basis as well (Southerland et al., 2013). Moyamoya disease, which is characterized by diffuse distal stenosis of intracranial carotid arteries due to intimal thickening leading to neovascularization (Fukushima et al., 2016), has been linked with six chromosomal loci (designated MYMY1–6). Moyamoya disease is associated with several genetic syndromes, including Down syndrome, Alagille syndrome, Neurofibromatosis 1, and sickle cell disease, though non-syndromic disease can also be inherited in families via an autosomal dominant mechanism with reduced penetrance (Wallace et al., 2016; Mineharu et al., 2006). A GWAS identified *RNF213* as a susceptibility gene for MYMY2 (OMIM 607151) (Kamada et al., 2011), and a recent study by Fukushima et al. found that the homozygous mutation p.Arg4810Lys in the *RNF213* gene resulted in pulmonary hypertension and Moyamoya disease in two patients (Fukushima et al., 2016). MYMY4 (OMIM 300845), which is an X-linked recessive syndrome characterized by Moyamoya disease, short stature, facial dysmorphism, and hypergonadotropic hypogonadism, is due to deletion of *BRCC3* and *MTCP1*/*MTCP1NB* on Xq28 (Miskinyte et al., 2011). MYMY5 (OMIM 614042), as previously mentioned, is due to heterozygous mutations in the *ACTA2* gene, though these patients do not exhibit the characteristic cerebrovascular features of typical Moyamoya disease, including collateral development (Guo et al., 2009). MYMY6, which is characterized by achalasia, hypertension, and Moyamoya disease, is caused by homozygous or compound heterozygous mutations in *GUCY1A3* that lead to disrupted nitric oxide signaling (Wallace et al., 2016; Herve et al., 2014). Additionally, Majewski osteodysplastic primordial dwarfism II (MOPD II) (OMIM 210720), an autosomal recessive disorder due to mutations in the pericentrin gene, can also manifest with cerebrovascular anomalies (19% of cases in one study), including Moyamoya disease and IAs (Hall et al., 2004).

Cervical artery dissection (CeAD), a major cause of ischemic stroke in young and middle-aged adults, can occur as a manifestation of several monogenic disorders, primarily vascular EDS, and possibly others, including different types of EDS, LDS, MFS, and osteogenesis imperfecta (Debette et al., 2014). Though some patients with CeAD present with other arterial anomalies and connective tissue aberrations, implying an underlying systemic vasculopathy (Debette and Leys, 2009), no consistent genetic association has been established to contribute to cervical artery dissection (Debette et al., 2014). However, via a GWAS of 1393 CeAD cases and 14,416 controls in the general population, Debette et al. demonstrated that the G allele of the rs9349379 SNP in the phosphatase and actin regulator 1 (*PHACTR1*) gene was associated with a significantly decreased risk for CeAD (OR = 0.75) (Debette et al., 2015). In a separate study, Debette et al. demonstrated that only 1% of 1934 patients with cervical artery dissection had a positive family history and that the inherited connective tissue syndromes listed above only accounted for a few cases (Debette et al., 2014). Therefore, cervical artery dissection appears to be a multifactorial disease (Debette et al., 2014). FMD, a non-atherosclerotic and noninflammatory vascular disease that can lead to stroke due to stenosis of extracranial carotid and vertebral arteries as well as arterial aneurysms and dissections, has also been associated with the rs9349379 SNP of the *PHACTR1* gene (OR = 1.39) (Kiando et al., 2016). Given that 7%–10% of FMD patients have a positive family history, current evidence indicates there is a genetic basis to FMD, which may be inherited via an autosomal dominant manner with incomplete penetrance (Olin et al., 2012, 2014; Pannier-Moreau et al., 1997; Guo et al., 2017). In a recent study, Guo et al. identified homozygous and compound heterozygous loss-of-function mutations in *YY1AP1* in several individuals with Grange syndrome (OMIM 602531), an autosomal recessive condition characterized by early-onset vascular disease similar to FMD (Guo et al., 2017). Interestingly, mutations in *YY1AP1* and *INO80D*, which both encode components of the INO80 chromatin remodeling complex, have been shown to lead to vascular disease (Guo et al., 2017; Shameer et al., 2014). In a WES study, Shameer et al. identified a homozygous missense mutation in *INO80D* in two siblings with aortic hypoplasia, early-onset atherosclerosis, and arterial stiffness (Shameer et al., 2014).

Conclusion

The vasculature represents a complex, interconnected fluid transport network which plays a dynamic and vital role in our maintenance and survival. Both rare monogenic and common polygenic disorders that disrupt the structure and thus function of the vasculature at the level of the endothelial cell, SMC, or connective tissue of the vessel wall can lead to aneurysm formation, arterial dissection, vascular malformations, and other vasculopathies, which can lead to rupture and/or downstream tissue ischemia. Unraveling the genetics of aneurysms, vascular malformations, and other vasculopathies via GWAS, genome-wide linkage studies, and next-generation sequencing has revolutionized our understanding of the biology of these diseases. We are already witnessing the impact of these discoveries in improving patient care and enabling personalized medicine based on underlying

clinical and molecular genetics. Through more widespread clinical genetic testing and continued genetic research, we will be able to offer prophylactic care at an earlier age to affected individuals and to design novel therapies for these potentially devastating diseases.

Introduction

Aging of the population and prolonged lifespan of patients with cardiovascular diseases due to contemporary therapeutic interventions has led to an increasing prevalence of heart failure (HF). Data from NHANES 2009 to 2012 estimates HF to affect more than 5.7 million American adults. Projections also show that the prevalence of HF will increase approximately by 50% from 2012 to 2030, resulting in greater than 8 million adults with HF (Writing Group Members et al., 2016). Despite recent advances in the therapeutic armamentarium, the mortality rate in patients with HF remains high (Heidenreich et al., 2013; Gerber et al., 2015).

HF with reduced ejection fraction (HFrEF) is categorized into ischemic and nonischemic causes, with the term dilated cardiomyopathy (DCM) often used interchangeably with nonischemic cardiomyopathy. Approximately 30%–40% of patients enrolled in registries have DCM and approximately 70% of these are classified as idiopathic (Writing Group Members et al., 2016; Heidenreich et al., 2013). Historically, a genetic origin of DCM had been suspected based on inheritance patterns observed in families with several members affected by the disease. Initial studies suggested an estimate familial involvement in 1%–2% of DCM (Codd et al., 1989). However, it has been recently recognized that about 20%–50% of patients with DCM have familial or a genetic cause of cardiomyopathy (Hershberger and Siegfried, 2011). The precise magnitude of the role of genetic predisposition, however, varies by disease type, race, and age of disease onset. As demonstrated by an analysis of the Framingham cohort (Ackerman et al., 2011), the relative risk of developing HF is 1.69 if one parent is affected and 1.92 if both parents have HF. Genetic predisposition for development of HF includes not only a Mendelian risk of developing a cardiomyopathy but also genetic variation that could lead to a maladaptive response to common risk factors such as hypertension or diabetes mellitus and potentially cardiotoxic chemotherapy drugs (Pereira and Weinshilboum, 2009). Genetics may also play a role in the variable clinical response to HF therapy (Vosberg, 1994). Moreover, in a subset of patients with HF, allele heterogeneity with variable penetrance leads to various phenotypes of inherited cardiomyopathies (Pereira and Weinshilboum, 2009).

The purpose of this review is to examine the role of genetics in the development and treatment of DCM, the use of genomic tools in identifying a cause of HF and variation in HF drug response, and discuss its implications for clinical practice.

Genetic Studies in HF: A Methodological Approach

Genetic traits associated with HF can be monogenic or complex. Monogenic traits demonstrate mutations, deletions, or insertions in the coding DNA of a single gene or mutations in noncoding regulatory regions in the 5′ or 3′ or intronic regions of the gene, or variants leading to alteration in gene splicing. Nevertheless, these disorders may not always be monogenic, and the clinical phenotype could also be influenced by mutations in additional genes.

Linkage Analysis

For most of these monogenic traits, direct DNA sequencing and/or linkage analysis has successfully yielded the causal genetic mutation. Linkage analysis was used to localize the chromosomal position of a causal gene, MYH7 or cardiac myosin heavy chain 7, for hypertrophic cardiomyopathy (HCM) (Richards et al., 2015). The key concept behind linkage analysis is that genetic loci are usually inherited together due to their location near one and other on the chromosome and if they are transmitted together from parent to offspring more often than expected under independent inheritance. Once markers across the genome of family members

Table 1 Genes associated with dilated cardiomyopathy

Gene	*Function*	*Approximate percentage of dilated cardiomyopathy cases*
LMNA-Lamin A/C	Nuclear membrane stability	6%
MYH6-Myosin 6	Muscle contraction	4.4%
MYH7-Myosin-7	Muscle contraction	4.3%
MYPN-Myopalladin	Muscle contraction	3.6%
TNNT2-Troponin T	Muscle contraction	3%
SCN5A-Sodium channel protein type 5-subunit A	Sodium influx	2.6%
MYBPC3-Myosin-binding protein C	Muscle contraction	2%
RBM20-RNA-binding protein 20	Spliceosome protein	2%
TMPO-Thymopoietin	Nuclear membrane stability-Lamin associated protein	1%
LAMA4-Laminin alpha 4	Transduction of contractile forces	1%
TCAP-Telethonin	Muscle contraction	1%
VCL-Metavinculin	Transduction of contractile forces	1%
LDB3-LIM domain-binding protein 3	Transduction of contractile forces	1%
DES-Desmin	Transduction of contractile forces	<1%
ACTC1-Actin	Muscle contraction	<1%
TPM1-Tropomyosin alpha-1 chain	Muscle contraction	<1%
PLN-Cardiac phospholamban	Sarcoplasmic reticulum Ca^{2+} regulator; inhibits SERCA2a pump	<1%
TNN3-Troponin I	Muscle contraction	<1%
ACTN2-Alpha actinin-2	Anchor for actin	<1%
TNNC1-Troponin C	Muscle contraction	<1%
CSRP3-Cysteine and glycine rich protein 3	Cytoskeletal	<1%
PSEN1/2-Presenilin 1/2	Transmembrane protein, γ-secretase activity	<1%
DMD-Dystrophin	Transduction of contractile forces	<1%
TAZ-Tafazzin	Mitochondrial	<1%
ILK-Integrin-linked kinase	Transduction of contractile forces	<1%
TTN-Titin	Muscle contraction	<1%
CRYAB-Alpha B crystaline	Cytoskeletal protein	<1%

have been identified, the estimated logarithm of the odds score represents the probability that a genetic marker and possible causal locus are linked in off springs as opposed to the null hypothesis of the absence of linkage in the pedigrees (Lohmueller et al., 2003). The initial linkage is validated by fine mapping linkage analyses (addition of markers to form a dense genotype set in the region of linkage). Although linkage analysis has been extensively used for identification of genes causally associated with monogenic diseases, its use for identification of susceptible loci responsible for complex traits in the absence of a familial transmission is limited. To perform linkage analysis it is essential to have at least a complete trio, an affected patient or proband, and his or her parents.

In the setting of DCM, mutations in the nuclear-envelope scaffolding protein lamin have been identified in 6% of inherited cases. The role of *LMNA* gene mutations in DCM was demonstrated by Fatkin and colleagues (Fatkin et al., 1999) who evaluated 11 families with autosomal dominant inheritance DCM and located a genetic variant on chromosome 1p1-q21, where nuclear-envelope proteins lamin A and lamin C are encoded by the *LMNA* gene. Since then several other gene mutations associated with DCM have been identified by linkage analysis of families with inherited cardiomyopathies (**Table 1**).

GWAS

A wide spectrum of common genetic variants both within the noncoding and coding regions of multiple genes and interaction with traditional risk factors or the environment could lead to modifications in gene expression, translation, and posttranslational products that in turn could contribute to the pathogenesis of complex traits (Ackerman et al., 2011; Pereira and Weinshilboum, 2009). Therefore, comprehensive analysis of susceptibility genetic loci for complex traits is more complicated. In contrast with monogenic traits, the correlation between genotype and phenotype is modest resulting in relative risks of up to 1.5 as demonstrated by genome-wide association studies (GWAS). This pattern of relatively weak genotype–phenotype correlation or "missing heritability" can perhaps be explained by epigenetic mechanisms such as DNA methylation and histone modification or by the presence of rare variants that are typically not assayed by GWAS platforms. Moreover, to identify susceptibility loci involved in complex traits by GWAS, large populations are required to achieve adequate statistical power. The importance of allele frequency (common versus rare) depends on the effect measure. As opposed to common variants (minor allele frequency (MAF) >5%), rare variants (MAF < 1%) may be associated with higher individual risk for a condition but the population attributable risk is low. Based on the common disease-common variant hypothesis complex traits result from interactions of multiple common genetic variants, most of which are shared by unrelated affected individuals and usually have lacked obvious functional association with the disease

and could be in linkage disequilibrium with functional variants (Bodmer and Bonilla, 2008). Conversely, the common disease-rare variant hypothesis (Pritchard, 2001) suggests that common disease susceptibility could be due to genetic variants with low population frequencies (MAF < 1%) usually with large effect sizes. Therefore unlike common variants, rare variants could be associated with greater risk for a disease condition, more likely to have relevance to gene function and the disease process (Bodmer and Bonilla, 2008).

In the past, the main approaches to identify susceptibility loci of complex traits were linkage analysis with fine mapping or candidate gene association studies. Candidate genes for association studies are usually selected on the basis of prior linkage study findings and/or prior biological knowledge of gene function as is relevant to disease pathogenesis. Subsequently, allele or haplotype (combination of polymorphic alleles that are located at closely linked loci and tend to be inherited together) frequencies between case and control groups are compared, and a statistical difference in frequencies between cases and controls provides evidence that the allele or haplotype is associated with the disease trait. The main limitation of this approach has been the lack or reproducibility and the inability to discover new disease-associated genes. The lack of reproducibility could be attributed to false positive tests, genetic and phenotypic heterogeneity (Goring et al., 2001; Hattersley and McCarthy, 2005).

GWAS test multiple genetic variants spread across the human genome for association with a specific trait and do not require prior knowledge of the biologic relevance of the tested genes. GWAS entail hybridization of DNA from a patient against an array of short oligonucleotide probes which are immobilized on the array. If any of the tested DNA sequences are complementary to probes on the array, they bind and become detected. The development of high-throughput genotyping technology and the analysis of high-resolution linkage disequilibrium maps of common genetic variants using data from the International HapMap Project (International HapMap Consortium, 2005) have facilitated the design and performance of case-control GWAS with large sample sizes and statistical power leading to identification of loci with known or unknown biologic function. Despite the increasing number of GWAS in the literature, a large number of susceptibility loci identified by the studies explain a small percentage of variability of complex traits, a phenomenon called "missing hereditability" (Maher, 2008). The residual variability can be explained by gene–gene interactions, epigenetic modifications, and the presence of rare alleles the detection of which require next-generation sequencing (NGS). Given the increasing number of GWAS in the literature, clinicians should be familiar with basic measures of validity of GWAS. Most importantly, the phenotype should be explicitly described, the genotype frequencies should follow the Hardy–Weinberg equilibrium, the level of significance should be adjusted for multiple comparisons (5×10^{-8} is usually considered a GWAS significant threshold), and finally the results should be replicated in other cohorts and a metaanalysis with these from other studies should confirm these findings.

Several studies have sought to determine the association of common susceptibility variants with the incidence and severity of HF. The first large-scale GWAS to investigate genetic factors that are associated with the onset of HF was the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) consortium. This metaanalysis included data from four community-based prospective cohorts of a total of 25,000 individuals followed up for about 11.5 years for the development of new-onset HF. After screening for approximately 2.5 million single-nucleotide polymorphisms (SNPs), two genetic loci were identified to be independently associated with incident HF. The first genome-wide significant locus was 58.8 kb from the gene *USP3* (encoding ubiquitin-specific peptidase 3) in individuals of European ancestry, and the second locus was 6.3 kb from the gene *LRIG3* (encoding leucine-rich repeats and immunoglobulin-like domains 3) in individuals of African ancestry (Smith et al., 2010). Although, GWAS have identified susceptibility loci for major risk factors of HF such as hypertension and coronary artery disease (Weintraub et al., 2017; Towbin et al., 2015), they have not been very successful in identification of loci directly related to HF, suggesting a complex interplay between traditional risk factors and genetic background.

The prospective metaanalysis from the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium was the first large-scale GWAS to attempt to discover genetic risk variants for HF. The CHARGE study included about 24,000 individuals (21,000 subjects of European ancestry and almost 3,000 subjects of African ancestry) and studied 2.5 million genetic markers spread throughout the genome. Data from 4 large, population-based cohort studies that included cardiovascular outcomes as primary study endpoints were analyzed (Liggett et al., 2006; Cresci et al., 2009). The threshold for a genetic locus to be significantly associated with HF risk in each ethnic cohort was set at a significance level of 5×10^{-7}. In the European subset, the locus associated with HF risk was at chromosome15q22 near *USP3* (ubiquitin-specific peptidase 3 gene) with a hazard ratio that was determined to be 1.53 (p value: 1.4×10^{-8}) for the minor allele. In the African ancestry group, the locus associated with HF risk was found at chromosome 12q14 with a similar hazard ratio (p value: 6.7×10^{-8}). In both ethnic subsets several "high signal" SNPs were identified that did not reach the prespecified significance level. These results suggest that HF not unlike other complex diseases may be a polygenic disease process. However, to exclude false positive associations, these results will have to be replicated in other HF cohorts. Also, the identification of loci that are in linkage dysequilibrium with the identified SNPs and may be causally related to HF may require in depth resequencing.

In a large-scale candidate gene, case-control study of 20,926 European-ancestry participants with 2526 incident HF events, common SNPs in ≈2000 genes from the ITMAT/Broad CARe (IBC) cardiovascular SNP array, identified a genome-wide significant locus ($p = 1.4 \times 10^{-8}$) rs1739843, located in an intronic region of the *HSPB7* gene at 1p36, that encodes a heat shock protein, and was associated with incident HF (Fatkin et al., 1999). In this study SNPs in genes that were already known to have biological associations with various disease processes were evaluated. These results were replicated in another multicenter European study (Stark et al., 2010). The significant SNP in *HSPB7* gene was in linkage disequilibrium with a SNP (rs10927887, encoding Arg83Gly) in the *CLCNKA* gene (gene encoding a chloride ion channel), sequencing of the latter suggested significant association of a loss-of-function variant with HF (White et al., 2003) with an odds ratio of 1.27 per allele copy. These findings identify an independent

genetic risk factor for HF. The variant CLCNKA risk allele associated with linked variants in the adjacent HSPB7 gene uncovers a genetic mechanism affecting the cardiorenal axis and provides genetic evidence supporting clinical observations that individual differences in salt-sensitivity can predispose to cardiovascular complications.

These genotype–phenotype association studies described above include patients with HF of diverse etiology (ischemic and nonischemic) and type (systolic and diastolic). Recent studies have focused specifically on identification of susceptibility loci for DCM. DCM accounts for 30%–40% of HF cases in registries. A GWA study of 1179 patients with DCM and LVEF<45% without coronary artery disease and 1108 controls used a DNA-pooling approach and identified 2 SNPs at different loci showing some evidence of association with DCM (Palmer et al., 2003). A region on chromosome 1p.36.13 which included the gene *HSPB7*, previously associated with incident HF (Mestroni et al., 1999), and a nonsynonymous SNP (rs2234962) located within the coding sequence of *BAG3* (BCL2-associated athanogene 3) region on chromosome 10q26 were replicated in an independent cohort of 1165 DCM patients and 1302 controls ($p < 5.0 \times 10^{-7}$). In humans, variants in *BAG3* are associated with variable phenotypes including muscular dystrophy and cardiomyopathy (Huang et al., 2004).

A more recent large-scale case-control GWA that employed a three-staged design to analyze 4100 DCM cases and 7600 controls identified and replicated multiple SNPs on chromosome 6p21 (McNamara et al., 2001). The noncoding SNP located in *HCG22* was significantly associated with idiopathic DCM ($p = 4.9 \times 10^{-9}$). With the use of RNA transcriptome arrays the authors demonstrated that the SNP was an expression quantitative trait locus for class I and class II major histocompatibility complex heavy myosin proteins.

The largest GWAS of cardiac structure and function was performed among 6765 African Americans and identified four genetic loci related to left ventricular mass, interventricular septal wall thickness, left ventricular internal diastolic diameter, and ejection fraction, which reached genome-wide significance (Fox et al., 2013). However, none of these variants were replicated in the consortium of European ancestry (EchoGEN). Although these genetic variants have been associated with cardiac structure and function, they have not been linked to the development of HF.

Using a candidate gene approach in one large genotype–phenotype association study, 50,000 SNPs in approximately 2000 genes linked to cardiovascular disorders were assayed using the CardioMetabo Chip. In this study, two SNPs were identified to have significant association with advanced HF (Cappola et al., 2010). One of these two variants was in an intronic region of the *HSPB7* gene which encodes one of the small heat-shock proteins, expressed in both cardiac and skeletal muscle cells and plays a role in stabilizing sarcomeric proteins. GWA studies have shown the same locus to be associated with both DCM and HF. (Stark et al., 2010; Villard et al., 2011; Garnier et al., 2015). These studies may add further mechanistic explanations of the association of this genetic variant with both ischemic and nonischemic DCM.

Next-Generation Sequencing

Advances in DNA sequencing have allowed high-throughput in-depth sequencing of an individual's entire genome. Specifically, NGS uses parallel sequencing of multiple small fragments of DNA to analyze the entire DNA sequence or DNA sequence of interest. The first-generation sequencing methods (e.g., Sanger, Maxam, Gilbert) analyze the sequence of large DNA fragments by aligning a series of variable length products polymerized along the DNA template (Biesecker and Green, 2014). First-generation sequencing is used for sequence analysis of a specific gene or genes but is expensive and turnaround times for results are slow. In NGS multiple DNA fragments are sequenced in parallel and thus allow rapid DNA sequencing at a lower cost. The first step in preparation of NGS platforms is amplification and fragmentation of a patient's DNA, followed by isolation of the fragments by attachment to small beads. Sequencing is performed based on these fragments, and the results are computationally aligned against a "reference" genome, released by the National Center for Biotechnology Innovation (NCBI). The utility of NGS is the ability to perform multiple gene sequence analysis including the whole exome (WES) or genome (WGS). Third-generation sequencing uses parallel sequencing and single-DNA molecules rather than amplified DNA fragments as templates. The advantage over NGS is the elimination of potential errors in DNA sequencing that can occur during the DNA amplification process. In cases of Mendelian disorders with large number of candidate genes such as DCM and HCM, targeted gene panels are used that provide sequence data for a limited subset of candidate genes that have been previously demonstrated to be associated with the disease or mutations in which were considered pathogenic. These panels may be preferable to exome sequencing due to higher depth of coverage, lower cost, and lower likelihood of identification of variants with unknown significance. A number of validated gene sequencing panels with approximately 120 genes (**Table 1**) are used in the diagnosis of hereditary cardiomyopathies, and these continue to expand with inclusion of newly discovered causative genes. NGS with gene panels may provide false negative results in affected individuals who may have pathogenic variants in genes that are yet to be identified as causative in DCM. Performing WES in a trio, that is, the proband and both biological parents may have a higher diagnostic yield in identifying a previously unidentified pathogenic variant (Li et al., 2017).

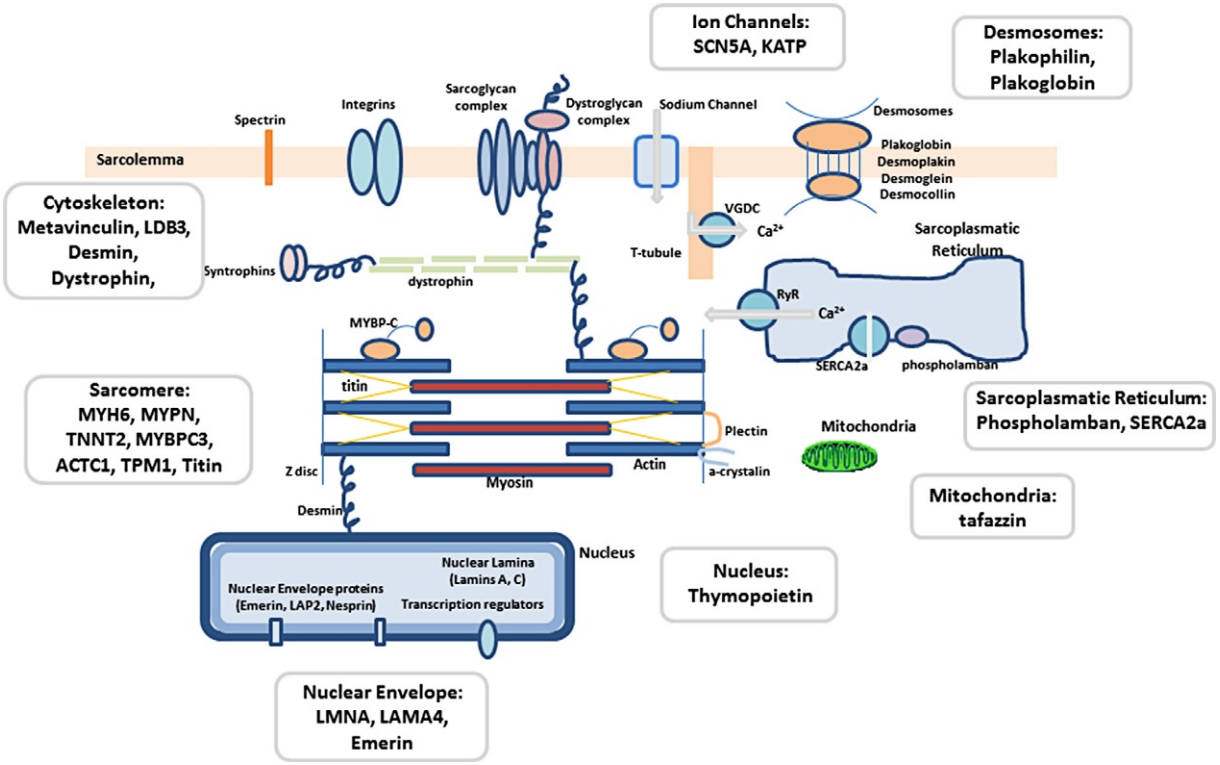
Genetics Causes of DCM

Familial DCM often displays an age-dependent penetrance, with patients typically manifesting disease in their fourth to sixth decades (Codd et al., 1989). The diagnosis is usually made when one or more first degree relatives are diagnosed with idiopathic DCM or if a first-degree relative had an unexplained sudden death under the age of 35 years. (Mestroni et al., 1999). The

prevalence of DCM has been estimated at approximately 1 in 2700 based on echocardiographic data from Olmsted County (Codd et al., 1989), but this is likely underestimated. Based on the same data the ratio of DCM to HCM prevalence was approximately 2 to 1.

Idiopathic DCM may be familial in approximately 1 in 5 patients with DCM when evaluated by obtaining a family history and by performing echocardiography. Obtaining a family history alone is insufficient to determine the familial nature of DCM as up to 40% of patients who have a familial pattern of transmission by echocardiography may be determined to not have a familial DCM. When patients with DCM are evaluated by genetic testing, pathogenic variants are found in up to 35% of cases indicating a high prevalence of familial DCM (Grunig et al., 1998).

Familial DCM is overall a very heterogeneous genetic disease, characterized by variable clinical presentation and age of onset, variable penetrance, and different modes of inheritance, depending on the gene/mutation involved. The most common pattern of inheritance observed is autosomal dominant inheritance. However, X-linked and mitochondrial inheritance also has been observed (Kamdar and Garry, 2016; Zaragoza et al., 2011). Mutations in greater than 40 genes have been implicated in familial DCM (**Table 1**, Figure). In total, these genes that are sequenced typically on standard cardiomyopathy gene panels account for 20%–48% of the molecular causes of the DCM (Grunig et al., 1998). It is important to note that the underlying genetic mutation should not override clinical diagnosis, since mutations in different genes can cause other cardiomyopathies such as HCM and left ventricular noncompaction as there appears to be an overlap in genetic causes of the various types of cardiomyopathy.



This concept can be exemplified by the phenotypic heterogeneity seen in the majority of HCM-susceptibility Z-disc genes that are also implicated in the pathogenesis of DCM (Bos and Ackerman, 2010). Similarly, the clinical presentations of both DCM and arrhythmogenic right ventricular cardiomyopathy (ARVC) can be caused by mutations in desmosomal protein genes (Elliott et al., 2010). Not only do mutations in the same gene yield distinct phenotypes, but sometimes a single mutation can manifest as HCM in one individual and DCM in another. One example of this phenotypic heterogeneity is the allelic heterogeneity seen in *TNNT2* gene, which encodes cardiac troponin T in DCM and HCM (Hershberger et al., 2013).

Mutations in the nuclear-envelope intermediate filament protein, LMNA, typically cause both DCM and progressive conduction disease, thus propagating the development of lethal arrhythmias and sudden cardiac death. Pathogenic variants in LMNA gene account for up to 5% of all cases of autosomal dominant DCM (van Tintelen et al., 2007). TTN, the gene encoding the sarcomere protein titin that represents the largest known protein in humans, genetic variation of which was associated with 25% of autosomal dominant cases of DCM (Schreiber and Kennedy, 2013). Most of the pathogenic variants found in the TTN gene were attributed mainly to truncation mutations, and the role of missense mutations in TTN is still unclear (Dahl et al., 2008). Sarcomere gene mutations account for up to 5% of all cases of DCM. These genes encode thick and thin filament sarcomere proteins and variants in which are also involved in the development of HCM and mainly include *MYH7*, *MYBPC3*, *ACTC1*, and *TNNT2* genes (Bonne et al., 1999). Pathogenic variances in mitochondrial DNA or in nuclear genes that code for mitochondrial components have also been

implicated in early-onset DCM. Patients with mitochondrial gene mutations often present in early childhood with DCM in conjunction with additional pathologies, including skeletal myopathies, neurological, or developmental diseases (Weintraub et al., 2017).

Patients with DCM as part of a neuromuscular syndrome classically have X-linked or autosomal recessive inheritance. Duchenne muscular dystrophy, Becker muscular dystrophy, and Emery–Dreifuss muscular dystrophy commonly present in childhood, with a predominant musculoskeletal phenotype with coexistent DCM. These dystrophies are caused by mutations in the DMD gene that encodes the protein dystrophin (Chen et al., 2013).

Genetic Testing in DCM: Recommendations and Implications

The role of genetic testing in DCM is a Class IIa recommendation (i.e., should be considered) (Hershberger and Siegfried, 2011) according to a HRS/EHRA expert consensus statement, since genetic testing can help confirm a molecular diagnosis of HF and facilitate screening of first-degree relatives (cascade screening). Cascade (also called stepwise) screening is a mechanism for identifying people at risk for a genetic disease by a process of systematic family evaluation. If a family member has abnormal cardiac screening, evaluation is then recommended in all first-degree relatives of this newly diagnosed patient. This stepwise screening should be continued until all consenting first-degree relatives of clinically affected have been evaluated.

The HF Society of America guidelines for evaluation of cardiomyopathies (Hershberger et al., 2009) recommend taking a comprehensive family history for three or more generations for all patients with cardiomyopathies (ARVC, DCM, HCM, LVNC, and restrictive), clinical screening for inherited cardiomyopathy in asymptomatic first-degree relatives, genetic and family counseling, consideration of genetic testing, and seeking further consultation with professionals who are expert in cardiovascular genetics. For DCM, clinical screening should consist of a history and examination, an electrocardiogram, an echocardiogram, and measurement of the creatine kinase level. Repeat clinical screening at regular intervals is also recommended and is outlined below. Genetic testing using a broad cardiomyopathy panel is typically offered to the most affected individual in a family or the proband to facilitate family screening. Genetic testing results may also affect clinical management of patients, for example, in patients with LMNA-associated cardiomyopathy who are susceptible to developing life-threatening arrhythmia regardless of left ventricular ejection fraction (LVEF), an implantable cardioverter–defibrillator (ICD) can be considered before the LVEF falls to below 35%.

Patients with DCM who have significant conduction tissue disease and/or a family history of premature sudden death, familial DCM due to mutations in the *LMNA* or *SCN5A* genes should be considered, and genetic testing in that situation is considered a Class I recommendation (Meune et al., 2006; Priori et al., 2015). In the presence of lamin A/C mutation the development of AV block is associated with poor outcomes and pacing therapy is insufficient to prevent SCD, thus supporting the use of prophylactic ICDs rather than pacemakers when cardiac involvement is present. Risk factors for sudden death and appropriate ICD therapy include nonsustained ventricular tachycardia, left ventricular ejection fraction <45%, male sex, and lamin A or C nonmissense mutations. Patients with laminopathies but with EF >30%–35% and indications for pacemaker or the aforementioned risk factors may be considered for an ICD (class IIa, Level of Evidence B) (Meune et al., 2006; Priori et al., 2015).

Identifying a pathogenic variant could help with counseling at-risk family members and determine the need and frequency of clinical evaluations. Due to the variable age of onset, a normal ECG and echocardiogram does not rule out the possibility of developing DCM in family members who are screened, and longitudinal follow-up of first-degree relatives should be performed (**Table 2**). Given the variable age of onset, clinical screening repeated at intervals is recommended, even if clinical genetic testing has not identified a disease-causing mutation in the family. The frequency of repeated screening is dependent on the results of genetic testing as well as on the type of cardiomyopathy (**Table 2**). If a disease-causing mutation is identified in the proband first degree relatives could be offered genotyping for the specific pathogenic mutation which would be far more cost-effective than performing an entire cardiomyopathy gene panel. The frequency of clinical screening in relatives known to be mutation positive should be performed at more frequent intervals due to an increased probability of those individuals developing cardiomyopathy (Hershberger et al., 2009). As a general rule, clinical screening of family relatives is recommended every 1–2 years up to age 20 years, every 2–3 years from 20 years to 40 years, and then every 3–5 years thereafter (Weintraub et al., 2017).

Table 2 Screening recommendations for inherited cardiomyopathies

Cardiomyopathy phenotype	*Screening interval (genetic testing and/or clinical family screening is negative)*	*Screening interval (mutation carrier)*	*Level of evidence*
Hypertrophic	Every 3 years until age of 30 (yearly during puberty); only if symptoms develop thereafter	Every 3 years until age of 30 (yearly during puberty); every 5 years thereafter	B
Dilated	Every 3–5 years beginning in childhood	Yearly in childhood; every 1–3 years in adults	B
ARVC	Every 3–5 years after age 10	Yearly after age 10 to 50 years of age	C
LVNC	Every 3 years beginning in childhood	Yearly in childhood; every 1–3 years in adults	C
Restrictive	Every 3–5 years beginning in adulthood	Yearly in childhood; every 1–3 years in adults	C

LVNC = left ventricular noncompaction.
ARVC = arrhythmogenic right ventricular cardiomyopathy.

Functional Significance of Genetic Variant Associated With DCM

The genes that have been implicated in DCM are diverse and encode the sarcomere, cytoskeleton, nuclear envelope, transcriptional pathways, and mitochondrial proteins. The mechanistic explanations of the development of DCM as a result of these mutations are complex. This can include alterations in force generation and transmission, altered metabolic profiles, abnormal nuclear integrity, altered protein degradation, and ion channel abnormalities which can finally lead to a final common pathway, resulting in LV dysfunction and HF (McNally et al., 2013).

Mutations in the nuclear-envelope intermediate filament protein, *LMNA*, typically cause DCM with progressive conduction disease, thus propagating the development of lethal arrhythmias and sudden cardiac death. Pathogenic variants in LMNA gene account for up to 5% of all cases of autosomal dominant DCM (van Tintelen et al., 2007). The lamin A/C gene (LMNA) encodes the A-type lamins A and C, which constitute the inner nuclear membrane. Several studies have shown that besides providing structural integrity to the cell nuclear envelope, particularly in heart and skeletal muscle, A-type lamins are involved in a number of other functions including mechanosensing, chromatin organization, DNA replication, transcription, and repair (Schreiber and Kennedy, 2013; Dahl et al., 2008). The variety of tissues involved, and variable functions of A-type lamins, may explain the increasing number of diseases associated with LMNA mutations, starting from the first case described in Emery–Dreifuss muscular dystrophy (EDMD) (Bonne et al., 1999) and then followed by more than 15 different laminopathy disorders described in man (Schreiber and Kennedy, 2013). The full range of functions of lamins and the mechanisms underlying these different phenotypes are complex and still incompletely understood. Genetic mutations of Lamin A gene causing cardiomyopathy are believed to cause loss-of-function and, either by haploinsufficiency or by dominant negative effect, lead to altered structural organization and/or altered protein expression and transcription factors critical for normal cardiomyocyte function (Schreiber and Kennedy, 2013; Dahl et al., 2008; Chen et al., 2013). A-type lamins form a molecular scaffold under the inner nuclear membrane and connect structurally with the cytoplasm by binding integral proteins of the nuclear envelope (Chen et al., 2013; Davidson and Lammerding, 2014). This network connects the nucleus to the extracellular matrix and provides nuclear anchorage, mechanical stress sensing, and resistance to pathologic deformation of the cell. Previous studies have shown that cells-expressing LMNA mutations exhibit disorganization of the proteinaceous meshwork, instability, and structural damage of the nuclear envelope. For example, the LMNA D192G mutation, which causes a severe form of DCM, is characterized by dramatic ultrastructural changes and disruption of the cardiomyocyte nucleus, as observed in heart tissue from patients and in cellular models (Sylvius et al., 2005). Further studies have suggested that cardiomyopathy mutations in LMNA lead to increased nuclear fragility resulting in cell death and progressive failure in tissues that are exposed to repetitive mechanical stress, such as seen in normal heart function (Davidson and Lammerding, 2014). Additional mechanisms associating LMNA mutations with DCM are through repetitive disruptions of the nuclear envelope, leading to impaired protein distribution into cell compartments, translocations of large amount of proteins to the cytoplasm that trigger cell apoptosis as well as impairment in gene expression derived from epigenetic changes in the chromatin that leads to disruption of intracellular signaling pathways important for cardiomyocyte function and survival (Tesson et al., 2014).

TTN, the gene encoding the sarcomere protein titin that represents the largest known protein in humans, was recently shown to explain over a 25% of all autosomal dominant cases of DCM (Gerull et al., 2002). Most of the pathogenic variants found in the TTN gene were attributed mainly to truncation mutations (Herman et al., 2012). Two main titin molecules exist in the sarcomere, and they are necessary for sarcomere assembly through there attachment at the Z-line and M-line (Knöll et al., 2002). Mutations that substantially disrupt the structure of full-length titin might cause DCM by means of several mechanisms. RNA- and protein-surveillance pathways most likely degrade some truncated titin peptides (Gramlich et al., 2009). Decreased titin levels could limit sarcomere formation and might cause cardiac dysfunction and remodeling. Truncated titin proteins in subjects with DCM would most likely be anchored at the Z-line but would not include the M-band residues that anchor titin to the middle of the sarcomere through myomesin, encode a kinase domain, and interact with many proteins. Moreover, the M-band portion of titin is implicated in sensing and modulating sarcomeric force. Therefore, loss of these interactions could lead to DCM through the disturbance of the normal regulation of sarcomeric force (Lange et al., 2005; Gräter et al., 2005). Further study of the functional consequences of TTN truncating mutations on myocardial physiological features and myocyte signaling is warranted. Elucidating the mechanisms underlying the functional effects of TTN truncating mutations and analysis of other classes of TTN genetic variations (e.g., missense variants) should improve our understanding of the importance of TTN in the pathogenesis of DCM.

Patients with DCM as part of a neuromuscular syndrome classically have X-linked or autosomal recessive inheritance. Duchenne muscular dystrophy, Becker muscular dystrophy, and Emery–Dreifuss muscular dystrophy commonly present in childhood, with a predominant musculoskeletal phenotype with coexistent DCM. These dystrophies are caused by mutations in the DMD gene that encodes the protein dystrophin (Towbin et al., 1993). Pathogenic variances in mitochondrial DNA or in nuclear genes that code for mitochondrial components have also been implicated in early-onset DCM. Patients with mitochondrial gene mutations often present in early childhood with DCM in conjunction with additional pathologies, including skeletal myopathies, neurological, or developmental diseases (Weintraub et al., 2017). Multiple genes were associated with the development of LVNC, predominantly inherited in an X-linked pattern. However, other patterns were described including mitochondrial inheritance. Gene mutations commonly involved in LVNC include the TAZ/G4.5 gene resulting in Barth syndrome, sarcomere-encoding gene mutations, most commonly in MYH7 and MYBPC3, as well as mutations in the SCN5A and DMD genes (Towbin et al., 2015).

Genetics to Assess Treatment Response in HF and Heart Transplantation

Standard medical therapy has dramatically improved survival in patients with HF. However patients often respond in a variable manner to medical therapy. Genetic variation may play an important role in this variable response to medications used to treat HF. Susceptibility loci within genes encoding proteins involved in neurohormonal pathways have been implicated in variable drug response. Although GWAS have identified drug–gene interactions in other cardiovascular conditions (Bruck et al., 2005), no such allelic variants have been associated with response to HF therapies.

Candidate gene analysis has identified the Arg389Gly variant in the beta-1 adrenergic receptor to play an important role in the variable response observed with bucindolol therapy.

The Arg389 variant is associated with greater agonist-promoted G protein coupling, resulting in a more active form of the beta-1 adrenergic receptor (Terra et al., 2005). Arg389 homozygotes exhibit enhanced chronotropy, contractility, and effective sympathetic blockade by bisoprolol (Terra et al., 2005). The gain-of-function Arg389 β1-adrenergic receptor polymorphism was associated with higher LVEF and peak oxygen consumption, better response to beta-blockade and overall improved survival with bucindolol therapy (Liggett et al., 2006; Cresci et al., 2009). However, these findings were not replicated in a substudy of the MERIT-HF trial (White et al., 2003). Polymorphisms Ser49Gly in the beta-1 adrenergic receptor gene and the Glu27Gln variant in the beta-2 adrenergic receptor gene have also been reported to modulate beta-blocker response in HF patients as homozygotes exhibit greater improvement in echocardiographic parameters with beta-blockers compared with wild-type subjects (Metra et al., 2010). Patients with HF who are homozygous for the Gln27 variant have a diminished response to carvedilol (Nelveg-Kristensen et al., 2015). However, subsequent larger studies have not confirmed these associations (White et al., 2003). Due to a lack of replication of findings of these candidate-gene and drug-response associations, genotyping to guide administration and dosing of beta-blockers in HF has not found clinical applicability.

Allelic variations of the genes encoding proteins of the renin–angiotensin–aldosterone axis have also been studied. One of the most commonly studied polymorphism is the insertion/deletion variant of the angiotensin-converting enzyme gene (*ACE I/D*). The deletion of a 250-bp DNA fragment was detected within the intron 16 of the angiotensin I-converting enzyme (*ACE*) gene that is associated with higher ACE activity, progression of left ventricular remodeling, and HF. Patients with this intronic deletion most benefit from administration of high doses of ACE inhibitors, suggesting that determination of ACE genotype may help to target therapy for patients with HF (Palmer et al., 2003; Huang et al., 2004; McNamara et al., 2001; Andersson et al., 1999; McNamara et al., 2004).

Prior studies in hypertensive patients demonstrated that DD homozygotes had increased plasma aldosterone levels compared with heterozygotes, despite long-term treatment with ACE inhibitors (McNamara et al., 2001). In the Genetic Risk Assessment of Cardiac Events Study of 479 patients with HF, the presence of the D variant was associated with lower transplant-free survival at 1 year, mainly in patients on low-dose ACE inhibitors or not treated with beta-blockers (McNamara et al., 2001; McNamara et al., 2004). These results were not replicated in a recent Danish cohort of 534 HF patients treated with ACE inhibitors which suggested no association between pharmacogenetic scores, including variants in genes encoding ACE, angiotensin II receptor type I, and bradykinin receptor, with mortality (Díaz-Molina et al., 2012).

As opposed to the SNPs in various genes encoding proteins of the neurohormonal axis, polymorphisms in genes encoding the hepatic P450 cytochrome enzymes CYP3A5 and CYP3A4 are important determinants of metabolism of tacrolimus which is the cornerstone of immunosuppressant therapy following heart transplant. A SNP in the third intron of *CYP3A5* (rs776746, 6986 G>A) affects the premessenger mRNA splicing, resulting in lack of the active protein. Individuals homozygous for this allele (*CYP3A5*3*) demonstrate reduced tacrolimus clearance and require lower medication doses to achieve the target plasma concentrations compared with carriers of the wild-type alleles (Elens et al., 2011). An additional SNP, the *CYP3A4*22* (rs35599367, intron 6 C>T) which results in reduced hepatic *CYP3A4* mRNA expression and enzyme activity, has been associated with decreased tacrolimus clearance and lower tacrolimus dose requirements (Deininger et al., 2016; Birdwell et al., 2015). Although the *CYP3A5* SNPs do not seem to affect prognosis after heart transplantation, they are increasingly being tested in heart transplant centers as they guide initial tacrolimus dosing requirements. The Clinical Pharmacogenetics Implementation Consortium [CPIC] dosing guideline for tacrolimus recommends increasing the starting dose by 1.5–2 times the recommended starting dose in patients who are CYP3A5 intermediate or extensive metabolizers, though total starting dose should not exceed 0.3 mg/kg/day (Parsa et al., 2011).

Genetics and HF Prognosis

Several SNPs have been demonstrated to be involved in HF phenotype and severity of the disease. A three-stage genome-wide, case-control, and case-only association study was performed, and 21 SNPs associated with cardiac hypertrophy were identified (Pugh et al., 2014). The control population consisted of 851 Amish individuals as part of the Heredity and Phenotype Intervention Heart (HAPI Heart) Study. The HF cohort consisted of unrelated prospectively enrolled patients from the University of Cincinnati College of Medicine ($n=1302$) and the University of Maryland School of Medicine ($n=308$), with left ventricular ejection fraction (LVEF) <35%.

One of the SNPs associated with hypertrophy (rs2207418, $p=8\times10^{-8}$) was associated with reduced ejection fraction (HFrEF) (RR 1.85, $p=0.0019$), and among HF patients, rs2207418 was associated with increased mortality (HR 1.51, $p=0.0004$). Among

HF patients in the European cohort of the CHARGE consortium population described above, analysis suggested a locus on chromosome 3p22 in the intron of a CKLF-like MARVEL transmembrane domain containing 7 (*CMTM7*), a chemokine-like factor gene to be associated with higher mortality, with an odds ratio about 1.5 ($p = 0.001$). No loci reached statistical significance for association with prognosis in HF patients of African ancestry (Morrison et al., 2010). An expansion of the CHARGE consortium analysis with data and follow-up from 2828 new HF cases from the Atherosclerosis Risk in Communities (ARIC) Study, the Cardiovascular Health Study (CHS), the Framingham Heart Study (FHS), the Health, Aging and Body Composition (Health ABC) Study, and the Rotterdam Study (RS) identified a SNP (rs9885413) on chromosome 5q22 associated with 36% increased risk of death ($p = 2.7 \times 10^{-9}$) but not with incidence of the disease in patients with HF. The SNP was associated with expression of *TSLP*, a gene encoding the cytokine TSLP that promotes Th2 immune response and is involved in angiogenesis and fibrosis (Smith et al., 2016).

Additional studies are needed to validate these finding and to investigate the use of this SNP in predicting severe HF phenotypes that may require more aggressive therapy.

Clinical Implications and Future Perspectives

Although the contribution of genetic variation to pathogenesis, progression, and outcomes of patients with HF is being increasingly accepted, the currently available data are limited by the heterogeneity in the phenotype of HF and the lack of reproducibility of the generally modest effect size (odds ratio ≤ 1.5) associated with susceptibility variants. One approach to overcome this limitation would be NGS (whole exome or whole-genome sequencing) to identify regions associated with HF risk; however this approach given the extent and complexity of data is fraught with statistical and bioinformatic interpretation complexity. Functional genomic studies to identify the role of noncoding or regulatory regions or loci in linkage disequilibrium to demonstrate the significance of genetic variants not only on gene but also on cardiac function are necessary. Applying genotyping and sequencing strategies to clinical practice is also challenging due to physician and patient perceptions, demonstration of incremental value of such information over existing clinical tests, insurance coverage, and stringent criteria applied to adopt such strategies into clinical practice guidelines.

In the case of inherited cardiomyopathies, when performing genetic testing, the standard approach is usually to perform a full screen of all known genetic variants in the index case (proband), and then perform focused genetic testing, if found to be pathogenic or likely pathogenic, in at-risk family members. The development of multigene panels and addition of new genes associated with cardiomyopathy enables a more accurate diagnostic yield. In one study, increasing the DCM gene panel from 5 to 46 genes increased the clinical sensitivity of the test from 10% to 37%, but at a cost of significant increase in variants of uncertain significance (VUS), with a parallel increase in inconclusive cases from 4.6% to 51% (Pugh et al., 2014).

However, whole-genome and -exome sequencing the cost of which is decreasing, information from which can be incorporated in the electronic medical record and the potential availability of this information as new pathogenic variants are discovered especially if standard cardiomyopathy gene panels are negative pose as attractive alternative testing strategies. Currently, clinical whole-exome sequencing is reserved for patients, and their parents (a trio) with undiagnosed syndromes or in families in whom targeted gene panels do not identify an etiologic genetic variant.

Irrespective of sequencing strategies, the importance of genetic counseling for all patients and first-degree relatives of patients with familial DCM, including discussion of risks, benefits, and options for such genetic testing should be emphasized, and if such expertise does not exist, referral of such patients to centers experienced in comprehensive genetic evaluation should be made.

Although several genomic studies as described above have identified multiple novel genes and loci implicated in HF and DCM, no novel drug targets have emerged from these studies. Gene editing is an emerging technique that can be applied to target pathogenic genes associated with DCM and may be useful especially in curing monogenic diseases. For example, Long et al have used gene editing to restore dystrophin expression in an animal model with muscular dystrophy with promising results (Long et al., 2016). The challenges lie in interpreting the massive amount of data generated from large genetic studies and in understanding which of these and how significant genetic variants directly lead to cardiomyopathy and HF especially if these are located in intergenic or intronic areas. However, these studies may shed light on to mechanistic pathways that may help in understanding the biology and pathogenesis of HF.

Conclusions

The role of rare genetic variation in the development, progression, and prognosis of cardiomyopathies is well established. However we currently lack evidence demonstrating the role of common genetic variation in complex forms of HF due in part to phenotypic heterogeneity and the need for additional studies of gene–gene, and gene–environmental interactions that may also influence susceptibility to develop HF. The decreased cost and increased availability of NGS, improved phenotype characterization, and incorporation of multiple "omics" platforms may allow the promise of an individualized approach to HF patients that would perhaps eventually improve outcomes in this complex and morbid disease process.

Formation of the Embryonic Cardiac Crescent and Heart Tube

In its earliest stages, the embryo exists as a bilayer disc, with two single cell thickness sheets of cells (epithelia) suspended between two fluid filled cavities, the yolk sac and the amniotic cavity (**Fig. 1A**). The ventral epithelium (facing the yolk sac) is the hypoblast, which will eventually be relegated to extraembryonic structures. The dorsal epithelium (facing the amniotic cavity) is the embryonic ectoderm, which will form the embryo. This single layer will transform into three embryonic germ layers: the ectoderm (nervous system and skin), mesoderm (heart, skeleton, muscle, and connective tissue), and endoderm (gut). Embryonic mesoderm and endoderm differentiate from the primitive ectoderm by a process known as gastrulation. Gastrulation can be observed in the embryo as a groove forming in the epiblast, starting at the tail end (caudal) and gradually extending toward the head (cranially) to an endpoint known as the prechordal plate (**Fig. 1B**). This groove is known as the primitive streak, and its leading edge is the primitive node. What forms this streak is cells detaching from the epiblast and invading the space between the epiblast and hypoblast. As this occurs, these cells transform into a new cell type (mesoderm) and are no longer part of an epithelium, but are migratory and dynamic cells. This is an example of a developmental process known as epithelial to mesenchymal transition (EMT). On the molecular level, these cells respond to EMT inducing signaling molecules including TGF-β and Notch (Mercado-Pimentel and Runyan, 2007; Luna-Zurita et al., 2010), losing cell polarity and downregulating cell–cell adhesion proteins such as E-cadherin to allow migration (Thiery and Sleeman, 2006). The heart forms from these migrating cells as a crescent-shaped structure cranial to the prechordal plate and extending along both sides. The cells making up this cardiac crescent are termed the lateral plate mesoderm

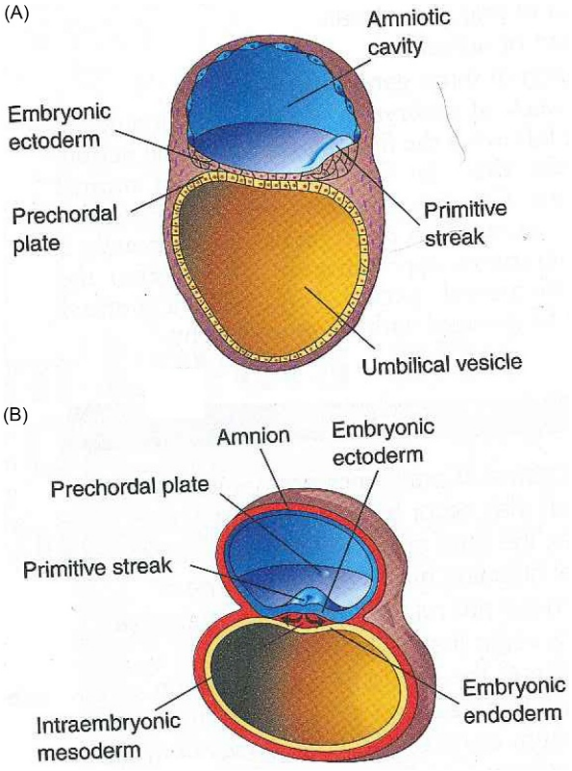

Fig. 1 The embryonic bilayer disc, and initiation of gastrulation; day 15–16 postconception. (A) Sagital section (cranial to the *left* of image, caudal to the *right*) through the embryo showing the embryo (ectodermal layer only) suspended between the amniotic cavity and the yolk sac. (B) Transverse section as the primitive streak begins at the caudal end of the embryo and extends cranially toward the prechordal plate. Cells delaminate from the ectoderm at the primitive streak and form the other two germ layers—mesoderm and endoderm- during the process of gastrulation. From Moore and Persaud, *The Developing Human*, *8th edition* Saunders Elsevier; 2008, p. 56.

(**Fig. 2A** and **B**). Fate mapping studies suggest that many cell fate decisions are set during gastrulation or even before (Fishman and Chien, 1997; Garcia-Martinez and Schoenwolf, 1993; Xin et al., 2013). For example, the apex of the cardiac crescent is formed from cells that have migrated through the primitive streak closest to the primitive node. These cells will contribute to the most anterior portion of the heart, connecting to the outflow tracts and the secondary heart field (see section "Formation of the Linear Heart Tube and Cardiac Looping"; **Fig. 2**; compare B and C). The cells on either side of this region have migrated through the midportion of the streak and will form the primitive ventricle (eventual left ventricle). Finally, the most lateral and caudal cells are those that have migrated through the most posterior part of the streak and will become the inflow and atrium. The exact details of when and how this occurs are still under debate and refinement as better techniques become available (Abu-Issa and Kirby, 2007; Cui et al., 2009; Ehrman and Yutzey, 1999). Fate-mapping studies using live-cell tracking and time-lapse imaging demonstrate that these cells move as a cohort (tissue motion) rather than individually migrating. In this way, the cells maintain their relative positions within a tissue and eventually within the organ (Cui et al., 2009). Although it is not yet apparent in the symmetric embryo at this early stage, the basic left–right asymmetry of the embryo is set during gastrulation. This occurs via concentration gradients of the factors sonic hedgehog (shh) and fibroblast growth factor 8 (fgf-8) created by ciliary motion at the primitive node. This in turn causes a cascade of downstream genes to be activated, including nodal, lefty, and pitx-2 (Capdevila et al., 2000; Rodriguez-Esteban et al., 2001; Tsukui et al., 1999) (**Fig. 2D**).

Formation of the Linear Heart Tube and Cardiac Looping

The cardiac crescent is a symmetric structure, and it will next fuse in the midline into an initially symmetric appearing heart tube as shown in **Fig. 2C, E** and **F**. This primitive heart tube is two cell layers thick. There is an inner endocardium and an outer myocardium. The endocardium will eventually form the inner lining of the heart and the valves, in processes that we will discuss in later sections. The myocardium is cardiac muscle, and will become thicker and organize into the contractile myocardium of the atria and ventricles. Fusion of the primitive heart tube occurs as the ectoderm dorsal to the crescent folds to create the neural canal, and the endoderm ventral to the crescent folds to create the foregut (**Fig. 2E**). As the foregut forms, it moves dorsally, pushing the cardiac crescent ventrally and medially, such that the two arms of the crescent fuse into a tube sitting directly in front of the foregut

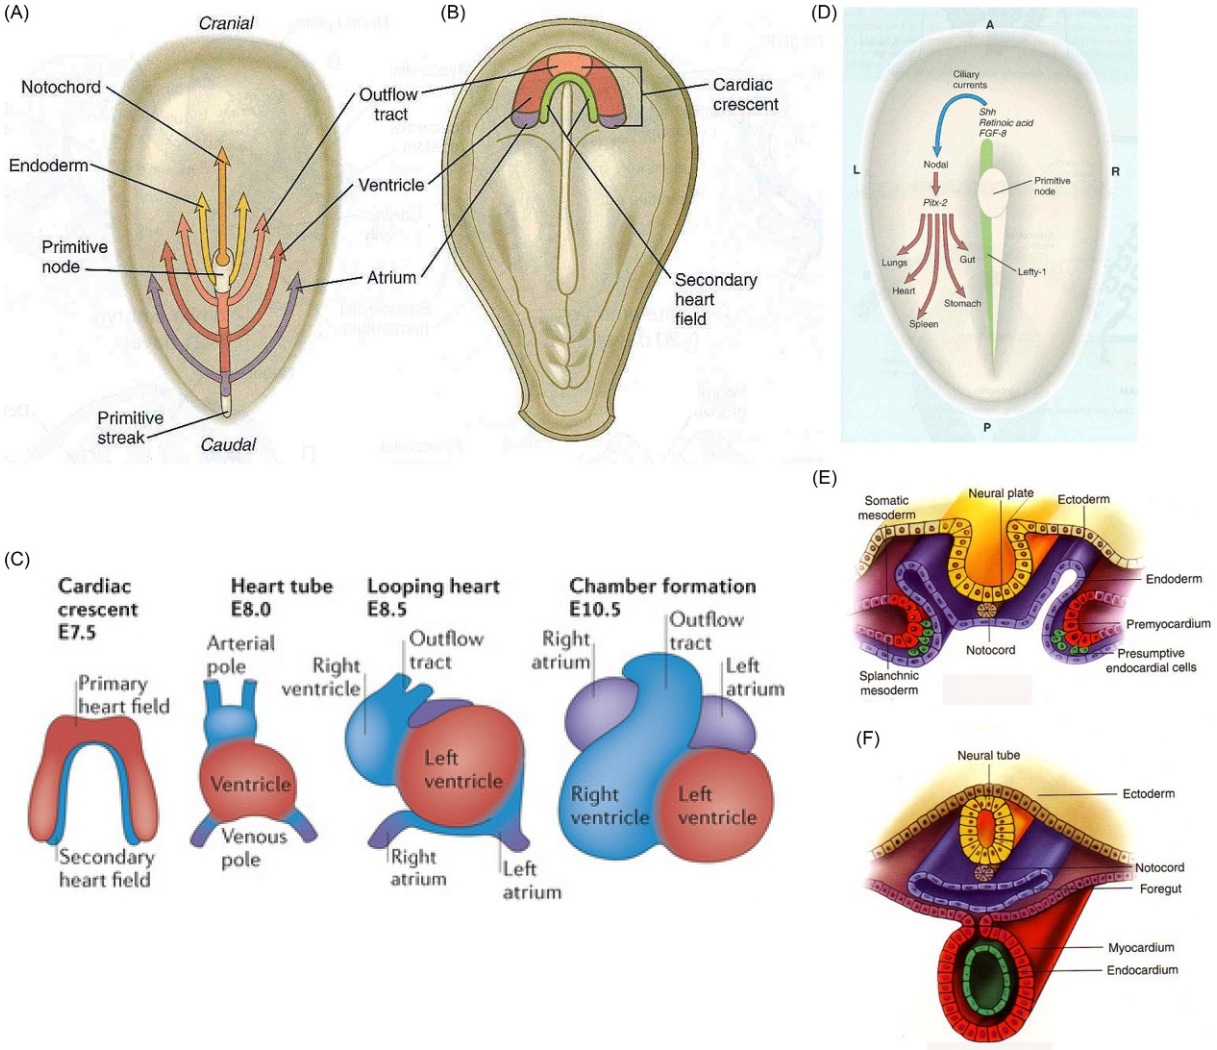

Fig. 2 Cell fate decisions in the heart are set at gastrulation, as is *left–right* asymmetry of the entire embryo. (A) Position of cells migrating through the primitive steak determines their eventual position in the developing heart. (Fig. 2F). As fusion of the heart fields occurs, the heart begins to beat. Blood has not yet been formed by the embryo, but fluid is pumped through the heart as it begins to beat. The posterior/inferior portion of the tube retains two limbs, the sinus venosus or inlet portion of the tube (Fig. 2C), which draws the fluid into the heart tube. The fluid then passes through the atrial and ventricular segments and is pumped out through the anterior/superior outflow tract, which connects to aortic sac and paired dorsal aortae. In a human fetus, this happens at approximately 22 days gestation, but in a mouse embryonic on day 8.

Within four days of heart tube formation, the heart tube undergoes a dramatic change in a shape known as cardiac looping. Here, the heart tube loses its symmetry, and forms an "S" shape, with distinct left and right sides (Steding, 2009) (Fig. 3A–E). Much is known about the molecular signaling and gene expression patterns involved in looping. Several cardiac transcription factors have been shown to be important to looping, including Nkx2-5, MEF2, and Hand2 (Yamagishi et al., 2001; Karamboulas et al., 2006; Jamali et al., 2001a,b; Christoffels et al., 2006a; Hiroi et al., 2001; Cui et al., 2009; Srivastava et al., 1997; Han et al., 2006; Han and

Olson, 2005; McFadden et al., 2005; Tsukui et al., 1999). Disruption of any of these factors in mice by gene knockout causes embryonic lethality, due to abnormal looping. Cardiac looping also involves differential growth, with higher proliferation of myocytes along the outer curvature (outflow tract and ventricular segments) than the inner curvature (inflow tracts and atrial segment; **Fig. 3E**) (Moorman and Christoffels, 2003). Furthermore, there is a migration of cells from a specialized pool of cardiac precursors anterior and medial to the original heart field known as the secondary heart field, as shown in **Fig. 3F**; also see **Fig. 2C** (Kioussi et al., 2002). These cells populate the outflow tracts and part of the ventricular segment, specifically the eventual right ventricle (**Fig. 3G–I**). (Kelly and Buckingham, 2002; Mjaatvedt et al., 2001; Waldo et al., 2001; Christoffels et al., 2006b). Discovery of the secondary heart field was primarily using cell lineage tracing studies. In chick hearts marked just after fusion of the heart tube, a population of unmarked cells interposed themselves between marked cells of the distal and middle heart tube one day later (Mjaatvedt et al., 2001). Studies in mouse compared to chick suggest that the anterior heart field in mouse forms most of the right ventricle (Kelly and Buckingham, 2002; Zaffran et al., 2004). What differences are there in humans remain unknown. Both differential growth and addition of secondary heart field cells serve to elongate the outflow tract and enlarge the ventricles relative to the atria (Moorman and Christoffels, 2003). In addition, there are mechanical forces involving the cytoskeleton, including nonmuscle actin bundles (Itasaki et al., 1991) and myosin (Linask and Vanauker, 2007), the motor protein dynein (Basu and Brueckner, 2008; Brueckner, 2001; Supp et al., 1997), and microtubules (Icardo and Ojeda, 1984).

Normal looping occurs with the ventricular segment and outflow tract out-pouching anteriorly and to the right (D-looping), and the sinus venosus and atria shifting posteriorly and to the left. Importantly, the sinus venosus also moves cranially such that it lines up with the outflow tracts along the horizontal body axis. This repositioning is critical for proper atrioventricular and ventriculoarterial connections.

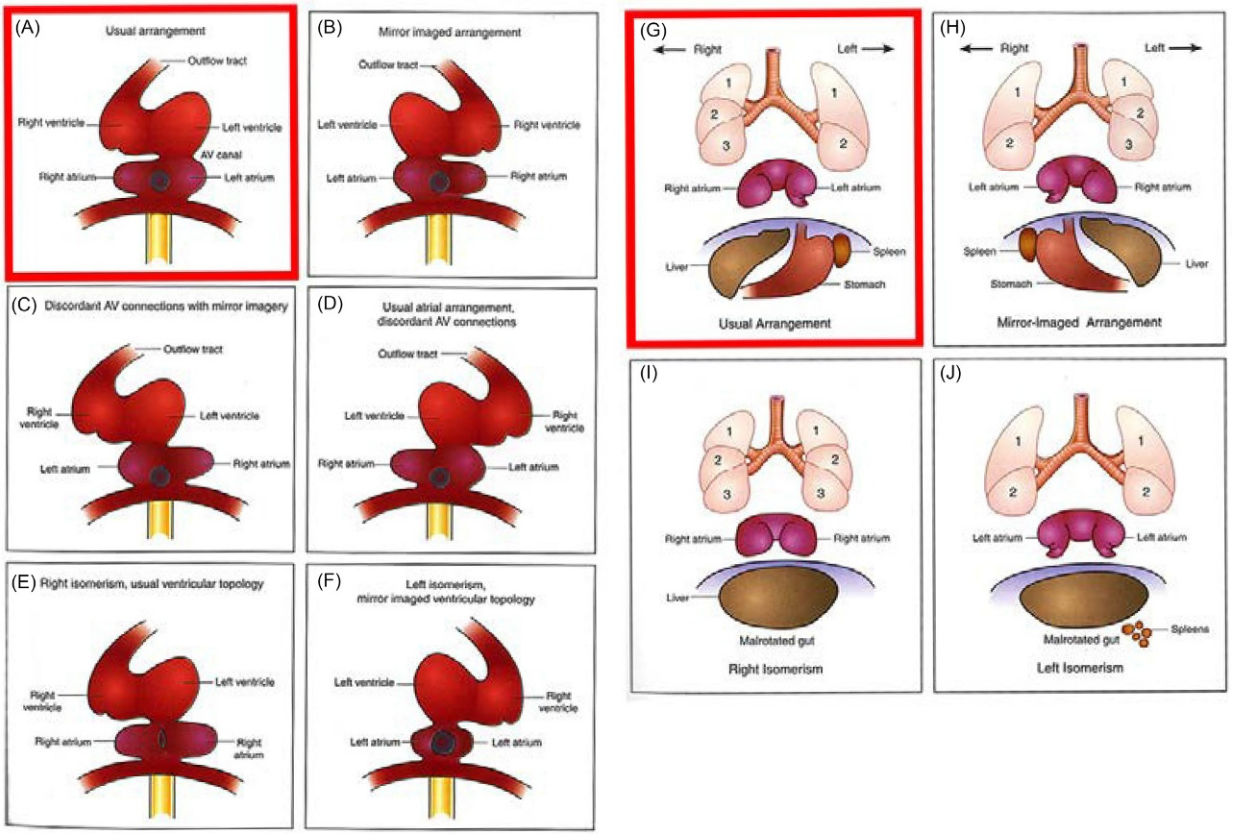

Fig. 4 Diagram of normal cardiac D-looping with normal AV connections (A). Also shown are several common abnormal looping patterns, including mirror image L-looping with normal AV connections (B), discordant AV connections with atrial situs inversus (C), and with normal atrial situs (D). Both C and D are usually associated with discordant ventriculoarterial connections, creating congenitally corrected transposition. Below are *right* and *left* atrial isomerism, or bilateral *right* sidedness (E) and bilateral *left* sidedness (F), generally found along with anomalies of the systemic and pulmonary veins, of cardiac septation and of the inflow and outflow tracts. *Right* and *left* isomerization syndromes also go along with abnormal sidedness on other asymmetric organs of the chest and abdomen, or heterotaxy. Shown in G is normal visceral organ arrangement. H shows mirror image, or situs inversus; I *right* isomerism and J *left* isomerism. Adapted from: Brown, N. and Anderson, R. (1999). Symmetry and laterality in the human heart: Developmental implications. In Harvey and Rosenthal (eds.) *Heart development*, p. 449 and 459. Academic Press.

Heart Defects Arising from Abnormalities of Looping

Sometimes, looping can occur to the left, with the venous pole and atria moving rightward and the ventricles and arterial pole moving leftward. This is referred to as L-Looping (**Fig. 4B**, D and F). The ventricles switch positions when L looping occurs: the right ventricle is on the left and left ventricle on the right. This is often associated with L malposition of the great arteries, in an interesting anomaly known as congenitally corrected transposition of the great arteries (CCTGA). Here the right atrium is connected to the left ventricle, which is then connected to the pulmonary artery (PA). The left atrium is connected to the right ventricle, which is connected to the aorta. Thus, the atrioventricular and ventriculoarterial connections are both incorrect, but the circulation of blood is actually correct—the two abnormal connections correct the circulation. CCTGA can be an isolated anomaly, or can occur with other congenital heart defects such as abnormal septation or abnormal valve development. Also in the category of abnormal laterality are global embryonic defects known collectively as heterotaxy (**Fig. 4H–J**). In heterotaxy, left–right assignments along the body axis are individually randomized. Thus, the heart can end up on the right side of the body instead of the left, sometimes with a right sided stomach and liver. In addition, it is possible to have an abnormal laterality within the heart, with the left and right atria switching positions (atrial situs inversus) or being bilaterally symmetric with two left atria, or two right atria. When laterality and/or looping are abnormal, each segment is independent of the last, leading to a complex set of possible anomalies.

Ventricular Inlet Septation: Endocardial Cushions

After cardiac looping has occurred, the orientation of the heart tube has changed, but the blood flow through it remains essentially the same: blood flows into the heart from the sinus venosus, through the atrial segment into the ventricle, then out the conotruncus to the aorta. Inflow and atrial segments are leftward, and after D looping, the ventricle and outflow segments are rightward. During the next phase of heart development, the atrioventricular (inlet) and ventriculoarterial (outlet) structures will realign and septate, forming four chambers, a right and left atrium and a right and left ventricle. All four chambers undergo extensive remodeling, with muscular septa dividing right and left atria and ventricles, and one-way valves between atrium and ventricle and between ventricles and outflow tracts. The four cardiac valves serve to ensure unidirectional flow through the heart as it pumps, opening and closing sequentially with the cardiac cycle. In human embryos, this occurs during week 7 of gestation (Dhanantwari et al., 2009; Steding, 2009).

The cardiac valves are formed primarily from a tissue known as the endocardial cushions. This is a second example of EMT in the developing heart. Within the primitive heart tube, even before looping, there are faint constrictions between the atrial and ventricular segments (AV groove) and in the forming conotruncus between the ventricular segment and the outflow tract. The endocardial cushions initially appear as swellings in the AV groove and conotruncus, caused by cells from the inner lining of the heart (endocardium) undergoing EMT and migrating into the extracellular matrix between the endocardium and the myocardium (**Fig. 5A, C** and D) (Lin et al., 2012). Signaling involving the TGF-β family of genes, BMP2, Notch1, and TBX20 among others, are important to this process. This signaling is back and forth between the myocardium and endocardium to initiate and maintain this process (Brown et al., 1996, 1999; Jiao et al., 2006; Combs and Yutzey, 2009).

In both the AV canal and in the conotruncus, four distinct cushions form, named by their anatomic locations. We will start with septation of the aterioventricular canal (**Fig. 5B**). In the AV canal, the cushions are superior, inferior, left, and right. The AV canal septates as the superior and inferior cushions grow toward one another and fuse in the midline. The AV valves themselves form from remnants of the four cushions, which thin out into acelluar fibroelastic structures called leaflets: a leftward mitral valve with two leaflets, and a rightward tricuspid valve with three. The developing tricuspid valve is shown in **Fig. 5D** and **E**. The valve delaminates from the ventricular wall as it forms, with the leaflets attached to a fibrous annulus or ring. The leaflets open on hingepoints at the annulus, allowing blood to flow freely from atrium to ventricle (ventricular filling phase, or diastole). They are supported by muscular (chordea tendinae) attached to the ventricular muscle, which ensures that they close tightly in the midline as the ventricle contracts and empties (ventricular contraction, or systole), to prevent backflow of blood. The septation of the inflow tracts, along with the formation of the atrial and ventricular septa (with contributions from endocardial cushion tissue, see below), forms the crux of the heart. This is the three-dimensional juncture between the four chambers: left (mitral), right (tricuspid), atrium, and ventricle.

Heart Defects Arising from Abnormalities of Inlet Septation and Endocardial Cushions

Abnormalities in the endocardial cushions are an important subtype of congenital heart lesions, known as endocardial cushion defects. Failure of complete fusion between the superior and inferior cushions in the midline results in a cleft within the anterior leaflet of the mitral valve. This is a milder form of an endocardial cushion defect, often associated with a primum atrial septal defect 888 and known as a partial atrioventricular canal. A more profound failure of proper AV cushion expansion and fusion results in a complete atrioventricular canal. Here the crux of the heart is unformed, as in **Fig. 5C**. There remains a common orifice overlying both the ventricles, with defects in the adjacent atrial and ventricular septa. The common atrioventricular valve has leaflet structure similar to the unseptated AV canal, **Fig. 5B**, with four or sometimes five separate leaflets.

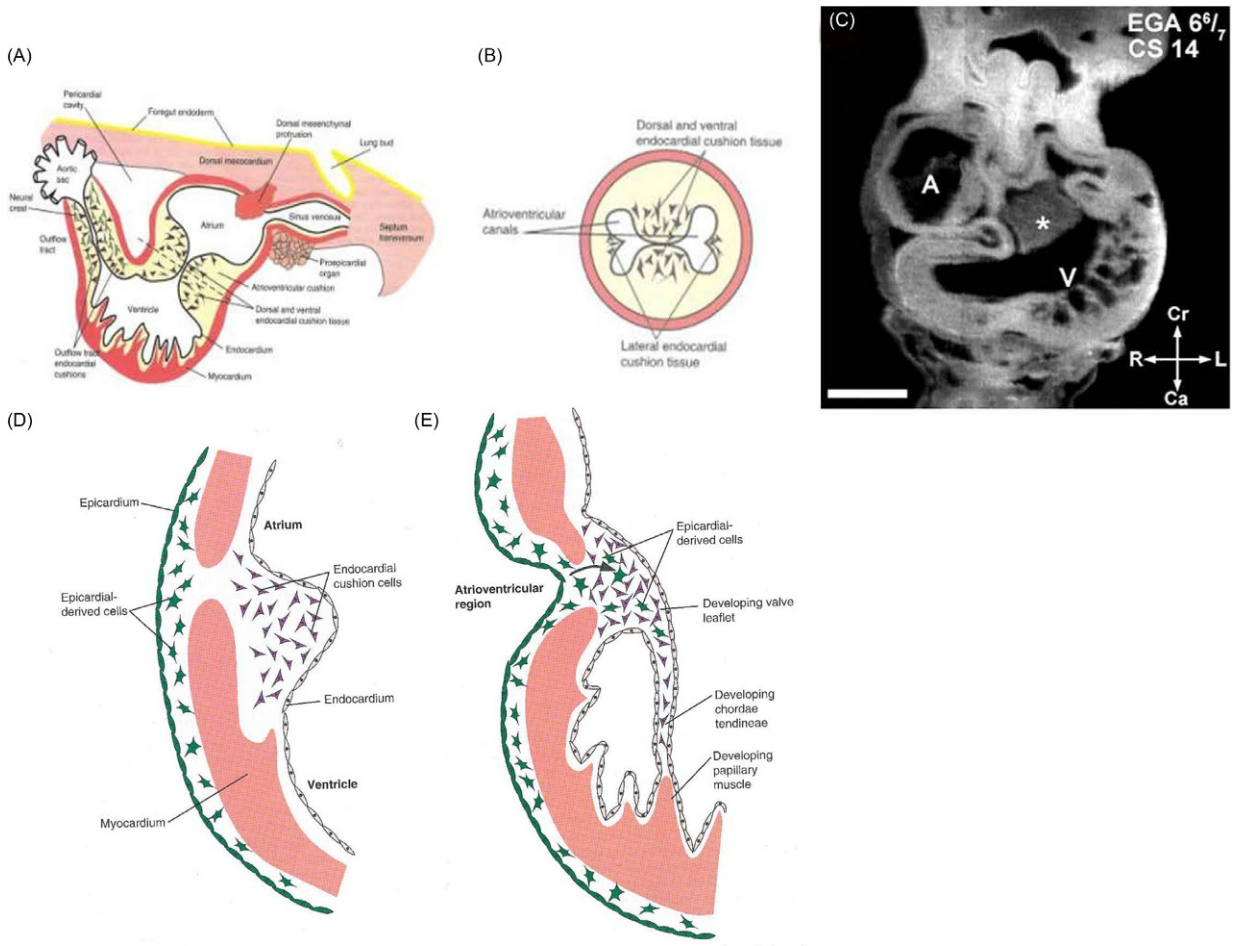

Fig. 5 Development of the endocardial cushions and atrioventricular valves: (A) Schematic diagram of cushion formation in the inflow and outflow tracts by EMT in the looped heart tube. Note continuity between the AV and conotruncal cushions along the inner curvature. Also shown are the neighboring tissues and cell populations contributing to the developing heart at this stage. (B) Schematic of the septating AV canal, leaflets named by position as shown. (D) and (E) are schematics of the subsequent delamination and formation of support structures of the AV valves (tricuspid valve is shown). (C) is an EFIC (episcopic fluorescence image capture) image of a sectioned paraffin-embedded human embryos at 6 6/7 weeks. Seen are atria (A), ventricles (V), and AV cushions (*). Scale bar = 0.515 mm. (A, B, D, E) From Schoenwolf et al. (2015). *Larsen's human embryology* (5th edn.), p. 284, 291. Philadelphia: Elsevier Churchill Livingstone. Human cardiac development in the first trimester: A high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation* **120** (4), 347.

Ventricular Outflow Tract Septation: Endocardial Cushions and Neural Crest

Septation of the outflow tract involves complex interactions between several resident and migrating cell types in a tightly regulated spatial and temporal manner. This includes the primary and secondary heart fields as already described, EMT of endocardium to form the conotruncal endocardial cushions, and addition of yet another population of external migrating cells, the neural crest. These populations are shown in **Fig. 6A**. Neural crest (shown in blue in **Fig. 6A**; secondary heart field in red) are ectodermal cells which originate from neural tissue in the anterior rhombencephalon and migrate through the pharyngeal region and into the aortic arches (Creazzo et al., 1998; Epstein et al., 2000; Li et al., 2003; Waldo and Kirby, 1993; Waldo et al., 1996). These neural crest cells are also important in the development of the nearby parathyroid, thyroid, and thymus glands. In addition, they innervate the heart and form much of the smooth muscle of the proximal aorta (Creazzo et al., 1998). In the conotruncus, recent data suggest a role for neural crest cells contributing to the development and patterning of the pulmonary and aortic valves as they begin to form (Phillips et al., 2013). In addition, neural crest cells surround the epithelia of the arch arteries and extend into the truncus and proximal conus, contributing cells to the truncal cushions (Neeb et al., 2013). The truncal cushions form the aorticopulmonary septum separating the two great arteries, the PA carrying blood to the lungs and the aorta carrying blood to the body (**Fig. 6D** and **E**). This occurs in a spiral, completing an almost 180 degree rotation (Carlson, 2004; Ya et al., 1998) (**Fig. 6C–H**). With this rotation, the PA is positioned directly anterior to the aorta at the level of the newly formed pulmonary and aortic valves, (**Fig. 6F** and **G**, level 3). Further along the outflow tract, the PA and aorta are more left-right to one another, as the spiral extends (**Fig. 6F** and **G**, level 2).

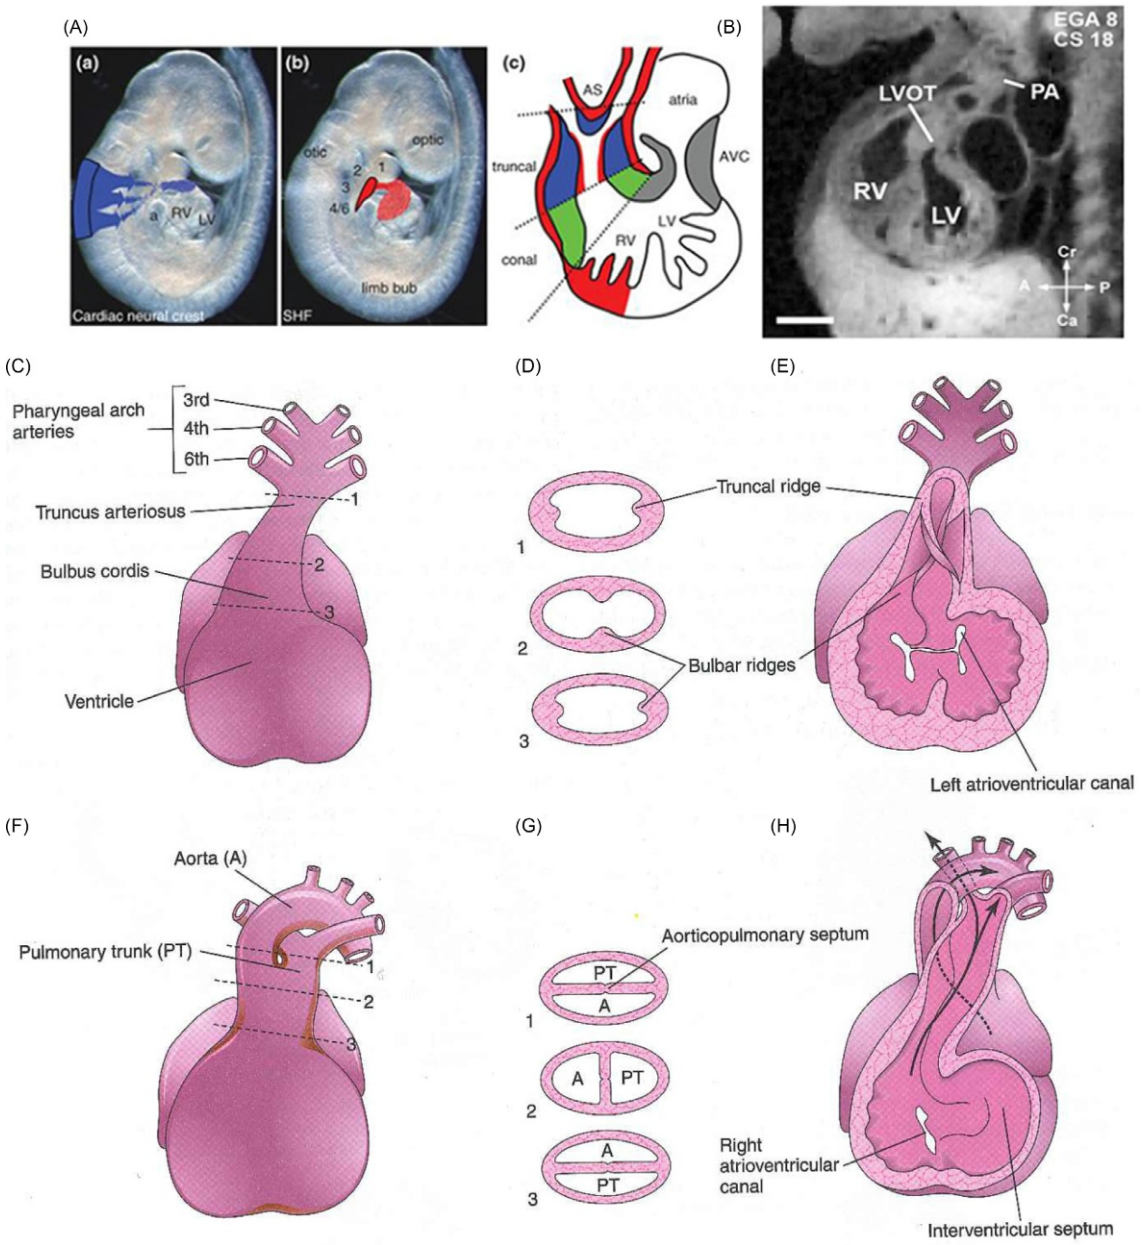

Fig. 6 Septation of the outflow tracts. (A) Contribution of neural crest (*blue*, A) and secondary heart field (*red*, B) migrating into developing outflow tracts in the mouse embryo. The schematic (C) shows the extent of these tissues, as well as the contribution from conal endocardial cushions (*green*). A, atria; RV, LV, *right* and *left* ventricles; 1–6 are numbered aortic arches; AS, aortic sac; AVC, atrioventricular canal. (B) EFIC image of an embryo at 8 weeks showing LV and developing LV outflow tract (LVOT) and the anterior RV and a portion of the PA. Scale bar = 1.35 mm. (C–H) Schematic of heart starting at 5 weeks gestation, with outflow tract beginning as a common truncus connected to the bulbus cordus and common ventricle. As the conotruncal cushions form, the aorticopulmonary septum forms in a spiral fashion as shown. *Dotted lines* in C, F represent levels of sections shown in D, G. (A) From: Neeb, Z., et al. (2013). Cardiac outflow tract anomalies. *WIREs Developmental Biology* **2**, 499–530. (B) From: Dhanantwari, P., Lee, E., Krishnan, A., et al. (2009). Human cardiac development in the first trimester: A high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation* **120** (4), 347. (C–H) From Moore and Persaud (2008). *The developing human* (8th edn.), p. 307. Saunders Elsevier.

As the aorta arches to the left, the proximal transverse arch passes anterior to the PA, completing a 180-degree turn of the spiral (Fig. 6F and G, level 1). This rotation not only involves the truncal cushions but also involves the rotation of the myocardial tube (Bajolle et al., 2006; Lomonico et al., 1986). With this rotation, the conus of the primitive heart tube is normally retained only by the right ventricle. The left ventricle connects directly to the aorta, as the aortic portion of the truncus shifts leftward. Continuity between the superior atrioventricular and left ventral conal cushions results in continuity between the mitral and aortic valves (see Fig. 5A, and schematic in Fig. 6A).

Heart Defects Arising from Abnormalities of the Ventricular Outflow Tracts

The outflow tracts of the heart are arguably the most complex area of the heart genetically and morphologically, and most prone to developmental defects.

If the 180-degree twist of the great artery septation does not occur or is incomplete, the result is transposition of the great arteries. This is defined by the aortic valve being anterior to the pulmonary valve. The left–right orientation of the valves is most commonly preserved (aortic rightward), although can vary within a 90-degree range, from directly anterior-posterior to directly side by side. L-transposition, aortic leftward, is most often associated with L-Looped ventricles or heterotaxy syndromes, and is rare in isolated transposition. TGF-beta signaling, important in left–right patterning and extracellular matrix remodeling and many other processes in normal development, appears to play an important role in this process both in mouse models and in human disease (Oh and Li, 1997; Rankin et al., 2000; Goldmuntz et al., 2002; Karkera et al., 2007).

Defects in expression of secondary heart field genes can lead to right ventricular hypoplasia and outflow tract abnormalities, including Tetralogy of Fallot and double outlet right ventricle (Ward et al., 2005; Zeisberg et al., 2005). These clinical entities are described in detail elsewhere in this text. Embryologically, malalignment of the conal and truncal cushions results in incomplete closure of the ventricular septum with malalignment of the overlying outflow tracts. In Tetralogy of Fallot, this results in an enlarged aorta overriding the ventricular septum, and an underdeveloped PA. If the malalignment results in both great arteries positioned over the right ventricle, this is known as double outlet right ventricle (van den Hoff et al., 1999; Waller et al., 2000). Clinically, a DORV includes a ventricular septal defect and presence of a conus segment of both ventricles (bilateral conus). As described above, the normal conus is a muscular "neck" within the right ventricle between the tricuspid and pulmonary valves that is not normally present in the left ventricle.

Defects in neural crest migration and/or survival also cause OFT heart defects. The importance of neural crest in outflow tract development has been well studied in animal models using neural crest ablation. Primarily among these are truncus arteriosus and interrupted aortic arch (Waldo et al., 1996; Waldo et al., 2005; Creazzo et al., 1998; Waldo and Kirby, 1993; Nishibatake et al., 1987; Kirby and Waldo, 1995). Again the clinical features of these defects are described elsewhere. Embryologically, truncus arteriosus is lack of separation of the aorta and PA, such that a common trunk persists connected to both ventricles, with a VSD allowing egress from both ventricles. The branch pulmonary arteries grow in from the lungs and connect directly to the common trunk. In interrupted aortic arch, the great arteries septate but malalignment of the conal septum results in hypoplasia of the left-sided outflow and malformation of the aortic arch. Neural crest defects also can also cause Tetralogy of Fallot, double-outlet right ventricle, and VSD as described above.

The genetics of DiGeorge syndrome and TBX1 mutation illustrates the complexity of conotruncal defects. DiGeorge syndrome has clinical features of a neural crest defect, with aortic arch abnormalities, parathyroid and thymic abnormalities (Liao et al., 2004). In human genetic studies, DiGeorge syndrome has been linked to a deletion of up to three megabases in chromosome 22 (22q11) based on kindred studies in families with the syndrome (Beaujard et al., 2009; Epstein, 2001; Merscher et al., 2001; Portnoi, 2009). The defect was recapitulated experimentally in mice, with identification of TBX1 as the specific responsible gene in these mice (Jerome and Papaioannou, 2001; Lindsay et al., 2001; Merscher et al., 2001). TBX1 is a transcription factor in a family known to be important in embryonic patterning; other than some differences in severity, suggesting a role for modifying genes, all of the features of human DiGeorge were seen in the mouse model (Jerome and Papaioannou, 2001). Yet isolated TBX1 mutations appear to be very rare as causes of clinical DiGeorge syndrome in humans (Beaujard et al., 2009; Portnoi, 2009; Rauch et al., 2010); most patients having a larger megabase deletion. Furthermore, TBX1 is not expressed by neural crest cells, but rather in the secondary heart field (Vitelli et al., 2002; Liao et al., 2008). Interestingly, overexpression of Tbx1 in mouse models are also associated with conotruncal defects, suggesting that there are critical levels of Tbx1 necessary for proper outflow tract development (Liao et al., 2004, 2008).

Development of the Ventricles and Ventricular Septum

The majority of the ventricular septum is muscular, and made up of a protrusion of ventricular myocardium that starts at the apex of the primitive ventricle and extends into the ventricular cavity (**Fig. 7A**, asterisk). As the septum extends upward, the separation becomes nearly complete (**Fig. 7B**, arrow). Remaining portions of the septum are closed by endocardial cushion tissue. First, the AV endocardial cushions form the posterior septum adjacent to the AV valves. Second, the conal cushions form the conal septum below the great arteries. An important feature of this process is that these regions of septum contain muscle as well as cushion tissue, and this muscle has its origin in the secondary heart field (Neeb et al., 2013).

Heart Defects Resulting from Incomplete Ventricular Septation

VSDs are among the most common heart defects seen clinically, and can be in isolation or in combination with more complex defects (Soto et al., 1980). The ventricular septum arises from several sources as already discussed. VSDs can be found as tissue defects or holes in any of these components: muscular, inlet (from deficiency of AV cushions), outlet (from deficiency of conotruncal cushions), or membranous, which is the portion of the septum at the juncture of the three components (Soto et al., 1980). The membranous portion of the septum is nonmuscular and made up of fibrous tissue, and is the most common of VSDs.

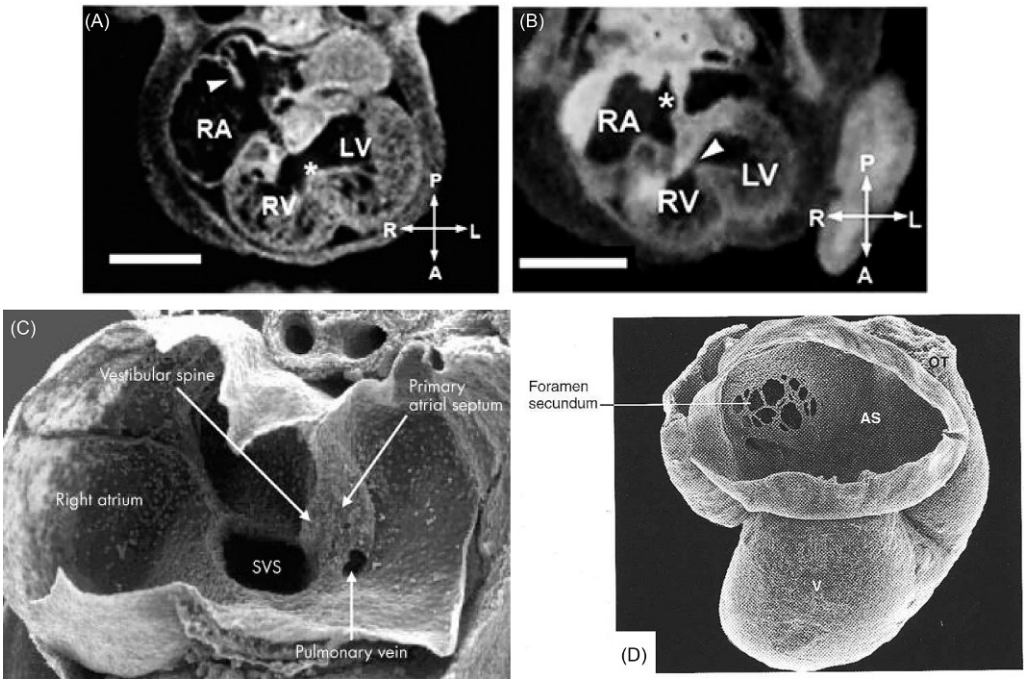

Fig. 7 Atrial and ventricular septation. (A) Human fetal MRI images in transverse plane, fetus at 7 5/7 weeks gestation. Shown are the four chambers of the heart (RA right atrium; RV right ventricle; LV left ventricle). Orientation as shown by the *arrows*: P (posterior), A (anterior), R (right), and L (left). The atrial septum primum is marked by the *arrowhead*, with the foramen primum below allowing shunting of blood from RA to LA. Between the ventricles, the muscular intraventricular septum forms but is not yet complete (*). Scale bar is 1.25 mm. (B) Fetus at 8 weeks gestation. Here the atrial septum primum (*) is fused with the endocardial cushions inferiorly; not seen is the foramen ovale that allows continues *right* to *left* atrial shunting in the fetus. The arrowhead shows a small residual ventricular septal defect in the *inlet* (posterior) septum, not yet closed by endocardial cushion tissue. Scale bar is 1.5 mm. (C, D) Further details of atrial septation. In C, note the close proximity of the systemic venous sinus (SVS) and pulmonary vein, with the primary atrial septum in between. Behind is the vestibular spine, or dorsal mesenchymal protrusion that extends the septum primum. (D) The foramen secundum, seen as perforations in the superior portion of the septum that appear as the septum primum extends toward the AV canal. Development of the Atria and Atrial Septum

The original atrial segment in the heart tube is replaced during remodeling of the atria and is left as remnants on each side, termed the right and left atrial appendages. Most of the remodeled right atrium comes from incorporation of the right horn of the sinus venosus, as the systemic veins incorporate into their final drainage patterns to the heart. The same is true for the pulmonary veins connecting to the left atrium and incorporating into the back wall (see next two sections). The atria are separated by a muscular wall, the atrial septum. Like the ventricular septum, the atrial septum begins as a ridge of muscular tissue, posterior and midline, which expands to divide the right side of the atrium containing the orifice of the sinus venous from the left side of the atrium containing the orifice of the common pulmonary vein (**Fig. 7C**). This structure is known as the septum primum, and it grows toward the fusing AV cushions (Wessels et al., 2000; Anderson et al., 2003). The leading edge of the primum septum is a mesenchymal tissue (mesenchymal cap) with origin from endocardial EMT, similar to the endocardial cushions. Another mesenchymal ingrowth, termed the dorsal mesenchymal protrusion, adds tissue to the extending atrial septum from the sinus venosus region. This mesenchyme has its origin in the secondary heart field (Briggs et al., 2016; Burns et al., 2016; Snarr et al., 2007). This is a thicker tissue than the rest of the atrial septum and provides a buttressing effect inferiorly. Superiorly, small perforations appear, enlarge, and coalesce within the primum septum such that it never forms a complete barrier to flow between the atria; this is termed the foramen secundum, (**Fig. 7D**). A second structure of atrial septal tissue next begins to form, the septum secundum (**Fig. 7C**, green) forms a crescent on the right atrial side of the septum primum, extending alongside the septum primum (Anderson et al., 2003). This creates a flap, allowing shunting of blood away from the lungs in the fetus. The central portion of the crescent remains incomplete, forming the fossa ovalis.

Heart Defects Resulting from Incomplete Atrial Septation

Since an atrial communication is normal in fetal circulation, all newborn infants retain a small atrial shunt, or patent foramen ovale (PFO). As long as this is a trivial communication, it is considered a normal variant to retain a PFO even into adulthood. On the other

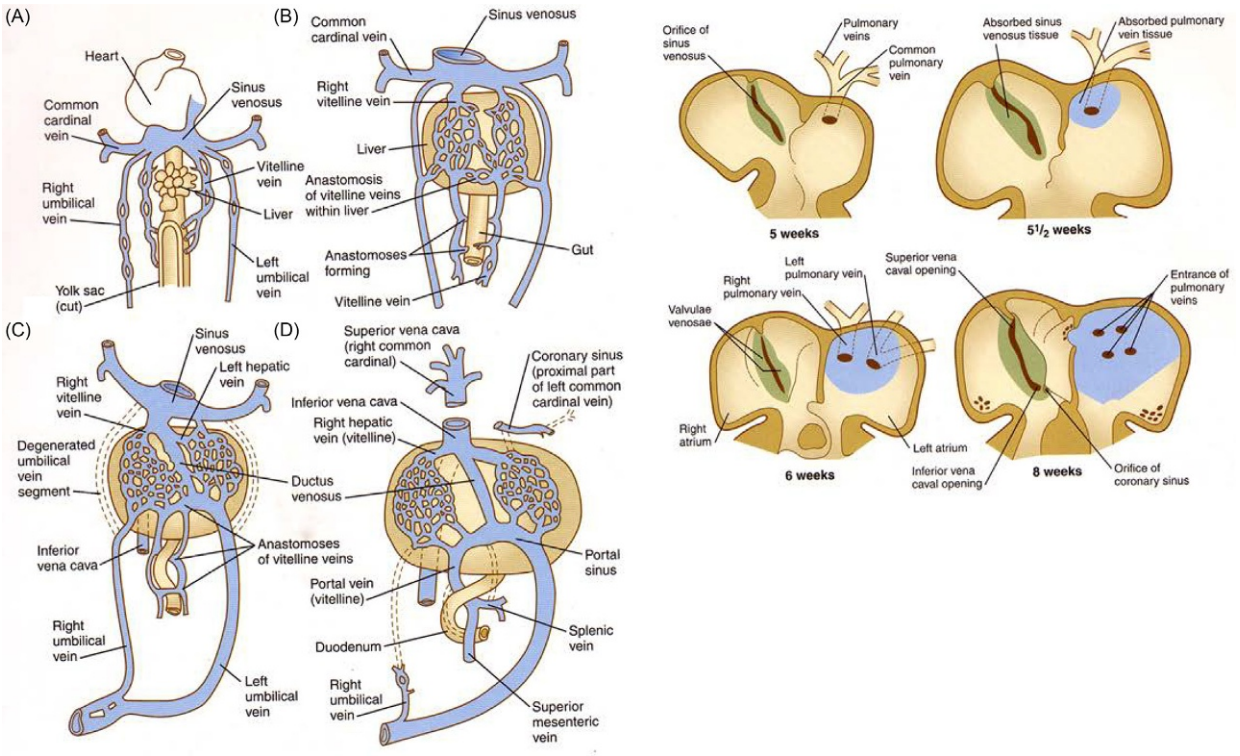

Fig. 8 Stages of development of the systemic veins (*left*) and pulmonary veins (*right*). From: Carlson, B. M. (2014). *Human embryology and developmental biology* (5th edn.), pp. 423–424. Philadelphia: Elsevier Saunders.

hand, a true deficiency in atrial septal tissue in the region of the foramen ovale constitutes a secundum ASD. Another type of ASD results from failure of the cushions to form the inferior-most part of the atrial septum results. This is termed a primum atrial septal defect, and is considered an endocardial cushion defect in the spectrum of the AV canal defects. Such defects do not close spontaneously, and may be associated with other endocardial cushion defects, most commonly an incompletely fused, or cleft mitral valve. Finally, there is a small contribution to the atrial septum near the junctions of the superior and inferior vena cava (IVC) (see below). Defects in this process result in a sinus venosus ASD, and there are superior or inferior types. Such defects again result from deficiency of atrial septal tissue, and do not close spontaneously.

Systemic Vein Development

The sinus venosus of the primitive heart tube is a symmetric structure, and in mammals receives three sets of paired (left and right) systemic veins: from the yolk sac (vitelline), placenta (umbilical), and embryo proper (cardinal) (Fig. 8A). The yolk sac is a structure that communicates with the primitive gut via the vitelline duct. The duct normally regresses completely, although the portion within the liver contributes to the hepatic and portal veins, including a small segment to the IVC (see Fig. 9A and below). The umbilical veins return from the placenta carrying oxygenated blood. These are the first to develop, by three weeks gestation. As the liver develops, the umbilical veins develop connections within the liver and the connection to the sinus venosus involutes. The cardinal veins carry the venous returning from the embryo to the heart. On each side, anterior and posterior cardinal veins join to form the common cardinal vein; the anterior carrying the venous returning from the upper body, and the posterior from the lower body. The right anterior and right common cardinal vein will form the superior vena cava in the mature circulation. The left common cardinal vein and left segment of the sinus venosus form the coronary sinus, which receives venous return from the coronary system. These structures are pulled rightward as the IVC forms, such that the opening (os) of the coronary sinus ends up in the right atrium once atrial septation is complete. The IVC is more complex, and made up of five segments, coming from urogenital, mesenteric and hepatic venous channels fusing together to the right of the spine as their leftward paired counterparts involute.

Heart Defects Resulting from Abnormal Systemic Vein Development

As numerous vessels go into making the IVC, interruption of the IVC can sometimes occur at various segments. This is most often in the setting of heterotaxy, but can occur in isolation. When the IVC is interrupted, a connection between the lower and upper will

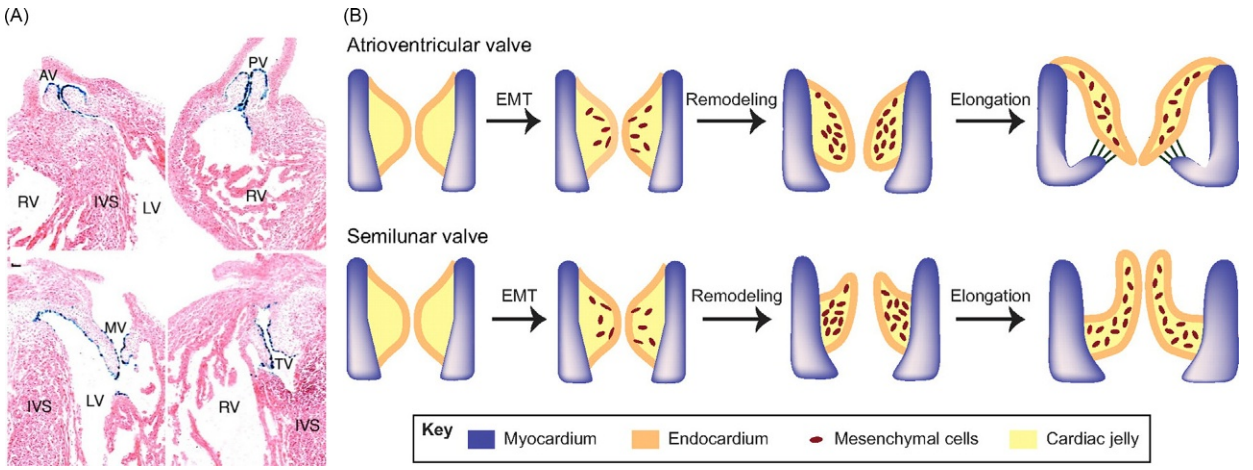

Fig. 9 Valve maturation. (A) Nfatc1 expression in the developing valves, as they begin to elongate. Note expression in the endocardial surface of the valves; mesenchymal cushion tissue in between. Nfatc1 coordinates valve endocardial cell lineage development required for heart valve formation. *Circular Research* **109** (2), 183–192. (B) From Lin, et al. (2012). Partitioning the heart: Mechanisms of cardiac septation and valve development. *Development* **139** (18), 3277–3299.

persist and enlarge, bringing the IVC blood up to the SVC. Sometimes both anterior cardinal veins persist, creating bilateral SVCs. A persistent left SVC most often drains into the coronary sinus (see above) but can drain directly to the roof of the left atrium as well. Most systemic venous anomalies in isolation are not a serious problem for the circulation, as all of the venous return ends up in the right atrium, and do not require surgical correction.

Pulmonary Vein Development

The pulmonary veins grow into the heart from the developing lung vasculature. A common pulmonary vein coming from both lungs fuses into the back of the left atrium (Wessels et al., 2000). As the atrium expands, the common pulmonary vein becomes further incorporated into the back wall, such that first two, then four of its branches eventually enter independently into the atrium, two from the left and two from the right lung (**Fig. 8B**).

Heart Defects Resulting from Abnormal Pulmonary Vein Development

As the common pulmonary vein approaches the back of the left atrium, there are nearly several structures that it can accidentally encounter and incorporate into. These include the coronary sinus, right atrium, and remnants of the cardinal system that normally regress. If this happens, these vessels will enlarge and persist, and the pulmonary vein will drain directly, or indirectly, to the right atrium. This is called total anomalous pulmonary venous return, and is life-threatening, generally requiring corrective surgery in the newborn. Partial anomalous pulmonary venous return is also possible, usually occurring in conjunction with an atrial septal defect (see other sections of this text for clinical details).

Cardiac Valve Maturation

Cardiac valve development begins with the endocardial cushions during week 7 of gestation, but maturation of the atrioventricular (mitral and tricuspid) and semilunar valves (aortic and pulmonic) takes several weeks for completion (Dhanantwari et al., 2009; Steding, 2009) (Combs and Yutzey, 2009; Hinton et al., 2006; Lincoln et al., 2004; Kanani et al., 2005; de Lange et al., 2004). Genes important in the maturation process include Wnt/β catenin, Notch 1, and Nfatc1. **Fig. 9A** shows Nfatc1 expression in the endocardial surface of all four of the developing valves. Targeted gene disruption studies show that Nfatc1 regulates EMT and proliferation of mesenchymal cells within the maturing valves (Wu et al., 2011). As the endocardial cushions enlarge, they protrude into the lumen of the heart. Here, subject to constant flow of blood, the protrusions condense and elongate (Lin et al., 2012). Endocardial cells overlying the cushions proliferate slowly, and there is programmed cell death (apoptosis) of mesenchymal cells underneath (**Fig. 9B**). The valves undergo extensive remodeling of the extracellular matrix; in the case of the semilunar valves, this results in a fibrous layer (primarily collagen) on the arterial side, a spogiosa layer (glycosaminoglycans) in the middle, and an elastic layer (elastin) on the ventricular side (**Fig. 9**) (Combs and Yutzey, 2009; Shelton and Yutzey, 2007; Hinton et al., 2006). In the case of the semilunar valves, this remodeling process of the endocardial cushions continues through the last trimester of pregnancy and into the neonatal period (Aikawa et al., 2006; Hinton et al., 2006).

Heart Defects Resulting from Abnormal Valve Development

Defects in valve development can be concomitant with defects in inflow or outflow tract development, or can occur later during valve maturations. Examples of valve defects that are a part of a broader developmental abnormality include the common atrioventricular valve in endocardial cushion defects, or the small pulmonary valve in Tetralogy of Fallot resulting from abnormal division of the outflow tract and hypoplasia of the rightward portion. Abnormal valves can also be found without other cardiac anomalies, with normal outflow tract sizes and position. These involve abnormal valve maturation resulting in abnormally partitioned valves, thickened valve leaflets, and/or incomplete leaflet delamination from the ventricular surface. A bicuspid aortic valve is a common example in which the aortic valve has two leaflets instead of three, which can result if either narrowing of the valve opening (stenosis) or incomplete closure with backflow of blood (insufficiency). Ebstein's anomaly of the tricuspid valve is an example in which the septal leaflet of the tricuspid valve incompletely delaminates, resulting in displacement of the valve into the body of the right ventricle. These clinical entities are covered elsewhere in this text. Genetic defects linked to abnormal valve development include the PTPN11 gene which Noonan's syndrome, characterized by a dysplastic and stenotic pulmonary valve (Tartaglia et al., 2001). The PTPN11 encodes for SHP-2, a signaling molecule important to growth factors, cytokines, and hormones (Tartaglia et al., 2001). This has been linked to a role in mediating growth (Chen et al., 2000), and interestingly appears to be a gain-of function mutation (Tartaglia et al., 2002). Mutations in the Notch1 receptor and its signaling pathway have been associated with the formation of aortic valves and with multiple stages of cardiac development (Garg et al., 2005; High and Epstein, 2008).

Aortic Arch Development

The primitive heart tube connects to the aortic sac, the precursor to the ascending aorta, and begins pumping to the developing systemic circulation of the embryo as soon as it is formed. The aortic sac connects to paired dorsal aortae posteriorly via an aortic root, which gives rise to a series of arches, the branchial arches (**Fig. 10A**). It is along these arches that the neural crest migrates into the conotruncus and support development of the arch arteries. Again these are paired structures, and there are a total of six pairs, although not all are patent at the same time. Arches 1–4 carry the blood flow in the 4-week embryo. Arches 1 and 2 mostly regress completely, although parts contribute to some of the arteries of the face. Arch 3 does not persist as an arch, but parts of it contribute to the formation of the carotid system. The left limb of arch 4 remains in continuity with the aortic root. Together they make up the aortic arch and its first branch, the brachiocephalic (innominate) artery. The right limb of arch 4 becomes part of the right subclavian artery, which retains its proximal connection with the brachiocephalic artery (Waldo et al., 1996). This arch remodeling occurred by 7 weeks of gestation. Arch 5 is small and not fully developed. Arch 6 forms with the developing PA vasculature, and makes up the proximal left and right pulmonary arteries and the ductus arteriosus (Waldo and Kirby, 1993). The ductal arch persists throughout fetal life as another means of right to left shunt, allowing blood from the right ventricle to bypass the pulmonary circulation and cross over into the descending aorta.

Heart Defects Resulting from Abnormal Aortic Arch Development

In some cases, either independently or as a part of another developmental cardiac defect, the right limb of arch 4 remains patent and the left forms the left subclavian artery — this forms a right aortic arch with mirror-image branching. Anomalies are seen with regression in any segment of the arch resulting in left or rightward arches with aberrant position of the subclavian arteries. No regression of an arch segment results in a double aortic arch, which can also be seen. Narrowing of the aortic arch, again either in isolation or in combination with other defects is known as coarctation of the aorta. Clinical features of coarctation are described elsewhere in this text.

Coronary Artery Development

The coronary arteries arise from the aorta just above the aortic valve, and have the important purpose of supplying blood to the heart muscle itself. The coronary arteries form first within the myocardium, then connect to the aorta via a coronary stem that forms within the aorta from peritruncal capillaries (Tian et al., 2013a, 2015; Liu et al., 2015; Mikawa and Fischman, 1992; Mikawa and Gourdie, 1996) (**Fig. 11A**). The coronary vessels form from several sources, as shown in **Fig. 11C–E**. Early in development, the proepicardial organ (PEO) appears as bilateral clusters of cells near the septum transversum, where the liver bud approaches the heart (**Fig. 11B** and **C**) (Mikawa and Gourdie, 1996; Reese et al., 1999, 2002). This is in close proximity to the sinus venosus, and there appears to be some movement of cells from one population to the other (Tian et al., 2015). The PEO is a transient structure that spreads out over the surface of the heart, forming an outer layer called the epicardium. Some of the epicardial cells delaminate and migrate into the myocardium, in another example of EMT in heart development. Cells from epicardial EMT contribute to coronary vessels as both endothelium (lining of blood vessels) and arterial wall smooth muscle (Mikawa and Gourdie, 1996; Reese et al., 2002). Recent studies have used detailed transgenic lineage tracing methods in mouse to show there are also important contributions to the coronary endothelium from the endocardium, also via EMT (Wu et al., 2012), and from the sinus venosus (Red-Horse et al., 2010; Tian et al., 2013b, 2014). To add to the complexity of cell lineages, this process appears to occur differently

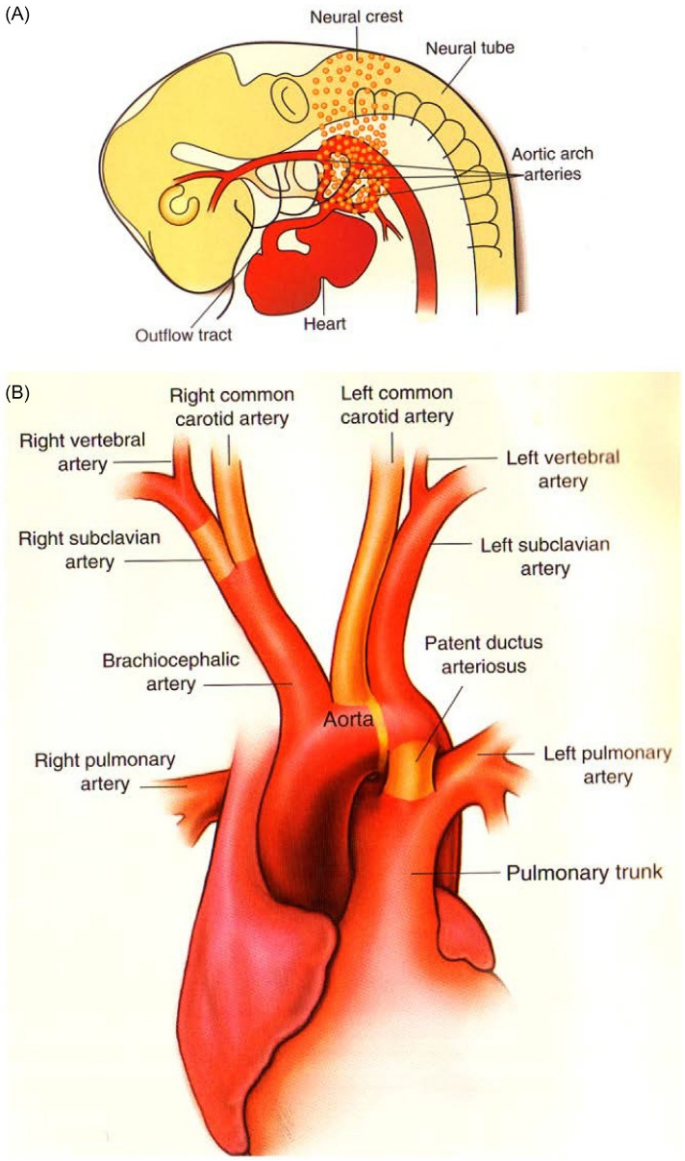

Fig. 10 Arch development. (A) Migration pattern of neural crest cells into pharyngeal arches 3, 4, and 6. (B) Normal aortic arch at term. Most of the pharyngeal arch segments have regressed. The third arch persists in part as the *left* and *right* common carotid arteries. The *left* fourth arch persists as the true aortic arch, while a portion of the *right* fourth arch makes up the proximal *right* subclavian artery. The sixth arch persists as the ductus arteriosus (ductal arch). From: Kirby, M. L. (1999). Contribution of neural crest to heart and vessel morphology. In Harvey and Rosenthal (eds). *Heart development*, pp.180–181. Academic Press.

in different segments of the ventricular myocardium (Tian et al., 2015; Wu et al., 2012). Regardless of the origin, the coronary vessels form, grow, and fuse with one another to form a working vasculature. Signaling from neural crest, epicardial-derived cells, and recently discovered intraaortic cardiomyocytes all appear to play an important guiding role (Arima et al., 2012; Eralp et al., 2005; Chen et al., 2014).

Heart Defects Resulting from Abnormal Coronary Development

Occasionally, a coronary artery (usually the left) can join into the PA instead of the aorta. This does not damage the fetal myocardium given the low oxygen state of the fetus, with little difference in oxygen tension between the aorta and PA bloodflow. After birth, however, ischemia sets in rapidly, causing myocardial ischemia and infarction in infancy (Huddleston et al., 2001). Other less dramatic examples are coronary arteries arising from the opposite sinus of the aortic root (left coronary from the right side) or from a single origin. This results in an abnormal course of the coronary artery over the heart, and may or may not be a clinical concern (Gersony, 2007).

Conduction System Development

Cardiomyocytes constantly depolarize and repolarize in an automatic fashion, and this is the mechanism for their contractility. The conduction system of the heart includes special myocytes that conduct action potentials rapidly allowing for coordination of myocyte contraction. This includes the sinoatrial node, or intrinsic pacemaker of the heart, the atrioventricular node, a region of slowed conduction between the atria and ventricles, and the His bundles, which transmit the action potential to the ventricular myocardium. Lineage tracing studies show conclusively that the cells of the conduction system differentiate in situ from myocytes (Waldo et al., 1994; Hyer et al., 1999; Cheng et al., 1999; Gourdie et al., 1998; Moorman et al., 1997). The conduction system tends to develop alongside coronary vessels, and the developing coronary vasculature appears to be a source of signaling for this transdifferentiation (Hyer et al., 1999). Conduction system myocytes express different markers, junctions, and have different action potential profiles from myocytes that allow for automaticity (Alyonycheva et al., 1997; Hoogaars et al., 2007; Moorman et al., 1997; Wessels et al., 1992; Takebayashi-Suzuki et al., 2001). Recently, lineage tracing studies in early chick embryos showed that the SA node arises from a population of cardiac mesoderm outside of the primary and secondary heart fields that coalesce in the heart near the right sinus horn (Bressan et al., 2013). Activation mapping of embryonic chick heart conduction shows that the primitive SA node begins to function soon after cardiac looping (the site of earliest activation prior to this actually being in the left sinus horn)

(Bressan et al., 2013). Once active, the SA node maintains the fastest depolarization and to 'set the pace' for the heart rate. This starts at about 1 month gestation in humans (Phoon, 2001).

Heart Defects Resulting from Conduction System Development

Conduction system disease can result from many defects at the cellular level, including abnormal action potential channels which are beyond the scope of this article. Relevant to our discussion of cardiac development are atrioventricular accessory connections. These are bridges of muscle between the atrium and ventricle that should regress with atrioventricular valve development and creation of fibrous discontinuity at the mitral and tricuspid annulus. Persistent accessory connections can allow for reentrant tachyarrhythmias, in which the electrical impulse transmitted to the ventricles are able to circle back up into the atrium setting up a loop of rapid conduction. Sometimes, these accessory connections are large enough to be detected on an electrocardiogram, and this is the hallmark of an entity known as Wolff–Parkinson–White syndrome. These connections most often are found in structurally normal hearts, but can accompany Ebstein's anomaly. Heterotaxy is another setting in which the conduction system may be significantly abnormal, with randomization of left and right signals; the sinus and AV nodes are often malpositioned. For further discussion of arrhythmias, please see this section elsewhere in this text.

Conclusion

We have reviewed heart development, with attention to the morphology, cell biology, genetics, and physiology of the heart as it forms and remodels. The field of developmental biology of the heart continues to advance rapidly on all of these fronts.

Creative, integrative approaches continue to be developed and applied to the study of heart development. Animal models continue to be refined, including tissue specific gene expression and knockout studies, to create complex models of human disease at the cell and whole organ level. Advanced imaging, including techniques that allow earlier and better visualization of the developing human heart, are highly useful tools. Cardiac MRI can visualize a human fetus as early as week 6 gestation (Dhanantwari et al., 2009), and cardiac ultrasound by 10–11 weeks. The common goals to be applied to human disease are early recognition of congenital heart malformations, prevention where feasible, and state of the art intervention to allow an abnormal heart to function as normally as possible. In the future, gene therapy, cardiac stem cell grafting, and in vitro tissue engineering will likely be added to the therapeutic potentials for patients with congenital heart malformations.

Introduction

Heart failure is one of the leading causes of comorbidity and death among adults in the United States, with an estimated prevalence of 5.7 million people affected (Mozaffarian et al., 2015). African Americans have the highest incidence and prevalence of heart failure compared with other races (Husaini et al., 2011). Understanding what is currently known about the causes, prevention, and treatments of heart failure in this population is imperative to improving outcomes.

Epidemiology

The prevalence of heart failure among African Americans living in the United States has been estimated at 3.6%–5.9%, compared with 2.4% for Caucasians (Heidenreich et al., 2013; Gupta et al., 2013). Incidence rates vary among studies, with one study finding a rate of 4.6 per 1000 person years (2.4 for Caucasians) (Bahrami et al., 2008). However, data from the Atherosclerosis Risk in Communities (ARIC) study showed an even higher incidence rate of 9.1 for African American men (Caucasian men = 6) and 8.1 for African American women (Caucasian women = 3.4) (Loehr et al., 2008).

The majority of African Americans with heart failure have heart failure with preserved ejection fraction (HFpEF), with the ARIC study finding that 73% of African Americans had HFpEF and that HFpEF was more common in women (Gupta et al., 2013). They are less likely to have an ischemic etiology (Husaini et al., 2011). African American women are also at higher risk for peripartum cardiomyopathy (Kao et al., 2013).

In addition to being at higher risk for developing heart failure, African Americans as a group have more rapid and severe progression. The average age at the time of diagnosis and first hospitalization is younger (Jolly et al., 2010; Kheirbek et al., 2016), rates of hospitalization are higher, and cardiac event-free survival is low compared with Caucasians (Kheirbek et al., 2016; Wu et al., 2016; Wierenga et al., 2016; Husaini et al., 2016). Although overall mortality is higher, mortality rates after a hospitalization for heart failure have been found to be paradoxically lower or similar to Caucasians in some studies, which could suggest differences in disease severity at the time of hospitalization, in etiology, or in comorbidities affecting long-term survival (Loehr et al., 2008; Gordon et al., 2010).

The increased prevalence of heart failure, increased mortality, and increased hospitalization in African Americans are likely multifactorial. Possible explanations include a higher prevalence of hypertension, diabetes, and obesity, as well as poorer control of risk factors such as hypertension and DMII (Zhao et al., 2014; Elperin et al., 2014; Eaton et al., 2016). Chronic kidney disease and anemia may also be risk factors (Bansal et al., 2016; Wang et al., 2016; Astor et al., 2004). The prevalence of hypertension within the ARIC cohort was 59% among African Americans without heart failure and 85% in those with HFpEF (Gupta et al., 2013). Obesity is also a significant comorbid condition occurring in 45% of African Americans without HF in the ARIC cohort and 71% of those with HFpEF. A retrospective analysis of data from the Jackson Heart Failure study found that obesity and morbid obesity were also common among African Americans, and both were associated with a higher risk of heart failure and heart failure hospitalizations (Krishnamoorthy et al., 2016). Similarly, a prospective study using data from the Women's Health Initiative found that African American women had higher baseline rates of hypertension, obesity, diabetes mellitus, and MI (Eaton et al., 2016). Risk factors for both HFpEF and HFrEF included coronary disease, diabetes, hypertension, and smoking; HFpEF was also associated with obesity, especially among African American women (Eaton et al., 2016).

A pooled analysis of four cohort studies, including the ARIC cohort, found that African Americans have a higher prevalence of hypertension, obesity, and DM compared with Caucasians (Ahmad et al., 2016). By age 45, only 36.1% of African Americans have zero of these risk factors, compared with 55% of Caucasians; thus, by age 45, the majority of African Americans have at least one heart failure

risk factor. African Americans with none of these risk factors have an increased heart failure-free survival time of 12.9 years compared with those with all three risk factors at age 45, suggesting that prevention of these risk factors may be key (Ahmad et al., 2016).

Poorer control of risk factors such as hypertension or obesity may also contribute to increased mortality and hospitalization. Of note, a significant proportion of deaths, especially for those with HFpEF, may be due to noncardiovascular causes, which may contribute to the higher mortality rate in African Americans with heart failure as they often have more comorbidities as well (Gupta et al., 2013). This may help to explain the paradox of lower or similar risk of death post hospitalization for heart failure but higher long-term mortality.

Disparities in cardiovascular care likely exist, although quality initiatives may mitigate some of these disparities. African American patients treated at hospitals participating in a registry-based performance improvement program for heart failure (OPTIMIZE-HF) received largely similar provisions of quality measures compared with other races; they were as likely or more likely to receive evidence-based medications, although fewer received complete discharge instructions or smoking cessation counseling compared with other races (Yancy et al., 2008). African Americans treated at these hospitals had lower inpatient mortality after adjustment for risk factors but similar 60- to 90-day mortality (Yancy et al., 2008).

Socioeconomic status also impacts the risk of developing heart failure and morbidity and mortality after diagnosis. African Americans are four times more likely to live in the lowest socioeconomic neighborhoods, and this is associated with higher rates of diabetes and hypertension (Puckrein et al., 2015). African Americans with heart failure who have a lower financial status have a 4–6 times increased risk of cardiac events than higher income Caucasians (Wu et al., 2016). Self-care may affect outcomes among patients with heart failure, and African Americans report fewer self-care activities (Wu et al., 2016) and have lower heart failure knowledge on average (Dickson et al., 2015). African Americans with both HFpEF and HFrEF have been found to have lower rates of medication adherence (Dickson et al., 2015; Zhang and Baik, 2014). Improving home care through caregiver coaching programs may be one effective strategy to reduce hospitalizations (Piamjariyakul et al., 2015).

Genetics has been postulated to play a role, although specific genetic polymorphisms are largely uncharacterized. The presence of genetic markers linked to African ancestry has been found to be associated with worse parameters of diastolic function in patients with HFrEF, although the causal mechanism or possible genetic polymorphisms have not been identified (Bernardez-Pereira et al., 2016). One known variant is a mutation in the transthyretin gene that is present in 3%–4% of African Americans and is associated with late onset amyloid cardiomyopathy and an increased risk of heart failure after age 65 (Buxbaum et al., 2010). However, this is likely a small contributor as the overall prevalence of overt cardiac amyloid is low even in carriers (Quarta et al., 2015). African Americans are more likely to possess a polymorphism in the guanine nucleotide-binding protein β-3 subunit (GNB3 TT) that has been associated with worse left ventricular ejection fraction (LVEF) 6 and 12 months after diagnosis with peripartum cardiomyopathy (Sheppard et al., 2016).

Heart Failure With Reduced Ejection Fraction: Medication Guidelines

The current American College of Cardiology/American Heart Association (ACC/AHA) recommendations for African Americans with HFrEF are summarized in Table 1. For all patients with stage C HFrEF, the American College of Cardiology and the American Heart Association recommend treatment with an ACE inhibitor (ACEi), angiotensin receptor blocker (ARB), or ARNI in addition to a beta-blocker and an aldosterone antagonist in selected patients (Yancy et al., 2013, 2016). An ARNI is recommended over an ACEi or ARB if tolerated in appropriate patients (Yancy et al., 2016). Ivabradine may also be used to reduce heart failure hospitalization for patients with HFrEF NYHA class II–III and LVEF $\leq$35%, who despite receiving a beta-blocker at maximally tolerated doses have a heart rate above 70 bpm and who are also receiving other guideline-directed therapy for heart failure (Yancy et al., 2016). In addition, combined isosorbide dinitrate and hydralazine (I/H) are recommended for African American patients with symptomatic HFrEF currently receiving optimal medical therapy (Yancy et al., 2013).

HFrEF: Renin–Angiotensin System Blockade in African Americans

ACEi or ARB use (for patients intolerant to ACEi) is likely equally effective in reducing mortality and preventing rehospitalizations for African Americans compared with Caucasians. A retrospective study of patients with HFrEF including 619 African Americans found similar protective effects for death or heart failure rehospitalization among African Americans and Caucasians (El-Refai et al., 2015). In addition, similar benefit has been observed for adding an ACEi or ARB after an acute MI with LV systolic dysfunction in African Americans compared with Caucasians (Prisant et al., 2008). However, an earlier cohort study looking at data from the studies of left ventricular dysfunction prevention and treatment trials found a decrease in heart failure hospitalizations for Caucasians, but not for African Americans and no change in mortality for either group, so some data are mixed (Exner et al., 2001). One important point for clinicians to be aware of is that African Americans do have a higher incidence of angioedema with ACEi and ARNI, although this is still a rare side effect (Bahrami et al., 2008). Data on how often eligible African Americans are prescribed an ACEi/ARB/ARNI are limited. Although one small retrospective study did find that they were less likely to be prescribed an ACEi (Dickson et al., 2015), African Americans discharged from hospitals participating in a performance improvement program for heart failure were more likely to be prescribed an ACEi compared with other races. This suggests quality improvement measures may help ensure African Americans and other patients are receiving appropriate evidence-based therapies (Yancy et al., 2008).

Table 1 ACC/AHA/HFSA recommendations for stage C patients with heart failure with reduced ejection fraction (Yancy et al., 2013)

Medication class/ medications	*Target population*	*COR*[a]	*LOE*[b]	*Effect/additional information*
RAAS blockade	All patients with chronic HFrEF	I		
ACE inhibitor (ACEi)	Use if ARNI not tolerated	I	A	Reduce morbidity and mortality in RCTs
Angiotensin II receptor blocker (ARB)	Use if ACEi or ARNI not tolerated	I	A	Reduce morbidity and mortality in RCTs
Angiotensin II receptor blocker neprilysin inhibitor (ARNI)	Use instead of/substitute for ACEi or ARB if tolerated	I	B-R	Reduced composite end point of CV death or HF hospitalization by 20% in RCT compared with enalapril
Beta-blockers (BB)	All stable patients with stage C HFrEF	I	A	Reduce mortality; use bisoprolol, carvedilol, or metoprolol succinate ER
Aldosterone receptor antagonists	(1) NYHA class II–IV and LVEF $\leq$35%, (2) after acute MI with LVEF $\leq$40% and symptoms of HF or DM	I	(1) A (2) B	Reduce morbidity and mortality; avoid use if eGFR $\leq$30 or potassium $\geq$5
Hydralazine/ isosorbide dinitrate	(1) African Americans with NYHA class III–IV HFrEF on GDMT[c], (2) patients with HFrEF intolerant of ACEi/ARB/ARNI	(1) I (2)IIa	(1) A (2) B	Further reduced mortality and heart failure hospitalizations in African Americans already on ACEi/ARB/ARNI, BB, and, if indicated, aldosterone antagonist
Ivabradine	NYHA class II–III stable chronic HFrEF, receiving GDMT including BB, in sinus rhythm with resting HR $\geq$ 70 bpm	IIa	B-R	One RCT showed reduction in hospitalization for heart failure, presumed mechanism slowing of heart rate, important to titrate BB up to target dose prior to consideration
Diuretics	Patients with HFrEF and fluid retention	I	C	Improve symptoms and exercise tolerance, unknown mortality effects
Digoxin	Consider in persistently symptomatic patients with HFrEF on GDMT	IIa	B-R	No mortality benefit; placebo-controlled trials showed reduction in symptoms, improved QOL and exercise tolerance and may modestly reduce hospitalizations. Low doses just as beneficial for HF; risk of toxicity including cardiac arrhythmia

[a]COR, class (strength) of recommendation—class I, (strong) benefit ⊠ risk; class IIa, (moderate) benefit ≫ risk; class IIb, (weak) benefit ≥ risk; class III: no benefit, (moderate) benefit = risk; class III: harm, (strong) risk > benefit (Yancy et al., 2016).

[b]LOE, level (quality) of evidence: level A, high-quality evidence from multiple RCTs, meta-analyses of high-quality RCTs, or one of more RCTs corroborated by high-quality registry studies; level B-R (randomized), moderate-quality evidence from one or more RCTs or meta-analyses of moderate-quality RCTs; level B-NR (nonrandomized), moderate-quality evidence from one or more well-designed, well-executed nonrandomized, observational, or registry studies or meta-analyses of such studies; level C-LD (limited data), randomized or nonrandomized observational studies with limitations of design or execution, meta-analyses of such studies, or physiological or mechanistic studies in human subjects; level C-EO (expert opinion), consensus of expert opinion based on clinical experience (Yancy et al., 2016).

[c]GDMT, guideline-directed medical therapy that is optimal medical therapy as recommended by ACCF/AHA guidelines (Yancy et al., 2013).

The data for the efficacy of aldosterone antagonists are not as clear. An analysis of data from the RALES study found no reduction in a combined end point of death or hospitalization in the African American subgroup prescribed spironolactone and also found a lower incidence of hyperkalemia, suggesting spironolactone may be less efficacious in African Americans (Vardeny et al., 2013). However, a retrospective analysis of data from the African American Heart Failure Trial (A-HeFT) found decreased mortality with the use of spironolactone and a trend toward increased event-free survival and time to first heart failure hospitalization but only for African Americans already taking hydralazine–isosorbide dinitrate (Ghali et al., 2008). The addition of aldosterone antagonists remain, however, part of standard guideline-directed therapy in symptomatic patients with heart failure.

HFrEF: Beta-Blockers in African Americans

Studies support a benefit for beta-blocker use in African Americans with HFrEF, although it is possible the magnitude of the protective effect is not as large as for Caucasians. A study including 523 African American patients using data from the Carvedilol Heart Failure Registry found similar reductions in hospitalizations and improvement in symptoms for African Americans and Caucasians taking carvedilol (Abraham et al., 2007). A second retrospective study also found a lower risk of death or rehospitalization for African Americans with HFrEF prescribed beta-blockers but with a smaller protective effect compared with Caucasians (Lanfear et al., 2012). Another small retrospective study found an improvement in LVEF, left ventricular end-diastolic dimensions (LVEDD), and mitral regurgitation after 1 year of beta-blocker treatment in African Americans and Caucasians, although African Americans were slightly less likely to have improvement in LVEF and LVEDD compared with Caucasians (Kelesidis et al., 2013).

Differential responses to beta-blockade have been observed in the general population as well, and there are known genetic polymorphisms in the beta-adrenergic receptors and in G-protein receptor kinase 5 (GPRK5), which regulate beta-adrenergic signaling. One study found similar beta-blocker effects on survival when African American and Caucasian patients were matched for two polymorphisms, one in GPRK5 and the other in one of the beta-blocker receptors (ADRB1), suggesting genetic polymorphisms in the beta-blocker signaling cascade may be responsible for the observed differences in the magnitudes of the effect (Cresci et al., 2009).

HFrEF: Hydralazine and Nitrates

The A-HeFT trial evaluated adding a fixed-dose combination of I/H to standard therapy in African American patients with NYHA class III or IV HFrEF. The trial was terminated early due to a 40% reduction in mortality in the treatment group, as well as significant improvement in the primary end point, a combined end point of weighted values for death, first hospitalization for heart failure, and change in quality of life (Taylor et al., 2004). The trial was designed after the Vasodilator Heart Failure Trial II (V-HeFT II) found that enalapril was more effective than I/H for patients with HFrEF, except in African Americans, where the two were comparable.

The approval of I/H as the first race-based drug was controversial. The A-HeFT trial design was criticized, since by only including African Americans it failed to show that the addition of I/H to standard therapy was superior in African Americans compared with other races or that it was ineffective in other races. The use of self-identified race was also controversial, as race is a social construct and those who identify as African American may not all share genetic differences that could explain a disproportionate effect. Others, however, saw it as a breakthrough for a group with a high incidence of and mortality from heart failure who are often underrepresented in major trials (Maglo et al., 2014).

Several different mechanisms for a possible differential response to I/H in African Americans have been proposed. African Americans with one genotype for the guanine nucleotide-binding protein beta-3 subunit, which plays a role in alpha-2 adrenergic signaling (GNB3 TT), had lower rates of death and hospital stay for heart failure and improved quality of life when treated with I/H compared with those who had other alleles (McNamara et al., 2014). The same allele, which is more common in African Americans, has also been associated with worse outcomes after a diagnosis of peripartum cardiomyopathy (Sheppard et al., 2016), suggesting increased alpha adrenergic tone may be both a risk factor for development/progression of heart failure and one of the treatment targets for I/H. A role for hydralazine enhancing nitric oxide's effects on vasodilation and inhibition of platelet aggregation has also been proposed (Chirkov et al., 2010), although this is debated. It has been suggested that African Americans might have differences in nitric oxide bioavailability that could account for I/H's observed benefits (McNamara et al., 2009).

More studies are needed to further assess the utilization of I/H in practice. Some studies have found that only 4.5%–22% of eligible African Americans were discharged home after a hospitalization for HFrEF with a prescription for I/H; however, further study is needed to assess whether this is true across other cohorts and to determine which factors might affect prescribing decisions at discharge (including whether patients are already prescribed other optimal medical therapy) (Yancy et al., 2008; Golwala et al., 2013).

HFrEF: Medical Devices

Research supports a similar mortality benefit compared with Caucasians for cardiac resynchronization therapy (CRT) in eligible African Americans with NYHA class II–IV HFrEF (Fontaine et al., 2016; Ziaeian et al., 2014). Studies have shown, however, that African American patients who are eligible for CRT may be less likely to receive it compared with Caucasians (Farmer et al., 2009; Piccini et al., 2008). African Americans also have a higher risk for SCD (Fender et al., 2014), and there is underutilization of implantable cardiac defibrillators (ICDs) for primary and secondary prevention in African Americans. The SCD-HeFT trial found no difference in the rate of ICD shocks and similar reductions in mortality between Caucasians and African Americans with ICDs (Mitchell et al., 2008). A study of elderly Medicare beneficiaries admitted after cardiac arrest also found similar mortality reductions although African Americans were less likely to receive an ICD (Groeneveld et al., 2003). However, the MADIT-II trial, which included a fairly small number of African Americans ($n = 102$), found no reduction in sudden cardiac death or mortality in African Americans (Vorobiof et al., 2006), and a prospective cohort study of patients with HFrEF receiving ICDs found African Americans were more likely to die without receiving an appropriate shock (i.e., to not benefit from the ICD) although a substantial number also received appropriate shocks (Zhang et al., 2014). The reason for possibly less response is unclear and warrants further study.

HFrEF: Advanced Circulatory Support and Transplant

There are limited data on outcomes for left ventricular assist devices specifically in African Americans. Small studies show similar outcomes and no difference in survival compared with Caucasians (Tsiouris et al., 2013; Aggarwal et al., 2012), and African American patients should be considered for advanced circulatory support in the same manner as all other patients. However, a study using data from the National Inpatient Sample from 2002 to 2003 found African Americans with heart failure or cardiogenic shock were less likely to undergo LVAD implantation (Joyce et al., 2009). Compared with Caucasians, more African Americans present

with critical heart failure and at higher risk for LVAD (Stulak et al., 2013). African Americans are also more likely to be sicker at the time of listing for transplant and have a higher mortality while awaiting transplant (Morris et al., 2016). Disparities in counseling and timely referral for transplant and advanced circulatory support should be addressed (Morris et al., 2016).

African Americans have higher mortality and risk of graft failure after cardiac transplant. Compared with both Caucasians and Hispanics, the risk of acute and chronic graft failure and mortality after heart transplant is higher (Morris et al., 2015; Kilic et al., 2015). Although African Americans are more likely to be transplanted at worse performing centers, this does not fully explain the effect (Kilic et al., 2015). There is a trend toward increased mortality even at high-performing centers, and African Americans transplanted at low-performing centers have higher than expected mortality (Kilic et al., 2015). While short-term posttransplant survival has improved equally in White, Black, and Hispanic recipients, long-term survival has not improved in Blacks or Hispanics (Morris et al., 2016; Singh et al., 2011). Although social inequities in access to care/high-performance centers likely do play a role, they do not appear to be the only reason for increased mortality. A more recent study demonstrated that disparities in access appeared to have improved after the ACA Medicaid Expansion (Breathett et al., 2017). Immunologic differences likely play an important role in the increased risk of acute and chronic rejection and cardiac allograft vasculopathy. Further study and attention to individualizing immunosuppressive regimens for African Americans may improve outcomes (Morris et al., 2016).

Heart Failure With Preserved Ejection Fraction

The majority of African Americans with heart failure actually have HFpEF, as many as 73% in the ARIC study (Gupta et al., 2013). There is little evidence to support mortality benefits for any particular class of drugs or treatment for HFpEF for the general population or for African Americans. Treatment is largely symptomatic with diuretics and focused on control of hypertension. One small retrospective study of African Americans with diastolic dysfunction did find lower progression of diastolic dysfunction among those prescribed calcium channel blockers (Prendergast et al., 2014). However, further research is needed to better define the optimal hypertension regimens (if one exists) and if any treatments influence mortality or rehospitalization.

End of Life and Palliative Care

Palliative care is underutilized by patients with advanced heart failure in general but even more so for African Americans (Givens et al., 2010). The best way to improve utilization of palliative care and focus on comfort/patient priorities at the end of life is not yet determined. One randomized trial of African American patients with advanced heart failure who had been hospitalized with a heart failure exacerbation found that a palliative care consultation during the hospitalization did not increase the likelihood of choosing comfort care (Hopp et al., 2016).

Future Study and Directions

Heart failure, both HFrEF and HFpEF, represents a major cause of morbidity and mortality for African Americans. More study and work are needed to prevent future cases and improve outcomes for patients with the disease. Improved prevention is needed, through improved treatment and prevention of hypertension, diabetes mellitus II, and obesity. Exercise has been found to offer similar protective effects against heart failure in African Americans compared with Caucasians (Bell et al., 2013). Better understanding of and efforts to address disparities in access and quality of care, socioeconomic status, and differences in medication adherence, self-care, and health literacy are essential. Such inequalities greatly affect both prevention efforts and outcomes for patients with existing heart failure.

Further studies are also needed to better clarify the best ways to prevent and treat HFpEF, both in African Americans and the general population. Some of the best studied pharmacological treatments in African Americans are beta-blockers and ACEi/ARBs, which have been shown to benefit African Americans; yet even for these medications, some studies have found conflicting results or suggested a lesser magnitude of effect. Further, large studies of these and less studied treatments such as aldosterone receptor antagonists, ICDS, and LVADs would help to further clarify treatments. Given the high incidence of heart failure in African Americans, future clinical trials should make an effort to ensure a large number of African Americans are included.

Lastly, further understanding the genetic basis for differential response to treatments in African Americans will help to individualize therapy based on a biological likelihood of response rather than relying on race that is in part a social construct that inevitably groups some patients together who have disparate genetic differences in susceptibility to heart failure and response to treatment.

Introduction

Recent advances in the detection and treatment of cancer have led to a vast improvement in cancer survival. In 2012, the estimated number of breast cancer survivors in the United States was 3 million (Moslehi, 2013). Between 2003 and 2012, the mortality due to non-Hodgkin's lymphoma and leukemia decreased by 2.5% and 1% per year respectively (Siegel et al., 2015). However, improved cancer survivorship comes at the cost of adverse cardiovascular effects associated with cancer therapies. Cardiovascular disease was the primary cause of mortality among elderly breast cancer survivors (Patnaik et al., 2011). Modern cancer therapies including radiotherapy, chemotherapy, and targeted therapies have the potential to cause heart failure (HF), hypertension, ischemia, cardiac arrhythmias, and conduction diseases (Bloom et al., 2016). Chemotherapy-induced cardiomyopathy is considered as a separate entity in this broad spectrum of cancer therapy-mediated cardiotoxicity (Mukku et al., 2016). In this article, we discuss the definitions, pathophysiology, mechanisms, imaging, prevention, and treatment of HF in cancer patients.

Definitions

There are no universally accepted definitions of cancer therapy-mediated cardiomyopathy (CTMC). One of the first definitions of cardiotoxicity was outlined in a trial evaluating the impact of doxorubicin on left ventricular ejection fraction (LVEF) (Alexander et al., 1979). In this study, a decline in LVEF by >15% from baseline level to below 45% on serial MUGA scan was defined as moderate cardiotoxicity. More recently, the Food and Drug Administration (FDA) defined anthracycline-mediated cardiotoxicity as >20% reduction in LVEF from normal baseline level or >10% reduction from low baseline LVEF (FDA Drug Label, 2007). The Cardiac Review and Evaluation Committee defined trastuzumab-mediated cardiotoxicity as an asymptomatic decline in LVEF of ≥10% or a symptomatic decline of ≥5% to a value <55% (Seidman et al., 2002). The American Society of Echocardiography and the European Association of Cardiovascular Imaging published a consensus statement which defined cardiotoxicity as a ≥10% reduction of LVEF to a value <53%, verified on subsequent imaging (Plana et al., 2014). The above-mentioned definitions of cardiotoxicity are based on arbitrary cutoffs. A broad definition for the diagnosis of CTMC should incorporate abnormal biomarkers and LV dysfunction detected by imaging techniques.

Pathophysiology and Mechanisms

There are a number of chemotherapeutic drugs that cause cardiovascular adverse effects without cardiomyopathy or symptomatic HF. In this review, we focus mainly on cancer therapies associated with cardiomyopathy and HF, particularly anthracyclines, HER2-targeted therapies, and VEGF inhibitors.

Ewer and Lippman classified cardiotoxicity based on the type and degree of structural abnormalities, in addition to the likelihood of reversibility (Ewer and Lippman, 2005). Type I cardiotoxicity is referred to typical pathologic changes in cardiac myocyte ultrastructure causing irreversible injury. Type 2 cardiotoxicity does not damage cardiac myocyte ultrastructure and there is an increased chance of recovery after chemotherapy is discontinued (Ewer and Lippman, 2005). Traditionally, anthracycline- and trastuzumab-mediated cardiotoxicity are categorized as type 1 and 2 cardiotoxicity, respectively. However, this oversimplified classification is controversial as it does not take into account the pathophysiologic mechanisms of other chemotherapeutic drugs (Mukku et al., 2016). For instance, sunitinib, a tyrosine kinase inhibitor, causes ultrastructural changes which can be categorized as type 1 cardiac toxicity but these changes have been shown to be reversible (Mukku et al., 2016). Recent studies have demonstrated that the early detection and timely initiation of cardioprotective medications can partially reverse anthracycline-mediated type 1 cardiotoxicity, and prevent progression to symptomatic HF (Cardinale et al., 2015). Conversely, trastuzumab-mediated cardiotoxicity can cause myocardial injury with elevation of troponins, and may not always be reversible (Cardinale et al., 2010).

Anthracyclines

Anthracyclines are a class of chemotherapeutic drugs used for the treatment of hematologic malignancies and solid tumors (Blum and Carter, 1974). In breast cancer patients, doxorubicin- and epirubicin-based chemotherapy regimens are used not only before and after definitive surgery but also in the metastatic setting (Bloom et al., 2016). Anthracyclines enhance the synthesis of reactive oxygen species, impair DNA repair by inhibition of topoisomerase II, and downregulate protein synthesis by binding to nuclear DNA (Chen et al., 2007; Tewey et al., 1984) (**Fig. 1**). While the inhibition of topoisomerase 2-α in rapidly proliferating cancer cells is responsible for its antitumor action, the inhibition of this enzyme in cardiac myocytes causes cardiotoxicity (Lyu et al., 2007). Studies have suggested that the risk of doxorubicin-mediated cardiotoxicity exists even at cumulative doses <250 mg/m^2; thus, a safe dose threshold remains unclear (Pein et al., 2004). However, it is important to note that the risk of cardiotoxicity with anthracyclines is dose dependent and is further amplified with the use of radiotherapy, the presence of traditional cardiovascular risk factors, and concomitant administration of other cardiotoxic agents such as cyclophosphamide and trastuzumab (Volkova and Russell, 2011).

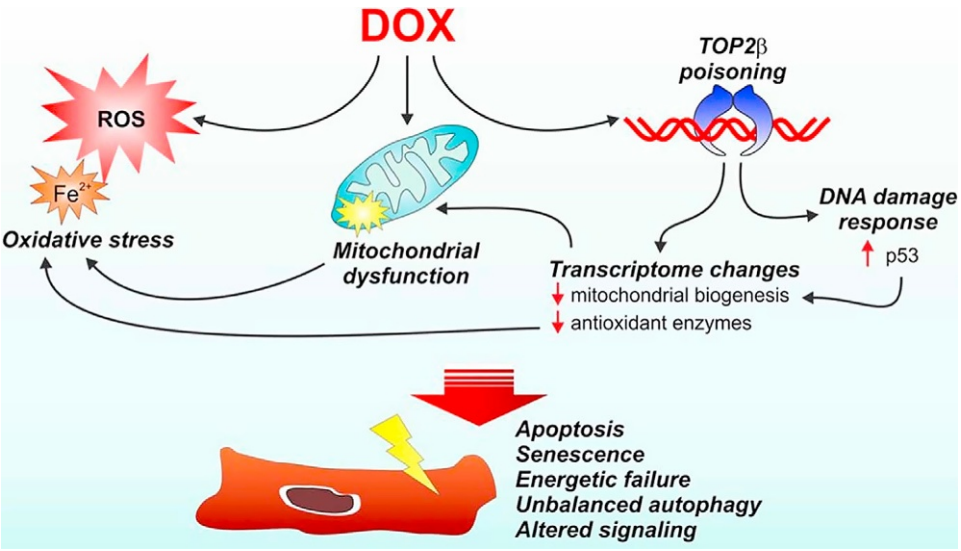

Fig.1 Cardiomyocyte-intrinsic molecular mechanisms underlying anthracycline cardiotoxicity. Anthracyclines, such as doxorubicin (DOX), lead to cardiotoxicity by promoting the production of reactive oxygen species (ROS), via direct (unstable DOX metabolites, such as DOX-semiquinone, react with oxygen and generate hydrogen peroxide and superoxide) and indirect (DOX chelates free iron and modulates the activity/expression of major iron-transporting/binding proteins) mechanisms. Alternatively, DOX can interact with cardiomyocyte topoisomerase 2β (Top2β), an enzyme responsible for managing DNA tangles and supercoils, thus inducing DNA double-strand breaks. DNA damage, in turns, activates the tumor suppressor protein p53, which is responsible for the activation of DNA repair proteins, but also of repression of genes involved in mitochondrial biogenesis/recycling and oxidative phosphorylation pathways. Finally, DOX can accumulate within mitochondria of cardiomyocytes and exacerbate metabolic failure of these organelles. Altogether, these molecular events contribute to cardiomyocyte death and ultimately to cardiac dysfunction. Adapted with permission from Mercurio, V., Pirozzi, F., Lazzarini, E., Marone, G., Rizzo, P., Agnetti, G., Tocchetti, C.G., Ghigo, A. and Ameri, P. (2016). Models of heart failure based on the cardiotoxicity of anticancer drugs. *Journal of Cardiac Failure*. **22**, 449-458.

HER2-Targeted Therapies

Human epidermal growth factor receptor- (HER2-) targeted agents include trastuzumab, lapatinib, and pertuzumab (Sendur et al., 2013). These drugs are used for the treatment of HER2-positive cancers, characterized by overexpression of the HER2 gene leading to an increased production of HER2 protein in malignant cells (Sendur et al., 2013).

Trastuzumab can cause dose-independent, potentially reversible cardiac dysfunction (Ewer and Lippman, 2005). The exact mechanism of trastuzumab-mediated cardiotoxicity is not known. Trastuzumab is a monoclonal antibody against HER2 protein, a receptor tyrosine kinase belonging to the ErbB family. Neuregulin ligand binds to ErbB receptor and promotes cardiac homeostatis (Lemmens et al., 2007). In HF, there is an increased production of neuregulin as this ligand is released by myocardial cells in response to stress (Baliga et al., 1999; Zhao et al., 1998; Ky et al., 2009). It has been proposed that the inhibition of the neuregulin ErbB pathway in cardiac myocytes by trastuzumab leads to myocardial dysfunction (Mercurio et al., 2016).

Patients receiving concurrent anthracycline therapy are at a higher risk of trastuzumab-mediated cardiotoxicity when compared to those on trastuzumab alone (Seidman et al., 2002). Age, diabetes, renal dysfunction, and previous heart disease are also associated with an increased risk of cardiomyopathy (Onitilo et al., 2014). Notably, when compared to trastuzumab, the risk of cardiotoxicity with other HER2-targeted therapies is significantly lower (Sendur et al., 2013).

VEGF Inhibitors

These drugs target vascular endothelial growth factor (VEGF) and include small molecule tyrosine kinase inhibitors (sorafenib, sunitinib) as well as monoclonal antibodies (bevacizumab) (Yang and Papoian, 2012; Choueiri et al., 2011). VEGF not only regulates the cardiac myocyte growth and function but also promotes the integrity and growth of coronary and systemic circulation (Mercurio et al., 2016). Inhibition of VEGF signaling may result in hypertension, thromboembolism, myocardial dysfunction, and HF (Schmidinger et al., 2008) (**Figs. 2–4**).

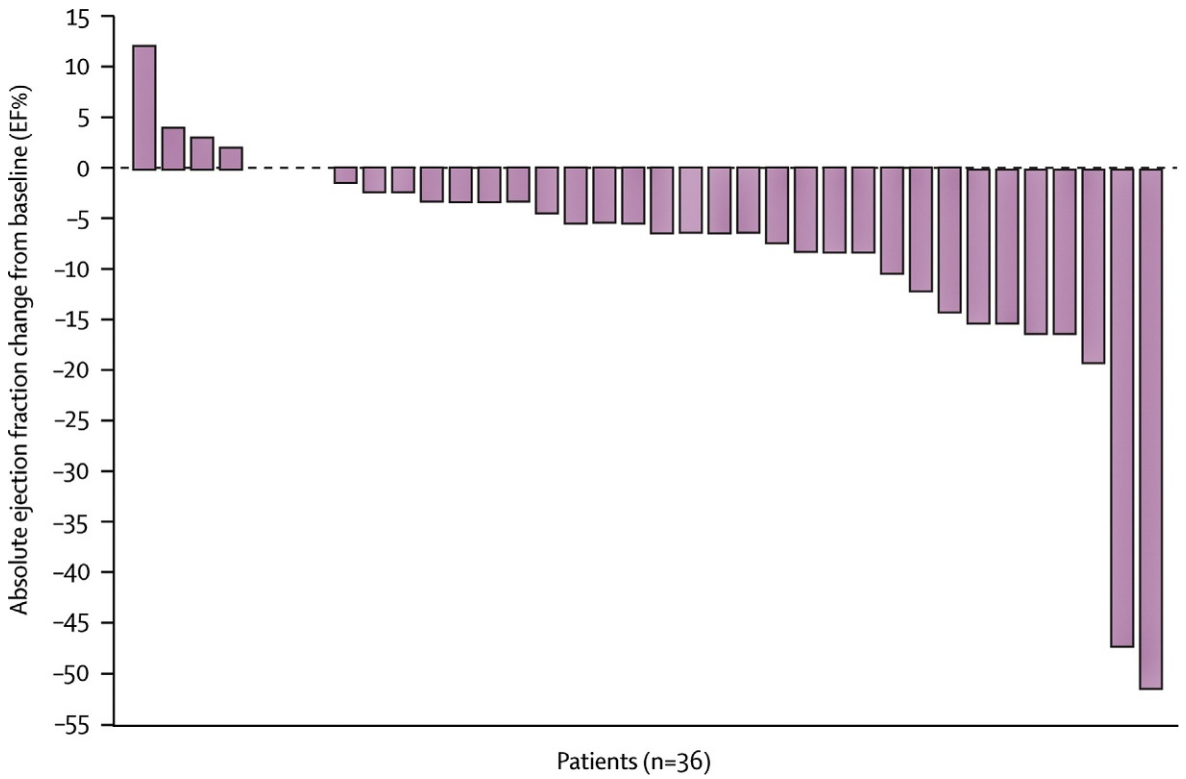

Fig. 2 Absolute maximum change in left ventricular ejection fraction (LVEF) from baseline in individual patients given the approved sunitinib dose. Individual data for absolute maximum change in LVEF from baseline to treatment with sunitinib 50 mg per day, 4 weeks on and 2 weeks off, is shown for all 36 patients. Three patients had no change in LVEF from baseline and are represented without bars. Adapted with permission from Chu, T.F., Rupnick, M.A., Kerkela, R., Dallabrida, S.M., Zurakowski, D., Nguyen, L., Woulfe, K., Pravda, E., Cassiola, F., Desai, J., George, S., Morgan, J.A., Harris, D.M., Ismail, N.S., Chen, J.H., Schoen, F.J., Van den Abbeele, A.D., Demetri, G.D., Force, T., Chen, M.H. (2007). Cardiotoxicity associated with tyrosine kinase inhibitor sunitinib. *Lancet.* **370**, 2011–2019.

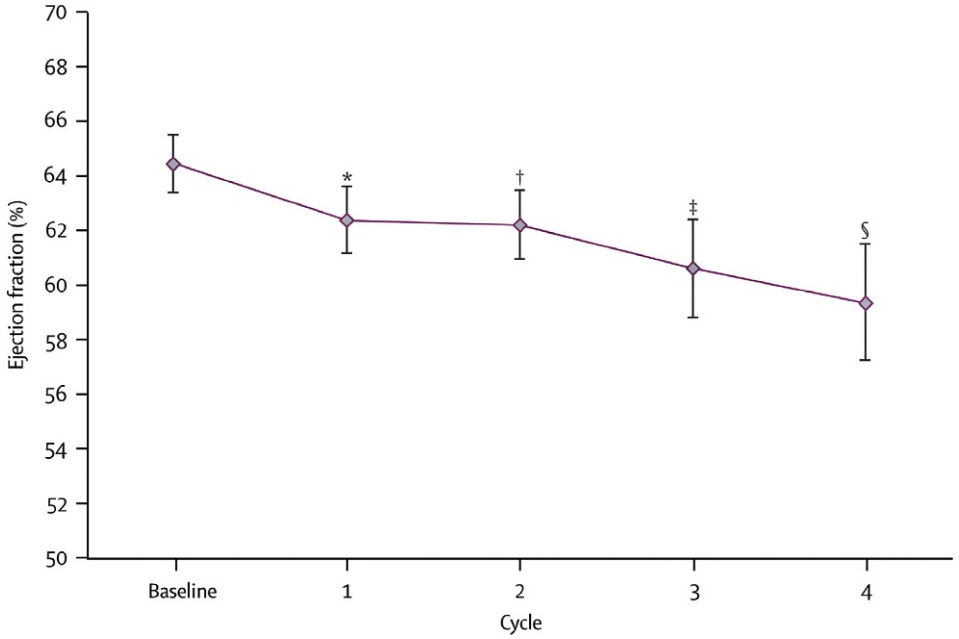

Fig. 3 Model of predicted change in mean left ventricular ejection fraction (LVEF) by treatment cycle. Repeated measures, mixed-model regression analysis of LVEF data derived from 36 patients during first four cycles of sunitinib treatment revealed progressive decrease in LVEF with an increase in number of sunitinib cycles. The model demonstrated an initial 2% decrease from baseline, followed by 1.5% decrease with cycle for every subsequent cycle. Predicted LVEF at baseline was 64.5%; after cycle 1, 62.4%; after cycle 2, 62.3%; after cycle 3, 60.6%; and after cycle 4, 59.4%. $^{*}P=0.048$ (cycle 1); $^{\dagger}P=0.044$ (cycle 2); $^{\ddagger}P=0.013$ (cycle 3); and $^{\S}P=0.007$ (cycle 4). Vertical bars represent SE. Adapted with permission from Chu, T.F., Rupnick, M.A., Kerkela, R., Dallabrida, S.M., Zurakowski, D., Nguyen, L., Woulfe, K., Pravda, E., Cassiola, F., Desai, J., George, S., Morgan, J.A., Harris, D.M., Ismail, N.S., Chen, J.H., Schoen, F.J., Van den Abbeele, A.D., Demetri, G.D., Force, T., Chen, M.H. (2007). Cardiotoxicity associated with tyrosine kinase inhibitor sunitinib. *Lancet.* **370**, 2011–2019.

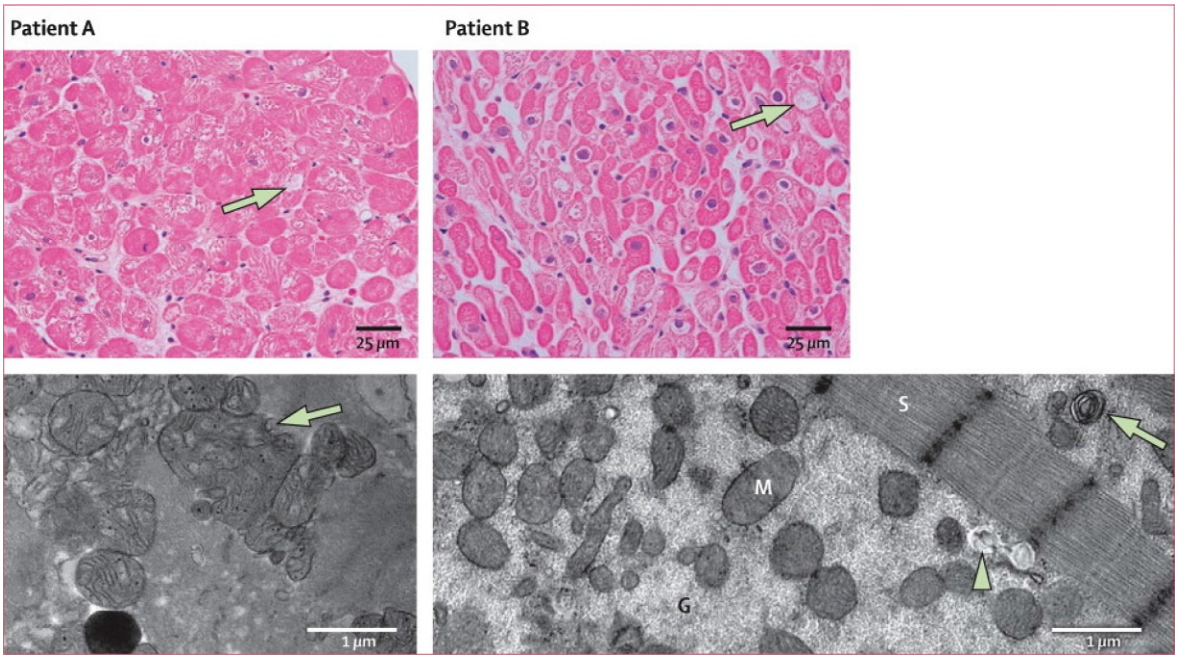

Fig. 4 Endomyocardial biopsy samples from two index patients who developed congestive heart failure on sunitinib. Light photomicrographs from patients A and B revealed myocyte hypertrophy with mild degenerative changes and diffuse, moderate cardiomyocyte vacuolisation (*arrows*). Oedema, interstitial or replacement fibrosis, regional infarct or focal cell necrosis, or myocarditis, or inflammation was not noted. Transmission electronmicrograph from patient A (bottom *left*) showed swollen, abnormal mitochondrial configurations (*arrow*) with effaced cristae. Transmission electronmicrograph from patient B (bottom *right*) showed numerous cytoplasmic granular densities consistent with glycogen accumulation (G), membrane whorl (*arrow*), and lysosomal precipitates (arrowhead). Sarcomeres (S) appeared well organized and structurally intact in patients A and B. (Light microscopy, stained with haematoxylin and eosin, bar = 25 μm; transmission electronmicroscopy, bar = 1 μm.). (2007). Cardiotoxicity associated with tyrosine kinase inhibitor sunitinib. *Lancet.* **370**, 2011–2019.

Radiotherapy-Induced Cardiotoxicity

Radiotherapy involves exposure to high-energy particles, X-rays, and gamma radiation which breakdown DNA and in turn impair cell proliferation and repair (Groarke et al., 2014). It mainly affects rapidly proliferating tumor cells that have a high metabolic rate. The effect on normal cells is influenced by their inherent susceptibility and the intensity of ionizing radiation (Groarke et al., 2014). Radiotherapy to the chest for breast cancer and Hodgkin's lymphoma can cause damage to the heart and vascular system (Jaworski et al., 2013). This may manifest 20–30 years after initial exposure (Tukenova et al., 2010). Based on current evidence, a safe threshold for radiotherapy is unknown (Tukenova et al., 2010; Darby et al., 2013).

Radiation therapy can damage all layers of the heart (Filopei and Frishman, 2012). Recent improvements in technology have decreased the incidence of acute pericarditis secondary to radiotherapy from 20% to 2.5%(Jaworski et al., 2013). In patients who receive $\geq$1500 centiGy radiation to the chest, the incidence of chronic pericarditis at 30 years is 3% (Mulrooney et al., 2009). Injury to the endocardium and valves can initially cause valve retraction as well as regurgitation and subsequently lead to stenosis (van Leeuwen-Segarceanu et al., 2011). The typical myocardial changes secondary to radiation exposure include diffuse interstitial fibrosis, capillary rarefaction, wall thickening, and luminal narrowing of arterioles and capillaries (Herrmann et al., 2014). Injury to the endothelial layer causing micro-hemorrhage and worsening of radiation-mediated inflammation leads to myocardial dysfunction (Seemann et al., 2012). Additionally, leaking of albumin into myocardial interstitium contributes to restrictive cardiomyopathy (Herrmann et al., 2014).

Risk Factors for Chemotherapy-Mediated Cardiomyopathy

There are a number of patient-related risk factors which contribute to cardiotoxicity. These include traditional cardiovascular risk factors such as hypertension, age, nicotine use, postmenopausal status, as well as preexisting coronary artery disease, LV dysfunction, or HF (Albini et al., 2010). A recent study attributed the development of cardiotoxicity at a relatively small dose of anthracycline to genetic polymorphism. This evidence suggests that some patients may have genetic predisposition to chemotherapy-induced cardiotoxicity (Blanco et al., 2012). Chemotherapy-related risk factors include administration of drugs in bolus form, use of larger doses, prior chest irradiation, prior treatment with anthracyclines, or concurrent use of chemotherapeutic agents (Valachis and Nilsson, 2015).

Biomarkers

Multiple studies have evaluated the utility of biomarkers for early detection and risk stratification of chemotherapy-mediated cardiotoxicity (Witteles, 2016). Two commonly used biomarkers are troponin and natriuretic peptide (Witteles, 2016).

Troponins are thought to be biomarkers of myocardial injury (Bloom et al., 2016). Changes in troponin levels with each cycle of therapy can serve as a marker of risk of cardiotoxicity (Bloom et al., 2016). In a study of over 700 patients undergoing high-dose chemotherapy, immediate elevation in troponin I levels suggested a high risk of future LV dysfunction. On the other hand, lack of troponin elevation predicted a low risk of cardiotoxicity (Cardinale et al., 2004). Troponin elevation after trastuzumab therapy is almost exclusively observed in patients with prior treatment with anthracyclines. Tropinin levels increase in the first 2–3 months of trastuzumab therapy and return to normal levels during the subsequent 3 months in the majority of patients (Cardinale et al., 2010; Ky et al., 2014; Morris et al., 2011; Sawaya et al., 2012). In some studies, troponin elevation after trastuzumab therapy was associated with increased risk of LVEF reduction and major adverse cardiac events (Cardinale et al., 2010). However, other studies suggested that troponin elevation was not predictive of subsequent cardiac events (Morris et al., 2011). Studies evaluating recently approved tyrosine kinase inhibitors did not provide any evidence to support troponin monitoring in these patients (Schmidinger et al., 2008; Hall et al., 2013; Perik et al., 2008).

The utility of natriuretic peptides as a predictor of left ventricular dysfunction is unclear. In one study, elevation of natriuretic peptides after treatment with doxorubicin predicted subsequent LV dysfunction (Lipshultz et al., 2012). However, another study did not show any link between biomarkers and ventricular dysfunction (Sawaya et al., 2012). Natriuretic peptides do not have any role in early detection of cardiac toxicity secondary to trastuzumab (Witteles, 2016). The role of monitoring natriuretic peptides for patients receiving VEGF inhibitors is not well defined. Asymptomatic elevation in natriuretic peptides was observed after the use of VEGF inhibitors but it did not conclusively predict future LV dysfunction (Hall et al., 2013).

Imaging

Echocardiography

Accurate estimation of LVEF is vital in cancer patients due to its potential implications on the chemotherapy regimen (Kongbundansuk and Hundley, 2014). Two-dimensional echocardiography is a commonly used tool for monitoring ventricular function in these patients (Plana et al., 2014; Cheitlin et al., 2003). Measurement of LVEF by this imaging modality may be limited by image quality. Another disadvantage is its inability to detect subtle changes in LVEF (Cheitlin et al., 2003). The American Society of Echocardiography recommends the use of contrast for a clear delineation of endocardial borders in breast implant patients

(Mulvagh et al., 2008). Three-dimensional echocardiography, with a lower inter-observer variability and high reproducibility, is a superior tool for assessment of LV function and to detect small changes in LVEF (Thavendiranathan et al., 2013a). The use of speckle tracking and strain imaging (Baliga and Young, 2011) can lead to the detection of small decline in ventricular function at an early stage (Sawaya et al., 2012). The reduction in global longitudinal strain may be noted even with a preserved LVEF. A decline of >11% in global longitudinal strain was a major predictor of cardiomyopathy in one study (Negishi et al., 2013). However, the use of this technology is limited by the lack of universal availability, absence of standard definitions, and nonuniformity of measurement between vendors (Bloom et al., 2016).

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (CMR) is superior to echocardiography for the assessment of ventricular size and function. The use of CMR can lead to a higher estimation of prevalence of chemotherapy-induced cardiomyopathy (Bloom et al., 2016; Armstrong et al., 2012). CMR also gives a noninvasive description of the myocardial tissue in terms of edema, scarring, and inflammation, which can help distinguish early and late cardiotoxicity in cancer patients (Thavendiranathan et al., 2013b). CMR may also have a prognostic role in cancer patients receiving chemotherapy. In one study, indexed LV mass by CMR was the strongest predictor of adverse cardiac events in patients with anthracycline-mediated cardiomyopathy (Neilan et al., 2012). In a different study evaluating the role of CMR, subepicardial late gadolinium enhancement in the lateral wall of left ventricle was observed in all patients in trastuzumab-mediated cardiomyopathy (Fallah-Rad et al., 2008). Although CMR is considered as a gold standard for the assessment of LV function, its routine use is limited by availability, cost, and other patient-specific variables such as claustrophobia and implantable cardiac devices (Bloom et al., 2016).

Radionuclide Imaging

In the past, multigated acquisition scan, due to its high reproducibility and availability, was the primary imaging modality for monitoring LV function (Jiji et al., 2012). Echocardiography has a higher inter-observer variability compared to multigated acquisition scan. But echocardiography is available at a lower cost and provides structural and functional information in addition to LVEF (Plana et al., 2014; Jiji et al., 2012). The main drawback of multigated acquisition scan is radiation exposure. Since the goal of medicine is to limit the radiation to "as low as reasonably achievable," one should evaluate the risk versus benefit of using this imaging modality for each individual patient (Plana et al., 2014).

Prevention Strategies

Prevention strategies can be broadly divided into (a) primary prevention—prophylactic treatment in patients at risk for cardiomyopathy and (b) secondary prevention—initiation of medical therapy in patients showing subclinical signs of cardiomyopathy such as elevated biomarkers (Khouri et al., 2012). A new approach described as primordial prevention is also being proposed. This refers to the institution of medical therapy after the primary cancer diagnosis but before the initiation of chemotherapy (Khouri et al., 2012).

Primary Prevention

Cancer patients with no known structural heart disease, who are receiving chemotherapy, are at risk for developing cardiomyopathy and are therefore considered to have Stage A HF. In the following section, we discuss the role of cardioprotective medications for primary prevention.

β-Blockers

Multiple studies have examined the role of β-blockers for the prevention of chemotherapy-mediated cardiotoxicity. Carvedilol is thought to have antioxidant and iron-chelating properties which prevent histopathologic changes induced by anthracyclines (Oliveira et al., 2004). In a randomized study involving 50 patients receiving anthracyclines, prophylactic administration of carvedilol attenuated cardiac dysfunction (Kalay et al., 2006). Nebivolol, used before planned chemotherapy, led to a greater preservation of LVEF (Kaya et al., 2013). Preliminary results of the recently completed MANTICORE (Multidisciplinary Approach to Novel Therapies in Cardiology Oncology Research) study suggest that the use of bisoprolol attenuates trastuzumab-mediated cardiotoxicity (Pituskin et al., 2015). The other β-blockers do not appear to have the same beneficial effects. While metoprolol is not cardioprotective (Georgakopoulos et al., 2010), propranolol may be potentially harmful for cancer patients (Choe et al., 1978) (**Figure 5**).

Renin–Angiotensin Inhibitors

Preclinical studies reveal that angiotensin II (Toko et al., 2002) and endothelin I (Bien et al., 2007) are involved in anthracycline cardiotoxicity. A study in rats suggested that renin–angiotensin inhibitors may be protective against anthracycline-mediated cardiotoxicity (Abd El-Aziz et al., 2001). Different mechanisms have been proposed to explain the beneficial effects of

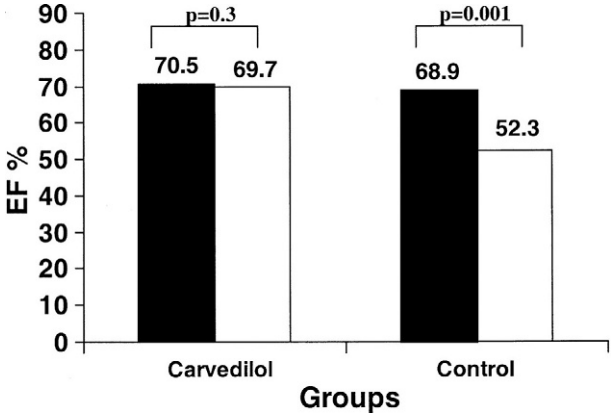

Fig. 5 Carvedilol in anthracycline-induced cardiomyopathy. Baseline LVEF (black bars) and after chemotherapy (white bars) in carvedilol ($N=25$) and control ($N=25$) groups. Data expressed as mean values. Adapted with permission from Kalay, N., Basar, E., Ozdogru, I., Er, O., Cetinkaya, Y., Dogan, A., Inanc, T., Oguzhan, A., Eryol, N. K., Topsakal, R., Ergin, A. (2006). Protective effects of carvedilol against anthracycline-induced cardiomyopathy. *Journal of the American College of Cardiology* **48**, 2258–2262.

renin–angiotensin inhibitors. These drugs have antifibrotic properties, decrease oxidative stress, and reduce the angiotensin-mediated inhibition of neuregulin/Erb system (Valachis and Nilsson, 2015). Evidence from multiple trials studying the efficacy of renin–angiotensin inhibitors in patients receiving chemotherapy has been largely equivocal. In one randomized study involving 125 patients with hematologic malignancies, enalapril did not reduce the incidence of anthracycline-mediated HF (Georgakopoulos et al., 2010). In another study involving patients receiving trastuzumab, the use of perindopril did not prevent a decline in LVEF (Pituskin et al., 2015). However, in the recently published PRADA (Prevention of Cardiac Dysfunction during Adjuvant Breast Cancer Therapy) trial, the use of candesartan, in breast cancer patients receiving anthracyclines and trastuzumab, prevented a significant decline in LVEF (Gulati et al., 2016).

Aldosterone Antagonists

Aldosterone antagonists are thought to protect against cancer therapy-mediated cardiac toxicity by its antifibrotic, antioxidant actions and by preventing apoptosis (Akpek et al., 2015). In a randomized study involving 83 patients with breast cancer, concomitant use of spironolactone and anthracyclines resulted in a greater preservation of LVEF (Akpek et al., 2015).

Combination of β-Blockers and Renin–Angiotensin Inhibitors

In the OVERCOME trial (Prevention of Left Ventricular Dysfunction with Enalapril and Carvedilol in Patients Submitted to Intensive Chemotherapy for the Treatment of Malignant Hemopathies), combined treatment with carvedilol and enalapril, in patients with hematologic malignancies, prevented a decline in LVEF and reduced the incidence of composite endpoint of death or HF (Bosch et al., 2013).

Secondary Prevention
