Intermediate-sized neuroblasts differentiate into multipolar postganglionic sympathetic neurones that secrete noradrenaline (norepinephrine) at their terminals. The smaller neuroblasts probably correlate with the small, intensely fluorescent (SIF) cells, types I and II, that store and secrete dopamine type I and are thought to function as true interneurones, synapsing with the principal postganglionic neurones. Type II cells probably operate as local neuroendocrine cells, secreting dopamine into the ganglionic microcirculation. Both types of SIF cells can modulate synaptic transmission in the ganglionic neurones. The large cells differentiate into masses of columnar or polyhedral phaeochromocytes (classic chromaffin cells) that secrete either adrenaline (epinephrine) or noradrenaline. These cell masses are termed paraganglia and may be situated near, on the surface of, or embedded in, the capsules of the ganglia of the sympathetic chain, or in some of the large autonomic plexuses. The largest members of the latter are the para-aortic bodies that lie along the sides of the abdominal aorta in relation to the inferior mesenteric artery. During childhood, the para-aortic bodies and the paraganglia of the sympathetic trunk partly degenerate and can no longer be isolated by gross dissection; even in the adult, chromaffin tissue can still be recognized microscopically in these various sites. Both phaeochromocytes and SIF cells belong to the amine precursor uptake and decarboxylation (APUD) series of cells and are paraneuronal in nature. Suprarenal chromaffin-like cells have been derived in culture from human pluripotential stem cells (Abu-Bonsrah et al 2018). For further reading about the mechanisms of chromaffin cell development see Unsicker et al (2013) and Hockman et al (2018).

Enteric nervous system

The enteric nervous system is different from the other components of the autonomic nervous system because it can mediate reflex activity independently of control by the brain and spinal cord. The number of enteric neurones that develop is believed to be of the same magnitude as the number of neurones in the spinal cord. The mechanisms by which neuronal diversity is generated in the enteric nervous system are unclear: to date, expression patterns of a number of transcription and signalling factors have been mapped in the developing murine and human enteric nervous systems using transcriptome and histochemical analyses (Memic et al 2018).

Neuronal and glial enteric nervous system precursors are derived from vagal and sacral neural crest. The axial levels of crest origin are shown in Fig. 14.20. Rostrally, adjacent to the early rhombencephalon formed by primary neurulation, vagal neural crest cells give rise to both neuroblasts and glial support cells throughout the gut. In experimental studies on chick and mouse embryos, vagal neural crest cells destined for the gut appear to travel through the rostral half of adjacent somites and are thought to gain enteric lineage from exposure to retinoic acid within the somatic mesenchyme. Vagal neural crest cells migrate ventrally to enter the gut, then turn caudally to populate the entire length of the gut progressing at a migratory speed of about 40 μm/hour (Nagy and Goldstein 2017).

Within the gut of chick and mouse embryos, vagal neural crest cells migrate more rapidly when in contact with each other in a wave front of chain migration. The cells proliferate as they migrate, and the end of proliferation promotes the onset of differentiation. Those cells at the leading edge of the wave front move into unpopulated regions of splanchnopleuric mesenchyme that support their migration and subsequent differentiation (Lake and Heuckeroth 2013, Nagy and Goldstein 2017). The submucosal plexus is formed by a secondary radial migration from the myenteric plexus. Enteric neural crest cells differentiate into sensory and motor neurones and interneurones, and into four types of glial cells with a transcriptome that overlaps with astrocytes, oligodendrocytes and Schwann cells (Charrier and Pilon 2017). Almost all enteric glia express myelin proteolipid protein, and have more genes in common with myelinating glia than with astrocytes (Rao and Gershon 2018). Neurospheres of human postnatal enteric neural stem cells transplanted into chick or mouse embryos interact and migrate within their hosts to form chimeric enteric ganglia (Cheng et al 2017). A population of vagal neural crest cells that colonize the foregut secondarily migrate into the developing pancreatic buds and give rise to the resident ganglia and Schwann cells around the islets of Langerhans (Hutchins et al 2018).

Caudally, from somites 28 onwards, neural crest cells and somites arise by secondary neurulation processes within the caudal eminence. Sacral neural crest cells migrate through the adjacent somites and then ventrally within the mesocolon towards the hindgut (which will form the distal part of the colon, rectum and cloaca); some crest cells subsequently contribute to components of the pelvic plexus (see Fig. 14.6).

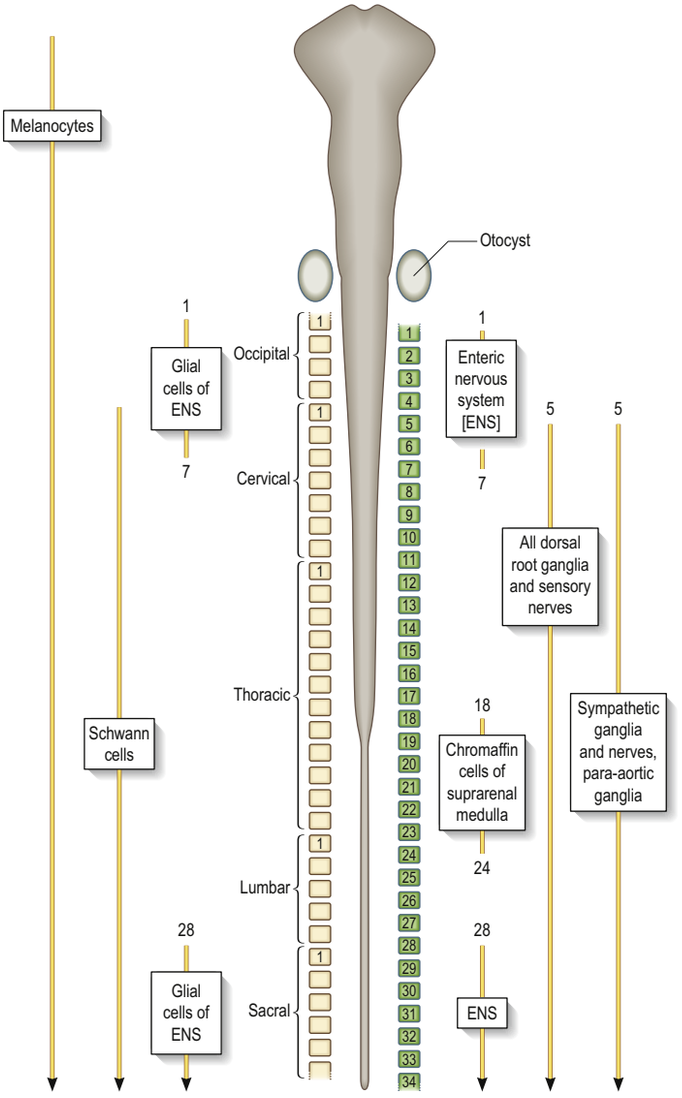

Fig. 14.20 Derivatives of neural crest cells in the trunk. The fate of crest cells arising at particular somite levels is shown.

Once within the gut wall, a regionally specific pattern of enteric ganglia formation occurs, possibly controlled by the local splanchnopleuric mesenchyme. In the mouse embryo, sacral neural crest cells do not colonize the distal colon until vagal neural crest cells are present, at which time the sacral neural crest cells migrate in a caudorostral direction (Mundell et al 2012). The cells lie initially within the developing mesentery, then transiently between the layers of the differentiating muscularis externa, and finally form a more substantial intramural plexus that is characteristic of the adult enteric nervous system.

The human gut has a partially established enteric nervous system with a full complement of enteric neurotransmitters by postmenstrual week 24. Maturation continues into the postnatal period: mucosal enteric glial cells that move into the mucosa after birth interact with the colonizing intestinal flora, suggesting a microbiota-driven homeostatic mechanism for gut function (Ashwell and Waite 2012, Kabouridis and Pachnis 2015). For details of the molecular mechanisms of enteric nervous system development see Rao and Gershon (2018).

Hirschsprung's disease appears to result from a failure of neural crest cells to colonize the gut wall appropriately. The proximal extent of the condition is variable but the rectum is always affected. This distribution suggests that Hirschsprung's disease is a failure of migration and differentiation of the most distal vagal neural crest and/or failure of migration and differentiation of the sacral neural crest derived from secondary neurulation. Histologically, ganglia and postganglionic neurones in the myenteric plexus of the affected segment of gut are either absent or reduced in number and postganglionic innervation of the muscle layers is also often defective. The condition is characterized by a dilated segment of colon proximally (or small bowel in cases of total colonic Hirschsprung's disease) and a lack of peristalsis in the segment distal to the dilation. The condition is also characterized by a transition zone with reduced innervation that may follow an asymmetric course around

the circumference of the bowel, which means that a single biopsy may be unreliable. Neonates with Hirschsprung's disease show delay in the passage of meconium, constipation, vomiting and abdominal distension. The condition is often associated with other defects of neural crest development, e.g. Waardenburg type II syndrome, which includes deafness and facial clefts with megacolon.

CENTRAL NERVOUS SYSTEM

Spinal cord

In the future spinal cord, the median roof plate (dorsal lamina) and floor plate (ventral lamina) of the neural tube do not participate in the cellular proliferation that occurs in the lateral walls and so remain thin. Their cells contribute largely to the formation of the ependyma.

The neuroblasts of the lateral walls of the tube are large and, at first, round or oval (apolar). They soon develop processes at opposite poles and become bipolar neurones. One process is then withdrawn so that the neuroblast becomes unipolar, although this is not invariable in the spinal cord. On further differentiation, dendritic processes develop and the cells become typical multipolar neurones lying in clusters of neuronal clones. The development of a longitudinal sulcus limitans on each side of the central canal of the cord divides the ventricular and intermediate zones in each lateral wall into a basal (ventrolateral) plate or lamina, and an alar (dorsolateral) plate or lamina (see Fig. 14.18). This separation signifies a fundamental functional difference. Neural precursors in the basal plate include the motor cells of the anterior (ventral) and lateral grey columns, while those of the alar plate exclusively form 'interneurones', some of which will synapse with the terminals of primary sensory neurones. Caudally, the central canal of the cord ends as a fusiform dilation, the terminal ventricle.

Anterior (ventral) grey column

The cells of the ventricular zone are closely packed at this stage and arranged in radial columns (see Fig. 14.14). Their disposition may be determined in part by contact guidance along the earliest radial array of glial fibres that cross the full thickness of the early neuroepithelium. The cells of the intermediate zone are more loosely packed. They increase in number initially in the region of the basal plate. This enlargement outlines the anterior (ventral) column of the grey matter and causes a ventral projection on each side of the median plane; the floor plate remains at the bottom of the shallow groove so produced. As growth proceeds, these enlargements are further increased by the development of the anterior funiculi (tracts of axons passing to and from the brain) and encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord. The axons of some of the neuroblasts in the anterior grey column cross the marginal zone and emerge as bundles of ventral spinal nerve rootlets on the anterolateral aspect of the spinal cord. These will eventually constitute both the α-efferents that establish motor end-plates on extrafusal striated muscle fibres and the γ-efferents that innervate the contractile polar regions of the intrafusal muscle fibres of the muscle spindles. As the ventral grey column matures the motor neurones become grouped into motor pools containing functionally coherent subsets of motor neurones that innervate individual muscles in the limb (Dewitz et al 2018). Motor neurone progenitors initially produce medial groups of neurons, later born neurones migrate radially through the medial group to settle in the lateral ventral horn. N-cadherin is required for this migration but does not specify the dorsoventral positioning of these cells (Dewitz et al 2018).

Neurones in different motor pools can be distinguished by their surface protein expression and transcription factor profiles. Motor pools that innervate limb muscles with related functions are grouped into minicolumns or columels, in a 3D organization that reflects the position of the muscles along the three main axes of the limb. Thus, for example, a dorsoventral motor columel and its resident pools displays a linear correlation with the distal-to-proximal position of its synergistic target muscles (Jessell et al 2011, Sürmeli et al 2011). *In vitro* culture of hPSCs along neuronal pathways has elucidated the developmental steps for patterning the rostrocaudal (*Hox* gene expression) and dorsoventral (Shh expression) axes of the neural tube and producing postmitotic neural precursor subtypes. Factors promoting further development of motor neurone progenitors have been established (Pantani 2016).

Lateral grey column

Some intermediate zone neuroblasts in the thoracic and upper lumbar regions in the dorsal part of the basal plate outline a lateral column. Their axons join the emerging ventral nerve roots and pass as preganglionic fibres either to the ganglia of the sympathetic trunk or related ganglia, the majority eventually myelinating to form white rami communicantes. The axons within the rami synapse on autonomic ganglionic neurones; postganglionic axons innervate smooth muscle cells, adipose tissue or exocrine glandular cells. Other preganglionic sympathetic efferent axons pass to the suprarenal medulla. An autonomic lateral column is also laid down in the mid-sacral region and gives origin to the preganglionic parasympathetic fibres that run in the pelvic splanchnic nerves, although this origin has recently been disputed (Espinosa-Medina et al 2016, Espinosa-Medina et al 2017, Horn 2018).

The ventral region of each basal plate initially forms a continuous column of cells throughout the length of the developing cord. This soon develops into two columns on each side: one is medially placed and concerned with innervation of the axial musculature, and the other is laterally placed and concerned with the innervation of the limb musculature. At limb levels, the lateral column enlarges enormously, but regresses at other levels.

Axons arising from ventral horn neurones, i.e. α-, β- and γ-efferent fibres, are accompanied at thoracic, upper lumbar and midsacral levels by preganglionic autonomic efferents from neuroblasts of the developing lateral horn. Numerous interneurones develop in these sites (including Renshaw cells); it is uncertain how many of these differentiate directly from ventrolateral lamina (basal plate) neuroblasts and how many migrate to their final positions from the dorsolateral lamina (alar plate).

In the human embryo the definitive grouping of the ventral column cells that characterizes the mature cord occurs early and by postmenstrual week 14 all the major groups can be recognized. As the anterior and lateral grey columns assume their final form, the germinal cells in the ventral part of the ventricular zone gradually stop dividing. The layer becomes reduced in thickness until it forms the single-layered ependyma that lines the ventral part of the central canal of the spinal cord.

Posterior (dorsal) grey column

The posterior (dorsal) column develops later, which means that the ventricular zone is transiently much thicker in the dorsolateral lamina (alar plate) than it is in the ventrolateral lamina (basal plate) (see Figs 14.14, 14.18). While the columns of grey matter are being defined, the dorsal region of the central canal becomes narrow and slit-like, and its walls come into apposition and fuse with each so that the central canal becomes relatively reduced in size and somewhat triangular in outline.

From about stage 13 advancing axonal sprouts invade the marginal zone. The first to develop are those destined to become short intersegmental fibres (from the neuroblasts in the intermediate zone) and fibres in the dorsal roots of spinal nerves that invade the dorsal marginal zone (from small dorsal root ganglionic neuroblasts). By about stage 16 the latter form a well-defined oval bundle near the peripheral part of the dorsolateral lamina (see Fig. 14.14). This bundle of small calibre axons increases in size and spreads towards the median plane, forming the primitive posterior funiculus. Later, fibres derived from new populations of large dorsal root ganglionic neuroblasts join the dorsal root and are destined to become larger calibre fibres. As the posterior funiculi increase in thickness, their medial surfaces come into contact, separated only by the posterior medial septum, which is ependymal in origin and neuroglial in nature. It is thought that the displaced primitive posterior funiculus may form the basis of the dorsolateral tract or fasciculus (of Lissauer). Experimental studies have shown that the connection of first order 1A afferent neurones from muscle spindles to the appropriate dorsoventral motor neurone pool is independent of the target motor neurones: these sensory afferents avoid synapsing on motor neurones that innervate antagonistic muscles at the same joint (Sürmeli et al 2011).

Maturation of the spinal cord

Long intersegmental axons begin to appear early in the second trimester; corticospinal axons are seen somewhat later. All nerve fibres initially lack myelin sheaths. Myelination starts in different groups at different times, e.g. along the ventral and dorsal nerve roots during the second trimester, and persists until overall growth of the CNS and PNS has finished. In many sites, slow growth continues for long periods, even into the postpubertal years. In the CNS, myelin is formed by oligodendrocytes derived from the ventricular zone of the neural tube, and in the PNS myelin is formed by Schwann cells derived from neural crest cells. A boundary zone controlled by neural crest-derived boundary cap cells separates these two myelin sources (see p. 241). The cervical and lumbar enlargements appear at the time of the development of their respective limb buds.

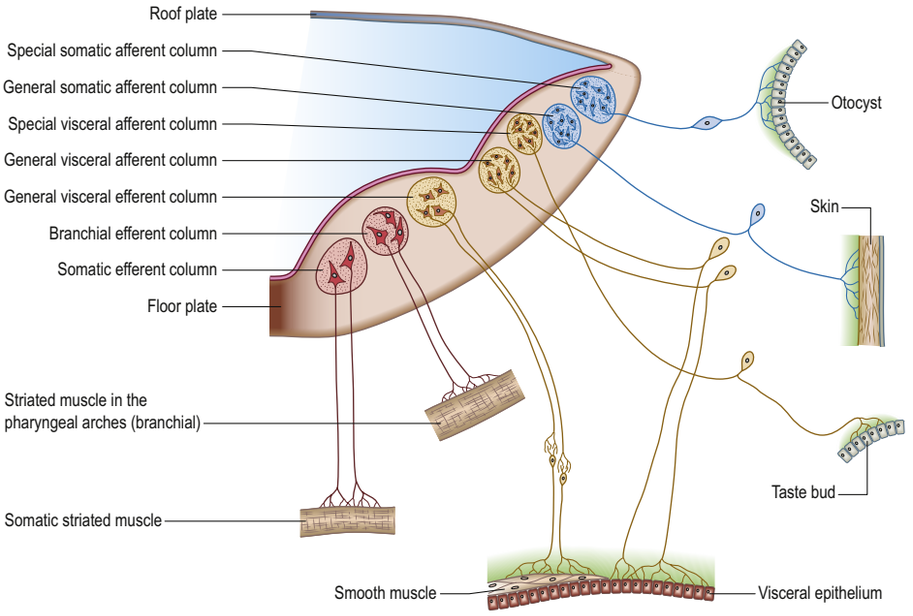

Fig. 14.21 Transverse section through the developing hindbrain of a human embryo about stage 16, showing the relative positions of the columns of grey matter from which the nuclei associated with the different varieties of nerve components are derived. Postganglionic neurones are associated with the general visceral efferent column; bipolar neurones are associated with the otocyst; unipolar afferent neurones are associated with the other alar plate columns.

Ascent of conus medullaris

The spinal cord occupies the entire length of the vertebral canal in early embryonic life; the spinal nerves pass at right-angles to the cord. From the second trimester, the vertebral column grows more rapidly than the spinal cord, which means that the relationship between the conus medullaris and the vertebral column changes as the conus gradually ascends to lie at higher vertebral levels (Barson 1970). Most of this relative rostral migration occurs during the first half of intrauterine life. By postmenstrual week 25 the terminal ventricle of the spinal cord has altered in level from the second coccygeal vertebra to the third lumbar, a distance of nine segments (Ch. 18, p. 300). As the change in level begins rostrally, the caudal end of the terminal ventricle, which is adherent to the overlying ectoderm, remains *in situ*, and the walls of the intermediate part of the ventricle and its covering pia mater become drawn out to form a delicate filament, the filum terminale. The separated portion of the terminal ventricle persists for a time; it usually disappears before birth, although it does occasionally give rise to congenital cysts near the coccyx. In the definitive state, the upper cervical spinal nerves retain their position roughly at right-angles to the cord: proceeding caudally, the nerve roots lengthen and become progressively more oblique. By postmenstrual week 40 the conus medullaris typically lies between the first and third lumbar vertebrae.

Determining the prenatal position of the conus medullaris relative to specific vertebrae is a widely used method of identifying the termination of the spinal cord. Studies of formalin-fixed fetuses, usually of preterm stillbirths that may be small for dates, have provided the main timescales. More recently, values have been derived from antenatal ultrasound and magnetic resonance imaging (MRI) examinations. The often wide discrepancies between published values attest to the fact that ageing preterm infants remains an inexact science. Measurements may be influenced by factors such as placental health, maternal diet, ethnic biometrical variation, fetal sex and the interpretation and correlation of results obtained using differing methodologies (cadaveric dissection, ultrasound, MRI).

Brain

A summary of the derivatives of the cerebral regions from caudal to rostral is given in Table 14.1.

Rhombencephalon

By the time the midbrain flexure appears, the length of the rhombencephalon is greater than that of the combined extent of the mesencephalon and prosencephalon. Rostrally, it exhibits a constriction, the isthmus rhombencephali (see Fig. 14.4A), best viewed from the dorsal aspect. Ventrally, the hindbrain is separated from the dorsal wall of the primitive pharynx only by the notochord, the two dorsal aortae and a small amount of mesenchyme; on each side, it is closely related to the dorsal ends of the pharyngeal arches.

The pontine flexure appears to 'stretch' the thin, epithelial roof plate, which becomes widened. The greatest increase in width corresponds to the region of maximum convexity, so that the outline of the roof plate becomes rhomboidal. By the same change, the lateral walls become separated, particularly dorsally, and the cavity of the hindbrain, (presumptive fourth ventricle), becomes flattened and somewhat triangular in cross-section. The pontine flexure becomes increasingly acute until, at the end of the first trimester, the laminae of its cranial (metencephalic) and caudal (myelencephalic) slopes are opposed to each other (see Fig. 14.22); at the same time, the lateral angles of the cavity extend to form the lateral recesses of the fourth ventricle.

At about stage 14 when the pontine flexure is first discernible, the association between the rhombomeres and the underlying motor nuclei of certain cranial nerves can be seen. The general pattern of distribution of motor nuclei is as follows: rhombomere 1 contains the trochlear nucleus, rhombomeres 2 and 3 contain the trigeminal nucleus, rhombomeres 4 and 5 contain the facial nucleus, rhombomere 5 contains the abducens nucleus, rhombomeres 6 and 7 contain the glossopharyngeal nucleus, and rhombomeres 7 and 8 contain the vagal, accessory and hypoglossal nuclei. Rhombomeric segmentation represents the ground plan of development in this region of the brainstem and is pivotal for the development of regional identity (see Figs 14.2, 12.4). With further morphogenesis, the obvious constrictions of the rhombomere boundaries disappear and the medulla once again assumes a smooth contour. The differentiation of the lateral walls of the hindbrain into basal (ventrolateral) and alar (dorsolateral) plates has a similar significance to the corresponding differentiation in the lateral wall of the spinal cord: ventricular, intermediate and marginal zones are formed in the same way.

Cell columns of the basal plate (ventrolateral lamina)

Cells of the basal plate form three elongated, discontinuous, columns: ventral, intermediate and dorsal (**Fig. 14.21**). The most ventral column is continuous with the anterior grey column of the spinal cord and will supply muscles considered 'myotomic' in origin. It is represented in the caudal part of the hindbrain by the hypoglossal nucleus, and it reappears at a higher level as the nuclei of the abducens, trochlear and oculomotor nerves (somatic efferent nuclei). The intermediate column is represented in the upper part of the spinal cord and caudal brainstem (medulla oblongata and pons), and its neurones supply branchial (pharyngeal) and postbranchial musculature. It is discontinuous, forming the elongated nucleus ambiguus in the caudal brainstem, which gives fibres to the glossopharyngeal, vagal and (cranial) accessory nerves, and continues into the cervical spinal cord as the origin of the (spinal) accessory nerve. At higher levels, parts of this column give origin to the motor nuclei of the facial and trigeminal nerves. The nucleus ambiguus and the facial and trigeminal motor nuclei are termed branchial (special visceral) efferent nuclei. Neurones in the most dorsal column of the basal plate (represented in the spinal cord by the lateral grey column) innervate viscera. This column is discontinuous in that its large caudal part forms some of the dorsal nucleus of the vagus and its cranial part forms the salivatory nucleus. These nuclei are termed general visceral (general splanchnic) efferent nuclei, and their neurones give rise to preganglionic, parasympathetic nerve fibres. The neurones of the basal plate and their three columnar derivatives are only motor in the sense that some of their number form either motor neurones or preganglionic

parasympathetic neurones. The remainder greatly outnumber the former and differentiate into functionally related interneurones and, in some loci, into neuroendocrine cells.

Cell columns of the alar plate (dorsolateral lamina)

Cell columns of the alar plate are discontinuous and give rise to general visceral (general splanchnic) afferent, special visceral (special splanchnic) afferent, general somatic afferent and special somatic afferent nuclei (their relative positions, in simplified transverse section, are shown in Fig. 14.21). The general visceral afferent column is represented by a part of the dorsal nucleus of the vagus, the special visceral afferent column by the nucleus of the tractus solitarius, the general somatic afferent column by the afferent nuclei of the trigeminal nerve, and the special somatic afferent column by the nuclei of the vestibulocochlear nerve. (The relatively simple functional independence of these afferent columns implied by the foregoing classification is, in the main, an aid to elementary learning. The emergent neurobiological mechanisms are much more complex and less well understood.) Although they tend to retain their primitive positions, some of these nuclei are later displaced by differential growth patterns, by the appearance and growth of neighbouring fibre tracts, and possibly by active migration.

It has been suggested that a neurone tends to remain as near as possible to its predominant source of stimulation, and that, to achieve this aim, it will migrate around intervening structures, towards the greatest density of stimuli. The curious paths of the axons arising from the facial nucleus and the nucleus ambiguus have been regarded as exemplars of this phenomenon of so called neurobiotaxis. At stage 16 the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the special visceral efferent column, and it is placed at a higher level than the abducens nucleus. As growth proceeds, the facial nucleus migrates at first caudally and dorsally, relative to the abducens nucleus, and then ventrally to reach its adult position. As it migrates, the axons to which its somata give rise elongate and their subsequent course is assumed to map out the pathway along which the facial nucleus has travelled. Similarly, the nucleus ambiguus initially arises immediately deep to the ventricular floor but, in the adult, it is more deeply placed and its efferent fibres pass first dorsally and medially before curving laterally to emerge at the surface of the medulla oblongata.

Myelencephalon

The caudal slope of the embryonic hindbrain constitutes the myelencephalon, which develops into the medulla oblongata (see Figs 14.4, 14.19, 14.22). The nuclei of the glossopharyngeal, vagal, accessory and hypoglossal cranial nerves develop in the positions already indicated: afferent fibres from the ganglia of the glossopharyngeal and vagus nerves form an oval marginal bundle in the region overlying the alar (dorsolateral) lamina. Throughout the rhombencephalon, the dorsal edge of this lamina is attached to the thin, expanded roof plate and is termed the rhombic lip. (The inferior rhombic lip is confined to the myelencephalon, the superior rhombic lip to the metencephalon.) As the walls of the rhombencephalon spread outwards, the rhombic lip protrudes as a lateral edge that becomes folded over the adjoining area. The rhombic lip may later become adherent to this area, and its cells migrate actively into the marginal zone of the basal plate. In this way, the oval bundle that forms the tractus solitarius becomes buried. Alar plate cells that migrate from the rhombic lip are believed to give rise to the olivary and arcuate nuclei and to the scattered grey matter of the nuclei pontis. While this migration is in progress, the floor plate is invaded by fibres that cross the median plane (accompanied by neurones that cluster in and near this plane), and it becomes thickened to form the median raphe. Some of the migrating cells from the rhombic lip in this region do not reach the basal plate and form an oblique ridge, the corpus pontobulbare (nucleus of the circumolivary bundle), across the dorsolateral aspect of the inferior cerebellar peduncle.

The lower part (caudal half) of the myelencephalon takes no part in the formation of the fourth ventricle and closely resembles the spinal cord in its development. The gracile and cuneate nuclei and some reticular nuclei are derived from the alar plate, and their efferent arcuate fibres and interspersed neurones play a large part in the formation of the median raphe.

The descending corticospinal fibres invade the ventral part of the medulla oblongata to initiate formation of the pyramids. Contemporaneously, the inferior cerebellar peduncle is formed dorsally by ascending fibres from the spinal cord, and by olivocerebellar, parolivocerebellar and external arcuate fibres, and two-way reticulocerebellar and vestibulocerebellar interconnections. (The reticular nuclei of the lower medulla probably have a dual origin from both basal and alar plates.) In a full-term neonate, the brainstem is more oblique and has a distinct bend as it passes through the foramen magnum to become the spinal cord.

Metencephalon

The rostral slope of the embryonic hindbrain is the metencephalon, from which both the cerebellum and the pons develop. Before formation of the pontine flexure, the dorsolateral laminae of the metencephalon are parallel with one another. After its formation, the roof plate of the hindbrain becomes rhomboidal and the dorsal laminae of the metencephalon lie obliquely. They are close at the cranial end of the fourth ventricle, but widely separated at the level of its lateral angles (see Figs 14.19, 14.22). Accentuation of the flexure approximates the cranial angle of the ventricle to the caudal, and the alar plates of the metencephalon now lie almost horizontally.

The basal plate of the metencephalon becomes the pons. Ventricular, intermediate and marginal zones are formed in the usual way, and the nuclei of the trigeminal, abducens and facial nerves develop in the intermediate layer. It is possible that the grey matter of the reticular formation is derived from the basal plate and that of the nuclei pontis from the alar plate by the active migration of cells from the rhombic lip. At about postmenstrual weeks 15–16 the pons is invaded by corticopontine, corticonuclear and corticospinal fibres, becomes proportionately thicker, and takes on its adult appearance; it is relatively smaller in the full-term neonate.

The region of the isthmus rhombencephali undergoes a series of changes that are notoriously difficult to interpret. They result in the incorporation of the greater part of the region into the caudal end of the midbrain. Only the roof plate, in which the superior medullary velum is formed, and the dorsal part of the alar plate, which becomes invaded by converging fibres of the superior cerebellar peduncles, remain as recognizable derivatives in the adult. Early in development, the decussation of the trochlear nerves is caudal to the isthmus, but it is gradually displaced rostrally until it reaches its adult position.

Fourth ventricle and choroid plexus

Caudal to the developing cerebellum, the roof of the fourth ventricle remains epithelial, and covers an approximately triangular zone from the lateral angles of the rhomboid fossa to the median obex (see Figs 14.19, 14.22). Nervous tissue fails to develop over this region and vascular pia mater is closely applied to the subjacent ependyma. At each lateral angle and in the midline caudally, the membranes break through, forming the lateral (Luschka) and median (Magendie) apertures of the roof of the fourth ventricle: they become the principal routes by which cerebrospinal fluid, produced in the ventricles, escapes into the subarachnoid space. The vascular pia mater (tela choroidea), in an inverted V formation cranial to the apertures, invaginates the ependyma to form vascular fringes that become the vertical and horizontal parts of the choroid plexuses of the fourth ventricle.

Cerebellum

The cerebellum develops from the rhombic lip (dorsal rhombomere 1 (r1)), the dorsal part of the alar plate of the metencephalon, which constitutes the rostral margin of the diamond-shaped fourth ventricle. This region is specified as the isthmus organizer (Yu et al 2013). Two rounded swellings develop and initially project partly into the ventricle, forming the rudimentary cerebellar hemispheres (**Fig. 14.22**). The most rostral part of the roof of the metencephalon originally separates the two swellings, but it becomes invaded by cells derived from the alar plate, which form the rudiments of the vermis. At a later stage, extroversion of the cerebellum occurs, its intraventricular projection is reduced and the dorsal extraventricular prominence increases. The cerebellum now consists of a bilobar (dumbbell-shaped) swelling stretched across the rostral part of the fourth ventricle (see **Fig. 14.22**). It is continuous rostrally with the superior medullary velum, formed from the isthmus rhombencephali, and caudally with the epithelial roof of the myelencephalon. With growth, a number of transverse grooves appear on the dorsal aspects of the cerebellar rudiment: they are the precursors of the numerous fissures that characterize the surface of the mature cerebellum (**Fig. 14.23**).

The first fissure to appear on the cerebellar surface is the lateral part of the posterolateral fissure, which forms the border of a caudal region corresponding to the flocculi of the adult. The right and left parts of this fissure subsequently meet in the midline, where they form the boundary between the most caudal vermian lobule, the nodule, and the rest of the vermis. The flocculonodular lobe can now be recognized as the most caudal cerebellar subdivision at this stage and it serves as the attachment of the epithelial roof of the fourth ventricle. Because of the expansion of the other divisions of the cerebellum, the flocculonodular

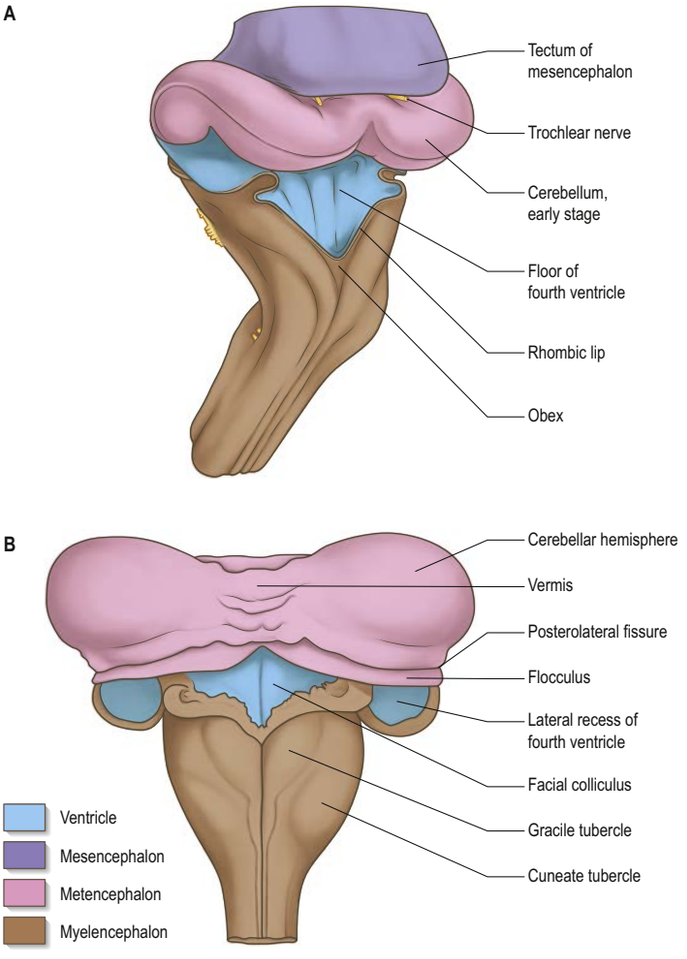

Fig. 14.22 **A**, The developing brainstem of a human fetus at approximately postmenstrual week 12, left dorsolateral aspect. **B**, The dorsal aspect of the developing cerebellum, postmenstrual weeks 17–20.

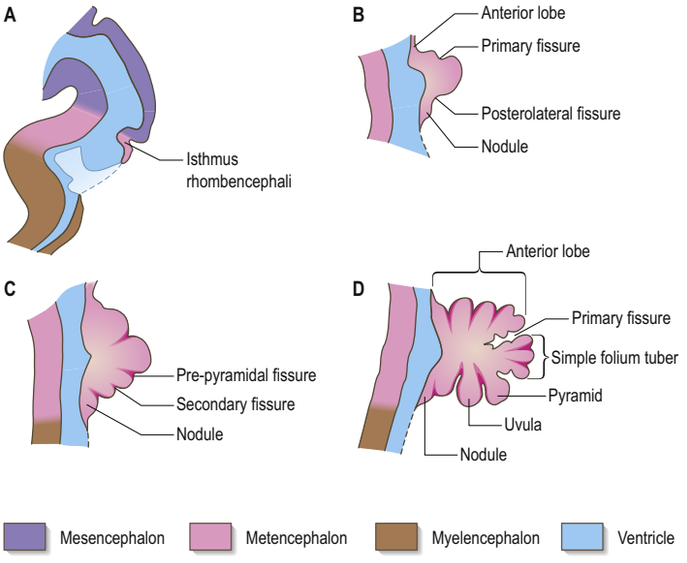

Fig. 14.23 Median sagittal sections through the developing cerebellum, at four chronologically later stages.

lobe comes to occupy an anteroinferior position in adults. At the end of the first trimester, a transverse sulcus appears on the rostral slope of the cerebellar rudiment and deepens to form the fissura prima that cuts into the vermis and both hemispheres, and forms the border between the anterior and posterior lobes. Contemporaneously, two short transverse grooves appear in the caudal vermis. The first is the fissura secunda (postpyramidal fissure), which forms the rostral border of the uvula and the second is the pre-pyramidal fissure, which demarcates the pyramid. The cerebellum now grows dorsally, rostrally, caudally and laterally, and the hemispheres expand much more than the inferior vermis, which therefore becomes buried at the bottom of a deep hollow, the vallecula. Numerous other transverse grooves develop, the most extensive being the horizontal fissure.

Cellular development of the cerebellum

The cerebellum consists of a cortex, beneath which are buried a series of deep nuclei. The organization of the cerebellar cortex is similar to that of the cerebral cortex, except that the latter typically has six layers while the former has only three. However, whereas in the cerebral cortex neuroblasts originate from the ventricular zone and migrate ventriculofugally towards the pial surface (in an 'inside-out' fashion), early in cerebellar development a layer of cells derived exclusively from the metencephalic rhombic lip initially migrates ventriculofugally to form a layer beneath the glia limitans over the surface of the developing cerebellum. These cells form the external germinative layer; later in development their progeny will migrate ventriculopetally (in an 'outside-in' manner), into the cerebellum. The cerebellum therefore has an intraventricular portion (cells proliferating from the ventricular zone) and an extraventricular portion (cells proliferating from the external germinative layer) during development. The extraventricular portion becomes larger at the expense of the intraventricular portion, the so-called extroversion of the cerebellum. Before the end of the first trimester, the main mass of the cerebellum is extraventricular.

The developed cerebellar cortex contains three layers, namely the molecular, Purkinje and granular layers. The early bilateral expansion of the ventricular surface reflects the production, by the metencephalic alar plate ventricular epithelium, of neuroblasts that will give rise to the radial glia, cerebellar nuclei and efferent neurones of the cerebellar cortex (the Purkinje cells) (Fig. 14.24). The radial glia play a role in guiding the Purkinje cells to the meningeal surface of the cerebellar anlage. During this early stage of cerebellar development, which is dominated by the production and migration of efferent cerebellar neurones, the surface of the cerebellar anlage remains smooth. The extroversion of the cerebellum begins later when cells of the external germinative layer, also termed the superficial matrix, begin proliferation and migration. These cells produce the granule cells which migrate inwards along the radial glia, through the layers of Purkinje cells, settling deep to them in the granular layer. This stage coincides with the emergences of the transverse folial pattern. Proliferation and migration of granule cells lead to a great rostrocaudal expansion of the meningeal surface of the cerebellum, forming the transverse fissures and transforming the multicellular layer of Purkinje cells into a monolayer. The development of the efferent neurones of the cerebellar cortex and nuclei precedes the development of its afferent organization: Purkinje cells and nuclear cells are formed prior to the granule cells, which are the recipients of the main afferent (mossy fibre) system of the cerebellum.

The early bilateral cerebellar anlage is changed into a unitary structure by fusion of the bilateral intraventricular bulges and the disappearance of the ependyma at this site; the merging of the left and right primitive cerebellar cortices over the midline; and the development of the cerebellar commissure by ingrowth of afferent fibres and outgrowth of efferent axons from the medial cerebellar nuclei.

The distinction between the efferent projections from the vermis and hemispheres is established at an early age. When the external germinative layer is initially formed, the multicellular Purkinje cell layer beneath is not uniform, but subdivided into clusters that form columns that extend rostrocaudally (Fig. 14.25). These clusters will give rise to Purkinje cell zones in the adult cerebellum that project to a single vestibular or cerebellar nucleus. The medial Purkinje cell clusters develop into the future vermis and their axons will synapse on neurones in the vestibular and fastigial nuclei. The lateral clusters belong to the future hemispheres and will grow axons that terminate in the interposed and dentate nuclei.

In the developing human brain, only the external germinative layer can be seen at postmenstrual weeks 17–18; the Purkinje cells become apparent between postmenstrual weeks 20 and 23. After postmenstrual week 30 four layers can be recognized: the external germinative layer (external granular layer), formed by 6–8 rows of densely packed small round cells; the Purkinje cell layer, formed by 5–6 layers of larger, round, immature neurones external to the internal granular layer; and the molecular layer, containing cells that resemble external granular layer cells in migration (Lavezzi et al 2006). The external granular layer involutes between postnatal months 5–7; it is only a discontinuous layer at postnatal month 10 and is totally absent by postnatal month 12, after which time the cerebellar cortex shows a three-layered structure. From postnatal months 5–7 the Purkinje cells are reduced in number and more widely spaced, displaying mature polygonal somata with evident axons and dendrites.

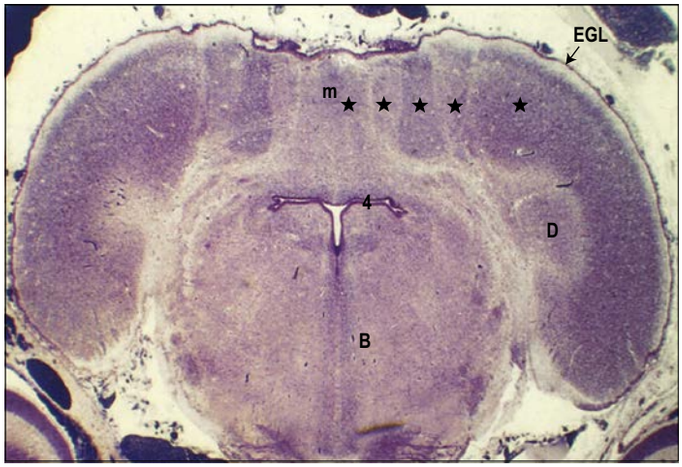

Fig. 14.25 Coronal section through the cerebellum and the brainstem of a human fetus about postmenstrual week 12. Purkinje cells are located in five multicellular clusters (stars) on both sides of the midline. The anlage of the dentate nucleus occupies the centre of the most lateral Purkinje cell cluster. Key: B, brainstem; D, dentate nucleus; EGL, external granular layer; m, midline; 4, fourth ventricle. Fig. 14.24 Histogenesis of the cerebellar cortex and the cerebellar nuclei. **A**, Purkinje cells and cells of the cerebellar nuclei are produced by the ventricular zone and migrate to their future positions. The cells of the superficial matrix (the external granular layer) take their origin from the ventricular epithelium at the caudal pole of the cerebellar anlage and migrate rostrally over its surface. **B**, After migration, the Purkinje cells constitute a multicellular layer beneath the external germinative layer. Cell production in the ventricular epithelium has stopped. The remaining cells transform into ependymal cells. **C**, Granule cells produced by the external germinative layer migrate inwards through the Purkinje cell layer to their position in the internal granular layer. Purkinje cells spread into a monolayer. **D**, The adult position of cortical and nuclear neurones.

Relatively little is known about the molecular mechanisms involved in cerebellar development in the human (but see Manto and Jissendi (2012), Yu et al (2013), Martinez et al (2013)). The cerebellum undergoes its major growth during the third trimester and infancy (Leto et al 2016). Very small preterm infants are at particular risk of later cerebellar dysfunction with consequences for cognition and behaviour. Because much of cerebellar maturation occurs postnatally there is interest in therapeutic agents that may improve long-term outcomes for such infants (Manto and Jissendi 2012). A summary of mammalian cerebellar development including human cerebellar anomalies is given by Leto et al (2016).

Mesencephalon

The mesencephalon or midbrain is subdivided early in development into two neuromeres, mesencephalon 1 and mesencephalon 2. It persists for a time as a thin-walled tube enclosing a cavity of some size, separated from that of the prosencephalon by a slight constriction and from the rhombencephalon by the isthmus rhombencephali (see Fig. 14.4; **Fig. 14.26**). Later, its cavity becomes relatively reduced in diameter and, in the adult brain, it forms the cerebral aqueduct. The basal (ventrolateral) plate of the midbrain increases in thickness to form the cerebral peduncles, which are at first of small size but enlarge rapidly in the early second trimester, when their numerous fibre tracts begin to appear in the marginal zone. The neuroblasts of the basal plate of mesencephalon 2 give rise to the nuclei of the oculomotor nerve and some grey masses of the tegmentum, while the nucleus of the trochlear nerve remains in the region of the isthmus rhombencephali. The cells that give rise to the trigeminal mesencephalic nucleus arise either side of the dorsal midline, from the isthmus rhombencephali rostrally across the roof of the mesencephalon. The progenitors of these cells do not express neural crest cell markers.

The cells of the dorsal part of the alar (dorsolateral) plates proliferate and invade the roof plate, which therefore thickens and is later divided into corpora bigemina by a median groove. Caudally, this groove becomes a median ridge that persists in the adult as the frenulum veli, and the corpora bigemina are later subdivided into the superior and inferior colliculi by a transverse furrow. The red nucleus, substantia nigra and reticular nuclei of the midbrain tegmentum may first be defined at the end of the first trimester. Their origins are probably mixed, from neuroblasts of both basal and alar plates.

The detailed histogenesis of the tectum and its main derivatives, the colliculi, will not be followed here but, in general, the principles outlined for the cerebellar cortex, the paleopallium and neopallium also apply to this region. A high degree of geometric order exists in the developing retinotectal projection (the equivalent of the retinogeniculate projection) and in the tectospinal projection. (For further reading, see Cang and Feldheim (2013).)

Prosencephalon

At an early stage, a transverse section through the forebrain shows the same parts that are displayed in similar sections of the spinal cord and medulla oblongata, i.e. thick lateral walls connected by thin floor and roof plates. Each lateral wall is divided into a dorsal area and a ventral area separated internally by the hypothalamic sulcus (see Fig. 14.26). This sulcus ends rostrally at the medial end of the optic stalk. In the fully developed brain, it persists as a slight groove extending from the interventricular foramen to the cerebral aqueduct. It is analogous to, if not the homologue of, the sulcus limitans. The thin roof plate remains epithelial but invaginated by vascular mesenchyme, the tela choroidea of the choroid plexuses of the third ventricle. Later, the lateral margins of the tela undergo a similar invagination into the medial walls of the cerebral hemispheres. The floor plate thickens as the nuclear masses of the hypothalamus and subthalamus develop.

At a very early period, before the closure of the rostral neuropore, the subdivision of the prosencephalon into the most rostral telencephalon and two subdivisions of the diencephalon, D1 and D2, is heralded (see Fig. 14.2). At this early time, two eye fields are separated by the future neurohypophysis in the floor of the future D1. After head folding, the eye fields expand as two lateral optic evaginations, that will become optic vesicles, one on each side of the early brain. For a time, they communicate with the cavity of the prosencephalon by relatively wide openings. The distal parts of the optic vesicles expand, while the proximal parts become

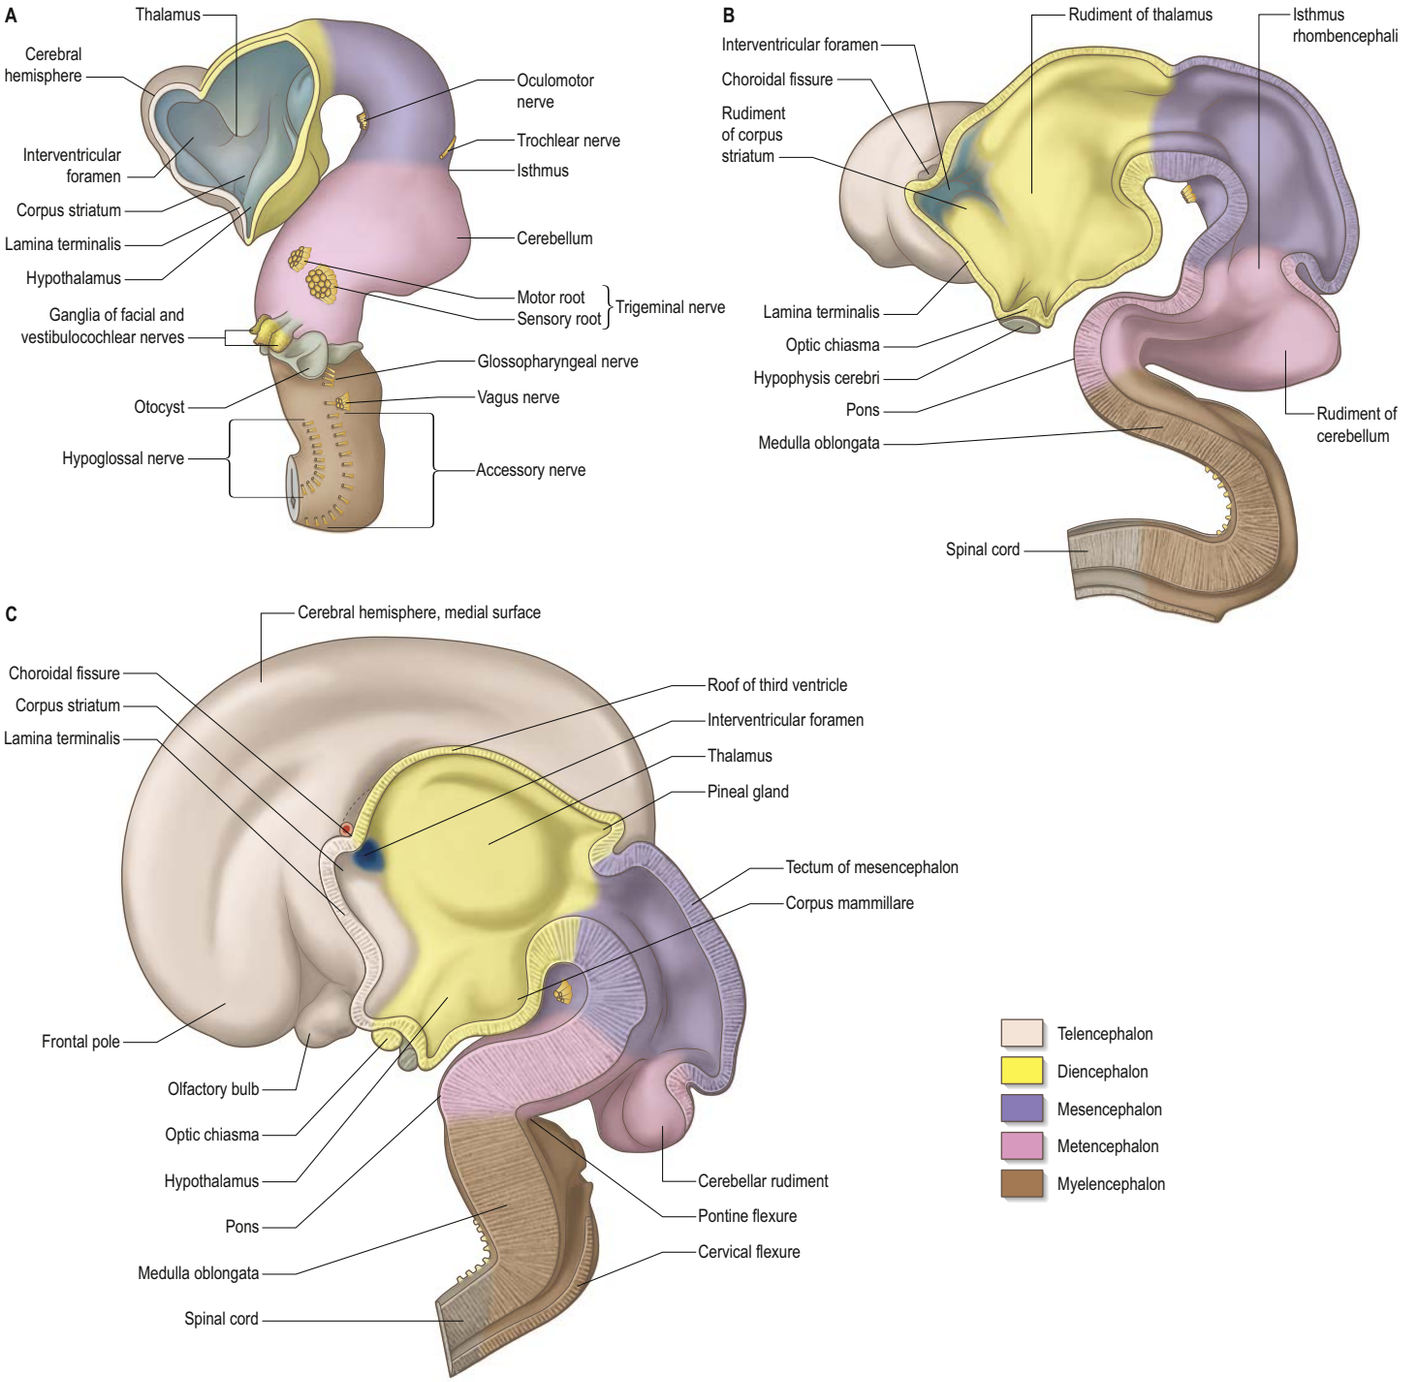

Fig. 14.26 The shape of the developing ventricular system and the expansion of the medial portion of the telencephalon. The roof of the metencephalon and myelencephalon has been removed in each case. **A**, A human embryo at stage 16, left lateral surface of the diencephalon and telencephalon removed. **B**, A human embryo at stage 18, median section. **C**, A human fetus, approximately postmenstrual week 12, median section.

the tubular optic stalks. The optic vesicles (described with the development of the eye in Ch. 15) are thus derived from the lateral walls of the D1 subdivision of the prosencephalon before the telencephalon can be clearly identified. The optic chiasma is often regarded as the boundary between the diencephalon and telencephalon.

As the most rostral portion of the prosencephalon enlarges, it curves ventrally, and two further diverticula expand rapidly from it, one on each side. These diverticula, rostrolateral to the optic stalks, subsequently form the cerebral hemispheres. Their cavities are the rudiments of the lateral ventricles and they communicate with the median part of the forebrain cavity by relatively wide openings that ultimately become the interventricular foramina. The rostral limit of the median part of the forebrain consists of a thin sheet, the lamina terminalis (see Fig. 14.26), which stretches from the interventricular foramina to the recess at the base of the optic stalks. The rostral part of the forebrain, including the rudiments of the cerebral hemispheres, consists of the telencephalon and the caudal part of the diencephalon; both contribute to the formation of the third ventricle, although the latter predominates. The fate of the lamina terminalis is described below.

Diencephalon

The diencephalon, D2, is broadly divided by the hypothalamic sulcus into dorsal (pars dorsalis diencephali) and ventral (pars ventralis diencephali) parts; each contributes to diverse neural structures. The dorsal part develops into the (dorsal) thalamus and metathalamus along the immediate suprasulcal area of its lateral wall, while the highest dorsocaudal lateral wall and roof form the epithalamus. The thalamus is first visible as a thickening that involves the rostral part of the dorsal area (see Fig. 14.26). Caudal to the thalamus, the lateral and medial geniculate bodies, or metathalamus, are recognizable at first as surface depressions on the internal aspect and as elevations on the external aspect of the lateral wall. As the thalami enlarge as smooth ovoid masses, the wide interval between them gradually narrows into a vertically compressed cavity that forms the greater part of the third ventricle. After a time these medial surfaces may come into contact and become adherent over a variable area, the connection (single or multiple) constituting the interthalamic adhesion or massa intermedia. The caudal growth of the thalamus excludes the geniculate bodies from the lateral wall of the third ventricle.

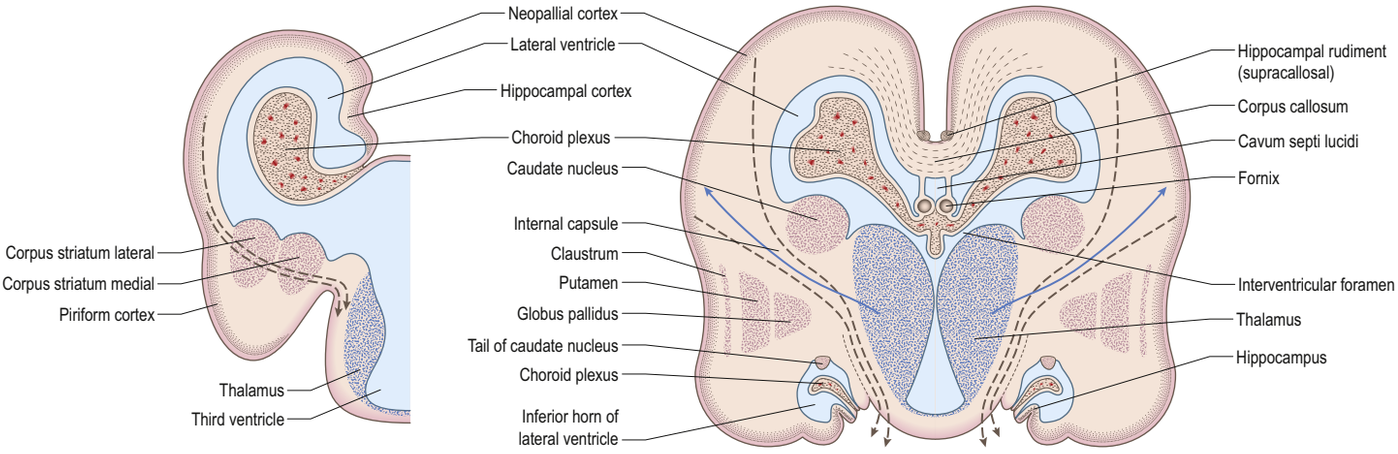

Fig. 14.27 The development of the basal nuclei and internal capsule, coronal views. (Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1972 Human Embryology: Prenatal Development of Form and Function. Baltimore: Williams and Wilkins.)

At first the lateral aspect of the developing thalamus is separated from the medial aspect of the cerebral hemisphere by a cleft that becomes obliterated as the thalamus fuses with the part of the hemisphere in which the corpus striatum is developing (**Fig. 14.27**). The subsequent development of the corticofugal and corticopetal projection fibres of the neocortex means that the thalamus becomes related to the internal capsule, which intervenes between it and the lateral part of the corpus striatum (lentiform nucleus). Ventral to the hypothalamic sulcus the lateral wall of the diencephalon, in addition to median derivatives of its floor plate, forms a large part of the hypothalamus and subthalamus.

The epithalamus, which includes the pineal gland, the posterior and habenular commissures and the trigonum habenulae, develops in association with the caudal part of the roof plate and the adjoining regions of the lateral walls of the diencephalon. Between stages 17–20 the epithalamus in the lateral wall projects into the third ventricle as a smooth ellipsoid mass, larger than the adjacent mass of the (dorsal) thalamus and separated from it by a well-defined epithalamic sulcus. Subsequent growth of the thalamus rapidly overtakes that of the epithalamus and the intervening sulcus is obliterated: structures of epithalamic origin become relatively diminutive topographically.

The pineal gland arises as a hollow outgrowth from the roof plate, immediately adjoining the mesencephalon. Its distal part becomes solid by cellular proliferation but its proximal stalk remains hollow and contains the pineal recess of the third ventricle. In many reptiles the pineal outgrowth consists of a rostral outgrowth (parapineal organ) that develops into the pineal or parietal eye, and a glandular caudal outgrowth that is homologous with the human pineal gland. The rostral outgrowth also develops in the human embryo but soon disappears entirely.

The nucleus habenulae, the most important constituent of the trigonum habenulae, develops in the lateral wall of the diencephalon. It is initially a close relation of the geniculate bodies, from which it is later separated by the dorsal growth of the thalamus. The habenular commissure develops in the cranial wall of the pineal recess. The posterior commissure is formed by fibres that invade the caudal wall of the pineal recess from both sides.

The ventral part of the diencephalon forms the subsulcal lateral walls of the third ventricle and takes part in the formation of the hypothalamus, including the mammillary bodies, the tuber cinereum and infundibulum of the hypophysis. The mammillary bodies arise as a single thickening that becomes divided by a median furrow during the end of the first trimester. The tuber cinereum develops rostral to the mammillary bodies as a cellular proliferation that extends forwards as far as the infundibulum. A wide-mouthed diverticulum forms in the floor of the diencephalon in front of the tuber cinereum and grows towards the stomodeal roof, coming into contact with the posterior aspect of a dorsally directed ingrowth from the stomodeum (Rathke's pouch). These two diverticula together form the hypophysis cerebri (see Fig. 14.10). An extension of the third ventricle persists in the base of the neural outgrowth as the infundibular recess. The remaining caudolateral walls and floor of the ventral diencephalon are an extension of the midbrain tegmentum, the subthalamus. This forms the rostral limits of the red nucleus, the substantia nigra, numerous reticular nuclei and a mass of interweaving, ascending, descending and oblique nerve fibre bundles.

Third ventricle and choroid plexus

The roof plate of the diencephalon rostral to the pineal gland continues over the median telencephalon, remaining thin and epithelial in character and is invaginated by the choroid plexuses of the third ventricle (see Fig. 14.27; **Fig. 14.28**). Before the development of the corpus callosum and the fornix, it lies at the bottom of the longitudinal fissure between and reaching the two cerebral hemispheres. It extends as far rostrally as the interventricular foramina and lamina terminalis. Here, and elsewhere, choroid plexuses develop by the close apposition of vascular pia mater and ependyma without intervening nervous tissue. With development, the vascular layer is infolded into the ventricular cavity and develops a series of small villous projections, each covered by a cuboidal epithelium derived from the ependyma. The cuboidal cells display numerous microvilli on their ventricular surfaces and complex folding of their basal plasma membranes. The early choroid plexuses secrete a protein-rich cerebrospinal fluid into the ventricular system, which may provide a nutritive medium for the developing epithelial neural tissues. As the latter become increasingly vascularized, the histochemical reactions of the cuboidal cells and the character of the fluid change to the adult type. Many regions of the lining of the third ventricle become highly specialized, and develop concentrations of tanycytes or other modified cells that are collectively termed the circumventricular organs, e.g. the subfornical organ, the organum vasculosum (intercolumnar tubercle) of the lamina terminalis, the subcommissural organ, and the linings of the pineal, suprapineal and infundibular recesses.

Telencephalon

The telencephalon consists of two lateral diverticula connected by a median region, the telencephalon impar. The rostral part of the third ventricle develops from the impar and is closed below and in front by the lamina terminalis. The lateral diverticula are outpouchings of the lateral walls of the telencephalon that may correspond to the alar lamina, although this is uncertain. Their cavities are the future lateral ventricles and their walls are formed by the presumptive nervous tissue of the cerebral hemispheres. The roof plate of the median part of the telencephalon remains thin and is continuous behind with the roof plate of the diencephalon (see Figs 14.26–14.27). The rostral parts of the hypothalamus, which include the optic chiasma, optic recess and related nuclei, develop in the floor plate and lateral walls of the prosencephalon, ventral to the primitive interventricular foramina. The chiasma is formed by the meeting, and partial decussation, of the optic nerves in the ventral part of the lamina terminalis. The optic tracts subsequently grow backwards from the chiasma to end in the diencephalon and midbrain.

Cerebral hemispheres

The cerebral hemispheres arise as diverticula of the lateral walls of the telencephalon, with which they remain in continuity around the margins of initially relatively large interventricular foramina, except caudally, where they are continuous with the rostral part of the lateral wall of the diencephalon (see Figs 14.4, 14.26). As growth proceeds each hemisphere enlarges forwards, upwards and backwards and acquires an oval outline, medial and superolateral walls, and a floor. As a result the medial surfaces approach, but are separated by, a vascularized mesenchyme and pia mater that fills the median longitudinal

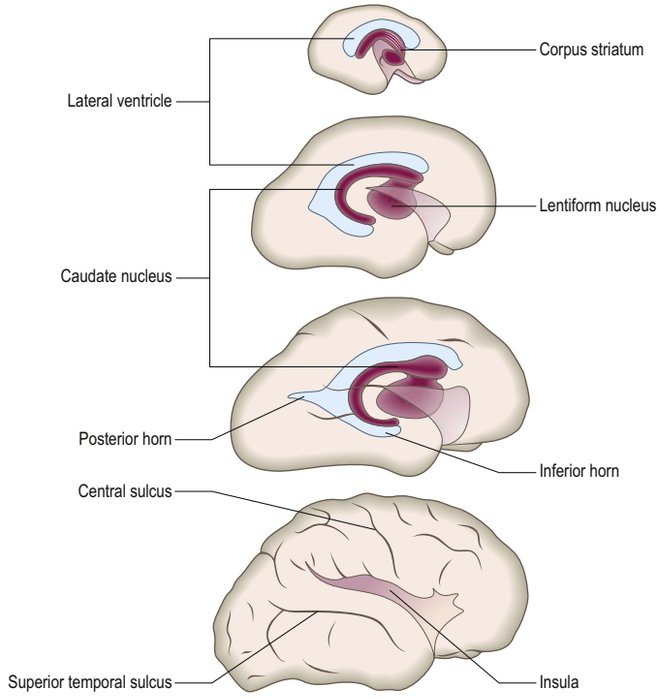

Fig. 14.29 Lateral views of developing brains show the formation of the basal nuclei and lateral ventricles as the telencephalon develops. (Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1972 Human Embryology: Prenatal Development of Form and Function. Baltimore: Williams and Wilkins.)

fissure (see Fig. 14.28). At this stage the floor of the fissure is the epithelial roof plate of the telencephalon, which is directly continuous caudally with the epithelial roof plate of the diencephalon.

At the early oval stage of hemispheric development, regions are named according to their future principal derivatives. The rostromedial and ventral floor becomes linked with the forming olfactory apparatus and is termed the primitive olfactory lobe. The floor (ventral wall, or base) of the remainder of each hemisphere forms the anlage of the primitive corpus striatum and amygdaloid complex, including its associated rim of lateral and medial walls (the striate part of the hemisphere). The rest of the hemisphere, i.e. the medial, lateral, dorsal and caudal regions, is the suprastriate part of the hemisphere. Although it is the largest in terms of surface area, initially it possesses comparatively thin walls. The rostral end of each oval hemisphere becomes the definitive frontal pole. As the hemisphere expands its original posterior pole moves relatively in a caudoventral and lateral direction, following a curve like a ram's horn. It curves towards the orbit in association with the growth of the caudate nucleus and other structures to form the definitive temporal pole. A new posterior part persists as the definitive occipital pole of the mature brain (**Figs 14.29-14.30**).

The migration and differentiation of neural progenitors to form nuclei is either minimal or limited throughout the brainstem and spinal cord. The progeny of these progenitors remain immediately extra-ependymal or partially displaced towards the pial exterior, and are arrested deeply embedded in the myelinating 'white matter' of the region. In marked contrast, proliferation and migration of neuroblasts in the cerebral hemispheres produce a superficial layer of grey matter in both the striate and the suprastriate regions, but not in the central areas of the original medial wall, where secondary fusion with the diencephalon occurs. The superficial layer of grey matter consists of neuronal somata, dendrites, the terminations of incoming (afferent) axons, extending outgrowing (efferent) axons, and glial and endothelial cells. Successive generations of neuroblasts migrate through the layers of earlier generations to attain subpial positions (see below and Fig. 14.33), which means that the outer, pial surface of the cerebral hemispheres expands at a rate greater than that of the hemispheres as a whole. The subpial region of grey matter is termed the cortex or pallium; a transient cortical subplate is seen. The growing hemispheres subsequently overlap, successively, the diencephalon and the mesencephalon, and then meet the rostral surface of the cerebellum. The temporal lobes embrace the flanks of the brainstem.

The terminology used to describe regions of the cortex is based on evolutionary concepts. The oldest portions of cortex receive information concerned with olfaction and are termed archicortex (archipallium) and paleocortex (paleopallium): both are subdivisions of an overall allocortex. The archicortex is the forerunner of the hippocampal lobe, and the paleocortex gives rise to the piriform area. The remaining cortical surface expands greatly in mammals, forming the neocortex that displaces the earlier cortices so that they come to lie partially internally in each hemisphere. The typically six-layered mammalian neocortex is also described as isocortex.

Lateral ventricles and choroid plexus

The early diverticulum or anlage of the cerebral hemisphere initially contains a simple spheroidal lateral ventricle continuous with the third ventricle via the interventricular foramen. The rim of the foramen is the site of the original evagination. The expanding ventricle develops the ram's horn shape of the surrounding hemisphere, becoming first roughly ellipsoid and then a curved cylinder that is convex dorsally (see Fig. 14.29). The ends of the cylinder expand towards, but do not reach, the frontal and (temporary) occipital poles; differentiating and thickening neural tissues separate the ventricular cavities and pial surfaces at all points, except along the line of the choroidal fissure. Pronounced changes in ventricular form accompany the emergence of a temporal pole. The original caudal end of the curved cylinder expands within its substance and the temporal extensions in each hemisphere pass ventrolaterally to encircle both sides of the upper brainstem (see Fig. 14.27). Another extension may develop from the root of the temporal extension in the substance of the definitive occipital pole and pass caudomedially; it is quite variable in size, often asymmetric on the two sides, and one or both may be absent. Although the lateral ventricle is a continuous system of cavities, specific parts are now given regional names. The central part (body) extends from the interventricular foramen to the level of the posterior edge (splenium) of the corpus callosum. Three cornua (horns) diverge from the body: anterior towards the frontal pole, posterior towards the occipital pole, and inferior towards the temporal pole. At these early stages of hemispheric development, in most instances the term pole is preferred to lobe: lobes are defined by specific surface topographical features that will appear over several postmenstrual weeks, and differential growth patterns persist for a considerable period.

The pia mater covers the epithelial roof of the third ventricle at this stage and is itself covered with loosely arranged mesenchyme and developing blood vessels. These vessels subsequently invaginate the roof of the third ventricle on each side of the median plane to form its choroid plexuses (see Fig. 14.27). The lower part of the medial wall of the cerebral hemisphere, which immediately adjoins the epithelial roof of the interventricular foramen and the rostral extremity of the diencephalon, also remains epithelial and consists of ependyma and pia mater. Elsewhere, the walls of the hemispheres are thickening to form the

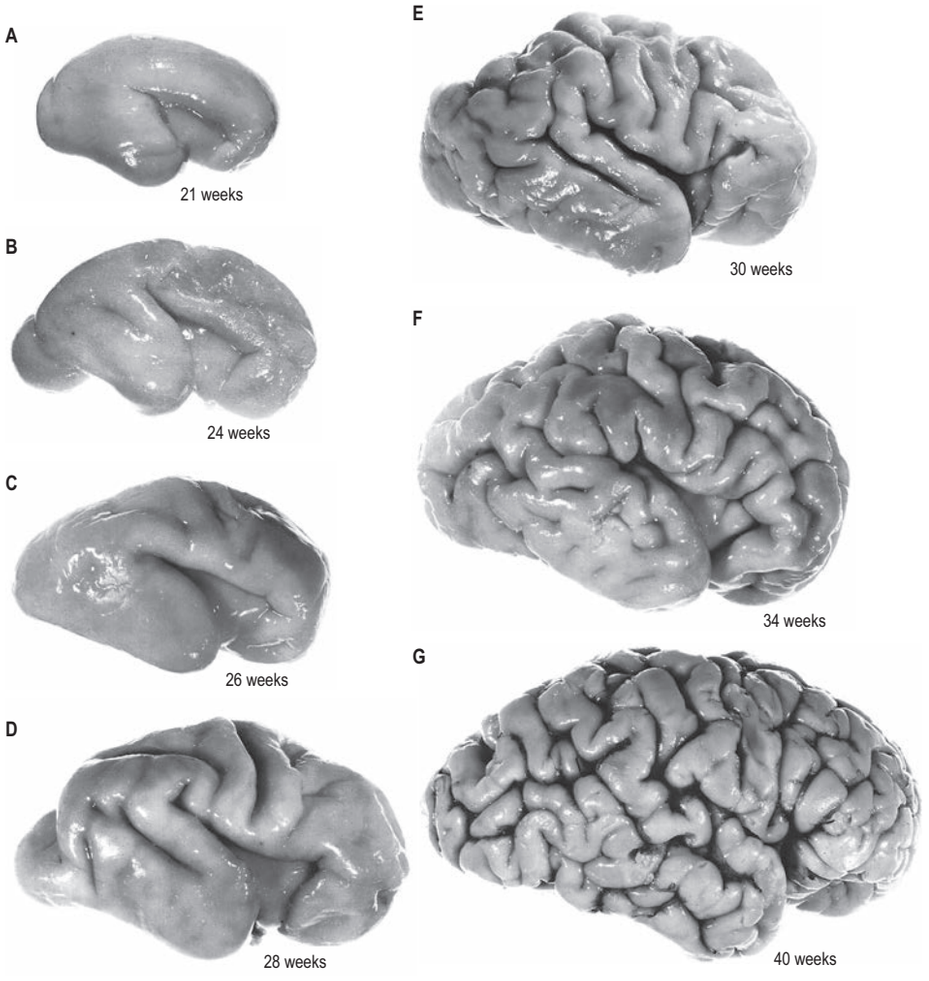

Fig. 14.30 A–G, The superolateral surfaces of human fetal cerebral hemispheres at the postmenstrual weeks indicated, showing the changes in size, profile and the emerging pattern of cerebral sulci with increasing maturation. Note the changing prominence and relative positions of the frontal, occipital and, particularly, the temporal, poles of the hemisphere. At the earliest stage **(A)**, the lateral cerebral fossa is already obvious: its floor covers the developing corpus striatum in the depths of the hemisphere and progressively matures into the cortex of the insula. The fossa is bounded by overgrowing cortical regions (frontal, temporal and parietal opercula) that gradually converge to bury the insula; their approximation forms the lateral cerebral sulcus. By the sixth month, the central, pre- and postcentral, superior temporal, intraparietal and parieto-occipital sulci are all clearly visible. In the subsequent stages shown, all the remaining principal and subsidiary sulci rapidly appear, and by postmenstrual week 40, all the features that characterize the adult hemisphere in terms of surface topography are present in miniature. (Photographs provided by Dr Sabina Strick, The Maudsley Hospital, London.)

pallium. The thin part of the medial wall of the hemisphere is invaginated by vascular tissue that is continuous in front with the choroid plexus of the third ventricle and constitutes the choroid plexus of the lateral ventricle. This invagination occurs along a line that arches upwards and backwards, parallel with and initially limited to, the rostral and upper boundaries of the interventricular foramen. This curved indentation of the ventricular wall, where no nervous tissue develops between ependyma and pia mater, is termed the choroidal fissure (see Figs 14.26C, 14.27). The subsequent assumption of the definitive form of the choroidal fissure depends on related growth patterns in neighbouring structures. Of particular importance are the relatively slow growth of the interventricular foramen; the secondary 'fusion' between the lateral diencephalon and medial hemisphere walls; the encompassing of the upper brainstem by the forward growth of the temporal lobe and its pole towards the apex of the orbit; and the massive expansion of two great cerebral commissures (the fornix and corpus callosum). The choroidal fissure is now clearly a caudal extension of the much-reduced interventricular foramen, which arches above the thalamus and is here only a few millimetres from the median plane. It diverges ventrolaterally near the caudal end of the thalamus, its curve reaching and continuing in the medial wall of the temporal lobe over much of its length (i.e. to the tip of the inferior horn of the lateral ventricle). The upper part of the arch will be overhung by the corpus callosum and it is bordered by the fornix and its derivatives throughout its convexity.

Basal nuclei

At first, growth proceeds more actively in the floor and the adjoining part of the lateral wall of the developing hemisphere, and thickenings of the ventricular zone formed by the rudimentary corpus striatum, often termed medial and lateral ganglionic (ventricular) eminences, develop from stage 18 (see Figs 14.26–14.29). The head of the caudate nucleus appears as three successive parts, medial, lateral and intermediate. Caudally, these merge to form the tail of the caudate nucleus and the amygdaloid complex, which both remain close to the temporal pole of the hemisphere. When the occipital pole grows backwards and the general enlargement of the hemisphere carries the temporal pole downwards and forwards, the tail of the caudate is continued from the floor of the central part (body) of the lateral ventricle into the roof of its temporal extension, the future inferior horn (see Fig. 14.29). The amygdaloid complex encapsulates its tip. Rostrally, the head of the caudate nucleus extends forwards to the floor of the interventricular foramen, where it is separated from the developing rostral end of the thalamus by a groove; the head subsequently expands in the floor of the anterior horn of the lateral ventricle. The lentiform nucleus develops from two cellular laminae, medial and lateral, that are continuous with both the medial and lateral parts of the caudate nucleus. The internal capsule appears first in the medial lamina and extends laterally through the lateral lamina to the cortex. It divides the laminae into two, the internal parts join the caudate nucleus and the external parts form the lentiform nucleus (see Figs 14.27–14.28): the remaining medial lamina cells give rise mainly to the globus pallidus and the lateral lamina cells to the putamen. The putamen expands concurrently with the intermediate part of the caudate nucleus.

Fusion of diencephalic and telencephalic walls

As the hemisphere enlarges, the caudal part of its medial surface overlaps and hides the lateral surface of the diencephalon (thalamic part), from which it is separated by a narrow cleft occupied by vascular connective tissue. A transverse section made caudal to the interventricular foramen would pass from the third ventricular cavity successively through the developing thalamus, the narrow cleft just mentioned, the thin medial wall of the hemisphere, and the cavity of the lateral ventricle, with the corpus striatum in its floor and lateral wall (see Fig. 14.27).

As the thalamus increases in extent it acquires a superior surface in addition to medial and lateral surfaces. The lateral part of its superior surface fuses with the thin medial wall of the hemisphere so that this part of the thalamus is finally covered with the ependyma of the lateral ventricle immediately ventral to the choroidal fissure. As a result the corpus striatum is approximated to the thalamus and is separated from it only by a deep groove that becomes obliterated by increased growth along the line of contact. The lateral aspect of the thalamus is now in continuity with the medial aspect of the corpus striatum so that a secondary union between the diencephalon and the telencephalon is effected over a wide area, providing a route for the subsequent passage of projection fibres to and from the cortex (see Fig. 14.27).

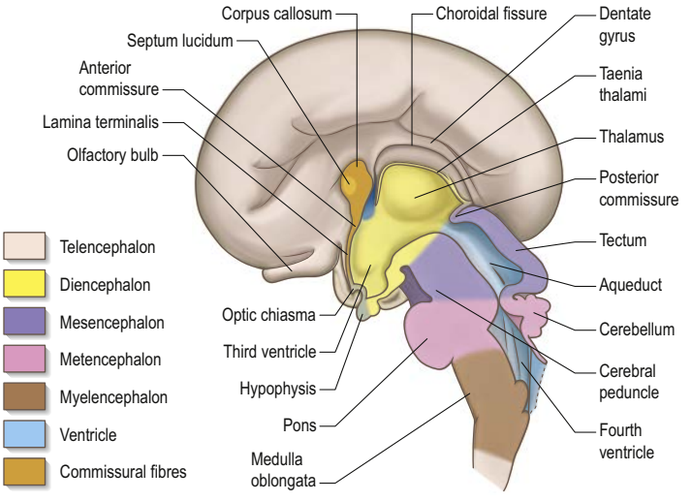

Fig. 14.31 The anterior and posterior commissures in the brain of a human fetus at postmenstrual week 16; medial aspect of the left half of the brain.

Formation of the insula

At the end of the first trimester, while the corpus striatum is developing, growth between the frontal and temporal lobes is relatively restricted. The region lateral to the striatum becomes depressed to form a lateral cerebral fossa with a portion of cortex, the insula, at its base (see Figs 14.29–14.30). As the temporal lobe continues to protrude towards the orbit, and with more rapid growth of the temporal and frontal cortices, the surface of the hemisphere expands at a rate greater than that of the hemisphere as a whole, and the cortical areas become folded, forming gyri and sulci. The insula is gradually overgrown by adjacent cortical regions that overlap it to form the opercula: the free margins of the opercula form the anterior part of the lateral fissure. This process is not completed until after birth. The lentiform nucleus remains deep to and coextensive with the insula.

Olfactory bulb

A longitudinal groove appears in the anteromedial part of the floor of each developing lateral ventricle at about the stage 17. It deepens and forms a hollow diverticulum that is continuous with the hemisphere by a short stalk. The diverticulum becomes connected on its ventral or inferior surface to the olfactory placode. Placodal cells give rise to afferent axons that terminate in the walls of the diverticulum. As the head increases in size, the diverticulum grows forwards, loses its cavity and becomes converted into the solid olfactory bulb. The forward growth of the bulb is accompanied by elongation of its stalk to form the olfactory tract. The part of the floor of the hemisphere to which the tract is attached constitutes the piriform area.

Olfactory nerve, limbic lobe and hippocampus

The growth changes in the temporal lobe that help to submerge the insula produce important changes in the olfactory and neighbouring limbic areas. The olfactory tract diverges into lateral, medial and (variable) intermediate striae as it approaches the hemispheric floor. The medial stria is clothed with a thin archicortical medial olfactory gyrus. This curves up into further archicortical areas rostral to the lamina terminalis (paraterminal gyrus, prehippocampal rudiment, parolfactory gyrus, septal nuclei) and these continue into the indusium griseum. The lateral stria, clothed by the lateral olfactory gyrus, and the intermediate stria (when present) terminate in the rostral parts of the piriform area, including the olfactory trigone and tubercle, anterior perforated substance, uncus and entorhinal area of the anterior part of the future parahippocampal gyrus. The lateral limit of the lateral stria is indicated by the rhinal sulcus. The forward growth of the temporal pole and the general expansion of the neocortex cause the lateral olfactory gyrus to bend laterally, the summit of the convexity lying at the anteroinferior corner of the developing insula. During the second trimester, much of the piriform area becomes submerged by the adjoining neocortex and, in the adult, only a part of it remains visible on the inferior aspect of the cerebrum.

The limbic lobe is the first part of the cortex to differentiate. At first it forms a continuous, almost circular, strip on the medial and inferior aspects of the hemisphere. Below and in front, where the stalk of the olfactory tract is attached, it constitutes a part of the piriform area. The portion outside the curve of the choroidal fissure constitutes the hippocampal formation (see Fig. 14.27; **Fig. 14.31**). In this region, the neural progenitors of the developing cortex proliferate and migrate. The wall of the hemisphere thickens, producing an elevation that projects into the medial side of the ventricle. The elevation is the hippocampus; it appears first on the medial wall of the hemisphere, in the area above and in front of the lamina terminalis (paraterminal area), and gradually extends backwards, curving into the region of the temporal pole, where it adjoins the piriform area. The marginal zone in the neighbourhood of the hippocampus is invaded by neurones to form the dentate gyrus. The hippocampus and the dentate gyrus extend from the paraterminal area backwards above the choroidal fissure and follow its curve downwards and forwards towards the temporal pole, where they continue into the piriform area. A shallow groove, the hippocampal sulcus, crosses the medial surface of the hemisphere throughout the hippocampal formation. The efferent fibres from the cells of the hippocampus collect along its medial edge and run forwards immediately above the choroidal fissure. Rostrally, they turn ventrally and enter the lateral part of the lamina terminalis to gain the hypothalamus, where they end in and around the mammillary body and neighbouring nuclei. These efferent hippocampal fibres form the fimbria hippocampi and the fornix.

Projection fibres, internal capsule

The growth of the neocortex, and its enormous expansion during the latter part of the first trimester, is associated with the initial appearance of corticofugal and corticopetal projection fibres and the internal capsule. The fibres follow the route provided by the apposition of the lateral aspect of the thalamus with the medial aspect of the corpus striatum. They divide the latter, almost completely, into a lateral part, the lentiform nucleus, and a medial part, the caudate nucleus; these two nuclei remain confluent only in their anteroinferior regions (see Figs 14.27–14.28). The corticospinal tracts are first identified at the end of stage 23 at the pyramidal decussation. The lateral corticospinal tracts are in the cervical cord by postmenstrual weeks 14–15 and in the anterior corticospinal tract from about postmenstrual week 16 (Jin et al 2016). The fibres destined for the cervical and upper thoracic regions, which innervate the upper limbs, are in advance of those that innervate the lower limbs, and these, in turn, are in advance of fibres that innervate the face; the timing of the appearance of reflexes associated with these three parts of the body is similarly staggered. The proportions of crossed and uncrossed fibres in each corticospinal tract vary; a dominant uncrossed corticospinal tract and a complete absence of pyramidal decussation have been found in posterior fossa anomalies such as occipital encephalocele, Dandy–Walker malformation and Joubert's syndrome. There is evidence of substantial plastic reorganization of the motor cortex and corticospinal projections following pre- or perinatal lesions to the corticospinal system (Eyre 2007). For further reading about the development of the human pyramidal tract, see ten Donkelaar et al (2004).

The majority of subcortical nuclear masses receive terminals from descending fibres of cortical origin and thalamocortical, hypothalamocortical and other afferent ascending bundles. The internal capsular fibres pass lateral to the head and body of the caudate nucleus, the anterior cornu and central part of the lateral ventricle, the rostroventral extensions and body of the fornix, the dorsal thalamus and dorsal choroidal fissure, and medial to the lentiform nucleus (see Figs 14.27–14.28).

Formation of gyri and sulci

Apart from the shallow hippocampal sulcus and the lateral cerebral fossa, the surfaces of the hemisphere remain relatively smooth and uninterrupted until postmenstrual week 21 (see Fig. 14.30). The parieto-occipital sulcus appears at about that time on the medial aspect of the hemisphere. Its appearance seems associated with an increase in the number of splenial fibres in the corpus callosum. Over the same period, the posterior part of the calcarine sulcus appears as a shallow groove extending forwards from a region near the occipital pole. It is a true infolding of the cortex in the long axis of the striate area and produces an elevation, the calcar avis, on the medial wall of the posterior horn of the ventricle.

The cingulate sulcus appears on the medial aspect of the hemisphere about postmenstrual weeks 18–20, and sulci appear on the inferior and superolateral aspects after postmenstrual week 21. The central, precentral and postcentral sulci appear, each in upper and lower parts that usually coalesce shortly afterwards, although they may remain discontinuous. The superior and inferior frontal, the intraparietal, occipital, superior and inferior temporal, occipitotemporal, collateral and rhinal sulci all make their appearance during the same period. Secondary and tertiary gyri form after neurones attain their final areal and laminar positions (Silver et al 2019). All the important sulci can be recognized by postmenstrual

week 32 (see Fig. 14.30). Preterm infants developing *ex utero* have less gyrification and shallower sulci by their equivalent postmenstrual week 40 than neonates born at full-term (postmenstrual week 40) (Engelhardt et al 2016a, Shimony et al 2016). Mathematical modelling of gyral patterns has identified distinct folding patterns and sex differences in the superior temporal, inferior frontal and cingulate gyri in healthy singleton, twin, preterm and full-term neonates (Duan et al 2019).

Development of commissures

The development of the commissures causes a very profound alteration of the medial wall of the hemisphere. At the time of their appearance, the two hemispheres are connected to each other by the median part of the telencephalon. The roof plate of this area remains epithelial, while its floor becomes invaded by the decussating fibres of the optic nerves and developing hypothalamic nuclei. These two routes are thus not available for the passage of commissural fibres passing from hemisphere to hemisphere across the median plane, and these fibres therefore pass through the rostral wall of the interventricular foramen, i.e. the lamina terminalis. The first commissures to develop are those associated with the paleocortex and archicortex. Fibres of the olfactory tracts cross in the ventral or lower part of the lamina terminalis and, together with fibres from the piriform and pre-piriform areas and the amygdaloid bodies, form the rostral part of the anterior commissure (see Fig. 14.31; **Fig. 14.32**). The two hippocampi become interconnected by transverse fibres that cross from fornix to fornix in the upper part of the lamina terminalis as the commissure of the fornix (hippocampal commissure). Various other decussating fibre bundles (known as the supraoptic commissures, although they are not true commissures) develop in the lamina terminalis immediately dorsal to the optic chiasma, between it and the anterior commissure.

The commissures of the neocortex develop later and follow the pathways already established by the commissures of the limbic system. Fibres from the tentorial surface of the hemisphere join the anterior commissure and constitute its larger posterior part. All the other commissural fibres of the neocortex associate themselves closely with the commissure of the fornix and lie on its dorsal surface. These fibres increase enormously in number and the bundle rapidly outgrows its neighbours to form the corpus callosum (see Figs 14.31–14.32).

The corpus callosum originates as a thick mass connecting the two cerebral hemispheres around and above the anterior commissure. The upper end of this neocortical commissural area extends backwards to form the trunk of the corpus callosum. The rostrum of the corpus callosum develops later and separates some of the rostral end of the limbic area from the remainder of the cerebral hemisphere. Further backward growth of the trunk of the corpus callosum then results in the entrapped part of the limbic area becoming stretched out to form the bilateral septum pellucidum. As the corpus callosum grows backwards, it extends above the choroidal fissure, carrying the commissure of the fornix on its undersurface. In this way, a new floor is formed for the longitudinal fissure, and additional structures come to lie above the epithelial roof of the third ventricle. In its backward growth, the corpus callosum invades the area hitherto occupied by the upper part of the archicortical hippocampal formation, and the corresponding parts of the dentate gyrus and hippocampus are reduced to vestiges, the indusium griseum and the longitudinal striae. The posteroinferior (temporal) archicortical regions of both dentate gyrus and hippocampus persist and enlarge.

Cellular development of the cerebral cortex

Cortical neurones are not generated within the cortex itself but in proliferative transient embryonic zones such as the ventricular (VZ) and subventricular (SVZ) zones (see Fig. 14.33). Precise patterns of cell division and the subsequent migration of the progeny of these divisions along the shafts of a transient population of radial glial cells transform the neuroepithelium of the embryonic forebrain into the adult cerebral cortex (Noctor et al 2004). Neurones are derived from a lineage of radial glia stem cells and transit amplifying intermediate progenitor cells; expansion in one or both cell populations has been proposed as a potential mechanism for neocortical expansion (Kriegstein and Gotz 2003, Lui et al 2011). The earliest-generated cortical neurones accumulate in an outside-in sequence to form the preplate. Subsequent generations of neurones migrate into the preplate, forming a series of layers called the cortical plate that splits the preplate into a superficial layer at the pial surface, the marginal zone, and a deeper layer, the subplate. Subplate neurones integrate into the intra- and extracortical circuitry and extend axons via the internal capsule towards the thalamus and superior colliculus at times before other cortical neurones have been born (Kanold and Luhmann 2010). In humans, the subplate is maximal at approximately postmenstrual week 25 and recedes after birth by postnatal month 6 (Kostovic et al 2012). The diverse cellular components of the subplate are embedded in an abundant hydrophilic extracellular matrix rich in secreted polymeric glycosaminoglycans, fibronectin

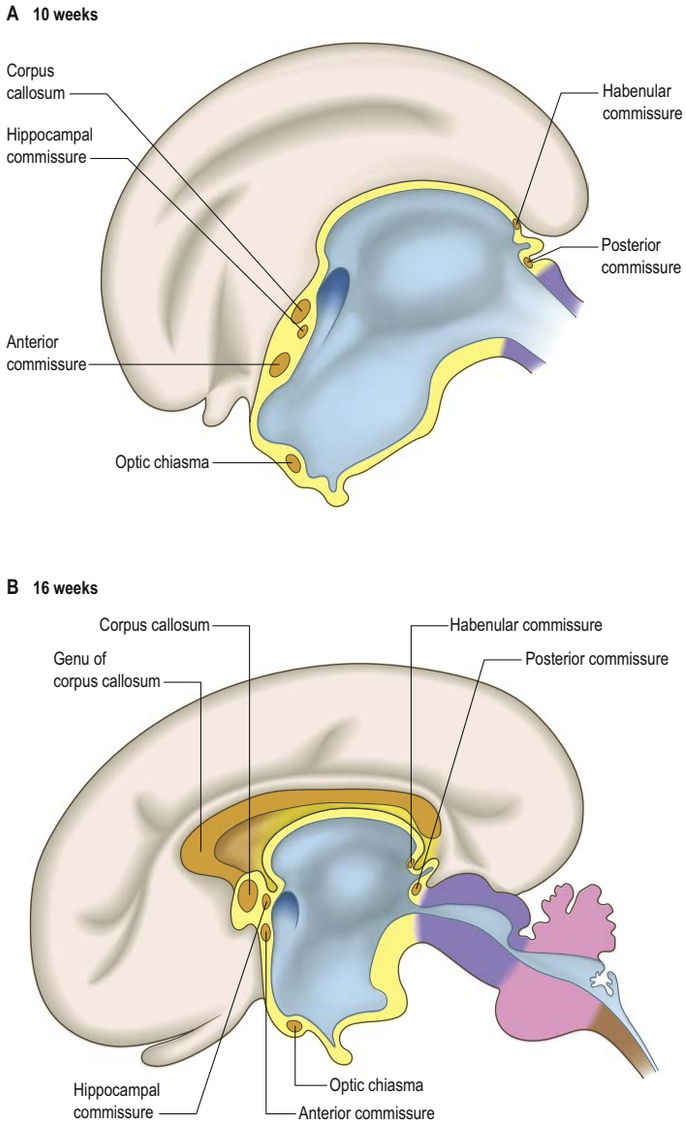

Fig. 14.32 Median sections showing the formation of the commissures. The telencephalon gives rise to commissural tracts that integrate the activities of the left and right cerebral hemispheres. These tracts include the anterior and hippocampal commissures and the corpus callosum. The small posterior and habenular commissures arise from the epithalamus.

and chondroitin sulphate proteoglycans that, for example, provide a major corridor for migrating GABAergic neurones (Hoerder-Suabedissen and Molnar 2015). Subplate neurones are vulnerable to injury during prenatal stages; their premature loss has been implicated in the pathogenesis of chronic deficits such as cognitive delay, behavioural problems and epilepsy associated with preterm birth (Jantzie et al 2015). They have also been implicated in the pathogenesis of cognitive developmental disorders such as autism and schizophrenia (Silver et al 2019, Molnar et al 2019).

Neurones migrate along radial glial processes (see Fig. 14.12). The migration of neuronal precursors from the ventricular and intermediate zones occurs radially towards the pial surface (Kriegstein and Noctor 2004). From the pial surface inwards, the following zones may be defined: marginal, cortical plate, subplate, intermediate, subventricular and ventricular (**Fig. 14.33**). (For a review of the nomenclature of the developing zones, see Bystron et al (2008).) The marginal zone, the outermost layer of the developing cerebral cortex, will form layer 1. The neurones of the cortical plate and subplate form the neurones of the remaining cortical laminae (2–6), the complexity varies in different locations and with further additions of neurones from the deeper zones. The intermediate zone gradually transforms into the white matter of the hemisphere. Meanwhile, other deep progenitor cells produce generations of glioblasts that also migrate into the more superficial layers. As proliferation wanes and finally ceases in the ventricular and subventricular zones, their remaining cells differentiate into general or specialized ependymal cells, tanycytes or subependymal glial cells.

The timing of proliferation of different cortical neurones varies according to their laminar destination and cell type. The first groups of

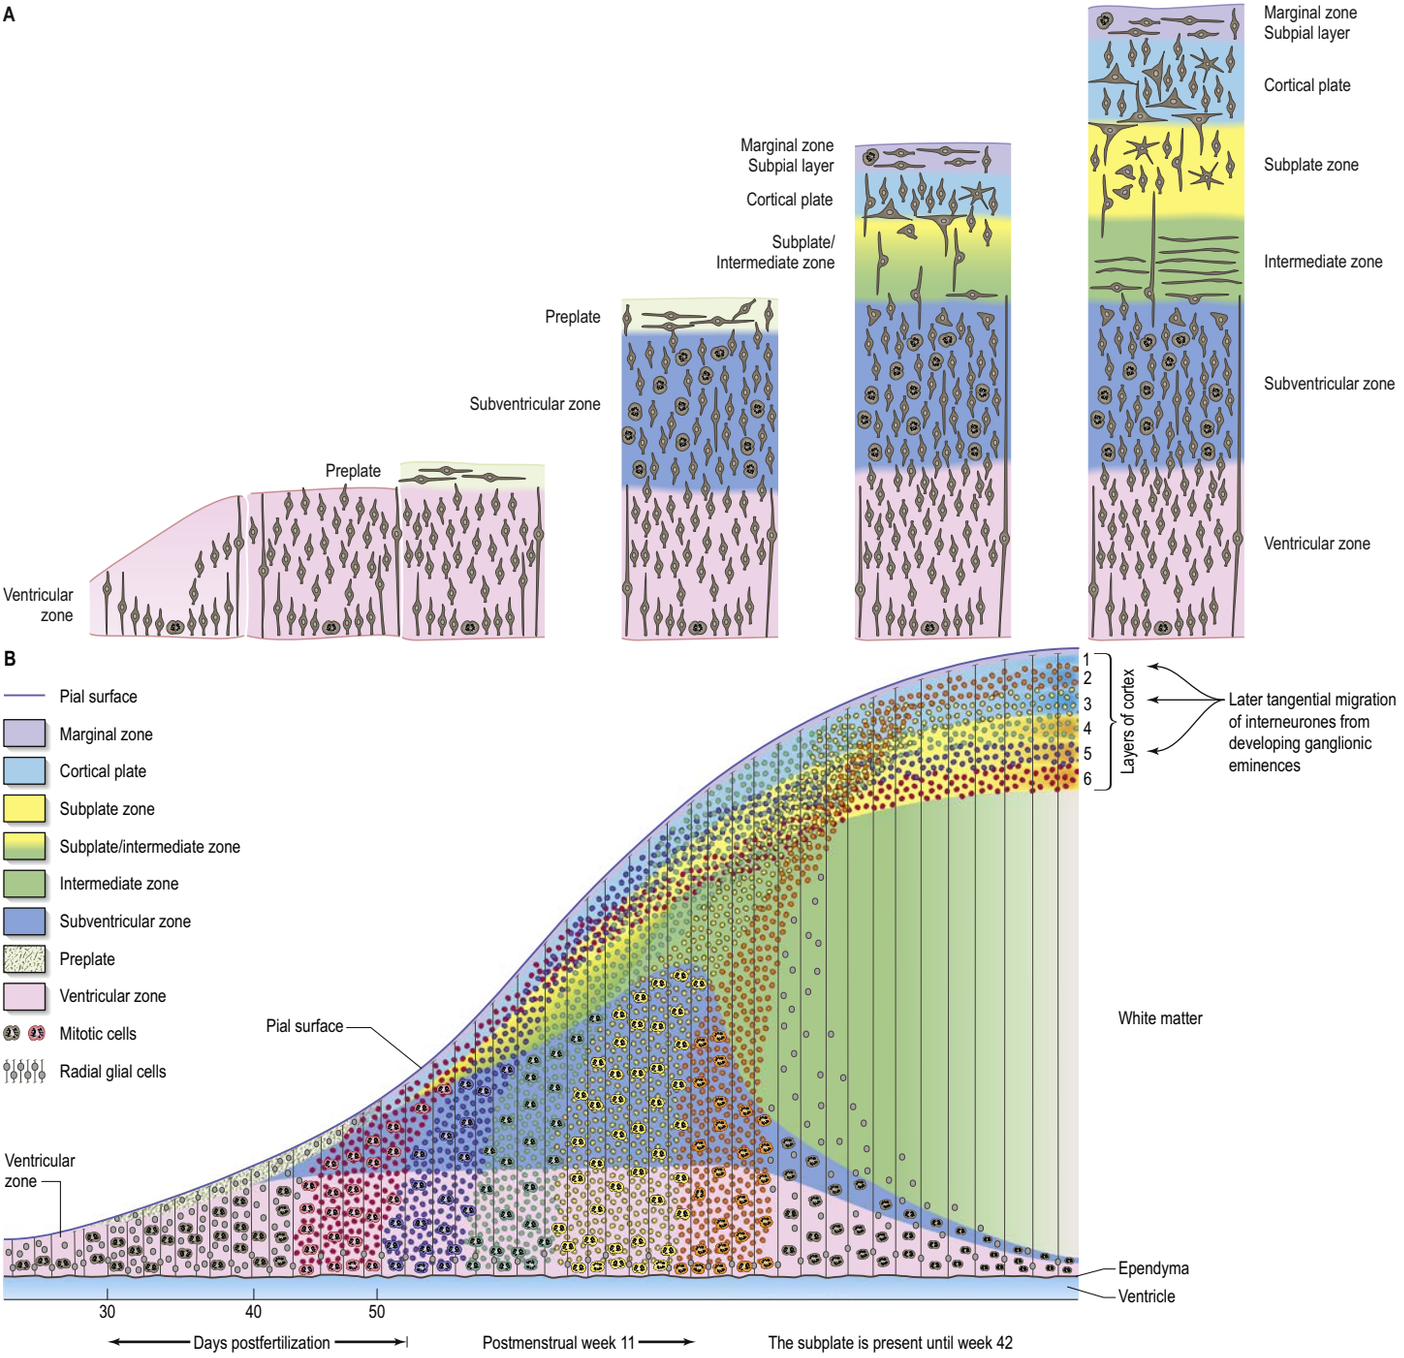

Fig. 14.33 A, The layers of the developing telencephalon. The early pseudostratified arrangement of the neural tube is defined by radial glia that extend from the ventricular surface to the pial surface. Neuroblasts and glioblasts divide in the ventricular and subventricular zones and migrate radially along the radial glia to form a cortical plate and then a subplate. The preplate, subplate, subventricular and ultimately the ventricular zones recede during development and early postnatal life. **B**, Successive migration of neuroblasts from the ventricular and subventricular zones to the cortex. The first cells to migrate to the cortical plate and subplate zone form the deep cortical laminae. Later cells migrate radially between these cells to the outer part of the developing cortex. Note the extensive early proliferation of the subventricular zone and its later diminution as the cells it contains migrate radially to the cortex. The effect of this radial cell migration towards the developing cortical surface is expansion of the cortical area rather than an increase in cortical thickness. Axons from cells in the cortex extend through the intermediate zone which becomes cerebral white matter. Once the earliest cortical layers have formed, cells originating from the ganglionic eminences migrate tangentially into the cortical layers and form interneurones.

cells to migrate are destined for the deep cortical laminae and later groups pass through them to more superficial regions. The subplate zone exists until postmenstrual week 42 and is most prominent during mid-gestation: it contains neurones surrounded by a dense neuropil and is the site of the most intense synaptogenesis in the embryonic cortex (Molnar et al 2019). The cumulative effect of this radial and tangential growth is evident in a marked expansion of the surface area of the cortex without a comparable increase in its thickness (Rakic 1988, 2009).

The phylogenetically oldest regions in the pallial walls of the mammalian cerebral hemisphere are the first to differentiate during ontogeny: they border the interventricular foramen and its extension, the choroidal fissure, the lamina terminalis and the piriform lobe. The pallidum contributes interneurones to the formation of the cerebral cortex. A significant portion of GABAergic inhibitory (non-pyramidal) cells are generated not in the cortical ventricular zone, but along the inner curving border of the developing lateral ventricle, in the ganglionic (ventricular) eminences that will later form the lentiform and caudate nuclei (see Figs 14.27–14.28). The ganglionic eminences have three anatomical subdivisions, medial, lateral and caudal, distinguished by the molecular markers and cell

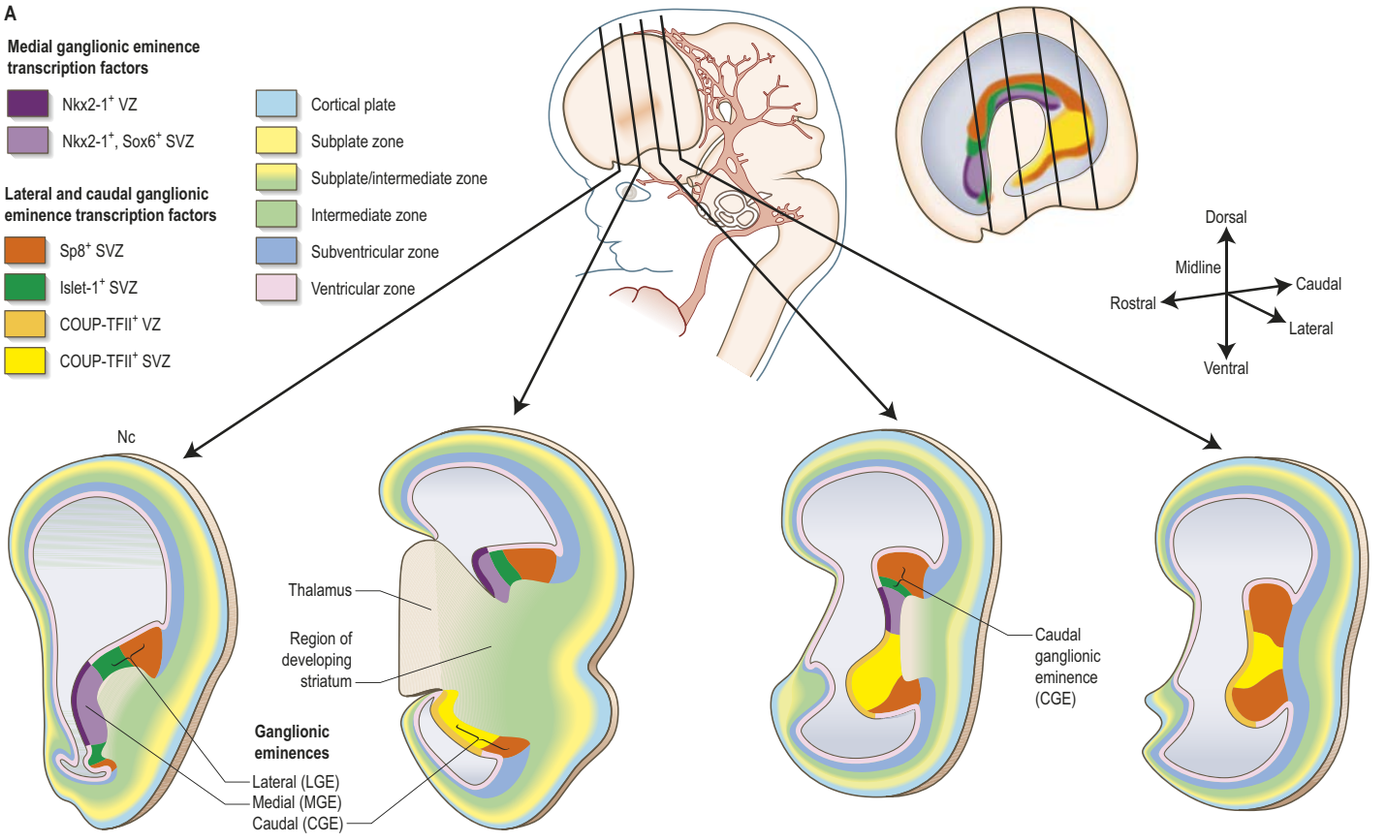

Fig. 14.34 A, Sections through the medial, lateral and caudal ganglionic eminences that are destined to become the caudate nucleus, part of the corpus striatum. Cells from these ganglionic eminences migrate into the subventricular zone and then to the subplate zone and cortical plate. The medial ganglionic eminence has strong Nkx2-1 expression in the ventricular (VZ) and subventricular (SVZ) zones. The lateral (LGE) and caudal (CGE) ganglionic eminences show expression patterns of Nkx2-1 and Sox6, COUP-TFII, Islet-1 (a transcription factor that marks the LGE SVZ and differentiating striatal cells in rodents) and Sp8. Sp8+ cells are mainly located in the SVZ; many of them express Ki67, a marker of proliferative cells. In the dorsal CGE, COUP-TFII+ cells are located mainly in the SVZ: most do not express Ki67. In the ventral CGE, COUP-TFII+ cells are in the VZ and SVZ, and many express Ki67. (Expression patterns as determined by Ma et al 2012.) (B–C, *continued online*)

types they produce (Fig. 14.34). Cortical interneurones are generated mainly in the caudal and medial parts of the ganglionic eminence and the preoptic area and migrate tangentially through the future striatocortical junction and the subplate to reach the cortex, governed by molecular cues including Semaphorin3a/f, CXCL12, Neuregulin1, Robo, and Ephrin (Métin et al 2006, Wonders and Anderson 2006, Ma et al 2012, Hansen et al 2013, Molnar and Butt 2013). Experimental evidence suggests that the developing cortical areal map is patterned in the same way as the rest of the body, by diffusible proteins (members of the FGF, Wnt, BMP and SHH families) that are released from signalling centres: in the cortex, FGF8 influences the rostrocaudal axis, and Wnts and BMP influence the dorsoventral axis. The extent to which these findings can be extrapolated from experimental animals, especially mice, to the developing human cortex remains speculative; there are indications that some mechanisms may be conserved (Silver et al 2019).

Although the biological significance of the inside-out gradient of neurogenesis is unclear, it is known that if the gradient is disturbed, by genetic or epigenetic factors, neurones display abnormal cortical function. Failure or delay in neuronal migration has been associated with a wide range of disorders, such as lissencephaly and schizophrenia (Wu et al 2014).

After the initial generation of neuroblasts the ventricular and subventricular zones give rise to glioblasts that migrate to the cortical subplate. Oligodendrocyte progenitor cells are prevalent initially in the subventricular zone and after postmenstrual weeks 19–22 in the subplate zone (Jakovcevski et al 2009). The cues that initiate myelination in some axons and not others are still unclear: regional differences in oligodendrocyte-lineage cells, which probably emerge after specification of oligodendrocyte precursors, may explain some differences in myelination between CNS regions (Osso and Chan 2017, Saab and Nave 2017). In human cerebral white matter, the oligodendrocyte lineage appears to involve three successive stages (pre-oligodendrocyte, immature oligodendrocyte and mature oligodendrocyte) from about postmenstrual week 22 (Back et al 2001). Ventrodorsal gradients of oligodendrocyte precursor cell density and of myelination have been described in the telencephalon.

The sequence of myelination of the motor pathways may explain, at least partially, the order of development of muscle tone and posture in the premature infant and full-term neonate. Myelination of the various subcorticospinal pathways (vestibulospinal, reticulospinal, olivospinal and tectospinal) starts at postmenstrual weeks 24–30 for the medial tracts, and at postmenstrual weeks 28–34 for the lateral tracts (Dubois et al 2014) (Fig. 14.35).

The vast species differences between invertebrate, murine, non-human primate and primate nervous systems pose particular, sometimes intractable, problems for neuroscientists exploring the evolution of the human cerebral cortex. Current understanding of the pre- and postnatal events that regulate the numbers of neurones and their associated glia; the dynamics of neuronal migration to proper layers, columns and regions; the enormous expansion of the cortical surface; and the development of connectivity, particularly networks mediating higher cognitive functions and language, remains in its infancy for the human cortex. (For further reading on the evolution of the neocortex, see Rakic (2009), Lui et al (2011), Geschwind and Rakic (2013), Lister et al (2013), Silver et al (2019).)

The Allen Human Brain Atlas (http://human.brain-map.org/) uses DNA microarrays for transcriptional profiling of several hundred locations spanning the adult human neocortex (Hawrylycz et al 2012), while the NIH Blueprint Non-Human Primate Atlas profiles individual cortical layers in the Rhesus monkey (http://www.blueprintnhpatlas.org/). Similarly, the BrainSpan Atlas of the Developing Human Brain (http://www.brainspan.org/) is a resource for studying the transcriptome across human brain development, using RNA sequencing on discrete cortical regions across an entire lifespan, and comparative DNA microarrays on laser-microdissected individual layers of different regions of the developing neocortex.

Culture of hPSCs (ESC and iPSCs) into 3D organoids has provided new ways to study cortical development: cells recapitulate temporal and spatial migration. Optimized culture methods have produced outer radial glial progenitor cells; self-organized cortical tissues show early-born neurones migrating to deep cortical plate layers and later-born cells migrating to the upper layers. Cerebral organoids showing discrete brain regions and tissues, including the hippocampus, midbrain/hindbrain boundary and choroid plexus, have been used to study neurodevelopmental disorders and neurodegenerative diseases (Lee et al 2017, Amin and Paşca 2018, Wang 2018). Spontaneous cellular network formation that exhibits periodic and regular oscillatory events dependent on glutamatergic and GABAergic signalling has been reported in long-term culture of cerebral organoids (Trujillo et al 2019).

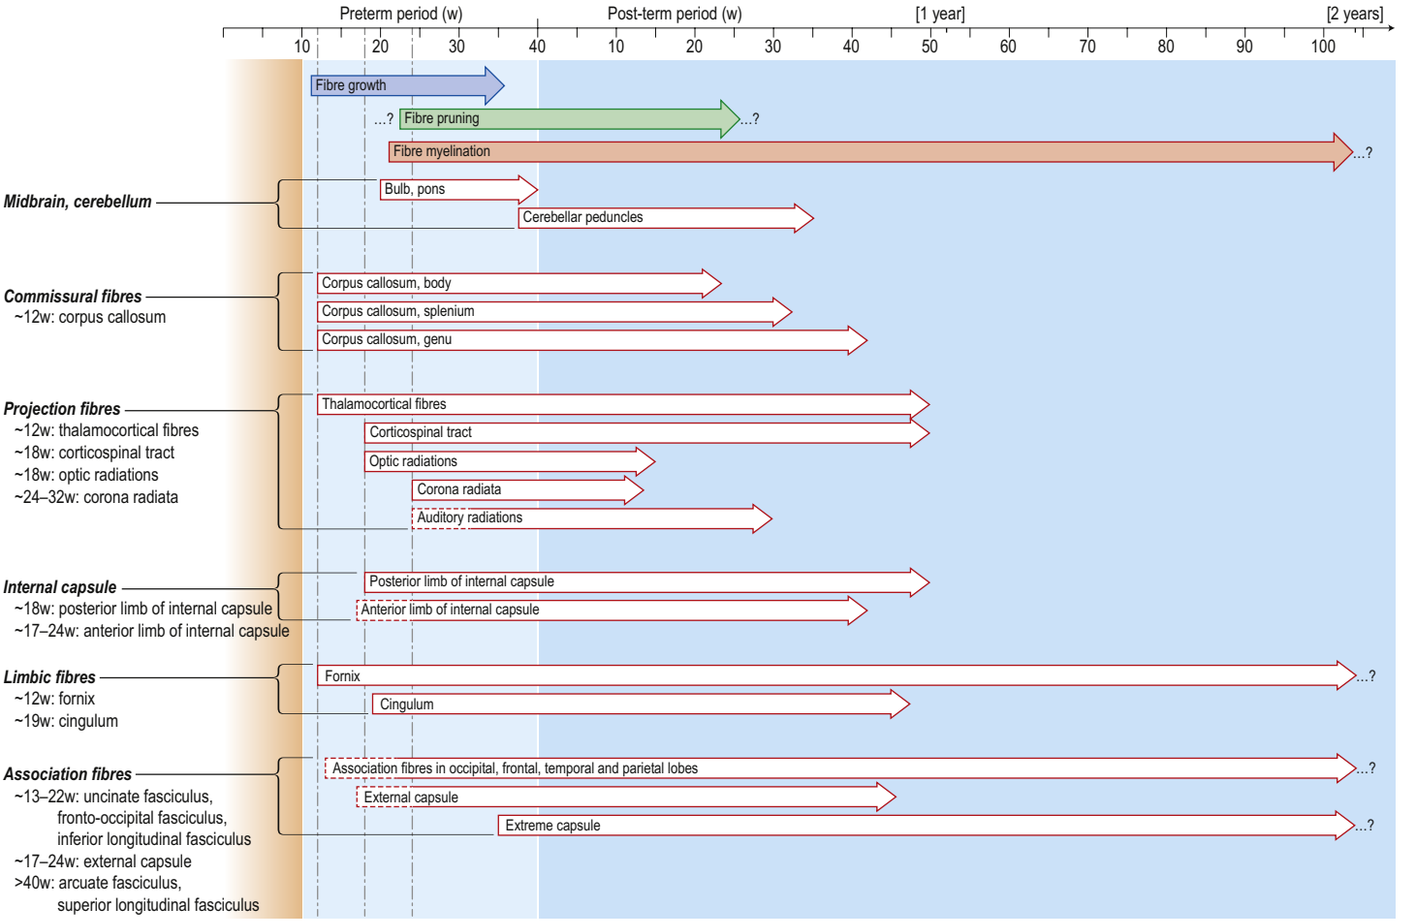

Fig. 14.35 A general timeline of white matter development. (Based on Dubois et al 2014.)

VASCULAR SUPPLY

Cerebral arteries

The cranial extensions of the dorsal aortae that supply the head receive blood entirely through the third aortic arches. The internal carotid artery is formed progressively from the third arch artery (which contributes its proximal part) (see Fig 17.9) and a further forward continuation that differentiates, at the time of regression of the first and second aortic arches, from the capillary plexus extending to the walls of the forebrain and midbrain. At its anterior extremity, this primitive internal carotid artery divides into cranial and caudal divisions. The former terminates as the primitive olfactory artery and supplies the developing regions implied (see Fig. 17.8). The latter sweeps caudally to reach the ventral aspect of the midbrain; its terminal branches are the primitive mesencephalic arteries. Simultaneously, bilateral longitudinal channels differentiate along the ventral surface of the rhombencephalon from a plexus fed by intersegmental and transitory presegmental branches of the dorsal aorta and its forward continuation. The most important of the presegmental branches is closely related to the trigeminal nerve, the primitive trigeminal artery. Otic and hypoglossal presegmental arteries occur and may persist. The longitudinal channels later connect cranially with the caudal divisions of the internal carotid arteries (each of which gives rise to an anterior choroidal artery supplying branches to the diencephalon, including the telae choroideae and midbrain), and caudally with the vertebral arteries through the first cervical intersegmental arteries. Fusion of the longitudinal channels results in the formation of the basilar artery. The caudal division of the internal carotid artery becomes the posterior communicating artery and the stem of the posterior cerebral artery. The remainder of the posterior cerebral artery develops comparatively late, probably from the stem of the posterior choroidal artery, which is annexed by the caudally expanding cerebral hemisphere, its distal portion becoming a choroidal branch of the posterior cerebral artery. The posterior choroidal artery supplies the tela choroidea at the future temporal end of the choroidal fissure; its rami advance through the tela to become confluent with branches of the anterior choroidal artery. The cranial division of the internal carotid artery gives rise to anterior choroidal, middle cerebral and anterior cerebral arteries. The stem of the primitive olfactory artery remains as a small medial striate branch of the anterior cerebral artery. The cerebellar arteries, of which the superior is the first to differentiate, emerge from the capillary plexus on the wall of the rhombencephalon.

The source of the blood supply to the territory of the trigeminal nerve varies at different stages in development. When the first and second aortic arch arteries begin to regress, the supply to the corresponding arches is derived from a transient ventral pharyngeal artery, which grows from the aortic sac and terminates by dividing into mandibular and maxillary branches.

Leptomeningeal arteries

At stages 20–23 the circle of Willis is completed. The anterior communicating arteries develop by stage 23. An anular network of leptomeningeal arteries, originating mainly from each middle cerebral artery, passes over each developing cerebral hemisphere. Caudally, similar meningeal branches arise from the vertebral and basilar arteries and embrace the cerebellum and brainstem. The further development of the telencephalon somewhat obscures this early pattern over the cerebrum.

The meningeal arteries so formed have been classified into three groups: paramedian, short circumferential and long circumferential arteries. They can be described both supratentorially and infratentorially, and all give off fine side branches and end as penetrating arteries. Of the supratentorial vessels, the paramedian arteries have a short course prior to penetrating the cerebral neuropil (e.g. branches of the anterior cerebral artery); the short circumferential arteries have a slightly longer course before becoming penetrating arteries (e.g. the striate artery); and the long circumferential arteries reach the dorsal surface of the hemispheres. Infratentorial meningeal arteries are very variable. The paramedian arteries, after arising from the basilar or vertebral arteries, penetrate the brainstem directly. The short circumferential arteries end at the lateral surface of the brain before

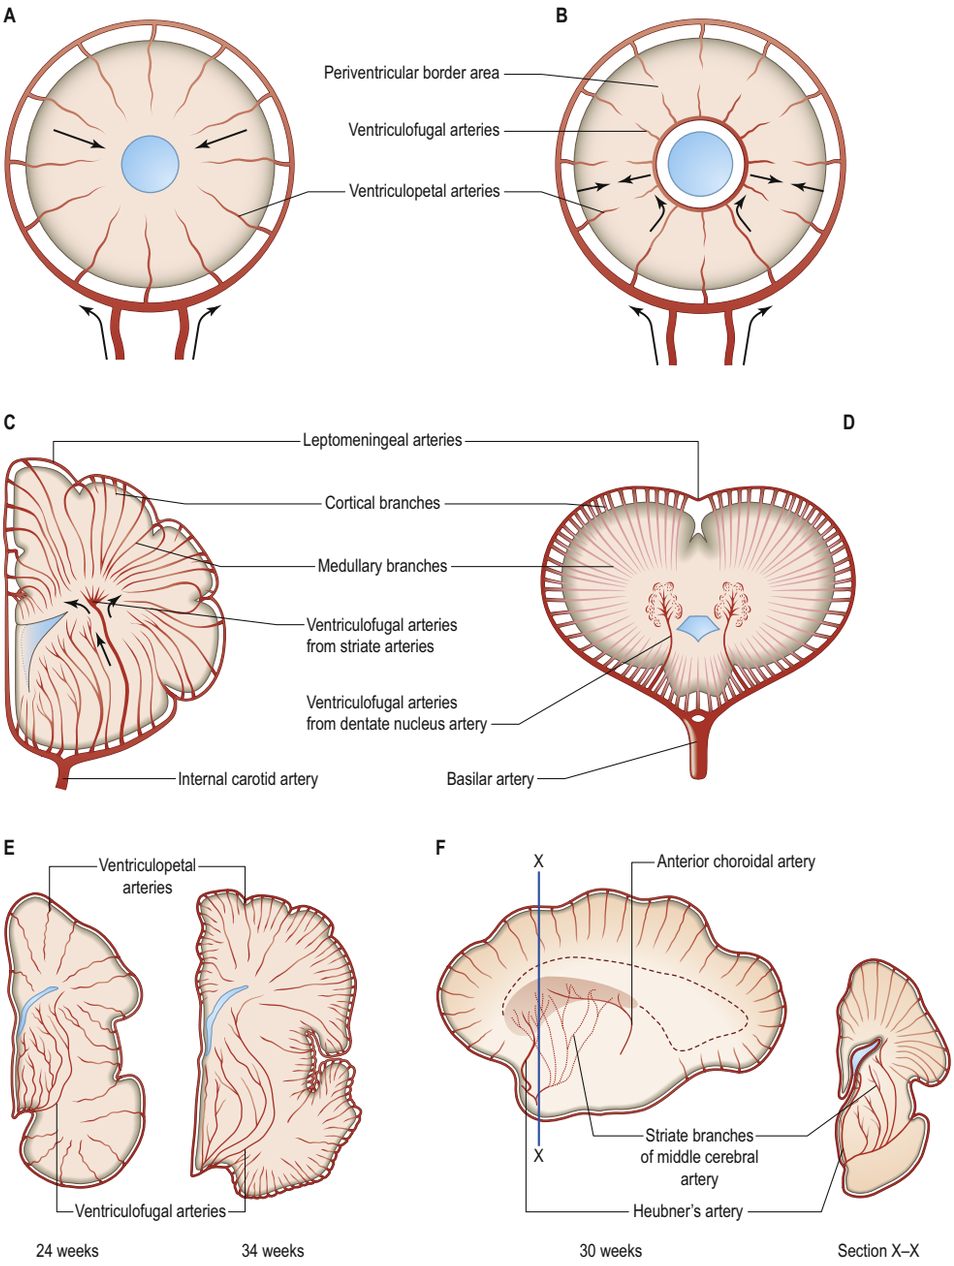

Fig. 14.36 Development of cerebral blood vessels. **A**, The brain is surrounded by a system of leptomeningeal arteries from afferent trunks at its base. Intracerebral arteries arise from this system and converge (ventriculopetally) towards the ventricle (the inner circle in this diagram). **B**, A few deep, penetrating vessels supply the brain close to the ventricle and send ventriculofugal arteries towards the ventriculopetal vessels without making anastomoses. **C**, The arrangement of ventriculopetal and ventriculofugal vessels around a cerebral hemisphere. **D**, The similar arrangement of vessels around the cerebellum. **E**, Changes in the arterial pattern of the human cerebrum between postmenstrual weeks 24 and 34. **F**, Arterial supply to the basal nuclei at postmenstrual week 30. (A–D, With permission from Van den Bergh R, Van der Eecken H 1968 Anatomy and embryology of cerebral circulation. Prog Brain Res 30:1–25; E–F, With permission from the BMJ Publishing Group from Hambleton G, Wigglesworth JS 1976 Origin of intraventricular haemorrhage in the preterm infant. Arch Dis Child 51:651–9.)

penetration and the long circumferential arteries later form the range of cerebellar arteries. These vessels, arranged as a series of loops over the brain, arise from the circle of Willis and brainstem vessels on the base of the brain.

By postmenstrual week 16 the anterior, middle and posterior cerebral arteries that contribute to the formation of the circle of Willis are well established. The leptomeningeal arteries arising from them display a simple pattern with little tortuosity and very few branches. With the increasing age of the fetus and acquisition of the gyral pattern on the surface of the brain, their tortuosity, diameter and number of branches all increase. The branching pattern is completed by postmenstrual week 28 and the number of branches does not increase further. Numerous anastomoses (varying in size from 200 to 760 μm) occur between the arteries in the depths of the developing sulci, nearly always in the cortical boundary zones of the three main cerebral arteries supplying each hemisphere. The number, diameter and location of these anastomoses change as fetal growth progresses, reflecting the regression and simplification of the complex embryonic cerebral vascular system.

Vascularization of the brain

The brain becomes vascularized by angiogenesis rather than by direct invasion by angioblasts. The first indication of pia mater, containing a plexus of blood vessels that forms on the neural surface, is seen at stage 11 around the caudalmost part of the rhombencephalon and extends to the mesencephalic level by stage 12. The pial basement membrane is formed from interaction between neural crest cells, the meningeal extracellular matrix and the basal processes (end feet) of the radial glial cells. Meningeal extracellular matrix-mediated activation of integrins promotes proliferation of basal radial glia progenitors, which in turn sustain the expression of the extracellular matrix genes (Silver et al 2019). Vessels in the pial plexus sprout and form branches that elongate at the junction between the ventricular and marginal zones; the branches project laterally within the inter-rhombomeric boundaries and longitudinally adjacent to the median floorplate. Additional sprouts later penetrate the inter-rhombomeric regions on the walls and floor of the hindbrain. Branches from the hindbrain elongate towards and join the branches in the inter-rhombomeric junctions, forming primary vascular channels between rhombomeres and longitudinally on each side of the median floorplate. Later additional sprouts invade the hindbrain within the rhombomeres, anastomosing in all directions.

Leptomeningeal perforating branches pass into the brain parenchyma as cortical, medullary and striate branches (Fig. 14.36). The cortical vessels supply the cortex via short branches that may form precapillary anastomoses, whereas the medullary branches supply the white matter. The medullary branches converge towards the ventricle but rarely reach it and often follow a tortuous course as they pass around bundles of nerves. The striate branches penetrate the brain through the anterior perforated substance and supply the basal nuclei

and internal capsule via a sinuous course; they are larger than the medullary branches and the longest reach close to the ventricle. The periventricular region and basal nuclei are also supplied by branches from the tela choroidea, which develops from the early pial plexus, becoming medially and more deeply placed as the telencephalon enlarges.

The cortical and medullary branches irrigate a series of corticosubcortical cone-shaped areas, each centred around a sulcus containing an artery. They supply a peripheral portion of the cerebrum and are grouped as ventriculopetal arteries. In contrast, striate branches arborize close to the ventricle and supply a more central portion of the cerebrum. Together with branches from the tela choroidea, they give rise to ventriculofugal arteries that supply the ventricular zone (germinal matrix of the brain) and also send branches towards the cortex. The ventriculopetal and ventriculofugal arteries run towards each other but do not anastomose. The ventriculopetal arteries form networks of small arterioles (see Fig. 14.36) and supply relatively more mature regions of the brain compared to the ventriculofugal vessels. The latter are subject to constant remodelling and do not develop tunicae mediae until ventricular zone proliferation is completed. The same pattern of centripetal and centrifugal arteries develops around the fourth ventricle. The ventriculofugal circulation is more extensive in the cerebellum than in the telencephalon. The arteries arise from the various cerebellar arteries and course with the cerebellar peduncles directly to the centre of the cerebellum, bypassing the cortex. The ventriculopetal arteries are derived from the meningeal vessels over the cerebellar surface and most terminate in the white matter.

At postmenstrual week 24 the blood supply to the basal nuclei and internal capsule is relatively well developed, via a prominent Heubner's artery (arteria recurrens anterior), a branch of the anterior cerebral artery. The cortex and the white matter regions are rather poorly vascularized at this stage. The distribution of arteries and veins on the lateral aspect of the cerebral hemispheres is affected by the formation of the lateral fissure and the development of cerebral sulci and gyri. Between postmenstrual weeks 12–20 the middle cerebral artery and its branches are relatively straight, branching in an open-fan pattern. At the end of postmenstrual week 20 the arteries become more curved as the opercula begin to appear and submerge the insular cortex. The area supplied by the middle cerebral artery becomes dominant when compared to the territories supplied by the anterior and posterior cerebral arteries. Early arterial anastomoses appear around postmenstrual week 16 and increase in size with advancing fetal age. The sites of anastomoses between the middle and anterior cerebral arteries move from the convexity of the brain towards the superior sagittal sinus and anastomotic connections between the middle and posterior cerebral arteries shift towards the basal aspect of the brain.

By postmenstrual weeks 32–34 marked involution of the ventricular zone (germinal matrix) has occurred and the cortex acquires its complex gyral pattern and an increased vascular supply. Ventricular zone capillaries are gradually remodelled to blend with the capillaries of the caudate nucleus. Heubner's artery eventually supplies only a small area at the medial aspect of the head of the caudate nucleus. In the cortex, there is progressive elaboration of cortical blood vessels (see Fig. 14.36). Towards the end of the third trimester, the balance of cerebral circulation shifts from one that is central and basal nuclei-orientated, to one that predominantly serves the cortex and white matter.

Vessels of the ventricular zone (germinal matrix) and formation of the blood–brain barrier

The capillary bed of the ventricular zone is supplied mainly by Heubner's artery and terminal branches of the lateral striate arteries from the middle cerebral artery. The capillary channels in the ventricular zone open at right-angles directly into the veins. Subependymal veins (septal, choroidal, thalamostriate and posterior terminal) flow towards the interventricular foramen where there is a change of direction and the veins recurve at an acute angle to form the paired internal cerebral veins.

Vessels within the ventricular and subventricular zones have been described as less mature than cortical vessels: their apparent fragility has been implicated in the aetiopathogenesis of intraventricular haemorrhage in premature infants. A rounded contour, relative paucity of pericytes, an immature basal lamina and a deficiency of glial fibrillary acidic protein (GFAP) in the ensheathing astrocyte end feet have all been cited as indicators of the immaturity of the microvasculature of the germinal matrix (Ballabh 2010). The ventricular and subventricular zones retain an embryonic capillary bed until cell proliferation is complete, which means that the highly cellular structure of the ventricular zone is a temporary feature. The capillary beds have the capacity to remodel after the ventricular cells finally differentiate as ependyma.

The direct mutual support of two epithelial layers and their shared basal laminae, rather than support of an epithelium by a lamina propria is unique, seen elsewhere only in the kidney glomerular basement membrane and alveolar-capillary membrane (see Fig 11.2). In the nervous system the cells of the neurovascular unit, endothelial, astrocyte and pericyte, form a blood–brain barrier that matures at different times in different brain regions during development. The permissive interactions between these epithelial phenotypes via their respective basal laminal secretions may contribute towards the patterning of the brain parenchymal spaces. Endothelial cells have a complex glycocalyx and are joined by tight and gap junctions; the integral membrane protein, occludin, spans the intracellular gaps between adjacent cells and claudins increase the hydraulic and electrical resistance across the endothelium (Pearce 2018). Pericytes, sparse in fetal vessels, are required for endothelial–astrocyte barrier formation and disruption of pericyte–endothelial cell interaction may lead to barrier dysfunction. Cerebral vessels differ during development: their proximity to the great arteries; position in the cortex or white matter; reactions to fluctuating oxygen and carbon dioxide tissue levels; expression of membrane receptors; and recent vasoreactivity to a given stimulus, all contribute to their extensive functional heterogeneity (Pearce 2018). Endothelial–astrocyte interactions can affect both neuronal migration and blood–brain barrier function (Keep et al 2019) (Ch. 3). It has been suggested that interstitial fluid from the neurovascular unit flows along an intramural perivascular pathway (Engelhardt et al 2016b).

The ventricular zone operates a brain–cerebrospinal fluid barrier during development but not once the ventricular zone has ceased as a dividing layer and the cells have differentiated to form ependyma. The choroid plexuses, sites of a blood–cerebrospinal fluid barrier, function during development and control paracellular transport to the cerebrospinal fluid (Neuwelt et al 2011).

Cerebral veins

The developing venous channels in the brain direct blood from the capillary networks along two main routes, superficial and deep, from pial vessels supplying the cortical and subcortical regions, and from the ventricular zone and subependymal regions, respectively. The arterial supply is ventriculopetal in the cortical/subcortical zone and ventriculofugal in the ventricular zone, whereas the venous return is ventriculofugal in pial veins and ventriculopetal in the subependymal region.

The pial capillary plexus supplies the developing cortical plate and subjacent developing white matter. Pial veins deep within the sulci drain this region, receiving superficial medullary veins at the grey/white matter interface and numerous fine short subcortical veins that may join arcuate veins within the cortex before draining into intracortical veins. The latter join cortical veins on the cerebral cortex that may attach to the dura or run within the dural layers towards the closest dural sinus. At the superior sagittal sinus, the cortical veins join at an acute angle, against the dural blood flow: this arrangement is thought to be due to differential growth of the cerebrum in the third trimester (Pearl et al 2011). Venous vessel density in the cortex and subcortical white matter is low between postmenstrual weeks 16 and 28 and increases after postmenstrual week 36. The superior, middle, inferior, anterior and posterior cortical cerebral veins appear more tortuous than the meningeal arteries. Rapid cortical development correlates with the regression of the middle cerebral vein and its tributaries and the development of ascending and descending cortical veins. Cortical cerebral veins and the anastomoses between them can be identified from postmenstrual week 16. The inferior anastomotic vein (of Labbé), an anastomosis between the middle and inferior cerebral veins, becomes recognizable at postmenstrual week 20, and the superior anastomotic vein (of Trolard), connecting the superior and middle cerebral veins, is seen after the end of postmenstrual week 30.

The ventricular zone capillary plexus is drained by a deep venous plexus that extends to the enlarging subcortical region. This plexus forms deep medullary veins within a region filled with migrating neurones and growing axons. Vessel density is high in this region between postmenstrual weeks 16–24, transiently decreases in postmenstrual weeks 28–36 and increases after postmenstrual week 39 (Takashima et al 2009). The deep medullary veins are very long veins; the deepest join arcades of larger veins until all drain into subependymal veins

Sympathetic axons are seen in the walls of arteries supplying the rostral brain regions by about postmenstrual weeks 19–23. Unlike adult cerebral arteries, cholinergic nerves appear at the same time: fetal and neonatal cerebral arteries dilate in response to low concentrations of acetylcholine (Pearce 2018). Fetal perivascular innervation includes sensory fibres from the trigeminal ganglion (able to release vasoactive intestinal polypeptide, calcitonin gene-related peptide, substance-P, somatostatin and cholecystokinin) and, particularly around the arteries that form the circle of Willis and in the pial circulation, nerves that release neuropeptide Y (Pearce 2018). Very little is known about the functions of the neurotransmitters that act on the fetal cerebral circulation.

within the ventricular zone that become the internal cerebral veins. Early in development the invagination of pia mater to form the choroid plexuses gives rise to the tela choroideae which are drained by a transitory vessel, the median prosencephalic vein (of Markowski); this vessel gives rise to bilateral veins of the lateral choroid plexuses, bilateral internal cerebral veins and the great cerebral vein that drains into the straight sinus (Pearl et al 2011).

The development of the primary head veins, dural stems and dural sinuses is described in Chapter 17.

Developmental venous anomalies

Developmental venous anomalies include any changes to the previously described developmental pattern such that the usual balance of cortical and medullary venous drainage is not evident. Lack of cortical veins may lead to parts of the cortex draining only into the subependymal network via larger deep medullary veins, in a ventriculopetal rather than ventriculofugal matter. Conversely, a significant connection between the deep medullary veins and an intracortical vein may result in a ventriculofugal rather than ventriculopetal flow. Enlarged deep medullary veins, recognized as caput medusa, is seen in both variants. A vein of Galen aneurysmal malformation is seen in up to 30% of intracranial vascular anomalies; the early median prosencephalic vein does not regress, but remains connected to one or more choroidal arteries and enlarges as a result of the retained arteriovenous anastomosis (Pearl et al 2011, Cao and Cai 2019).

Interventricular haemorrhage

Anatomical variability of the course of the subependymal veins draining the proliferating ventricular zone (germinal matrix) is reported to be a predisposing factor for germinal matrix haemorrhage–interventricular haemorrhage (GMH–IVH), together with the level of developmental maturity of the ventricular zone capillary bed and its drainage. Each subependymal vein exhibits a U-shaped curve at the level of the interventricular foramen as it passes from the caudate–thalamic groove to its confluence with the internal cerebral vein. Increased vessel curvature (a more acute angle) is associated with blood flow alterations, increased luminal shear stress and possible venous thrombosis. Anomalous subependymal vein curvature in premature infants with GMH–IVH has been positively associated with unilateral haemorrhage occurring only in the hemisphere with a subependymal vein variant (Tortora et al 2018).

Periventricular leukomalacia

In fetuses and preterm infants of less than postmenstrual week 30 the blood vessels in the ventricular zone (germinal matrix) contain no smooth muscle, collagen or elastin fibres and have a disproportionately small number of reticulin fibres. In later preterm infants, the basal lamina surrounding the vessels is deficient in fibronectin, and thicker and more irregular than cortical vessels. In the periventricular regions at this time, the widening intermediate zone is filled with neuroblastic and glioblastic progeny from the ventricular and subventricular zones and the medial and lateral eminences migrating to the cortical subplate; axons extending from differentiating cortical neurones to the developing basal nuclei; axons extending from differentiating basal nuclei neurones to the cortex, all with their associated populations of pre-oligodendrocytes. This region represents a boundary zone between cortical and subcortical white matter supplied by superficial cortical arteries and veins, and the ventricular and subventricular zones supplied by the deeper striate arteries and deep medullary veins, and can be regarded as a watershed area between ventriculopetal and ventriculofugal circulations. Perturbation of cerebral blood flow in this watershed area can lead to a spectrum of developing white matter injury (see below).

THE NEONATAL BRAIN

Preterm neonate

Those babies born premature and with very low birth weight have been shown to have an altered cortical thickness that is still present in late teenage years (Bjuland et al 2013). It is not clear whether such changes are a consequence of preterm delivery, of perinatal brain injury or of fetal inflammatory response syndrome. Approximately 50% of preterm births are associated with clinical and subclinical chorioamnionitis (Maltepe and Penn 2018). Extremely and very preterm infants are usually stabilized by assisted ventilation, however, ventilation-induced lung injury in preterm infants also causes alveolar injury and release of cytokines that contribute to a systemic inflammatory response affecting the brain in those without prior infection (Barton et al 2015). Very preterm infants are also thought to be at risk of altered postnatal brain growth because of epigenetic regulation (DNA methylation) of the serotonin transported gene, as a consequence of early neonatal intensive care stress (Fumagalli et al 2018).

Preterm infants born before postmenstrual week 27 are at risk during early postnatal life of perturbation of the intermediate zone and the developing white matter (Ment and Sould 2012, Molnar and Rutherford 2013). Serial postnatal MRI scans of a group of infants delivered before postmenstrual week 27 (postnatal age counted sequentially in postmenstrual weeks), found increasing pathological changes with age, with about 20% showing white matter changes by 28 postmenstrual weeks, 50% showing changes during postmenstrual week 29 and about 80% exhibiting diffuse white matter signal anomalies by postmenstrual week 40 (Volpe 2017).

It was thought that in the preterm infant, where autoregulation of cerebral blood flow is limited, hypoperfusion of the intermediate zone was sufficient to cause local ischaemic lesions resulting in periventricular leukomalacia (PVL). PVL can also occur in full-term infants with congenital cyanotic heart anomalies. It is now thought that the disturbance of the differentiation of pre-oligodendrocytes (which are particularly affected by swings in cerebral ischaemia and reperfusion), accompanying astrocytosis and microgliosis, and prenatal systemic infection and inflammation cause hypomyelination (Volpe et al 2011, Back 2017). Histopathological studies now identify a spectrum of white matter injury from macroscopic lesions that are easily recognized on MRI, to microscopic focal necrotic lesions; the terms severe, moderate and mild white matter injury have been recommended to describe the condition (Volpe 2017). Studies on the long-term effects of preterm delivery note that even late preterm birth (postmenstrual weeks 34–37) has long-term effects. The late preterm brain may be unable to cope with postnatal conditions that may add to the problems of immaturity: for example, speech and language acquisition are delayed, as are school readiness and academic performance (Woythaler 2019).

Full-term neonate

Because the head is large at birth, measuring one-quarter of the total body length, the brain is also proportionally larger. The brain of a full-term (postmenstrual week 40) neonate ranges from 300 g to 400 g in weight, with an average of 350 g; the brains of neonatal males are slightly heavier than those of females. The brain occupies 97.5% of the cranial cavity from birth to 6 years of age, after which the space between the brain and skull increases in volume until the adult brain occupies only 92.5% of the cranial cavity. The cerebral ventricles are relatively larger in the neonatal brain than they are in the adult with a total of 10–15 ml of cerebrospinal fluid when delivered vaginally and 30 ml when delivered by caesarean section (as the head moves down the birth canal and is compressed, the cerebrospinal fluid is pushed out into the venous sinuses, whereas this does not happen in a caesarean delivery).

The sulci of the cerebral hemispheres appear after postmenstrual week 24. At full term, the general arrangement of sulci and gyri is present, but the insula is not completely covered, the central sulcus is situated further rostrally, and the lateral sulcus is more oblique than in the adult. The caveat here is that most of the developmental stages of sulci and gyri have been identified in the brains of premature infants where sulci are shallower at their equivalent postmenstrual week 40 than those of full-term neonates (Engelhardt et al 2016a, Shimony et al 2016). Of the cranial nerves, the olfactory nerve and the optic nerve at the chiasma are relatively much larger than they are in the adult, whereas the roots of the other cranial nerves are relatively smaller.

Reflexes present in the perinatal period

At birth mammals exhibit a range of coordinated motor movements that enhance their survival; these are species-specific. In humans, early reflex patterns, often somewhat erroneously termed 'primitive' reflexes, indicate the patterns of activity of multiple muscle groups present at birth (Feldman and Chaves-Gnecco 2018). Five tests of neurological development are most useful in determining developmental age. Lower

limb flexor tone is detectable from about postmenstrual week 29. The pupillary reflex is consistently absent before postmenstrual week 29 and present after postmenstrual week 31; the glabellar tap, a blink in response to a tap on the glabella, is absent before postmenstrual week 32 and present after postmenstrual week 34; the neck-righting reflex appears between postmenstrual weeks 34–37; the traction response, where flexion of the neck or arms occurs when the baby is pulled up by the wrists from the supine position, appears after postmenstrual weeks 33; head-turning in response to light appears between postmenstrual weeks 32 and 36. The Babinski response, which involves extension of the great toe with spreading of the remaining toes in response to stimulation of the lateral aspect of the sole of the foot, is frequently elicited in neonates and reflects the level of myelination of the pathways. Early reflexes disappear in a predictable sequence reflecting postnatal myelination; their persistence suggests abnormal myelination of higher inhibitory pathways, seen in neurological developmental disorders and perinatal hypoxic–ischaemic brain injury (Futagi et al 2012, Feldman and Chaves-Gnecco 2018).

By full-term the neonate at rest has a strong flexor tone accompanied by adduction of all limbs. Neonates also display a distinct preference for a head position facing to the right, which appears to be independent of handling practices. The usual reflexes that can be elicited in a full-term (postmenstrual week 40) neonate include Moro, asymmetric tonic neck response, rooting–sucking, grasp, placing (contacting the dorsum of the foot with the edge of a table produces a 'stepping over the edge' response), stepping, and trunk incurvation (elicited by stroking down the paravertebral area with the infant in the prone position) (Futagi et al 2012). Examination of the motor system and evaluation of these reflexes allow assessment of the nervous system in relation to developmental age. The neonate also exhibits complex reflexes, such as nasal reflexes and sucking and swallowing. Early reflexes are tested during the routine examination of the newborn (Walker 2018). Production of otoacoustic emissions from sensory cell activity in the inner ear in response to sound is now routinely tested in neonates as an assessment of normal hearing. An adult-like auditory reflex (medial olivocochlear reflex) is present postnatally from about postmenstrual week 36 (Abdala and Mishra 2013).

Nasal reflexes produce apnoea via the diving reflex, sneezing, sniffing, and both somatic and autonomic reflexes. Stimulation of the face or nasal cavity with water or local irritants produces apnoea in neonates. Breathing stops in expiration, with laryngeal closure, and neonates exhibit bradycardia and a lowering of cardiac output. Blood flow to the skin, splanchnic areas, muscles and kidneys decreases, whereas flow to the heart and brain is protected. Different fluids produce different effects when introduced into the pharynx of preterm infants. A comparison of the effects of water and saline in the pharynx showed that apnoea, airway obstruction and swallowing occur far more frequently with water than with saline, suggesting the presence of an upper airway chemoreflex. Reflux of gastric content into the oesophagus is a well-recognized cause of apnoea and constitutes an acute life-threatening event in infants. Reflex responses to the temperature of the face and nasopharynx are necessary to start pulmonary ventilation: in the past, midwives often blew on the faces of neonates to induce the first breath.

Sucking and swallowing are a particularly complex set of reflexes, partly conscious and partly unconscious. As a combined reflex, sucking and swallowing require the coordination of several of the 12 pairs of cranial nerves. A neonate can, within the first couple of feeds, suck at the rate of once per second, swallow after five or six sucks, and breathe during every second or third suck. Air moves in and out of the lungs via the nasopharynx, and milk crosses the pharynx *en route* to the oesophagus without apparent interruption of breathing and swallowing, or significant misdirection of air into the stomach or fluids into the trachea. Swallowing movements are first noted at about postmenstrual week 11; *in utero* fetuses swallow 450 ml of amniotic fluid per day. Sucking and swallowing in premature infants (1700 g) is not associated with primary peristaltic waves in the intestine; however, in older babies and full-term neonates, at least 90% of swallows will initiate primary peristaltic waves.

The taste of the fluid, as well as nutrient content, affects the efficiency of nutritive sucking in the early neonatal period. There is more sucking with milk than with 5% dextrose: sucking activities increase with solutions that are determined to be sweet by adult appraisal. In full-term neonates, the placing of a spoon or food on to the anterior part of the tongue elicits an extrusion reflex: the lips are pursed and the tongue pushes vigorously against the object. By postnatal months 4–6, the reflex changes and food deposited on the anterior part of the tongue is moved to the back of the tongue, into the pharynx, and swallowed (see Ch. 40 for a description of swallowing in the adult). Rhythmic biting movements occur by postnatal months 7–9, even in the absence of teeth.

Postnatal brain maturation

Postnatal brain growth velocity is illustrated by the change in brain volume from 25% of adult volume at full-term delivery to 75% of adult volume by the end of the first postnatal year. This growth can be accounted for partly by increase in the size of neuronal cell bodies, the profusion and dimensions of their dendritic trees, axons and collaterals, and by the growth of the neuroglial cells and cerebral blood vessels, but mostly it reflects the myelination of many of the axons. During the second and subsequent years, growth proceeds much more slowly. The brain reaches 90% of its adult size by year 5, 95% by year 10, and adult size between years 17–18, largely as a result of the continuing myelination of various groups of nerve fibres.

Maturational progression of neonatal and postnatal brains can be evaluated using diffusion tensor magnetic resonance imaging (DTMRI). A number of studies have assessed the growth status of white matter tracts from prenatal ages to early childhood (Huang et al 2006, Huang et al 2009, Lodygensky et al 2010, Dubois et al 2014, Huang and Vasung 2014, Dubois et al 2016) (see Fig. 14.35). Evidence from diffusion tensor imaging (DTI) suggests that myelination is a dominant process during the first year of life, starting centrally and spreading peripherally, and spreading rostrally from the occipital to the frontal lobe (Dubois et al 2016). Myelination of the corticospinal tracts starts in full-term neonates at about postnatal days 10–14 in the internal capsule and cerebral peduncles, and then proceeds simultaneously in both regions. Myelin appears to start first around longer axons, which presumably explains why, in the preterm infant, axial extension precedes flexion, whereas finger flexion precedes extension.

Comparison of postnatal rates of myelination in human and primate brains shows that humans achieve approximately 60% of adult myelination during adolescence (compared to 96% in chimpanzees at comparable stages of growth). Myelin growth continues in humans to the end of the third decade. Miller et al (2012) suggest this schedule of neural connectivity in humans might contribute to the development of functional circuitry with greater plasticity and capacity to be shaped by postnatal environmental and social interactions. The greatest delay in myelination is seen in the prefrontal cortex, an area where many neural circuits concerned with learning and memory develop only after sexual maturity has been attained.

Autism spectrum disorders are at present viewed as a range of neurodevelopmental conditions with increasing prevalence. In China the prevalence increased from 10.3/10,000 in 2009 to 26.6/10,000 in 2013, and in the United States, it affected 1 in 152 children in 2002 and 1 in 68 in 2012 (Wang et al 2017). Prevalence in the UK showed a five-fold increase in incidence rates during the 1990s, with rates in 8-year-old children then reaching a plateau (Taylor et al 2013). The condition is thought to arise from increased proliferation of neuroprogenitor cells in the subventricular zone that leads to hyperexpansion of cortical surface areas. Early deficits in visual receptive and attention abilities are reported. At 2–4 postnatal years infants and children have increased grey matter volume, although this diminishes in adolescence and adulthood (Piven et al 2017, Wang et al 2017).

Sucking develops, generally, slightly later than swallowing, although mouthing movements have been detected in premature babies as early as postmenstrual weeks 18–24, and infants delivered at postmenstrual weeks 29–30 make sucking movements a few days after birth. Coordinated activities are not noted before postmenstrual weeks 33–34. The concept of non-nutritive and nutritive sucking has been introduced to account for the different rates of sucking seen in a neonate. Non-nutritive sucking, when rhythmic negative intraoral pressures are initiated that do not result in the delivery of milk, can be spontaneous or stimulated by an object in the mouth. This type of sucking tends to be twice as fast as nutritive sucking; the sucking frequency for non-nutritive sucking is 1.7 sucks/second in preterm infants of postmenstrual weeks 37–38, 2 sucks/second in term (postmenstrual week 40) neonates, and 2.7 sucks/second at postnatal months 7–9. Corresponding times for nutritive sucking are about 1 suck/second in term neonates, increasing to 1.5 sucks/second by postnatal month 7.

Difficulties in sucking and swallowing in infancy may be an early indication of disturbed nervous system function. There is a correlation between feeding styles of neonates and later eating habits. Children who were obese at 1 and 2 years of age, as measured by triceps skin-fold thickness, had a feeding pattern in the first month of life that was characterized by sucking more rapidly, producing higher pressures during prolonged bursts of sucking, and having shorter periods between bursts of sucking. Fewer feeds and higher sucking pressure seem to be associated with greater adiposity (Agras et al 1987). It has been noted that the levels of appetite-regulation hormones in fully breastfed infant serum are higher than in formula-fed infants at 4 postnatal months (Vásquez-Garibay et al 2019). Infants who are unable to feed orally in the first few weeks of life as a result of a congenital anomaly such as oesophageal atresia may develop food aversion.

Prior to preterm or full-term birth, the mother and fetus share circadian and other synchronized homeostatic physiological rhythms. After delivery, via processes similar to those seen in the postnatal synchronization of the optic pathways to ensure the development of the lateral geniculate nuclei and optic cortex, and of the auditory pathways to ensure postnatal maturation of hearing, the establishment of close mutual interactions between carer and neonate forms the basis for continuing infant cortical maturation and epigenetic upregulation of postnatal developmental genes. The continuing close reciprocal bond between carer and infant, with synchronization of a range of physiological rhythms, is described as the mother–infant dyad (Provenzi et al 2018).

Establishment of the mother–infant dyad initially promotes infant motor activity, skin tactile input and via establishment of oral feeding routines, autonomic sensory experiences. Synchrony of interactions, mutual eye contact, and mutual responsiveness of the mother–infant dyad appears to be set by postnatal month 4 (Navarez 2014). Later, the mother and family members encourage mirroring of behaviour (smiling and talking to the infant) and the infant becomes aware of its own sensory somatic states induced by the result of its motor actions. In this way the culturally driven rules for play and emotional display are transmitted to the infant. From psychological and sociological perspectives (i.e. through concepts of constructivist interactionism), the multiple ongoing interactions with the infant by family members (playing with the infant), and the resultant homeostatic interactions ongoing within the infant (feelings generated by their own movement), promote the development of cognitive pathways (Cantor et al 2018). The development of these 'salience' networks and pathways (anterior insula to anterior cingulate) in the neonate are important for normal postnatal adaptive behaviour responses (Molnar et al 2019). Failure of these postnatal processes is recognized in stress responses and withdrawn behaviours in infants; infants do not cry if they learn no one will come, inhibiting their emotional expression even when their cortisol levels are high. In later life such individuals may have difficulties regulating intense feelings. Mothers who get less support during these times are reported to demonstrate more restraint, avoidant and anxious attachment to their offspring, which subsequently affects the infant. Establishment of the mother–preterm infant dyad is difficult, with immature salience network development involved in neuropsychiatric disorders seen in adults born preterm (Molnar et al 2019). The preterm infant is less alert, hypersensitive to stimulation, inefficient at oral feeding, with lower capacity for self-regulation. Mothers of preterm infants have heightened stress and anxiety and may respond by either overstimulation or subsequent decreased stimulation; maternal anxiety is associated with preterm infants being less facially responsive and this can lead to difficulty over time with responsive maternal facial interactions (White-Traut et al 2013). For details of the mother–infant dyad and the neurobiology of postnatal development see Navarez (2014).

CHAPTER
15

Development of the eye

The development of the eye involves a series of inductive interactions between neighbouring tissues in the embryonic head. These are the neurectoderm of the forebrain (which forms the sensory retina and accessory pigmented structures), the surface ectoderm (which forms the lens and the corneal epithelium) and the intervening neural crest mesenchyme (which contributes to the fibrous coats of the eye and to tissues of the anterior segment of the eye). A broad anterior domain of neurectoderm, characterized by the activation of several homeobox-containing transcriptional regulator genes, including *PAX6*, *RAX*, *SIX3* and *OTX2*, and the repression of caudalizing Wnt signalling, develops the potential to form optic vesicles. Subsequent interactions between mesenchyme and neurectoderm, involving midline expression of the gene (*SHH*) encoding the secreted protein sonic hedgehog, subdivides this eyefield region into bilateral domains at the future sites of the eyes (Chow and Lang 2001). Loss of *SHH* function causes holoprosencephaly and a range of anomalies that can include cyclopia, due to incomplete separation of the prosencephalon (Dubourg et al 2004).

In three-dimensional culture of murine embryonic stem cells supplemented with the correct growth factors and Matrigel® (to promote basement membrane formation), but in the absence of surface ectoderm or lens epithelium, a neuroepithelial vesicle develops and undergoes dynamic shape change to form a two-layered optic cup (Eiraku and Sasai 2012). The tissue so formed demonstrated interkinetic nuclear migration and a stratified architecture similar to that of postnatal retina, including appropriate synapses. Similar results, i.e. production of retinal architecture and retinal pigment epithelial cells, have been reported using human embryonic stem cells (Nakano et al 2012, Zhu et al 2013).

The parallel process of lens determination appears to depend on a brief period of inductive influence that spreads through the surface ectoderm from the rostral neural plate and elicits a lens-forming area of the head. Reciprocal interactions that are necessary for the complete development of both tissues take place as the optic vesicle forms and contacts the potential lens ectoderm (Saha et al 1992, Fuhrmann 2010, Nakano et al 2012). The vascular tissue of the developing eye forms by local angiogenesis or vasculogenesis of angiogenic mesenchyme (Hughes et al 2000). Development of the choroidal vasculature is followed by the (temporary) fetal hyaloid vasculature and then the retinal vasculature. (For further reading see O'Rahilly (1966, 1983).)

EMBRYONIC COMPONENTS OF THE EYE

The first morphological sign of eye development is a thickening of the diencephalic neural folds in stage 10 (28–29 days postfertilization, see Fig. 23.2), when the embryo has seven to eight somites. This optic primordium (eye field) extends on both sides of the neural plate and crosses the midline at the primordium chiasmatis. A slight transverse indentation, the optic sulcus, appears in the inner surface of the optic primordium on each side of the brain. During rostral neuropore closure in stage 11 the walls of the neuromere diencephalon 1 (see Fig. 14.2) begin to evaginate at the optic sulcus, projecting laterally towards the surface ectoderm and by stage 13 (postfertilization days 31–33), the optic vesicles are formed. Failure of the specification and development of the optic vesicle is associated with mutation of several transcriptional regulatory genes expressed in the eye field and leads to anophthalmia (absence of the eye) (Graw 2003). Each optic vesicle is surrounded by a sheath of mesenchymal cells derived from the head mesenchyme and neural crest; its lumen is continuous with that of diencephalon 1. Regional differentiation is apparent in each of the source tissues of the eye. The optic vesicle is visibly differentiated into its three primary parts. At the junction with the diencephalon, a thick-walled region marks the future optic stalk; laterally, the tissue that will become the sensory (neural) retina forms a flat disc of thickened epithelium in close contact with the surface ectoderm; and the thin-walled part that lies between these regions will later form the pigmented layer of the retina (retinal pigmented epithelium). The area of surface ectoderm that is closely apposed to the distal optic vesicle thickens to form the lens placode, and the mesenchymal sheath of the vesicle begins to show signs of angiogenesis. During stage 14 (postfertilization days 33–34), the lens placode and optic vesicle undergo coordinated morphogenesis. Filopodia tether the presumptive optic and lens vesicles to coordinate epithelial invagination. The lens placode invaginates, forming a pit that pinches off from the surface ectoderm to form the lens vesicle (**Fig. 15.1**). The surface ectoderm reforms a continuous layer that will become the corneal epithelium. The lateral part of the optic vesicle invaginates to form a cup, which is incompletely formed and open at the ventral surface (optic fissure); the inner layer (facing the lens vesicle) will become the sensory (neural) retina, and the outer layer, influenced by signals from the surrounding extraocular mesenchyme, becomes the retinal pigmented epithelium. As a result of these folding movements, what had been the apical (luminal) surfaces of the presumptive neural retina and retinal pigmented epithelium of the optic vesicle now face one another across a much-reduced lumen, the intraretinal space. The pigmented layer becomes attached to the mesenchymal sheath, but the junction between the pigmented and sensory layers is less firm and is the site of pathological detachment of the retina. The two layers are continuous at the lip of the cup (**Fig. 15.2**). The narrow part of the optic vesicle between the base of the cup and the brain forms the optic stalk. The distal part of the optic stalk also invaginates, forming a wide groove, the choroid (optic) fissure, through which mesenchyme migrates and differentiates to form the ingressing hyaloid artery. These infoldings involve differential growth, changes in cell shape, cell movement and high levels of proliferation in the inner neuroepithelial layer. The hyaloid artery forms part of the vasculature of the eye. It transiently supplies the developing lens and the inner part of the retina until a retinal vasculature forms and eventually regresses by apoptosis (Lutty and McLeod 2018).

As growth proceeds, the fissure closes and the artery is included in the distal part of the stalk. The fusion process is characterized by apoptosis at the margins of the fissure. Failure of the optic fissure to close is a rare anomaly that may be accompanied by a corresponding deficiency in the choroid, retina and iris (congenital coloboma) and is often associated with microphthalmia (small eyes). Reduced growth of the optic cup caused by mutation of the homeobox gene *VSX2*, important for specification and growth of the neural retina, is one known cause of microphthalmia (Graw 2003). Anophthalmia, microphthalmia and coloboma are also associated with mutation of the *SOX2* gene.

DIFFERENTIATION OF THE FUNCTIONAL COMPONENTS OF THE EYE

The developments just described bring the embryonic components of the eye into the spatial relationships necessary for the passage of light into the globe and onto the retina. The next phase of development involves further patterning and phenotypic differentiation in order to develop the specialized structures of the adult organ needed for focusing and sensing of light.

The optic cup becomes patterned, from the base to the rim, into regions with distinct functions. Several secreted factors, including bone morphogenetic proteins (BMP), retinoic acid and SHH, and transcriptional regulator genes, including *PAX6* and *PAX2*, are important for specifying each region (Chow and Lang 2001, Sinn and Wittbrodt 2013). The outer layer of the optic cup remains as a thin layer of cells, which begin to acquire pigmented melanosomes and form the pigmented epithelium of the retina at stage 17. In a parallel process that begins before invagination, the cells of the inner layer of the cup proliferate to form a thick pseudostratified neuroepithelium, the future neural retina, over the base and sides of the cup. The peripheral region around the lip of the cup extends, and is further differentiated into the components of the prospective iris at the rim, and the ciliary body a little further back, adjacent to the neural retina (see Fig. 15.2). The development of this pattern is reflected in regional differences in the expression of various genes that encode transcriptional regulators and that are therefore likely to play key roles in controlling and coordinating development. Distinct sets of genes are expressed prior to and during overt cell-type differentiation. For example, *PAX6* is expressed in the prospective ciliary and iris regions of the optic cup; individuals heterozygous for mutations in *PAX6* lack an

iris (aniridia), suggesting a causal role for this gene in the development of the iris. The genes expressed in the eye are also often active at a variety of other specific sites in the embryo. This may, in part, account for the co-involvement of the eye and other organs in syndromes that result from single genetic lesions, e.g. *PAX2* mutation causes coloboma and kidney defects (Graw 2003).

Developing neural retina

The developing neural retina consists of an outer nuclear zone, which contains dividing neuroepithelial retinal progenitor cells, and an inner marginal zone, which is initially devoid of nuclei. At about stage 16 the cells of the nuclear zone invade the marginal zone, and by stage 18 the nervous stratum of the retina consists of inner and outer neuroblastic layers. Cell lineage analyses have shown that seven retinal cell types are all derived from a common multipotential retinal progenitor cell that undergoes mitosis at the apical (ventricular) surface. Different types of retinal cells are born (i.e. cease dividing) in a conserved sequence during development: ganglion cells, amacrine cells, cone photoreceptors and horizontal cells develop early, whereas bipolar cells, rod photoreceptors and Müller glial cells develop later (Cepko et al 1996). Newly born cells migrate from the apical (ventricular) surface to the appropriate cell layer in the developing retina, establishing its characteristic laminar structure. The developing ganglion cell layer first separates from the neuroblastic layers by formation of the inner plexiform layer. The inner nuclear layer, containing developing amacrine, horizontal, bipolar and Müller glial cells, is then separated from the outer nuclear layer, containing the developing rod and cone photoreceptors, by the formation of the outer plexiform layer. Mature retinal neurones first appear in the central part of the retina. By postmenstrual weeks 29–32 all the named layers of the retina can be identified. The photoreceptor cells continue to differentiate after birth, generating an array of increasing resolution and sensitivity; the macula does not reach maturity until 15–45 months after birth (Hendrickson and Yuodelis 1984).

The divergent differentiation of the pigmented and sensory layers of the retina from the initially bipotential neuroepithelium of the optic vesicle involves activation of region-specific regulatory genes, e.g. *VSX2* in the presumptive neural retina and *MITF* in the presumptive pigmented epithelium (Bharti et al 2006). Patterning by gene expression is an important aspect of establishing regional identity of the optic cup and the subsequent maturation of these respective tissues. Soluble factors from the retina elicit the polarized distribution of plasma membrane proteins and the formation of tight junctions in the pigmented epithelium. Neural retinal differentiation is mediated by several growth factors, including fibroblast growth factors, SHH and retinoic acid. Basic helix–loop–helix proneural transcriptional regulatory genes also play a central role in regulating retinal cell fate. However, the pigmented epithelium initially retains the potential to become neural retina and will do so if the embryonic retina is wounded, demonstrating the plasticity of the early commitment to pigment epithelium or neural retinal fate.

The retinal vasculature forms by the aggregation of spindle-shaped cells (vascular mesenchymal cells) that emanate from the optic disc by postmenstrual week 15 and form vascular cords, consistent with vessel formation by vasculogenesis, which give rise to the inner plexus of the retina. Vessel formation in the temporal and peripheral retina occurs by angiogenesis. New vessel segments sprout by endothelial cell migration from pre-existing vessels and grow tangentially by angiogenesis into the neuroepithelium (Hughes et al 2000). Three parallel interconnected vascular networks located in the nerve fibre and plexiform layers develop with arteries and veins entering and exiting through the optic nerve. The foveal area never develops a retinal vasculature (Provis and Hendrickson 2008).

Optic nerve

The optic nerve develops from the optic stalk. The centre of the optic cup, where the optic fissure is deepest, will later form the optic disc, at the transition zone where the neural retina is continuous with the corresponding invaginated cell layer of the optic stalk; the developing

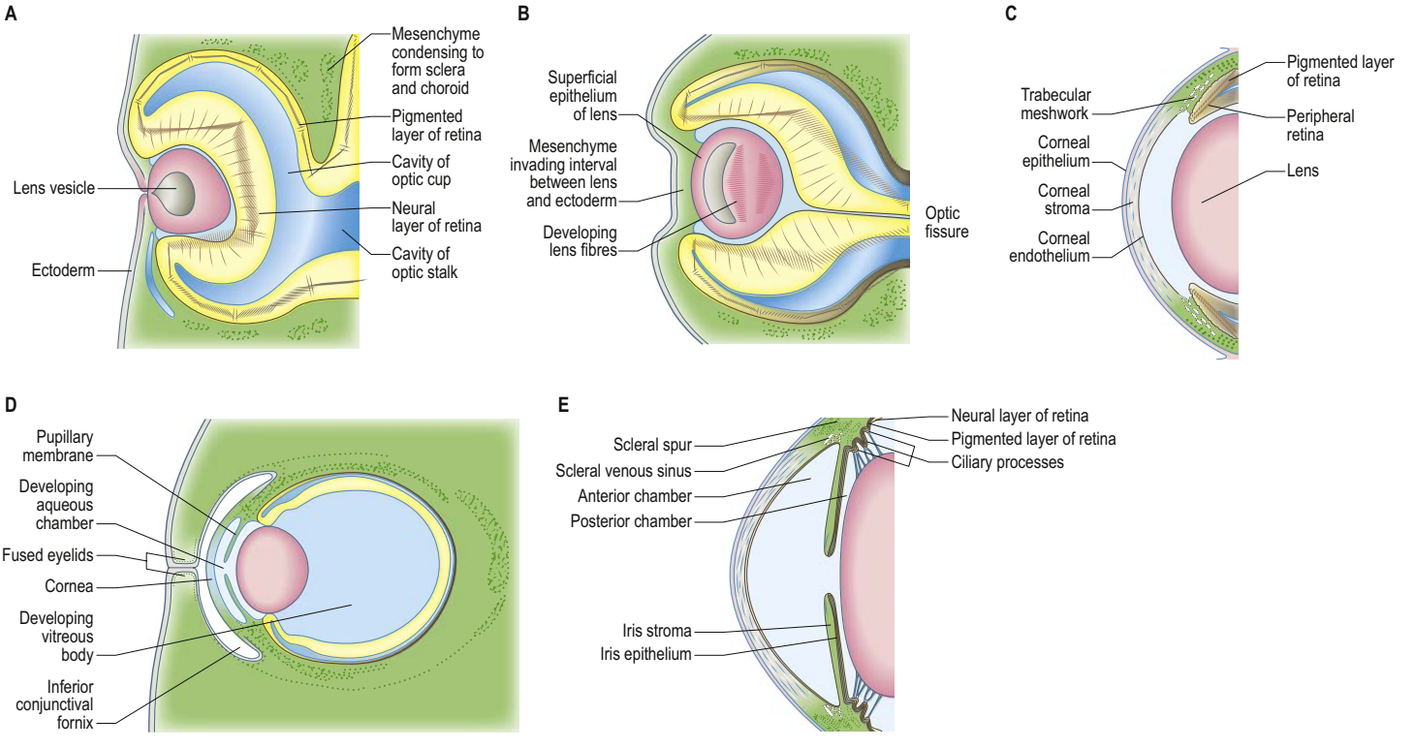

Fig. 15.2 Sections through the developing eyes of human embryos. **A**, The thick nervous and the thinner pigmented layers of the developing retina and the lens at about stage 16. The two layers of the embryonic optic cup are separated by the cavity of the optic cup. **B**, Section through the optic cup and optic fissure by stage 17. Mesenchyme has moved between the lens and surface ectoderm and the cavity of the optic cup is reduced. **C**, Later, more detailed view of the structures anterior to the lens. Anterior growth of both the peripheral retina and the pigmented layer of the retina, together with local mesenchymal proliferation, will give rise to the ciliary body and iris. The surface ectoderm anterior to the lens forms the corneal epithelium, whereas the corneal endothelium and stroma differentiate from invading neural crest mesenchyme. **D**, The development of the eye and surrounding structures by postmenstrual week 11. The eyelids have developed and are fused; the extent of the conjunctival fornices can be seen. The aqueous chamber is developing and the vitreous body is present. The eye is surrounded by neural crest mesenchyme. **E**, Details of the developing uveal tract. The anterior and posterior aqueous chambers are separated by the iris and the lens is attached to the ciliary body.

axons of the ganglion cells, therefore, pass directly into the wall of the stalk and convert it into the optic nerve. Retinal ganglion cell axons projecting into the stalk promote the optic stalk neuroepithelium to differentiate into astrocytes. Myelination of the axons within the optic nerve begins shortly before birth but the process is not completed until some time later. The optic chiasma is formed by the meeting and partial decussation of the axons within the two optic nerves in the ventral part of the lamina terminalis (at the junction of the telencephalon with the diencephalon in the floor of the third ventricle). Beyond the chiasma, the axons continue as the optic tracts, and pass principally to the lateral geniculate bodies and to the superior tectum of the midbrain. Multiple axonal guidance molecules that influence both intraretinal and chiasmal axon guidance have been identified (Erskine and Herrera 2014). Graded expression molecules (members of the Eph family of receptor tyrosine kinase receptors and ephrin ligands) provide spatial identity to cells in the retina and target cells in the midbrain, and are important for the topographic mapping of retinal ganglion cell axons to form a projection map that is representative of visual input.

Ciliary body

The ciliary body is a compound structure. Its epithelial components are derived from the region of the inner layer of the retina, between the iris and the neural retina, and the adjacent outer layer of pigmented epithelium. The cells here differentiate in close association with the surrounding mesenchyme to form highly vascularized folds that secrete aqueous fluid into the anterior segment of the eye.

The inner surface of the ciliary body forms the site of attachment of the lens. The outer layer is associated with smooth muscle derived from mesenchymal cells in the choroid that lie between the anterior scleral condensation and the pigmented ciliary epithelium.

Iris

The iris develops from the tip of the optic cup, where the two neuroepithelial layers remain thin and are associated with pial blood vessels. The muscles of the sphincter and dilator pupillae are unusual in that they are of neurectodermal origin, developing as a result of the further growth and differentiation of the two layers of the optic cup. Mesenchymal cells, largely composed of neural crest cells that have migrated anterior to the lens, form the collagen-rich iris stroma; they overlay the pigmented epithelium of the iris, which is continuous with the ciliary body and retina and is of neurectodermal origin. The mature colour of the iris develops after birth and is dependent on the relative contributions of the pigmented epithelium on the posterior surface of the iris and the neural crest-derived melanocytes in the mesenchymal stroma of the iris. If only epithelial pigment is present, the eye appears blue, whereas if there is an additional contribution from the melanocytes, the eye appears brown. Aniridia, the absence of the iris, is commonly caused by heterozygous mutations of *PAX6*.

Lens

The lens develops from the lens vesicle (see Figs 15.1F, 15.2A). Initially, this is a hollow ball of actively proliferating epithelium, but by stage 16 there is a discernible difference between the thin anterior (i.e. outward-facing) epithelium and the thickened posterior epithelium. Cells of the posterior wall lengthen and fill the vesicle (see Fig. 15.2B,C), reducing the original cavity to a slit by about stage 18. The posterior cells lose their mitochondria and nuclei and become filled with a very high concentration of proteins (crystallins), that render them transparent; they also become densely packed within the lens as primary lens fibres. Cells at the equatorial region of the lens subsequently elongate and contribute secondary lens fibres to the body of the lens in a process that continues into adult life, sustained by continued proliferation of cells in the anterior epithelium.

The polarity and growth of the lens appear to depend on the differential distribution of soluble factors that promote either cell division or lens fibre differentiation, and are present in the anterior chamber and vitreous humour, respectively. Congenital cataracts can be associated with mutations in genes that encode structural lens proteins, particularly crystallin proteins, as well as genes that encode transcriptional regulatory factors expressed specifically in the lens, such as *MAF* and *PITX3*, which are needed for normal lens development and which also

influence normal growth of the globe of the eye (Graw 2003, 2010). Complete absence of the lens (aphakia) can be caused by mutation of the transcriptional regulatory factor gene *FOXE3*.

The developing lens is surrounded by a vascular mesenchymal condensation, the vascular capsule. The posterior part of the capsule is supplied by branches from the hyaloid artery, and the anterior part, the pupillary membrane, is supplied by branches from the anterior ciliary arteries. During postmenstrual weeks 13–16 the hyaloid artery gives off retinal branches. By postmenstrual weeks 21–24 all of the vessels have atrophied, except the hyaloid artery; this becomes occluded during postmenstrual weeks 29–32, although its proximal part persists in the adult as the central artery of the retina. Atrophy of the hyaloid vasculature and of the pupillary membrane appears to be an active process of programmed tissue remodelling that is macrophage-dependent; visual impairment occurs in persistent hyperplastic primary vitreous, a condition in which normal regression of the hyaloid vasculature fails to occur. The hyaloid canal carries the vessels through the vitreous and persists after they have become occluded. In the full-term neonate, the canal extends more or less horizontally from the optic disc to the posterior aspect of the lens, but when the adult eye is examined with a slit-lamp, it can be seen to follow an undulating course, sagging downwards as it passes forwards to the lens. With the loss of its blood vessels, the vascular capsule disappears and the lens becomes dependent for its nutrition on diffusion via the aqueous and vitreous humours. The lens remains enclosed in the lens capsule, a thickened basal lamina derived from the lens epithelium. Sometimes, the pupillary membrane persists at birth, giving rise to congenital atresia of the pupil.

Vitreous humour (vitreous body)

The vitreous humour develops between the lens and the optic cup as a transparent, avascular gel of extracellular substance stabilized by collagen fibrils. The vitreous proteins are derived from surrounding tissues including the developing ciliary body. Initially the lens rudiment and the optic vesicle are in contact, but they draw apart after closure of the lens vesicle and formation of the optic cup, and remain connected by a network of delicate cytoplasmic processes. This network, derived partly from cells of the lens and partly from those of the retina, is the primitive vitreous body. At first, these cytoplasmic processes are connected to the whole of the neuroretinal area of the cup but, later, they become limited to the ciliary region, where, by a process of condensation, they form the basis of the zonular fibres (suspensory ligaments) of the ciliary zonule. The vascular mesenchyme enters the cup through the choroidal fissure and around the equator of the lens and associates locally with this reticular tissue and thus contributes to the formation of the vitreous body.

Anterior segment

Neural crest mesenchymal cells migrate ventrally around the optic cup and between the surface ectoderm and the lens to contribute to the development of anterior segment structures, including the ciliary body, the iris, the cornea and the iridocorneal angle tissues (see Fig. 15.2C–E) (Gould et al 2004). The anterior chamber initially appears as a cleft in this mesenchymal tissue. The mesenchyme superficial to the cleft forms the stroma (substantia propria) and endothelium of the cornea, and that deep to the cleft forms the stroma of the iris and the pupillary membrane. Tangentially, this early cleft extends as far as the iridocorneal angle, where communications are established with the scleral venous sinus (canal of Schlemm). Mesenchymal cells of neural crest origin lying at the angle of the anterior chamber differentiate to form a specialized meshwork of trabecular beams (collagen fibrils covered by cells). The open spaces of the meshwork become open to the anterior chamber as the beams develop. The scleral venous sinus develops deep to the trabecular meshwork. Initially a vascular structure lined by endothelial cells, the canal acts as an aqueous sinus during postmenstrual weeks 17–20 (McMenamin 1989). The forward-growing optic cup rim differentiates into the ciliary epithelium and the iris; the posterior chamber is formed between the iris, the lens capsule, the zonular fibres and the ciliary processes. The latter produce the aqueous humour that flows through the pupil and is drained in the iridocorneal angle, mainly by the trabecular meshwork and the scleral venous sinus. In this way, the walls of the anterior and posterior segment chambers furnish both the sites of production, and the channels for circulation and reabsorption, of the aqueous humour. The *FOXC1* and *PITX2* transcriptional regulatory genes are expressed in the neural crest cells migrating into the presumptive anterior segment, and regulate differentiation of the anterior segment tissues. Anterior segment dysgenesis, involving malformation of the iris, cornea and angle, occurs when these genes are mutated (e.g. Axenfeld–Rieger syndrome) and is often associated with raised intraocular pressure and glaucoma (Gould et al 2004).

Cornea

The cornea is induced in the front of the anterior chamber by the lens and optic cup. The (external) corneal epithelium is formed from surface ectoderm. The primordial corneal endothelium lining the front of the anterior chamber (inner corneal epithelium) is formed from neural crest mesenchymal cells that migrate along the inner surface of the developing cornea and differentiate to form specialized fibroblasts (keratocytes) that secrete the extracellular matrix of the corneal stroma (see Fig. 15.2C–E). A regular array of collagen fibres (lamellae) is established between inner and outer corneal epithelial layers and serves to reduce scattering of light entering the eye. The most anterior region of the stroma (Bowman's layer) develops as an acellular zone packed with collagen fibrils that confer strength on the layer. From postmenstrual weeks 9–12, the corneal endothelium is organized as a monolayer of cells and develops a strong, laminated basal lamina (Descemet's membrane) adjacent to the stroma. The endothelium maintains corneal transparency by regulating the water content of the stroma.

Choroid and sclera

The choroid and sclera differentiate as inner vascular and outer fibrous layers, respectively, from the neural crest mesenchyme that surrounds the optic cup. The choroid is continuous with the leptomeningeal internal sheath of the optic nerve, and the sclera is continuous with the outer dural sheath of the optic nerve. Choroidal vasculature can be seen by stage 18 around the retinal pigmented epithelium. It forms a complete vascular plexus by postmenstrual weeks 21–22, supplying the photoreceptor cells and the ciliary body (Lutty and McLeod 2018).

DIFFERENTIATION OF STRUCTURES AROUND THE EYE

Extraocular muscles

Development of the extrinsic ocular muscles is complex, involving coordinated juxtaposition of specific muscle precursors, cranial motor nerve outgrowth and neural crest mesenchyme. During gastrulation, when the earliest cells are migrating through the primitive node to form the prechordal plate and notochordal process, they transiently express myogenic markers. In stages 9–10 a population of prechordal mesenchyme cells migrate laterally from the lateral edge of the prechordal plate toward the unsegmented paraxial mesenchyme on each side of the notochord. After neurulation is complete, bilateral premandibular, intermediate and caudal cavities develop adjacent to the neural tube. The walls of these 'head cavities', previously termed 'preotic somites', are lined by flat or cylindrical cells that do not exhibit the characteristics of a germinal epithelium.

At the level of the premandibular head cavity, as the oculomotor nerve grows towards the developing eye, the prechordal mesenchyme becomes apparent as a condensation of premuscle cells at its ventrolateral side. This condensation later subdivides into the blastema of the superior, inferior, medial and lateral recti and inferior oblique. Similar events occur in the intermediate head cavity associated with the trochlear nerve and the premuscle cells that form superior oblique, and the caudal head cavity associated with the abducens nerve and premuscle cells that form lateral rectus (see Figs 12.4 and 17.7).

The early myogenic properties of the prechordal mesenchyme have been demonstrated experimentally. If transplanted into limb buds, these cells are able to develop into muscle tissue but their timing of expression of myosin heavy chain isoforms is different from that of limb myoblasts (Wachtler and Jacob 1986). Myotube formation starts later and progresses at a slower pace than in the limb, and coexpression of MyHCI/1st and MyHCI/2nd are both seen from the earliest stages of development, whereas only MyHCI/1st is seen in the limb. These early myoblasts retain their distinct differences from other skeletal muscles as they mature: they are smaller, loosely arranged and belong to very small motor units (Porter and Baker 1996, Pedrosa-Domellöf et al 2000). Extraocular muscle tendons derive from neural crest mesenchyme that connects to the sclera and the orbit. In cases of anophthalmia the relative location and structure of extraocular muscles can be identified (Pedrosa-Domellöf et al 2000, Bohnsack et al 2011). Abnormal development of the extraocular muscles or their motor neurones, in some cases due to single gene defects, causes

congenital fibrosis of the extraocular muscles and eye movement disorders (Whitman et al 2004).

Eyelids

The eyelids are formed as small cutaneous folds of surface ectoderm with a core of neural crest mesenchyme (see Fig. 15.2D). During postmenstrual weeks 10–11 their edges come together and unite over the cornea to enclose the conjunctival sac; they usually remain united until about postmenstrual week 24. When the eyelids open, the conjunctiva lining their inner surfaces and covering the scleral region of the eye fuses with the corneal epithelium. Transforming growth factor alpha (TGF-α) and several other growth factors regulate the mesenchyme–epithelium interactions and cell migration that are required for eyelid formation; keratinization is thought to play an important role in lid separation. The eyelashes and lid glands, i.e. sebaceous glands associated with the eyelashes and tarsal (Meibomian) glands, develop from ectoderm, as do the lacrimal and accessory lacrimal glands. Orbicularis oculi, which closes the eyelids, develops on each side from skeletal myoblasts from the second pharyngeal arch that invade the developing eyelids. The muscles that widen the palpebral fissure develop within the orbit from mesenchymal cells; the superior and inferior tarsal muscles are smooth muscle, whereas levator palpebrae superioris is striated muscle that is attached to each upper eyelid by a tendon derived from the neural crest (Plock et al 2005). (For a detailed timetable for upper eyelid development in staged human embryos and fetuses see Byun et al (2011).)

Lacrimal apparatus

The ectodermal epithelium of the superior conjunctival fornix proliferates and gives rise to a series of tubular buds that form the alveoli and ducts of the lacrimal gland. The buds are arranged in two groups: one forms the gland proper and the other forms its palpebral process (de la Cuadra-Blanco et al 2003). The lacrimal sac and nasolacrimal duct are derived from ectoderm in the nasomaxillary groove (between the lateral nasal process and the maxillary process of the developing face) (see Fig. 17.12). The ectoderm thickens to form a solid cord of cells, the nasolacrimal ridge, which subsequently sinks into the mesenchyme and becomes canalized during postmenstrual weeks 9–12 to form the nasolacrimal duct. The lacrimal canaliculi arise from the cranial extremity of the cord as buds that establish openings (puncta lacrimalia) on the margins of the lids. The inferior canaliculus isolates a small part of the lower eyelid to form the lacrimal caruncle and plica semilunaris.

Neonatal and infant eye

Low birthweight and preterm infants are at risk of developing retinopathy of prematurity, a proliferative retinopathy involving proliferation of the retinal vasculature into the vitreous (Kashani et al 2014, Hartnett et al 2014, Hartnett 2015). Fetuses and preterm infants younger than postmenstrual week 30 have no pupillary light reflex or pupillary constriction, with variable responses developing until postmenstrual weeks 32–34. Fetuses are not exposed to light. Preterm neonates born at less than postmenstrual week 32 have little ability to limit the light entering the eye because their eyelids are mostly open and are very thin when closed (Graven 2004). Preterm infants appear to have better visual acuity at term equivalent age than full-term neonates (Wirth et al 2018). Retinal development in the fetus is active between postmenstrual weeks 22 and 40, becoming associated with REM sleep from about postmenstrual weeks 28–30. Eye movement activity is seen in fetuses particularly during postmenstrual weeks 28–29 and then again from postmenstrual weeks 36–37 to 38–39 (Okawa et al 2017). Preterm neonates fail to gain the normal endogenous *in utero* visual stimulation during this time and begin exogenous visual stimulation in an immature system (Wirth et al 2018). They will be susceptible to strong competing stimuli such as intense noise, pain, movement and bright light; sedation that changes sleep patterns may also affect retinal maturation (Graven 2004).

At full term (postmenstrual week 40), the eye is 65% of its adult size. It grows rapidly for the first year, slightly slower until 3 years and then more slowly until puberty. There is proportionately less growth of anterior, compared to posterior, structures and the globe of the eye becomes more spherical. The neonatal lens is more spherical than that of the adult, which helps to compensate for the relative shortness of the eye. The visual acuity of neonates is estimated to be 20/400 and can reach 20/30–20/20 by 2–3 years of age; there is a general trend for infants to be far-sighted (Olitsky et al 2011). The convergence reflex usually appears after postnatal month 4 in full-term neonates; it is seen in preterm infants at about postnatal month 4 regardless of the actual date of delivery (Wirth et al 2018). Extraocular muscle coordination is usually achieved by postnatal months 3–6 and persistent deviation of an eye requires evaluation. Preterm infants have reduced reflex and tear secretion, and tears may not be present with crying until more than 3 months of age (Olitsky et al 2011).

Maturation of the visual pathways occurs in early infancy and slows in childhood, with adult levels of visual acuity attained by postnatal year 4. The visual pathways, lateral geniculate body and occipital visual cortex are patterned postnatally by exposure to visual stimuli. By postmenstrual weeks 38–40 neonates focus on the edges of objects, lines, shapes and movement, and focus their attention to the human face (preferably main caregiver). Each shape patterns columns of neurones within the visual cortex; direct light into the eyes does not create columns. Colour input becomes attached to patterned directional columns from postnatal months 2–3. The critical period for visual development occurs from the end of the second trimester to postnatal year 3 (Graven 2004).

Any condition that impedes the generation of aligned, high-resolution images on the retina may result in amblyopia due to loss of appropriate patterning of these brain regions from the deprived eye, followed by progressive expansion of axonal input from the functioning eye. The visual cortex of animals dark reared from birth remains immature, whereas specific use of the affected eye promotes reversal of cortical inhibition (Stryker and Löwel 2018). Amblyopia affects about 1–5% of people, caused by strabismus and anisometropia, where the two eyes have different focusing powers. Examination of the eyes is part of neonatal screening, performed within 72 hours of delivery and again at postnatal weeks 6–8; the assessment includes the red reflex, which is the reflection of the back of the retina seen in flash photography that may be changed in congenital cataract, retinoblastoma or neuroblastic tumour. It is difficult to assess visual acuity in infants and techniques rely on assessing preferential looking. Over 90% of children with amblyopia have significant refractive error that should be treated ahead of any strabismus. Treatment of amblyopia has been occlusion of vision in the unaffected eye with a patch to force reliance on the amblyopic eye and thus patterning of the lateral geniculate body and visual cortex. Studies on the effectiveness of this treatment have shown that children benefit most from 3–6 hours of occlusion per day for a period of 3 months. Although occlusion is the usual treatment modality, atropine eye drops, causing blurring of vision by pupillary dilation, or computer games that present images separately to each eye with reduced contrast to the unaffected eye, are considered promising. These treatments have been shown to improve vision but the residual deficit in children with moderate amblyopia is 2 lines of a visual acuity chart (Jefferis et al 2015).

Growth of the eyeball and achievement of the appropriate axial length to focus correctly onto the retina is associated with daylight entering the eyes over childhood. The prevalence of myopia has increased and is now affecting 80–90% of young adults in East Asia and 40–60% in Europe and North America. This change has been correlated with less time spent outdoors in daylight (Guo et al 2017).

CHAPTER 16

Development of the ear

INNER EAR

The production of a precisely positioned and functionally well-tuned inner ear depends on genetic patterning and a cascade of transcription signals expressed by numerous tissues, including the developing inner ear and its surrounding periotic mesenchyme, the adjacent hindbrain, neural crest and notochord (Ohyama et al 2010, Sienknecht 2013).

The first signs of inner ear development are visible shortly after those associated with the developing eyes. Two patches of ectodermal thickening, the otic placodes, appear lateral to the hindbrain at stage 9. Each placode invaginates as an otic pit, adjacent to rhombomeres 5 and 6 of the hindbrain and dorsal to the second pharyngeal cleft (Ch. 17; see Fig. 17.1B). During stage 12 (30–32 days postfertilization, see Fig. 23.3) the pit is pinched off from the surface ectoderm to form a simple, hollow epithelial sac, the otic vesicle (otocyst or auditory vesicle) (**Fig. 16.1**).

Regions of the vesicle differentiate into prosensory domains, which give rise to the membranous labyrinth and the vestibulocochlear (statoacoustic) ganglia of the eighth cranial nerve. The first morphological evidence of this differentiation is visible during stage 14 (postfertilization days 32–34), when the otic vesicle loses its initial piriform shape. A tubular diverticulum, the endolymphatic appendage, develops from its dorsomedial rim. The remainder of the vesicle, the utriculosaccular chamber, differentiates into an expanded pars superior and a narrower pars inferior. The endolymphatic appendage elongates and its tip expands into an endolymphatic sac that is connected to the pars superior by a narrow endolymphatic duct.

Two plate-like diverticula, one vertical and one horizontal, emerge from the dorsal part of the pars superior. The epithelia in the centre of each outgrowth coalesce to form a fusion plate; the central part of this plate is eventually resorbed, leaving the anlagen of the semicircular canals. The vertical plate gives rise to the anterior and posterior semicircular canals, which share a common crural attachment to the utriculosaccular chamber, and the horizontal plate gives rise to the lateral semicircular canal. A small expansion, the ampulla, forms at one end of each semicircular canal.

The central part of the utriculosaccular chamber, which now represents the membranous vestibule, becomes divided into a small ventral saccule and a larger dorsal utricle, mainly by horizontal infolding extending from the lateral wall of the chamber towards the opening of the endolymphatic duct. In this way, communication between the utricle and saccule is restricted to a narrow utriculosaccular duct. The latter becomes acutely bent on itself; its apex is continuous with the endolymphatic duct. While this is happening, the membranous labyrinth rotates so that its long axis, which was originally vertical, becomes more or less horizontal.

The ventral tip of the pars inferior begins to elongate. A medially directed evagination, the cochlear anlagen, is evident in the ventral part of the utriculosaccular chamber by stage 15. The proximal region of this cochlear duct continues to increase in length and its distal region becomes progressively more coiled, reaching 2.5 turns by postfertilization week 10 (**Fig. 16.2**)(Pechriggl et al 2015). When the duct has achieved its final length and spiral configuration, its proximal part becomes constricted, forming the ductus reuniens by which the saccule remains connected to the cochlea. The cochlea is initially patterned into several prosensory domains. The central domain will give rise to the organ of Corti. Molecular signals regulating the induction and differentiation of the organ of Corti are complex (Kelly and Chen 2009, Chacko et al 2016): a combination of bone morphogenetic protein (BMP), fibroblast growth factor and Notch signalling is required to define the sensory and non-sensory territories in the cochlear duct (Ohyama et al 2010, Whitfield 2015).

Cells derived from the otocyst differentiate into the bipolar neurones that populate the vestibular and cochlear ganglia; sustentacular cells (Wan et al 2013); the unique endolymph-producing epithelia of the stria vascularis; the absorbing epithelia of the endolymphatic sac; the general epithelial lining of the membranous labyrinth; and specialized cells in the six sensory patches of the inner ear (crista ampullaris of the three semicircular canals, maculae of the utricle and saccule, organ of Corti in the cochlea). Each of the sensory patches consists of mechanosensory hair cells and non-sensory supporting cells arranged into mosaic patterns that are essential for normal hearing and balance. The only cells in the mature inner ear that are not of otocyst origin are melanocytes in the stria vascularis, derived from the neural crest.

The very different morphologies of the mature cristae, maculae and organ of Corti reflect the differential expression of multiple genes during their development and maturation. The formation of the utricle and saccule occurs during a time that coincides with the initiation of hair cell planar polarity. The development of core planar cell polarity in the orientation of stereocilia in the mechanosensory hair cells of the mammalian inner ear is described in an extensive and conflicting literature (Deans 2013, Ezan and Montcouquiol 2013).

At the same time as these changes are taking place, mesenchymal cells surrounding the developing membranous labyrinth undergo chondrogenesis to form an encasing cartilaginous otic capsule. Between postmenstrual weeks 16–23 the otic capsule ossifies to form almost all of the bony labyrinth of the internal ear within the petrous temporal bone; the modiolus and osseous spiral lamina ossify directly from connective tissue. The cartilaginous capsule is initially incomplete and the cochlear, vestibular and facial ganglia are temporarily exposed in the gap between its canalicular and cochlear parts. They subsequently become covered by an outgrowth of cartilage that will enclose the facial nerve.

Vacuoles filled with perilymph develop in the embryonic connective tissue between the cartilaginous capsule and the epithelial wall of the membranous labyrinth. The rudiment of the periotic cistern or vestibular perilymphatic space can be seen in the reticulum between the saccule and fenestra vestibuli by stage 17. The cochlear scalae (scala vestibuli and scala tympani) develop by fusion of these spaces; the mechanism is uncertain (Kim et al 2011). The two scalae gradually extend along each side of the cochlear duct and a communication, the helicotrema, opens between them when they reach the tip of the coiled duct. An overview of human inner ear development is given in Lim and Brichta (2016).

The rudiment of the eighth cranial nerve appears in stage 13 as the vestibulocochlear (statoacoustic) ganglion that lies between the otocyst and the hindbrain and is initially temporarily fused with the ganglion of the facial nerve. Neuroblasts (fate already specified in the ectoderm of the otic placode) delaminate from the anteroventral region of the otic vesicle, proliferate and migrate to the site of the presumptive ganglion, where they coalesce. They differentiate into mature bipolar sensory neurones and become segregated into vestibular and spiral ganglia, each associated with the corresponding division of the eighth cranial nerve. These neurones are unusual because they are exclusively placodal in origin, unlike neurones in most cranial ganglia with a dual placodal and neural crest origin, and many of their somata become enveloped in thin myelin sheaths. Their peripheral processes collectively provide the afferent innervation of the labyrinthine hair cells, relaying balance and auditory information. Tantalizing evidence about the transcriptional networks that encode the positioning of sensory hair cells and spiral ganglion neurones along a frequency (tonotopic) gradient within the developing cochlea, and that ensure that the two cell types make appropriate functional connections, is appearing in animal models (Appler and Goodrich 2011, Appler et al 2013, Coate and Kelley 2013). The olivocochlear bundle, an outgrowth of axons from neurones in the superior olivary complexes in the pons, accompanies the axons of the developing eighth cranial nerve; these axons provide the inner ear with an efferent innervation, mainly to the outer hair cells in the organ of Corti, where they are associated with modulation of hearing. *In utero*, the fetus receives sound by bone conduction. interaural sound differences are not established until birth, whether preterm or term.

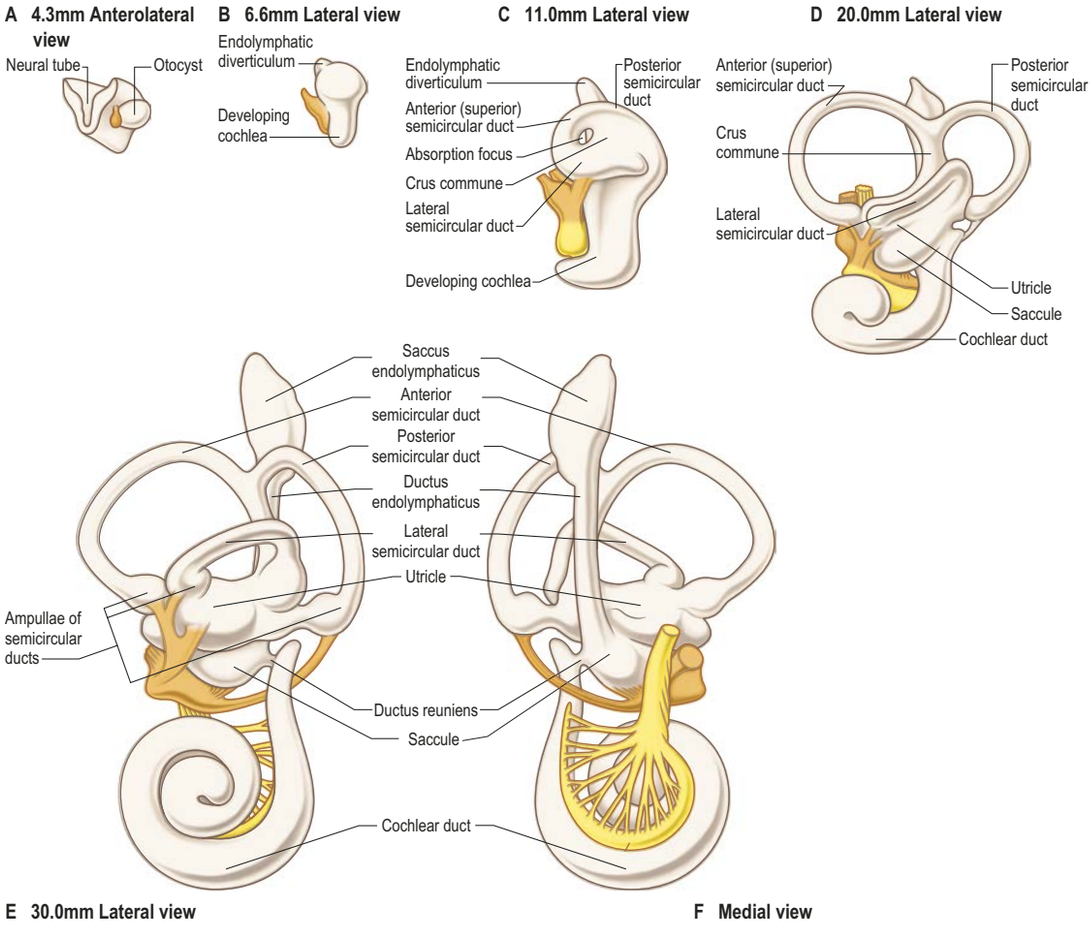

Fig. 16.1 A–F, The stages in the development of the membranous labyrinth from the otocyst, at the embryonic stages and aspects indicated. Note the relationship of the vestibular (orange) and cochlear (yellow) parts of the vestibulocochlear nerve.

MIDDLE EAR (TYMPANIC CAVITY AND PHARYNGOTYMPANIC (AUDITORY) TUBE)

All the components of the external and middle ears develop from the first and second pharyngeal arches. The pharyngotympanic tube and tympanic cavity initially form as bilateral extensions of the early pharynx (see Fig. 17.4). They become visible in stage 13 as hollow tubotympanic recesses of the first pharyngeal pouches. The more lateral part of each recess widens and develops into the early tympanic cavity. The tubotympanic recess at first lies inferolateral to the cartilaginous otic capsule (Ch. 17) but this spatial relationship alters as the capsule enlarges and the tympanic cavity becomes anterolateral. A cartilaginous process grows from the lateral part of the otic capsule to form the tegmen tympani (Rodríguez-Vázquez et al 2011). The process curves caudally to form the lateral wall of the pharyngotympanic tube, incorporating the tympanic cavity and the proximal bony third of the pharyngotympanic tube into the petrous region of the temporal bone. The mastoid antrum appears as a dorsal expansion of the tympanic cavity during the late second and early third trimester (it can be seen on ultrasound at postmenstrual week 34). The tympanic ring, a bone derived from first pharyngeal arch mesenchyme, is of particular importance in supporting the tympanic membrane (see below) (Takechi et al 2016).

The middle ear ossicles are of neural crest origin, derived from crest cells that have migrated from rhombomeres 1–4 into the mesenchyme of the first and second pharyngeal arches. The malleus and incus develop from the dorsal end of the first arch, derived from Meckel's (ventral mandibular) cartilage (Burford and Mason 2016). The incus and malleus are homologous to the quadrate and articular bones of birds and reptiles and take part in the earliest jaw articulation in suckling marsupials (Anthwal et al 2013, Maier and Ruf 2016). A transitory connection of the incus, but not the malleus, to the otic capsule has been reported (Rodríguez-Vázquez et al 2018). The stapes develops from the second arch, although possibly not from the proximal end of Reichert's cartilage (Rodríguez-Vázquez 2005). Its characteristic shape reflects the growth and elongation of the stapedial artery during stages 16–20, and the formation of a ring of cartilage (anulus stapes) around the vessel; the latter involutes by stage 21. The stapedial footplate forms within the otic capsule (paraxial mesenchyme) by stage 22; this part of the stapes has a dual origin from both paraxial and neural crest mesenchyme (Rodríguez-Vázquez 2005, Tucker 2017).

The two anlagen of each stapedius muscle appear close to the stapedial artery and facial nerve within the second arch mesenchyme in stage 18. The pyramidal eminence is formed within a condensation of mesenchyme around the bell of the stapedius muscle (Rodríguez-Vázquez 2009). Tensor tympani starts to appear near the extremity of the tubotympanic recess at almost the same time in the first arch mesenchyme.

Neural crest mesenchyme fills the early middle ear cavity and later retracts to create the true tympanic cavity. The hypotympanum (the portion of the tympanic cavity inferior to the level of the inferior margin of the external acoustic meatus) is lined by endodermal epithelium. Experimental studies on transgenic mice have shown that the epitympanic recess is lined by neural crest cells that have undergone mesenchymal to epithelial transition (Thompson and Tucker 2013, Takechi et al 2016). From stage 18 onwards the ossicles start to differentiate into cartilage, but remain embedded in the mesenchymal roof of the tympanic cavity until postmenstrual weeks 29–32, when the mesenchyme is resorbed. As this happens, the ossicles become suspended within the developing tympanic cavity, supported by forming ligaments and becoming covered by the mucosa of the middle ear as the tympanic cavity expands. The differentiation of the middle ear mucosa in the developing and postnatal mouse is described in Tucker et al (2018). The human tympanic cavity fills with air after birth and further postnatal developmental changes contribute to the functional maturation of the middle ear.

EXTERNAL EAR

The external acoustic meatus is traditionally described as developing within the first pharyngeal cleft, and is clearly visible from stage 12 on lateral views of human embryos (see Fig. 17.3). In mouse embryos, developmental studies of gene expression suggest that the external acoustic meatus forms more rostrally from invagination of the ectoderm of the first arch rather than at the first pharyngeal cleft (Minoux et al 2013, Anthwal and Thompson 2016, Tucker 2017). By the end of the embryonic period, the surface ectoderm has developed into a bilaminar epithelium: the basal germinative layer gives rise to the epidermis and the superficial layer to the periderm which grows throughout fetal life by mitotic activity independent of the developing epidermal stratum basale (see Fig. 7.30). The periderm has tight junctions and acts as a protective barrier that prevents adhesion between intimately apposed,

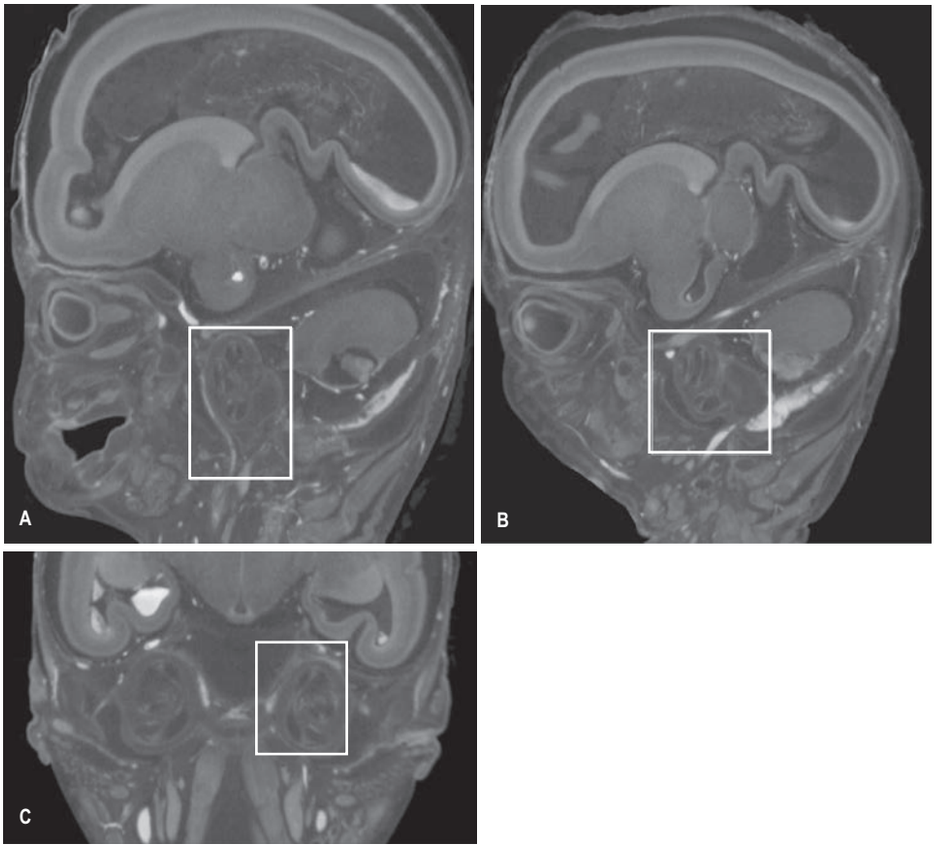

Fig. 16.2 MicroCT images of the inner ear in a 14-postmenstrual-week fetus. **A**, Semicircular ducts (white rectangle), right sagittal section. **B**, Cochlea (white rectangle), left sagittal section. **C**, Semicircular ducts (white rectangle), coronal section. Fig. 16.3 The development of the external acoustic meatus (external auditory canal).

adhesion-competent epithelia (Hammond et al 2019). Both periderm and epidermis line the open primary external acoustic meatus (**Fig. 16.3**).

A solid epidermal meatal plate forms and extends from the edge of the open primary canal toward the developing tympanic ring, a structure that is essential for the formation of the external acoustic meatus (Takechi et al 2016). The underlying mesenchyme forms the cartilaginous part of the final canal (see Fig. 17.4). The cells within the meatal plate separate from postmenstrual weeks 13–14 and an open canal is formed by postmenstrual week 18, with ongoing epidermal mitosis generating movement of keratinous debris to the exterior (Fig. 16.3) (Michaels and Soucek 1989, Nishimura and Kumoi 1992). The osseous part of the external acoustic meatus develops postnatally from the tympanic ring of the temporal bone whereas the cartilaginous part develops much earlier, independently of the osseous part (Ikari et al 2013).

The tympanic membrane is formed from three sources, ectoderm-derived cells of the meatal plate, the endodermal-derived floor of the tubotympanic recess and the neural crest mesenchyme that intervenes between these layers. The tympanic membrane is supported by the tympanic ring which starts to ossify later than other viscerocranial bones. Four ossification centres appear about postmenstrual week 14 (see Fig. 17.6), but the bone is not completely developed until 2 years of age. In the neonate the tympanic membrane and ossicles have already reached adult size but the external acoustic meatus is much smaller than in the adult.

The first indication of auricular development is the appearance of mesenchymal proliferations beneath the ectoderm of the caudal border of the first pharyngeal arch and the cranial border of the second pharyngeal arch, at stage 15 (O'Rahilly and Müller 1987). These proliferations, traditionally termed auricular hillocks and numbered 1–6, were thought to contribute equally to the auricle, and are apparent by stages 22–23. However, 3D reconstructions of human embryonic auricles have demonstrated that the bulk of an auricle arises from second pharyngeal arch mesenchyme and that the tragus and anterior external acoustic meatus are derived from first pharyngeal arch mesenchyme (Veugen et al 2019). The lobule is the last part of the auricle to develop.

Common congenital anomalies of the auricle are described in Chapter 42.

HEREDITARY DEAFNESS

Prelingual deafness is the most common congenital anomaly, affecting 2–6/1000 newborns: at least two-thirds of cases reported in the developed world are due to genetic factors, classified as non-syndromic (typically sensorineural and accounting for approximately 70% of cases) and syndromic (may be sensorineural, conductive or mixed and accounting for approximately 30% of cases). A number of genes likely to be mediators of genetic hearing loss have been identified, including *TGFB1*, *BMP4*, *ERK1/2*, *EYA1* and many *GPCR* genes (Stamatiou and Stankovic 2013). The range of affected chromosomes and the specific genes involved in sensorineural deafness is given by Hildebrand et al (2010). The structural abnormalities resulting from absent or aberrant gene expression during the development of the inner ear include labyrinthine dysplasias (e.g. a reduction in the number of cochlear turns or an enlargement of the endolymphatic duct); disorganization of the patterns of stereocilia in sensory hair cells and loss of cytoskeletal components in these cells; and defects in K^+ recycling across gap junctions between activated hair cells. Structural anomalies resulting from altered gene expression in the middle and external ear include failure of complete cavitation of the middle ear and canal atresia, with defects in the external and middle ear impacting on each other, highlighting the close association of these structures during development.

NEONATAL AND INFANT EAR

The onset of hearing occurs from about postmenstrual week 20 with fetuses exposed to the intrauterine sound environment. Permanent hearing loss is more common in preterm infants (30/1000) than in full-term neonates: preterm infants with no hearing loss may have changes in postnatal auditory processing. The effects of early perinatal acoustic exposure are not yet known (Durante et al 2018). Two neonatal hearing tests are used in routine screening: evoked otoacoustic emissions, the detection of low-level sounds emitted by the cochlea in response to a sound stimulation; and automated auditory brainstem response, the recording via an electroencephalograph of wave generation in response to click stimuli in the external ear. The screening should occur before postnatal week 4 and it is recommended that those who fail should have further diagnostic evaluation before postnatal month 3 (Stewart and Bentley 2019).

Bonus e-book content

Fig. 16.2 MicroCT images of the inner ear in a 14-postmenstrual-week fetus.

Loss of auditory input to the temporal cortex affects its postnatal patterning and maturation, in a similar manner to the effect of loss of visual input from the retina in amblyopia. Although cortical regions are present at full-term birth, the interconnections mature during postnatal experience (Kral et al 2017). Auditory temporal resolution (i.e. the ability to detect time intervals between sound stimuli) is necessary for the auditory perception of rhythm, and to discriminate frequency and duration of phonemes (units of sound) (Durante et al 2018). Neonates can discriminate their mother's voice before postnatal month 1. They are initially sensitive to acoustic differences but later specialize and remain sensitive to distinctive phonemes in their mother language (Saito et al 2019). Congenital deafness is associated with delay in speech and language acquisition and consequent learning difficulties. Cochlear implants are an optimal therapy for prelingually deaf infants, if implanted within postnatal years 1–3 (Kral 2013) (Ch. 43). Untreated congenital deafness in animals and humans gives rise to changes to the cochlear nuclei, the inferior colliculi and reduced white matter volume in the auditory cortex (Berger et al 2017).

CHAPTER 17

Development of the head and neck

Head and neck development is distinct from that of the trunk, utilizing region-specific genes, signalling mechanisms and morphogenetic processes. The boundary between the head and trunk is not always clear. The neck is contiguous rostrally with the head but it also joins and shares developmental processes caudally with the back (Ch. 18) and the upper limb (Ch. 19). Studies of developmental gene expression in vertebrate and non-vertebrate embryos are elucidating the conserved mechanisms within the tissues interacting in this region (Kuratani et al 2019) (Commentary 2.1). Studies on human embryos have necessarily been mainly descriptive but observations from lineage and genetic studies in mouse embryos together with clinical genetics studies, have provided major insights into the underlying mechanisms. The description of human development provided here is derived from the following sources, which incorporate primary data by the authors, as well as references to older primary source material: Hamilton et al (1962), Patten (1968), O'Rahilly and Müller (1987, 2001), Hinrichsen (1990), Steding (2009). References to experimental studies in the mouse and human clinical studies are provided in the text.

It is important to note that the term mesenchyme simply describes a loose cellular tissue organization with a rich extracellular matrix, in contrast to the sheets of simple epithelia that form the outer ectodermal and inner endodermal layers of early embryos. Prior to the migration of neural crest cells from the edges of the cranial neural folds to their final destinations, the only mesenchyme in the embryonic head is 'primary mesenchyme', i.e. mesenchymal cells formed by epithelial–mesenchymal transformation in the primitive streak. This is the mesodermal germ layer. There is no lateral plate mesoderm in the head; all of the cranial mesoderm is paraxial. Thus cranial mesenchyme is derived from mesodermal, neural crest and placodal sources, each of which has specific distributions and specific derivatives.

Evolution of the vertebrate head is a consequence of the origin of a novel cell population, the neural crest. Neural crest cells form a wide variety of neural derivatives throughout the body and neural and non-neural derivatives in the head (Ch. 14), where they also give rise to connective and skeletal tissues and make major contributions to the skull. In mammalian embryos, cranial neural crest cells undergo epithelial to mesenchymal transformation and emigrate from the edges of the still-open cranial neural folds. **Fig. 17.1** shows stylized views of human embryos at an early stage of neural crest migration (Fig. 17.1A) and at the end of the crest migration (Fig. 17.1B). **Fig. 17.2C–D** shows the same developmental stages in mouse embryos with neural crest cells identified by staining techniques. In the head, cranial and vagal neural crest populations are generated from the dorsal neural folds according to positional information from brain segments (rhombomeres) and the lateral migration of the neural crest cells through adjacent somites.

The first transverse division to form in the early embryonic brain is the preotic sulcus (see Fig. 17.1A; **Fig. 17.2A**), which defines the boundary between prorhombomeres A and B. This early division is of major functional and organizational significance because it separates the regions of origin of the skeletogenic neural crest populations that make a major contribution to the skull from those that form skeletal structures in the neck (hyoid bone and larynx). During cranial neurulation, the prorhombomeres undergo subdivision so that, by the time the brain region of the neural tube closes, seven rhombomeres can be clearly distinguished. The occipital region (adjacent to the four occipital somites) remains unsegmented (**Fig. 17.2B**) and by analogy with the segmented rhombencephalon, it is also referred to as prorhombomere D/rhombomere 8. The segmental organization of the embryonic head caudal to prorhombomere A is related to the expression of evolutionarily conserved *HOX* genes (written *Hox* in the mouse) that have their rostral boundaries at specific rhombomere divisions; they are also expressed in the corresponding neural crest cells (Santagati and Rijli 2003, Hutchins et al 2018). Genetic experiments in the mouse and other vertebrates have shown that skeletal patterning of the first pharyngeal arch depends on the absence of *Hox* gene expression in the neural crest cells migrating into it, whereas skeletal patterning of the second arch depends on the crest cell expression of *Hoxa2*. In marked contrast investigation of *Hox* gene expression in arches 3–6 has suggested that skeletal patterning functions reside within the environment into which the neural crest cells migrate. (See Brunskill et al 2014 for gene expression maps of neural crest, paraxial mesoderm and ectodermal populations in mouse embryos during the early stages of craniofacial development.)

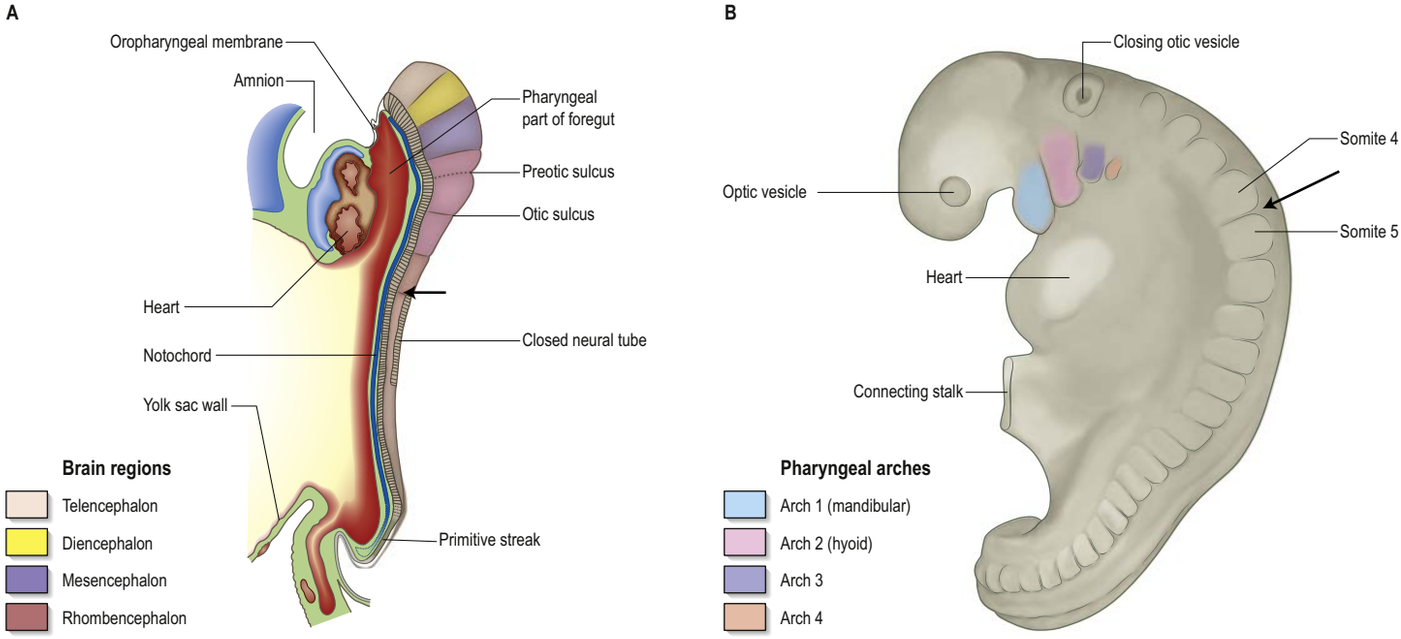

Fig. 17.1 Human embryos during the early stages of head development. The occipital–cervical boundary is indicated by an arrow in **A** and **B**. **A**, A sagittal section of a stage 10 embryo, in which neural tube closure has begun in the future occipito-cervical region. **B**, A lateral view of a stage 12 embryo (see also Fig. 14.2). (Embryonic stages 10–23 correlated to postfertilization days of development and postmenstrual weeks of pregnancy are shown in Fig. 23.3.)

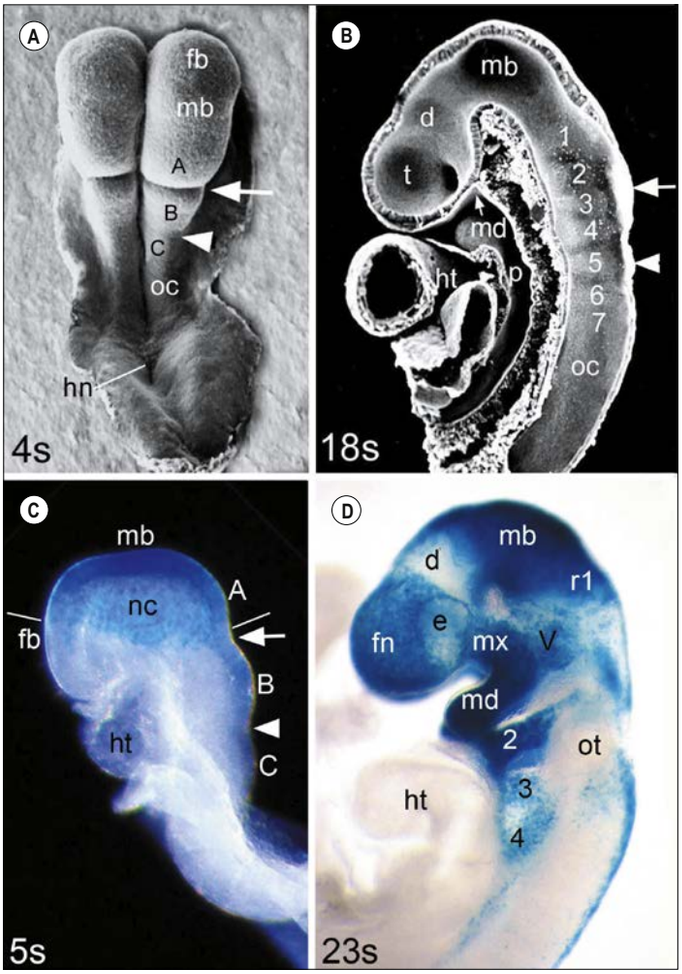

Fig. 17.2 Mouse embryo heads during the period of cranial neural crest cell migration. **A–B**, Scanning electron micrographs (**A**, dorsal view; **B**, median section) of embryos near the start (4 somite pairs) and end (18 somite pairs, interior view) of the period of neural crest cell migration. At the 4-somite stage, the neural folds are convex and the hindbrain is divided into prorhombomeres A, B and C by the preotic (arrow) and otic (arrowhead) sulci; at the 18-somite stage, the neural tube is closed and the hindbrain is divided into seven rhombomeres (numbered) and the unsegmented occipital region (oc). Rathke's pouch is indicated by a small arrow on **B**. **C–D**, Lateral views of embryos at the 5- and 23-somite stage, respectively, carrying a permanent marker for neural crest cells and the neural epithelium from which the trigeminal crest cells originate (blue stain). **C**, Trigeminal neural crest cells (nc) migrate as a veil-like mass beneath the surface ectoderm, originating as a continuous group from prorhombomere A, the midbrain and the caudal diencephalic region (d) of the forebrain, into the frontonasal region (fn) and the first arch (white lines indicate the level of the migrating edge). **D**, After migration, frontonasal neural crest cells (fn) cover the telencephalon and rostral diencephalon, surrounding the eye (e); maxillary (mx) and mandibular (md) neural crest populates the first pharyngeal arch; the trigeminal ganglion primordium (V) is also present. Hyoid neural crest cells from prorhombomere B have populated the hyoid arch and the primordium of ganglion VII/VIII, rostral to the otocyst (ot); vagal crest cells from prorhombomere C are migrating into arches 3 and 4, and starting to form the primordia of the glossopharyngeal and vagal ganglia, caudal to the otocyst. Other abbreviations: fb, forebrain; hn, Hensen's node; ht, heart; mb, midbrain; p, pharynx; r1, rhombomere 1 of the hindbrain; t, telencephalon. (A and B, With permission from Morriss-Kay GM, Wilkie AOMW 2005 Growth of the normal skull vault and its alteration in craniosynostosis. J Anat 207:637–53. C and D, With permission from Jiang X, Iseki S, Maxson RE et al 2002 Tissue origins and interactions in the mammalian skull vault. Dev Biol 241:106–16.)

In the mouse, the lineage marker Wnt1-Cre/R26R has enabled neural crest cells to be traced from the stage at which they leave the neural epithelium through to their final locations in mature tissues. These studies show three separate populations of neural crest cells migrating from the cranial neural folds; each gives rise to both neuronal and non-neuronal progeny (Jiang et al 2002). The first (trigeminal) population originates from the diencephalic region of the forebrain, the midbrain and prorhombomere A of the hindbrain (which subsequently divides to form rhombomeres 1 and 2) (see Figs 17.2A–B). The neural crest cells with a neuronal fate contribute to the trigeminal ganglion. The non-neuronal cells migrate extensively to surround the telencephalon and part of the diencephalon, forming the frontonasal mesenchymal populations and also migrate lateral to the rhombencephalon to form the mesenchyme of the maxillary and mandibular regions of the first arch (see Figs 17.2C–D).

The second (hyoid) population emigrates from prorhombomere B (which forms rhombomeres 3 and 4); some cells condense to form the otic ganglion before the main population continues into the second pharyngeal arch. The third (vagal) population has a more extensive origin, from the neural folds caudal to the otocyst, i.e. prorhombomere C. These cells will contribute to the ganglia of the glossopharyngeal and vagal nerves. The non-neuronal vagal crest cells migrate into pharyngeal arches 3, 4 and 6 and some of them continue into the heart where they contribute to the division of the cardiac outflow tract (Jiang et al 2000). The neural crest also gives rise to the parasympathetic ganglia and parasympathetic postganglionic nerves in the head and neck. For a full account of the neuronal derivatives of neural crest cells, see Chapter 14. In human embryos, histological methods have revealed equivalent cranial neural crest cell origins and migration routes to those of the mouse (O'Rahilly and Müller 2007).

Caudal to the segmented region of the cranial neural tube, neural crest cells from the occipital region (prorhombomere D/rhombomere 8) migrate with occipital myoblasts to form the hypoglossal cord. They eventually differentiate to form the connective tissue of the tongue and the occipital myoblasts form the intrinsic tongue musculature. No sensory ganglia are formed from the occipital neural crest in human embryos.

Ectodermal placodes appear as patches of columnar or pseudostratified epithelium within the otherwise squamous epithelium of the surface ectoderm. Three pairs of placodes contribute to sense organs, forming the olfactory epithelium, the lens and the otocyst. They each undergo morphogenesis to form a pit and then (for the lens and otic pits) a closed cyst (vesicle). Epibranchial (epipharyngeal) placodes are situated near the proximal end of each pharyngeal arch. Some of their cells undergo epithelial to mesenchymal transformation, joining the underlying neural crest cell condensations to form sensory neuroblasts in the ganglia of cranial nerves V, VII, IX and X. Some cells from the otocyst and an adjacent placode similarly delaminate to contribute to the ganglia of cranial nerve VIII.

EMBRYONIC PHARYNX AND PHARYNGEAL ARCHES

The most cranial portion of the foregut, the embryonic pharynx, is the scaffolding around which the face, palate and anterior neck structures are built. The development of this region from neural crest, paraxial mesoderm, surface ectoderm and foregut endoderm involves spatiotemporal coordination of cell movement, tissue growth and tissue interactions. As successive populations of neural crest cells migrate around the pharynx at progressively more caudal levels, five pairs of pharyngeal arches are formed (numbered 1, 2, 3, 4 and 6 for consistency with comparative anatomy terminology, although this numbering has been queried because it does not seem to reflect the situation across the vertebrates as a whole (Graham et al 2019)). This process is complete by stages 14–15 (**Fig. 17.3**). For details of the age in postfertilization days of the stages given see Fig. 23.3. Pharyngeal clefts (grooves) separate the arches externally and are matched internally by internal depressions, the pharyngeal pouches (see Fig. 17.3). Pharyngeal arches are also known as branchial arches, reflecting their evolutionary origin supporting the gills in the earliest vertebrates.

Each pharyngeal arch consists of an epithelial covering of ectoderm externally and endoderm internally and is filled with mesenchyme that is mainly of neural crest origin (see Fig. 17.3). Understanding the origin and fates of the structures within the pharyngeal arches is aided by considering their conformity to, or deviation from, a basic plan: the cartilages, muscles, nerves and arteries associated with each arch are summarized in **Table 17.1**. The neural crest cells of arches 1–4 form a skeletal element and associated connective tissue: in all arches they give rise to the outer walls of an aortic arch blood vessel with an endothelial lining that develops by angiogenesis from the heart outflow tract endocardium. Paraxial mesoderm also forms the muscle associated with each pharyngeal arch. Motor and sensory innervation is supplied by arch-specific cranial nerves. For an overview of the organization of these tissues in the pharynx, see Fig. 12.4; for their fate, see Figs 17.5–17.7.

The first pharyngeal arch, unlike the other arches, possesses a dorsal and ventral process, and appears C-shaped in lateral view. The main 'mandibular' component forms the lower jaw and the dorsal process contributes to maxillofacial and palatopharyngeal structures and to the middle ear. The second pharyngeal arch is termed the hyoid arch because of its

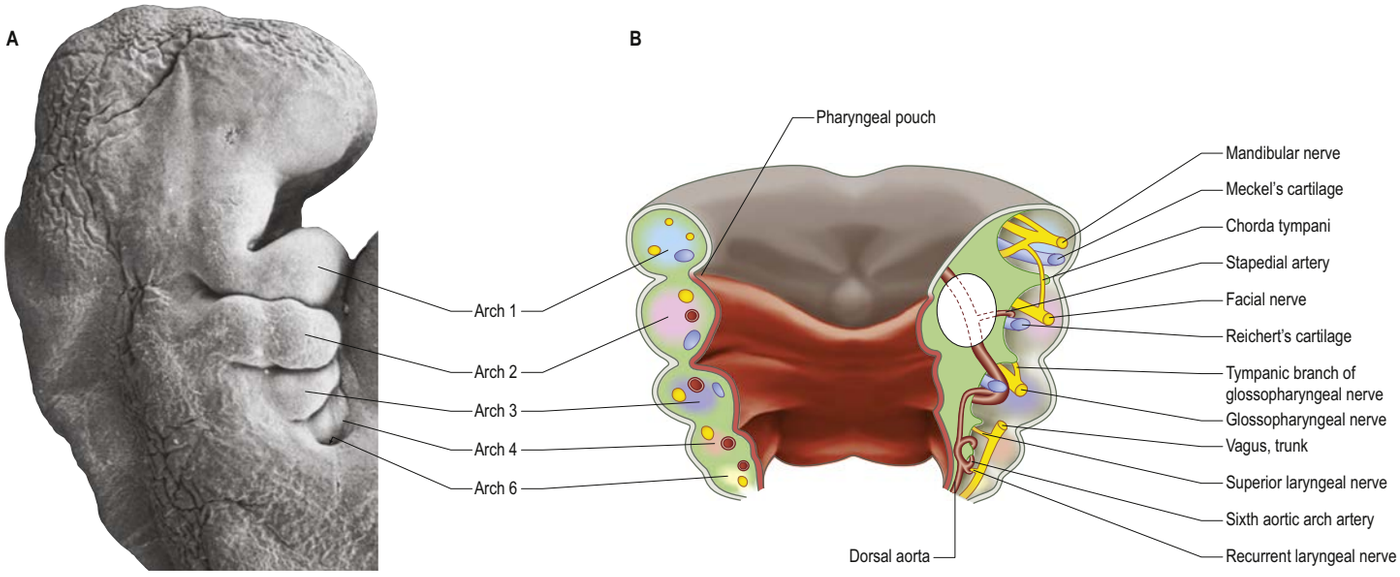

Fig. 17.3 Pharyngeal arch development. **A**, A scanning electron micrograph of a human embryo (stage 14/15), showing the right lateral aspect of the pharyngeal arches; auricular hillocks are visible on arch two. **B**, The pharyngeal region (stage 15) viewed from the dorsal aspect. The whole left side and part of the right side of the endodermal roof of the pharynx has been removed to show the grooves in its lateral walls and floor, and the nerves, arteries and cartilages of the arches. The position of the right otocyst is shown as a clear oval. (A, Courtesy of Professort G Steding, Georg-August-University of Göttingen, Göttingen, Germany.)

TABLE 17.1

Chart of derivatives of the pharyngeal arches

Arch number	Arch name	Embryonic cartilage	Cartilage derivative	Muscle	Nerve	Artery
1	Mandibular	Meckel's	Incus Malleus Anterior ligament of malleus Spine of sphenoid Sphenomandibular ligament Genial tubercle of mandible	Tensor tympani Muscles of mastication Mylohyoid Anterior belly of digastric Tensor veli palatini	Trigeminal (V) mandibular division	First aortic arch artery [transitory]
2	Hyoid	Reichert's	Stapes Styloid process of temporal bone Stylohyoid ligament Lesser horn and upper part of body of hyoid bone	Stapedius Stylohyoid Muscles of the face, auricle and scalp Buccinator Platysma Posterior belly of digastric	Facial (VII)	Stapedial artery [transitory]
3	Third		Greater horn and lower part of body of hyoid bone	Stylopharyngeus	Glossopharyngeal (IX)	Common carotid artery, first part of internal carotid artery
4	Fourth		Thyroid cartilage	Cricothyroid	Vagus (X) superior laryngeal branch	Proximal part of subclavian artery on the right Arch of aorta between origins of left subclavian arteries
6	Sixth		Other laryngeal cartilages	Other intrinsic laryngeal muscles	Vagus (X) recurrent laryngeal branch	Part between the pulmonary trunk and dorsal aorta becomes ductus arteriosus on left, disappears on right
4+6	Fourth + sixth			Pharyngeal constrictors Palatal muscles except tensor veli palatini	Pharyngeal plexus (IX, X)	

contribution to the hyoid bone (and to other parts of the hyomandibular apparatus in fishes). The third, fourth and sixth arches are not named.

The left and right mandibular arches, first seen at stage 10, grow ventromedially in the floor of the pharynx to meet in the median plane, forming the ventral border of the early mouth immediately above the developing heart. The maxillary processes are not clearly visible as surface structures until stage 13; their enlargement coincides with the proliferation of the frontonasal mesenchyme to form the nasal swellings (see Fig. 17.10A–B). The hyoid arches appear at stage 11, the third arches at stage 12 and the fourth arches by stage 13. The sixth arch can only be identified by the arrangement of the arch arteries and nerves, and by a slight projection on the pharyngeal aspect. The floor of the pharynx is formed mainly by ventral apposition of the arches of the two sides. The inferior border of the second arch grows over the lower arches and encloses an ectodermal depression termed the cervical sinus (Fig. 17.4).

Skeletal elements of the pharyngeal arches

In human embryos, neural crest mesenchyme in the first three arches gives rise to ligaments, tendons, connective tissue and cartilage that

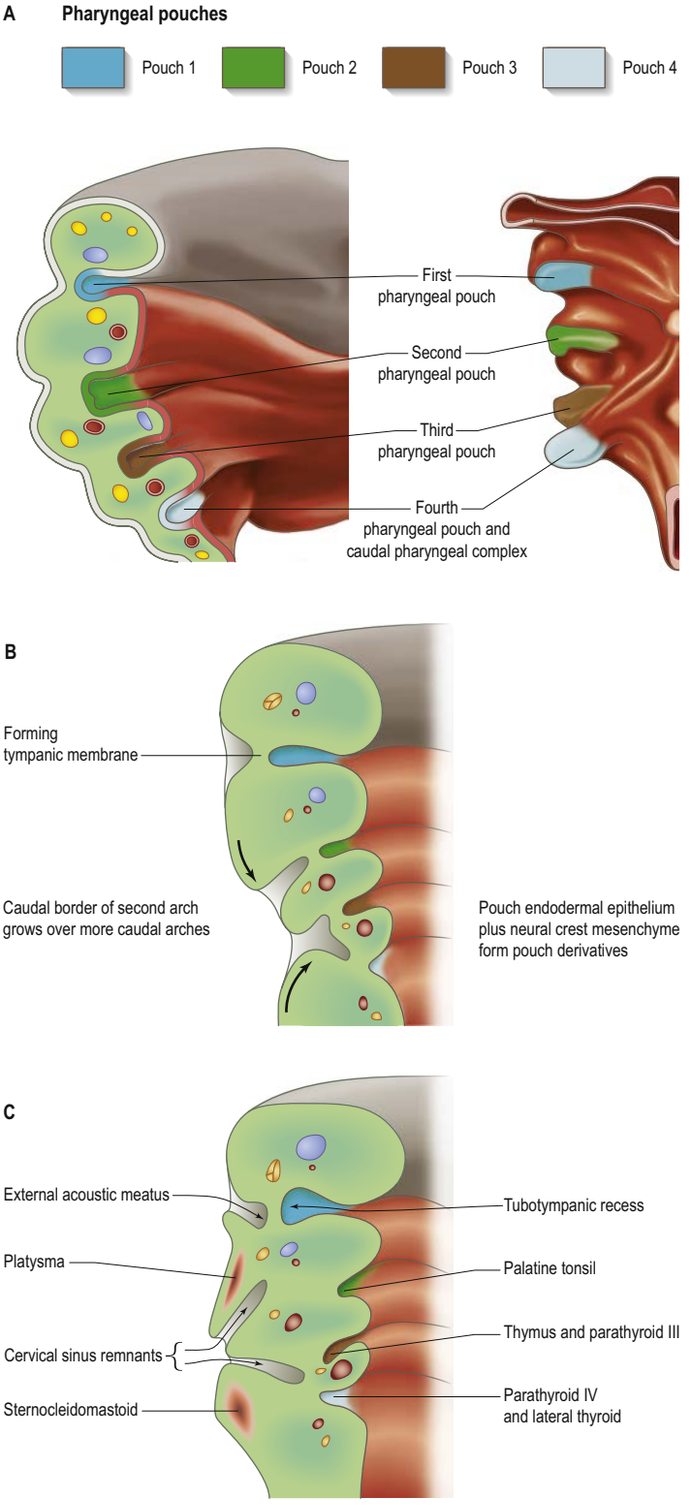

Fig. 17.4 Pharyngeal pouch development. **A**, The arrangement of the early pharyngeal pouches: on the left, the internal aspect of the pharyngeal floor viewed from above; on the right, the external aspect of the pharyngeal floor viewed from below. **B**, A coronal section of the left side of the pharynx at stage 18, showing changes to the pharyngeal pouches internally and pharyngeal clefts externally. **C**, A coronal section of the left side of the pharynx at stage 19. See also Fig. 17.19 for further development.

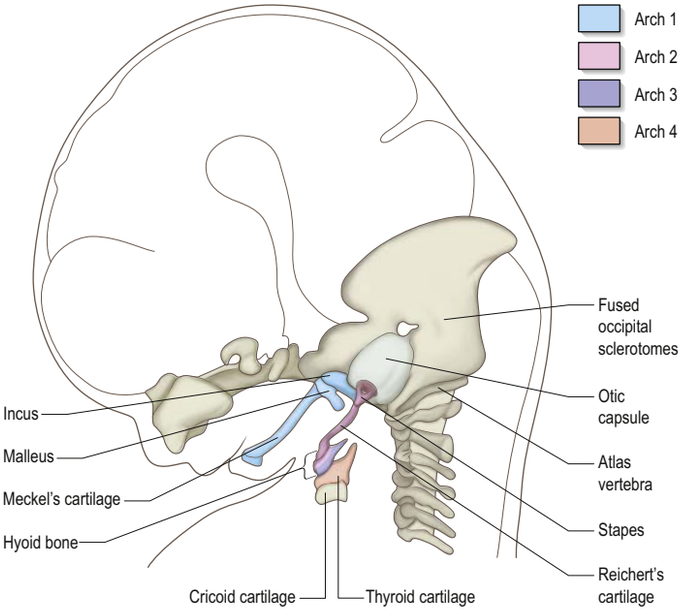

Fig. 17.5 The chondrocranium and arch cartilage derivatives at stage 20.

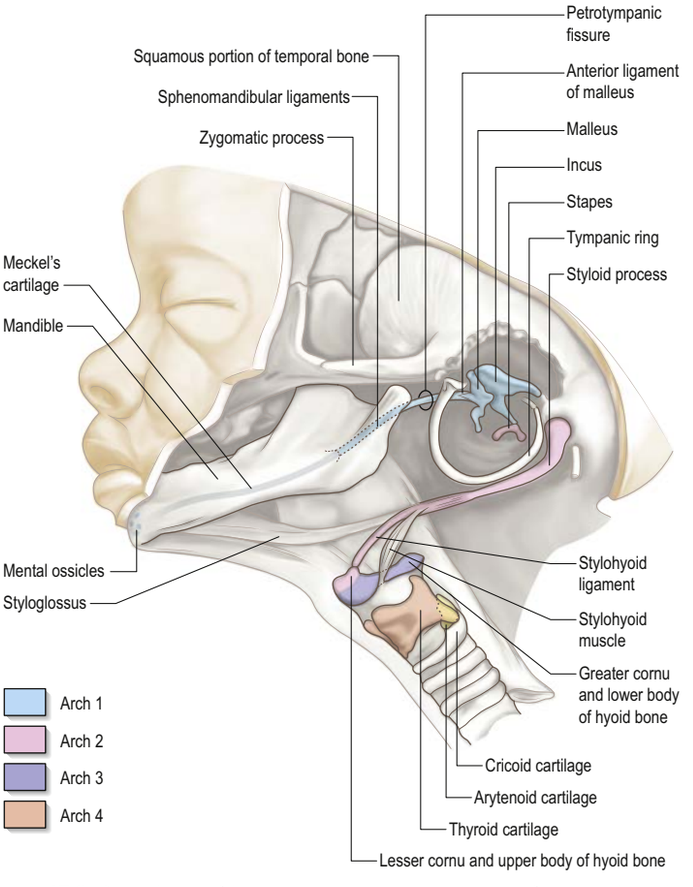

Fig. 17.6 Derivatives of the pharyngeal arch cartilages after about post-menstrual week 15.

forms skeletal elements that subsequently chondrify in part or in their entirety. Where chondrogenesis is complete, the element contacts the skull base lateral to the hindbrain (Figs 17.5–17.6). No cartilages form in the fourth and sixth arches in human embryos (de Bakker et al 2018).

The first arch cartilage, Meckel's cartilage, is a structure around which the embryonic lower jaw skeleton arises. After the mandible forms by intramembranous ossification of the neural crest mesenchyme lateral to it, Meckel's cartilage degenerates but its sheath persists as the anterior malleolar and sphenomandibular ligaments. At its proximal end, endochondral ossification forms two of the middle ear bones, the malleus and incus. These are homologous with the articular and quadrate bones that form the reptilian jaw articulation, where the quadrate forms from the caudal end of the palatopterygoquadrate cartilage. The mammalian evolutionary derivatives of this cartilage are thought to include part of the greater wing of the sphenoid bone, the roots of its pterygoid plates and the incus.

The second arch cartilage, Reichert's cartilage, forms from neural crest mesenchyme that extends from the proximity of the otic capsule dorsally toward the median plane ventrally. It gives rise to the stapes, which is the most ancient of the three auditory ossicles, homologous with the rod-shaped columella auris of reptiles and birds, and the styloid process proximally and the lesser cornua of the hyoid bone distally: the stylohyoid ligament develops between these two bones (see Fig. 17.6). Cartilage in the third arch, also derived from neural crest

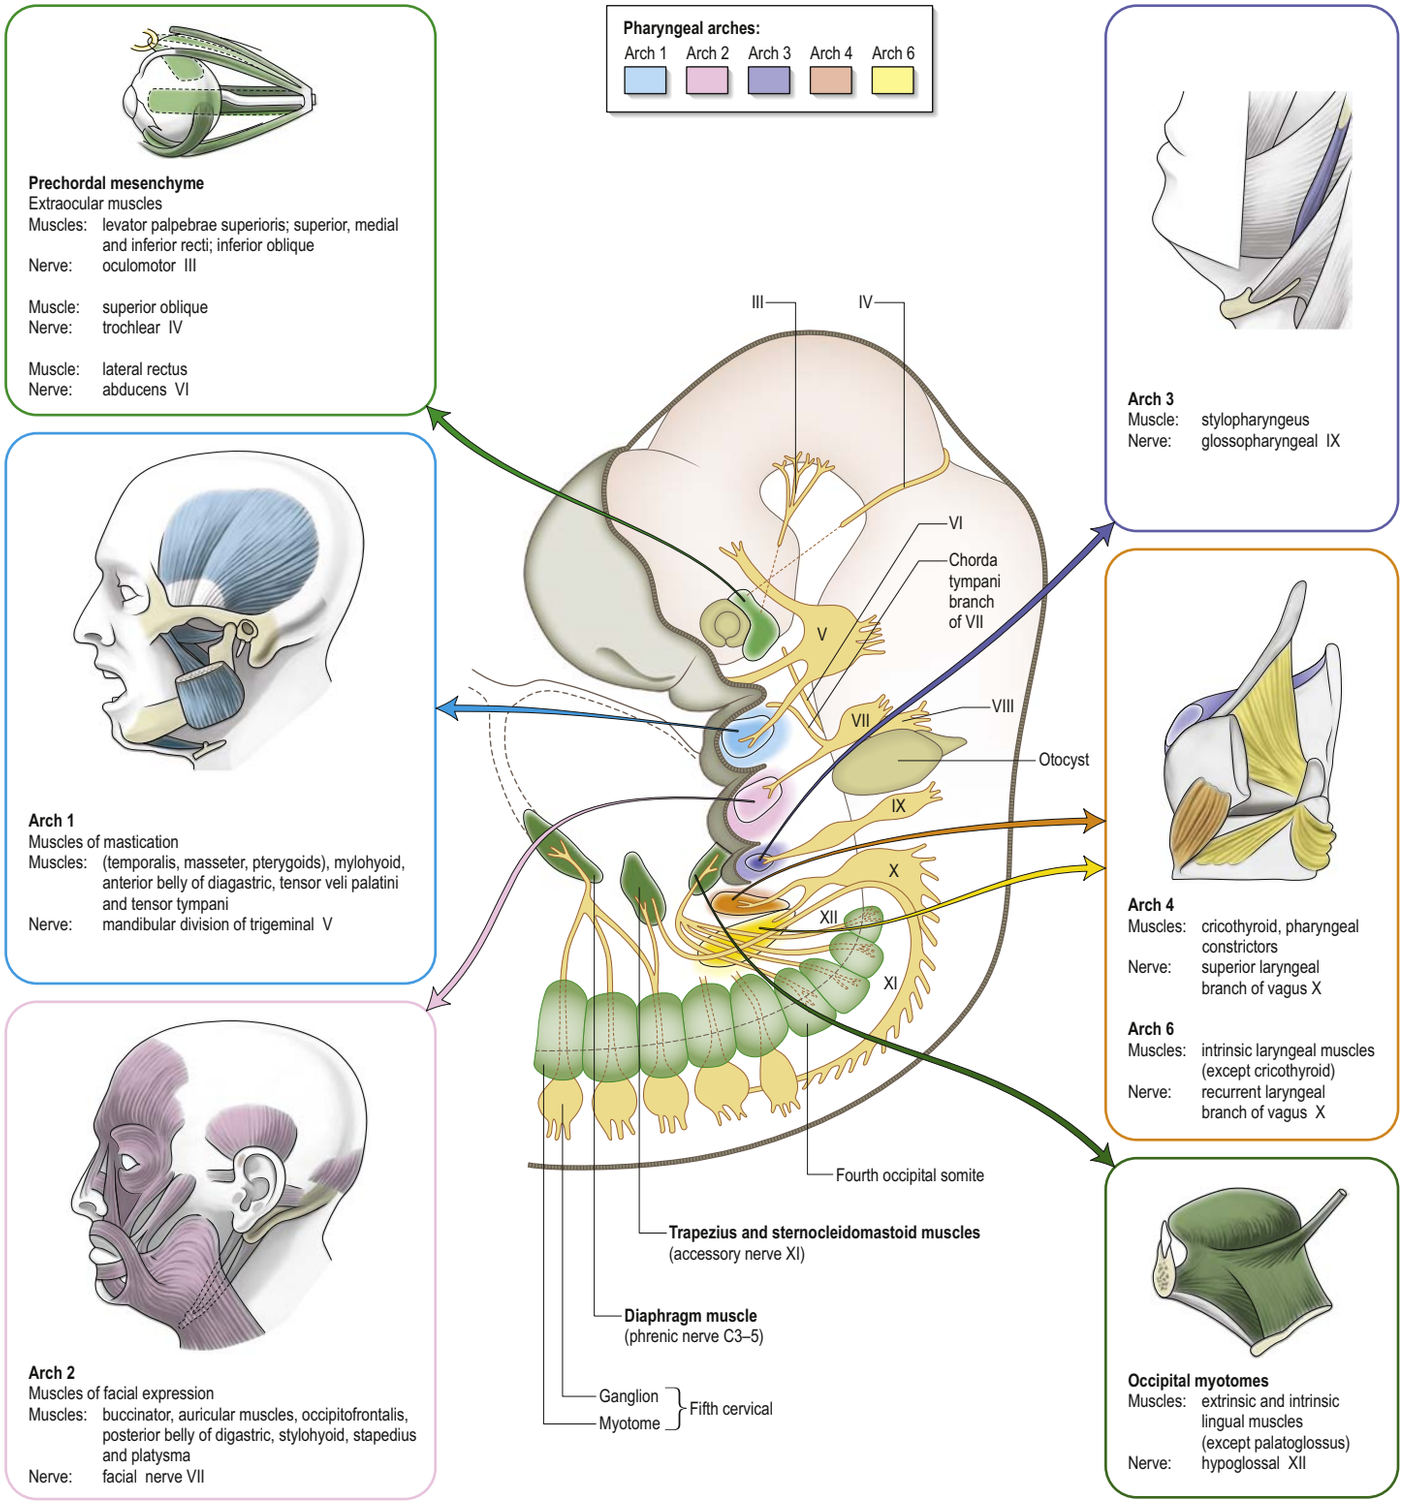

Fig. 17.7 The muscular derivatives of the prechordal mesenchyme, unsegmented paraxial mesoderm and rostral somites.

mesenchyme, gives rise to the greater cornua of the hyoid bone. The body of the hyoid bone develops from a ventral mesenchymal population without contributions from the distal second and third arch cartilages. The laryngeal cartilages associated with arches 4 and 6 (thyroid, cricoid and arytenoid) arise from mesenchymal condensations in the ventral neck: fourth and sixth arch cartilages are not seen in human embryos (de Bakker et al 2018).

Muscles of the pharyngeal arches

The striated muscle of each arch is derived from cranial paraxial mesoderm, which is unsegmented rostral to the occipital region, whereas more caudally segmentation gives rise to four pairs of epithelial somites that are similar to those of the trunk, except that the first pair is rather poorly defined. Myoblasts migrate from the paraxial mesoderm to sites of future muscle differentiation and form premuscle condensations prior to the development of any skeletal elements. The pattern of primary myotube alignment for any one muscle is specified by the surrounding neural crest-derived mesenchyme. The rate and pattern of muscle maturation are closely associated with the development of the skeletal elements. Fig. 17.7 illustrates the muscle masses of each arch, their innervation and their derivatives in the adult.

The muscle mass of the mandibular part of the first arch forms tensor tympani, tensor veli palatini, mylohyoid, anterior belly of digastric and the masticatory muscles. Tensor tympani retains its connection with the skeletal element of the arch through its attachments to the malleus, and tensor veli palatini remains attached to the base of the medial pterygoid process, which may itself be derived from the dorsal cartilage of the first arch. All of these muscles are supplied by the mandibular nerve, the mixed nerve of the first arch. The maxillary division

of the trigeminal nerve has no motor component, because no muscles are derived from maxillary mesenchyme.

The muscles of the second arch migrate widely but retain their original nerve supply from the facial nerve. Their migration is facilitated by the early obliteration of part of the first pharyngeal cleft and pouch. Stapedius, stylohyoid and posterior belly of digastric remain attached to the hyoid bone but the facial musculature, platysma, auricular muscles and occipitofrontalis all lose their connection with it.

The muscle masses from the third and fourth arches form the musculature of the pharynx, larynx and soft palate. Stylopharyngeus is a third arch muscle, and is innervated by a branch of the glossopharyngeal nerve. All of the intrinsic laryngeal muscles are innervated by the vagus nerve: the cricothyroid by the superior laryngeal branch to the fourth arch and the others by the recurrent laryngeal nerve, which has been considered to be the sixth arch nerve. Precise arch origins are not clearly defined for the palatal muscles (except tensor veli palatini), or for the pharyngeal constrictors; these muscles all receive their nerve supply via the pharyngeal plexus (see Ch. 40). The extraocular muscles are not associated with the pharyngeal arches but are derived from mesenchyme arising from the prochordal plate that migrates to differentiate adjacent to the eyes (Ch. 15).

Nerves of the pharyngeal arches

The cranial nerves associated with each arch arise from the adjacent hindbrain (see Fig. 17.7; see also Figs 12.4, 14.19). They are the trigeminal (V), facial (VII), glossopharyngeal (IX), vagus (X) and cranial and spinal accessory (XI) nerves. The motor nerves extend from the basal plate of the hindbrain to innervate the striated muscle of the arches and are termed special visceral efferent nerves because they innervate pharyngeal musculature. Sensory nerves extend peripherally and centrally from cranial ganglia that are formed partly from neural crest and partly from cells that delaminate from epibranchial placodes; they convey general and special somatic afferent axons. Each arch is innervated by a mixed nerve, but the nerves of the first three arches also have a purely sensory branch that innervates the arch rostral to its 'own' arch; this sensory nerve is called the pretrematic branch because it extends rostral to the cleft (trema) between the two arches (see Figs 17.3, 17.7). The nerves to the mandibular arch include the mandibular division of the trigeminal nerve, which is mixed, and the chorda tympani, the purely sensory pretrematic branch of the facial nerve. The maxillary branch of the trigeminal and the tympanic branch of the glossopharyngeal are also considered to be pretrematic nerves. The ophthalmic branch of the trigeminal nerve, which supplies the frontonasal area, is not an arch nerve; in fishes, its ganglion is separate from the first arch nerve ganglion.

The vagus nerve supplies the fourth and sixth arches (see Fig. 17.7). The recurrent laryngeal branch initially loops under the sixth arch artery on both sides, but the asymmetric changes to the vascular system affect the symmetry of this nerve. On the right, when the sixth aortic arch lateral to the right pulmonary artery degenerates, the recurrent laryngeal nerve usually loops under the fourth arch-derived subclavian artery; on the left, it loops round the ductus arteriosus (which is retained as the ligamentum arteriosum in the adult). Further details of cranial nerve development and composition are provided in Chapter 14.

Blood vessels of the pharyngeal arches

Pharyngeal arch arteries

The heart outflow tract initially develops by vasculogenesis soon after neural crest cells have invaded the early pharyngeal arches. Angiogenic mesenchyme migrates into the neural crest-populated areas and forms the endothelial lining of the vessels, and neural crest contributes to the outer layers of the walls (Jiang et al 2000, Yoshida et al 2008). The first aortic arch artery is part of the original vascular circuit that links the aortic sac of the heart to the paired dorsal aortae, blood returning to the heart via the allantoic, vitelline and common cardinal veins (see Fig. 13.1C). As the heart descends relative to the forebrain and other rostral structures, the aortic sac (ventral aortic root) gives rise to paired aortic arches at successively more caudal levels, each of which passes laterally on each side of the pharynx to join the dorsal aortae. The dorsal aortae are not invested by neural crest cells, and nor are the more distal (cranial) parts of the carotid arteries, which form by angiogenesis (Ch. 13). The whole complement of aortic arches never coexists, thus the first aortic arch degenerates through remodelling of the cranial arteries before the sixth is formed.

When the first and second aortic arch arteries begin to regress, the blood supply to the corresponding pharyngeal arches is derived from a transient ventral pharyngeal artery, which terminates by dividing into mandibular and maxillary branches. The second aortic arch artery at first anastomoses with the ventral pharyngeal artery and passes through the mesenchyme of the stapedial cartilage, which condenses around it, forming the foramen of the stapes.

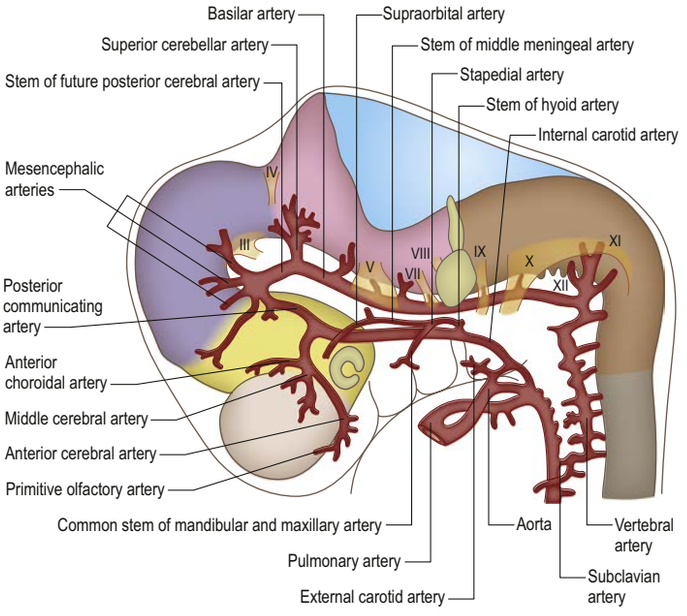

Fig. 17.8 The arterial system of the head at about stage 17.

Further development of the third, fourth and sixth aortic arches (**Figs 17.8–17.9**) produces the main arteries to the head and the great vessels arising from the heart. The common carotid artery arises from an elongation of the aortic sac, and the third arch artery becomes the proximal part of the internal carotid artery. The external carotid artery arises as a sprout from the common carotid; it incorporates the stem of the ventral pharyngeal artery, and its maxillary branch communicates with the common trunk of origin of the maxillary and mandibular branches of the stapedial artery and annexes these vessels. The proximal part of the common trunk persists as the root of the middle meningeal artery (see Fig. 17.8). More distally, the meningeal artery is derived from the proximal part of the supraorbital artery. The maxillary branch becomes the infraorbital artery and the mandibular branch forms the inferior alveolar artery. When the definitive ophthalmic artery differentiates as a branch from the terminal part of the internal carotid artery, it communicates with the supraorbital branch of the stapedial artery, which becomes the lacrimal artery distally, and retains an anastomotic connection with the middle meningeal artery. The dorsal stem of the original second arch artery remains as one or more caroticotympanic branches of the internal carotid artery.

The fourth aortic arch on the right forms the proximal part of the right subclavian artery, whereas the corresponding vessel on the left constitutes the arch of the definitive aorta between the origins of the left common carotid and left subclavian arteries. With elongation of the neck, longitudinal anastomoses in the cervical region link intersegmental arteries and their branches, and direct blood flow to the developing brain in the vertebral arteries in parallel with the internal carotid arteries (see Figs 17.8–17.9).

The sixth aortic arch is associated with the developing lung buds. Initially, each bud is supplied by a capillary plexus from the aortic sac. As the sixth aortic arch develops, it becomes the channel for blood from the aortic sac to the developing lung buds as well as to the corresponding dorsal aorta, the latter being the main channel. Soon after formation of the sixth aortic arch, the outflow tract of the heart is divided by an influx of neural crest cells, which form the spiral aorticopulmonary septum (Jiang et al 2000) that separates the aortic sac into the pulmonary trunk and ascending aorta. The part of the sixth aortic arch between the pulmonary trunk and the dorsal aorta is lost on the right but on the left becomes the ductus arteriosus which remains the main channel for blood to pass from the right ventricle to the descending aorta until the lungs and their associated blood vessels expand at birth. After birth, the ductus arteriosus is functionally closed by contraction of the circular muscle of the tunica media leaving a ligamentous remnant, the ligamentum arteriosum (Ch. 13) (see Fig. 17.9). The right dorsal aorta caudal to the right subclavian artery also degenerates, leaving the left dorsal aorta as the definitive descending aorta (see Fig. 17.9).

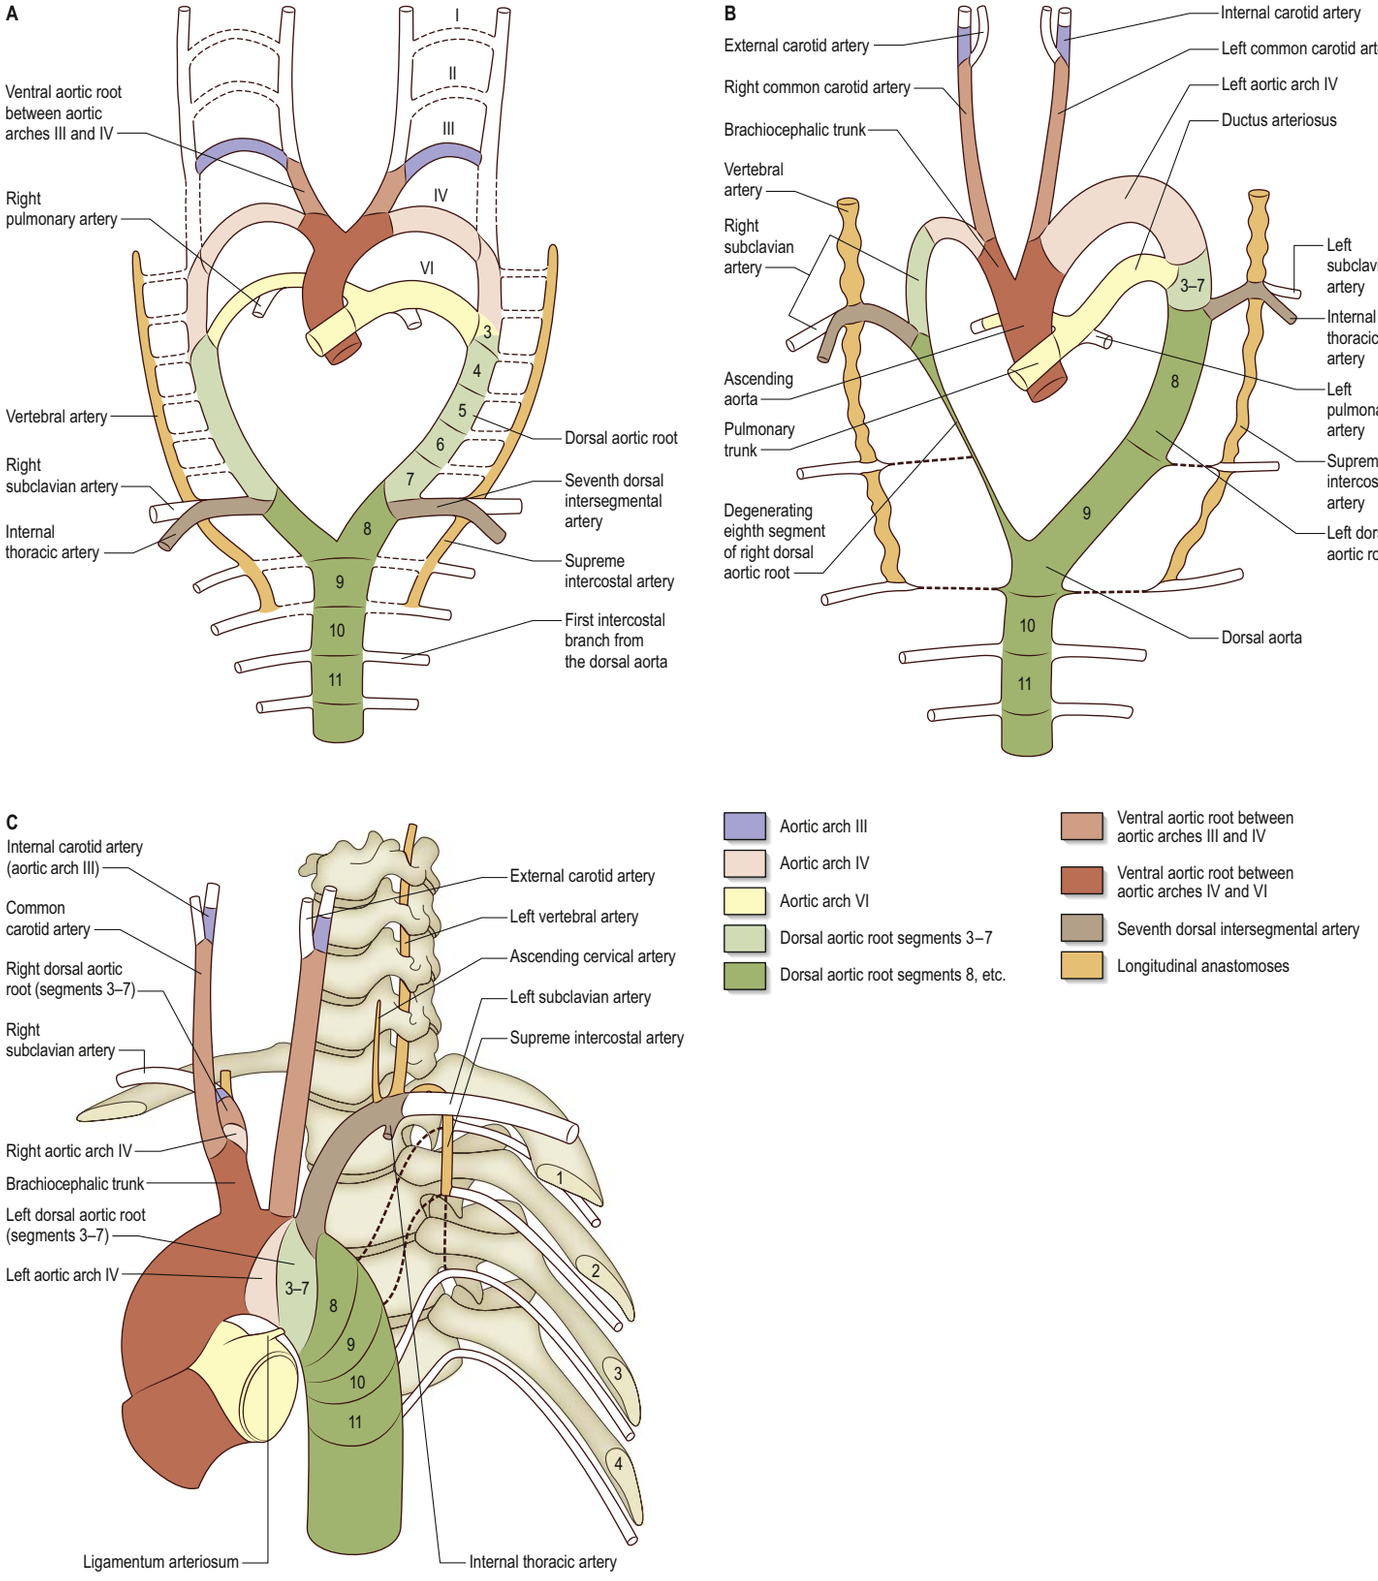

Fig. 17.9 The aortic arch arteries and their derivatives.

Venous drainage of the pharyngeal arches and head

Blood returning from the early head flows into a close-meshed capillary plexus continuous cranially with a transitory primordial hindbrain channel that lies on the neural tube medial to the cranial nerve roots and later becomes the primary head vein. This vessel runs caudally from the medial side of the trigeminal ganglion, lateral to the facial and vestibulocochlear nerves and the otocyst, then medial to the vagus nerve, to become continuous with the precardinal vein and a lateral anastomosis subsequently brings it lateral to the vagus nerve (see Figs 13.1, 13.17).

The ventral pharyngeal vein drains the mandibular and hyoid arches into the common cardinal vein (Fig. 17.10A) and with neck elongation into the cranial part of the precardinal vein, which later becomes the internal jugular vein (Fig. 17.10B). The ventral pharyngeal vein receives tributaries from the face and tongue, and becomes the linguofacial vein. As the face develops, the primitive maxillary vein extends its drainage into the territories of supply of the ophthalmic and mandibular divisions of the trigeminal nerve, including the pterygoid and temporal muscles, and it anastomoses with the linguofacial vein over the lower jaw. This anastomosis becomes the facial vein: it receives blood from the retromandibular vein from the temporal region, and drains through the linguofacial vein into the internal jugular vein. The stem of the linguofacial vein is now the lower part of the facial vein, whilst the dwindling connection of the facial with the primitive maxillary vein becomes the deep facial vein.

The external jugular vein develops from a tributary of the cephalic vein within the tissues of the neck and anastomoses secondarily with

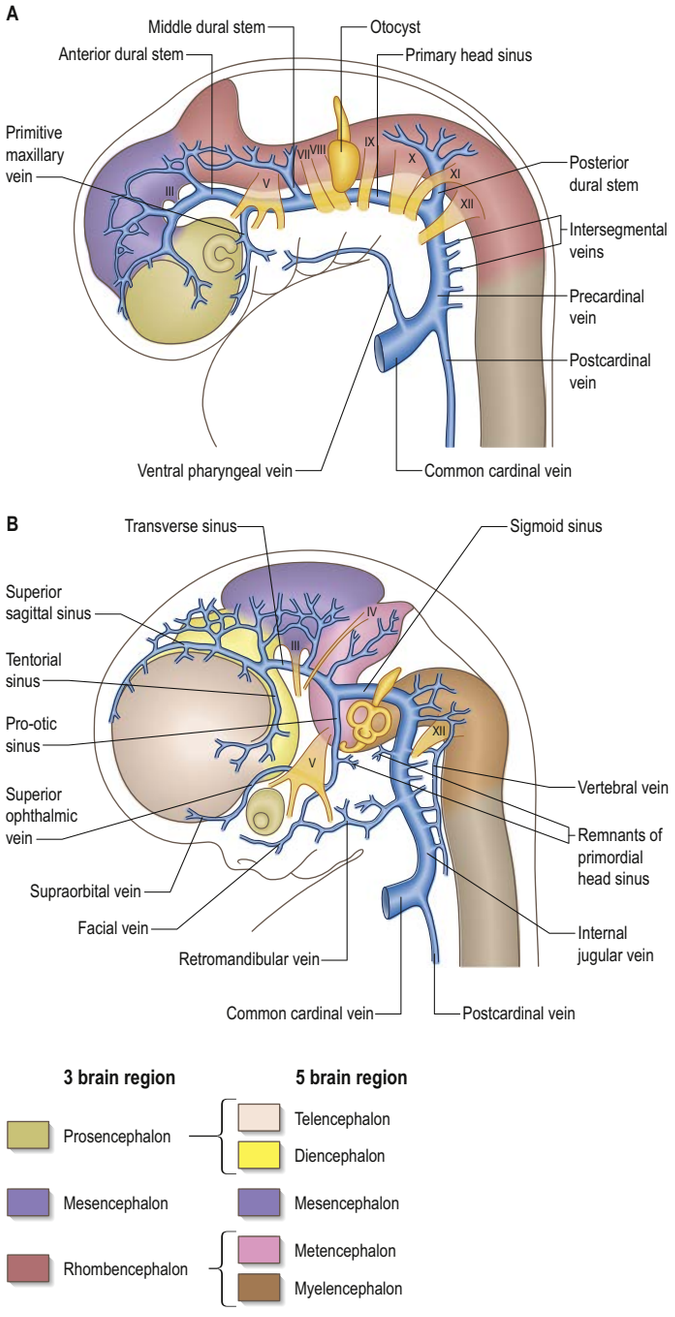

Fig. 17.10 Successive stages in the development of the veins of the head and neck: **A**, about stage 16; **B**, about stage 22.

the anterior facial vein. At this stage, the cephalic vein forms a venous ring around the clavicle, by which it is connected with the caudal part of the precardinal vein. The deep segment of the venous ring forms the subclavian vein and receives the definitive external jugular vein. The superficial segment of the venous ring dwindles, but may persist minimally in adult life. The deep aspects of the maxillomandibular facial prominences, the retrogingival oral cavity, the pharyngeal walls and their lymphoid and endocrine derivatives, and the cervicothoracic oesophagus thus all have drainage channels that connect with the precardinal complex. Laryngeal and tracheobronchial veins also drain to the precardinal complex, whilst the capillary plexuses, developed in the (splanchnopleuric) walls of the fine terminal respiratory passages and alveoli, converge on pulmonary veins of increasing calibre, finally making secondary connections with the left atrium of the heart.

Pharyngeal ectoderm and clefts

Surface ectoderm lines the roof of the embryonic pharynx from the outer margin up to and including the invagination of the adenohypophysial (Rathke's) pouch (see Figs 14.9–14.10). It also completely covers the first arch, including the lateral walls and floor of the stomodeum, unlike the more caudal arches, which are lined with endoderm. The external surface ectoderm of the first arch ultimately produces the keratinized stratified squamous epithelium of the epidermis, including hair follicles, sweat and sebaceous glands, and the specialized epithelium of the vermilion part of the lips. Within the oral cavity, first arch ectoderm forms the mucous membranes of the internal surface of the lips and cheeks, the palate, the presulcal part of the tongue, the epithelial components of the salivary and mucous glands, and the enamel organs of the developing teeth (see Figs 17.15–17.16). The first pharyngeal cleft is obliterated ventrally; its dorsal end deepens to form the external acoustic meatus, including its ceruminous glands and the outer surface of the tympanic membrane (see Fig. 17.4). Developmental studies of gene expression in the pharyngeal arches in chick and mouse embryos are calling into question the traditional view of pharyngeal cleft development based on external appearance. In mouse embryos the external acoustic meatus forms more rostrally from an invagination of the ectoderm of the first arch rather than at the first pharyngeal cleft (Minoux et al 2013; Tucker 2017). Three auricular hillocks are observed on the first and second arches each side of the first pharyngeal cleft, during stages 15–16. It was thought that these contributed equally to the auricle (pinna) of the external ear, however, 3D reconstruction in human embryos up to stage 23 has shown that cells from the second arch form almost the entire auricle, whereas the first arch ectoderm and mesenchyme give rise to the tragus and anterior part of the external auditory meatus (Veugen et al 2019) (Ch. 16).

The external contours of the arches and clefts are modified as the skeletal and muscular elements develop. During stages 18–19 the second, third and fourth pharyngeal clefts form the rostral and caudal parts of a depression, the cervical sinus. As shown in Fig. 17.4, the sinus is adjacent to extensions from the occipital myotomes that contribute to sternocleidomastoid, trapezius and platysma. Fusion of the hyoid arch with the cardiac elevation closes the cervical sinus, excluding the third, fourth and sixth arches from contributing to the skin of the neck and also results in platysma, which lies within the superficial fascia, extending along the neck to the ventral thoracic wall.

Pharyngeal endoderm and pouches

The four pharyngeal pouches appear in sequence craniocaudally during stages 10–13. The rostral pharynx is broad and dorsoventrally compressed (see Fig. 17.19). Laterally, the endoderm of the pouches approaches the ectoderm of the pharyngeal clefts to form thin closing membranes (see Fig. 17.4). The approximating ectoderm and endoderm between the first cleft and pouch form the outer and inner surfaces of the tympanic membrane. The ventral end of the first pouch is obliterated, but its dorsal end persists and expands as the head enlarges. This, together with the adjoining lateral part of the pharynx, and possibly with a contribution from the dorsal part of the second pharyngeal pouch, constitutes the tubotympanic recess. The recess forms the middle ear cavity, the pharyngotympanic tube and epitympanic recess. Expansion of the middle ear cavity around the ear ossicles occurs late during fetal life, by breakdown of the mesenchyme around the ossicles so that the cavity comes to surround them, except at their attachments to the tympanic membrane and fenestra ovalis (fenestra vestibuli, oval window).

The ectoderm of the pharyngeal clefts and the endoderm of the pouches become increasingly separated by mesenchyme. The blind recesses of the second, third and fourth pouches are prolonged dorsally and ventrally as angular, wing-like diverticula (see Fig. 17.19) and the pouch endoderm thickens and evaginates into localized neural crest-derived mesenchymal condensations. Further development of the second, third and fourth pouches is summarized in Fig. 17.19 and described in the associated text.

FACE, NASAL CAVITIES, PALATE AND MOUTH

Face

By stage 12 migration of the most rostral neural crest cell population is complete and the sequence of morphogenetic changes that will form the face begins (**Fig. 17.11**). Neural crest cells have populated the mandibular arch and its maxillary extension, and formed the frontonasal mesenchyme that covers the telencephalon and caudal diencephalon (see Fig. 17.2). They also contribute to the primordium of the trigeminal nerve, whose first fibres begin to extend at stage 13. The three divisions of the trigeminal nerve will provide sensory innervation to the frontonasal, maxillary and mandibular parts of the face, respectively.

Localized mesenchymal proliferation results in the formation of four paired processes, namely the medial and lateral nasal, maxillary and mandibular processes. The lateral and medial nasal processes surround

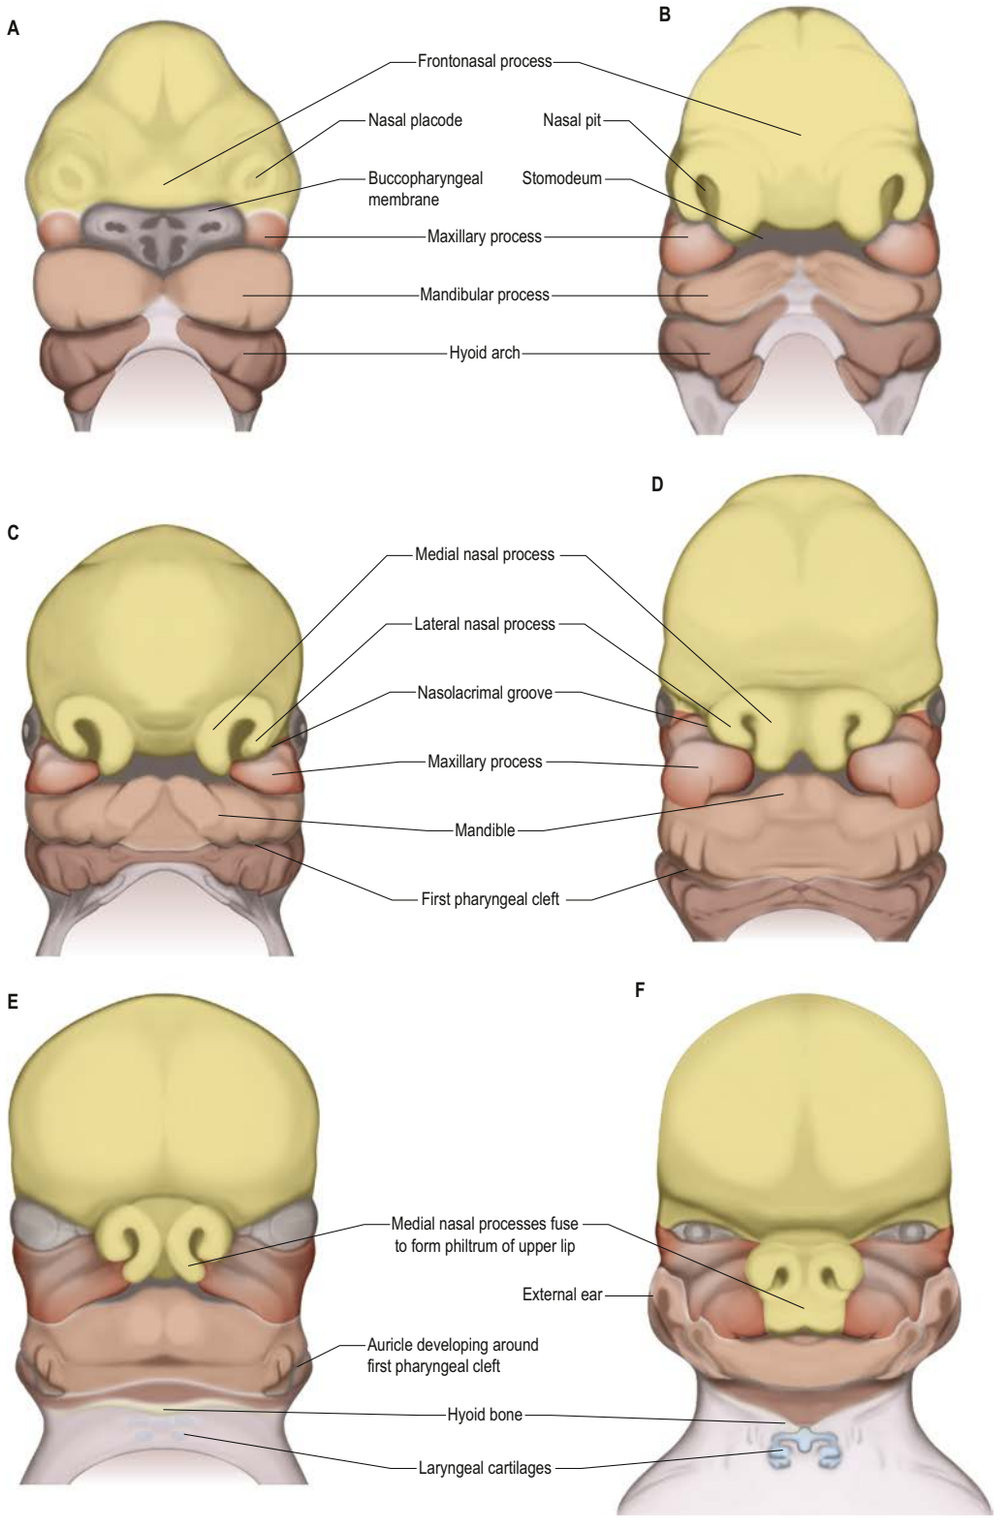

Fig. 17.11 Development of the face: **A**, stage 12–13; **B**, stage 14; **C**, stage 16; **D**, stage 17; **E**, stage 20; **F**, stage 23.

the nasal placodes, causing them to sink deep to the surface, forming the nasal pits. The two medial nasal processes approach each other to form the nasal septum between them and extend downwards to form the premaxillary component of the upper lip and jaw and the primary palate. Concomitant with formation of the nasal processes, proliferation of the maxillary mesenchyme forms the maxillary processes that make contact with the medial and lateral nasal processes at stages 16–17 (see Fig. 17.11). Fusion of the maxillary processes with the medial nasal processes unites the premaxillary and maxillary parts of the upper jaw and lip; failure of this process on one or both sides causes unilateral or bilateral cleft lip (see Fig. 17.18). Superiorly, this fusion closes the cleft at the lower edge of the nasal pits, completing the future nostrils. Fusion of the maxillary with the lateral nasal processes is a much simpler process and rarely gives rise to anomalies. At stage 16 the epithelium of the groove between these fusing processes thickens to form the lacrimal lamina, the primordium of the nasolacrimal system. At stage 19 it separates from the surface ectoderm, forming the lacrimal cord beneath the surface. The cord becomes canalized to form the nasolacrimal duct in postfertilization week 10 (de la Cuadra-Blanco et al 2006). The original site of the lacrimal lamina marks the lateral division between frontonasal and maxillary contributions to the face: the sensory nerve supply of these territories is from the ophthalmic and maxillary divisions of the trigeminal nerve, respectively (**Fig. 17.12**).

At the start of facial development, the stomodeal opening extends across the whole width of the embryonic head. A wide mouth is maintained until differential growth brings the eyes and the lateral parts of the maxillary–mandibular structures from the sides to the front of the face in stages 20–23. Although differential growth makes the mouth opening proportionately smaller, progressive fusion of the lateral regions of the maxillary and mandibular processes also makes an important contribution to decreasing the width of the mouth and to forming the cheeks. Differences in mouth width within the human population are mainly

due to variation in the extent of maxillomandibular fusion. The period from stages 18 to 22 is the final period of major morphogenetic change in facial development. In addition to formation of the mouth and cheeks, it is marked by further narrowing of the nasal region and philtrum, and the ascent of the ears. By stage 19 the face is recognizably human, although differential growth will continue to bring about changes in proportion and the relative position of the features. (For further reading about the genetics of normal-range variation in facial morphology see Indencleef et al (2018), Richmond et al (2018).)

The contribution made by the frontonasal process to surface epithelial derivatives extends from the skin of the forehead, over the supraorbital and glabellar regions, including the upper eyelid and conjunctiva, to the external aspect of the nose and philtrum of the upper lip. During later development, the maxillary nerve invades the skin of the philtrum and nasal alae, so that the trigeminal nerve distribution does not completely coincide with the tissue origins (compare Figs 17.11 and 17.12). A detailed 3D reconstruction of a stage 23 human embryo reported heterochronous skeletal muscle development: genioglossus, hyoglossus and styloglossus and all the extraocular muscles except levator palpebrae superioris were identified (Warmbrunn et al 2018).

Nasal cavities and palate

After formation of the nasal pits, the original olfactory placodal cells lie deep within each pit, adjacent to the underlying telencephalon. They differentiate into olfactory neuroblasts, supporting (sustentacular) cells and stem cells. Neurites begin to extend from the olfactory neuroblasts and reach the olfactory region of the telencephalon by stage 16. The earliest pioneer neurites cross a mesenchyme-filled gap between the placode and the brain. The remaining placodal cells differentiate into columnar supporting cells, rounded basal cells and, by invagination, the duct-lining and secretory acinar cells of the glands of Bowman. Basal infiltration by lymphocytes is a relatively late event.

Once the nasal cavities have formed, the roof of the oral cavity is regarded as the primitive palate (not to be confused with the primary palate, which forms from the most rostral part of the primitive palate). Each nasal cavity has an arcuate shape, extending upwards over the primary palate to the differentiating olfactory epithelium and then down again towards the oral cavity, from which it is separated by an epithelial choanal membrane. Towards the end of stage 18 the choanal membranes degenerate to form internal openings, the choanae, lateral to the primary palate; the nasal cavities are now a duct from the external environment to the oral cavity. Within the nasal cavity, the non-olfactory areas of the ectodermal lining and subjacent mesenchyme differentiate to form the mucous membrane of the nasal vestibule, conchae and paranasal sinuses.

At stage 17 the internal aspect of each maxillary process begins to bulge into the oral cavity as a palatal process; the palatal processes are the primordia of the secondary palate (**Fig. 17.13**). The tongue is well developed by this stage, and its domed form fills the space between the nascent palatal shelves laterally and the primitive palate superiorly. The mandible is still short, relative to the maxillary region, and does not extend as far as the primary palate. Further growth of Meckel's cartilages brings the mandibular region and tongue forwards, extending to a position below the primary palate. At the same time, the palatal processes continue to grow, projecting vertically downwards on either side of the tongue. At stage 23 (postfertilization days 56–58), the tongue descends and the palatal shelves rotate, bringing them to a horizontal position above the tongue (see Fig. 17.13). The rapidity of the process of shelf elevation is caused, at least in part, by swelling of the palatal mesenchyme due to accumulation and hydration of hyaluronan in the extracellular matrix (Ferguson 1991). This occurs during a period of continuous growth in head height but almost no growth in head width. This latter factor is important because, if palatal shelf elevation is delayed so that it occurs during a period of growth in facial width, the unfused processes may be unable to make contact in the midline, resulting in a cleft palate (see Fig. 17.18). Other factors affecting palatal closure include the growth in length of Meckel's cartilages and the change in position of the maxillae relative to the anterior cranial base, both having the effect of lifting the head and upper jaw away from the mandible during postfertilization weeks 9–10, facilitating withdrawal of the tongue from between the palatal shelves and creating space for their elevation. Mouth opening, tongue protrusion and hiccup movements have also been noted at this time, and it may be that these movements and their associated pressure changes assist palatal shelf elevation.

Midline fusion of the two palatal shelves involves adherence and breakdown (by apoptosis) of the apposed epithelial surfaces. The shelves also fuse with the posterior border of the primary palate, except over a small median area, where a nasopalatine canal maintains connection between the nasal and oral cavities for some time and marks the future position of the incisive fossa. During the period of palatal shelf development, a median downgrowth from the primitive palate forms the definitive nasal septum and is supported by cartilage. The fusing medial edges of the elevated palatal shelves also fuse with the free edge of the nasal

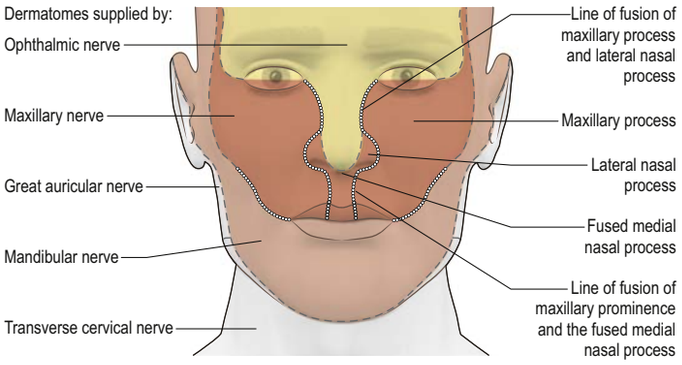

Fig. 17.12 The parts of the adult face derived from the ophthalmic (frontonasal), maxillary and mandibular divisions of the skin of the face, showing the lines of fusion and definitive innervation.

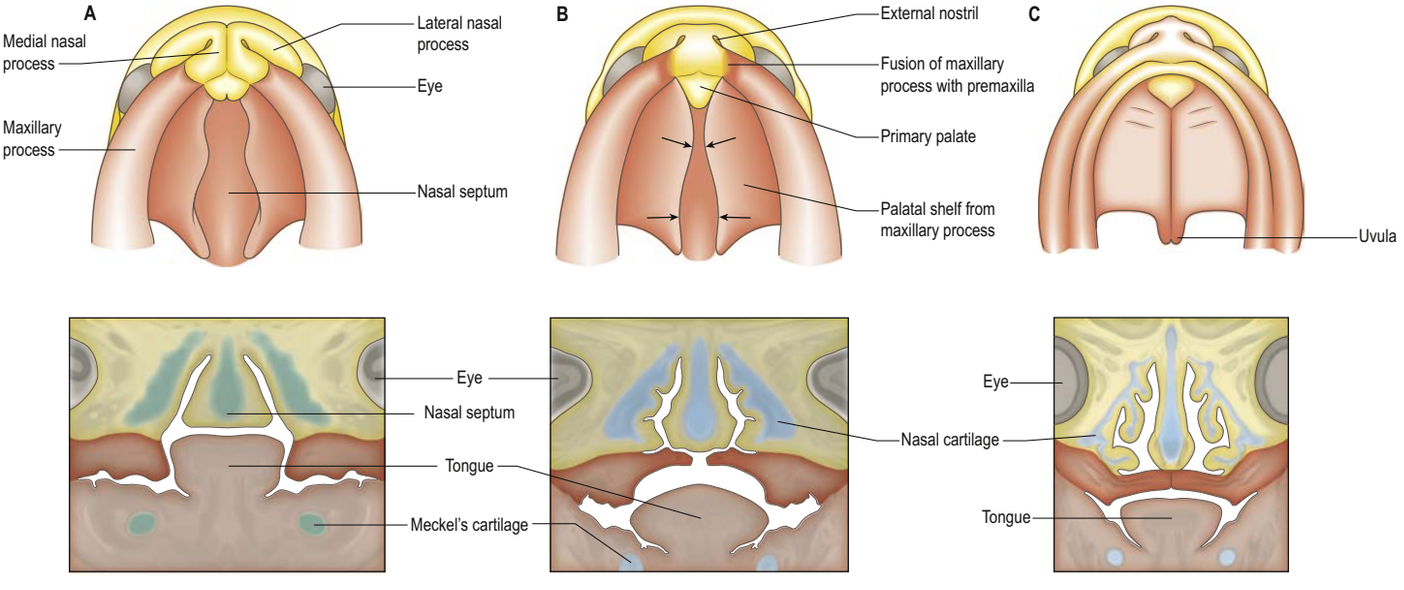

Fig. 17.13 Development of the palate. **A–C**, Developmental progression over stages 18–23; ventral views (top row) and coronal sections (bottom row).

septum, forming separate right and left nasal cavities above the secondary palate. The original positions of the choanae are now covered by the palatal shelves so that the nasal cavities extend from the nostrils to the free (caudal) edge of the palate at the nasopharynx. Bone forms by both intramembranous ossification within the palatal mesenchyme to form the hard palate, except near its caudal border, and by endochondral ossification of the cartilaginous nasal septum. At this time, the free edge of the palatal shelves lies directly below the former position of the attachment of the adenohypophysial (Rathke's) pouch to the roof of the oral cavity. Caudal to the hard palate, its free edges grow to form the soft palate and uvula, which extend into the oropharynx. Myogenic mesenchyme from the first (tensor veli palatini only) and third pharyngeal arches migrates into the soft palate and around the caudal margins of the pharyngotympanic tube. Separation of the definitive nasal and oral cavities is now complete. Three elevations appear on the lateral wall of each nasal cavity: the superior, middle and inferior conchae (see Fig. 17.13). Nasal septal deviation can be identified in the fetus within the second trimester; males are apparently affected more often than females (Salwinski et al 2010). It is thought that the magnitude of nasal septal deviation and the relationship between any septal deviation and the anterior sphenoid body is established by postnatal year 7 (Goergen et al 2017).

On either side of the septal cartilage, a pair of small diverticula, the vomeronasal organs, form at stage 17 within the nasal septum. From postmenstrual weeks 12–19 the vomeronasal organ has an olfactory epithelium-like appearance, with cells termed estheziocytes; luteinizing hormone-releasing hormone (LHRH)-immunoreactive cells are present in nerve fascicles extending from it to the olfactory bulb (Boehm et al 1994). In many species, the vomeronasal organ has a pheromonal communication function; although most adult humans have a vomeronasal organ, its olfactory-type structure and LHRH immunoreactivity are lost during later fetal life and a pheromonal function in adults has not been established (Ch. 39). It has been identified in fetuses in the second trimester and is present in childhood and adult life (Vasuki et al 2016, Stoyanov et al 2018).

Bilateral dorsal expansions of the first and second pharyngeal pouches form the tubotympanic recesses, which will become the tympanic cavities and pharyngotympanic tubes (Ch. 16). A number of focal proliferations of nasopharyngeal endoderm become invaded by lymphoid tissue.

Mouth

The oropharyngeal membrane breaks down at stage 13 and communication is established between the ectoderm-lined (stomodeal) and the endoderm-lined (oropharyngeal) parts of the oral cavity, creating a continuous cranial foregut cavity. Formation of the hard and soft palates separates this area into the nasal cavity and nasopharynx above and the definitive oral cavity below. The oral cavity is demarcated from the oropharynx posteriorly by the oropharyngeal isthmus, which is formed by the free edge of the soft palate and uvula above, and the palatoglossal arch laterally.

Tongue

Because the mandibular arch grows more rapidly than the other arches, it makes the greatest contribution to the pharyngeal floor. By stage 14 three swellings are apparent: a small median elevation, the tuberculum impar or median tongue bud, and paired lateral lingual swellings distally (**Fig. 17.14A**). These three swellings fuse to form the anterior two-thirds (presulcal part) of the tongue (**Fig. 17.14B**). A small median diverticulum, the foramen caecum (thyroid diverticulum), invaginates immediately caudal to the median tongue bud (**Fig. 17.14B-C**; see Fig. 17.19). Caudal to the median tongue bud, a small swelling, the copula, forms in the floor of the second arch. The hypobranchial eminence forms in the floor of the third arch, grows over the second arch (which does not contribute to the tongue) and fuses with the anterior tongue rudiment along a V-shaped line, the sulcus terminalis, at stage 17. Another transverse groove separates the developing tongue from the caudal (fourth arch) swelling that will form the epiglottis. A sulcus forms along the ventral and lateral margins of the developing tongue and deepens, internal to the future dental laminae, to form the linguogingival sulcus (groove) (Fig. 17.14C).

The composite character of the mucous membrane of the tongue is reflected in its sensory innervation. The first arch-derived part is innervated by the lingual branch of the mandibular nerve, and by the chorda tympani of the facial nerve. The third arch-derived part is innervated by the glossopharyngeal nerve, which invades the tissue immediately distal to the sulcus limitans, including innervation of the (cicum)vallate papillae. The vallate papillae begin to differentiate within the mucous membrane at around postmenstrual week 10 and increase in number until the end of the second trimester. The fourth arch-derived root of the tongue, near the epiglottis, is innervated by the vagus. The motor innervation is from the pharyngeal plexus (for palatoglossus) and hypoglossal nerves, which extend around and under the pharynx together with myogenic cells migrating from the occipital myotomes during stages 14–15. Tongue development is morphologically complete by stage 23 but sensory papillae continue to differentiate

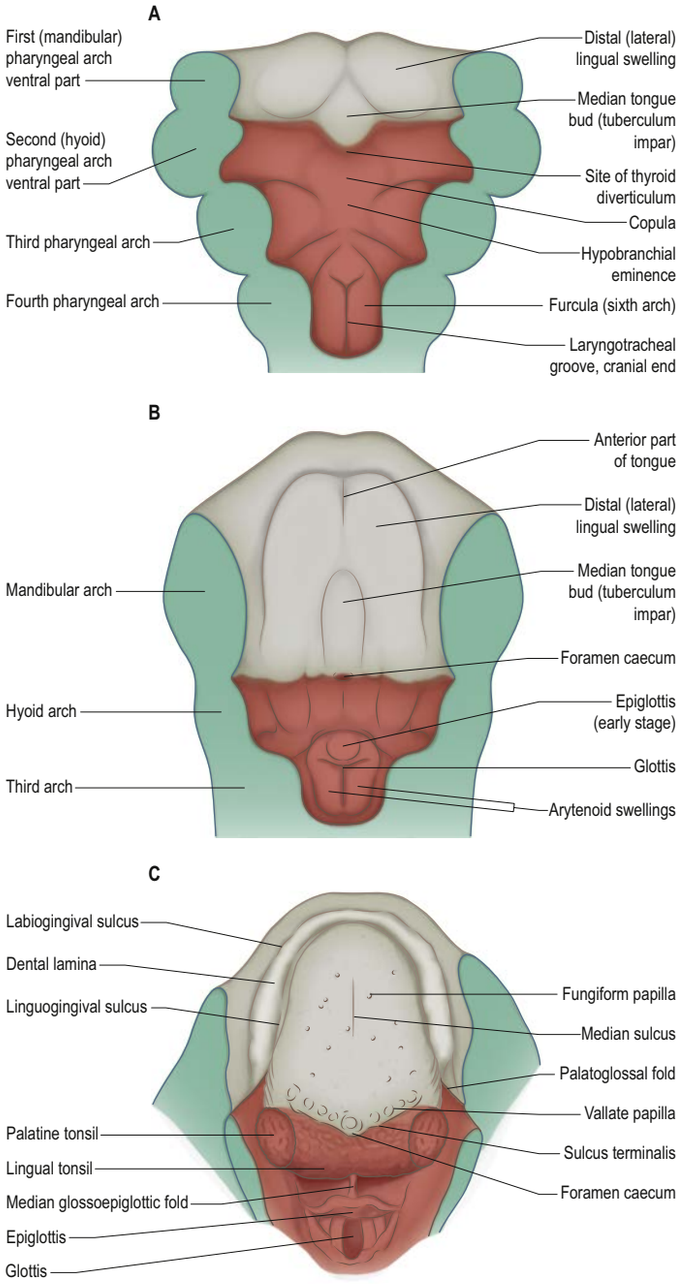

Fig. 17.14 Development of the pharyngeal floor and tongue. **A**, Stage 14, showing median and lateral swellings in the floor of the first arch. **B**, After fusion of the swellings. **C**, The tongue and oropharynx at birth.

Teeth and gingivae

Demarcation of the lips begins after fusion of the facial primordia at stage 18, during the period of secondary palatal development. Two parallel epithelial thickenings, an outer labiogingival lamina and an inner dental lamina, form around the interior border of the mouth in both upper and lower jaws (see Fig. 17.14C). The linguogingival sulcus is formed as an indentation between the dental lamina and the tongue. At stage 22 each labiogingival lamina indents the underlying mesenchyme to form a shallow groove that deepens to form the labiogingival sulcus between the lips and gingivae. Laterally, the epithelial lining of the oral cavity forms the inner aspect of the cheeks.

Tooth formation involves a sequence of reciprocal interactions that are controlled by a large number of genetic factors, mediated by the extracellular matrix components of the mesenchyme and the epithelial basement membrane, including laminin, collagen IV, nidogen and

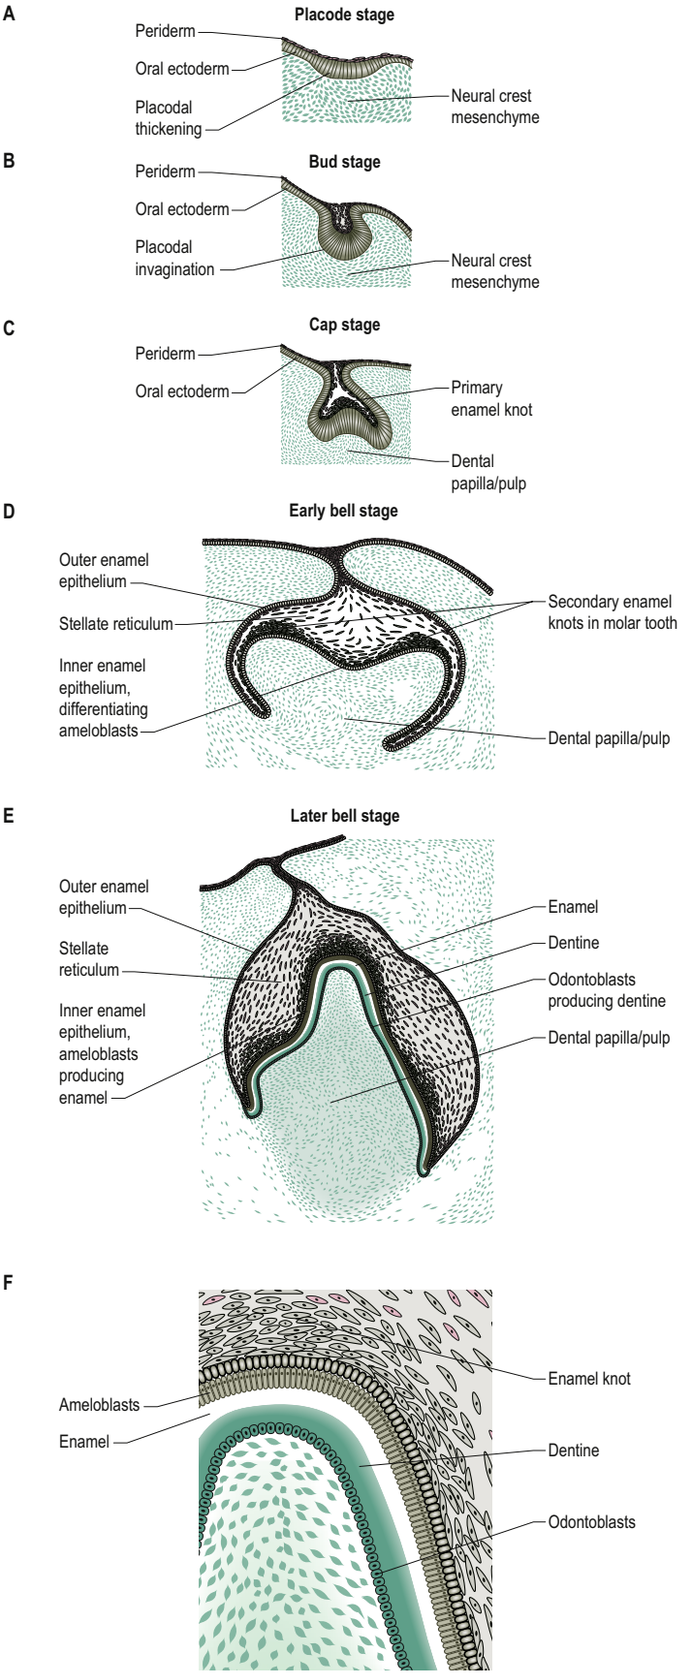

Fig. 17.15 A–E, Stages of tooth development from placodal to late bell stage. **F**, Details of the formation of enamel and dentine by ameloblasts and odontoblasts.

sulphated proteoglycans (Thesleff 2016). During stage 22, 10 localized thickenings of the upper and lower dental laminae, the dental placodes, initiate formation of the dental epithelial components of the tooth primordia (Fig. 17.15A). They expand into dental sacs surrounded by vascular mesenchyme in the bud stage (Fig. 17.15B). The cap stage is formed around postmenstrual week 10, as the basal area of epithelium proliferates to form an enamel knot (Fig. 17.15C). This is the signalling centre that initiates formation of the tooth crown (Jernvall and Thesleff 2012);

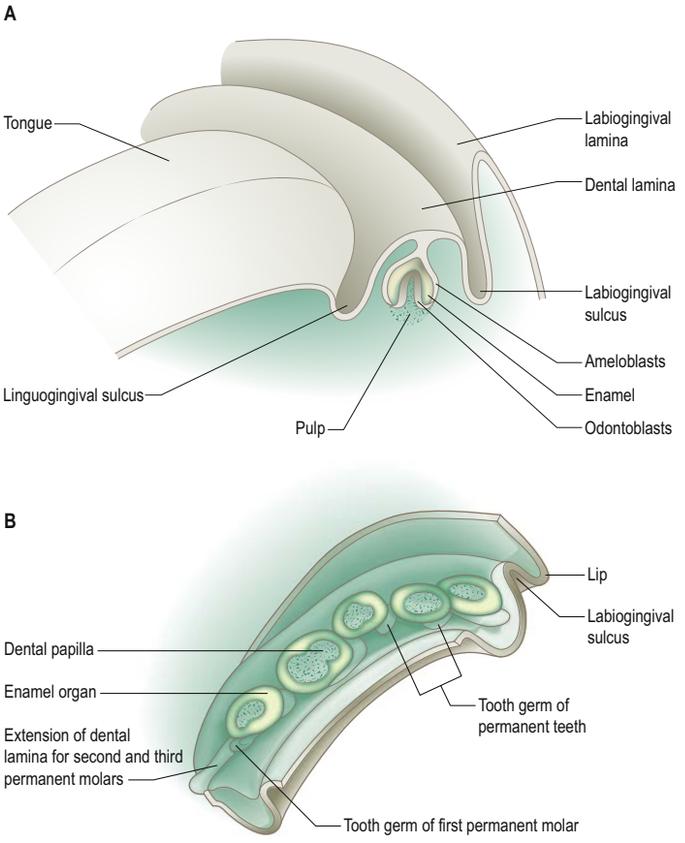

Fig. 17.16 The lip, gums and developing teeth after postmenstrual week 24. **A**, Oral view. **B**, The right half of the lower jaw viewed from below; the midline is upper right.

it overlies a mesenchymal condensation, the dental papilla. Collectively, this unit constitutes a tooth germ and alveolar bone forms the tooth socket around it. The tooth germ becomes bell-shaped as the lateral and basal parts of the sac (inner and outer enamel epithelia) becomes separated by the stellate reticulum, a loose group of cells with a proteoglycan-rich extracellular matrix. The inner enamel epithelium grows rapidly and is already multi-cusped for the premolars and molars (Fig. 17.15D) and single-cusped for the incisors and canines (Fig. 17.15E). During the bell stage, the cells of the inner enamel epithelium differentiate into tall columnar ameloblasts, and the underlying layer of mesenchymal cells differentiates into columnar odontoblasts (Fig. 17.15F). The odontoblasts produce and secrete dentine, which induces the ameloblasts to form enamel that is laid down in successive layers: after mineralization, it is the hardest tissue in the body. Enamel and dentine production from the bell-shaped tooth germ both begin at postmenstrual week 24 (Fig. 17.16). The dental papilla mesenchyme below the odontoblast layer forms the pulp, which becomes vascularized and innervated.

Salivary glands

The salivary glands arise bilaterally as the result of epithelial–mesenchymal interactions between the ectodermal epithelial lining of the stomodeal part of the oral cavity and the subjacent neural crest-derived mesenchyme. The parotid gland can be recognized at stage 15 as an elongated furrow running dorsally from the angle of the mouth between the mandibular and maxillary prominences. The groove, which is converted into a tube and becomes the parotid duct, loses its connection with the epithelium of the oral cavity, except at its ventral end, and extends dorsally into the soft tissue of the cheek. After fusion of the lateral parts of the maxillary and mandibular prominences, the parotid duct opens on the inside of the cheek at some distance from the angle of the mouth. As the gland develops, its branches interweave with branches of the facial nerve; it lies between the masseter and the ear by full-term and extends to cover the parotid duct during early infancy and childhood.

The submandibular and sublingual glands form as solid diverticula that undergo branching morphogenesis, each tree-like structure later acquiring a lumen. The blind ends of the branches form acini, in which cells differentiate to form serous cells initially, and mucus-secreting cells postnatally. The submandibular gland is identifiable at stage 18 as an epithelial diverticulum into the mesenchyme from the floor of the caudal part of the linguogingival sulcus. It increases rapidly in size and

Experimental studies in mice (which have only incisors and molars) have revealed that regional differences in signalling pathways within maxillary and mandibular mesenchyme govern the type of tooth produced (Tummers and Thesleff 2009). Fibronectin is present in the basement membrane of the internal enamel epithelium during the bell phase. It assists attachment of the pre-odontoblasts and is essential for their differentiation and becomes progressively more abundant during the later fetal period. Collagen I is the major supportive extracellular scaffold in the maturing dental papilla and stellate reticulum.

branches several times. At first, the connection of the submandibular gland with the floor of the mouth lies at the side of the tongue, but as the edges of the linguogingival sulcus come together, from behind forwards, they enclose the elongating duct. The orifice of the submandibular duct is thus located progressively more distally until it is below the tip of the tongue, close to the median plane. The sublingual gland arises at stage 20 as a number of small epithelial thickenings within and lateral to the linguogingival sulcus. Each thickening canalizes separately, so multiple sublingual ducts open on the summit of the sublingual fold, while others join the submandibular duct.

The minor salivary glands are distributed throughout the wall of the oral cavity, except for the gingivae and hard palate, and form in a similar manner to the major glands but undergo very little branching and remain within the submucosa.

Lymphoid tissues

Tonsils form at several sites around the oro- and nasopharynx, where focal proliferations of endoderm become invaded by lymphoid tissue. The endodermal epithelial lining grows into the surrounding mesenchyme as a number of solid buds, which are excavated by degeneration and shedding of their central cells, forming tonsillar fossae and crypts. Lymphoid cells accumulate around the crypts at about postmenstrual weeks 17–20 and become grouped as lymphoid follicle in which T- and B-cell regions can be identified. The palatine tonsils develop from the ventral parts of the second pharyngeal pouches (see Fig. 17.4). The slit-like intratonsillar cleft that extends into the upper part of the tonsil is possibly a remnant of the second pharyngeal pouch. Lymphoid tissue similar to that of the palatine tonsils is found in the first pouch (tubal tonsils), the surface of the posterior part of the tongue (lingual tonsils), and in the dorsal pharyngeal wall (adenoid or pharyngeal tonsil).

Anomalies of facial development

Available with the *Gray's Anatomy* e-book

NECK, GLANDS AND PHARYNX

By the time the facial swellings have merged to form a recognizably human face (stage 19), Meckel's cartilage has grown sufficiently to project outwards as a potential chin but the face is still orientated towards, and close to, the cardiac prominence (see Fig. 17.5). By this time formation of the posterior part of the neck is well advanced, with cartilaginous cervical vertebrae, muscles, nerves and blood vessels. The anterior neck forms gradually, as the relatively rapid growth of the anterior structures, including the larynx, trachea, oesophagus, common carotid arteries and jugular veins, takes place. Growth of the anterior neck lifts the head to a forward-facing orientation, simultaneously increasing the angle between the spinal cord and brainstem. Growth of the first pharyngeal arch occurs at a more rapid rate than the lower arches, so that Meckel's cartilage and the developing membrane bone of the mandible project further forwards. The hyoid bone primordium remains small, defining the future angle between the anterior neck and lower jaw. Lateral neck structures develop after the caudal edge of the second pharyngeal arch has fused with the ectoderm over the heart. Myoblasts derived from paraxial mesoderm invade the second pharyngeal arch as it forms and by this stage are present in the superficial connective tissue beneath the anterior neck skin; these spread out from the underside of the chin to the upper thorax and differentiate to form platysma. The muscle maintains the attachment of the skin beneath the lower jaw to the underlying tissues and is the main human remnant of the panniculus carnosus, the subcutaneous muscle that is present throughout the skin of many mammals.

Arch anomalies, predominantly second arch, represent 20% of the neck masses seen in children; remnants of lower pharyngeal clefts are seen in a spectrum of anomalies presenting as branchial cysts, fistulae or sinuses. Fistulae present typically in infants and young children, and cysts in older children and adults. Both first and second cleft anomalies are classified into subtypes; on ultrasound examination they are thin-walled, anechoic and well-circumscribed, and found along the line of the original cleft (Adams et al 2016).

There is much discussion concerning the head–trunk interface and its evolutionary progression and heterochronic development in species used in embryonic research (Commentary 2.1). The exact zones of transition between neural crest, paraxial and somatopleuric-derived mesenchymal populations are not yet established in the human embryo: it is known that zonal delimitation varies between species. The interface between cranial nerve-innervated pharyngeal arch muscles and spinal nerve-innervated trunk muscles occurs at the lower neck and the upper parts of the pectoral girdle. While deep epaxial myotomal populations are clearly derived from somites and remain associated with developing vertebrae, the myotomal populations of the shoulder and lower neck arise from the ventrolateral border of somites adjacent to the limb bud that migrate into the limb and then back to the shoulder and lower neck region (Valasek et al 2011, Mekonen et al 2016) (Chs 18–19). The more superficial muscles of the neck have various origins: parts of splenius, trapezius and sternocleidomastoid are derived from overlapping, undefined interfaces between the various myotomal origins in this region. The local mesenchymal populations that differentiate into endo-, peri- and epimysium, and the boundary zone of the myotendinous junction, as well as entheses and bone precursors, confer patterning information in these regions. Both the proximal and distal connections of trapezius are formed from post-otic neural crest cells, albeit with differences between avian and murine embryos (Matsuoka et al 2005). The neural crest generates areas of endochondral ossification in the cervical vertebral column and scapula associated with trapezius attachment. Defects in the fate choices of neural crest cells might explain a number of syndromes that have pharyngeal, laryngeal, occipital, cervical and shoulder dysmorphologies with co-occurrence of swallowing problems; related syndromes include Klippel–Feil, Sprengel deformity and cleidocranial dysplasia (Matsuoka et al 2005) (Chs 18, 19).

Glands of the neck

Further development of the pharyngeal floor and the second to fourth pharyngeal pouches gives rise to the thyroid gland, and paired palatine tonsils, parathyroid glands and thymus, i.e. glands that are ultimately disposed in the neck and anterior mediastinum.

Thyroid gland

The thyroid gland is a midline derivative of the pharynx. It is first identifiable in stage 11–12 embryos as a median thickening of endoderm lying in the floor of the pharynx between the first and second pharyngeal pouches and immediately dorsal to the aortic sac. The foramen caecum is the site of a median diverticulum that appears in the furrow immediately caudal to the median tongue bud (see Fig. 17.14B–C; **Fig. 17.19**). It extends caudally as the thyroglossal duct, passing ventral to the primordium of the hyoid bone and reaches the rostral border of the aortic sac by stage 15. The tip of the duct bifurcates and the tissue mass subsequently divides to form the isthmus and lateral lobes of the thyroid gland. The endoderm-derived epithelial tissue is invested by vagal neural crest mesenchyme, which gives rise to the connective tissue capsule and interlobular septa, and perifollicular mesenchyme, which carries the neurovascular and lymphatic supply to the gland. The gland has three stages of development: Stage 1 (postmenstrual weeks 10–18) is characterized by active folliculogenesis and gradual accumulation of colloid, into which the follicular cells release thyroglobulin, the substrate for tyrosine iodination and subsequent synthesis of the thyroid hormones T_4 and T_3. Stage 2 (postmenstrual weeks 18–29) is quiescent, with little change in the epithelium:colloid ratio and follicular size. Stage 3 (after postmenstrual week 29) is characterized by a gradual increase in the epithelium:colloid ratio and a decrease in follicular size (Bocian-Sobkowska et al 1997). This suggests that stimulation of the gland by pituitary-derived thyrotropin (TSH) is enhanced in the third trimester. T_4 is present at low levels from postmenstrual weeks 10–22, and increases during postmenstrual weeks 22–40. Normograms of fetal thyroid size from ultrasound examination between postmenstrual weeks 14–38 have been correlated to skull biparietal diameter (Gietka-Czernal et al 2012).

Failure of downgrowth of all or part of the thyroid gland from the pharyngeal floor results in ectopic thyroid tissue within the tongue (lingual thyroid), between the foramen caecum and the epiglottis. Occasionally, parts of the midline thyroglossal duct persist and may occur in lingual, suprahyoid, retrohyoid or infrahyoid positions; they may form aberrant masses of thyroid tissue, cysts, fistulae or sinuses, usually in the midline. Nodules of glandular tissue may also be found laterally, posterior to sternocleidomastoid.

Parathyroid glands

The parathyroid glands develop from interactions between the third and fourth pharyngeal pouch endoderm and local neural crest mesenchyme. Each third pharyngeal pouch has dorsal and ventral sites of proliferation (see Fig. 17.19B). The epithelium on the dorsal aspect of the pouch and the region of its duct-like connection with the cavity of

Malformations involving the neural crest

Congenital malformations of the face may be initiated early, mainly related to abnormal migration, proliferation and/or apoptosis of neural crest cells, or later, during the morphogenetic phase of facial development. Craniofrontonasal syndrome is characterized by a broad forehead and hypertelorism, premature fusion of one or both coronal sutures, a central nasal groove, and sometimes cleft lip and palate; there are also extracranial features. It is caused by deletions of the gene *EFNB1*, which is known to play essential roles in boundary formation between tissues, including those between neural crest and adjacent non-crest cells (Twigg et al 2004). Mandibulofacial dysostosis (Treacher Collins syndrome) is characterized by incomplete orbits, reduced jaws and auditory ossicles (hence conductive deafness), abnormal external ears and fistulae or cysts, suggesting involvement of the first and second arch components of the cranial neural crest. It is caused by haploinsufficiency of the gene *TCOF1*. Hemifacial microsomia (Goldenhaar's syndrome) affects only one side of the face and comprises a small mandible (sometimes with absence of the temporomandibular joint), malformed or absent ears with accessory ear tags, and facial clefts. Experimental evidence in animals suggests that it is due to haemorrhage of the stapedial artery, which may have a genetic basis. Deficient growth of the mandible (micrognathia) is usually associated with other defects. In Pierre Robin sequence (**Fig. 17.17**), the small size of the mandible obstructs descent of the tongue, resulting in a U-shaped cleft palate; a conotruncal septum defect is present in one-quarter of cases, suggesting possible involvement of the cardiac neural crest. The condition is usually an isolated genetic occurrence but can be inherited as an autosomal dominant trait and can occur as part of syndromes such as Stickler, CHARGE and velo-cardio-facial syndrome (Morice et al 2018). Further details and references for facial malformations may be found in Morriss-Kay and Wilkie (2005), Hennekam et al (2010) and Evans et al (2018).

Clefts of the face and palate

Cleft lip occurs when one or both medial nasal processes fail to fuse with the corresponding maxillary process(es). The severity of clefting varies from a small notch in the upper lip to a double cleft extending into both nostrils (**Fig. 17.18A–D**). In a unilateral cleft lip, the nasal septum deviates to the non-cleft side. This is because the muscles on the medial side of the cleft (transverse muscles of the nose and orbicularis oris) are not inserted into either the muscles of the contralateral side (Fig. 17.18B). The three functional groups of superficial facial muscles – nasolabial (transverse nasalis, levator labii superioris and levator labii superioris alaeque nasi), bilabial (orbicularis oris) and labiomental (depressor anguli oris) – are all displaced inferiorly. A further consequence is the underdevelopment of the incisor-bearing part of the maxilla. These abnormalities in turn influence the mucocutaneous tissues, resulting in the displacement of the skin of the nostril to the upper part of the lip, retraction of the labial skin and anomalies of the soft tissues on either side of the mucocutaneous junction.

A narrow or incomplete cleft of the hard palate is likely to be due to a growth defect in the palatal shelves and/or a delay in shelf elevation, and/or to failure of fusion of the apposed palatal shelves. Broader clefts (**Figs 17.18D–E**), in which the tongue lies between the still-vertical shelves, are caused by a greater developmental delay that may be associated with abnormality of other structures in the face and elsewhere in the body. In the mildest forms of cleft palate, only the soft palate, and sometimes just the uvula, is cleft (**Fig. 17.18F**). A submucous cleft, which may be detected as a median V-shaped notch of the soft palate, can cause speech difficulties. Very rarely, muscle hypoplasia, particularly of the musculus uvulae, causes palatopharyngeal incompetence.

Cleft lip with or without cleft palate (CL/P) is multigenic or multifactorial in origin, i.e. it has both genetic and environmental components (Hennekam et al 2010). CL/P has a frequency of 0.5–3.6/1000 live births, with a 2 : 1 male to female ratio. Isolated cleft palate is genetically unrelated to CL/P, and has a frequency of 0.4/1000; it is more common in females. Clefts of the face are rare (1/50,000–1/175,000 births) and are mainly caused by pressure from amniotic bands rather than from dysmorphogenesis, although a morphogenetic component cannot be ruled out when the cleft is along a line of fusion, e.g. maxillary–mandibular. Median cleft lip (true hare lip) is also rare, because this is not a line of morphogenetic fusion. Median grooving of the nose occurs with hypertelorism in various frontonasal dysplasias, suggesting a developmentally early broadening of the median region of the face.

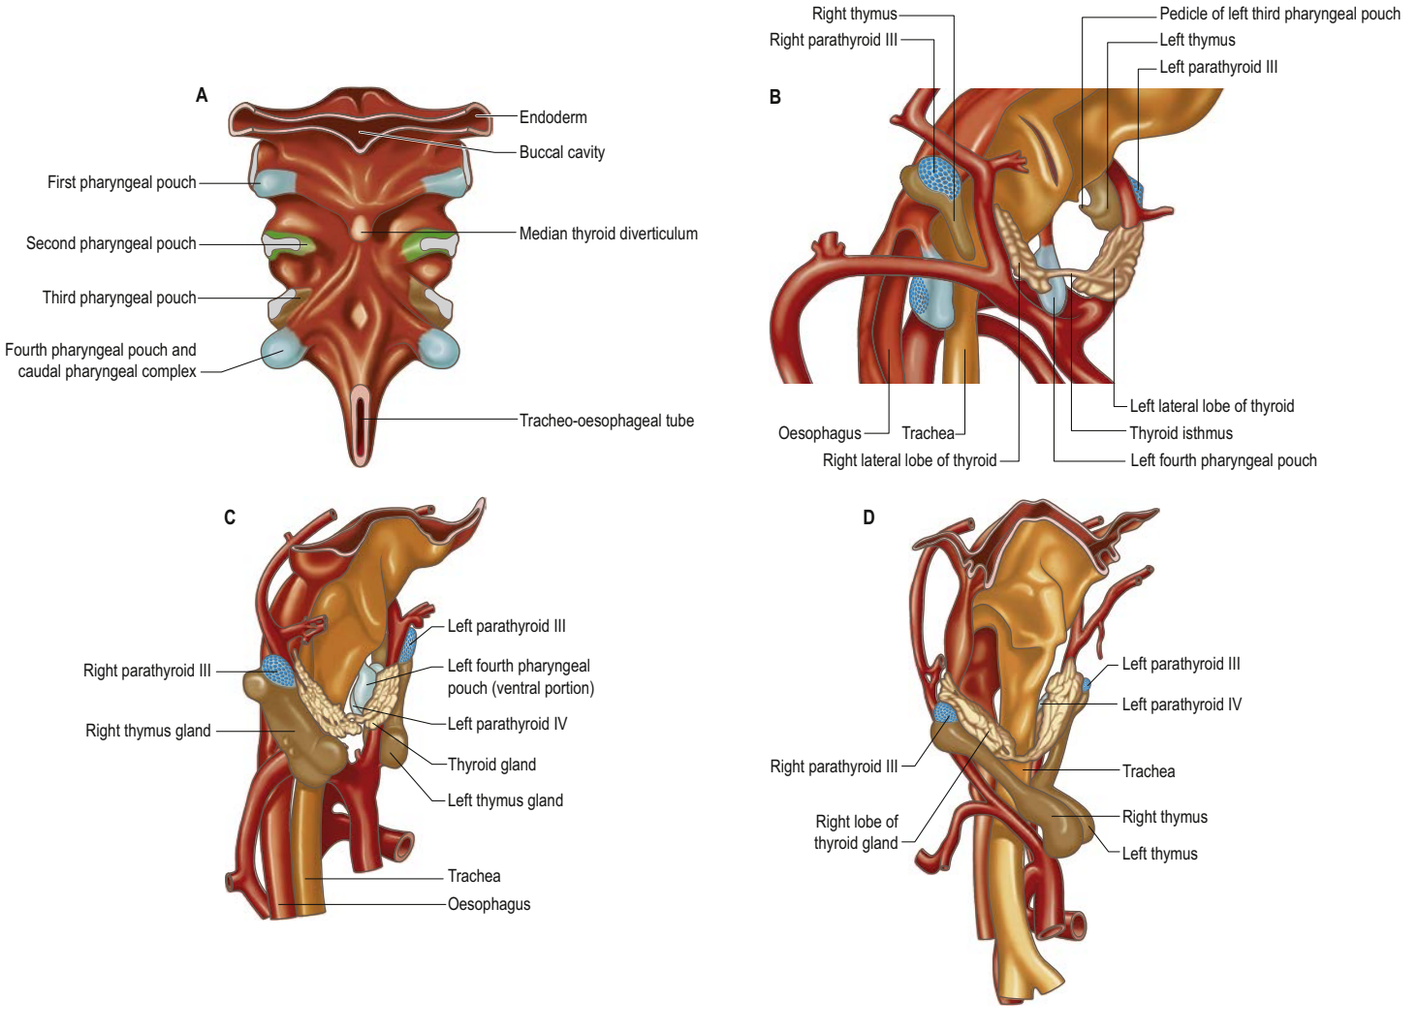

Fig. 17.19 **A**, The ventral aspect of the endoderm of the pharynx, showing the pharyngeal pouches. The areas of contact of the pharyngeal endoderm with the surface ectoderm are shown as flattened surfaces. Note that the colours of the pharyngeal pouches and the median thyroid diverticulum are retained in **B**, **C** and **D**. **B**, Ventral and dorsal diverticuli of the third and fourth pharyngeal pouches and midline thyroid gland at stage 16–17. **C**, The thymus, thyroid and parathyroid glands at stage 18–19. **D**, The thymus, thyroid and parathyroid glands at about stage 21. (Redrawn with permission from Hamilton WJ, Boyd JD, Mossman HW 1962 Human Embryology: Prenatal Development of Form and Function. Cambridge: Heffer.)

the pharynx becomes differentiated as the primordium of the inferior parathyroid gland (parathyroid III). Although the connection between the pouch and the pharynx is soon lost, the connection between the dorsal parathyroid and the ventral thymic rudiment of the third pharyngeal pouch persists for some time and both descend (move caudally). The superior parathyroid glands (parathyroid IV) develop from the dorsal recess of the right and left fourth pharyngeal pouches. They make contact with, and appear to be anchored by, the lateral lobes of the thyroid gland and thus remain cranial to the descended parathyroid III glands. Vagal neural crest mesenchyme provides the connective tissue elements, and invading angiogenic mesenchyme gives rise to fenestrated capillaries and lymphatics.

Thymus

The thymus gland plays a pivotal role in the development of immunological competence. It is formed from the ventral part of the third pharyngeal pouch on each side (see Fig. 17.19). It cannot be recognized prior to the differentiation of the inferior parathyroid glands at stage 16, but thereafter it is represented by two elongated diverticula that soon become solid cellular masses and grow caudally into the surrounding vagal neural crest mesenchyme. Ventral to the aortic sac, the two thymic rudiments meet but do not fuse, and they are subsequently united only by connective tissue. The thymus gland becomes located in the anterior mediastinum of the thorax once the neck is fully developed and the heart has descended (see Fig. 23.14A, J, K). The connection with the third pouch is soon lost, but the stalk may persist for some time as a solid, cellular cord.

As the thymus proliferates and descends, the local neural crest-derived mesenchyme controls the pattern and development of the gland. Defective development of the vagal neural crest, which affects the heart and peripheral neural ganglia, also results in thymic deficiencies, as seen in DiGeorge syndrome and Pierre Robin sequence. Neural crest mesenchyme forms connective tissue septa that produce the lobulated architecture of the gland (Hutchins et al 2018). Angiogenic mesenchyme, including lymphoid stem cells, invades this local mesenchyme, and by postmenstrual week 10 more than 95% of the cells in the gland belong to the T-cell lineage, with a few erythroblasts and B lymphocytes. Hassall's corpuscles are also present. By postmenstrual week 12 the mesenchymal septa, blood vessels and nerves have reached the newly differentiating medulla, which allows the entry of macrophage lineage precursors. Macrophages and interdigitating cells are first seen at postmenstrual week 14. Granulopoiesis occurs in the perivascular spaces. By postmenstrual week 17 the thymus appears fully differentiated. After this time, it produces the main type of thymocyte that is present throughout life (designated TdT^+). The fetal thymus shows linear growth between postmenstrual weeks 23 and 37, correlated to estimated fetal weight. Cord blood collected at term delivery indicates higher levels of regulatory T lymphocytes (Treg cells) in fetuses showing reduced thymus growth or low fetal weight; preterm infants have higher percentages of Treg cells in cord blood. It is suggested that reduced fetal thymus growth is compensated by increased release of Treg cells to ensure suppression of autoreactivity and anti-maternal immunity (Diemert et al 2016). The gland begins to atrophy shortly after puberty.

Caudal pharyngeal complex

The most caudal endodermal evaginations of the pharynx are the fourth pharyngeal pouch and the ultimobranchial body, a small diverticulum medial to the main pouch. Collectively, these diverticula are termed the

caudal pharyngeal complex (see Fig. 17.19), and they are connected to the pharynx via the pharyngobranchial duct. They are surrounded by vagal neural crest and by the tissues of the developing thyroid gland. The cells of the ultimobranchial body become incorporated into the lateral thyroid lobes and give rise to the calcitonin-secreting 'C' or parafollicular cells of the thyroid gland. Parafollicular cells are seen singly early in the second trimester, and mostly in an intrafollicular position by the end of the trimester (Das et al 2017).

Pharynx, larynx, trachea and oesophagus

In human embryos, the hyoid bone is formed from five cell populations: the distal ends of mesenchymal condensations recognized as future second and third pharyngeal arch cartilages and a solitary midline condensation of mesenchyme (de Bakker et al 2018). This mesenchymal condensation forms a cylindrical structure and differentiates into cartilage between stages 15 and 20, which is earlier than cartilage formation in the distal parts of the arch cartilage anlagen. It has been suggested that the midline mesenchymal population arises from cells in the hypobranchial eminence or copula, which would mean that the body of the hyoid bone in human embryos is not derived from a pharyngeal arch cartilage (Rodríguez-Vázquez et al 2011).

Reichert's cartilage undergoes chondrogenesis only at its longer proximal (cranial) styloid segment continuous with the otic capsule, and at a distal segment in contact with the midline hyoid condensation; its intervening portion is always mesenchymal (Rodríguez-Vázquez et al 2006). The stylohyoid ligament does not arise from a cartilage anlage (Rodríguez-Vázquez et al 2015).

Chondrogenesis occurs in the proximal part of the second arch in stage 18, when the precursors of stylopharyngeus, stylohyoid and styloglossus (the three muscles that are attached to the styloid process) appear. During this stage the external carotid artery is forming between the cartilage and stylohyoid. Chondrogenesis is seen in the distal segment in stage 21, and by postfertilization week 10 the adjoining mesenchyme between the proximal and distal segments disappears, coinciding with a decrease in neck flexion and the growth of facial structures (Rodriguez-Vázquez et al 2015).

The larynx forms at the cranial end of the laryngotracheal groove, caudal to the epiglottis (see Figs 17.5–17.6, 17.14). The thyroid cartilage appears as two lateral plates, each chondrified from two centres and united in the mid-ventral line by a fibrous membrane, within which an additional centre of chondrification develops. Fourth and sixth arch cartilages have not been detected in human embryos: the thyroid and cricoid cartilages are derived from ventral mesenchymal condensations in the neck (de Bakker et al 2018).

The cricoid cartilage arises at stage 20 from two centres that soon unite ventrally, gradually extend, and ultimately fuse on the dorsal surface of the tube as the cricoid lamina, with the appearance of a modified tracheal cartilage. Paired arytenoid swellings appear within the ventral tissue of the sixth arches from stage 22, one on each side of the cranial end of the laryngotracheal groove. As they enlarge, they approximate to each other and to the caudal part of the hypobranchial eminence, where the epiglottis develops. The opening into the larynx, at first a simple slit, is converted into a T-shaped cleft by the enlargement of the arytenoid swellings. The vertical limb of the T lies between the two swellings with its horizontal limb lying between the swellings and the epiglottis. The arytenoid swellings differentiate into the arytenoid and corniculate cartilages (see Fig. 17.6), and the ridges that join them to the epiglottis become the definitive aryepiglottic folds, within which the cuneiform cartilages differentiate from the epiglottis.

The lower part of the larynx, the trachea, bronchi and lungs develop from the laryngotracheal groove (Ch. 20). This groove forms at stage 12 between two ridges extending from the floor of the caudal part of the pharynx into the mesenchyme surrounding the sinus venosus and inflow tract of the heart (see Figs 13.1C, 21.2B). Formation of the groove initiates separation of the respiratory and alimentary tubes. It remains at a constant level during the embryonic period, and the trachea lengthens distally as its bifurcation point descends. The splanchnopleuric mesoderm that surrounds the developing trachea and oesophagus induces the different histogenic pathways of the two tubes. By stage 22 the mesenchyme around the trachea is beginning to undergo chondrogenesis at regular intervals to form C-shaped cartilages whereas the mesenchyme around the oesophagus has a wide submucosal zone and muscular coats. The respiratory diverticulum becomes surrounded by angiogenic mesenchyme that forms the pulmonary blood vessels and connects to the developing sixth aortic arch artery (Chs 13, 20). Continued dorsal, sagittal connection between the enteric gut and respiratory airway, laryngo-tracheo-oesophageal cleft, is a rare anomaly that may be fatal; there may be clefting of the cricoid cartilage and along the thoracic trachea to the carina (Leboulanger and Garabédian 2011). Tracheo-oesophageal fistulae are considered in Chapter 20. For further details of tracheal development see Chapter 20, for early development of the oesophagus see Chapter 21.

MENINGES AND VENOUS SINUSES

The meninges may be divided in development into the pachymeninx (dura mater) and leptomeninges (arachnoid mater, subarachnoid space with arachnoid cells and fibres, and pia mater). The cells forming the meningeal layers originate from mesenchyme in the trunk and caudal regions of the head, and from neural crest in regions rostral to the mesencephalon. They form a loose mesenchyme, traditionally termed meninx primitiva, or primary meninx, that surrounds the early developing neural tube. (For a detailed account of the development of the meninges in the human, consult O'Rahilly and Müller (1986).)

Those mesenchymal populations projecting from the rostral end of the notochord, and those in the region of the prechordal plate, extend rostrally into the mesencephalic flexure and form the earliest cells of the tentorium cerebelli and the dura of the future chondrocranial skull base by stage 19. The medial part of the tentorium becomes thinner and disappears, leaving an incomplete partition that separates a subarachnoid area containing the telencephalon and diencephalon from one containing the cerebellum and rhombencephalon. The precursors of the venous sinuses are also present by stage 19, and the region of the future falx cerebri is seen by stage 20, although the dorsal regions of the brain are not yet covered with putative meninges. By stage 23 the dura is almost complete over the rhombencephalon and mesencephalon but is only present laterally around the telencephalon. Subarachnoid spaces and most of the cisternae are present from this time, after the arachnoid mater becomes separated from the primitive dura mater by the accumulation of cerebrospinal fluid (which now has a net movement out of the ventricular system).

The differentiation of the skull and meninges is closely associated with the development of venous channels returning blood from around the early brain and influences the final disposition and drainage routes of the venous plexuses that form bilateral primary head veins. Superficial venous channels draining the ectoderm and outer leptomeninges gain confluence with developing radicles that will ultimately drain into the external jugular venous complex. Deeper venous plexuses lateral to the brain coalesce to form anterior, middle and posterior dural stems that join the primary head vein (see Fig. 17.10). The anterior stem drains the prosencephalon and mesencephalon, and enters the primary head vein rostral to the trigeminal ganglion. The middle stem drains the metencephalon and empties into the primary head vein caudal to the trigeminal ganglion (V) and rostral to the root of the facial nerve (VII). The posterior stem drains the myelencephalon and enters caudal to the vagus nerve (X) where the primary head vein is confluent with the precardinal vein. It should be noted that the superficial venous channels retain some connections with the deeper meningeal venous channels during development, and become emissary veins.

Bilateral growth and expansion of the telencephalon gives rise to the growing cerebral hemisphere. Venous plexuses drain into networks of capillary venules along the dorsal margins of the anterior and middle dural stems and into a sagittal plexus in the position of the future falx cerebri. Rostrodorsally the sagittal plexus forms the superior sagittal sinus and ventrally it forms the inferior sagittal and straight sinuses and part of the great cerebral vein; drainage is commonly into the left transverse sinus. The convex surface of the cerebral hemispheres and the ventral aspect of the diencephalon are drained along the ventrolateral edge by a transitory tentorial sinus, to the transverse sinus. With growth of the temporal lobe, the tentorial sinus becomes elongated and attenuated, eventually disappearing; its territory is drained by enlarging anastomoses of pial vessels that become the basal veins, radicles of the great cerebral vein.

Changes to the early anterior dural stem as a consequence of early bilateral telencephalic enlargement leads to retention of the rostral part of the primary head vein medial to the trigeminal ganglion, the dwindling caudal part of which becomes the inferior petrosal sinus. The anterior dural stem receives the primitive maxillary vein which becomes the main trunk of the primitive supraorbital vein and is the superior ophthalmic vein in the adult.

The middle dural stem enlarges as the pro-otic sinus and receives the main venous drainage of the orbit and its contents and drains into the forming transverse sinus, and at a later stage, into the cavernous sinus. The cavernous sinus is formed from a secondary plexus derived from the primary head vein and lies between the otic and basioccipital

cartilages. This plexus also gives rise to the inferior petrosal sinus which drains through the primordial hindbrain channel into the internal jugular vein. The superior petrosal sinus arises later from a ventral metencephalic tributary of the pro-otic sinus and communicates secondarily with the cavernous sinus. The pro-otic sinus, meanwhile, has developed a new and more caudally situated stem, the petrosquamosal sinus, which drains into the sigmoid sinus. With progressive ossification of the skull, the pro-otic sinus becomes diploic.

The development of the venous drainage and portal system of the hypophysis cerebri is closely associated with that of the venous sinuses.

SKULL

The skull has two major functional and anatomical components: the neurocranium and the viscerocranium. The neurocranium is composed of the calvaria and basicranium; it surrounds and protects the brain and the special sense organs of olfaction, vision, hearing and balance. The viscerocranium forms the skeleton of the face, palate and pharynx, and mediates the functions of feeding, breathing and facial expression; it also protects the tongue and forms the middle ear and the bony external acoustic meatus.

A conceptual plan of the skull base, viewed superiorly and laterally, and its relation to the mesenchymal condensations of the future pharyngeal arch cartilages, aids understanding of the development of the foramina at the base of the skull and the position of the cranial nerves (**Fig. 17.20**). The dorsoventral disposition of this region is shown in sagittal section in Fig. 17.22A. The position of the notochord can be seen in both figures. Adjacent to the notochord on each side paraxial mesenchymal extends laterally to the otic capsules. Rostrally the notochord ends at the site of the neurohypophsial outgrowth, caudally it is incorporated into the upper cervical vertebrae. Rostral to cartilaginous condensations around the adeno- and neurohypophyses, skull base mesoderm supports the enlarging eyes and developing olfactory structures. The cranial nerves can be enumerated rostrally from the hypoglossal canal. The position of the developing internal carotid artery and the divisions of the trigeminal nerve and nerves to the extraocular muscles can be seen between portions of the developing sphenoid bone. A lateral view of the skull base with the neural crest mesenchymal condensations forming the pharyngeal arches reveals the juxtaposition of the first and second arch condensations (producing the incus, malleus and stapes) with the otic capsule and indicates the future relationship of the developing middle ear ossicles.

The most rostral neural crest cell population makes a major contribution to the skull, forming the whole viscerocranium and the rostral part of the neurocranium (**Fig. 17.21**). The boundary between neural crest and cranial mesenchyme lies between the frontal and parietal bones (coronal suture) of the calvaria. The skull base is formed by neural crest rostral to the tip of the notochord, and is sclerotome-derived (i.e. from paraxial mesenchyme) in the notochordal region (McBratney-Owen et al 2008). The tip of the notochord lies immediately caudal to the hypophysial fossa (**Fig. 17.22A**). Broadly speaking, the bones of the skull base are formed by endochondral ossification (chondrocranium), whereas those of the calvaria and face ossify directly from mesenchymal condensations, i.e. by intramembranous ossification. The occipital, temporal and sphenoid bones and the mandible are of compound structure with respect to their tissue origins and/or type of ossification. The following account is based largely on descriptive studies on human embryos and fetuses (O'Rahilly and Müller 1987, 2001, 2007), together with details of cell lineage based on investigations in the mouse.

Chondrocranium

The first cranial skeletal structures to differentiate are the cartilages of the skull base, sensory capsules, viscerocranium and occiput (see Figs 17.5, 17.22). Development of the pharyngeal arch-related cartilages of the viscerocranium and ear ossicles is described in Chapter 16. Before any mesenchyme condenses to initiate the formation of cranial cartilage, the major cranial nerves and blood vessels are already in place, suggesting that the foramina of the skull base are specified before the bones are formed. Observations in chick embryos have demonstrated that the presence of these structures inhibits condensation and chondrogenesis of the surrounding mesenchyme, leading to the formation of foramina (Akbareian et al 2015). The adenohypophysial (Rathke's) pouch is still connected to the roof of the oral cavity as the skull base cartilage forms (dashed lines in **Fig. 17.22A**). The notochordal sheath is rich in sulphated glycosaminoglycans, which play a role in inducing condensation and chondrification of the occipital sclerotome-derived mesenchyme around it.

Intramembranous bones are shown in cream. Cranial nerves are indicated by the appropriate Roman numeral. **A**, A sagittal section through the cranial end of the developing axial skeleton at about stage 16, showing the extent of the notochord. **B**, The superior aspect of the skull base at about postmenstrual week 11. **C**, The lateral aspect of **B**. **D**, The lateral aspect of the cranium at about postmenstrual week 14.

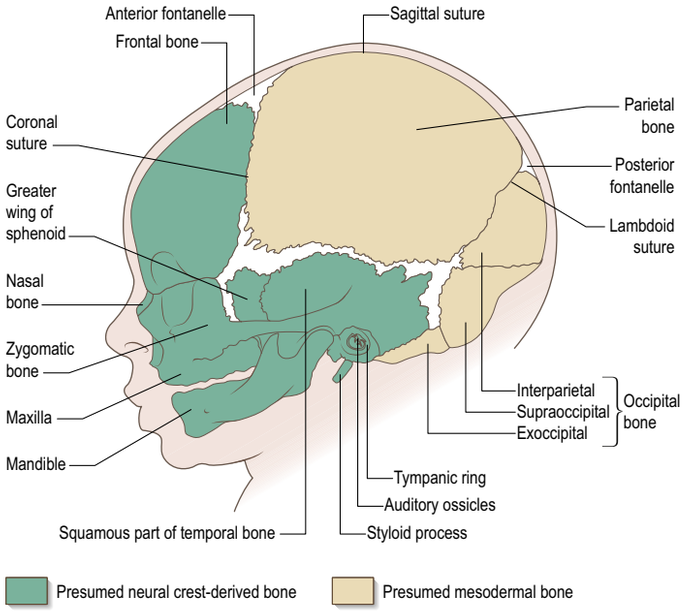

Fig. 17.21 The newborn skull, showing the presumed tissue origins of the bones (based on combined mouse and human data).

The structures referred to in the following account are illustrated in Fig. 17.22, which shows the cartilaginous skull base at about postmenstrual week 11. The central regions of all four occipital sclerotomes contribute to the parachordal cartilage, which surrounds the notochord and extends as a flat plate on either side of it by the end of the stage 20, forming the basioccipital component of the occipital bone (see also Fig. 18.13). Laterally, the exoccipital components (derived from sclerotomes 3 and 4) chondrify soon afterwards. They extend around the hindbrain to form the occipital arch, which is developmentally equivalent to the neural arch components of vertebrae. Roots of the hypoglossal nerve run between the parachordal and exoccipital cartilages, so that when the exoccipital and parachordal components fuse, they leave foramina for these nerve roots (see Figs 17.22B, 18.12). The supraoccipital part of the occipital cartilage extends dorsally from the exoccipital cartilage to complete the foramen magnum. Further development of the occipitocervical junction is considered in Chapter 18 and formation and ossification of the occipital bone is considered in Bernard et al (2015).

After formation of the exoccipital cartilages, differentiation also extends further rostrally in the medial part of the skull base, with formation of the hypophysial cartilages on either side of the hypophysial stalk. They unite in the median plane to form the primordium of the postsphenoid cartilage, cradling the hypophysis and retaining a perforation for the hypophysial stalk until postmenstrual weeks 10–12. This part of the basisphenoid cartilage will form the sella turcica and hypophysial fossa with the rostral presphenoid cartilages forming the jugum of the sphenoid body. This is the last part of the medial part of the skull base to differentiate as cartilage, bridging the gap between the postsphenoid and the nasal capsule.

At stage 17 mesenchyme begins to condense and later to chondrify around the nasal pits, forming the outer part of the nasal capsule and the nasal septum. The roof of each nasal capsule is completed slightly later, when cartilage differentiates around the olfactory nerve bundles (as they extend from the nasal placode-derived olfactory epithelium) to form the cribriform plates of the ethmoid bone. During postmenstrual weeks 9–12 cartilaginous conchae form. The whole nasal capsule is well developed by the end of postmenstrual week 12, and consists of a common median septal part, sometimes initially termed the interorbitonasal septum or mesethmoid, and the outer ectethmoid. The conchae ossify during postmenstrual weeks 17–20; the superior and middle conchae form part of the ethmoid bone, and the inferior pair become separate elements. Each lateral part of the nasal capsule becomes ossified as the orbital plate and ethmoidal labyrinth, with spaces ('cells') that communicate with the nasal cavity and become filled with air after birth (see Ch. 39). Part of the capsule remains cartilaginous as the septal and alar cartilages of the nose, and part is replaced by the intramembranous vomer and nasal bones.

Orbital cartilages surround the eye but do not undergo ossification in their entirety. The most rostral of them becomes continuous with the presphenoid cartilage by differentiation of a cartilaginous bridge that forms the caudal boundary of the optic foramen, enclosing the optic nerve; this later ossifies to form the lesser wing of the sphenoid bone (orbitosphenoid). The greater wing of the sphenoid (alisphenoid) has both intramembranous and endochondral components; the endochondral part initially differentiates as a cartilage surrounding the mandibular branch of the trigeminal nerve, forming the foramen ovale. This condensation extends medially to join the rostral edge of the hypophysial cartilage on each side. It also extends rostrally to surround the maxillary branch of the trigeminal nerve, forming the foramen rotundum. It extends laterally to join the intramembranous part of the bone, which replaces the caudal part of the orbital cartilage. The greater and lesser wings of the sphenoid are separated by the oculomotor, trochlear and abducens nerves and by the first (ophthalmic) division of the trigeminal nerve.

The otic capsule differentiates from a mesenchymal condensation around the otocyst, after its morphogenesis to form the cochlea and semicircular canals. Differentiation of cartilage begins laterally, at the same time as the hypophysial cartilages are first detectable and is complete by stage 20. Chondrogenesis around the point of exit of the vestibulocochlear nerve creates the internal acoustic meatus. Chondrogenesis of mesenchyme around the carotid arteries joins each hypophysial cartilage to the otic capsule, forming the carotid canals. A gap occupied by the jugular vein and the glossopharyngeal, vagus and accessory nerves remains between each otic capsule and the parachordal cartilage and becomes the jugular foramen. Chondrogenesis of the mesenchyme between the separate cartilages completes formation of the cartilaginous skull base and sensory capsules, which together form a continuous framework around the pre-existing blood vessels and cranial nerves by postmenstrual week 11 (see Fig. 17.22).

Establishing the dates of ossification, endochondral or intramembranous, in fetuses is not straightforward. At the transition time, when an embryo at the end of stage 23 (postfertilization days 53–58, or postfertilization weeks 8–9, see Fig. 23.3) becomes a fetus, the same age is then expressed from the date of the maternal last menstrual period, as postmenstrual weeks 10–11. Many schemes are used to age fetuses and it is not always clear what anthropometric units have been correlated to estimate an age given as postmenstrual weeks. Crown rump length is still used, although O'Rahilly and Müller (1999) recommended a move to greatest length; some studies age fetuses by femur length or foot length, but studies correlating these measurements to fetal age are limited. Variation of growth rate during the fetal period and differences in maternal ethnicity, height and weight affect fetal size. In this text, the postmenstrual age of fetuses based on publications has been carefully reviewed and crown rump length has been converted to postmenstrual weeks based on the fetal growth charts of Papageorghiou et al (2014) (see Chapter 23). For these reasons the age of appearance of ossification centres are estimations only. The process of endochondral ossification in the skull is essentially the same as that of the long bones, except that each ossification centre is equivalent to a primary centre, and follows a specific programme of growth and patterning. Growth takes place within synchondroses, the cartilaginous areas between adjacent ossification centres. The first ossification centres to appear are those of the lesser and greater wings of the sphenoid, at postfertilization weeks 8 and 9, respectively. A single basisphenoid ossification centre appears at postmenstrual week 11; three presphenoid and four postsphenoid ossification centres appear at postmenstrual week 16. Bone replaces most of the cartilage until only the major synchondroses remain; these enable the endochondral skull base and sensory capsules to continue growing until they reach their final size at puberty or earlier. At birth, unossified chondrocranium persists in the alae, lateral nasal cartilage and septum of the nose, the sphenoethmoidal junction, the spheno-occipital and sphenopetrous junctions, the apex of the petrous temporal bone (foramen lacerum), and between ossification centres of the sphenoid and occipital bones. As indicated above, parts of the chondrocranium do not ossify, but are replaced by adjacent intramembranous bone, e.g. the greater wing of the sphenoid (alisphenoid). In general, endochondral ossification centres form later than intramembranous ossification sites, which first appear after stage 19.

Calvaria

The bones of the calvaria (roof and lateral walls of the neurocranium) are formed entirely by intramembranous ossification. They are also described as dermal bones, since they are considered to be the evolutionary descendants of dermal plates formed as a protective cover for the brain in fish. In humans, as in all mammals, the major part of the calvaria is formed by paired frontal and parietal bones and the

unpaired interparietal (membranous part of the occipital bone). The squamous part of the temporal bones and the alisphenoids contribute to the lateral walls. Lineage data from mouse studies indicate that the frontal bones abutting at the metopic suture, and the squamous temporal bones are of neural crest origin; the parietals are of paraxial origin; and the interparietal is mixed (Jiang et al 2002). The coronal suture forms at the neural crest/paraxial mesodermal interface, as does the sagittal suture, due to a small tongue of neural crest-derived tissue lying between the two developing bones. These tissue interfaces are significant for initiating the molecular signalling system that governs growth of the calvaria. Growth at the borders of adjacent bones, i.e. in the sutures, is the major mechanism of calvarial growth. The presence of fetal dura is not required for initial suture morphogenesis, which appears to be controlled by mesenchymal cell proliferation and fibrous extracellular matrix synthesis induced by the overlapping of the advancing osteo-inductive fronts of the calvarial bones. It is thought that a signal is transferred to the underlying dura that induces changes in localized regions beneath the sutures. Once a suture has formed, it serves as a primary site for cranial bone growth and constant interaction with the dura is required to avoid ossiferous obliteration (Opperman 2000). A sequence of events that maintains a balance between cell proliferation and osteogenic differentiation is mediated by an intercellular signalling system that includes the transcription factor TWIST and ligand–receptor interactions between fibroblast growth factors (FGFs) and their receptors (FGFRs). Mutations in the genes encoding these proteins cause premature fusion of the cranial sutures (craniosynostosis), which results in deficient growth in the plane perpendicular to the suture (**Fig. 17.23**; Morriss-Kay and Wilkie 2005, Twigg and Wilkie 2015). Mutations in an increasingly large number of skull development-related genes have been identified in a quarter of craniosynostosis cases (Wilkie et al 2017). In addition to the expansion-related growth that takes place in the sutures, appositional growth, where bone is laid down on, and resorbed from, the bone surfaces, plays an important role in remodelling the calvarial bones to maintain a degree of curvature that matches the curved surface of the growing brain. Appositional growth can also provide some compensatory expansion of the skull in craniosynostosis (see Fig. 17.23).

The frontal and parietal bones are initiated as basolateral mesenchymal primordia, that extend upwards between the dermal connective tissue and the mesenchymal dura mater. They do not, as previously thought, differentiate within the mesenchyme of an 'ectomeninx' that surrounds the brain. As the frontal and then the parietal primordia extend upwards, the differentiating osteoblasts secrete osteoid, which then undergoes mineralization. Only the mineralized parts of the bones are detected in alizarin-stained specimens and ultrasound scans. Clear frontal bone primordia are detectable in the superciliary arch region of alizarin-stained human embryos by postfertilization week 8. As they become mineralized above this level, the parietal bone primordia can also be seen. The two bones appear to be separated by a wide gap at the coronal suture, but this gap only shows the separation of the mineralized parts of the bone and the unmineralized edge of the parietal bone actually overlaps the caudal edge of the frontal bone. After the upgrowth phase, mineralization takes place centrifugally from the central points of the frontal and parietal bones, which, by this time, form convex plates over the curvature of the underlying brain (see Fig. 17.22D).

The interparietal bone (supranuchal squamous portion of the occipital bone) forms from two ossification centres that appear by stage 23. These are considered to be homologous with the paired postparietal bones of reptiles. The fact that they unite to form a single bone in mammals may be due to the interpolation of a small area of neural crest that migrates from the hindbrain after neural tube closure (Jiang et al 2002). Two further ossification centres develop laterally at postmenstrual week 12. A wide gap initially occupied by cartilage between the interparietal and parietal bones disappears as the membrane bones grow towards each other, forming the lambdoid suture when they abut. The lambdoid suture contributes growth to the caudal border of the parietal bones and to the upper part of the occipital bone. Synostosis of this suture is relatively rare (fewer than 5% of craniosynostosis cases) and has a less severe effect on overall skull growth than coronal and median fusions. Between the interparietal bone and the foramen magnum, the calvaria is completed by endochondral ossification of the supraoccipital component of the occipital bone.

In addition to the sutures that are formed where two membrane bones abut, fontanelles are formed where three or four bones meet. In the median plane, these are the anterior fontanelle, at the junction of the metopic and sagittal sutures, and the posterior fontanelle, at the junction of the sagittal and lambdoid sutures. The anterolateral fontanelle lies between the frontal, parietal, greater wing of the sphenoid and squamous temporal bones: after closure its site is the pterion. The posterolateral fontanelle lies between the parietal, petrous temporal, exoccipital and basioccipital bones; after closure, its site is the asterion. The size of the fontanelles at birth, and the timing of their closure, are highly variable. Delayed growth of the skull bones causes ossification defects, including cranium bifidum and parietal foramina, for which several genetic defects have been identified. Cleidocranial dysplasia is a defect of ossification affecting the intramembranous part of the clavicle as well as the calvaria and is caused by haploinsufficiency of the bone master gene *RUNX2*.

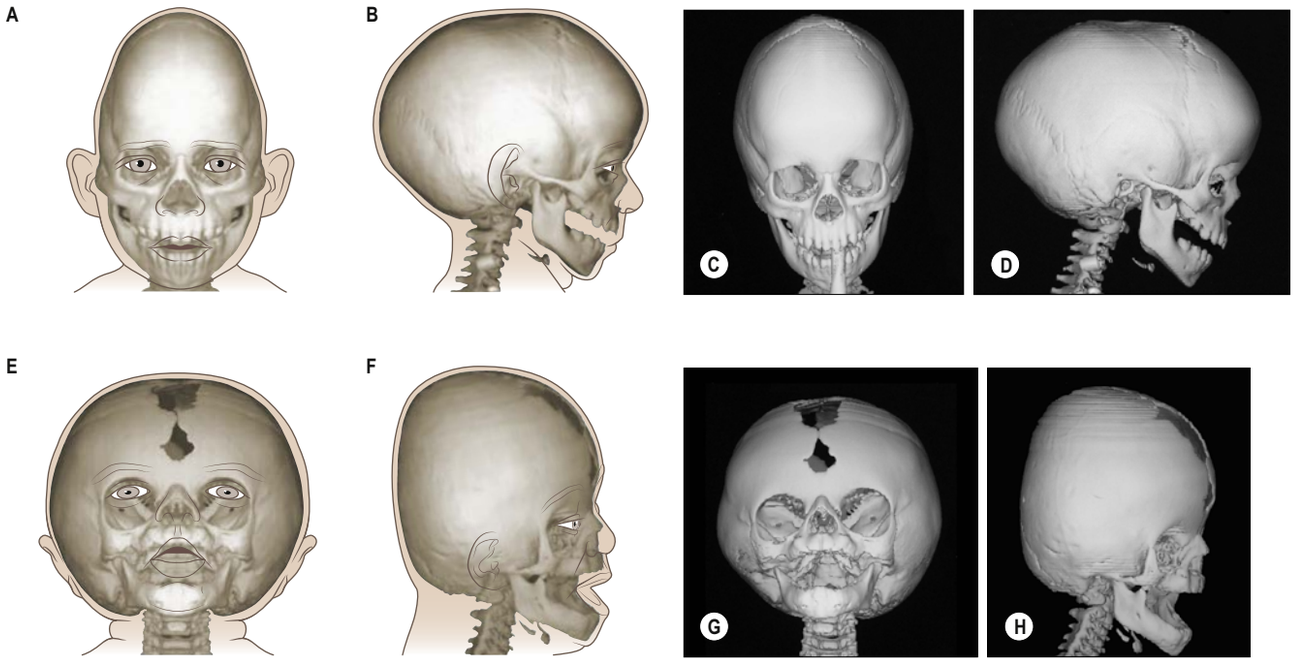

Fig. 17.23 Craniosynostosis. **A–B**, Line drawings of frontal and lateral views of sagittal synostosis. **C–D**, Three-dimensional computed tomography (3D-CT) scans. Premature fusion of the sagittal suture has restricted growth in breadth of the skull but there is compensatory growth in the fronto-occipital plane. **E–F**, Line drawings of frontal and lateral views of bicoronal synostosis. **G–H**, 3D-CT scans. Premature fusion of both coronal sutures has restricted growth in the fronto-occipital plane but there is compensatory growth in breadth. The pairs of CT scans are not from the same patients as those indicated in the line drawings; the endotracheal tube has been digitally removed from **D**. (CT scans courtesy of P Anslow.)

Membrane bones of the face and viscerocranium

The face and viscerocranium are formed from neural crest-derived membrane bones. From forehead to chin the facial skeleton includes the frontal, lacrimal and zygomatic and nasal bones and the vomer, maxilla and mandible. The maxilla and mandible form from first arch mesenchyme, as do the medial pterygoid plates of the sphenoid bone, the palatine and the tympanic bones.

During migration, the trigeminal neural crest cells divide into a frontonasal population that migrates superior to the eye and comes to surround the telencephalon and part of the diencephalon, a mandibular population that migrates into the first pharyngeal arch, and a maxillary population that forms the maxillary swelling (see Fig. 17.2). The frontal, lacrimal, nasal bones, the vomer and the premaxillary (incisor tooth-bearing) part of the maxilla are derived from the frontonasal mesenchyme; the maxilla and zygomatic bone are derived from the maxillary mesenchyme; and the mandible and tympanic ring are derived from the mandibular mesenchyme. The maxilla and premaxilla have primary ossification centres by stages 19–20, and three further ossification centres (orbitonasal, nasopalatine and zygomatic) form in the maxillary mesenchyme around stage 23. These components fuse to form a single bone in humans, in contrast to some mammals, in which the incisor-bearing premaxillary part remains separate. By stage 23 ossification centres for most of the facial and viscerocranial bones are present, except for the tympanic ring, for which four ossification centres appear at about postmenstrual week 14. They fuse to form the sickle-shaped bone that supports the tympanic membrane (see Fig. 17.6).

The mandible is the first membrane bone to begin ossification and its single ossification centre appears in stages 18–20. It is a developmentally complex bone. Although the body of the bone is formed by intramembranous ossification adjacent to Meckel's cartilage, the coronoid region and condyle are formed by endochondral ossification in cartilage that develops after formation of the membrane bone. These secondary ossification centres form between postmenstrual weeks 10–14. Distal cartilage forms two further secondary ossification centres, the mental ossicles between postmenstrual weeks 25 and 28. This complex system enables the mandible to grow at both proximal and distal ends, analogous to a long bone.

The temporomandibular joint forms later than other diarthrodial joints. Mesenchymal condensations of the mandibular condyle and zygomatic process of the squamous part of the temporal bone are present between stages 21–23. Joint capsule development begins at this stage; the inferior joint cavity appears at the end of postfertilization week 9, when the articular disc can be seen and chondrogenesis commences in the mandibular condyle. The superior joint cavity is seen from postfertilization week 11. Buccal movements, seen from postfertilization weeks 7–8, are thought to be important for the development of the joint. The posterior region of the joint is associated with the tympanosquamosal fissure; Meckel's cartilage, the discomalleolar ligament, chorda tympani nerve and anterior tympanic blood vessels pass through it. Intramembranous ossification of the area of insertion of lateral pterygoid begins during postmenstrual week 13 and endochondral ossification of the condylar cartilage is seen from postmenstrual week 17 (Carvalho de Moraes et al 2015).

Antenatal ultrasound imaging of the head and neck

The fetal head appears oval on transthalamic and transventricular planes and is symmetric and broader posteriorly (see Fig. 23.5). Biparietal skull diameter, taken through a plane of section that traverses the third ventricle and thalami, is the most accurate index of fetal age and the expected date of delivery and is routinely measured between postmenstrual weeks 15–28. Head circumference, measured through a plane that traverses the third ventricle and thalami plus the cavum septi pellucidi anteriorly and the tentorial hiatus posteriorly, is routinely measured and used to estimate pre- and post-term head growth (see Fig. 23.5). The size of the cisterna magna can be estimated to note hypoplasia of the posterior fossa of the skull. Increased thickness of the nuchal tissues at the back of the neck, measured from the outer edge of the occipital bone to the outer skin edge, is part of screening for Down's syndrome (Nafziger and Vilensky 2014). Nuchal translucency is increased in a number of trisomies and in fetuses with congenital heart defects (Chen 2010). The causes of this are complex and include an increase in hyaluronic acid in the extracellular matrix in the nuchal skin folds, aberrant jugular lymphatic flow and disturbed venous–lymphatic differentiation leading to local oedema (de Mooij et al 2010).

Prenatal diagnosis of asymmetric craniosynostosis and of craniofacial syndrome has been reported. Ultrasound evaluation of facial structures is possible by postmenstrual weeks 16–17. Standard facial views can visualize orbital size and position, eye size and nasal hypoplasia. Routine ultrasound has identified 93% of cases of cleft lip and palate, 67% of isolated cleft lip and 22% of cleft palate only (Evans et al 2018). Anomalies of the fetal neck are uncommon.

Based on a 13-year cohort of patients, this study considers the extent to which identified genetic causes of craniosynostosis can contribute to genetic counselling.

Yoshida T, Vivatbutsiri P, Morriss-Kay G et al 2008 Cell lineage in mammalian craniofacial mesenchyme. Mech Dev 125:797–808.

The availability of a mesoderm cell marker here demonstrates the completely complementary distribution of mesoderm and neural crest-derived cell populations in the mouse skull. Angiogenic and myogenic mesenchymal markers further show that these populations invade neural crest areas at early stages.

During vaginal birth, the overlap of the frontal and parietal bones enables them to slide over each other at the coronal suture. During the neonatal period, when the baby cries and intracranial pressure rises, the overlapping bones slide apart, increasing the fronto-occipital diameter of the skull. Growth at the coronal suture provides the major increase in the fronto-occipital plane of the calvaria. Premature synostosis of the coronal sutures restricts growth in this plane, causing brachycephaly; unilateral coronal synostosis leads to plagiocephaly, in which one side of the skull fails to grow in the fronto-occipital plane. Uni- and bilateral coronal synostosis comprises 20–25% of all forms of craniosynostosis.

Postnatal growth of the skull is characterized by changing proportions of its components and the extremely rapid growth of the brain in the first 2 postnatal years. The metopic and sagittal sutures are formed when the upwardly extending frontal and parietal bones, respectively, abut in the median plane. Growth within these sutures increases the breadth of the skull. The timing of fusion of the metopic suture is variable, but is complete by the end of the first year in most infants. Premature fusion of the sagittal suture results in the formation of a narrow, elongated skull. Sagittal synostosis is the most common form of craniosynostosis (40–55%). The sagittal suture continues as an active growth centre until puberty, with remodelling of the frontal bones mediated by appositional growth.

The paranasal sinuses begin to form in late fetal life as diverticula from the nasal cavity that gradually invade the maxilla, frontal, ethmoid and sphenoid bones. At birth, small ethmoidal and maxillary sinuses are present and become pneumatized during the first postnatal month; pneumatization of the sphenoid bone begins around postnatal month 4. The frontal sinus remains an out-pouching from the nasal cavity to term delivery, developing over the first 2 postnatal years; it is fully pneumatized by 14–15 years (Ma et al 2013). Thickening of the skull bones is accompanied by increasing size of the sinuses, and by a change in form of the sutures, from straight to wavy lines and, finally, to the complex interdigitations seen in the adult. After growth ceases, the skull sutures contain inert connective tissue and some cartilage; in old age, some of them are completely replaced by bone (natural synostosis).

The inner ear and the temporal bone grow very little after birth, so the increasing breadth of the skull draws the petrous temporal bone out laterally, creating the bony external acoustic meatus. The tympanic ring (with the tympanic membrane) lies at the surface of the meatus in the neonatal skull and remains at the proximal (inner) end of the deepening canal. The squamous temporal bone increases in size so that it contributes a greater proportion of the calvaria at puberty and in the adult than in the neonate (**Fig. 17.24**). By postnatal year 2 the mastoid process of the temporal bone has developed air-filled spaces (mastoid air cells) that are continuous with the middle ear cavity.

The suture between the primary (premaxilla-derived) and secondary parts of the palate is still patent in the neonate and there is a steady increase in maxillary volume postnatally, to accommodate the development and eruption of the permanent dentition (Langford et al 2003). At full-term birth, each quadrant of the jaws has five unerupted deciduous teeth and the germs of the first five permanent teeth. Permanent teeth develop in accessional positions from the lingual aspects of the deciduous tooth germs and, for the 12 permanent molar teeth, from posterior extensions of the dental laminae on each side of both jaws (see Fig. 17.16). Mineralization begins in both deciduous and permanent teeth before birth. The deciduous teeth have well-developed crowns by full term: eruption through the gingivae usually begins with the lower incisors between postnatal months 3–6. After eruption, the gingivae remain attached to the neck of each tooth by the upper part of the periodontal ligament, while the major part of the ligament attaches the tooth root to the bone of the tooth socket. The type of transition to extrauterine life is permanently recorded in the primary teeth and can be reliably demonstrated in forensic dental identification. The circadian growth rhythm of dentine and enamel deposition in tooth germs is temporarily blocked by the metabolic stress of delivery; the resultant change in enamel prism deposition is seen as a neonatal line or ring that can be detected in all deciduous teeth and permanent first molar teeth of live births. The thickness of the line is related to birth difficulties, being thinner in caesarean section and thicker in vaginal delivery (Sabel et al 2008, Canturk et al 2014).

During the first 5 years there is as much anteroposterior as vertical growth of the maxilla, after which there is relatively more vertical growth. Growth of the face occurs in the sutures between the membrane bones in a similar manner to that of the calvarial sutures. Postnatally, the face grows more rapidly than the calvaria, in contrast to the fetal period during which rapid growth of the brain has a dominant influence on regional skull growth. Habitual mouth breathing due to nasal obstruction may cause variable adaptation of facial muscles leading to anomalous maxillary or mandibular growth in children; lower anterior facial height (philtrum to midline mandibular distance), is greater in mouth breathers, in whom the mandible may be smaller with less rotation (Souki et al 2012).

In the full-term neonate there is no space between the hard palate and the tongue when the mouth is closed, which means that the entire surface of the neonatal tongue, which is short and broad, lies within the oral cavity. The oropharynx and nasopharynx join without any sharp junctional demarcation to a pharynx that is one-third of the relative length seen in the adult. By 5 years of age an oblique angle is formed at this junction, and in the adult, the nasopharynx and oropharynx join at almost a right-angle. The hyoid bone and larynx are initially relatively high and the epiglottis may extend above the soft palate with the laryngeal airway in directly continuous with the posterior nares (see Fig. 40.11). The hyoid bone and larynx descend during the first postnatal year and by the fourth or fifth year, form part of the anterior wall of the oropharynx (see Fig. 23.15). The anatomical arrangement of the laryngeal structures enables the infant to breathe while suckling, as milk passes on either side of the laryngeal opening to reach the oesophagus (see Fig. 40.12).

During breastfeeding, three oral spaces are identified, a median space between the tongue and hard palate occupied by the nipple when suckling and which bifurcates posteriorly to produce channels on each side of the soft palate and epiglottis, and two lateral spaces, the lateral arcuate cavities, that are formed between the tongue and cheeks. The upper and lower gingivae within these spaces do not touch during suckling. The hard palate is only slightly arched and its mucous membrane is corrugated by five or six irregular transverse folds (rugae) that assist with gripping the nipple. Each cheek is supported by a mass of subcutaneous fat, the suctorial pad, that lies between buccinator and masseter. Studies on the biomechanical processes of milk extraction during breastfeeding have shown that balanced postnatal muscular development is promoted by forward movement of the mandible and raising and lowering the tongue. Tongue movements can generate vacuum pressures of some −145 mmHg: tongue lowering decreases the pressure. In bottle feeding the main action the infant uses is sucking and the tongue only controls the milk outlet through bilateral contraction of buccinator. Children who have never breastfed have a greater prevalence of posterior cross bite in both mixed and permanent dentition and of abnormal swallowing patterns and mouth breathing (which may also have compromised occlusal development) than children who

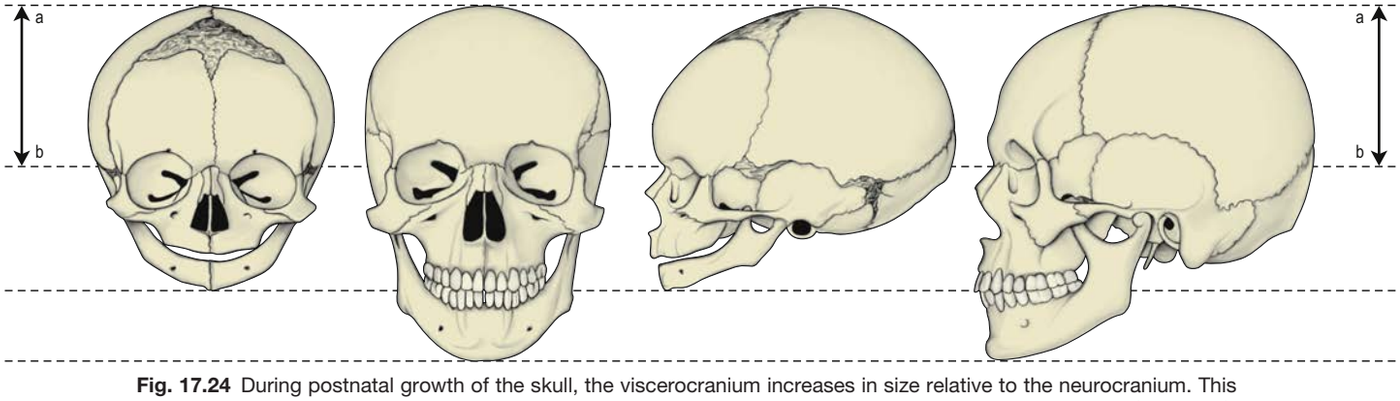

Fig. 17.24 During postnatal growth of the skull, the viscerocranium increases in size relative to the neurocranium. This diagram shows that, with the height of the cranial vault expressed as similar in newborn and adult skulls (lines a↔b), the facial skeleton increases particularly rapidly during childhood and puberty.

have breastfed for more than 6 months postnatally (Chen et al 2015, Boronat-Catalá et al 2017). Preterm infants have poor suck–swallow–breathe coordination and an inability to generate adequate vacuum strength (Geddes et al 2017).

Non-nutritive sucking does not appear to act in synergy with breastfeeding to promote malocclusion. It is seen as early at postmenstrual weeks 13–16 and considered a normal part of fetal and neonatal development. A sucking reflex remains to 12 postnatal months after which time the infant has learned to feed (Feştilă et al 2014). Infantile swallowing, with the jaws apart and lip musculature forming a tight contact around the mother's breast, is different to the adult swallowing pattern with the lips relaxed, teeth together and the tongue against the hard palate. The transition from infant to adult swallowing is usually present by 9–10 years; it is never achieved by 10–15% of the population (Feştilă et al 2014).

Structures that descend to the mediastinum are considered in Chapter 20. Within the neck in the full-term neonate, the trachea is relatively small in relation to the larynx; it has thicker walls and cartilage plates that are relatively closer together than in the adult. It commences at the upper border of the sixth cervical vertebra, a relationship that is conserved with growth. It bifurcates at the level of the thoracic vertebrae 3 or 4, descending to lie level with the upper border of the thoracic vertebra 5 in the adult (endotracheal intubation in the neonate is described in Chapter 20). In extremely preterm infants, later phonation and voice quality appears to be affected by supraglottic hyperfunction, a secondary response to structural laryngeal pathology caused by neonatal intubation (Reynolds et al 2016). The prevalence of voice anomalies is reported to be above 50% in children intubated for longer than 28 days in the neonatal period (Hseu et al 2018).

The thyroid gland is relatively large in the neonate, where it has a long, narrow isthmus connecting lobes that do not yet contact the upper part of the trachea. Thyroid volume at birth varies due to variations in maternal iodine intake; the volume is lower at postmenstrual week 36, in preterm infants delivered before postmenstrual week 28, than in infants delivered at full term (Ng et al 2018). It usually attains half the adult size by 2 years of age. The parathyroid glands are as variable in size and position as they are in the adult. They double in size between birth and puberty. Parathyroid hormone (parathormone, PTH) is produced from postmenstrual week 12. It is essential for calcium homeostasis and is involved in the remodelling of growing bones.

The oesophagus begins and ends one to two vertebral levels higher than in the adult, extending from between the fourth and sixth cervical vertebrae to the level of the ninth thoracic vertebra. The narrowest constriction is at its junction with the pharynx, where the inferior pharyngeal constrictor constricts the lumen; in this region there is a risk it may be traumatized with medical instruments or catheters. The pharyngo-oesophageal phase of swallowing is controlled by multiple afferent and efferent cranial nerves, excitatory and inhibitory neurones and central pattern generators. In the preterm infant oromotor inertia, oral pooling and delayed initiation of the pharyngeal phase of swallowing can cause cough with feeding, wet gurgly breathing and nasopharyngeal regurgitation. Laryngeal penetration and aspiration, where food passes into the laryngeal vestibule above the level of the vocal folds or between the true vocal folds, respectively, can breach airway protection reflexes. About 25% of preterm infants show dysphagia; the incidence of laryngeal aspiration ranges from 25% to 85% in infants with swallowing dysfunction. (For further reading about the factors and mechanisms of dysphagia in the high-risk infant, see Jadcherla (2016).)

Yoshida T, Vivatbutsiri P, Morriss-Kay G et al 2008 Cell lineage in mammalian craniofacial mesenchyme. Mech Dev 125:797–808.
The availability of a mesoderm cell marker here demonstrates the completely complementary distribution of mesoderm and neural crest-derived cell populations in the mouse skull. Angiogenic and myogenic mesenchymal markers further show that these populations invade neural crest areas at early stages.

CHAPTER
18

Development of the back

Vertebrae and their alternating intervertebral discs are one of the main manifestations of body segmentation or metamerism. A chain of segments arranged in sequence allows the overall structure to bend when it is moved by the associated muscles. The original body segments, the somites, are formed from paraxial mesenchymal populations found lateral to the neural tube and notochord in the early embryo (Ch. 12). The somites provide the embryonic cell populations for the axial skeleton and skeletal muscle. The vertebrae form from immediately cranial and caudal somites by the recombination of two neighbouring somite halves in a process called resegmentation, while the muscles that are attached to adjacent vertebrae are derived from a single somite. Each vertebra develops from bilateral origins to form a midline centrum, two lateral arches bearing transverse processes that develop lateral and dorsal to the neural tube, and a midline fused dorsal portion with a spinous process. Individual vertebrae may be distinguished by modifications of these component parts. After resegmentation a single vertebra contains cells originating from four individual somites: the cranial and caudal halves of longitudinally abutting somites of one side of the body that unite with the corresponding two halves of the contralateral somites. The intervertebral discs have a dual origin: the anulus fibrosus develops from the sclerotome and the nucleus pulposus develops from the notochord.

SEGMENTATION OF PARAXIAL MESENCHYME

Epithelial epiblast cells that ingress through the lateral aspect of the primitive node and the rostral primitive streak (see Fig. 10.3) become committed to a somitic lineage as they undergo an epithelial to mesenchymal transition. The position of ingression of the epiblast informs the specific destination of the cells. Those ingressing through the lateral portion of Hensen's node form the medial halves of the somites, whereas those ingressing through the primitive streak, approximately 200 µm caudal to the node, form the lateral halves of the somites. The two somite halves do not appear to intermingle. After passing through the streak the mesoblastic cells retain contact with epiblast and hypoblast basal laminae both during migration and after reaching the lateral sides of the notochord. Here the cell population is referred to as paraxial mesenchyme. The unsegmented mesenchymal population (presomitic mesenchyme), also termed segmental plate, subsequently undergoes a mesenchymal to epithelial transition to form somites in a process called somitogenesis. The first pair of somites in human embryos develops at stage 9 (about 26 postfertilization days; see Fig. 23.3) and 38–39 pairs of somites are present at stage 14 (Mekonen et al 2017).

Somitogenesis is an autonomous process. Somites will form from cultured presomitic mesenchyme with or without the presence of neural tube tissue or primitive node tissue. Transcriptome profiling of human paraxial mesenchyme, presomitic and mature somite cells, derived from stage 13–14 human embryos, has identified some of the regulatory pathways in the human and highlighted specific differences from equivalent mouse embryo somitic stages (Xi et al 2017). Myogenic, osteogenic and chondrogenic cells have been grown in 3D culture from both human embryonic stem cells (hESCs) and human induced pluripotential stem cells (hiPSCs), cultured according to specific human profiling information for somitogenesis (Xi et al 2017, Nakajima et al 2018).

Bilateral segmentation of the paraxial presomitic mesoblastic populations, which divide into discrete epithelial spheres, occurs as a sequential process along the craniocaudal axis. In avian embryos, a pair of somites is formed every 90 minutes until the full number is obtained. The molecular pathway for this synchronous segmentation has been termed the segmentation clock and has been identified as a conserved process in vertebrates from fish to mammals. It is based on the rhythmic production of messenger RNAs (mRNAs) for the transcription of genes related to Notch, a large transmembrane receptor, and a number of other factors, including members of the Wnt and fibroblast growth factor (FGF) signalling pathways.

Intrinsically coordinated pulses of mRNA expression appear as a wave within the presomitic mesoblast as each somite forms. As new cells enter the paraxial mesenchyme caudally, they begin phases of upregulation of the cycling genes, followed by downregulation of these genes. During each cycle, the most cranial presomitic mesoblast will segment and undergo mesenchymal to epithelial transformation to form the next somite. Experimental evidence from chick embryos shows that newly formed paraxial mesoblast cells undergo 12 such cycles before they finally form a somite, the period from ingression through the primitive streak to segmentation into a somite taking approximately 18 hours (Pourquié and Kusumi 2001). The somite number and the rate of somite formation varies between vertebrate species, taking 2 hours in mouse and 5 hours in human embryos (Ebisuya and Briscoe 2018). Those vertebrates with elongated bodies and many somites form somites more rapidly relative to their developmental rate than those with shorter bodies, a finding that supports the concept that somite number is controlled, in part, by species-specific cyclical properties of the presomitic mesoblast (Richardson et al 1998, Gomez et al 2008).

The final determination of somitic boundary formation has not yet been fully elucidated but seems to require a periodic repression of the Notch pathway genes. The caudal presomitic mesoblastic cells are thought to be maintained in an immature state by their production of FGF8, and become competent for segmentation when FGF8 levels drop below a certain threshold. For an overview of vertebrate segmentation and its clinical implications, see Pourquié (2011) and Hubaud and Pourquié (2014).

SOMITE DEVELOPMENT

Five main stages can be identified in somitogenesis and somite development (**Figs 18.1–18.2**). A local portion of the most cranial paraxial mesoblast undergoes compaction. The compacted cells undergo a mesenchymal to epithelial transformation, resulting in an epithelial sphere of cells that surrounds free somitocoele cells. This stage marks segmentation of the paraxial mesenchyme and somite formation. Shortly after the somite boundaries have been defined, the mesenchymal sclerotome

Fig. 18.1 A scanning electron micrograph of a lateral view of an embryo, showing the somites. The cranial somites are at the upper border and the more caudal somites are at the lower border. Note the change in size of the cranially more advanced somites. (Photograph by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

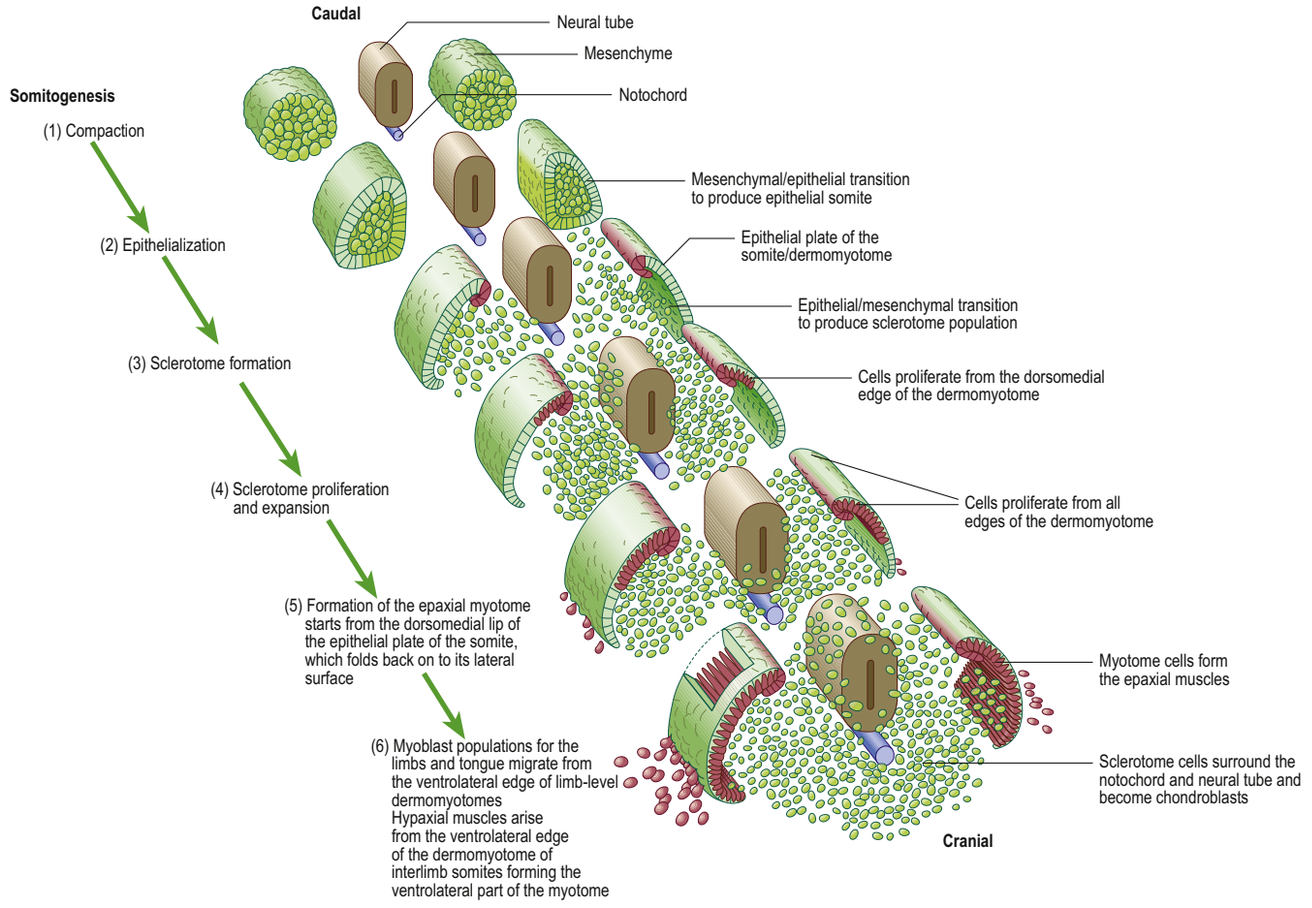

Fig. 18.2 The stages of somite development. Development occurs in a craniocaudal progression. The more cranially placed somites (at the lower right of the figure) are further developed than those caudally placed (at the upper left of the figure). The stages in somite development are given on the left of the figure; more detailed information is given on the right.

is formed by a region-specific epithelial to mesenchymal transition of the ventral and ventromedial walls of the somite. As the embryo enlarges, the sclerotomal populations on each side become contiguous with the notochord and the neural tube. The rest of the dorsal lateral somitic epithelium remains as the epithelial plate of the somite, also termed the dermomyotome, a proliferative epithelium that will give rise to (nearly) all of the striated muscles of the body. Formation of the epaxial myotome begins. Segmentation of the paraxial mesoblast, mesenchymal to epithelial transformation to form epithelial somites and the resultant somite developmental processes (epithelial to mesenchymal transformation to form the sclerotome) all occur in a craniocaudal progression caudal to the otic vesicle from stage 9.

Cells of the spherical epithelial somite are polarized. Their apical region contains Golgi apparatus, actin and α-actinin close to the luminal surface, while their basal surface, corresponding to the outer circumference of the somite, rests on a basal lamina that contains collagen, laminin and fibronectin. Basal, filopodia-like processes pass through this basal lamina to contact the basal laminae of the neural tube medially, notochord ventromedially and surface ectoderm dorsolaterally. Dorsoventral patterning of the somites is dependent on the activity of Sonic Hedgehog (SHH) from the notochord/neural tube floor plate, Wnt1 and Wnt3a from the neural tube roof plate, and Wnt6 from the overlying ectoderm. A role of somitic filopodial processes in signal transduction is likely for Wnt signalling from the surface ectoderm (Sagar et al 2015).

The diverse sclerotomal cell populations have been studied mostly in the chick embryo, where the fates of the cells have been tracked (Christ et al 2004) (**Figs 18.3–18.6**). The main mass of the sclerotome is termed the central sclerotome, the portion close to the notochord is termed the ventral sclerotome, and the portions adjacent to the dorsomedial and ventrolateral dermomyotomal margins are termed the dorsal sclerotome and lateral sclerotome, respectively. The central sclerotome remains close to the dermomyotome and will give rise to the pedicles and ventral parts of the neural arches, and the proximal ribs. The ventral sclerotomal cells that laterally abut the notochord, proliferate and fuse with their contralateral counterparts to form an axial cell population within the extracellular matrix of the perinotochordal space, now termed the perinotochordal sheath. The dorsal sclerotomal cells develop relatively late, invade the space between the surface ectoderm and growing neural tube, and form the dorsal part of the neural arches. The lateral sclerotomal cells give rise to distal parts of the ribs (Scaal 2016). Generally, there is a dorsolateral expansion of the whole sclerotome rather than the medial migration of a population of sclerotomal cells (Gasser 2006), as can be seen in Figs 18.3–18.5. Sclerotomal cells also give rise to the meninges surrounding the spinal cord, local tendons and ligaments, and endothelial cells of blood vessels (Christ et al 2004). The somitocoele cells, which remain mesenchymal throughout somite formation, give rise to the vertebral joints, intervertebral discs and the proximal ribs (Mittapalli et al 2005).

The dermomyotome is a proliferative rectangular epithelial cell sheet that releases cells from its four borders (**Fig. 18.7**). Proliferation at the dorsomedial edge produces muscle precursor cells that elongate along the cranial to caudal extent of the dermomyotome underneath its ventral (apical) surface as they move laterally. With a slight delay, cells similarly elongate from the cranial and caudal edges of the dermomyotome. The cells that are produced from these three edges are termed the epaxial myotome and will give rise to skeletal muscle dorsal to the vertebrae, i.e. the epaxial (back) musculature. Cells produced by the ventrolateral edge of the dermomyotome are termed the hypaxial myotome. Cells from occipital and cervical somites migrate ventrally, giving rise to the intrinsic muscles of the tongue and respiratory diaphragm respectively. Cells arising adjacent to the limb buds migrate laterally to enter them (Ch. 19). At interlimb levels, the ventrolateral edge of the epithelial dermomyotome extends into the body wall and gives rise to the intercostal and abdominal muscles. Dermomyotomal cells that do not form myotomal muscle fibres contribute to the dermis and subcutis of the back (Scaal and Christ 2004).

It was once thought that the somite gave rise to segmental portions of the dermis of the skin, as well as bone and muscle. However, it is now clear that the somitic contribution to the skin from the epithelial plate is limited to de-epithelialization of dermomyotomal cells over the epaxial muscles alone, a much smaller distribution than the segmental portion of skin usually implied by the term dermatome. The concept that an embryological dermatome, derived from the somite, produces all of the dermis of the skin is no longer tenable.

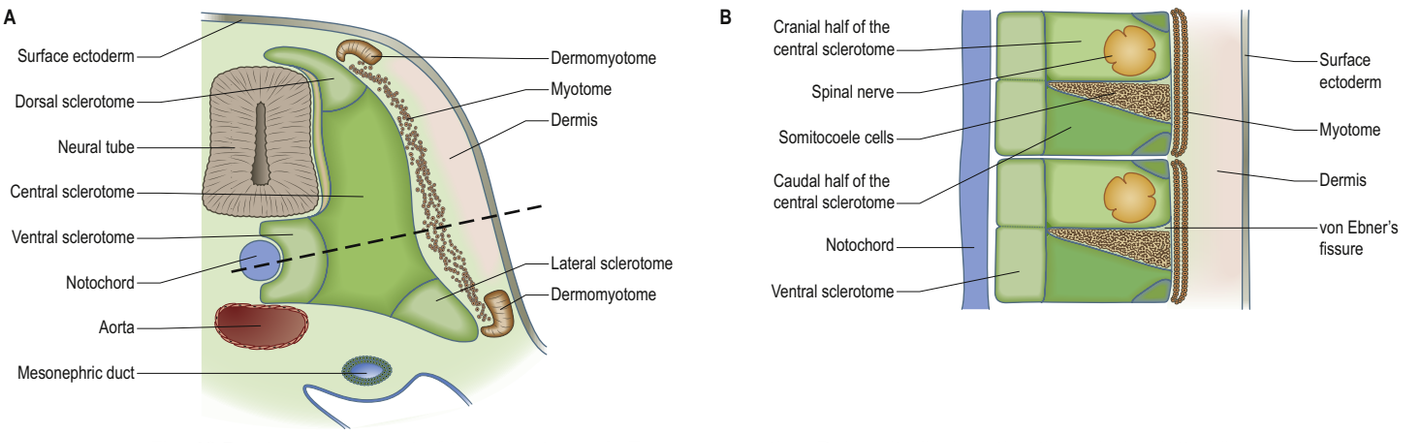

Fig. 18.5 Later development of the sclerotome. **A**, Transverse section. **B**, Longitudinal section through the dotted line indicated in **A**, showing the sclerotomal subdivisions.

The regularity of somite formation provides criteria for staging embryos. The staging scheme proposed by Ordahl (1993) noted that morphogenetic events occur in successive somites in a craniocaudal progression. The somite most recently formed from the unsegmented paraxial mesenchyme was designated as stage I, the next most recent as stage II, and so on. When the embryo has formed an additional somite, the stages of the previously formed somites increase by one Roman numeral. According to this scheme, in the chick embryo, compaction occurs at stage 0, epithelialization at stage I, formation of mesenchymal sclerotome cells from stage V, and myotome formation from stage VI. Early migration of the ventrolateral lip of the dermomyotome and production of myotome cells are still occurring at stage X.

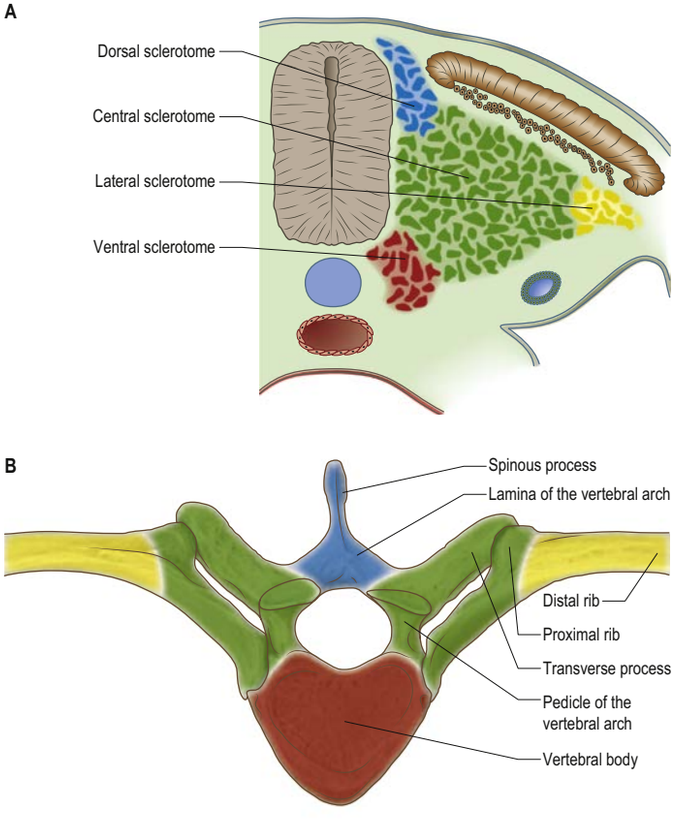

Fig. 18.6 Contributions of sclerotome cells to the vertebrae. **A**, Sclerotomal subcompartments. **B**, The derivatives of the sclerotomal subcompartments (shown in similar colours) in a thoracic vertebra. (Courtesy of Professor Martin Scaal, Germany.)

DEVELOPMENT OF SCLEROTOMES

Sclerotomal cell populations form from the ventral half of the epithelial somite. An intrasegmental boundary (fissure or cleft, sometimes termed von Ebner's fissure), initially filled with extracellular matrix and a few cells, appears within the sclerotome and divides it into loosely packed cranial and densely packed caudal halves. The dermomyotome covers both half-sclerotomes dorsally. The bilateral sclerotomal cell populations of each segment migrate towards the notochord and surround it to form the perinotochordal sheath. They undergo a matrix-mediated interaction with the notochord, differentiating chondrogenetically to form the cartilaginous precursor of the vertebral centrum. The perinotochordal sheath starts to express type II collagen, and this is believed to mark a chondrogenic fate in those mesenchyme cells that contact it. Each vertebra is formed by the combination of much of the caudal half of one bilateral pair of sclerotomes with much of the cranial half of the next caudal pair of sclerotomes, their fusion around the notochord producing the blastemal centrum of the vertebra (**Figs 18.8–18.10**). The mesenchyme adjoining the intrasegmental sclerotomic fissure now increases greatly in density to form a well-defined perichordal disc that intervenes between the centra of two adjacent vertebrae and is the future anulus fibrosus of the intervertebral symphysis ('disc') (see below).

The basic pattern of a typical vertebra is initiated by this recombination of caudal and cranial sclerotome halves (resegmentation) (see Fig. 18.9; **Fig. 18.11**), followed by differential growth and sculpturing of the sclerotomal mesenchyme that encases the notochord and neural tube. The centrum encloses the notochord and lies ventral to the neural tube. Sclerotomal differentiation starts in human embryos at about stage 10, when 10 somite pairs are present. The loosely packed cranial and densely packed caudal halves of the sclerotome can be seen at stage 15, with the neural processes extending dorsolaterally to the spinal ganglia (Mekonen et al 2017). The neural arch consists of paired bilateral pedicles (ventrolaterally) and laminae (dorsolaterally) that coalesce in the midline dorsal to the neural tube to form the spinous process. This is seen initially in the mid-thoracic region by postfertilization week 9. On each side, three further processes project cranially, caudally and laterally from the junction of the pedicle and laminae. The cranial and caudal projections are the blastemal articular processes (zygapophyses) that become contiguous with reciprocal processes of adjacent vertebrae; their junctional zones mark the future zygapophysial or facet joints. The lateral projections are the true vertebral transverse processes. Bilateral costal processes (ribs) grow anterolaterally from the ventral part of the pedicles (i.e. near the centrum) from the neighbouring perichordal disc, and, at most thoracic levels, with accessions from the next adjacent caudal pedicles. The costal processes expand to meet the tips of the transverse processes. Transverse processes are first seen in lower cervical and thoracic vertebrae during stage 18 (see Fig. 18.6). The definitive vertebral body is compound, formed from a median centrum (derived from the cells of the perinotochordal sheath), and bilaterally from the expanded pedicle ends (derived from the migrating sclerotomal populations) (see Fig. 18.11). These portions of the vertebral body fuse at the neurocentral synchondroses.

The segmental nature of the vertebrae is promoted by the notochord and neural floor plate, which induce the ventral elements of the vertebrae and repress dorsal structures such as the spinous processes.

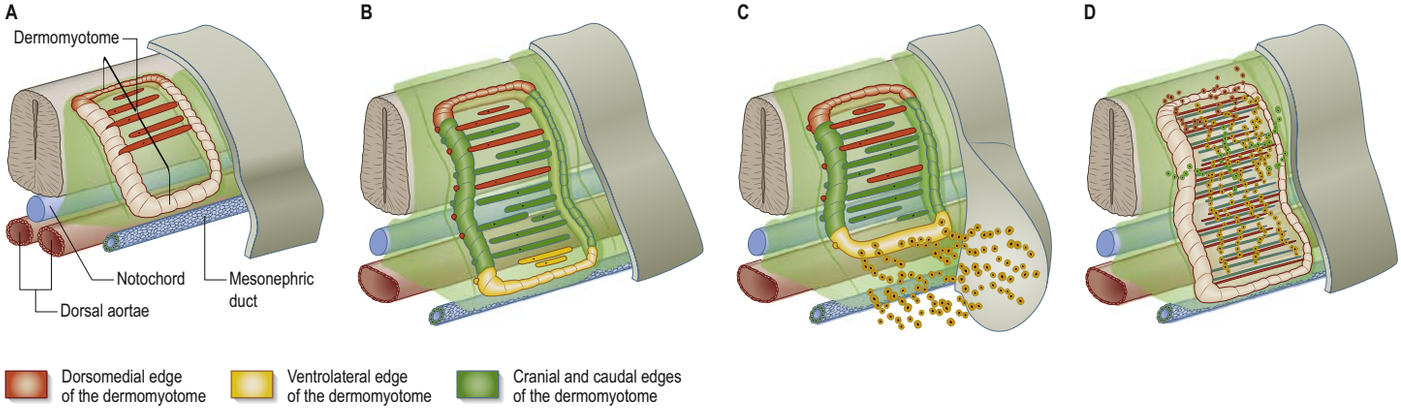

Fig. 18.7 A–D, Epaxial and hypaxial muscle origin from the dermomyotome. **A**, Early dermomyotome proliferation. **B**, The dermomyotome at interlimb level, producing epaxial myoblasts. **C**, The dermomyotome at limb level. Hypaxial dermomyotome cells de-epithelialize from the ventrolateral edge and migrate into the limb bud. **D**, The local dermis is formed later by superficial de-epithelialization of dermomyotome cells.

Experimental excision of the notochord in early chick embryos results in fusion of the centra and formation of a cartilaginous plate ventral to the neural tube. Dorsal segmentation is influenced by the spinal ganglia: experimental removal of the ganglia results in fusion of the neural arches and the formation of a uniform cartilaginous plate dorsal to the neural tube. Vertebrae are specified as to region very early in development. If a group of thoracic somites is transplanted to the cervical region, ribs will still develop. In marked contrast, the sclerotome is restricted and the myotome will produce muscle characteristic of its new location.

Intervertebral discs

Vertebral centra are derived from caudal and cranial sclerotomal halves. An intervertebral disc is formed from the free somitocoele cells within the epithelial somite that migrate with the caudal sclerotomal cells and from notochordal cells. Genetic labelling experiments in the mouse embryo indicate that notochordal cells act as embryonic precursors to all cells found within the nucleus pulposus of the mature intervertebral disc (McCann et al 2012). The sclerotomal mesenchyme that forms the centra of the vertebrae replaces the notochordal tissue that it surrounds. The notochord expands between the developing vertebrae as localized aggregates of cells and matrix that form the nucleus pulposus of the intervertebral disc (see Figs 18.8, 18.11). The intermediate part of each perichordal disc, forming the anulus fibrosus, surrounds the nucleus pulposus and differentiates into an external laminated fibrous zone and an internal cuff that lies next to the nucleus pulposus: the inner zone contributes to the growth of the outer. In human embryos, the growth rate of the vertebral bodies is such that the volume increases three times between stage 17 and postfertilization week 10, whereas the intervertebral discs show little volume increase until stage 23, after which their growth rate increases to match that of the vertebral bodies (Mekonen et al 2017).

The original sclerotomes are coextensive with the individual metameric body segments. Each sclerotomic fissure, perichordal disc and maturing intervertebral disc lies opposite the centre of each corresponding segment (somite). It follows therefore that the discs correspond in level to, and form the ventral boundaries of, the intervertebral foramina and their associated mixed spinal nerves, ganglia, vessels and sheaths. The foramina are bounded by the capsules of the synovial facet joints dorsally; the rims of the vertebral notches of adjacent vertebrae lie cranially and caudally. All the structures listed (and other associated structures) are therefore often designated segmental, whereas vertebral bodies are designated intersegmental. (For further discussion of resegmentation theories, see Müller and O'Rahilly (1986), Huang et al (2000) and Ward et al (2017).)

Development of vertebrae

The initial movements of sclerotomal cells round the neural tube and the expression of type II collagen signal the blastemal stage of vertebral development (see Fig. 18.11). In human embryos, vertebral bodies consist of loose mesenchyme until stage 17, and intervertebral discs are composed of dense mesenchyme continuous with the neural processes. Both mesenchymal populations show cartilage differentiation from stage 18. Each centrum chondrifies from one cartilage anlage. Each half of a neural arch is chondrified from a centre, starting in its base and extending dorsally into the laminae and ventrally into the pedicles, to meet, expand and blend with the centrum. There are 33 or 34 cartilaginous vertebrae by stage 23, but the spinous processes have not yet developed and so the overall appearance is of total spina bifida occulta. Fusion of the spines starts in the thoracic region at postfertilization week 9 and is seen in the sacral region by postfertilization week 15. For details of neural arch closure at all vertebral levels see Mekonen et al (2017). The transverse and articular processes are chondrified in continuity with the neural arches. Intervening zones of mesenchyme that do not become cartilage mark the sites of the facet joints and the complex of costovertebral joints, within which synovial cavities later appear.

A typical vertebra is ossified from three primary centres, one in each half-vertebral arch and one in the centrum (see Fig. 46.34). Centres in arches appear at the roots of the transverse processes and ossification spreads backwards into laminae and spines, forwards into pedicles and posterolateral parts of the body, laterally into transverse processes, and upwards and downwards into articular processes. Conventionally, centres in vertebral arches are said to appear first in upper cervical vertebrae and then in successively more distal vertebrae, reaching lower lumbar levels by about postmenstrual week 12. However, a radiographic study of unsexed human fetuses found a pattern that differed from such

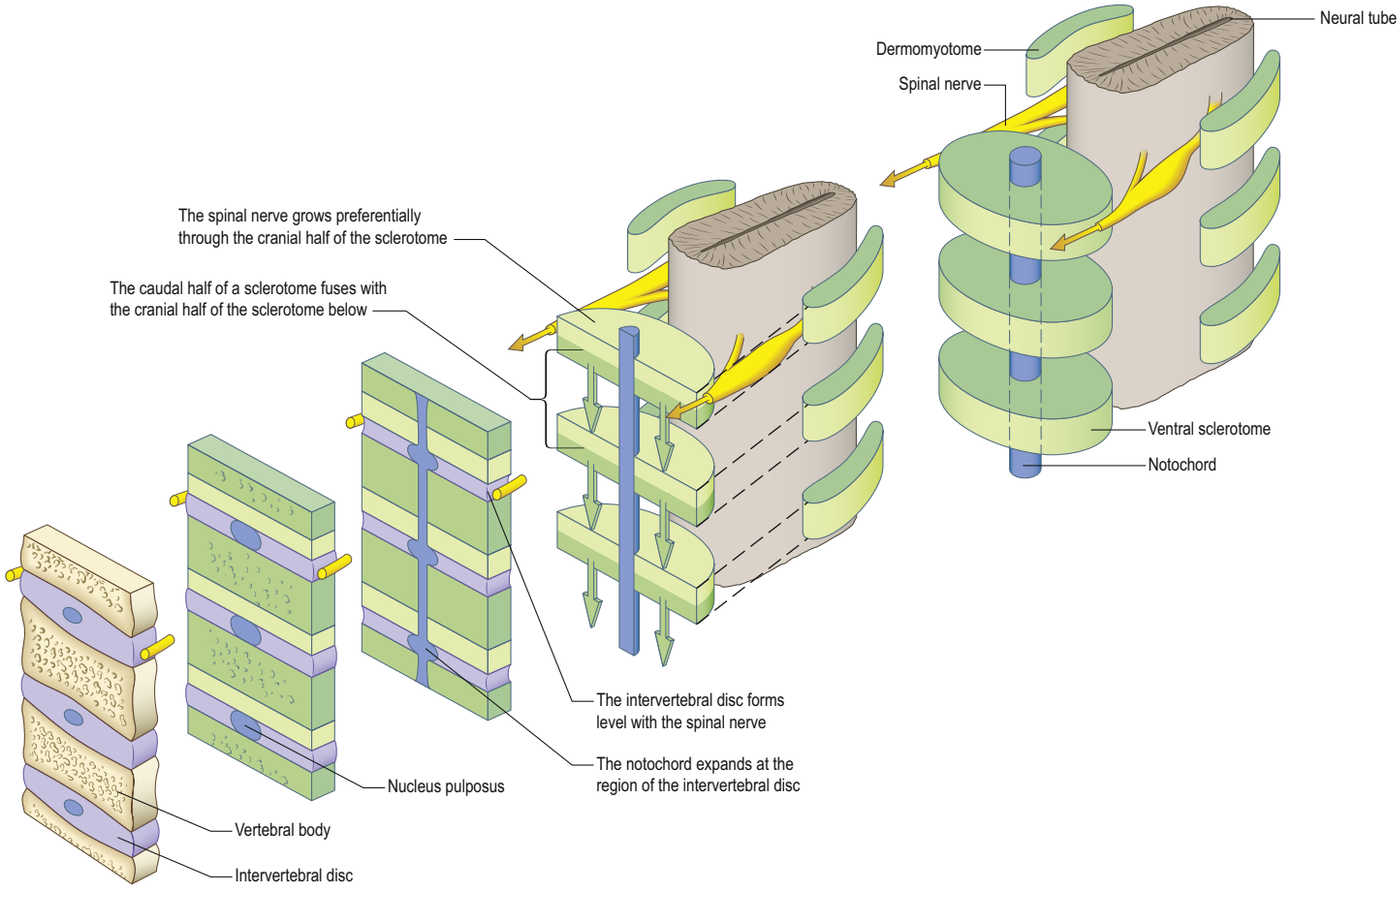

Fig. 18.8 The formation of vertebrae and intervertebral discs from the mesenchymal sclerotomes. Each vertebra is formed from the cranial half of one bilateral pair of sclerotomes and the caudal half of the next pair of sclerotomes.

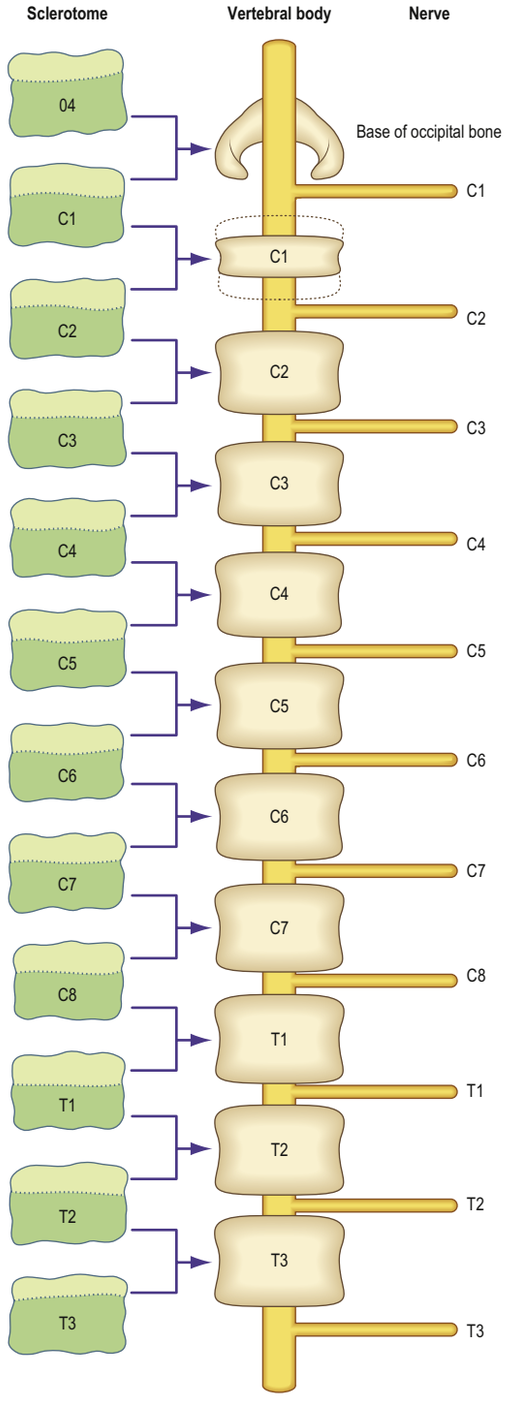

Fig. 18.9 The contribution of the somites to the vertebrae. Each somite induces a ventral root to grow out from the spinal cord. When the sclerotomes recombine, the cranial half of the first cervical sclerotome fuses with the occipital sclerotome above contributing to the occipital bone of the skull. The cervical nerves, beginning with C1, exit above the corresponding vertebra. Nerve C8 exits below the seventh cervical vertebra (C7), and thereafter nerves arise below their numbered vertebrae. (With permission from Larsen WJ 1997 Human Embryology, 2nd ed. Edinburgh: Churchill Livingstone.)

a simple craniocaudal sequence. Centres first appeared in the lower cervical/upper thoracic region, quickly followed by others in the upper cervical region. After a short interval, a third group appeared in the lower thoracolumbar region and remaining centres then appeared, spreading regularly and rapidly in craniocaudal directions (Bagnall et al 1977).

The major part of the vertebral body, the centrum, ossifies from a primary centre dorsal to the notochord. Centra are occasionally ossified from bilateral centres that may fail to unite. Suppression of one of these produces a cuneiform vertebra (hemivertebra), one cause of lateral spinal curvature (scoliosis). At birth and during the early postnatal years the centrum is connected to each half-neural arch by a synchondrosis or neurocentral joint. In thoracic vertebrae, costal facets on the bodies are posterior to neurocentral joints.

During the first year, the arches unite first in the lumbar region and then throughout the thoracic and cervical regions. In typical upper cervical vertebrae, centra unite with arches during year 3, but union is not complete in lower lumbar vertebrae until year 6. The upper and lower surfaces of the bodies and apices of the transverse and spinous processes are cartilaginous until puberty, at which time five secondary centres appear: one in the apex of each transverse and spinous process and two anular epiphyses (ring apophyses) for the circumferential parts of the upper and lower surfaces of the vertebral body. Costal articular facets are extensions of these anular epiphyses and they fuse with the rest of the bone at about 25 years. There are two secondary centres in bifid cervical spinous processes. Exceptions to this pattern of ossification are described in the appropriate subsections in Chapter 46.

Occipitocervical junction

In humans, the occipitocervical (craniovertebral, spinomedullary) junction between the head and neck is placed at the boundary between the fourth and fifth somites (Müller and O'Rahilly 1994, 2003, Hita-Contreras et al 2014). At stage 12 it is identified by the presence of hypoglossal nerve rootlets (**Fig. 18.12A**) and at stages 14–15 it lies between the hypoglossal rootlets and the first spinal ganglion (**Fig. 18.12B–C**). In avian embryos, where all embryonic stages may be obtained experimentally, the occipitocervical boundary occurs within the fifth somite (Wilting et al 1995). The onset of avian sclerotome formation in occipital and upper cervical somites is initiated simultaneously in multiple somites and occurs later than at thoracolumbar levels, in contrast to the serial cranial to caudal progression of somite maturation in the trunk (Maschner et al 2016).

The segmental pattern present in the development of the somites can be seen rostrally in the developing skull base. Occipital somites are rostral to the first cervical nerve (see Fig 17.7). The first somite, defined by its position caudal to the vagal neural crest or ganglion, can be seen between stages 9–12. Mesenchymal condensations equivalent to the centra of occipital somites 2, 3 and 4 become apparent and form the basiocciput. Occipital sclerotomes 3 and 4 are the most distinct at stage 14, by which time the first three sclerotomes have fused. The hypoglossal rootlets pass through the less dense portion of occipital sclerotome 4, accompanied by the hypoglossal artery. Occipital sclerotome 4 forms an incomplete centrum axially and exoccipital elements laterally. Exoccipital elements are regarded as corresponding to neural arches and they form the rim of the foramen magnum. The occipital condyles develop from the cranial part of sclerotome 5, derived from the first cervical somite. The centra of occipital segments 1–4 are fused by stage 15 in the human embryo and form the basiocciput. The dorsocranial boundary of the foramen magnum is formed by stage 23 (Mekonen et al 2017).

In the occipitocervical junctional region, the centra formed from sclerotomes 5, 6 and 7 have a different fate from those more caudally placed, whereas the lateral portions of these sclerotomes generally develop similarly to those of lower ones. In a study of occipitocervical segmentation in human embryos, Müller and O'Rahilly designated the three complete rostral centra that develop in the atlanto-axial region X, Y and Z (**Fig. 18.13**; Müller and O'Rahilly 1986, 2003). They noted that the height of the XYZ complex is equal to that of three centra elsewhere. X is on the level of sclerotome 5, and Y and Z are in line with sclerotome 6 and with the less dense portion of sclerotome 7. During stage 17 a temporary intervertebral disc appears peripherally between Y and Z. It begins to disappear in stage 21, although remnants may be found in the adult. No disc develops between X and Y. The origin of the anterior arch of the atlas is unclear: it is evident at stages 21–23 at the level of X or, sometimes, between X and Y. The posterior arch of the atlas arises from the dense area of sclerotome 5 at the level of X. The XYZ complex belongs to the axis, which means that the atlas does not incorporate a part of the central column (Müller and O'Rahilly 1994). The posterior arch of the axis arises from the dense area of sclerotome 6 and is at the level of Y and Z, particularly Z. XYZ correspond to the three parts of the median column of the axis, where X represents the tip of the dens, Y represents the base of the dens, and Z represents the centrum of the axis. The latter differs from other cervical vertebrae in that it is thicker and square-shaped. A review of the development and associated anomalies of this region is given in Shoja et al (2018).

Most defects of the atlas do not contribute to abnormal occipitocervical anomalies and are not associated with basilar invagination. Abnormalities of the axis are usually concerned with fusion of the dens with the centrum of the second cervical sclerotomes. Using the classification of the three complete centra that develop in the atlanto-axial region as X, Y and Z (Müller and O'Rahilly 1986, 2003), failure of fusion of X with the YZ complex produces an ossiculum terminale, a

The bony elements of the occipitocervical junction may be thought of as a central pillar (basiocciput and dens of the axis) surrounded by two rings (the rim of the foramen magnum and occipital condyles superiorly, and the anterior and posterior arches of the atlas inferiorly). Bony anomalies involving this embryologically complex region may produce altered, unstable anatomical relationships that result in the compression of underlying neural and/or vascular structures and may also compromise cerebrospinal fluid dynamics (Menezes 2008, Pang and Thompson 2011, 2014). The development of the cervical spine, particularly of the upper cervical vertebrae, is closely related to the development of the basiocciput and exocciput, and anomalous development will affect both regions. For example, abnormal prolapse of the dens into the foramen magnum, a condition termed basilar invagination, has been attributed variously to hypoplasia of the basiocciput, occipital condyles or atlas; deficiencies in the bony arches of the atlas with spreading of the lateral masses; or atlanto-occipital assimilation (Smith et al 2010). Malfusions of the caudal portion of occipital sclerotome 4 and the cranial portion of cervical sclerotome 1 may produce defects of the occipital condyles. The pro-atlas, a transient bony structure derived from the fourth occipital sclerotome, usually fuses with the three upper occipital sclerotomes to form the occipital bone and the dorsal part of the foramen magnum. Very rarely, remnants of the pro-atlas persist into adult life: several malformations and anomalies of the most caudal of the occipital sclerotomes have been attributed to failures of pro-atlas segmentation (Menezes and Fenoy 2009, Muhleman et al 2012).

Chiari malformation type I (CM-I) is defined radiographically as a displacement of the cerebellar tonsils of 5 mm or more below the foramen magnum in young adults. Classic CM-I is thought to be a congenital anomaly, in which the normally developing hindbrain is compressed within a hypoplastic posterior cranial fossa, forcing the cerebellar tonsils down through the foramen magnum. Patients with classic CM-I have a characteristically shallow posterior cranial fossa, particularly below Twining's line (a line joining the tuberculum sellae and internal occipital protuberance). Basioccipital shortness means that the foramen magnum is constricted transversely; the suggested pathogenesis is premature stenosis of the basi-exoccipital and exosupra-occipital synchondroses (Milhorat et al 2010). Tonsillar herniation is aetiologically heterogeneous and there are many causes that do not appear to be related to skull-base hypoplasia; CM-I can occur in association with disorders that appear to be unrelated to skull-base hypoplasia and may be acquired (Tubbs et al 2007).

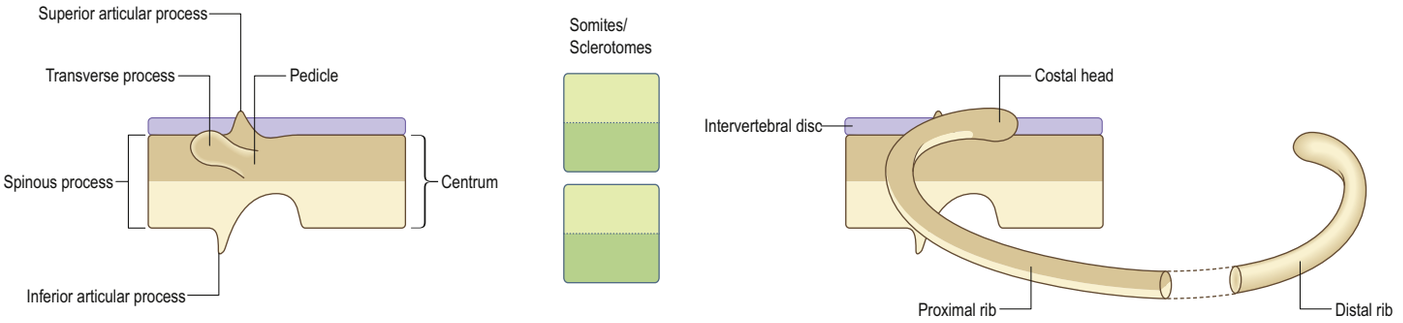

Fig. 18.10 The contribution of two adjacent somites to one vertebra and rib. The intervertebral disc and the costal head are derived from somitocoele cells from one somite, which migrate with the caudal half of the sclerotome. The proximal rib is formed from caudal and cranial somite halves with no mixing of cells; in the distal rib, there is more mixing of cranial and caudal cells as segmentation diminishes in the ventral body wall. (Redrawn with permission from Christ B, Huang R, Wilting J 2000 The development of the avian vertebral column. Anat Embryol (Berl) 202:179–94.)

dissociated apical odontoid epiphysis. Failure of fusion of the XY complex with Z at the dentocentral synchondrosis, or maintenance of the transitory intervertebral disc at this point, produces an os odontoideum, thought to be induced by excessive movement at the time of ossification of the dens (Crockard and Stevens 1995). Hypoplasia and aplasia of the X and Y centra, and aplasia of the Z centrum, will all lead to a reduced size of the dens: there are widely differing views about whether this will lead to atlanto-axial instability. For further details of the development of the human craniovertebral joints and associated ligaments, see Hita-Contreras et al (2014).

Third to seventh cervical vertebrae

The vertebral arches appose by postfertilization week 10 in the human embryo. In cervical vertebrae 3–7, the transverse process is dorsomedial to the foramen transversarium (see Fig. 18.13). The costal process, corresponding to the head, neck and tubercle of a rib, limits the foramen ventrolaterally. The distal parts of these cervical costal processes do not usually develop, but do so occasionally in the case of the seventh cervical vertebra, and may even develop costovertebral joints: these cervical ribs may reach the sternum (Ch. 20). Shifts of axial identity may also occur at more caudal levels, e.g. between lumbar and sacral vertebrae, and are based on expression anomalies of *Hox* genes, known as homeotic transfomations (Scaal 2016).

The seventh cervical vertebra is transitional in shape between typical cervical and thoracic vertebrae. The laminae are longer than other cervical vertebrae in the neonate and lie almost perpendicular to the basal plane; the inferior articular facets are more upright, and resemble those of thoracic vertebrae; and, in the lateral view, the superior articular facets extend transversely to the top of the transverse processes.

Anomalies of the lower cervical vertebrae are generally caused by inappropriate cervical vertebral fusion, collectively termed Klippel–Feil syndrome. This term includes all congenital fusions of the cervical spine, from two segments to the entire cervical spine. Affected individuals have a low posterior hairline, short neck and limitations of head and neck movement. Scoliosis and/or kyphosis is common. In both humans and mice these phenotypes have been linked to loss of expression of the homeobox gene *Meox1* (Mohamed et al 2013).

Thoracic vertebrae

At stage 23 the neural processes of thoracic vertebrae are short, slightly bifurcated and joined by collagenous fibres, the transverse processes are prominent and the three facets for articulation with the ribs at the costovertebral and costotransverse joints are present. At postfertilization week 9, the thoracic vertebral arches are the first to close (Mekonen et al 2017). In the neonate, the thoracic neurocentral and posterior synchondroses are not fused: the posterior synchondroses close within 2–3 postnatal months, and the neurocentral synchondroses remain open until 5–6 postnatal years. In general, the thoracic spine develops ahead of the cervical and lumbar spine. From postfertilization week 9, ossification begins in the cartilaginous vertebrae in a craniocaudal progression.

Ribs

Ribs usually develop in association with the thoracic vertebrae and can be identified in stage 15 embryos. Occasionally, they can arise from the seventh cervical and first lumbar vertebrae, associated with ectopic *Hox* gene expression (homeotic transformation).

The costal processes attain their maximum length as the ribs in the thoracic region. Each rib originates from lateral sclerotomal populations and forms from the caudal half of one sclerotome and the cranial half of the next subjacent sclerotome (see Fig. 18.10). The head of the rib develops from somitocoele cells from one somite that migrate with the caudal half of the sclerotome. The proximal portion of the rib forms from both caudal and cranial sclerotomal halves but there is no mixing of cells from these origins. The distal portion of the rib forms from caudal and cranial sclerotomal halves and these cells mix as the rib extends into the ventral body wall and segmentation diminishes.

The ribs arise anterolaterally from the ventral part of the pedicles and form bilateral costal processes that expand to meet the tips of the transverse processes. As they elongate laterally and ventrally they come to lie between the myotomic muscle plates. In the thorax, the costal processes grow laterally to form a series of precartilaginous ribs (Figs 18.6, 18.11). The transverse processes grow laterally behind the vertebral ends of the costal processes, at first connected by mesenchyme that later becomes differentiated into the ligaments and other tissues associated with the costotransverse joints. The capitular costovertebral joints are similarly formed from mesenchyme between the proximal ends of the costal processes and the perichordal disc, and the adjacent parts of two (sometimes one) vertebral bodies, derived from the neural arch. Ribs 1–7 (vertebrosternal) curve round the body wall to reach the developing sternal plates. Ribs 8–10 (vertebrochondral) are progressively more oblique and shorter, only reaching the costal cartilage of the rib above, and contributing to the costal arch. Ribs 11–12 are free (floating), and have cone-shaped terminal cartilages to which muscles become attached. For clear images of rib development in the human embryo and fetus see Mekonen et al (2015, 2016).

Lumbar vertebrae

The ribs do not develop distally in lumbar vertebrae (see Fig. 18.11). Their proximal parts become the 'costal processes', while the morphologically true transverse processes may be represented by the accessory processes of the vertebrae. Occasionally, movable ribs may develop in association with the first lumbar vertebra. Lumbar intervertebral discs are thicker than thoracic discs. By stage 23 the peripheral part of the anulus fibrosus can be seen, and the notochordal cells are expanding internally to form the nucleus pulposus.

Sacrum

Sacral vertebrae have lower centra and are narrower overall from side to side than their thoracic and lumbar counterparts. Each sacral vertebra is composed of a centrum and bilateral neural processes. O'Rahilly et al (1990) divided the neurocentral junctional area into two parts, anterolateral or alar and posterolateral, and found the alar element in sacral vertebra 1 to be novel, because it was absent in lumbar vertebra 5. There is support for this view if the course of the dorsal rami of the spinal nerves is used to distinguish the costal elements ventrally from the transverse elements dorsally. The alar elements of the sacral vertebrae are ventral to the sacral dorsal rami, and both costal and transverse portions are posterolateral. The alar element of S1 and S2 forms the auricular surface of the sacrum. At stage 23 the cartilaginous sacral vertebrae have joined and the outline of the future bone can be recognized. Individual pedicles and laminae are very small and can be detected in S3–S5. For images of the closure of the sacral vertebral canal see (Mekonen et al 2017).

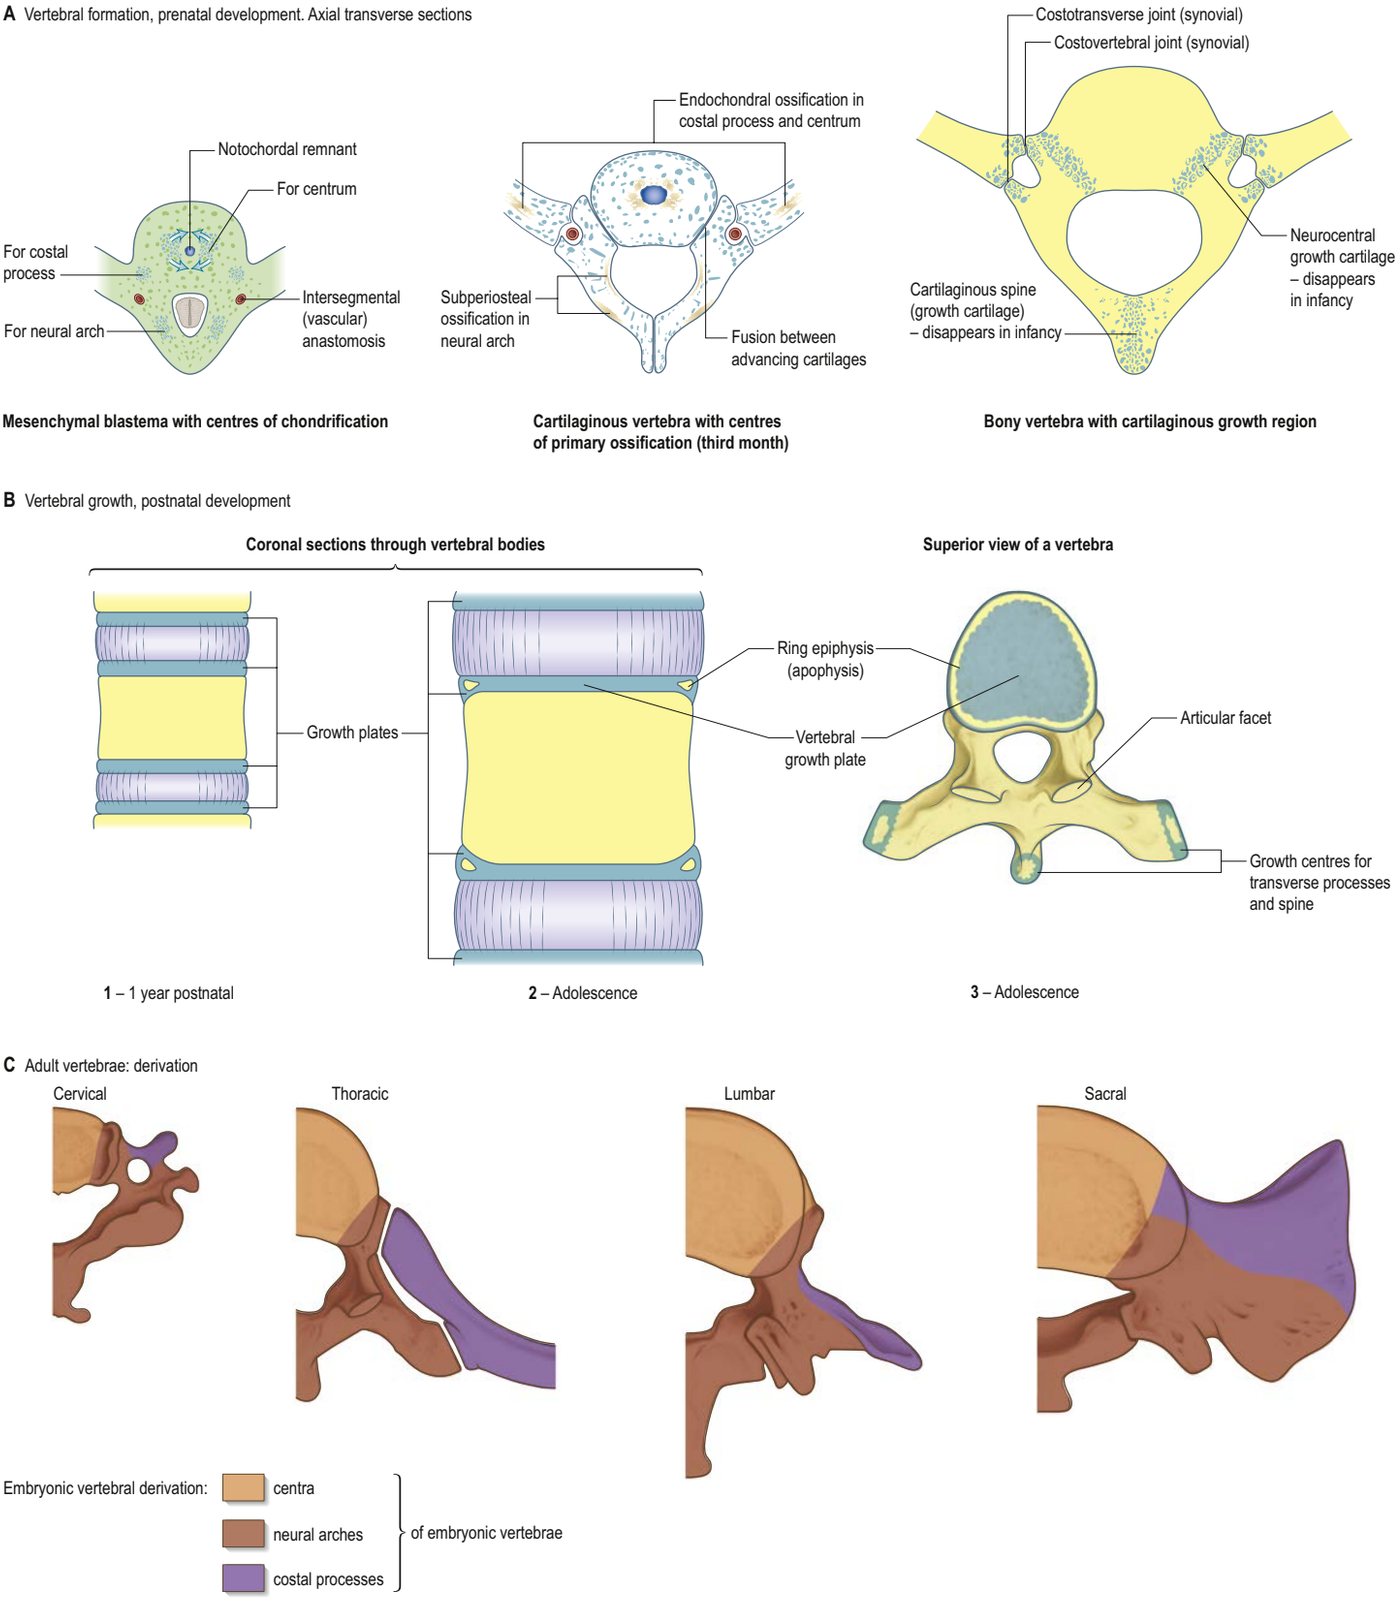

Fig. 18.11 A–B, Vertebral development through blastemal, cartilaginous and pre- and postnatal stages of ossification. **C**, The derivation of the principal morphological parts of adult vertebrae.

Ossification of the vertebral column proceeds in a craniocaudal direction and after postmenstrual week 16, it has progressed to L5. Ossification of each additional vertebra occurs over a period of 2–3 weeks; S2 is ossified by postmenstrual week 22.

The sacral vertebrae are derived by secondary neurulation processes from the caudal eminence. All tissues of the caudal region of the embryo are produced in this way and can lead to anomalies of the sacrum, pelvis, cloacal region and urogenital and enteric sphincters. Very rarely, anomalous sacral or lumbosacral vertebrae may develop, often in association with a maternal history of diabetes. When there is sacral agenesis, motor paralysis is profound below the affected vertebral level, whereas the sensory disturbance does not relate to the vertebral level so closely, and sensation may be present down to the knees. Urinary bladder involvement is a consistent feature. In cloacal anomalies and cases of classic bladder exstrophy, a range of dimensional and rotational anomalies are seen (Ch. 22). The sacrum is larger with approximately 25% more surface area and 40% larger total volume. Sacroiliac joint angles are 10° larger, i.e. more toward the coronal plane than normal, and the bony pelvis has more inferior rotation than normal. 3D CT imaging has demonstrated a range of previously unknown rotational anomalies (Ch. 19) (Gearhart and Mathews 2016).

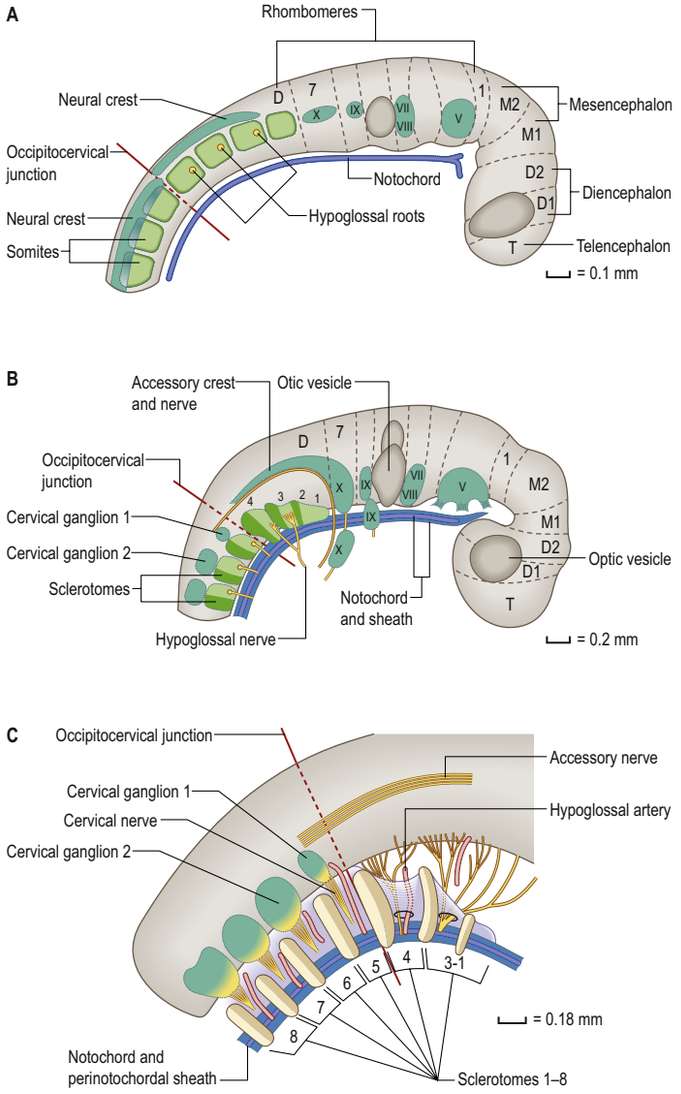

Fig. 18.12 Reconstructions of the occipitocervical region of human embryos. **A**, Stage 12: occipital somites innervated by hypoglossal fibres (small yellow circles). Three cervical somites are shown. The crest-derived ganglia of cranial nerves V, VII, VIII, IX and X are shown in green. Neural crest associated with the occipital somites is hypoglossal and perhaps accessory (also shown in green). **B**, Stage 14: the somites have transformed into sclerotomes and moved ventrally. The less dense cranial and dense caudal parts of the sclerotomes and occipital sclerotomes 1–4 are indicated. Hypoglossal fibres and cervical ventral rami migrate through the less dense parts of the sclerotomes. The occipital neural crest is now seen to be mostly accessory. The cervical crest is subdivided into spinal ganglia. A perinotochordal sheath can be seen extending rostrally to the termination of the notochord. **C**, Stage 15: the dense parts of sclerotomes 1–8 are shown. Intersegmental arteries are visible in the less dense areas of the sclerotomes, as are the spinal nerve fibres. In all diagrams, the occipitocervical junction is indicated by the red line. (After Müller F, O'Rahilly R 1994 Occipitocervical segmentation in staged human embryos. J Anat 185: 251–8, with permission from Blackwell Publishing.)

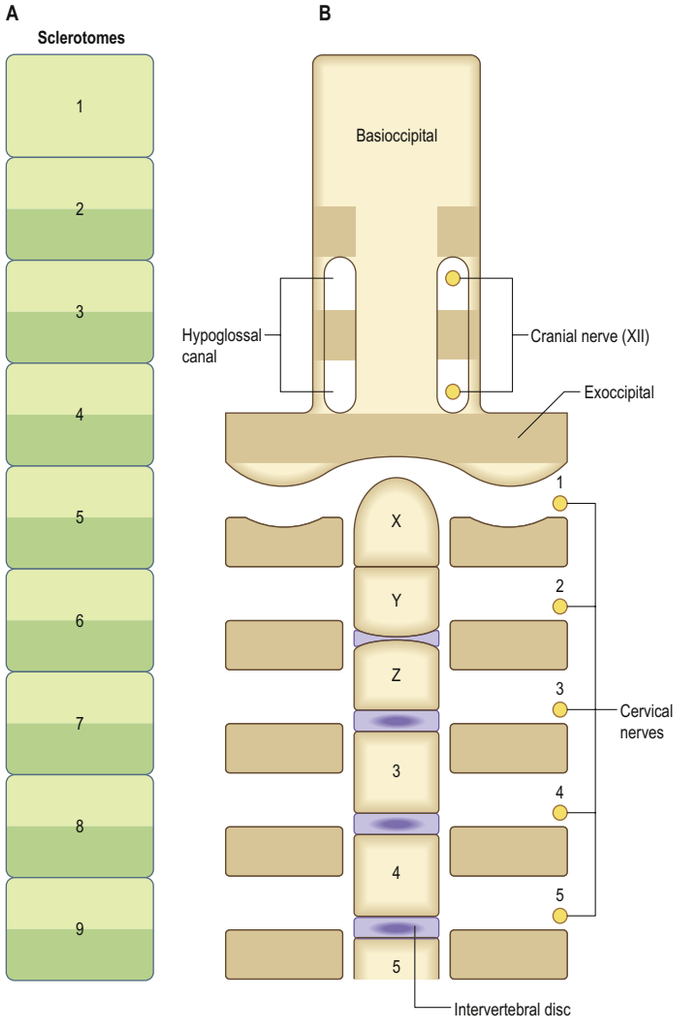

Fig. 18.13 The relationship between the centra and neural arches of the vertebrae and the related spinal ganglia and nerves. A scheme of the details of the early development of the occipitocervical region. **A**, The column of sclerotomes from occipital somite 1. **B**, A dorsal view of the developing vertebrae, with the centra in the middle and the bilateral components of the neural processes laterally. X, Y and Z are three centra that will produce the tip of the dens of the axis (X), the base of the dens of the axis (Y) and the centrum of the axis (Z). An intervertebral disc appears temporarily between Y and Z during stage 17. No disc develops between X and Y. The occipital condyles are derived from the first cervical sclerotome. (After Müller F, O'Rahilly R 1994 Occipitocervical segmentation in staged human embryos. J Anat 185: 251–8, with permission from Blackwell Publishing.)

Spina bifida

Spinal dysraphism is a generic term covering a wide range of developmental anomalies of the vertebral column and spinal cord, characterized by a failure of fusion of midline structures (Sepulveda et al 2012). The spectrum of defects includes non-fusion of the entire neural tube with no vertebral arch development (craniorachischisis); non-fusion of the rostral portion of the neural tube with no calvarial or occipital development (anencephaly); and non-fusion of caudal portions of the neural tube and local failure of vertebral arch development (spina bifida) (see Fig. 14.3; **Figs 18.14–18.16**). Spina bifida may be obvious at birth or before (e.g. spina bifida cystica and spina bifida aperta), or not obvious at birth (spina bifida occulta). Spina bifida cystica occurs where the meninges have developed adjacent to or over the defective neural tissue. Local accumulation of cerebrospinal fluid may push a defective neural plaque or spinal cord superficial to the level of the vertebrae, so forming a meningomyelocele. Alternatively, if one or two spinous processes are absent, a meningeal sac may protrude in the midline above a formed spinal cord, producing a meningocele. In spina bifida aperta, the exposed spinal cord has no cystic covering, although it may be covered by thin membranes. Meningomyelocele occurs in thoracolumbar, lumbar or lumbosacral regions; sacral lesions are less common. The vertebral lesion usually extends cranially further than the neural lesion, with deformities of the vertebral bodies and laminae. Vertebrae may be wedge-shaped or hemivertebrae, and ribs may be fused or absent. In spina bifida occulta, dysraphism primarily affects the vertebrae; the neural and meningeal elements are not herniated to the surface and so the underlying defects are masked by the skin. This closed form of spina bifida affects about 5% of the population and usually occurs in the lumbosacral or sacral segment. Affected individuals have bifid spinous processes often at the lumbosacral junction and there may also be a pigmented naevus, angioma, hirsute patch, dimple or dermal sinus on the overlying skin.

Tethering of the cord and diastematomyelia

Best Pract Res Clin Obstet Gynaecol 26:593–624.)

Prior to antenatal diagnosis of spina bifida by ultrasonography, most live births with spina bifida cystica had a meningomyelocele. Prenatal diagnosis of meningomyelocele and termination of affected fetuses have resulted in a significant decrease in the incidence of live births with this condition. Individuals with postnatal spina bifida repair are considered to be affected not only by the initial neurulation failure but also by the secondary effects of loss of cerebrospinal fluid into the amniotic fluid and the progressive damage to neural tissue caused by exposure to amniotic fluid. Nearly all neonates with the condition have Arnold-Chiari II malformation and over 90% will develop hydrocephalus requiring ventriculoperitoneal shunting (Saadai and Farmer 2012). Clinical trials of fetal meningomyelocele repair, between postmenstrual weeks 23–25, have found decreased hindbrain herniation after elective caesarean delivery at postmenstrual week 37 and reduction in the postnatal incidence of ventriculoperitoneal shunt-dependent hydrocephalus (Moldenhauer and Adzick 2017). The multidisciplinary surgical procedures involved are complex and not without risk to the mother (Asch and Sauerbrei 2018).

The greatest change of vertebral length occurs within the second and third trimesters. During the second trimester, the rapid relative growth of the vertebral column compared to the spinal cord results in a rostral displacement of the caudal end of the spinal cord from the second coccygeal vertebra to the third lumbar vertebra by postmenstrual week 25 (Ch. 14). When there is any degree of spina bifida, the upward movement of the caudal end of the spinal cord is limited, and the cord is said to be tethered. In neonates, neurological deficits caused by this condition become apparent soon after birth; some individuals may show degrees of urinary dysfunction later in life. Very rarely, tethering symptoms may be associated with abnormal development of the vertebral centra, e.g. when a midline cartilaginous or osseous spicule or a fibrous septum projects into the vertebral canal. These obstacles may split the spinal cord or intraspinal nerve roots into two columns, a condition termed diastematomyelia. Usually, patients with this condition have a cutaneous abnormality, such as a dimple, pigmented naevus or patch of hair, along their back at the level of the tethering.

junction), in the axial, coronal and sagittal planes. In the coronal plane, the posterior ossification centres have a characteristic 'railtrack' appearance; the twelfth rib is adjacent to the twelfth thoracic vertebra and the first sacral vertebra is level with the top of the iliac wing. Longitudinal scans of the fetal spine can demonstrate scoliosis and hemivertebrae.

DEVELOPMENT OF DERMOMYOTOMES

The dermomyotome forms from the dorsal half of the early somite and gives rise to all the skeletal muscle in the trunk and limbs and to the intrinsic muscles of the tongue. Muscles in the head arise from the unsegmented paraxial mesenchyme rostral to the occipital somites. The dorsomedial lip (border) of the dermomyotome is an infolding of the epithelial plate of the somite and becomes a proliferative epithelial site from which mediolateral growth of the dermomyotome itself occurs. The neural tube, the notochord/neural floor plate complex and the (early) dorsally placed ectoderm are all required for myogenesis. A balance between levels of Shh from the notochord and Wnts from the dorsal neural tube and ectoderm promotes myogenesis; high levels of either lead to sclerotomal or non-myogenic dermomyotomal development (Scaal and Christ 2004). Myogenic determination factors, MyoD, myogenin, Myf5 and herculin/MRF4, can first be detected in the medial half of the somite as early as stage II in chick embryos, several hours prior to the onset of myotome formation.

The mode of formation of mononucleated, postmitotic, primitive myotubes from the dermomyotome has been elucidated in the chick but not yet confirmed in mammals (Gros et al 2004) (**Fig. 18.17**). In this model, all four borders of the dermomyotome give rise to myotomal cells, produced in two phases. First, cells are produced from the dorsomedial dermomyotomal lip by direct ingression and bidirectional extension. Second, myotomal precursor cells are released by the caudal dermomyotomal border, followed, in turn, by the cranial dermomyotomal border, and lastly, by the ventrolateral dermomyotomal lip. Those myotomal cells arising from the dorsomedial dermomyotomal border contribute cells exclusively to the epaxial domain, while those from the ventrolateral border contribute cells exclusively to the hypaxial domain. The cells arising from the cranial and caudal borders move into both epaxial and hypaxial domains (Scaal and Christ 2004) (see Fig. 18.8). Later in development, proliferative muscle progenitor cells originating from the de-epithelializing dermomyotome contribute to fetal muscle growth (Gros et al 2005).

Epaxial muscle: dorsal trunk muscles

Epaxial muscles arise from the dorsomedial lip of the dermomyotome. Early myotome cells are postmitotic embryonic myoblasts. Later in development, they fuse to form syncytia that produce the intrinsic skeletal muscles of the back. They bridge the early segmental borders and join vertebrae together. The epaxial muscles are innervated by the dorsal rami of each pair of spinal nerves. At later stages, satellite cells originating from the dermomyotome enter the myotome. The mechanism of development of endo-, peri- and epimysium in relation to the epaxial muscles has not been conclusively determined.

The development of epaxial muscle in the human embryo has been studied in staged human embryos. From stage 16 epaxial myotomes merge into a longitudinally continuous muscle mass that extends from the occiput to the second lumbar vertebra. By stage 17 this longitudinal muscle mass has segregated into lateral and medial columns and the medial column further segregates into intermediate and medial columns by stage 18. Development appears to be from lateral to medial and gives rise to all of the intrinsic back muscles. Caudal to the third lumbar vertebra, the epaxial compartment does not develop the same muscle mass columns seen at more proximal levels (Mekonen et al 2016, Warmbrunn et al 2018): the caudal zone of tissues that encompass the lower lumbar and sacral vertebrae is derived by secondary neurulation processes from the caudal eminence and there is no neural plate at these levels (Ch. 14). The ways in which the neural tube, neural crest and splanchnopleuric and somatopleuric mesenchymal populations develop from this caudal zone are not yet clear: it is possible that the developmental patterning processes identified in cervical and thoracic regions do not operate at this level.

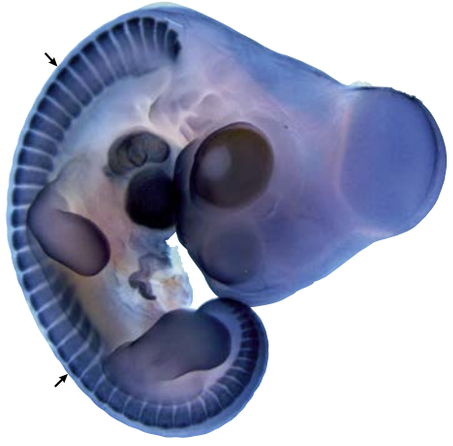

Fig. 18.17 The metameric structure of the myotomes (arrows) of a 5-day-old chick embryo, visualized by whole-mount immunohistochemistry with an antibody staining for myosin heavy chain.

Hypaxial muscle: ventrolateral trunk muscles

Two modes of production of hypaxial musculature are seen, depending on the axial level (see Fig. 18.7). At cervical and trunk levels, myotubes are produced by the ventrolateral edge of the dermomyotome in a manner similar to the production of epaxial muscles. As development proceeds, lateral growth of the dermomyotome means that the ventrolateral border extends ventrolaterally into the developing lateral and ventral body wall, in a process that depends on the homeobox-containing transcription factor Pitx2 (Eng et al 2012). The somite structures that extend into the somatopleure of the abdominal and thoracic walls thus consist of two layers, dermomyotome and myotome, that give rise to the muscle blastemata for the intercostal and abdominal oblique muscles, transversus abdominis and rectus abdominis. The number of somatopleuric mesenchymal cells within the muscle-forming zone increases, and myotubes can be seen for the first time. There is a subsequent ventral shift of the already separated muscle blastemata within the growing abdominal wall as they attain their definitive positions. Muscle differentiation continues and muscular connective tissue, tendons and aponeuroses develop. In the human embryo at stage 15 separate epaxial and hypaxial muscle compartments are evident as the hypaxial muscles extend into the lateral body wall. The interlimb hypaxial musculature is continuous with the musculature of the cervical region and upper limb and caudally extends to the lower boundary of the forming umbilical ring and lower limb mesenchyme (Mekonen et al 2015). Three muscle sheets can be identified by stage 18, corresponding to external abdominal oblique, internal abdominal oblique and transversus abdominis; these layers are homologous throughout mammalia (Hall et al 2017). Between stages 18 and 23 the infra-umbilical region expands caudally, the caudal boundaries of external abdominal oblique, internal abdominal oblique and transversus abdominis extend to the ilium and the cranial boundaries descend 6 body segments to their definitive attachments to the ribs. Rectus abdominis is seen from stage 18. For details of the formation of hypaxial muscles see (Mekonen et al 2015).

At occipital, cervical and limb levels, a ventrolateral dermomyotomal lip is not formed in the same way: cells undergo epithelial to mesenchymal transformation and migrate to their destination. Myoblasts move from the occipital dermomyotomes into the developing mandibular processes to form the intrinsic muscles of the tongue (Ch. 17), and from cervical dermomyotomes into the developing respiratory diaphragm (Ch. 20). Those opposite the early limb buds migrate into the limbs as dorsal and ventral muscle masses that give rise to the shoulder, hip and appendicular muscles (Ch. 19). The muscles of the perineal region are derived from a portion of the ventral muscle mass that migrates into the lower limb and then subsequently migrates back into the cloacal region after cloacal division by the urorectal septum. The muscle masses form layers similar to those in the ventrolateral trunk: the layers are the external anal and urethral sphincters, bulbospongiosus, ischiocavernosus, transverse superficial peroneal muscle and levator ani (Ch. 22). This arrangement is patterned by the local somatopleuric mesenchyme which regulates the extended myotomal sheets of the ventrolateral body wall and gives rise to the associated muscular connective tissues, tendons and aponeuroses (Hall et al 2017). (For a review of dermomyotomal development, see Scaal and Christ (2004).)

Other structures derived from the somites

Dermal precursors arise from the central portion of the dermomyotome and (possibly) from the dorsomedial dermomyotome lip (see Fig. 18.7). The cells undergo an epithelial to mesenchymal transformation, leave the dermomyotome and migrate to the dorsomedial subectodermal

In spina bifida, the posterior ossification centres show abnormal widening in the axial plane; forming a U or V shape, they splay outwards from each other and are no longer parallel. Anomalies of the spine (spina bifida) are among the most common fetal malformations noted on antenatal ultrasound examination (Asch and Sauerbrei 2018). The Northern Congenital Abnormality Survey reported a total prevalence at birth and termination of 17.9 cases/10,000 between 1984 and 1996 in the UK and Ireland, compared with the prevalence in Europe of 11.5 cases/10,000 over the same time period. The prevalence in the years 1991–2012 was estimated to be 12.8 cases/10,000 in England and Wales (19% live births, 81% terminations and 0.5% still birth and fetal deaths at less than postmenstrual week 20). There was little change in prevalence between the years 1998 and 2012 in the UK, whereas in the United States the introduction of mandatory fortification of flour with folic acid in 1998 was followed by a 23% reduction in the occurrence of neural tube defects (Morris et al 2016).

space overlying the dorsal neural tube. Their transformation seems to be controlled by factors from the neural tube. There is a sharp boundary between dermis that is somite-derived (covering the back) and that which is derived from the somatopleuric mesenchyme of the lateral plate (covering the limbs, part of the lateral and all of the ventral body wall).

Somitic cells are now considered to give rise to smooth muscle cells within and around the developing somites and within the tunica media of the descending aorta (Wiegreffe et al 2007). All compartments of the epithelial somite, including the somitocoele cells, give rise to angioblasts. The early ventral half of the somite gives rise to the endothelium of ventrolateral blood vessels. Angioblastic cells arising from the dorsomedial dermomyotome migrate mainly into the dorsal dermis, whereas those arising from the dorsolateral part move to the ventrolateral body wall and limbs (Scaal and Christ 2004, Christ et al 2007).

CHAPTER 19

Development of the limbs

OVERARCHING CONCEPTS

The limbs develop from permissive and instructive interactions between epithelium and mesenchyme at specified times and places along the lateral body wall. The outgrowths are initiated at defined positions along the embryonic axis where these cell lines continue to proliferate, giving rise to local thickenings that soon develop into limb buds (Gros and Tabin 2014). The early limb bud elongates and, gradually, the different limb regions become apparent. A broad plate forms at the tip and, within it, digital rays develop that mark the position of the forming digits. The digits later separate and become tipped with nails. **Fig. 19.1** shows the main stages in the development of a human upper limb; the stages in development of the lower limb are basically the same.

Upper and lower limb buds protrude laterally from the trunk, encased in an ectodermal epithelium rimmed by a longitudinal ridge of columnar epithelial cells: the apical ectodermal ridge. The ectoderm will ultimately form the epidermis of the skin. Beneath the epithelium is a mixed population of mesenchymal cells derived from the proliferating epithelial somatopleuric lateral plate (Ch. 12, p. 205); these cells have already undergone restriction to develop into upper or lower limbs before the limb buds are visible. They give rise to the connective tissues, bone, cartilage, ligament, tendon, muscle attachment and encasing layers, loose connective tissue and dermis. Muscle in the limb originates from paraxial mesenchyme cells that migrate from the somites; this cell population also contributes to some of the endothelial cells that produce an extensive vascular network in the early limb bud. Motor and sensory nerves and their associated Schwann cells, together with melanocytes destined for the skin, migrate into the developing limb somewhat later; motor neurones derive from the neural plate; sensory neurones, Schwann cells and melanocytes are derived from the neural crest.

Specification of the axes of the limbs

For descriptive, experimental and conceptual purposes, various 'axes', borders, surfaces and lines in relation to the developing limb bud are defined and named (**Fig. 19.2**). An imaginary line from the centre of the elliptical base of the bud, through the centre of its mesenchymal core to the centre of the apical ectodermal ridge, defines the proximodistal axis of the limb bud (previously known in descriptive embryology simply as the axis). Named in relation to the proximodistal axis, the cranially placed limb border is the preaxial border and the caudally placed limb border is the postaxial border. (In vertebrate embryos used as experimental models, e.g. chick embryos, the pre- and postaxial borders are termed anterior and posterior borders, respectively.) Any line that passes through the limb bud from preaxial to postaxial border, orthogonal to the proximodistal axis, constitutes a craniocaudal axis. The dorsal and ventral ectodermal surfaces clothe their respective aspects from preaxial to postaxial borders, and any line that passes from dorsal to ventral aspect, orthogonal to both proximodistal and craniocaudal axes, constitutes a dorsoventral axis. It should be noted here that the terms dorsal and ventral axial lines are to be used exclusively in relation to developing and definitive patterns of cutaneous innervation of the limbs and their associated levels of the trunk.

The three developmental axes (proximodistal, craniocaudal and dorsoventral) can be identified in the human developing limb bud by stage 13 (31–33 days postfertilization, see Fig. 23.3). Experiments on wing buds of chick embryos have shown that a different set of cell–cell interactions control the development of structures in relation to each of the three principal axes of the limb bud: proximodistal (e.g. humerus to fingers), craniocaudal (e.g. thumb to little finger) and dorsoventral (e.g. extensors to flexors) (see Fig. 19.2). The same sets of interactions take place in chick leg limb buds. These experiments are described in detail in Hinchcliffe and Johnson (1980).

Outgrowth of the limb bud along its proximodistal axis is controlled by interactions between the apical ectodermal ridge and underlying somatopleuric mesenchyme, and is accompanied by the sequential formation of limb structures along the proximodistal axis. Growth and development along its craniocaudal axis involves an interaction between a small population of mesenchyme cells on the postaxial border of the limb bud, termed the zone of polarizing activity, or polarizing region, and adjacent mesenchyme. The development of the dorsoventral axis of the limb involves an interaction between the surface ectoderm on the sides of the limb bud and the underlying mesenchyme. These sets of cell–cell interactions are coordinated so that the developing limb develops properly with respect to all three axes.

Early differential growth of parts of the limb bud results in two main changes to the originally symmetric axes of the limb. The dorsal aspect of the limb grows faster than the ventral, which causes the limb bud to curve around the body wall; the ventral surface of the limb (closest to the body wall) remains relatively flat, but the dorsal surface bulges into the amniotic cavity. The apical ectodermal ridge, originally facing laterally, becomes increasingly directed caudally (upper limb) and ventrally (lower limb) as the limbs extend around the body.

Apical ectodermal ridge

The apical ectodermal ridge (AER, or apical ridge) is required for limb bud outgrowth. When it is removed from a chick wing bud, outgrowth ceases and a truncated wing results with the level of truncation depending on the stage at which the ridge is removed; severe truncations result when the AER is removed from early limb buds while progressively more distal structures develop when the AER is removed at later stages. The importance of the AER is further demonstrated by grafts of a second AER to a wing bud inducing a new outgrowth that develops digits (Saunders et al 1976, Tickle 2017) (**Fig. 19.3**). The molecular basis of the cell–cell interactions between apical ridge and underlying mesenchyme is conserved between different vertebrates; the apical ectodermal ridge of a mouse limb bud can promote outgrowth of a chick wing bud.

There is evidence that the limb mesenchyme beneath the apical ectodermal ridge provides a factor that is essential for maintaining activity of the ridge (the so-called apical ectodermal ridge maintenance factor). Thus, the craniocaudal extent of production of apical ectodermal ridge maintenance factor determines the length of the apical ectodermal ridge. When cells from the proximal region of a chick leg bud are grafted to the tip of a wing bud beneath the apical ectodermal ridge, the apical ridge is maintained and outgrowth continues. It should be noted that the grafted cells produce the structures according to their new position, but because they are leg cells, they form toes rather than wing digits (Saunders and Gasseling 1959) (see Fig. 19.3). In addition, leg mesenchyme will pass information to local wing ectoderm, eliciting appropriate epidermal development: in this case, formation of scales rather than feathers.

For many years it was thought that a timing mechanism linked to limb bud outgrowth specified the pattern of structures along the proximodistal axis. The timing mechanism was postulated to operate at the tip of a developing limb bud beneath the apical ectodermal ridge in the zone of proliferating undifferentiated mesenchyme cells, which was therefore called the progress zone. It was assumed that, as cells left the progress zone during limb bud outgrowth, their proximodistal fate becomes fixed. Thus, cells spending a short time at the tip of the limb bud would be specified to form proximal structures, while cells spending a longer time would be specified to form distal structures (Summerbell et al 1973). It was suggested that the proximodistal pattern is specified in the very early limb bud (Dudley et al 2002) and that the prespecified structures are progressively elaborated as the bud grows out. It now seems that the proximal part of the limb (humerus/femur) is specified in the very early limb bud by signals from the body wall (Cooper et al 2011, Rosello-Diez et al 2011) while the more distal structures are specified as the bud grows out by a timing mechanism (Saiz-Lopez et al 2015).

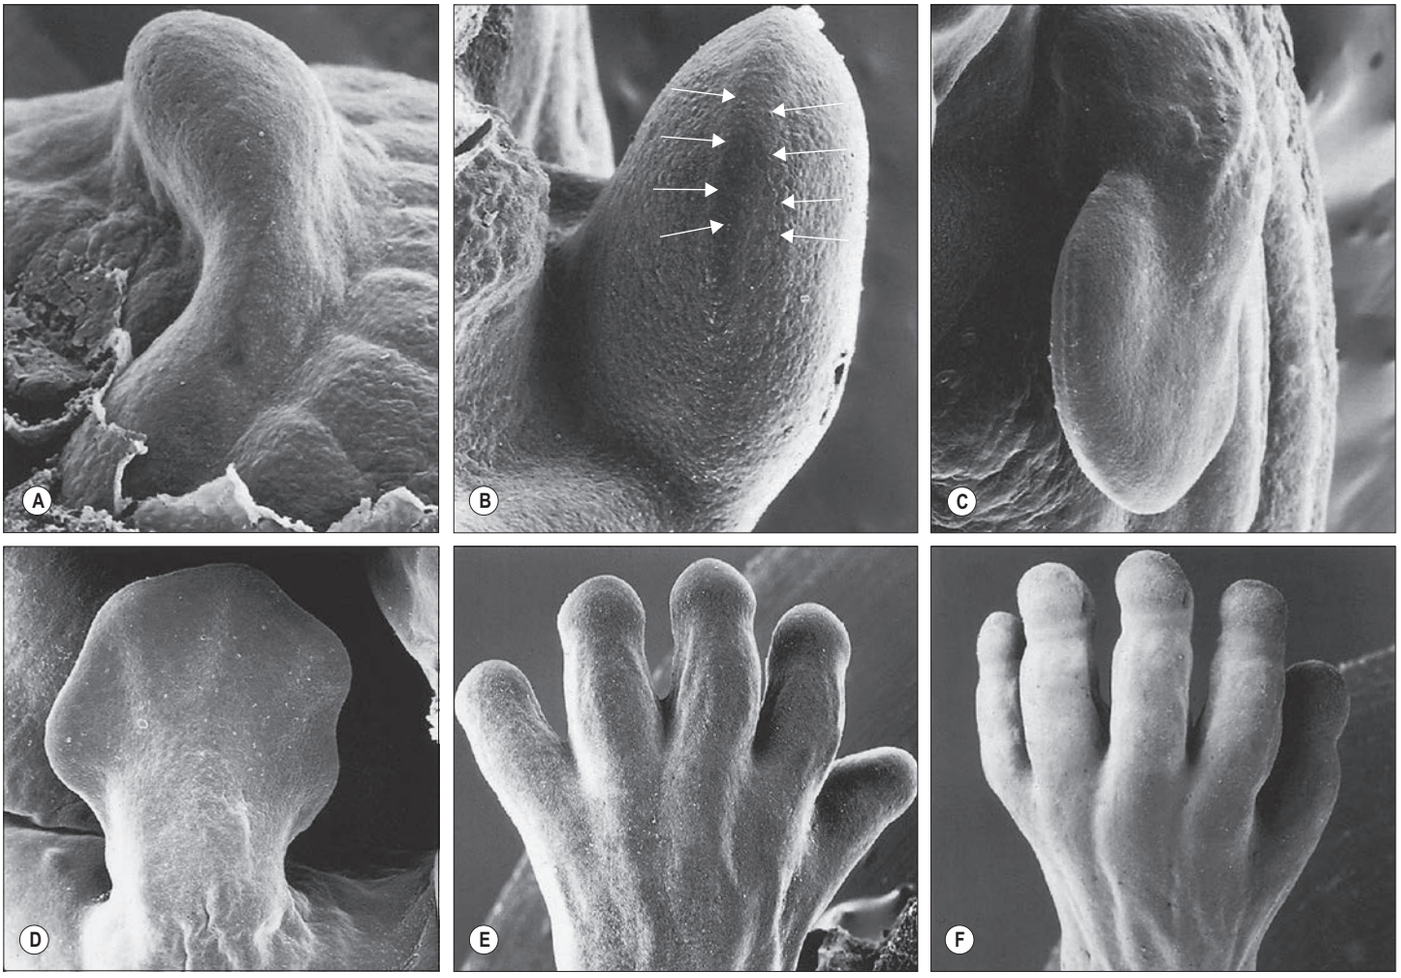

Fig. 19.1 Scanning electron micrographs to show the development of the upper limb. **A**, An early limb bud viewed from the postaxial border. **B**, A limb bud viewed from the postaxial border; the apical ectodermal ridge (arrows) can be seen. **C**, A limb bud, dorsolateral view; the shoulder and elbow region can be discerned, and a hand plate has formed. The apical ectodermal ridge is still obvious at the margin of the hand plate. **D**, Digital rays are present in the hand plate and the margin of the plate is becoming notched. **E**, The fingers are nearly separated and proliferation is commencing at the distal end of each digit to form the nail bed. **F**, The fingers each have tactile pads distally, and nail development continues. (Photographs courtesy of P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

Zone of polarizing activity

The zone of polarizing activity (or polarizing region) at the postaxial border was discovered by a grafting experiment on chick wing buds (Saunders and Gasseling 1968, Tickle 2017). When a polarizing region is grafted to the preaxial border of an early chick wing bud, so that there are polarizing region cells at both borders, duplication of distal limb structures occurs, with two ulnae (instead of an anterior radius and posterior ulna) and a mirror-image pattern of six digits (the normal chick wing has three digits (see Fig. 19.3)). The digit closest to the polarizing region is always the most postaxial digit (in the chick wing, traditionally designated as digit 4), while more preaxial digits develop further away. Thus, it was proposed that the polarizing region is the source of a diffusible morphogen which controls both digit pattern and digit number. Digit pattern is specified by concentration of the morphogen although timing is also important, e.g. an additional digit can be specified by a prolonged exposure to a low morphogen concentration or by a short exposure to a high morphogen concentration. Digit number is controlled by regulating the width of the limb bud: both directly, via promoting cell proliferation, and indirectly, by controlling production of the apical ectodermal ridge maintenance factor. The width of the limb bud is also limited by zones of programmed cell death on the preaxial and postaxial borders. (It should be noted that, in the literature relating to work on animal embryos, pre- and postaxial borders are termed anterior and posterior borders, respectively, and therefore the regions in which programmed cell death occurs are termed the anterior and posterior necrotic zones.) When the length of the apical ectodermal ridge is reduced, fewer digits form (oligodactyly), while, when the apical ectodermal ridge becomes longer, more digits form (polydactyly). Other regions of apoptotic cell death occur between the digits and result in separation of the digits, but these appear later than the anterior and posterior necrotic zones; the resultant debris in the necrotic zones is removed by macrophages.

Grafts of the zone of polarizing activity only generate mirror-image digit patterns when placed beneath or adjacent to the apical ectodermal ridge in a chick wing, suggesting that the apical ridge produces a factor that maintains polarizing region activity. A positive feedback loop, in which the polarizing region and the apical ectodermal ridge mutually maintain each other's activity, ensures that development of craniocaudal and proximodistal axes is coordinated. Like that of the apical ectodermal ridge, the function of the polarizing region is conserved across species and grafts of the postaxial border of limb buds from mammals, including human limb buds (Fallon and Crosby 1977), generate additional chick digits. This shows that the polarizing region produces the same molecular signal in both birds and mammals, but that the character of a digit depends on the responding cells.

Ectodermal axial specification

Signals from the ectoderm control the dorsoventral axis. It is possible to remove the surface ectodermal epithelium (like peeling off a glove) from the mesenchymal core of an early chick limb bud. When the ectodermal epithelium from a left limb bud is recombined with the mesenchymal core from a right limb bud, keeping the craniocaudal axis in register, the distal part of the limb that develops conforms to the polarity of the ectoderm rather than the polarity of the mesenchyme (MacCabe et al 1974) (see Fig. 19.3). This can be seen in the pattern of muscles, orientation of the joints and eventual characteristic differentiation of the epidermis.

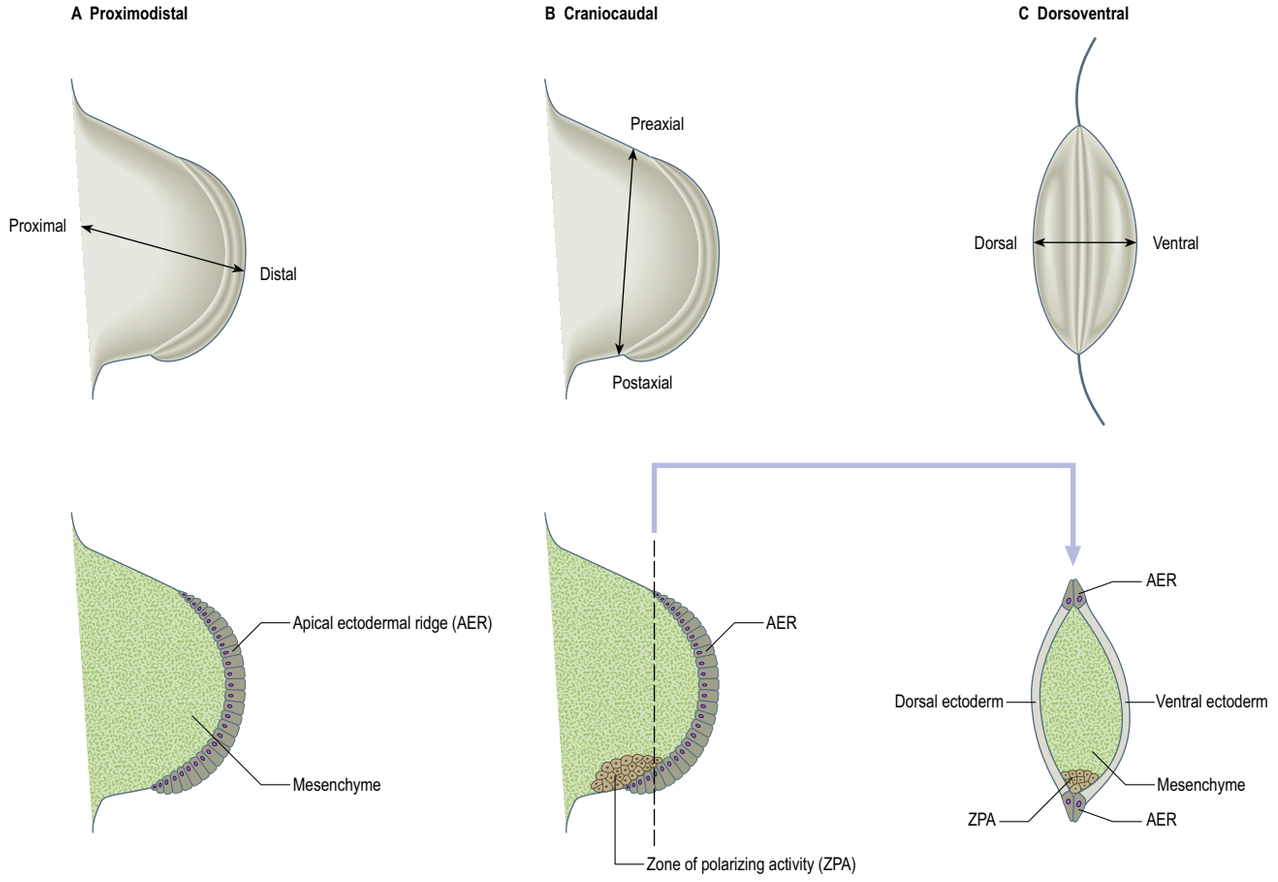

Fig. 19.2 Axes of the developing limb and specification of structures along the different axes. **A**, Proximodistal; limb bud viewed from the dorsal side. **B**, Craniocaudal; limb bud viewed from the dorsal side. **C**, Dorsoventral; limb bud viewed from the distal end. The development of limb structures and the ectodermal specializations are controlled by the limb mesenchyme. Outgrowth of limb bud is controlled by the apical ectodermal ridge and accompanied by the laying down of structures along the proximodistal axis; craniocaudal pattern is controlled by the zone of polarizing activity (polarizing region); dorsoventral pattern is controlled by signals from dorsal and ventral ectoderm, shown in cross-section; the section taken in the plane is shown by the dotted line. The limb bud in the diagram is equivalent to that of a human embryo at approximately stage 14.

Genes and molecules in limb development

The apical ectodermal ridge produces fibroblast growth factors, extracellular cell–cell signalling molecules that act on the underlying mesenchyme cells and are essential for limb bud outgrowth (Niswander et al 1993). Fibroblast growth factors also maintain the activity of the polarizing region. The latter expresses *Sonic hedgehog* (*Shh*), a gene encoding another class of secreted protein that acts as diffusible morphogen (Riddle et al 1993). Sonic hedgehog protein (Shh) plays a pivotal role in the specification of the craniocaudal digit pattern: it spreads across the chick wing bud so that cells at different positions across the craniocaudal axis are exposed to different Shh concentrations (Tickle and Towers 2017). In mouse limb buds, the two most postaxial digits (corresponding to the little finger and the ring finger in the hand) come from the polarizing region itself and are specified by the length of exposure to Shh (Harfe et al 2004). Responding cells transduce the signal through the Gli family of transcription factors. (The Gli proteins are bifunctional effectors of Shh signalling and can lead to either activation or repression of expression of target genes.) Shh secreted by the polarizing region also acts on adjacent mesenchyme cells, controlling their proliferation and maintaining the expression of the Gremlin gene, encoding an extracellular antagonist of secreted bone morphogenetic proteins (BMP). Gremlin functions as the apical ectodermal ridge maintenance factor by antagonizing BMP signalling which would otherwise inhibit fibroblast growth factor (*Fgf*) expression in the apical ectodermal ridges (Zuniga et al 1999, Zeller et al 2009). Dorsal limb ectoderm expresses *Wnt7a*, a gene encoding another extracellular signalling molecule that acts as a dorsalizing signal (Parr and McMahon 1995).

Among the genes expressed in response to cell–cell signalling molecules in the limb bud and which form dynamic and overlapping domains of expression are 5′ members of the *Hoxa* and *Hoxd* gene complexes. *Hox* genes code for transcription factors that act in a cell-autonomous fashion to control expression of many target genes. There are two phases of *Hoxd* and *Hoxa* expression in the developing limb. In the first phase in the early limb bud, the expression of 5′ *Hoxd* genes (*Hoxd9*, *d10*, *d11 d12* and *d13*) is activated sequentially and in progressively more restricted distal and proximal domains, while the expression of 5′ members of the *Hoxa* gene complex is activated similarly, but slightly later than the *Hoxd* genes, in overlapping domains along the proximodistal axis. The first phase of *Hox* gene expression establishes the growth and pattern of proximal limb structures, i.e. upper and lower arm; the second phase, which occurs in the broad digital plate, establishes the growth and pattern of distal structures, i.e. the hand/foot. Regulatory gene sequences in the DNA on either side of the *Hoxd* complex have been identified that control the switch in expression from the first phase to the second phase as the limb bud develops (Andrey et al 2013). The gene encoding the transcription factor Lmxb1 is expressed in the dorsal part of the limb, in response to Wnt7a signalling by dorsal ectoderm, and establishes the pattern of dorsal structures.

The molecular basis of limb development is conserved in humans. Mutations associated with many of the genes described above are responsible for human congenital limb malformations. Details can be found in Ferretti and Tickle (2006), Zuniga et al (2012) and Pickering and Towers (2014). There are, however, many human congenital limb anomalies for which the genes involved are not known. A global gene expression analysis of developing mouse limbs estimates that several thousand genes, maybe around 35% of the genome, participate in some aspect of limb development (Taher et al 2011), with relatively fewer genes (hundreds) preferentially expressed in either forelimb or hindlimb. The first genome-wide study on developing human limbs has documented patterns of histone modifications marking active regulatory sequences in the DNA that control gene expression, with the aim of identifying regulatory regions of genes active specifically in human limb buds (Cotney et al 2013).

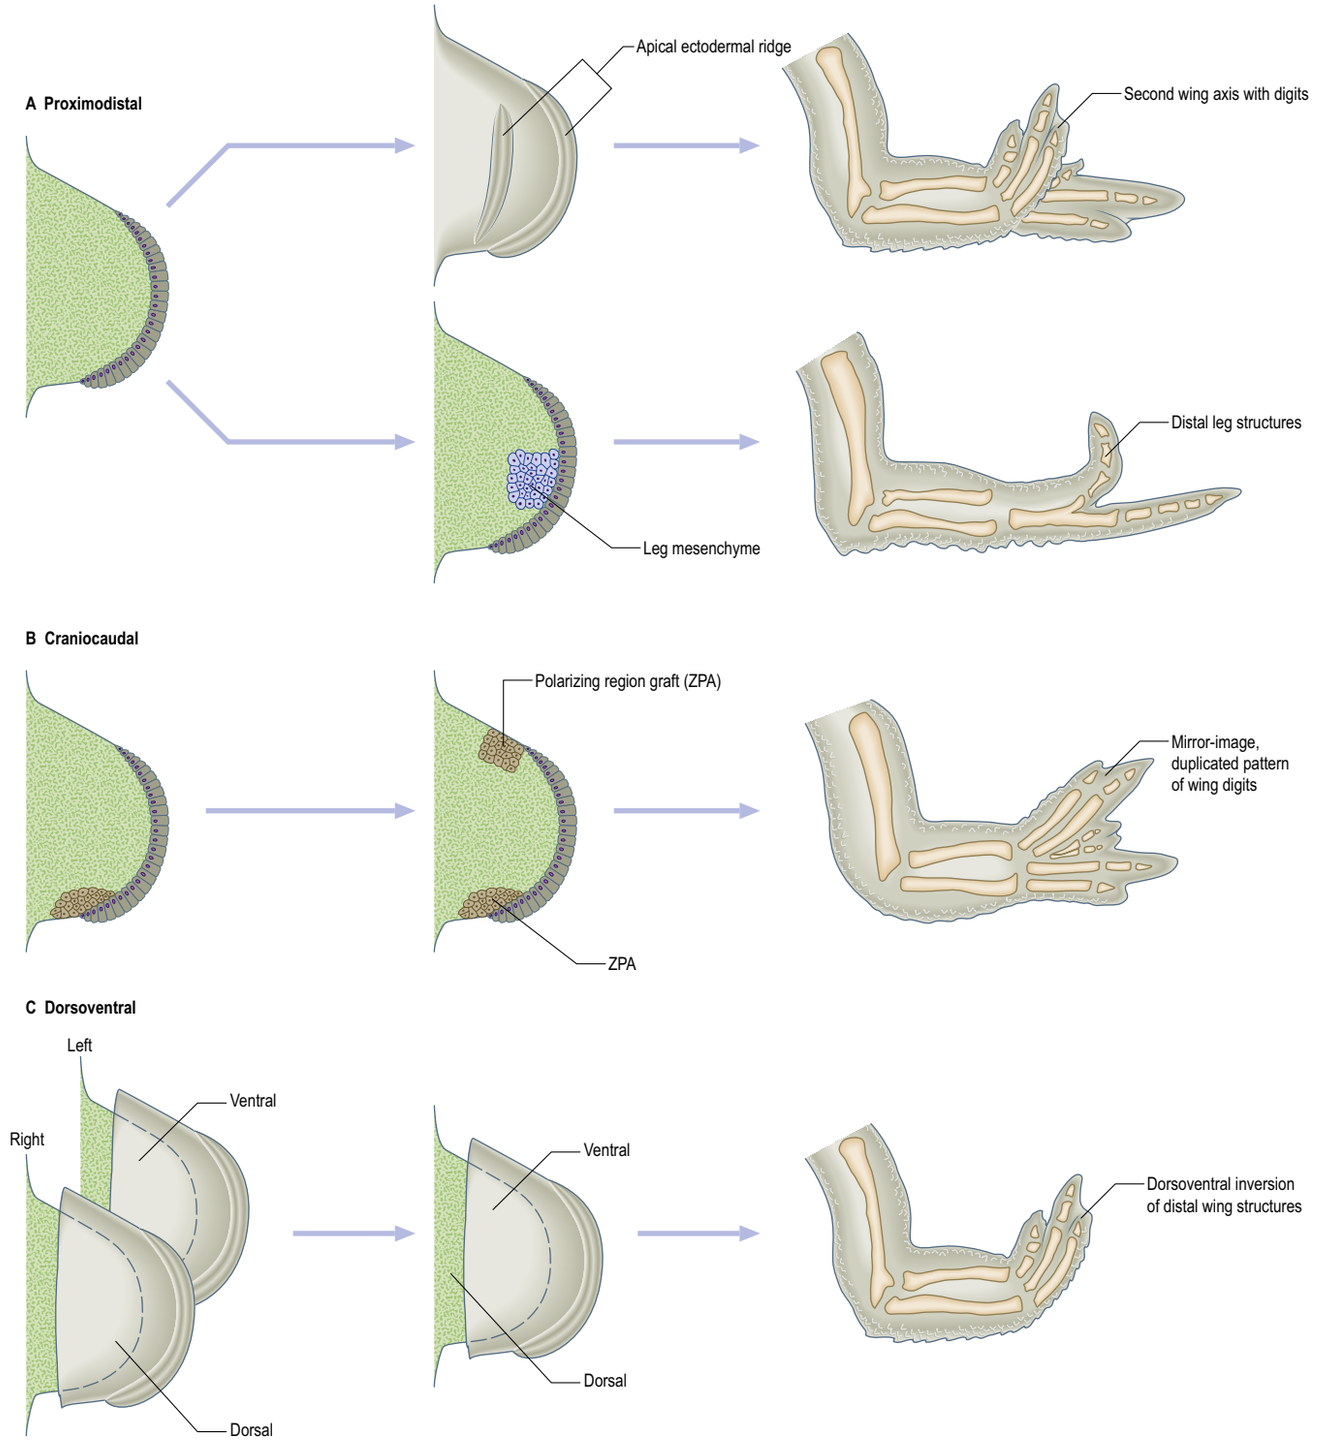

Fig. 19.3 A–C, Experimental manipulations that identified the fundamental cell–cell interactions involved in patterning the three main axes of the limb in the chick. Abbreviation: ZPA, zone of polarizing activity.

DEVELOPMENT OF LIMB TISSUES

Connective tissue and bone

Somatopleuric mesenchyme in the limb buds gives rise to the connective tissues of the limb. Cell lineage analyses in early chick limb buds show that a single mesenchyme cell can give rise to the major types of connective tissue including cartilage, perichondrium, tendon and epi-, peri- and endomysial layers around the muscles. The first signs of the formation of skeletal elements are regions of increased cell density in the core of the limb bud. The cells in these regions go on to differentiate into chondrocytes, which produce large quantities of extracellular matrix, in which they become embedded, giving rise to a cartilage model of the bone that will eventually develop. One centre of chondrogenesis forms in the proximal region of an early human limb bud; two centres of chondrogenesis then form more distally as the limb bud lengthens, followed by five centres in the broadened distal tip. The Sox9 transcription factor is essential for chondrocyte differentiation in mouse embryos; the *Sox9* gene is expressed before and during deposition of cartilage (Wright et al 1995). *Sox9* gene transcripts are expressed in the humerus and forearm skeletal elements of human embryos at approximately 44 days postfertilization, and in the carpals, metacarpals and phalanges, in addition to the more proximal elements, at approximately 52 days postfertilization (Fig. 19.4). Mutations in human *Sox9* are associated with campomelic dysplasia, a skeletal dysmorphology syndrome (Foster et al 1994). Some bony eminences, which are sites of entheses, have been shown to derive from chondrogenic foci which form separately and later than the cartilage model of the long bones (Blitz et al 2013). The cells co-express *Sox9* and the transcription factor *scleraxis* (*Scx*) and blockage of *Scx* arrests eminence development. Scleraxis is also expressed in the early limb subjacent to the ectoderm in tendon progenitors and later in the cells of all tendons. Studies of *Scx* knockout mice show that *Scx* is required for the differentiation of

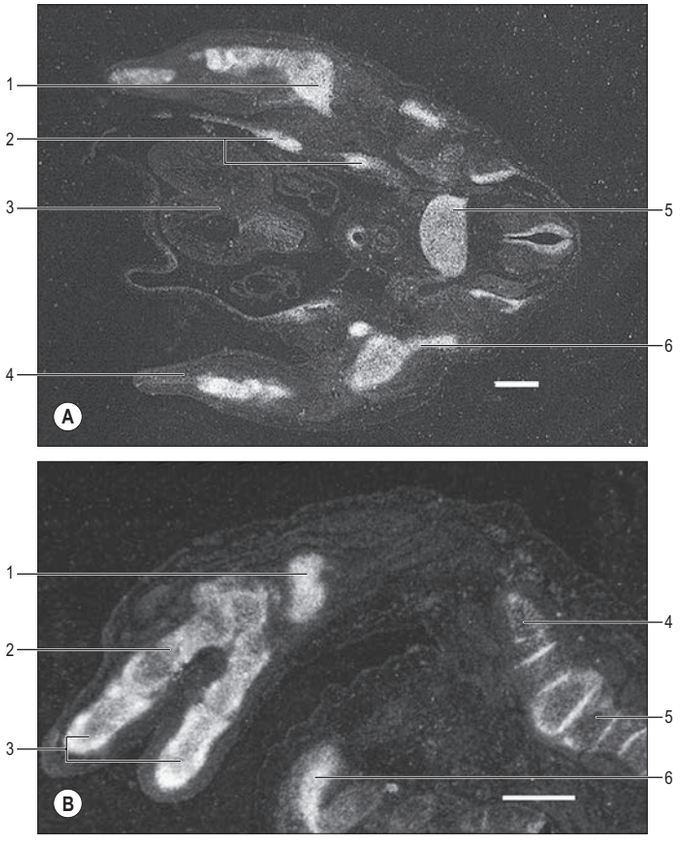

Fig. 19.4 *Sox9* expression in the skeleton of developing limbs of human embryos. **A**, Stage 18; Key: 1, humerus; 2, ribs; 3, heart; 4, forearm; 5, vertebral body; 6, scapula. **B**, Stage 21; Key: 1, carpal; 2, metacarpal; 3, phalanges; 4, humerus; 5, scapula; 6, rib. *Sox9* transcripts are detected in sections with radioactively labelled probes followed by autoradiography. Positive signal is represented by silver grains that show up as white areas. Scale bars represent 500 μm in both **A** and **B**. (The human tissue was provided by the joint MRC–Wellcome Human Developmental Biology Resource (http://www.hdbr.org) at the Institute of Human Genetics, Newcastle upon Tyne, UK. Courtesy of Dr Susan Lindsay, Institute of Human Genetics, University of Newcastle upon Tyne, UK.)

force-transmitting tendons but not for muscle-anchoring tendons (Muchison et al 2007). A population of *Scx*$^{+}$/*Sox9*$^{+}$ progenitor cells have been shown to give rise to *Scx*$^{-}$/*Sox9*$^{+}$ chondrocytes and *Scx*$^{+}$/*Sox9*$^{-}$ tenocytes/ligamentocytes. The *Scx*$^{+}$/*Sox9*$^{+}$ cells contribute particularly to establishing the enthesis organ between the cartilage and tendon. The closer the tendon is to the cartilage primordium (anchoring tendon), the more tenocytes arise from the *Scx*$^{+}$/*Sox9*$^{+}$ lineage. In general, the number of tenocytes derived from this lineage decreases with increasing distance from the cartilage model, although there is variation between individual force-transmitting tendons (Sugimoto et al 2013). For further details on tendon development see Delgado Caceres et al (2018).

Two methods of bone ossification occur (Ch. 5). In intramembranous ossification mesenchymal bone precursors differentiate directly into osteoblasts; in endochondral ossification, osteoprogenitor cells which give rise to osteoblasts enter the cartilage models of the long bones via vascular invasion. Initially a periosteal collar forms, and osteoblasts proliferate and secrete bone matrix within the mid-section of the future diaphysis, forming a primary ossification centre; this extends proximally and distally until it reaches the future epiphysial levels, where growth plates (epiphysial plates) will be established. For further details on the cellular development of cartilage and bone, see Chapter 5. For further details on the development of specific limb bones, see appropriate regional chapter. It should be noted that maternal nutrition and vitamin status affects fetal bone growth and that despite vitamin supplementation in Western countries, pregnant women in northern latitudes may remain vitamin D deficient in winter pregnancies. Infant femur length was shorter in pregnancies with early serum 25-hydroxyvitamin D below the median value (Walsh et al 2013).

The first evidence of bone formation in human embryos is intramembranous ossification of the clavicle (stage 18–19) followed by the mandible. Endochondral ossification of cartilage models of long bones is initially seen in the limbs in stage 21–23 human embryos (50–58 days postfertilization). By postmenstrual week 10, columns of chondrocytes can be seen at the epiphysial level of most bones. However, only the lower end of the femur and upper end of the tibia develop secondary ossification centres before birth.

Joints

Regions of developing cartilage are easily recognized histologically in the developing limb because they consist of widely spaced cells surrounded by matrix. These regions are separated by transverse bands of relatively flattened cells – interzones – which mark the sites of future joints. Their subsequent development varies according to the type of joint that is formed.

In developing fibrous joints, the interzone is converted into collagen, which is the definitive medium connecting the bones involved. In developing synchondroses, the interzone becomes growth cartilage of the modified hyaline type; in developing symphyses, it is predominantly fibrocartilage. In developing synovial joints, the interzonal mesenchyme becomes trilaminar when a more tenuous intermediate zone appears, splitting the mesenchyme into two dense strata. As the skeletal elements chondrify, and in part ossify, the dense strata of the interzonal mesenchyme also become cartilaginous; subsequent cavitation of the intermediate zone establishes the cavity of the joint. The loose mesenchyme around the cavity forms the synovial membrane and probably also gives rise to all other intra-articular structures, such as ligaments, discs and menisci. In joints containing discs or menisci, and in compound articulations, more than one cavity may appear initially, sometimes merging later into a complex single cavity. For details of the genes expressed in joint development consult Decker et al (2014). As development proceeds, thickenings in the fibrous capsule can be recognized as the specializations peculiar to a particular joint. (In some joints, such accessions to the fibrous capsule are derived from neighbouring tendons, muscles or cartilaginous elements.) Although the initial stages in the process of cavitation of joints are independent of movements, a true joint cavity can generally form only in the presence of movements (Shea et al 2015).

Muscles

It is well established that all limb myogenic precursor cells originate from the somites (Chevallier et al 1977, Kardon et al 2003). These cells are committed at an early stage and can be identified in the lateral halves of the somites. After the mesenchymal sclerotome cells have migrated from the epithelial somite, the remaining dorsolateral portion is termed the epithelial plate or dermomyotome of the somite (see Fig. 18.2). Cells from the dorsomedial edge of the dermomyotomes form the axial musculature, whereas, at limb levels, cells de-epithelialize and migrate from the ventrolateral edges of the dermomyotome into the limb bud. The myogenic precursor cells do not differentiate into muscle before their migration into the limb, probably because of inhibitory signals produced by the somatopleuric mesenchyme. Muscle differentiation depends on the key activity of the MyoD family of transcription factors (Weintraub et al 1991).

The myogenic precursor cells colonize the limb bud in a proximodistal direction but never reach the most distal portion of the limb. Experiments in chick embryos revealed that myogenic cells are still indifferent regarding their region-specific determination when they first enter the limb. Thus, when brachial-level somites are grafted opposite the leg-forming region, or when pelvic-level somites are grafted opposite the wing-forming region, a normal limb musculature develops, irrespective of the origin of the somites, i.e. putative myoblasts, unlike the somatopleuric (lateral plate) mesenchymal cells, are not specified to be wing or leg (Chevallier et al 1977). Other experiments in the chick wing show that the muscle pattern developed in the limb reflects the pattern of the skeletal elements: duplication or lack of lower arm elements is accompanied by the duplication or lack of the corresponding muscles (Robson et al 1994).

It is thought that in all classes of tetrapods the first myogenic cells to arrive in the limb bud form principal dorsal and ventral premuscle masses that undergo specific spatiotemporal sequences of divisions and subdivisions as the limb lengthens. In human embryos, this leads to the individualization of about 19 muscles in the upper limb and 14 muscles in the lower limb. In the upper limb, the premuscle masses first divide into three masses, the next division gives rise to the muscles attached to the carpus, and the final division produces the long muscles of the digits. A similar pattern is seen in the lower limb. The mechanisms that divide the muscle masses are not known; one suggestion is

that they are created by invading somatopleuric cells which ultimately form the myotendinous junctions, and endo-, peri and epimyseal layers which complete the composite anatomical muscle. For details on the development of the myotendinous junction see Charvet et al (2012) and Subramanian and Schilling (2015). For further development of skeletal muscle, see Chapter 5.

The literature suggests that all musculoskeletal elements are in their appropriate positions in human limbs by postmenstrual week 10. For detailed accounts of the process, consult O'Rahilly and Gardner (1975) and Uhthoff (1990). For reviews on limb development, including tissue formation, see Lane and Tickle (2003).

Vessels

Arteries

The early limb bud receives blood via intersegmental arteries that contribute to a primitive capillary plexus. At the tip of the limb bud a terminal plexus is constantly renewed in a distal direction as the limb grows (see **Fig. 19.5**). Later, one main vessel, the axial artery, supplies the limb and the terminal plexus.

The development of the vasculature in the early limb precedes the morphological and molecular changes that occur within the limb mesenchyme as tissues begin to form. Cartilage differentiation within the early chick limb bud occurs only after local vascular regression begins, and only in areas with few or no capillaries (Hallmann et al 1987). It is not known whether the presence, or lack, of blood vessels affords different local environmental stimuli for mesenchymal cells (by varying the supply of nutrients to the tissue), or whether the local environment is controlled by the endothelial cells. Experimental work on chick wing buds suggests that the position of the central artery in the primitive limb bud vasculature depends on Shh signalling from the polarizing region (Davey et al 2007).

In the developing skin in mouse embryo limbs, although there is no initial association between sensory nerves and blood vessels, later nerve–vessel alignment is seen. The skin arterial branching pattern coincides with the branching pattern of pre-established sensory nerves. Arterial differentiation is preceded by the local action of nerve-derived vascular endothelial growth factor A (VEGF-A) (Li et al 2013).

Veins

A terminal capillary plexus develops at the tip of the early limb bud; it expands as a superficial venous plexus with radicles coalescing along the pre- and postaxial borders of the limb, as a marginal vein. As the limb enlarges, the marginal vein can be subdivided into pre- and postaxial veins, which run along their respective borders and which are the precursors of the superficial veins of the limb. Generally, the preaxial (superficial) veins join the deep veins at the proximal joint, and the postaxial (superficial) veins join the deep veins at the distal joint of the limb. Deep veins develop *in situ* alongside the arteries.

Lymphatic channels

It was thought that lymphatic vessels in the limb derived from outgrowths from the main cardinal veins. However, studies on the initiation of *Prox1* expression in lymphatic vessels in mammals have identified intersomitic vessels and the superficial venous plexus of the growing limb as additional sources of lymphatic endothelial cell progenitors, especially in the dermis (Kazenwadel and Harvey 2016).

Nerves

During development, the spinal cord opposite the limbs becomes specialized, with the formation of longitudinal minicolumns (columels) along its rostrocaudal axis. The columels consist of groups of individual pools of differentiated motor neurones, precisely organized according to function (Jessell et al 2011). Motor neurones within each individual pool innervate a particular muscle. Neurones in medial pools express the transcription factor Islet1 and their axons innervate ventral limb muscles, while neurones in lateral pools express the related transcription factor, Lim1, and innervate dorsal limb muscles. Neurones also express different Hox proteins according to their position along the rostrocaudal axis of the spinal cord, and this determines not only their identity and their position within the spinal cord but also their specificity of limb muscle innervation (Dasen et al 2005, Catela et al 2016).

Motor axons enter the developing limbs earlier than sensory axons at the time when dorsal and ventral muscle masses have started to form. Guidance of the growing axons is not dependent on the presence of migrating myoblasts; when these are absent, the main nerve trunks in the limb still form, although the smaller motor branches that would innervate individual muscles do not form (Lewis et al 1981, Honig et al 2005). Neurones entering the chick embryonic limb appear to have a heterochronic delay before multinucleated muscle fibres are formed and associated with nerve endings, whereas in mammalian embryos, although nerve contact with primary myotubes is not necessary for initial myoblast migration, muscle fibre differentiation requires nerve ending contact. The temporal shift in early myoblast expression of *Pax3* to later expression of *Pax7* coincides with interaction with nerve endings (Hurren et al 2015). Motor axons grow into the dorsal and ventral muscle masses and innervate muscle groups in a proximo–distal progression. Correct axonal routing depends on both repulsive and attractive cues. The pathfinding of motor axons is an important model system for understanding binary axon guidance decisions: glial cell (line)-derived neurotrophic factor (GDNF) attracts motor neurone growth cones, and interacts synergistically with ephrin-As to determine growth cone directionality (Drescher 2011). Experimental studies in mice and chickens have shown that axons of neurones in lateral pools grow into the dorsal part of the limb as a result of repulsive interactions between the receptor EphA4 (expressed by these motor neurones) and its ligand, ephrinA (expressed by ventral limb cells). The axons of EphB-expressing motor neurones in medial pools grow into the ventral part of the limb as a result of repulsive interactions with ephrinB-expressing cells in the dorsal limb (Drescher 2011). The dorso-ventral differences in Ephrin expression in the limb are controlled by the system that establishes the dorso-ventral axis of the limb and that results in dorsal expression of Lmxb1.

Sensory neurones in the dorsal root ganglia opposite the limbs send axons peripherally to terminate in the skin and to innervate proprioceptors in the limb muscles. The trajectories of sensory axons into the limb can be influenced by their interaction with motor axons. When sensory axons grow into a developing limb, it has already been invaded by motor axons and the environment will have been altered by any extracellular factors these axons may have secreted. If motor axons are removed before sensory axons extend into a limb, those sensory axons, that would normally terminate in muscle (Ia afferent axons), appear unable to do so and instead become cutaneous nerves (Honig et al 1986, 1998, Honig and Rutishauser 1996).

The developing skin (ectoderm and immediately underlying somatopleuric mesenchyme) is essential for the normal development of cutaneous sensory axons. If the ectoderm is removed, the cutaneous nerves that would project to it are absent. This can be prevented by applying the signalling molecule BMP4 (Honig et al 2004, 2005). Cutaneous sensory axons are not matched to particular regions of skin in the limb and can innervate regions outside their usual anatomical dermatomes, or expand into regions of skin where the cutaneous innervation is eliminated (Wang and Scott 2002).

Proprioceptive sensory neurones are characterized by expression of the transcription factor Runx3 and also express a neurotrophic factor receptor (TrkC) that binds specifically to the neurotrophic factor NT-3. NT-3 is expressed in the limb bud and may serve as a short-distance guide to the ingrowing axons (Genc et al 2004). There is a reciprocal interaction with the neuronal soma: in the absence of NT-3, proprioceptive neurones in the dorsal root ganglia die. The central processes of the proprioceptive sensory neurones innervating limb muscle form monosynaptic connections to motor neurones in the spinal cord after their peripheral axons have extended into the limbs. However, the pattern for these sensory/motor connections appears to be specified early. The proximo–distal position of the sensory endings in the limb is linked to the dorso–ventral location of the target motor neurones in the spinal cord, such that proximal sensory axons will connect to ventral motor columels (Sürmeli et al 2011). NT-3 is also expressed in ventral neural tube and, as in the periphery, may help guide the axons to the correct location in the spinal cord.

The different types of sensory endings show activation at different developmental times, thus mechanoreceptors and proprioceptors are active ahead of nociceptive neurones prenatally. A third wave of mechanosensitivity acquisition by nociceptors occurs just after birth (Lechner et al 2009).

Embryonic and fetal movements

Observations in model organisms have shown that embryonic movements are vital for development of the musculoskeletal system of the limb (Pitsillides 2006, Nowlan et al 2010). These movements generate

strain and stresses on the skeletal tissues. When movement is reduced or eliminated and the limb skeleton is no longer subject to appropriate mechanical stimulation, the development of joints and endochondral ossification is abnormal. In human embryos, simple movements of an extremity have been detected sporadically as early as postfertilization week 7 by ultrasonography. Combined movements of limb, trunk and head commence between postmenstrual weeks 12 and 16, and trunk and lower limb movements are perceived consistently by the mother from about postmenstrual week 16 (quickening). Movements of the fetus often involve slow and asymmetric twisting and stretching movements of the trunk and limbs, which resemble athetoid movements. There may also be rapid, repetitive, wide-amplitude limb movements, similar to myoclonus. Forces generated by movements in human fetuses have been measured by novel cine-magnetic resonance imaging and the resultant stresses and strains on the developing limb skeleton determined *in utero* (Verbruggen et al 2018). The forces generated by fetal kicks increases between postmenstrual weeks 20 and 30, and even though this movement then decreases, the overall stresses and strains on the fetal limb skeleton rise during the third trimester.

By postmenstrual week 32, symmetric flexor movements are most frequent. By term, the quality of the movements has generally matured to smooth, alternating movement of the limbs, with medium speed and intensity. The reduced effect of gravity *in utero* may cause certain fetal movements to appear, on ultrasonography, more fluent than the equivalent movements observed postnatally. The number of spontaneous movements decreases after postmenstrual week 35 and, from this time, there is an increase in the duration of fixed postures. This restriction of normal fetal movements in late gestation reflects the degree of compliance of the maternal uterus. Movement patterns of preterm babies from postmenstrual week 27 have been observed and anomalous general movements categorized (Einspieler et al 2016). These studies add to the general knowledge of maturation of the preterm musculoskeletal system and predict later movement deficits. It is not known whether the different stresses and strains of early gravitational forces and limitations of movement imposed by medical access cause their own epigenetic effects in the preterm infant.

In addition to promoting normal musculoskeletal development, movements of the fetus encourage skin growth and flexibility indirectly. Fetuses with *in utero* muscular dystrophies, or other conditions that result in small or atrophied muscles, have webs of skin, pterygia, which pass across the flexor aspect of the joints and severely limit movement. Multiple pterygium syndrome is characterized by webbing across the neck, the axillae and antecubital fossae. Usually, the legs are maintained straight and webbing is not seen at the hip and knee. A group of congenital disorders, collectively termed 'multiple congenital contractures', may result from genetic causes, or limitations of embryonic and fetal joint mobility, or may be secondary to muscular, connective tissue, skeletal or neurological abnormalities. These conditions may be recognized on prenatal ultrasound examination by the appearance of fixed, immobile limbs in bizarre positions, or by webbing in limb flexures. Specific syndromes, lethal multiple pterygium syndrome and congenital muscular dystrophy, have been described.

PECTORAL GIRDLE

The pectoral girdle develops at an interface between the tissues forming the head and neck, the back and the upper limb. Each of these regions appears to have different cell lineages and heterochronic gene expression contributing to the development of similar tissues that reflect the evolution of the neck and shoulder region (Commentary 2.1).

Early limb development is patterned by somatopleuric mesenchyme via permissive interactions with the limb ectoderm, and cartilage differentiation to a chondrogenic phenotype is initiated by local increases in mesenchyme cell density. A number of mesenchymal populations have been suggested as giving rise to the pectoral girdle: cells adjacent to the paraxial mesenchyme of somites 1–3 (which have been described, possibly erroneously, as occipital lateral plate); somatopleuric mesenchyme; the hypaxial rather than the epaxial domain of specific somites; neural crest cells, which give rise to and pattern the connective tissues in the head. Studies on chick embryos have shown that the clavicle arises from mesenchymal populations just caudal to the pharyngeal arches at the head/trunk interface, and that lateral scapular structures are derived from the somatopleuric mesenchyme, whereas the medial border of the scapula originates from dermomyotomes of somites 17–24, which switch from a myogenic to a chondrogenic fate (Wang et al 2005, Valasek et al 2010, 2011, Nagashima 2016). The sternum is derived from somatopleuric mesenchyme, although there is evidence of neural crest within the manubrium.

Pectoral girdle muscles have a similar heterogeneous origin. Upper limb myoblasts derived from somites migrate laterally from the ventrolateral border of cervical dermomyotomes and form dorsal and ventral masses prior to migration into the limb bud. After a brief period within the limb bud, a subset of these myoblasts migrates medially, out of the limb bud and back towards the axial mesenchyme to form the pectoral muscles ventrally and latissimus dorsi dorsally. This origin of the superficial pectoral girdle muscles has been described as an 'in–out' mechanism (from the trunk into the limb and then from the limb back towards the trunk) (Valasek et al 2011). Only myoblasts undergo this second, medial, migration out of the limb bud. The somatopleuric mesenchyme remains within the proximal limb anlagen and produces the glenohumeral joint and coracoid process. The deep pectoral girdle muscles, serratus anterior and the rhomboid muscles arise from the hypaxial domain of those somites forming the medial border of the scapula (Valasek et al 2011).

Trapezius and sternocleidomastoid muscles (evolutionarily related to the cucullaris muscle in the chick), are derived from upper occipital somites and innervated by the accessory nerve (see also Pu et al 2016) (see Fig. 17.7); the myoblasts migrate into neural crest mesenchyme which forms their connective tissue. The proximal and distal attachments of trapezius, to the nuchal line of the occipital bone and the upper part of the spine of the scapula, respectively, are derived from post-otic neural crest cells, as is the attachment of sternocleidomastoid muscle to the clavicle (Matsuoka et al 2005). Gene expression of the pectoral girdle muscles reflects the myoblast origins. *Pax3* and *Pax7* are normally expressed during trunk muscle development, but not in head myogenic precursors; *Tbx5* is expressed in the upper limb but does not extend to the dorsal midline. Pharyngeal arch muscle related genes, *MyoR*, *Pitx2* and *Tbx1*, are expressed early in the myoblast populations giving rise to the trapezius and sternocleidomastoid muscles, but the muscles themselves differentiate later, in line with the head and not the trunk myogenic programme (Theis et al 2010).

A 'muscle scaffold model' proposed by Matsuoka et al (2005), which links the patterning effects of mesenchyme populations, which form endo-, per- and epimysium as well as tendons, to muscle attachment sites, may explain a range of anomalies based on defects of post-otic neural crest and which affect the pharynx and larynx as well as the shoulder region, e.g. Klippel–Feil disease, Sprengel deformity and cleidocranial dysplasia.

UPPER LIMB

In human embryos, the upper limb bud is first visible as a thickening along the lateral longitudinal axis of the body wall opposite somites 8–10, at the level of the entrance to the cranial intestinal portal during stage 12 (30–32 days postfertilization). It enlarges, protruding laterally from its elliptical base at the body wall as a symmetric bud, with a curved border and an apical ectodermal ridge forming its distal tip. Initially, it has equal and relatively flat dorsal and ventral ectodermal surfaces and a somatopleuric mesenchymal core. By stage 13 the upper limb bud is curved ventrally. By stage 14 it has elongated and is opposite the developing ventricles of the heart; it is directed caudally because of preferential elongation of the preaxial part of the bud. At stage 15 the upper limb can be subdivided into definite regions. The proximal portion, still showing the dorsal bulge and ventral curve, is the shoulder and upper arm region; the next distal portion can now be identified as the forearm; the most distal portion is now expanded into a flattened hand plate.

At stage 16 there are the first indications of digit rays in the hand plate. The limb may be close to the body wall or may be abducted. By stage 17 the upper limb has an elbow region and well-defined digit rays; the hand plate may show a crenated rim, indicating the start of tissue removal between the digits (see Fig. 19.1). Crenation of the hand plate between the digit rays continues in stage 18 embryos (42–44 days postfertilization). Changes during stages 19–23 are concerned with growth of the limb and separation of the digits. The hands now curve over the cardiac region. The distal phalangeal portions of the fingers enlarge at stage 21, forming the nail beds. The finger tip is the only part of the human limb that can regenerate and does so as long as enough of the nail remains (Jafari et al 2017). The digit tips of mice also regenerate and have been used as an experimental model to investigate the processes involved. It is hoped that new clinical approaches can be found to promote regenerative responses in damaged limbs (Dolan et al 2018).

Most of the bones in the appendicular skeleton are derived from somatopleuric mesenchyme. Prechondroblasts are present in the upper limb at stage 13 and condensations of cartilage can be detected at stage 16, when the humeral anlage can be recognized. Cavitation of the

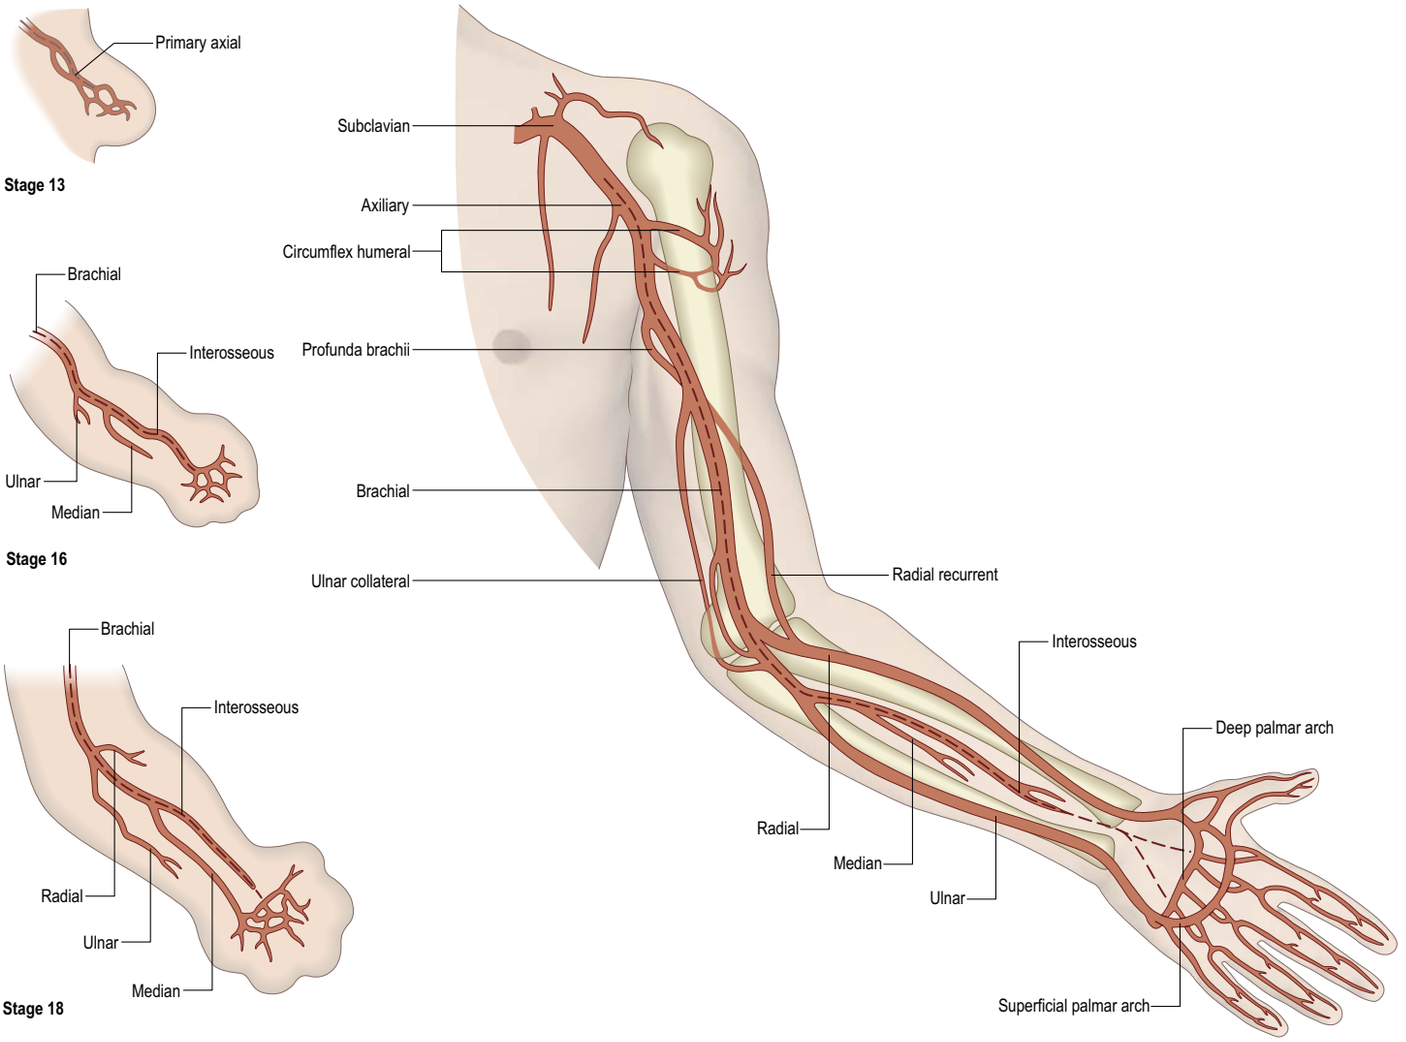

Fig. 19.5 Stages in the development of the arteries of the arm. The path of the axial artery is indicated by an interrupted line.

shoulder and elbow joints occurs at postfertilization weeks 7–8. By stage 17 when the radius and ulna chondrify, the branched tips of the radial, median and ulnar nerves have migrated to the distal hand plate. The carpals chondrify at stage 18, when the hand plate shows notching of the digital rays; the distal phalanges of the hand chondrify in stages 21 and 22. Ossification is earliest in the clavicle, between stages 18 and 20. It begins in the humerus during stages 21 and 22, in the ulna in stages 22 and 23 and in scapula and radius in stage 23. For more details see O'Rahilly and Gardner (1975), Gupta et al (2000).

Vessels

Arteries

In the upper limb, usually only one arterial trunk, the subclavian, persists; it probably represents the lateral branch of the seventh intersegmental artery. Its main continuation, the axial artery of the upper limb, becomes the axillary and brachial arteries, passes into the forearm deep to the flexor muscle mass and terminates as a deep plexus in the developing hand (Fig. 19.5). The original axial vessel ultimately persists as the anterior interosseous artery and the deep palmar arch. A branch from the main trunk passes dorsally between the early radius and ulna as the posterior interosseous artery; a second branch accompanies the median nerve into the hand, where it ends in a superficial capillary plexus. The radial and ulnar arteries are the latest arteries to appear in the forearm. Initially, the radial artery arises more proximally than the ulnar artery, crosses anterior to the median nerve, and supplies biceps brachii. Later, the radial artery establishes a new connection with the main trunk at or near the level of origin of the ulnar artery, and the upper portion of its original stem usually disappears. On reaching the hand, the ulnar artery links up with the superficial palmar plexus, from which the superficial palmar arch is derived. The median artery commonly loses its distal connections and is reduced to a small vessel. The radial artery passes to the dorsal surface of the hand, gives off dorsal digital branches, traverses the first intermetacarpal space and joins the deep palmar arch.

Anomalies of the arterial tree in the forelimb are fairly common: there are several potential causes. The arteries have multiple and plexiform sources; the principal arteries, anastomoses and periarticular networks emerge according to a temporal sequence; and some paths that are initially functionally dominant subsequently regress. In general, anomalous patterns may present as differences in the mode and proximodistal level of branching; the presence of unusual compound arterial segments; aberrant vessels that connect with other principal vessels, arcades or plexuses; vessels that occupy exceptional tissue planes (e.g. superficial fascia instead of the usual subfascial route), or vessels that have unexpected neural, myological or osteoligamentous relationships.

Veins

In the upper limb, the preaxial vein becomes the cephalic vein and drains into the axillary vein at the shoulder. The postaxial vein becomes the basilic vein, which passes deep in the arm to continue as the axillary vein.

Ultrasound antenatal imaging

In the routine, postmenstrual week 18–20 ultrasound fetal assessment, shortening of long bones below 2 standard deviations should lead to a full assessment of all bones (McHugo 2007). Whereas the majority of lethal short limb dysplasias show marked shortening by this time, nonlethal short limb dysplasias seen at birth are not apparent at postmenstrual week 20. Normally, the humerus should be slightly longer than the radius and ulna. The term rhizomelia is used where limb shortening affects the proximal bones more than the distal bones.

NEONATAL UPPER LIMB

In general, the upper limbs in the neonate are proportionately shorter than they are in the adult and extend to the upper thigh, although the trunk is much shorter in the neonate (see Fig. 23.16). At postmenstrual week 37, the arm (shoulder to elbow) is longer than the forearm (elbow to wrist); the arm is not as long as the leg (Pomeroy et al 2014). Only primary centres of ossification are present in the upper limb, apart from a secondary centre in the head of the humerus. The elbow of the newborn can flex to 145° but lacks some 10–15% of full extension. The neonate has a relatively strong reflex grasp within the first few days. The fingernails usually extend to the fingertips or just beyond. They are soft at birth but soon dry and become quite firm and sharp. For details of neonatal blood vessel cannulation in the upper limb see Chapter 13 (peripheral arterial puncture).

DEVELOPMENTAL ANOMALIES OF THE UPPER LIMB

Available with the *Gray's Anatomy* e-book

PELVIC GIRDLE

The pelvic girdle develops in close proximity to cloacal structures. The anterior portion of the pelvic girdle is intimately associated with the normal development of the caudal part of the urogenital system and the anterior body wall. Studies on the development of the lower limb in avian species and the mouse show that the perineal muscles, including the sphincters, derive from somitic myoblasts that have previously entered the hindlimb bud. Similar to the developmental process seen in the upper limb, somitic myoblasts originating from the ventrolateral edge of the dermomyotome migrate into the somatopleuric mesenchyme of the early lower limb bud. The myoblasts coalesce into a single entity before dividing into dorsal and ventral muscle masses. The cells of the ventral muscle mass then divide again, with one population continuing to develop within the limb and the other migrating ventrally towards the genital tubercle (Valasek et al 2005). In the avian embryo, myoblasts from somites 26–29 enter the limb only, and those from somites 30–33 form both cloacal and limb muscles, whereas those from somite 34 form cloacal muscles solely. Within pelvic girdle development, myoblasts do not attain their position by somitic hypaxial domain extension; all myoblasts migrate into the region. Interestingly, the population of myoblasts giving rise to perineal muscles are innervated by axons derived from neurones located in Onuf's nucleus, whereas those that remain in the limb bud gain innervation from anterior horn motor neurones (Valasek et al 2005).

The bony pelvis forms from two hemipelves, each of which develops from one cartilaginous focus. The timetable of chondrogenesis and ossification has been described (Okumuta et al 2017, Verbruggen and Nowlan 2017). Ossification of the pelvis starts with the ilium, which undergoes endochondral ossification at about postmenstrual weeks 9–10 (Baumgart et al 2018). Development of trabecular bone in the ilium is evident from about postmenstrual week 22 and a mature trabecular morphology is present at full-term birth (Cunningham and Black 2009a, 2009b). It has been suggested that the trabecular pattern, previously assumed to develop consequent to weight bearing and bipedal gait, is initiated through genetic patterning plus intrauterine muscular movements which confer biomechanical loading onto the ilium and pelvis.

The development of the superior pubic rami is related to the normal development of the cloacal membrane. In cases of bladder exstrophy (see Fig. 22.11), the superior pubic rami are shortened and do not meet at the pubic symphysis. There is a 4 cm pubic diastasis at birth, which increases to 8 cm at age 10 years, compared with a mean normal width of the pubic symphysis of 0.6 cm at all ages (Wild et al 2011). The ischiopubic segment of the pelvis is 30% shorter, the iliac wings are externally rotated and the acetabuli are retroverted (Wild et al 2011). The mechanisms suggested for this abnormal development are premature rupture of an abnormally cranially placed cloacal membrane, obstruction of medial migration of somatopleuric mesenchyme, and local apoptosis of ventral mesenchyme (Stec 2011, Gearhart and Mathews 2016). It is thought that some combination of the three is likely.

The sacroiliac joint can be recognized by postfertilization week 7; its development is slightly different from that of other synovial joints in that the development of the ilium is ahead of that of the sacrum. Reconsideration of the role of the sacroiliac joint in the transfer of load from axial to appendicular skeleton has been prompted by study of the relative growth of regional surface areas of the ilium from birth to adulthood (Yusof et al 2013). Cavitation of the hip joint has been reported at postfertilization week 7–8. Cloacal anomalies including bladder exstrophy affect the sacroiliac joints with 10° larger sacroiliac joint angles, i.e. more toward the coronal plane than sagittal, and 14.7° inferior rotation compared to unaffected individuals. 3D CT imaging has demonstrated a range of previously unknown rotational anomalies of the pelvis, including external rotation of the posterior pelvis/iliac wings; external rotation of the anterior pelvic segment; coronal rotation of the sacroiliac joint; acetabular retroversion; convergence of the iliac wings; femoral retroversion (Gearhart and Mathews 2016).

LOWER LIMB

The lower limb is first recognizable as a laterally projecting thickening in the body wall opposite somites 24–29 at stage 13 (31–33 days post fertilization); by stage 14 it lies close to the wide umbilical cord. During stages 15–17 (35–41 days post fertilization) the limb projects laterally and outgrowth is fairly symmetric. The core of mesenchymal cells is derived from both somatopleuric and paraxial mesenchyme.

By stage 17 the lower limb still has a flattened foot plate and, although a hip region can be identified, there is no true knee. In stage 18 the lower limb appears to be flexed and abducted at the hip with the knee bent, giving the appearance that the knee is facing laterally. The femur, tibia and fibula begin to chondrify in stages 17 and 18, and the sciatic nerve extends distally to the tibia by stage 18. The patella begins chondrification in stages 21 and 22. The soles of the feet face the umbilical cord, and the foot plate has digit rays. The tarsus and metatarsus start to chondrify in stages 18 and 19. During stages 20–23 (47–58 days post fertilization) the digit rays separate and toes are clearly defined by stage 23. The feet can finally touch at stage 21, when the umbilical cord becomes proportionally smaller and the embryo larger. Ossification of the femur, tibia and fibula starts in stages 22 and 23. For more details see O'Rahilly and Gardner (1975).

Vessels

Arteries

The blood supply to the lower limb is derived from the lateral branch of the fifth lumbar intersegmental artery, which arises from the dorsal root of the umbilical artery passing to the placenta, and continues into the limb bud as the axial artery. The arterial supply to the developing lower limb is thus far less oxygenated than the arterial supply to the upper limb, which receives blood directly from the heart via the subclavian artery. It is possible that the development of several arteries in the distal part of the leg in the embryonic period, some of which subsequently regress, is a reflection of the lower oxygenation of these tissues. During development, the lower limb undergoes medial rotation and extension, so that the original dorsal (extensor) portion of the limb becomes directed ventrally. This relative movement suggests that very different patterning mechanisms operate in the lower limb compared to those in the upper limb and an early complex vasculature may be a product of that difference.

There have been relatively few studies on the early development of the vasculature of the lower limb (Mandell et al 1985, Levinsohn et al 1991, Senior 1991a, 1991b). The terminology used to describe the developing vessels is specific and will be used here. **Table 19.1** describes and illustrates the changes to the axial artery, the new vessels that arise and the vessels that regress, during stages 13–20. The mature vascular pattern is established by the end of the embryonic period.

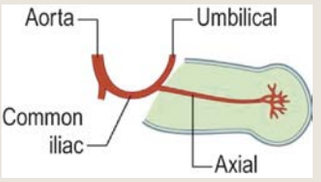
Veins

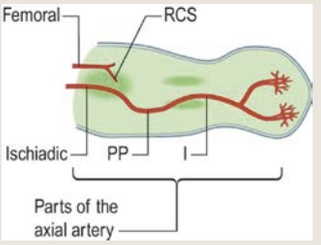
The superficial veins of the lower limb are derived from the marginal vein which runs along the periphery of the extending limb bud beneath the pre- and post-axial limb borders. The preaxial vein becomes the long saphenous vein, which drains into the femoral vein at the saphenous opening. The postaxial vein becomes the short saphenous vein, which passes deep and joins the popliteal vein. The earliest valves in the short saphenous vein have been noted at postmenstrual week 13. The number

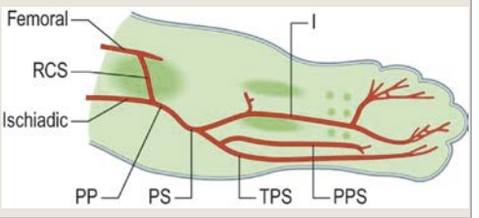
Approximately 1 in 600 neonates will have a congenital anomaly of the hand or forearm, 30% of which will be bilateral (Goldfarb et al 2015). They occur with an approximately equal frequency in males and females. A defect is twice as likely to occur in the upper limb as in the lower limb. The most critical period for the development of anomalies is during stages 12–16.

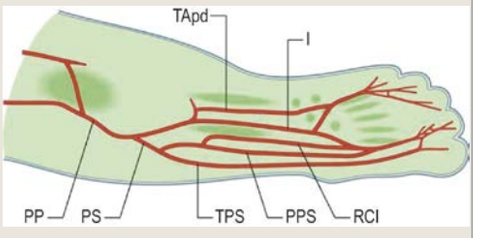
For many years, congenital limb anomalies were grouped according to the pattern of deficiency, although the clinical picture did not always relate to the developmental process occurring in the limb (Swanson 1976). More recent classifications of upper limb anomalies are based on developmental molecular biology and pathogenetics (Oberg et al 2010, Tonkin et al 2013, Tonkin 2017).

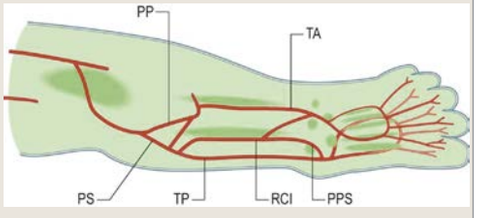
Limb reduction defects











Limb reduction defects are categorized as failures of development. The basis of limb reductions seen in infants whose mothers took thalidomide during their pregnancy seems likely to be due to death of mesenchyme cells in the early limb bud, causing phocomelia. Proximal segments of the limb were lost, although, in some cases, normal distal segments still formed. There is evidence from experiments in chick embryos that thalidomide interferes with vascularization of the limbs (Vargesson 2009, 2015), and this could lead to mesenchymal cell death. A protein to which thalidomide binds has been identified but it is not yet clear how this is related to thalidomide teratogenicity (Ito et al 2010). Although chorionic villus sampling was reported to be associated with limb reduction defects in the 1990s, present data confirm that sampling between postmenstrual weeks 10 and 13 does not increase the risk; sampling before this time is not recommended (Wapner and Dugoff 2019).

Inheritance of autosomal dominant genes may cause anomalies of the hand. This could, for example, result in absence of the central digit ray of the distal hand plate and subsequent absence of the middle or ring finger and its metacarpals. Extra preaxial digits can result from ectopic polarizing activity due to mutations in regulatory regions in the DNA that control expression of the *Shh* gene, specifically in the developing limb bud (Anderson et al 2012). Other changes in digit number may be the result of alterations in limb bud width and the length of the apical ectodermal ridge.

Anomalies of the digits

Syndactyly, the fusion of adjacent digits, is the most common congenital anomaly of the hand and occurs in about 1 in 2000 live births; it is twice as common in males. It occurs because of failure to remove mesenchymal cells between the digit rays during stages 19–23. Third, fourth, second and first web spaces are affected in decreasing frequency and the condition is bilateral in half of cases (Jordan et al 2012). Clinodactyly is a congenital condition in which the little finger is curved towards the ring finger. It can occur in isolation, or in association with chromosomal abnormalities like Down's syndrome. Camptodactyly is a congenital condition in which the little finger, and sometimes the ring finger, are held in a fixed, flexed position. Symphalangism is a rare congenital disorder in which there is fusion of the interphalangeal joints. The affected finger is stiff, skin creases are absent over the affected joint, there is minimal joint space, and sometimes the digit is shorter than normal. Several different types of brachydactyly, shortening of the digits, can be recognized according to which digits and which parts of these digits are affected. The genetic basis of different types of brachydactyly has now been determined, which is particularly gratifying because brachydactyly was the first condition in humans to be recognized as a dominant Mendelian condition (Gao and He 2004).

TABLE 19.1 The development of the arteries of the lower limb during stages 13–20.

Stage	Axial artery	Developing arteries	Regressing arteries	Arterial status
11–12	First appearance of the lower limb bud. The lower limb axial artery arises from the fifth lumbar intersegmental branch of the aorta.			
13–16	The axial artery courses through the lower limb bud to the developing digital plate where it branches into a terminal plexus (future dorsal and plantar networks).			
16–17	The axial artery is now described as ischiadic proximally and popliteal profunda (PP) and interossea (I) as it progresses distally.	The external iliac artery, which arises just proximal to the origin of the ischiadic artery, extends distally towards the knee as the femoral artery. A branch, the ramus communicans superior (RCS), passes dorsally to join the ischiadic artery. Perforating branches of the profunda femoris artery initially anastomose with the proximal part of the ischiadic artery.		
18	Elongation of the axial artery forms the popliteal superficialis (PS) between the popliteal profunda and interossea arteries.	Two new vessels arise from the popliteal superficialis artery. These are the tibialis posterior superficialis (TPS) and the peronea posterior superficialis (PPS). Both vessels join the plantar network. There are now three arteries in the leg.	The proximal portion of the ischiadic artery starts to regress. Parts persist in the adult as the inferior gluteal artery and the arteria comitans nervi ischiadici.	
19		Two further vessels arise. They are the tibialis anterior pars distalis (TApd) from the interossea artery and the ramus communicans inferior (RCI) from the peronea posterior superficialis. The original plantar network is remodelled into a medial plantar artery (from the distal part of tibialis posterior superficialis) and a lateral plantar artery (from the distal continuation of the confluence of the interossea, ramus communicans inferior and the peronea posterior superficialis) which together form the plantar arch. There are now five arteries in the leg.		
20		The arteries in the leg at this stage are the tibialis anterior (TA), tibialis posterior (TP) and the ramus communicans inferior. The latter is confluent with the peronea posterior superficialis in the tarsal region and becomes the fibular (peroneal) artery. The plantar arch is now supplied solely by the tibialis posterior. There are now three arteries in the leg.	Popliteal profunda, interossea artery and peronea posterior superficialis arteries.	

of valves increases from 1 to 8 between postmenstrual weeks 13–18; there are more valves in the proximal than in the distal portion of the short saphenous vein (Czarniawska-Grzesińska and Bruska 2002).

Ultrasound antenatal imaging

Femur length is routinely measured to assess growth velocity (along with head circumference and abdominal circumference) and to predict the expected date of delivery. The longest axis of the ossified diaphysis is identified with soft tissue noted beyond both ends. The distal epiphysis is excluded (**Fig. 19.6**). Overall limb length correlates to the ecogeographic principles, Bergmann's and Allen's rules, that mammalian species have greater body mass in colder climates and limbs tend to be shorter in cold environments and longer in warm environments (Bogin 2012). Appropriate fetal biometry comparison charts are necessary for accurate evaluation (Ogasawara 2009). Identification of short femur length is associated with a higher risk of chromosomal abnormalities (Mathiesen et al 2014) and a significantly higher likelihood of the fetus being small for gestational age and at risk of early preterm delivery

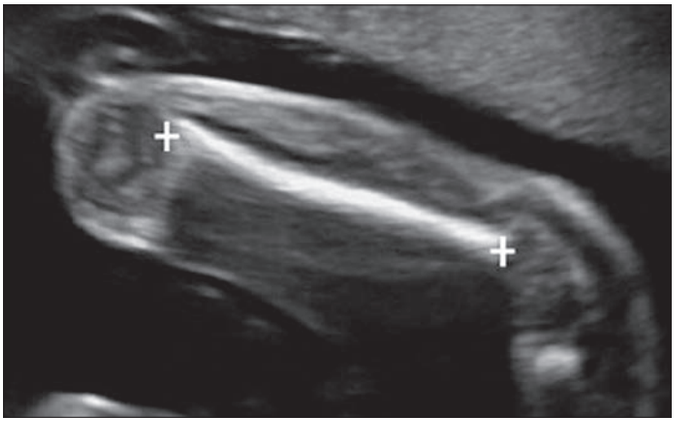


Fig. 19.6 An ultrasound image showing femur length. (With permission from To M, Pereira S Routine fetal anomaly scan. In: Coady AM (ed) Twining's Textbook of Fetal Abnormalities, 3rd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

(Özlü and Ozcan 2013, Mathiesen et al 2014). It has been estimated that identification of isolated short femur length below the 10th or 5th percentile at mid-gestation is associated with more than a three-fold risk of the development of fetal growth restriction and increased risk of early preterm birth before postmenstrual weeks 34–37 (Goetzinger et al 2012). Although the cause of this relationship must be multifactorial, it has been suggested that changes in placentation and chronic fetal hypoxia may lead to a fetal adaptive response in which highly oxygenated blood is diverted to the brain and heart at the expense of the extremities.

NEONATAL LOWER LIMB

In the neonate, the pelvis is cone-shaped. The transverse diameter of the true pelvis is 2.2 cm, its anteroposterior diameter is 2.8 cm and the length between the inlet and outlet is 2 cm. The sacrum is proportionately larger than in the adult and the sacral promontory is higher. When walking begins, the sacrum descends between the ilia and the promontory develops. The ilia, ischia and pubic bones are variably ossified at birth; they meet at the triradiate epiphysis in the acetabulum, which in the neonate is cartilaginous, relatively large and shallow.

In human neonates the lower limbs are less developed compared to the upper limbs. Genotypic factors have been implicated, but this disparity may also reflect the lower oxygen saturation levels in the blood that flows to the lower limb and that also passes to the umbilical arteries and placenta. Clinical evidence has shown that postnatally increased blood flow to the limbs is linked to greater growth; children living at high altitude have reduced tibial length and lower blood oxygen saturation (Bogin 2012).

At term (postmenstrual week 37), the thigh (hip to knee) is longer than the leg (knee to ankle) (Pomeroy et al 2014). The femoral neck is much shorter than in the adult and forms an acute angle with the shaft, which at this stage is quite straight: the adult curvature is acquired with walking. The head of the femur is larger than the acetabular fossa and nearly one-third remains external, which means that the ligament of the head of the femur is relatively very long. Dislocation of the hip joint is relatively easy: the femoral head can be removed from the acetabular fossa laterally but not posteriorly. The fetal position, where the lower limbs are in a flexed position, is often assumed by postnatal babies: it keeps the thighs in continuous abduction and stretches the adductors. The muscles that will be used for walking are weak and the lack of gluteal development, in particular, gives the typically diminutive buttocks of the neonate.

Although the legs appear to be bowed, the tibia and fibula are straight. The illusion of bow legs is caused by the shape of the soft tissues and the slightly more advanced development of the lateral head of gastrocnemius compared to its medial head. The calcaneus and the talus each have an ossification centre at birth, and a centre is frequently present in the cuboid. The feet are usually inverted and they have a greater degree of dorsiflexion, caused by the relatively greater area of the trochlea of the talus. Plantar flexion is limited, in part reflecting the shortness of the extensor muscles of the foot. At birth, the footprint outlines the whole plantar surface, reflecting the deposition of subcutaneous fat beneath the longitudinal and transverse arches, and so most babies appear flat-footed. For details of neonatal blood vessel cannulation in the lower limb see Chapter 13 (Peripheral arterial puncture).

A review of the molecular basis of limb development particularly focusing on how cell–cell interactions are integrated.

Developmental dysplasia of the hip (previously known as congenital dislocation of the hip) refers to an abnormal configuration of, or relationship between, the femoral head and the acetabulum that occurs either before or after birth in approximately 1 in 1000 live births with a female : male ratio of 6 : 1. (In 2% of cases, hip dislocation is not evident at birth but manifests in the first few months of the life.) It covers a continuum of disorders that ranges from shallowness of the acetabulum to instability and subluxation of the femoral head and, ultimately, to frank dislocation. Acetabular anteversion may occur (Li et al 2009). The aetiology is considered to be multifactorial and is associated with first pregnancies, suggesting that both maternal and uterine musculature restricts fetal movement and puts postural strain on the fetal hips.

Developmental dysplasia of the hip is seen more frequently in breech delivery, especially if the knees are extended; breech position at any time after postmenstrual week 36 is a risk factor for the condition. The incidence is similar in preterm and term infants born in the breech position (Quan et al 2013). The left hip is more frequently affected than the right, possibly because, in breech presentation, the fetus lies with the right shoulder anterior and the left thigh closest to the maternal sacrum. The physiological effects that cause the maternal ligaments to become temporarily lax prior to delivery are also considered to affect the fetus and to contribute to laxity of the hip capsule. Risk factors are breech delivery, female gender, a positive family history, clicking of the hips and hips that can be easily dislocated at clinical examination (de Hundt et al 2012). Ultrasound is the definitive investigation used for early detection together with clinical examination; magnetic resonance imaging (MRI) may be required to identify the underlying bony and soft tissue anatomy.

The collodiaphysial angle (CDA; neck–shaft angle, Mikulicz angle) is the angle between the long axis of the femoral shaft and the head and neck of the femur; the normal adult range varies between 125° and 140° (see Fig. 77.30). Where the CDA is enhanced, usually above 135°, a coxa valga deformity occurs. Where CDA is decreased (usually defined as less than 120°), a coxa vara deformity occurs; the mechanism is thought to be a failure of medial growth of the physial plate. The resulting lower limb is shortened and abduction is restricted.

The adult femur normally aligns on the tibia obliquely, creating an angle of 174° facing laterally. A medial angulation of the leg in relation to the thigh is called genu varum, and a lateral angulation, where the upper part of the knee is displaced inwards with the lower part displaced outwards, is called genu valgum. The hip–knee (femoral–tibial) angle in children is +3.6° (varum) between the ages of 1 and 2 years, and −2.5° (valgum) between the ages of 2 and 3 years. The prevalence of lower limb deformities physiologically decreases after 5 years of age; the angle is +0.3° after the age of 7 years, which is within 1° of adult reference values (Sabharwal and Zhao 2009). Both deformities cause unequal weight distribution that hastens destruction of knee cartilages; persistence of genu varum/valgum until late childhood may require correction in order to prevent arthrosis. (For further reading, see Goldman and Green (2010).) Congenital dislocation of the patella may be noted in the neonate with flexion contracture of the knee, genu valgus, external tibial torsion and foot deformity. It is irreducible and treated surgically. The patella ossifies between postnatal years 3 and 5 and so it is not visible on X-ray in infancy and early childhood (Wada et al 2008).

The patella may be absent or hypoplastic, an anomaly that may be isolated or may be associated with other defects (Mizobuchi et al 2007).

Congenital talipes equinovarus, or club foot, derives its name from a combination of *talus* and *pes*, together with terms describing an elevated heel resembling that of a horse (*equino*), which is also turned inwards (*varus*). It is a common neonatal anomaly and occurs in approximately 1 per 1000 live births, with males affected twice as often as females. There is some degree of inheritance, so it is not entirely an effect of intrauterine positioning or of oligohydramnios (abnormally little amniotic fluid). Both bones and soft tissues are affected, which means that it is difficult to distinguish between primary and secondary effects. A number of theories have been proposed to explain the underlying pathogenetic mechanism(s), including abnormal tendon and ligament attachments, defective development of the talus and delayed muscle maturation. One theory is that the talus undergoes defective development and that all the other anomalies arise as a consequence of this initial defect. The talus is decreased in size by up to 25%. It has a foreshortened neck and decreased body/neck angle, and the subtalar facets are medially rotated. The navicular is small and medially deviated relative to the talus. The calcaneus is also small and shows varus displacement and equinus tilt; the anterior facets correspond to those of the talus (Barlow and Clarke 1994). The entire affected foot and calf are smaller than their normal counterparts. The foot is inverted and supinated, and the forefoot is adducted. The heel is small, rotated inwards and elevated. The calcaneus is inverted beneath the talus. MRI analysis of the lower legs of patients who had been treated for idiopathic congenital talipes equinovarus showed that leg muscle volume was consistently reduced (Duce et al 2013). Treatment varies between splintage and repeated complex surgery, which reflects the highly variable severity of the condition and individual response to therapy. Positional talipes equinovarus is usually attributed to intrauterine position of the foot, is passively correctable and does not require surgery, whereas fixed talipes equinovarus is not passively correctable and usually requires surgery.

'Flat feet' are common in childhood. The majority are 'flexible' and simply related to posture, whereas 'rigid' flat feet are caused by structural anomalies. The description of 'rocker bottom' foot is associated with many congenital syndromes. The foot is flat and rigid, and the plantar surface appears curved with the apex of the curve at the midtarsal joint. The condition shows an equinus position of the hindfoot. The talus may be vertical and palpable on the plantar surface. A majority of infants with this condition also have neurological anomalies.

CHAPTER
20

Development of the lungs, thorax and respiratory diaphragm

DEVELOPMENT OF THE RESPIRATORY TREE

The development of the respiratory system can be conceptualized as the growth of six intertwined trees: the bronchial tree of conducting airways and terminal gas-exchanging sacs; the systemic arterial and venous trees that perfuse and drain the airways; the pulmonary arterial and venous trees that supply and drain the alveolar membrane, anastomose with the systemic and venous trees, and are pivotal in the provision of blood oxygenation and carbon dioxide excretion after birth; and the lymphatic tree. Development of each tree is related to that of the others and all proceed proximo-distally in terms of growth and expansion. Uniquely, the lungs develop while not fulfilling their postnatal function, but they must function efficiently immediately after birth or the neonate will require respiratory support and may die of respiratory failure. (For overviews of lung developmental biology, see Roth-Kleiner and Post 2005, Kimura and Deutsch 2007, Maeda et al 2007, Morrisey and Hogan 2010, Warburton 2017). Knowledge of the molecular basis of lung development is based on studies of the *in vitro* growth of human and animal (usually mouse and rat) explants, and using knockout and transgenic mice. Anomalous lung development is an important factor in the aetiogenesis of airway diseases such as asthma and COPD (Bush 2016).

The development of the respiratory diverticulum can first be seen at stage 12 (approximately 30–31 days postfertilization; see Fig. 23.3) when there is a sharp onset of epithelial proliferation within the foregut at regions of the endoderm tube destined to become the lungs, stomach, liver and dorsal pancreas. The specialized respiratory epithelium forms from the endoderm and the other elements of the airway wall are of mesenchymal origin. The future respiratory epithelium bulges ventrally into the investing splanchnopleuric mesenchyme, then grows caudally as a bulb-shaped tube (**Figs 20.1–20.2**; see Fig. 21.3). By stage 13 the caudal end of the tube has divided asymmetrically to form the future primary bronchi. The right primary bronchus becomes orientated more caudally as it grows, whereas the left extends more transversely. The trachea is clearly recognizable at stage 14 and from this time the origin of the trachea remains close to its site of evagination from the future oesophagus. Longitudinal growth of the trachea causes the region of the future carina to descend, until ultimately it lies within the thorax. Failure of complete separation between trachea and oesophagus will result in the baby being born with one of the variants of tracheo-oesophageal fistula (see below).

Trachea

The trachea and oesophagus arise from the foregut just caudal to the pharyngeal pouches. Tracheal development starts at stage 12 as a ventral outgrowth from the endodermal foregut into the mesenchyme that surrounds the sinus venosus and inflow tract of the heart (**Figs 20.1B–C**; see Figs 21.3, 21.5). The point at which the original respiratory diverticulum buds from the foregut, the laryngotracheal groove, remains at a constant level during the embryonic period, and the trachea lengthens distally as the point of bifurcation descends. The respiratory diverticulum generally becomes surrounded by angiogenic mesenchyme which connects to the developing sixth aortic arch artery and is essential for airway branching. By stage 17 the mesenchyme around the trachea is beginning to condense to form cartilage.

Initially, the tracheal mesenchyme is continuous with that surrounding the ventral wall of the oesophagus (see Fig. 20.2). Progressive lengthening and continued division of the tracheal bud, together with deviation of the lung buds dorsally, isolates the oesophagus and trachea within tissue-specific mesenchyme and facilitates regional differentiation, not only between the trachea and lungs, but also within the lungs themselves, i.e. the number of lobes, or the degree of growth and maturity of a particular lung. Each lung develops by a process of dichotomous branching. For branching to occur, a cleft must develop in the tip (or side) of the epithelial tube, the epithelium then evaginates each side of the cleft, forming new branches that lengthen, and the process is then repeated. The mesenchyme is flattened and densely packed at the tips of the developing epithelial buds, whereas it forms an ordered row of cuboidal cells along the side of the bud and in the clefts. Cells in both arrangements send processes towards the epithelial basal lamina, which is thicker in the clefts but so attenuated as to be almost indistinguishable on the tips of the buds where the epithelium and mesenchymal cells form intimate contacts. Tenascin, an extracellular matrix molecule, is present in the budding and distal tip regions, but absent in the clefts. Conversely, fibronectin, an extracellular matrix molecule found commonly in basal laminae, is found in the clefts and along the sides of the developing bronchi, but not on the budding and distal tips. It is likely that branching morphogenesis is not rigidly pre-specified after the first 'stereotypical' generation and adapts to the space available within the mesenchyme (Blanc et al 2012, Lang et al 2018).

The splanchnopleuric mesenchyme controls the branching pattern of the respiratory tree. Experimental recombination of tracheal mesenchyme with bronchial respiratory endoderm results in inhibition of bronchial branching, whereas recombination of bronchial mesenchyme with tracheal epithelium induces bronchial outgrowths from the trachea. Experimental exposure of rat fetal airway to chick mesenchyme produces a branching pattern typical of a chick airway.

Smooth muscle and nerves are found outside the airways at this early developmental stage. Airway smooth muscle is innervated and contractile: there is experimental evidence that GDNF (glial derived neurotrophic factor) may play a role in the early innervation of developing airways (Tollet et al 2002). Phasic contraction and relaxation of airways is important in growth factor release and moving secreted fluid from distal to proximal regions of the bronchial tree.

Failure of separation of the oesophagus and trachea is described below under disorders of the proximal airways. The development of the oesophagus is described in Chapters 17 and 21.

Lungs

Branching morphogenesis of the conducting airways is generally complete by postmenstrual week 16: the airways subsequently increase in size, but not in number. Alveolar development is largely (but not completely) a postnatal phenomenon. The development of pre-acinar blood vessels follows the conducting airway development. The airways act as a template for blood vessel development by *de novo* vasculogenesis driven by epithelial-derived VEGF. Development of intra-acinar blood vessels follows the development of the alveolar ducts and alveolar sacs. Vascular development is also complex and has been recently reviewed (Cornett et al 2013, Lange et al 2014, Bolte et al 2018). Lung development is described histologically as progressing through embryonic, pseudoglandular, canalicular, saccular and alveolar phases. (For further details see Bush 2005.)

Embryonic phase (0–7 postfertilization weeks: appearance of lung buds and main pulmonary arteries)

The endodermal epithelial lung buds grow dorsally, passing each side of the relatively smaller oesophagus, and bulge into the splanchnopleuric mesenchyme of the medial walls of the laterally situated pericardioperitoneal canals (see Figs 20.2, 21.5). Proliferation of this splanchnopleuric coelomic epithelium, which is especially evident in stage 13 and decreases in stage 14, produces splanchnopleuric mesenchyme that becomes arranged in zones around the developing endoderm. This investing mesenchyme will eventually produce the supporting walls of the conducting airways, differentiating into the mucosal and submucosal laminae propriae (containing fibrocytes that

Lung development depends on the balanced expression of transcription factors that are also expressed in other developing organs (Xu et al 2012, Morrisey et al 2013). The early lung develops by branching morphogenesis (see Fig. 11.5). An early transcription factor, NKX2.1 (TTF-1), is involved in regulating pulmonary immune function, and mutations in this gene lead to combinations of lung, brain and thyroid disease (Hamvas et al 2013). BMP-4 and fibronectin induce the formation of a cleft between two branches. Branching is promoted by receptor tyrosine kinase and their ligands and by inhibition of FGF10 in mesenchymal MMPs. It is inhibited by Gremlin (a BMP4 antagonist), transforming growth factor β (TGFβ) family members and Sonic Hedgehog (Shh) produced in the distal epithelial cells (Stabile et al 2007). Lung morphogenesis is also regulated by interactions between the canonical Wnt/β-catenin and Kras/ERK/Foxm1 signalling pathways that control the regional and developmental expression of the transcription factor SOX9 (Ustiyan et al 2016). (For further information on miRNAs and RNA binding proteins, see Wang et al (2015) and Ameis et al (2017)). Understanding the genetic control of lung development is now informed by molecular techniques (Kho et al 2010) and proteomic analyses. Surfactant protein genes are expressed from postmenstrual week 13 (Ardini-Poleske et al 2017, Moghieb et al 2018). Epigenetic influences on lung development that have been identified include passive tobacco smoking (Li et al 2005, Magnus et al 2015).

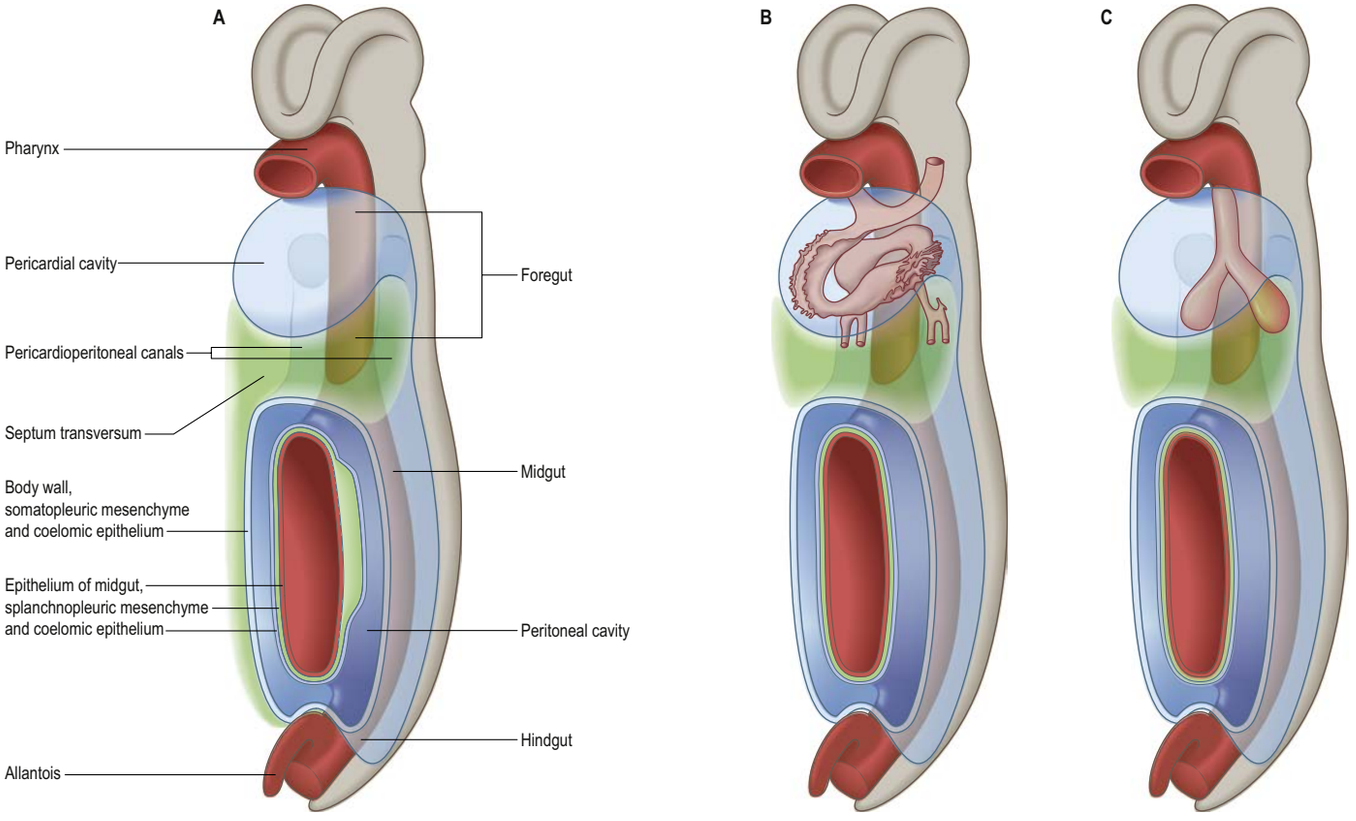

Fig. 20.1 **A**, The arrangement of the epithelial populations in an embryo at about stage 11. The future thoracic region lies caudal to the pharynx and extends to the upper part of the septum transversum. **B**, The heart is shown in situ within the pericardial cavity. Venous tributaries return blood from the body, yolk sac and placenta, and arterial trunks pass each side of the pharynx. **C**, The respiratory diverticulum arises in the midline from the lower portion of the pharynx, and lung buds extend dorsally into the pericardioperitoneal canals.

synthesize the type I and II collagen, elastin, proteoglycans and glycosaminoglycans of the extracellular matrix) and smooth muscle cells.

Angiogenic mesenchyme is apparent around the primary bronchi at stage 15. It forms an extensive capillary network around each lung bud, receiving blood from the developing sixth aortic arch artery and draining it into an anastomosis connected to the dorsal surface of the left atrium in the mediastinal mesenchyme (Ch. 13). The pulmonary arteries arise from the sixth aortic arch arteries and the pulmonary veins develop from a solitary channel derived from the dorsal mesocardium that establishes continuity with the vascular plexus formed in the mediastinal mesenchyme. The pulmonary veins become surrounded by myocardium to the level of the second bifurcation; the veins themselves expand and are incorporated into the roof of the left atrium, which means that cardiac muscle is found in the central branches of the pulmonary venous tree (Hislop 2005).

After stage 15 the coelomic epithelium projecting into the pericardioperitoneal canals and covering the lung buds will follow a differentiation pathway to form the visceral pleura. Lobar or secondary bronchi can be seen at stage 16 and bronchopulmonary segments are present at stage 17 (see Fig. 21.3E). Later stages of respiratory development involve the repeated division of the bronchial tree to form the subsegmental bronchi.

Pseudoglandular phase (5–17 postfertilization weeks: development of airways and blood vessels to the level of acinus)

By stage 17 the separation of the lungs from the digestive system is complete and the pseudoglandular phase of pulmonary development, including the development of the lower conducting airways and the appearance of the acinar structures, begins. During this period, virtually the complete branching structure of the future bronchial tree is laid down in 20 generations.

The growth and branching of the endoderm epithelium is controlled by the local investing splanchnopleuric mesenchyme. The airways begin to differentiate during this stage. Primitive ciliated cells appear at about postfertilization week 7, initially in the region of the membranous trachea, and in the cartilaginous region by postfertilization week 12; ciliogenesis is complete at birth in humans. The proximal airways develop basal cells from postfertilization week 11. Mucous glands develop by postfertilization week 12 and enlarge in the submucosa: secretory activity has been identified in the trachea at postfertilization week 14. The splanchnopleuric mesenchyme condenses around the epithelium, and from stages 16–17 it differentiates into connective tissue cell types and smooth muscle proximal to the tips of the developing airways. Smooth muscle cells are innervated from stage 23. Human tracheal smooth muscle cells have a fluctuating resting membrane potential associated with the spontaneous development of tone and peristalsis-like contractions of the airway of a myogenic nature, probably modified by neuro-humoral factors. Club cells develop in the peripheral airways during the pseudoglandular period and produce a surfactant apoprotein and a10-kDa protein (CC10) with immunomodulatory and anti-inflammatory activity. Cartilage also develops during this period, and is found in the airways in an adult distribution by postmenstrual week 24. By the end of this period, airway branching and pre-acinar vascular patterns are mature. A normal airway 'template' is essential for normal alveolar formation: a degree of pulmonary alveolar hypoplasia is inevitable in conditions characterized by an anomalous airway branching pattern (e.g. both ipsilateral and contralateral to a respiratory diaphragmatic hernia).

Further endothelial proliferation is seen in the pseudoglandular phase when capillary networks form around the developing lung buds; they will become capillary anastomoses around the future alveoli. The splanchnopleuric mesenchyme differentiates into myointimal cells and the tunica media of the developing blood vessels. Vimentin is expressed in the cells around developing vessels in the pseudoglandular stage, and is replaced by desmin in the saccular phase.

Canalicular phase (17–27 postmenstrual weeks: formation of respiratory airways and blood–gas barrier thins)

Two to three generations of branching occur during the canalicular phase, after which the amount of mesenchyme around the branching tips of the dividing respiratory tree decreases and the distal airspaces widen. At 23 postmenstrual weeks, longitudinal histological sections of

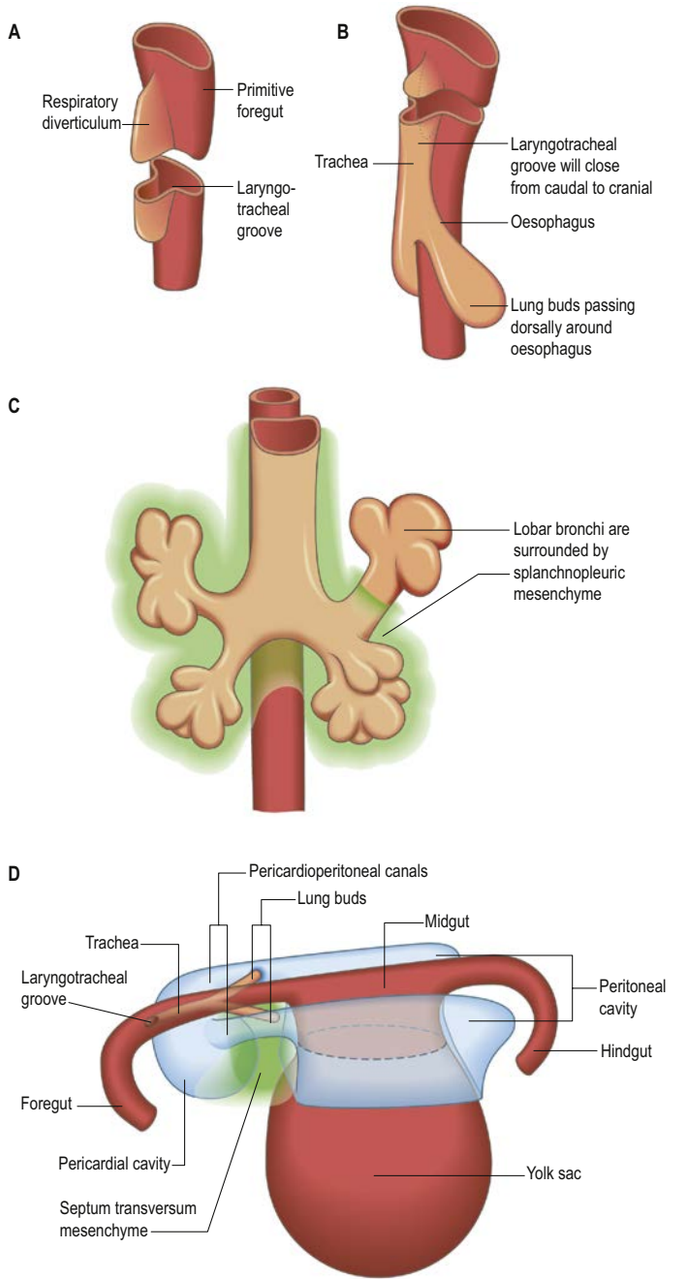

Fig. 20.2 Development of the respiratory tree and diaphragm. **A–C**, Development of the endodermal respiratory tree. **D**, Major epithelial populations in the early embryo from a left dorsolateral view: the lung buds are bulging into the laterally placed pericardioperitoneal canals.

the future distal regions show a sawtooth margin, which may indicate the site of further acini. Peripheral growth is accompanied by an increase in the capillary network around the distal airspace: in many places, the capillaries are in close contact with the respiratory cuboidal epithelium. The primitive endodermal cuboidal epithelial cells, previously the predominant cell in this part of the lung, differentiate into type I epithelial cells (pneumocytes) and type II epithelial cells (pneumocytes) containing lamellar bodies that form the intracellular storage bodies of surfactant. Type II pneumocytes are believed to be the stem cells of the alveolar epithelium. Apposition of the capillary networks to the thin type I pneumocytes and reduction of the interstitial tissue of the lung are prerequisites for future effective gas exchange. By postmenstrual week 24, the histological characteristics of the airways, including cartilage distribution, are the same as in the adult.

Saccular/alveolar phase (28 postmenstrual weeks–term: first appearance of alveoli in humans)

Thin-walled terminal saccules are apparent at the saccular stage and will become alveolar ducts as development proceeds. The expansion of the prospective respiratory airspaces that occurs during this period is accompanied by a further decrease in the amount of mesenchymal interstitial tissue, and the capillary networks become ever more closely opposed to the pneumocyte epithelium. Secondary crests develop from the invaginations of the saccule walls, although this may be an apparent movement when the saccule walls expand each side of a subjacent blood vessel. As an alveolar crest protrudes into a saccule, part of the capillary network becomes drawn into it. After the later expansion of the saccules on each side of the crest, a double capillary layer becomes annexed between what are now alveolar walls. During the saccular stage, elastin is deposited beneath the epithelium (an important step for future alveolar formation), and surfactant production, from type II pneumocytes, matures (essential for the survival of a preterm neonate).

Alveolar phase

An epithelial layer is usually supported by an underlying lamina propria, as in the conducting airways. The mutual support of two epithelial layers, a specialized epithelium and an endothelium, where both contribute to the generation of mutual basal laminal proteins, is very unusual and seen elsewhere only in the kidney glomerular basement membrane and in the brain (see Fig. 11.2). This close relationship develops during the alveolar phase between type I pneumocytes and pulmonary endothelium. A number of genes and growth factors are expressed during the formation and maturation of the type I pneumocyte:endothelium interface (alveolar–capillary membrane; blood–gas barrier) and in the final fibrocyte deposition of matrix molecules between developing alveoli. Retinoic acid regulates the expression of a number of growth signalling molecules, homeobox genes and lung epithelial genes. TGF-β, platelet- derived growth factor (PDGF) and fibroblast growth factor are involved in the final stages of conducting airway branching. TGFβ is also involved in septal formation and the induction of myofibroblasts which co-localize at ridges signalling the start of alveolar crest development. Myofibroblasts are found later at the tips of alveoli and play a particular role in production of elastin: their failure to produce elastin leads to a lack of alveoli. PDGF also stimulates myofibroblasts: PDGF-null mice fail to form secondary septa. Mechanical stretching of developing lung tissue stimulates human smooth muscle cell differentiation and increases tropoelastin content. Elastin gene expression, possibly modulated through retinoic acid, appears to play a pivotal role. (For further reading about factors controlling alveogenesis, see Hind et al (2009), Chao et al (2016), Ng-Blichfeldt et al (2017).)

Exactly when the saccular structure of the lung can be termed alveolar is not yet clear: estimates range from postmenstrual weeks 28 to 32. The formation of millions of alveoli is accomplished by a complex process of folding and division of type I pneumocytes. Mechanical stretch drives type II to type I cell differentiation. The existing walls of the alveoli become thinner as type I pneumocyte cells flatten, forming primitive alveoli. Septa (ridges) initially form where the type I pneumocytes meet subjacent capillaries and myofibroblasts. Subsequent areal expansion of type I pneumocytes, of more than ten times, and increased capillary development, combine to form new alveoli. Mouse embryo studies indicate that each type I pneumocyte may form the walls of multiple adjacent alveoli (Yang et al 2016). Vessels remain within the developing secondary septa whereas the myofibroblasts are temporary. The process of remodelling of the final capillary network between adjacent alveoli is not yet elucidated, however, it has been noted that type I pneumocytes secrete VEGF (Yang et al 2016).

The distal airspaces expand during late gestation and continue to do so after birth. The number of alveoli present at birth (variously estimated as between none to 5 x10^7) is controversial; the number probably increases particularly rapidly over postmenstrual weeks 41–64 (postnatal months 0–6). This process is accompanied by fusion of adjacent capillary networks, so that shortly after birth there is an extensive double capillary net. Fusion of these layers is apparent at postnatal day 28, extensive at 1.5 years and probably complete by 5 years. The alveolar stage is now considered to continue beyond infancy and throughout childhood (whereas heterochronic differences in rat and mouse development show that alveolar formation is exclusively post-natal in these animals).

Development of the intrapulmonary vasculature and lymphatics

Two vascular circulations arise in the developing lungs, bronchial and pulmonary. Two or three bronchial arteries grow from the descending aorta from stages 21–22. They enter the lung at the hilum and branch, the airways acting as a template for their development. The vessels

extend adjacent to the developing airways and eventually form subepithelial and adventitial plexuses that reach the distal portions of the bronchioles by birth. Bronchial arteries also supply the pleura near the hilum and form vasa vasorum in the adventitia of the large arteries and veins. The bronchial veins from the periphery of the lungs drain into the pulmonary veins. Postnatally, inflammatory lung conditions such as asthma, cystic fibrosis and bronchiectasis cause hypertrophy of the bronchial circulation and these vessels may bleed, sometimes giving rise to massive haemoptysis (McCullagh et al 2010). Some congenital thoracic anomalies have a systemic arterial blood supply.

The earliest pulmonary vessels form in the mesenchyme by vasculogenesis: the capillaries coalesce to form small blood vessels alongside the branching airways. Pulmonary arteries form adjacent to the conducting airways, joining the angiogenic mesenchyme of the sixth aortic arch arteries. Pulmonary veins develop from mediastinal mesenchyme in the dorsal mesocardium and become separated from the airways by the growth of alveoli and lymphatic vessels. By stage 15 a circulation is present from the aortic sac through a branching network of pulmonary arteries into capillary plexuses around the two lung buds, and returning via pulmonary veins to the developing left atrium. As each new distal airway forms in the mesenchyme, a new angiogenic plexus forms as a halo around it, and coalesces with the pulmonary vessel already alongside the proximal airway. In this way, addition of the newly formed tubules to the existing pulmonary vessels is sustained. Vessel formation occurs at least until the end of the pseudoglandular stage and has been shown to be controlled by production of VEGF from type I pneumocytes (Yang et al 2016). As the arteries increase in size they acquire a muscular wall, initially from the bronchial smooth muscle of the adjacent airway and then from the splanchnopleuric mesenchyme. The muscle layer is thick relative to the lumen, and this in part increases resistance to blood flow. Although only 10% of blood flow goes through the pulmonary circulation during intrauterine life, it is important for normal lung development. By postmenstrual week 20, the structure of the pulmonary vessels is the same as it is in the adult. Vascular innervation follows muscularization; the vasoactive peptides contained in these nerves are predominantly vasoconstrictor.

As the pulmonary veins enlarge, they become separated from the airways by the lymphatic vessels that lie within the mesenchyme. At around postmenstrual week 12, the peripheral veins develop a single layer of smooth muscle cells in their walls. This layer is derived exclusively from the splanchnopleuric mesenchyme and not from bronchial smooth muscle (as occurs in the arteries). The lumen of each vein is relatively large and the wall is relatively thin at all levels. Arteries and veins continue to develop in the canalicular phase, probably by angiogenesis (dividing cells are seen in the peripheral capillaries). The epithelium of the most peripheral conducting airways flattens when the developing capillaries come to lie immediately subjacent to it. (For a review of the development of the pulmonary circulation see Hislop (2005)).

Lymphatic capillaries and vessels run within bronchovascular bundles. Lymphatic channels develop from outgrowths of vascular endothelial cells: the molecular trigger for lymphatic sprouting is VEGF-C and D, acting through the VEGF receptor 3 (Janér et al 2006). See Kulkarni et al (2011) for a review of lymphatic development.

Intrauterine maturation of the lungs

More than 30 different cell types found within the adult lung mature during development. Only a few important changes relevant to human disease will be highlighted here.

Pulmonary surfactant is produced by type II alveolar epithelial cells, and stored in lamellar bodies; surfactant production is under complex molecular control (Xu et al 2010). Surfactant proteins (Sp) B and C are surface active, whereas A and D are part of the collectin family of pattern recognition receptors. Surfactant is crucial for maintaining the functional integrity of alveoli: the main morbidity of extreme prematurity reflects surfactant deficiency causing neonatal respiratory distress syndrome (treatment has been transformed by the availability of exogenous surfactant). Mutations in the genes encoding *SpB* and *SpC*, *ABCA3* (responsible for surfactant processing) and the transcription factor *NKX2.1* (controlling *SpB*, *SpC* and *ABCA3* expression) can all present in the neonatal period in full-term babies (notionally 40 postmenstrual weeks) with relentlessly progressive respiratory distress and diffuse ground glass shadowing on imaging studies (Spagnolo and Bush 2016). Fetal breathing movements appear to be important in surfactant synthesis: the functional maturation of the surfactant system can be accelerated therapeutically by the administration of steroids to the mother with important benefits to the preterm baby (Roberts et al 2017).

Normal lung development requires sufficient intrathoracic space, normal fetal breathing movements and sufficient amniotic fluid. There is evidence that perturbation of fetal lung blood flow also affects lung growth, even though most of the right ventricular output of the heart is shunted away from the lungs through the ductus arteriosus: pulmonary valve stenosis is associated with pulmonary hypoplasia. Although many fetal organs are able to grow to normal proportions even if they are in abnormal locations, this is not the case for the lungs. Lung growth becomes impaired by restricted expansion. Absence or impairment of fetal breathing movements, and defects affecting respiratory diaphragmatic activity, are all associated with pulmonary hypoplasia. Distension of the developing lung may provide a major stimulus to growth during normal development. It is believed that normal fetal breathing movements increase the lung volume and stimulate growth of the distal airspaces. Fetal breathing movements involve rhythmic activation of the respiratory diaphragm and the muscles of the upper respiratory tract. Even though such movements are necessarily very small compared with those seen after birth, because the fetal airways are filled with lung fluid, there is evidence that these phasic movements are important in the release of growth factors. Fetal breathing becomes more prominent in the second and third trimesters, by which time the fetus spends nearly one-third of the time breathing (Hagen-Ansert 2018). One effect of the absence of fetal breathing movements, for example in severe neuromuscular diseases of antenatal origin such as severe (type I) spinal muscular atrophy and spinal muscular atrophy with respiratory distress, is pulmonary hypoplasia (Inanlou et al 2005).

During development, the mucous glands of the trachea and bronchi secrete a chloride-rich fluid that usually passes up the respiratory tract to mix with the amniotic fluid secreted by the fetal kidneys. Amniotic fluid volume, pressure and, possibly, content significantly influence lung development by maintaining appropriate lung distension. Renal agenesis, severe congenital urinary obstruction and oligohydramnios (Potter's syndrome; Potter's sequence), leads to pulmonary hypoplasia at birth. In renal agenesis, reduced bronchial branching occurs as early as postmenstrual weeks 12–14 (i.e. at a time before amniotic fluid is produced by the metanephric kidneys), which suggests that a direct renal factor supports lung development. Later, the presence of amniotic fluid is necessary for normal fetal lung development. The fetal lung is a net fluid secretor, the output of fluid reaching as high as 5 ml/kg/hour shortly before birth. Most of the fluid produced within the lungs remains there because of the mechanical effect exerted by amniotic fluid pressure, and normally only a small amount of this fluid contributes to the amniotic fluid. The normal functioning of the kidneys regulates the volume and pressure of the lung airway fluid and may in turn provide the pressure needed for expansion and enlargement of the bronchial and pulmonary systems. Interestingly, obstruction to the fetal airway causes accelerated maturation of alveoli, a finding that has been used therapeutically in congenital diaphragmatic hernia, based on studies showing that intermittent inflation and deflation of an intra-tracheal balloon in a lamb model resulted in better lung growth and maturation (Ruano et al 2014). This treatment is the subject of interventional trials in human fetuses (https://www.totaltrial.eu/; Van der Veeken et al 2018).

Two other cell types that participate in normal lung development, neuroendocrine cells and pulmonary lipofibroblasts, have been implicated in postnatal paediatric interstitial lung disease with early onset of respiratory distress (Spagnolo and Bush 2016).

Antenatal influences on intrauterine lung development

There is increasing evidence from epidemiological studies that antenatal factors have long-lasting effects on lung development. The earliest major effect is congenital respiratory diaphragmatic hernia (see below): this leads to both ipsilateral and contralateral abnormalities in branching patterns in the first 16 postmenstrual weeks that cannot be corrected subsequently, even by intrauterine tracheal balloon occlusion. Inevitably abnormal branching leads to abnormal alveolarization. The most important influence on later development is maternal smoking; there is evidence that maternal exposure to pollution is also an important cause of subsequent airflow obstruction (Morales et al 2015). Animal studies have confirmed that antenatal nicotine exposure leads to structural changes in the fetal lung (Bush 2016), and it should be remembered that e-cigarettes contain nicotine. Other factors that may be important include maternal hypertension in pregnancy and maternal antibiotic and paracetamol usage (Rusconi and Gagliardie 2018).

Congenital anomalies of the trachea, bronchi and lungs

Neuroendocrine cells are found in the normal developing airway: neuroendocrine cell hyperplasia of infancy (NEHI) is characterized by persistence of bombesin-positive neuroendocrine cells. Abnormal glycogen-containing cells derived from lipofibroblasts (Deutsch and Young 2016) result in pulmonary interstitial glycogenosis (PIG), which is not related to any of the systemic glycogen storage diseases. Both conditions tend to remit over time, and in neither case is it known whether the abnormal cells are of pathophysiological significance or merely markers of another process. These likely represent part of a spectrum of pulmonary dysmaturation syndromes, including alveolar capillary dysplasia-congenital alveolar dysplasia, see Bush et al (2018) and Bush et al (2019).

The concept of the lung as six 'trees' has been mentioned earlier; all except the systemic venous tree may contribute to a congenital thoracic malformation (Bush et al 2018). Congenital anomalies of the heart and great vessels, and of the chest and abdominal walls, may adversely impact lung development. It is somewhat artificial to describe airway malformations in isolation. The possibility of associated vascular abnormalities must always be considered and descriptions of what is seen clinically should be kept separate from speculations about the putative developmental origins of an anomaly.

Disorders of the proximal airways

Tracheomalacia and bronchomalacia

Abnormalities in cartilage development lead to the affected airways being 'floppy', and collapsing during inspiration or expiration, depending on whether they are outside or inside the bony thorax, respectively: these anomalies are termed tracheomalacia when the trachea is affected, and bronchomalacia when the bronchi are involved. The abnormality may involve a small, localized area, or may be more generalized (e.g. Williams–Campbell syndrome, a congenital deficiency of the airway cartilage, in which there is diffuse bronchomalacia from the second to the seventh generation of bronchi). Tracheobronchomalacia usually presents in early infancy with cough, tachypnoea, stridor and wheeze; it may also be associated with cardiac or respiratory anomalies, such as absent pulmonary valve syndrome, or tracheo-oesophageal fistula, respectively (Wallis et al 2019). Patients with significant obstruction and apnoea may be treated by the insertion of airway stents if the disease is localized, although there is only limited long-term experience in children with stents; generalized disease may mandate respiratory support, either with non-invasive mask ventilation during sleep, or via a tracheostomy, depending on severity. Surgical treatment by aortopexy is controversial.

Tracheo-oesophageal fistulae

Laryngo-tracheo-oesophageal clefts are very rare retained connections between the enteric gut and trachea (Leboulanger and Garabédian 2011). Tracheo-oesophageal atresia is rare, with an incidence of 1 in 3000 to 1 in 4500 births. Oesophageal atresia with or without tracheo-oesophageal fistula may present antenatally with polyhydramnios due to failure of movement of amniotic fluid into the gut after fetal swallowing, and choking and inability to swallow saliva in the neonatal period. Tracheo-oesophageal fistulae are the most common abnormalities of the lower respiratory tract, and occur in about 1 in 3000 births. They are diagnosed antenatally if associated with oesophageal atresia, polyhydramnios and an absent or small stomach. In the neonate they present with recurrent respiratory distress and choking spells and attempts to pass a gastric tube are unsuccessful. Later presentation in adult life has been described.

Five types of tracheo-oesophageal fistulae may be recognized (**Fig. 20.3**). Prenatally, polyhydramnios may be a clinical feature, but may not be apparent until the third trimester. In almost all cases, the oesophagus ends blindly and the stomach is connected to the lower end of the trachea. Because of this connection, the abdomen becomes rapidly distended with air once the baby is delivered and starts breathing. In two of the five types of tracheo-oesophageal fistulae there is no communication between the stomach and the upper gut. Such cases are identifiable on ultrasound, because the stomach should always be visible at a postmenstrual week 20 ultrasound examination, and its absence should prompt further evaluation.

Tracheo-oesophageal fistula is commonly associated with other congenital anomalies, including cardiovascular defects (30%), anorectal (15%) and genitourinary (15%) anomalies. These defects may be combined in the VATER, VACTER and VACTERL associations, which involve varying combinations of vertebral defects, anorectal atresia, cardiac anomalies, trachea-oesophageal fistula and oesophageal atresia, together with radial aplasia and other limb abnormalities, renal abnormalities and the presence of a single umbilical artery (Gottlieb and Andropoulos 2018).

Complete cartilage rings

The normal large airway cartilages are horseshoe-shaped, with the ends of the horseshoes joined by the membranous part of the trachea. Meyerholz et al (2010) suggested that tracheal cartilage shape is abnormal in cystic fibrosis in both human infants and the pig model; however, the rings are not continuous in this condition. Complete cartilage rings may develop in the trachea and large airways, and the posterior membranous part of the airway may be absent in a single cartilage or in long segments of the airway. This anomaly may be associated with vascular anomalies such as pulmonary artery sling (where the left pulmonary artery originates from the right pulmonary artery and not from the main pulmonary trunk). Extensive severe disease may present with neonatal respiratory distress; later presentations include apparently steroid-resistant asthma. Tracheal transplantation has been used to treat long segment tracheal stenosis.

Disorders of the distal airways

Agenesis and aplasia of the lungs

Agenesis and aplasia of the lungs are extremely rare congenital anomalies, where there may be unilateral or bilateral absence of the lung. In agenesis, the airway stump is absent, i.e. the trachea is absent in bilateral disease, or the primary bronchus is absent in unilateral disease. In aplasia, there is a rudimentary airway stump, but no distal lung; the contralateral lung is enlarged, with a greater number of alveoli, but has a normal bronchial branching pattern. Individuals with aplasia may present with recurrent infection, dyspnoea and reduced exercise capacity, and there may be pooling of bronchial secretions, with secondary infection and overspill of infected secretions into the contralateral normal lung.

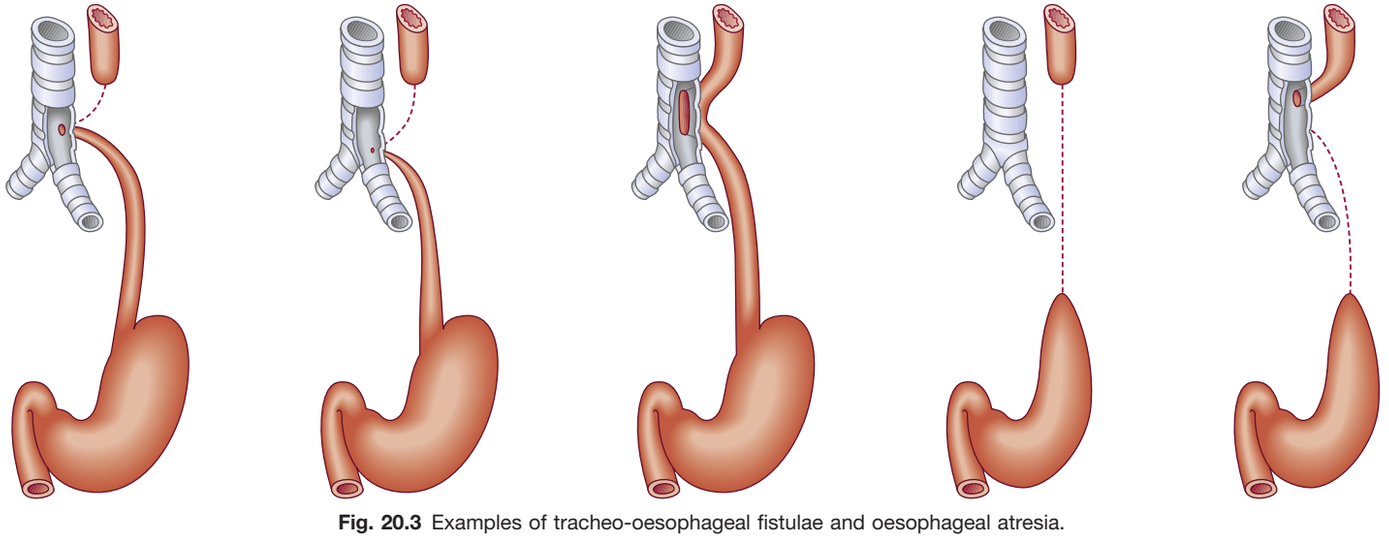

Fig. 20.3 Examples of tracheo-oesophageal fistulae and oesophageal atresia.

Bronchial atresia

Bronchial atresia is a congenital condition in which a major bronchus or segmental airway ends blindly or with a thin membrane. Pulmonary development normally occurs distally, and over time this tissue becomes distended with debris and mucus (bronchocele), with adjacent over-inflated lung tissue. Bronchial atresia characteristically affects the left upper lobe (64% of cases): the chest radiographic findings are of a perihilar ovoid density with strands projecting into a localized area of hyperlucent lung. The left lower lobe is affected in 14% of cases and the right lower and right middle lobe in 8% of cases. The majority of cases are asymptomatic and are revealed as incidental findings on chest radiographs. However, many eventually become the seat of recurrent infection and require operative removal. Some infants may show a congenital large hyperlucent pulmonary lobe (CLHL), a condition termed 'congenital lobar emphysema' although it has nothing to do with adult emphysema. Presentation in severe cases is with neonatal respiratory distress, in which case early surgery is required, otherwise it may be a chance radiographic finding later in life, in which case no action is needed.

Bronchogenic and other cysts

Cysts of various types, by order of frequency, may be found in the carinal (51%), right para-tracheal (19%), para-oesophageal (14%), hilar (9%) and pericardial, retrosternal and para-vertebral (7%) regions. Clinically they are part of the spectrum of congenital thoracic anomalies and can only be classified in more detail pathologically when the wall of the cyst is examined. They may have a systemic blood supply and venous drainage. Multicystic abnormalities, described as various types of congenital cystic adenomatous malformations (CCAM) and sequestrations (intra- and extrapulmonary), are best considered generically as CTM spectrum, at least until examined pathologically, and even then, features of CCAM and sequestration may be found in the same malformation, rendering classification difficult. Presentation may be with a range of problems, from intractable neonatal respiratory distress to a chance finding in adult life. If the infant is symptomatic, then surgical resection is indicated. Treatment of the asymptomatic malformation is controversial; some centres would operate electively on all but the tiniest malformations, because of fears of missing a pleuropulmonary blastoma or malignant transformation, whereas others would manage even large asymptomatic cystic malformations conservatively. Evidence for and against these approaches is summarized in Bush et al (2018).

DEVELOPMENT OF THE THORACIC WALL AND RESPIRATORY DIAPHRAGM

Postnatal function of the lungs requires development of the pleural cavities, respiratory diaphragm and thoracic wall, all structures that will generate the negative intrathoracic pressure required to pull air into the lungs when the thoracic cavity enlarges. The thorax as an entity is not apparent in embryos until the end of the embryonic stage of development (stage 23, 53–58 days post fertilization).

In stage 14 embryos, the heart is at the level of the upper cervical somites, above the upper limb buds and undergoing septation of its compartments (Ch. 13), and the thoracic somites are opposite the midgut. Caudal to the heart, septum transversum mesenchyme (see Figs 20.1, 21.5) is being invaginated by endodermal epithelial cells from the foregut hepatic primordium.

Pleural cavities

The pleural cavities develop from parts of the intraembryonic coelom, an epithelial tube that develops within the embryo from stage 9 and gives rise to all of the body. Embryonic head folding brings this original planar intraembryonic structure into a 3D tube with a large, ventral, pericardial cavity, smaller dorsolateral pericardioperitoneal canals on each side of the foregut, and a peritoneal cavity confluent with the extraembryonic coelom (chorionic cavity) that surrounds the midgut and yolk sac (see Figs 13.1, 20.2, 20.4). The walls of the pericardioperitoneal canals are composed of a germinal epithelium that changes spatially and temporally giving rise to populations of mesenchyme which surround and support adjacent structures. The medial walls of the pericardioperitoneal canals proliferate to form splanchnopleuric mesenchyme that surrounds the developing endodermal foregut, trachea and lung buds, the lateral walls give rise to somatopleuric mesenchyme adjacent to the somites and lateral body wall ectoderm. In stage 12 embryos the luminal walls of the pericardioperitoneal canals are separate. The canals are filled with fluid, continuous with that in the extraembryonic coelom which provides a primitive type of circulation up to stage 13, enabling transfer of oxygen and nutrients to the deeper embryonic structures. Sampling of this fluid from the chorionic cavity via coelocentesis has provided a source of fetal stem cells and proteomic analysis has revealed the differences between coelomic and amniotic fluid (Aiello et al 2018). In stage 12 embryos, the epithelium at the caudal ends of the pericardioperitoneal canals is not proliferative, but very thin and permeable to fluid movement between the intraembryonic coelom and the developing hepatocardiac channels, thus providing a route for the transfer of fluid into the developing blood circulation.

At stage 13 the trachea can be seen as a midline projection from the foregut that extends caudally and bifurcates forming lung buds (see Fig. 21.3). During stage 15 right and left lung buds project dorsally, lateral to the oesophagus, pushing into the splanchnopleuric mesenchyme and displacing the medial walls of the pericardioperitoneal canals (**Fig. 20.4**). The presence and continuing dichotomous growth of the lung buds subdivides the pericardioperitoneal canals into primary pleural coeloms around the lung buds cranially, and paired peritoneal coeloms caudally, contiguous with the wider peritoneal coelom around the mid- and hindguts. The communications with the pericardial and peritoneal coeloms are termed the pleuropericardial and pleuroperitoneal canals, respectively. The descent of the heart as the pharyngeal arches form, together with the changes to the inflow tract of the heart, result in morphological shifts in the relative position of the common cardinal veins that affect the craniocaudal and dorsoventral position of the lung buds. As the lung buds continue to grow and expand, the primary pleural cavities and their cranial and caudal connections become increasingly smaller and eventually separate by different morphological processes. Separation of the pleural cavities from the pericardial and peritoneal cavities is expedited by concomitant changes to the venous system and growth of other thoracic and abdominal viscera.

Growth and movement of the common cardinal veins produces a curved elevation of tissue, the pulmonary ridge, on the lateral wall of each pericardioperitoneal canal partially encircling it. The ridge is continuous with the dorsolateral edge of the septum transversum. As it enlarges into the adjacent pericardioperitoneal canal, each developing lung bud abuts on the ridge and expands caudal to the common cardinal vein, causing the growing ridge to hollow, forming two diverging membranes that meet at the septum transversum. The cranially placed ridge, containing the common cardinal vein, is now termed the pleuropericardial membrane (see Fig. 20.4A). It also contains the elongating phrenic nerve, which reaches the septum transversum by this route. The secondary pleural cavity forms by excavation of the somatopleuric mesenchyme of the body wall (**Fig. 20.5**). The apical part of the lung forms by local invasion and splitting of the body wall cranially on the lateral aspect of the common cardinal vein, which means that the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The remaining connection with the pericardial cavity, which lies medial to the vein, is gradually narrowed to a slit and soon obliterated by the apposition and fusion of its margins. Closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera (heart and great vessels, lungs, trachea and oesophagus), and not by active growth of the pleuropericardial membrane across the opening to the root of the lung. As the right common cardinal vein is larger than the left (because of changes to the venous return to the heart; see Figs 13.1, 13.8, 13.19), closure occurs first on this side; failure of closure is usually found on the left side.

The caudal part of the hollowed pulmonary ridge is termed the pleuroperitoneal membrane (pleuroperitoneal fold) (see Fig. 20.4). It contains mesenchymal populations from the cephalic pole of the mesonephros as well as the septum transversum. As the lungs expand into the pleural coelom, the ridge grows dorsolaterally to ventromedially across the pleuroperitoneal canal, abutting and fusing with the opposite wall and separating the now complete pleural cavity from the peritoneal cavity. The pleuroperitoneal membrane contributes to the respiratory diaphragm (see below). The right pleuroperitoneal canal closes earlier than the left, which presumably explains why an abnormal communication persisting between the pleural and peritoneal cavities is more frequently encountered on the left. In addition to extension of the

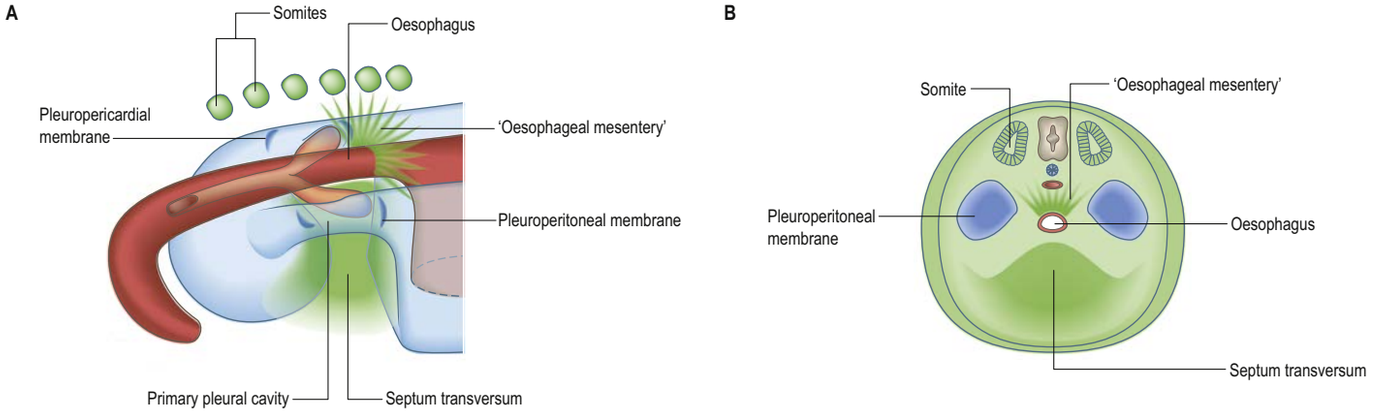

Fig. 20.4 A, Dorsolateral view of the foregut between the pericardioperitoneal canals. The respiratory diverticulum arises from the ventral side of the pharynx and grows caudally. Bilateral lung buds extend dorsally and the most lateral parts project into the dorsolateral pericardioperitoneal canals. Later changes in position of the common cardinal veins contribute to the formation of the pericardiopleural membranes cranial to the developing lungs, whereas folds of coelomic epithelium (pleuroperitoneal membranes) separate the pleural cavities from the peritoneal cavity. **B**, Components of the respiratory diaphragm.

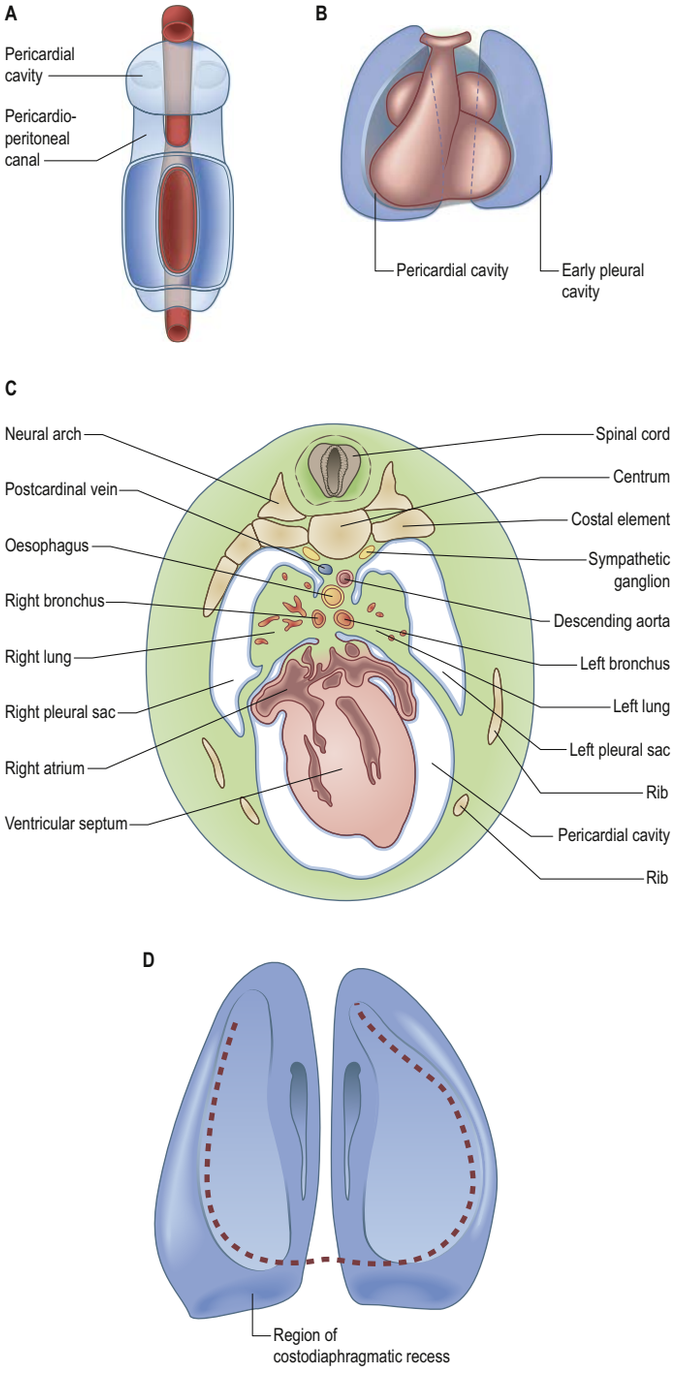

Fig. 20.5 **A**, Ventral view of the intraembryonic coelom forming early body cavities. **B**, The parietal pericardium is shown surrounding the developing heart ventrally, with the parietal pleura of the lungs dorsal and lateral on each side. **C**, A transverse section through the thoracic region, showing the ventral extensions of the pleural sacs on each side of the pericardium that split the body wall mesenchyme. **D**, An anterior view of the pleural sacs. The position of the pericardium is shown by a dotted line. Dorsolateral growth of the pleural sacs also splits the body wall dorsocaudally, defining the costodiaphragmatic recess.

pleural cavities in a cranial direction, the lungs and their associated visceral and parietal pleurae also enlarge ventromedially and dorsocaudally. In the ventromedial extension, the lungs and pleurae excavate and split the somatopleuric mesenchyme covering the pericardium, separating the latter from the ventral and lateral thoracic walls (see Fig. 20.5B–D). The ventrolateral fibrous pericardium, parietal serous pericardium and mediastinal parietal pleura, although topographically deep, are therefore somatopleuric in origin. In the caudodorsal extension, the expanding pleural cavities extend into the mesenchyme dorsal to the suprarenal glands, the gonads and (degenerating) mesonephric ridges. The somatopleuric mesenchyme is peeled off the dorsal body wall to form a substantial portion of the dorsolumbar part of the diaphragm (see Fig. 20.5C).

Until the end of the embryonic period the shape of the early pleural cavities is determined by the growing lungs. The somatopleuric pleural walls form the parietal (costal, diaphragmatic and mediastinal) pleurae and the splanchnopleuric pleural walls, the visceral pleurae. As the pleural mesothelium differentiates, subpleural tissue is thicker where it is associated with superficial veins, and is generally thicker over the basal areas of the lungs than the apices (Yamamoto et al 2018). Differentiated mesothelial cells display pinocytotic vesicles and microvilli, at higher density in visceral than parietal pleura, and in caudal than cranial regions. They secrete glycosaminoglycans, proteoglycans and phospholipids which contribute to a glycocalyx that is non-adhesive for intracoelomic movements. The parietal pleural mesothelial cells are involved in drainage of pleural liquid to underlying lymphatic channels, via stomata between the mesothelial cells (in a manner similar to the parietal peritoneum). Anomalous development of this drainage route may negatively affect prenatal or perinatal control of pleura fluid volume and lead to congenital chylothorax (Bellini et al 2013).

Respiratory diaphragm

The respiratory diaphragm develops as a composite mesenchymal structure that is invaded by myoblast from cervical somites 3–5 (see Figs 17.7, 20.4). The majority of the early diaphragm is formed from a portion of the septum transversum mesenchyme above the developing liver. The septum transversum is a population of mesenchyme cells that arise from the coelomic wall of the caudal part of the pericardial cavity. As this population proliferates, it forms a condensation of mesenchyme, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. The endodermal hepatic bud grows into the caudal part of the septum transversum, whereas the cranial portion forms the respiratory diaphragm (see Fig. 21.5).

The oesophagus and developing stomach are dorsal to the septum transversum and the pleuroperitoneal canals are dorsolateral (see Figs 20.1, 20.4, 20.5). As development proceeds, the lower portion of the oesophagus inclines ventrally, ventral to the descending thoracic aorta. Although the oesophagus has no true ventral or dorsal mesentery within the developing thorax, in descriptions of respiratory diaphragmatic development, the portion of mesenchyme between the oesophagus and aorta at the level of the forming diaphragm is often homologized with part of a dorsal meso-oesophagus.

The later extension of the pleural cavities ventromedially and dorsolaterally into the somatopleuric mesenchyme of the body wall enlarges the area of the developing respiratory diaphragm, particularly dorsally when the costodiaphragmatic recesses develop. The pleuroperitoneal membranes contribute relatively small bilateral areas to the diaphragm, however, as they are the only portion that closes the connection between the pleural and peritoneal cavities, anomalous development will cause a diaphragmatic hernia.

After the septum transversum has undergone a progressive change in its relative position, skeletal muscle myoblasts migrate into the respiratory diaphragm from occipital myotomes from about stage 13. The dorsal border of the septum transversum, which initially lies opposite the second cervical segment, migrates caudally as the embryo grows and the heart enlarges. At first the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm (about stage 13, 31–33 days post fertilization), the dorsal border migrates more rapidly. When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (derived from spinal cord segments C3, C4 and C5) and portions of the corresponding myotomes grow into it and accompany it in its later migrations. The dorsal border of the septum transversum does not come to lie opposite the last thoracic and first lumbar segments, the final position occupied by some of the dorsal attachments of the diaphragm, until the end of the second month. The main derivatives of the central part of the respiratory diaphragm lie at considerably more cranial levels. The cervical myoblasts populate the outer rim of the mesenchymal area and the dorsolateral part which extends caudally behind the developing suprarenal (adrenal) glands. Although histological sections of this region provide clear images of adjacent structures, the curvature of embryos and the difficulty of accurately aligning sectional planes make this developmental process particularly difficult to visualize in 3 dimensions. For details of the closure of the pleuroperitoneal canals in human embryos and fetuses see Hayashi et al (2011).

Respiratory diaphragmatic herniae

Available with the *Gray's Anatomy* e-book

Respiratory diaphragmatic herniae may result from failure of fusion of the component parts or from a primary defect. Posterolateral defects (Bochdalek's hernia) are the most common (85–90%) and may be bilateral (5%) or unilateral. Of the unilateral defects, the left side is more commonly affected (80%) (Chandrasekharan et al 2017). Although these hernias have been attributed to failure of fusion of the pleuroperitoneal membrane, there is increasing evidence that the primary abnormality is lung hypoplasia, and the herniation of the abdominal contents is secondary, which has important implications for treatment (Jesudason 2002). A non-muscular membranous sac, possibly derived from the pleuroperitoneal canal wall is present in 10–15% of cases, signifying the early occurrence of this lesion prior to closure of the pleuroperitoneal canal. Hernias between the costal and sternal origins (Morgagni hernia) are rare (1–2%) (**Fig. 20.6**). Midline defects in the central tendon arise from septum transversum defects. The incidence of congenital diaphragmatic hernias is about 1 : 3000 to 1 : 5000 in neonates, with a prenatal incidence of 1 : 2000.

Respiratory diaphragmatic hernias can usually be diagnosed by antenatal ultrasound examination. The presence of bowel in the thorax and mediastinal shift may be seen sonographically and radiographically (**Fig. 20.7**). The main causes of death in babies with diaphragmatic hernias are pulmonary hypoplasia and pulmonary hypertension. Pulmonary hypoplasia is related to the abnormal branching of the airways both ipsilaterally and contralaterally and the resulting reduced numbers of alveoli. Pulmonary hypertension is related to pulmonary hypoplasia, and to the increased muscularization and reactivity of the pulmonary circulation. There may be associated anomalies, including trisomy 13 and 18, and diaphragmatic hernia may be part of a number of syndromes, many of which may lead to termination of the pregnancy or to death of the neonate. For a review summarizing the recurrent genetic causes of congenital diaphragmatic hernias, see Wynn et al (2014).

Diaphragmatic eventration is a condition in which an abnormal diaphragmatic silhouette is seen on X-ray with an abnormal medial bulge into the thorax; it is associated with paradoxical motion of the diaphragm during respiratory movements. It may be a benign condition, often a chance finding, requiring no treatment or it may lead to respiratory symptoms, requiring plication, and it is occasionally associated with rib and cardiac anomalies.

Thoracic wall, ribs, sternum

The ventral thoracic wall of the embryo consists of minimal amounts of mesenchyme between the ectoderm and pericardial cavity. The ribs and intercostal muscles develop from thoracic somites adjacent to the neural tube (Ch. 18). Hypaxial portions of the myotomes at these levels migrate ventrally between stages 14–18, and the spinal nerves follow marginally later. The intercostal muscles form as the hypaxial myotomal sheet grows around the body wall, separating into three layers, still in continuity with myoblasts that will give rise to the abdominal muscles once the umbilical cord origin becomes proportionally smaller.

Rib primordia are identifiable in stage 15 and grow into the hypaxial muscle sheet. The vertebral column is bent ventrally in a primary, concave curve. The origin of the umbilical cord (umbilical ring) is proportionately large at stage 15 and is opposite ribs 5–11; by stage 17 the umbilical ring is opposite ribs 11 and 12 because the trunk has lengthened. During stages 15–17, ribs 1–7 are of a similar length and extend half way along the lateral body wall; ribs 8–12 are shorter. In stage 18 the ribs begin to bend ventrally and by stage 20 ribs 1–8 also bend mediocranially towards the putative sternum. Although the ribs do not change their orientation from this time, by stage 23 they have increased in length three-fold as the thorax and upper abdomen circumference increases (Mekonen et al 2015).

The sternum is first visible in stage 18 as a presternal condensation above the first rib, and a pair of lateral sternal bars. The presternal condensation forms the manubrium and extends to the second rib by stage 23, at which time the sternal bars are caudal to the putative manubrium. The sternal bars join with ribs 2–5 and approach each other at the ventral midline. The sternal bars extend to connect with the lower ribs in stage 23 and remain bifid until postfertilization week 10 (Mekonen et al 2015). For details of postnatal development of the sternum see Bayaroğullari et al (2014).

Congenital anomalies of the thoracic wall

Vertebral anomalies, including formation of hemivertebrae and block vertebrae (where cranial and caudal sclerotomal halves do not separate), may contribute to scoliosis. Five per cent of scoliosis is congenital and it may be associated with numerous other anomalies, e.g. the VACTERL (Vertebral; Anorectal; Cardiac; Tracheal; Esophageal; Renal; Limb) association or with congenital syndromes such as Marfan syndrome and congenital neurofibromatosis. The diagnosis may be missed at birth. Syndromes in which the chest wall does not develop properly and the lungs are hypoplastic include Jeune syndrome, asphyxiating thoracic dystrophy (an autosomal recessive condition that may be associated with short limb dwarfism and polydactyly) and Poland's syndrome, which consists of unilateral pectoral aplasia and dysdactylia (Martin and Hackam 2017). Rib cage anomalies also occur in thanatrophic dwarfism, achondroplasia, chondroectodermal dysplasia and giant exomphalos. Many of these conditions are fatal soon after birth; milder forms may improve with time, but affected individuals may need prolonged respiratory support. Ellis van Creveld and Sesenbrenner's syndromes also affect chest wall and rib development and are related to mutations in primary (non-motile) cilia genes.

Anomalies of the sternum and ventral body wall include ectopia cordis, a condition in which the heart is outside the body without a surrounding pericardium. This very rare condition is thought to be caused by failure of the heart to descend into the thorax: cervical, cervicothoracic, thoracic, thoracoabdominal and abdominal types have been classified (Engum 2008). The condition can be detected on second trimester ultrasound examination. Less serious and more prevalent sternal anomalies include pectus excavatum, the most common, seen in 1 in 300–400 live births (male : female ratio 3 : 1) and pectus carinatum, seen 1 in 10,000 live births (male : female ratio 6 : 1) (Gottlieb et al 2018).

Ultrasound antenatal imaging of the thorax and fetal lungs

The fetal thorax is symmetrically bell-shaped on coronal section and almost circular in axial section. Fetal chest size is estimated by measuring the chest circumference on axial section at the level of the four-chamber-heart view. Such measurement can confirm or exclude reduced chest volume (Karl and Chaoui 2015). The relative circumference of the thorax and heart remains the same in the second and third trimesters. The respiratory diaphragm is best viewed in sagittal view as a dome on each side of the body with no difference in its height on either side. Diaphragmatic hernias can be diagnosed from about postmenstrual week 18 by the presence of the stomach bubble or gut within the thoracic cavity and mediastinal shift; the liver may also herniate into the chest (Bulas 2018).

Pulmonary hypoplasia, an absolute decrease in lung volume and weight for gestational age, may be identified but cannot be confirmed. It is normally associated with oligohydramnios and renal agenesis. Unilateral hypoplasia may be suggested by rotation and displacement of the heart on ultrasound examination. In bilateral pulmonary hypoplasia the heart appears relatively large with a reduced chest volume. However, intrauterine growth retardation may also cause similar findings. Increased echogenicity of the lungs indicates conditions that prevent the normal circulation of lung fluid (for further details consult Coady and Bower (2015)). Details of prenatal lung anomalies and their detection are given in Epelman et al (2013) and of ultrasound examination of the fetal thorax in Hagen-Ansert (2018). Fetal breathing movements become more prominent in the second and third trimesters; at least 30 seconds of continuous, rhythmic breathing movements are considered normal within a 30 minute sonography examination (Benson and Doubilet 2018). Maternal activity affects fetal breathing; it is stimulated by increased sugar and decreased by maternal cigarette smoking (Hagen-Ansert 2018).

Other thoracic structures are noted in the ultrasound examination. The fetal thymus can be identified in the anterior mediastinum at 14 postmenstrual weeks. The normal thymus has an average transverse diameter of 12 mm at 19 postmenstrual weeks and 33 mm at 33 postmenstrual weeks; the normal, average thymic perimeter is 128 mm at 38 postmenstrual weeks. Although imaging and measurement of the thymus is not routinely performed, acute thymic involution has been noted in association with chorioamnionitis, and thymic measurements showing aplasia or hypoplasia may be seen in DiGeorge syndrome (Bulas 2018). Pleural effusion, an accumulation of fluid within the pleural cavity can be bilateral or unilateral; when unilateral and right-sided it is commonly a chylothorax caused by an anomaly of the thoracic duct (Hagen-Ansert 2018).

Postnatal development of the respiratory system

Functional changes in the lungs at birth

Just prior to birth, the placenta is the organ of respiration. Virtually all the venous return to the right heart is shunted away from the lungs through the foramen ovale and the ductus arteriosus. Pulmonary vascular resistance is maintained at a very high level by the muscular precapillary pulmonary vessels. At birth, the umbilical cord is tied and cut, and within seconds the lungs must take over all respiratory function in order to maintain life. In the non-compromised full-term neonate, it is advised that cord clamping should be delayed for at least one minute to enhance venous return of blood to the lungs during the first few postnatal breaths.

With the onset of postnatal breathing the lung must change from secreting fluid to absorbing it. The mechanisms that mediate these dramatic changes are obscure. However, it is clear that the first breath results in pulmonary vasodilatation by at least two mechanisms. First, the mechanical effect of traction on the vasculature: as the chest wall expands, it pulls open the pulmonary vessels. Second, oxygen entering the lungs for the first time produces pulmonary vasodilatation. The demonstration that pulmonary vascular resistance (PVR) falls, even if an experimental animal fetus is delivered into an atmosphere of pure nitrogen, implies that other mediators, including cyclo-oxygenase metabolites, are important. The gene for cyclo-oxygenase 1 (but not 2) in endothelium and vascular smooth muscle shows enhanced expression in late fetal and early post-natal life. Endothelin receptor expression increases around the time of birth, implying a role for this system in postnatal adaptation. The role of nitric oxide in postnatal adaptation is controversial, and there are likely to be important species differences. Nitric oxide synthase (NOS) is more abundant in young compared with mature animals, and smooth muscle sensitivity to nitric oxide may be greater at birth than in older animals. The effects of mediators may differ ante- and postnatally, e.g. endothelin (ET)-1 causes vasodilatation in fetal sheep, but vasoconstriction postnatally in lambs.

Most arteries and veins are present and the morphology of the blood–gas barrier is the same as in adults, however, until lung alveoli become filled with air and stretched by the first breaths the functional relationship between the expanding pulmonary capillary endothelial cells and the type I pneumocytes is not yet fully established. The endothelial cells of the precapillary arteries are still squat and have narrow bases on the subendothelium, a low surface : volume ratio and many surface projections. Five minutes after birth, the endothelial cells are thinner and gradually show less cell overlap, the surface : volume ratio increases, fewer cell projections are seen, the vessel wall becomes thinner and the lumen diameter increases (**Fig. 20.8**).

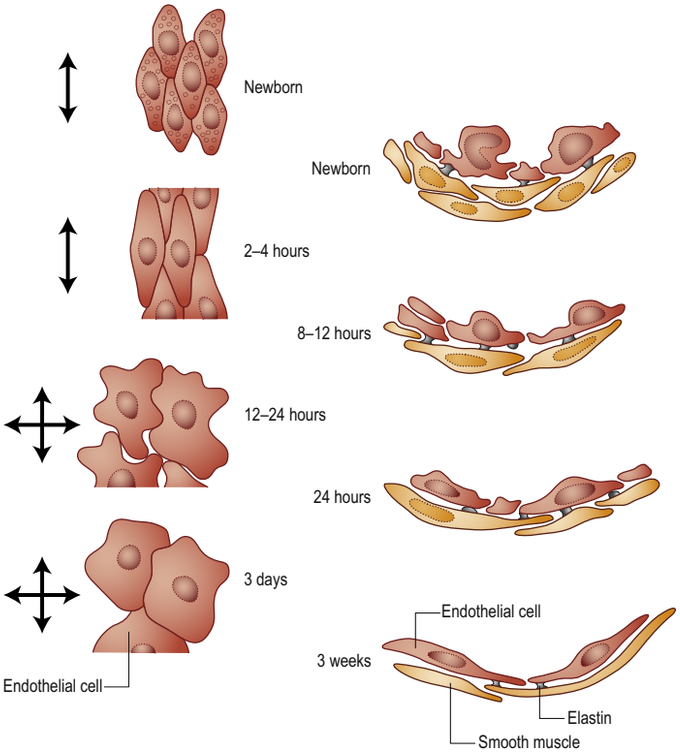

Fig. 20.8 *En face* views (left) and transverse sections (right) showing the changes in the endothelial and smooth muscle cells of small muscular pulmonary arteries accompanying terminal bronchi from the neonatal period to postnatal week 3. (With permission from Haworth SG 1992 Pathophysiological and metabolic manifestations of pulmonary vascular disease in children. Herz 17:254–61.)

As respiration is established but before structural remodelling has taken place, pulmonary vascular resistance may rise steeply if the neonate becomes even minimally hypoxic or acidaemic. The fetal shunts (foramen ovale and ductus arteriosus) reopen and right to left shunting causes profound hypoxaemia, 'persistent fetal circulation'. At full-term delivery the lung volume is small but related to body weight. All airways are present and differentiated (cartilage, glands, muscle, nerves) with one-third to one-half of the adult complement of alveoli present, giving sufficient surface area for gas exchange.

Lungs at birth in preterm infants

There appears to be a relationship between those organs with specialized epithelia abutting endothelium with fused basal laminae and their sensitivity to damage by prematurity and haemodynamic shifts (see Fig 11.2). The alveolar–capillary membrane, the glomerular basement membrane and the blood–brain barrier are specifically affected by preterm birth, where changes in oxygen tension and blood pressure can change the normal developmental trajectory, and any one of these sites is affected by changes in the others. These sites are also particularly affected by postnatal haemodynamic shifts within the still embryonic blood vessels, such that either the tissue becomes more hypoxic than the fetal environment, or hyperoxic when cardiac shunts change postnatally. Either change can cause damage, resulting in acute inflammation and healing, with cytokines entering the fetal circulation and affecting other vulnerable developing organs.

Extremely premature babies, who are treated with surfactant and ventilated using low-pressure, high-rate strategies, show arrest of alveolar development and pulmonary hypoplasia. Arrest of development is also seen in outer cortical glomeruli and in the migration of neuroblasts and glioblasts to the cortical plate in preterm infants. However, in the kidney and brain the connection between the specialized epithelia and adjacent endothelium is stable in some mature areas, for example, the glomerular basement membrane in the kidney functions prenatally and does not undergo significant mechanical change at birth. In contrast, lung alveoli and pulmonary capillaries expand during the first postnatal breaths, initiating postnatal maturation of ventilation perfusion matching. In the preterm infant the initial extent of lung expansion is crucial. As few as three large assisted ventilatory breaths may cause sufficient damage to the expanding alveolar type I pneumocytes and associated pulmonary alveolar capillaries to initiate an inflammatory response and cytokine release triggering a systemic inflammatory response (Barton et al 2015). Ventilation-induced lung injury contributes to subsequent healing processes and leads to bronchopulmonary dysplasia (also known as chronic lung disease). Impaired haemodynamic autoregulation effects the cerebral blood flow and leads to either hypoxia/ischaemia or cerebral haemorrhage, and affects the permeability of the blood–brain barrier (Barton et al 2015, Volpe 2017).

Preterm males may have worse respiratory distress than females after control for other risk factors, such as degree of prematurity; it is possible that in male fetuses surfactant production is delayed (Anadkat et al 2012, Jackson 2018). Androgens delay fetal lung maturation while stimulating fetal lung growth: type II cells in males are less mature than in females during the canalicular phase.

More than half of preterm infants develop respiratory distress syndrome due to lung immaturity and surfactant deficiency. Shear stress in the alveoli and terminal bronchi, caused by repetitive reopening of collapsed alveoli and overdistention of open alveoli, leads to type I pneumocyte damage and protein exudate into the alveoli and terminal airways (this is the basis of hyaline membranes). The exudate may impair the function of the limited surfactant that is present in immature lungs. Reopening collapsed alveoli requires the generation of highly negative intrathoracic pressure, thus the preterm infant shows retractions of the thoracic wall and use of accessory muscles during inspiration. Expiratory grunting, caused by partial closure of the glottis, helps maintain end-expiratory pressure and patency of unstable alveoli (Jackson 2018). Hyperoxia or dexamethasone treatment of experimental rats during the alveolarization period permanently abrogates alveolar development, suggesting that iatrogenic damage to the developing alveoli when ventilating a preterm baby with oxygen-enriched mixtures is probably irreversible, and ventilation-induced lung injury may now be the basis of bronchopulmonary dysplasia (Voynow 2017). The long-term effects of preterm birth and its treatment are changing over the years. Survivors from the pre-surfactant era have disease dominated by airflow obstruction. Importantly even babies born at 33–34 postmenstrual weeks have persistent postnatal airflow obstruction (Kotecha et al 2012).

Neonatal thorax

In the normal full-term neonate, the trachea is relatively small in relation to the larynx. The walls of the trachea are relatively thick and the tracheal cartilages are relatively closer than they are in the adult. The trachea begins level with the upper border of the sixth cervical vertebra, a relationship that is conserved with growth, and it bifurcates at the level of the third or fourth thoracic vertebra.

A number of differences between the neonatal and adult thorax and respiratory diaphragm are significant in early postnatal life, especially in the preterm infant. The full-term neonatal thorax has a rounded circumference whereas the adult profile is dorsoventrally flattened. The compliance of the adult chest wall and lung are approximately equal, but the neonatal chest wall is up to five times more compliant than the lungs and so is easily deformable: indrawing of the chest wall is an important sign of increased work of breathing in the neonate. The respiratory diaphragm is relatively flat at birth and gains its dome shape as the thorax and abdominal viscera grow. The arrangement of the ribs and diaphragm in the neonate means that contraction of the diaphragm pulls the compliant ribs inwards. This does not contribute to inspiration and leads to chest distortion: it may be opposed by the stabilizing action of the expiratory muscles. The neonatal respiratory diaphragm exhibits an exaggerated asymmetric movement: the posterior portion shows a considerably greater excursion than the anterior portion.

A neonate undertakes relatively greater work in order to breathe, and is much more vulnerable to developing respiratory muscle fatigue and respiratory muscle failure than an adult. Experimental animal studies suggest that neonates may be especially vulnerable to respiratory muscle failure because of the initial immaturity of synapses. Moreover, myosin isoforms are developmentally regulated in the diaphragm, and the reduced power output and work performance of the neonatal diaphragm may reflect these molecular differences. In expiration, there may be active braking of airflow, caused by inspiratory muscle activity and partial constriction of the larynx.

At all ages, there is a reduction, if not loss, of tonic intercostal activity during rapid eye movement (REM) sleep. The mechanism is believed to be related to a descending spinal inhibition of the muscle spindle system. In addition, although during REM sleep the respiratory diaphragm descends further, this inspiratory effort is dissipated in sucking in the ribs and enlarging the abdomen, such that the rib cage and abdominal ventilatory movements become out of phase. The neonate is at particular risk in this respect, because the chest wall is flexible, and much of the infant sleep activity is of the REM type. Furthermore, the

upper airway musculature may lose tone during REM sleep, so that the soft tissues of the pharynx are sucked in during inspiration, limiting the cross-sectional area of the upper airway and further increasing the work of breathing.

Endotracheal intubation in the neonate

The insertion of an endotracheal tube is a procedure that may be required for resuscitation of the neonate at birth and subsequently to enable artificial ventilation. The larynx is more funnel-shaped than in the adult. It is located at the level of the middle of the body of the third cervical vertebra in preterm infants, and at the interspace between the third and fourth cervical vertebrae in full-term infants (Fiadjoe et al 2018). Visualization of the infant larynx is difficult because, unlike the adult, the angle between the plane of the tongue and the plane of the glottic opening is more acute; the epiglottis is omega-shaped and narrow and angled away from the axis of the trachea; and the vocal cords are angled with a higher attachment ventrally than dorsally. The cricoid cartilage is functionally the narrowest portion of the upper airway in infants.

An endotracheal tube is introduced, usually orally initially, and guided through the vocal cords under direct vision using a laryngoscope. The length of the trachea (vocal cords to carina) in full-term neonates and infants to 1 year of age varies from 5 to 9 cm. Once in place, the tip of the tube should be in the mid-trachea, well above the carina. The required length of the tube can be estimated according to birth weight; although correlation to foot length has also been noted to be as accurate as weight (Fiadjoe et al 2018). Confirmation of correct positioning of the endotracheal tube is obtained from a chest X-ray (Schmölzer et al 2013). Long-term endotracheal intubation in extremely preterm infants is associated with subglottic stenosis and later dysphonia. Voice anomalies have been reported in more than 50% of children born preterm with endotracheal intubation longer than 28 days, and in those with prolonged admission to a neonatal intensive care unit (Hseu et al 2018).

Postnatal lung development

Available with the *Gray's Anatomy* e-book

Normal postnatal pulmonary arterial development

Immediately after birth, dramatic remodelling of the pulmonary vasculature occurs to effect an abrupt reduction of pulmonary vascular resistance. This process continues at a rapid rate throughout the first 1–2 postnatal months, while the lungs adapt to extrauterine life, and then more slowly throughout childhood. Failure to remodel in the presence of an anatomically normal heart leads to persistent pulmonary hypertension. Normal postnatal pulmonary arterial development in the full-term neonate can be divided into three stages:

Stage one lasts from birth to about postnatal day 4, and concerns the immediate adaptation to extrauterine life. The endothelial cells expand and the vessel wall becomes thinner (see Fig. 20.8). The smooth muscle cells show a significant reduction in diameter during this time.

Stage two lasts from around day 4 to 3–4 postnatal weeks, and is the time when the cells deposit matrix around themselves to fix their new positions. At birth, the internal elastic lamina of the small muscular arteries consists only of amorphous elastin in a basal lamina-like matrix. By 3 postnatal weeks, a definitive elastic lamina is evident, although it is heavily fenestrated, permitting contact between the endothelial cells and the smooth muscle cells.

Stage three continues into adulthood. The intrapulmonary arteries increase in size and their walls increase in thickness. However, the maturation of all of the pulmonary vascular smooth muscle cells, from the hilum to the precapillary bed, is not advanced until 2 years. As the distal airspaces expand, the capillary networks fuse from one alveolus to another, forming, for a period, an extensive double capillary net: this process can be seen from postnatal day 28, becomes more extensive by 1.5 years, and it is believed to be complete by 5 years.

The first 4-6 years of life seem to be a key time window, after which there is no catch-up growth in lung function (Bush 2016). Postnatal lung development is also impaired by exposure to tobacco smoke, and there is increasing evidence that air pollution, early polysensitization to aeroallergens and attacks of severe wheeze also adversely impact on normal lung growth.

Figures 2–7 illustrate in 3D reconstructions, over stages 15–23, the lengthening and medial growth of the ribs and formation of the sternum. Hypaxial muscle growth is shown and the closure of the ventral body wall discussed. This paper provides accurate embryonic staging, in line with O'Rahilly and Müller (2010), illustrates the conversion of serial histological sections to 3D images using computer software and compares successive embryonic stages.

Morrisey EE, Hogan BL 2010 Preparing for the first breath: genetic and cellular mechanisms in lung development. Dev Cell 18:8–23.
This paper presents an overview of the molecular mechanisms of lung development.

The amount and type of connective tissue in the lung change after birth. The neonatal lung has abundant type III and type IV collagen, but little type I collagen. Types III and IV collagen are not mechanically strong, suggesting that the neonatal lung has a phenotype that facilitates the changes in cell shape and orientation that characterize adaptation to extrauterine life. It is probable that the rapid deposition of type I collagen postnatally contributes structural stiffness to the blood vessel walls.

Conducting airways undergo profound postnatal changes, and exhibit increased smooth muscle and bronchoconstrictor responsiveness. Although the precise molecular signalling for these processes is unknown, it appears to be tightly developmentally regulated.

Lung volume increases most rapidly during the first year of life and also increases more rapidly than airway calibre during this time, a finding which is consistent with the concept of dysanaptic lung growth, i.e. a dissociation between the growth of the lung parenchyma and the airways. It was thought that most of the alveoli were formed by two years of age, with subsequent lung growth primarily resulting from an increase in the size of individual alveoli. However, measurements of alveolar size throughout childhood and adolescence using hyperpolarized helium have shown that neo-alveolarization as well as an increase in alveolar size continues through childhood and adolescence (Narayanan et al 2012). This has important implications for diseases characterized by neonatal arrest of alveolarization, for example after ventilation of the extreme preterm baby there is more scope for recovery than previously thought, but also more potential harm from childhood perturbations. Forced vital capacity measured by the raised volume, rapid thoracoabdominal compression technique is reported to be the same in male and female infants and very young children (Jones et al 2000), which is consistent with post mortem morphometric measurements. By the second year of life the rate of increase in forced vital capacity is similar to that reported in older children.

The best data on the evolution of spirometry over the life course are from the Global Lung Initiative (Quanjer et al 2012), based on more than 160,000 data points. Briefly, spirometry rises to reach a plateau at age 20–25 years and thereafter declines steadily. During childhood, lung volumes and flow rates increase linearly with height, with a greater intercept and more positive slope in boys compared to girls (Stanojevic et al 2008). The linearity of these changes is interrupted by puberty (Rosenthal et al 1993a, 1993b, Rosenthal and Bush 2002), when important shape changes occur in the thorax, particularly in boys, and are mirrored by changes in the size of the underlying lung (and in particular the alveoli) as manifest by an abrupt increase in vital capacity, forced expired volume in one second, and total lung capacity. Thereafter, the change in lung size again proceeds in a linear fashion. High resolution CT scanning has been used to measure airway dimensions (de Jong et al 2006), although this technique should be used with caution because of the radiation exposure.

There is little in the way of structural data to set alongside epidemiology. The reticular basement membrane is first detected at about 30 postmenstrual weeks, thickens throughout childhood and adolescence, and plateaus or possibly declines in thickness with age (Tsartsali et al 2011). In terms of airway smooth muscle, limited data from endobronchial biopsies suggested that this did not change from age three years throughout childhood (O'Reilly et al 2013). Autopsy data suggest an increase in airway smooth muscle over the first two years of life. Goblet cells also increase over the same timeframe (Hislop and Haworth 1989).

CHAPTER 21

Development of the peritoneal cavity, gastrointestinal tract and its adnexae

POSTPHARYNGEAL FOREGUT

The primitive gut is divided by head- and tail-folding into three main compartments. The foregut extends from the buccopharyngeal membrane to its continuation into the central midgut region via the cranial intestinal portal. The midgut extends between the intestinal portals and, in the early embryo, is in wide communication with the yolk sac. The hindgut extends from the caudal intestinal portal to the cloacal membrane. The cranial end of the foregut, the embryonic pharynx, is intimately associated with head and neck development (Ch. 17). The portion of foregut that passes dorsal to the pericardial cavity gives rise to the respiratory diverticulum and oesophagus within the thorax (Chs 17 and 20). Caudal to the developing respiratory diaphragm, the enteric gut is conventionally subdivided into three embryological portions: fore-, mid- and hindgut. There are no corresponding fundamental morphological and cytological distinctions between the three parts (**Fig. 21.1**), and so the foregut produces a portion of the duodenum, as does the midgut, and the midgut similarly produces large intestine, as does the hindgut. The differences between the portions of the gut develop as a result of interactions between the three embryonic tissue layers that give rise to the gut: namely, the endodermal inner epithelium, the thick layer of splanchnopleuric mesenchyme and the outer layer of proliferating splanchnopleuric coelomic epithelium.

The mucosal epithelial layer and connected ducts and glands are derived from the endodermal epithelium. The lamina propria and muscularis mucosa, the connective tissue of the submucosa, the muscularis externa and the future serosal lamina propria are all derived from the splanchnopleuric mesenchyme. The outer splanchnopleuric coelomic epithelium forms the epithelial component of the serosa (peritoneum, a mesothelium). Both epithelia, inner and outer, express cell polarity markers and form specific apical junctional complexes; they are highly proliferative and appear histologically as pseudostratified epithelia with interkinetic nuclear migration matching the timing of the cell cycle. In the endodermal layer, this proliferation results in lengthening of the inner endodermal epithelium. In the splanchnic coelomic epithelium, which acts as a barrier throughout development to contain locally secreted morphogens, proliferation not only increases the surface area and gives rise to the subjacent mesenchymal population, but also generates biomechanical tension across the whole composite tube, which by differentiative temporo-spatial patterning contributes to regional gut development (Grosse et al 2011, Guo et al 2014, Ariza et al 2016, Chevalier et al 2018).

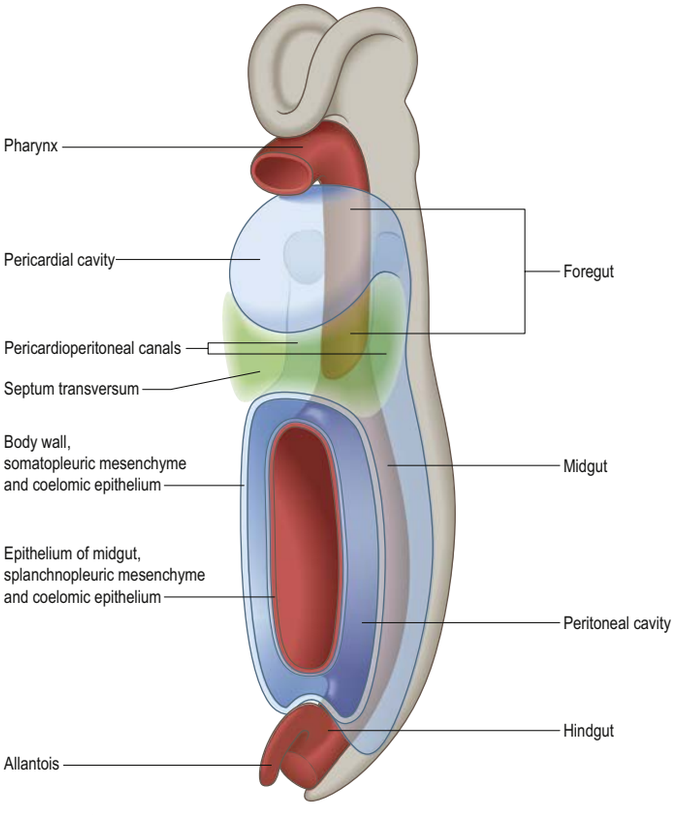

Fig. 21.1 Major epithelial populations within the early embryo. The early gut tube is close to the notochord and neural tube dorsally. The splanchnopleuric layer of the intraembryonic coelomic epithelium is in contact with the foregut ventrally and laterally, with the midgut laterally, and the hindgut ventrally and laterally.

Throughout the gut, blood vessels, lymphatics and lymph nodes develop from local populations of angiogenic mesenchyme. The nerves, which are distributed within the enteric and autonomic systems, are derived from the neural crest. There is a craniocaudal developmental gradient along the gut, in that the stomach and small intestine develop in advance of the colon.

Fig. 21.1 shows the fundamental relationship of the intraembryonic coelom to the developing gut. **Fig. 21.2** shows the gut in a stage 12 embryo in relation to the other developing viscera, especially the heart and liver. **Fig. 21.3** shows the overall development of the gut from stages 13 to 17. These diagrams should be compared. See Fig. 23.3 for a comparison of stages to postfertilzation days and the clinical scale of postmenstrual weeks.

All regions of the gut develop from epithelial–mesenchymal interactions that are dependent on the sequential expression of a range of basic and specific genes; on the regulation of the developmental clock, seen in all areas of development; and on endogenous regulatory mechanisms and local environmental influences (Lebenthal 1989). Although all these factors pertain to the whole range of developing tissues, local differences in any one of these factors along the length of the developing gut promote the differentiation of, for example, the gastric mucosa and hepatocytes; the rotation of the midgut; and the final disposition of the sessile portions of the fully formed gastrointestinal tract. The Hedgehog (Hh) ligands, Shh, Ihh and Dhh, are expressed in the developing gut: Shh and Ihh in the endodermal epithelium and Dhh in endothelial cells. These ligands bind to the Patched receptors (Ptch-1 and Ptch-2), which activate the transcription factor Gli3. Knockout of Shh and Ihh has been associated with oesophageal atresia, gut malrotation, decreased development of the muscularis propria, enteric neurone anomalies and imperforate anus (Kolterud et al 2009). The gut is functional prior to birth and able to interact with the extrauterine environment in preterm infants.

Oesophagus

The oesophagus can be distinguished from the stomach at stage 13 (31–33 days postfertilization). It elongates during successive stages and its absolute length increases more rapidly than the embryo as a whole. By stage 15 it is surrounded by splanchnopleuric mesenchyme derived from the walls of the pericardioperitoneal canals. Cranially, it is dorsal to the developing trachea and the two tubes share the mesenchymal population between them; more caudally it is medial to the developing lung buds (Fig. 21.3). The terminal, pregastric segment of the oesophagus is surrounded ventrally by the most cranial part of the septum transversum mesenchyme and dorsally by splanchopleuric mesenchyme, which forms a short, thick, dorsal meso-oesophagus with the lower medial walls of the pericardioperitoneal canals. Caudally these mesenchymal populations are continuous with their respective primitive dorsal and ventral mesogastria. Although the oesophagus has only limited areas related to a primary coelomic epithelium at its caudal end, it is important to note the subsequent development of the para-oesophageal right

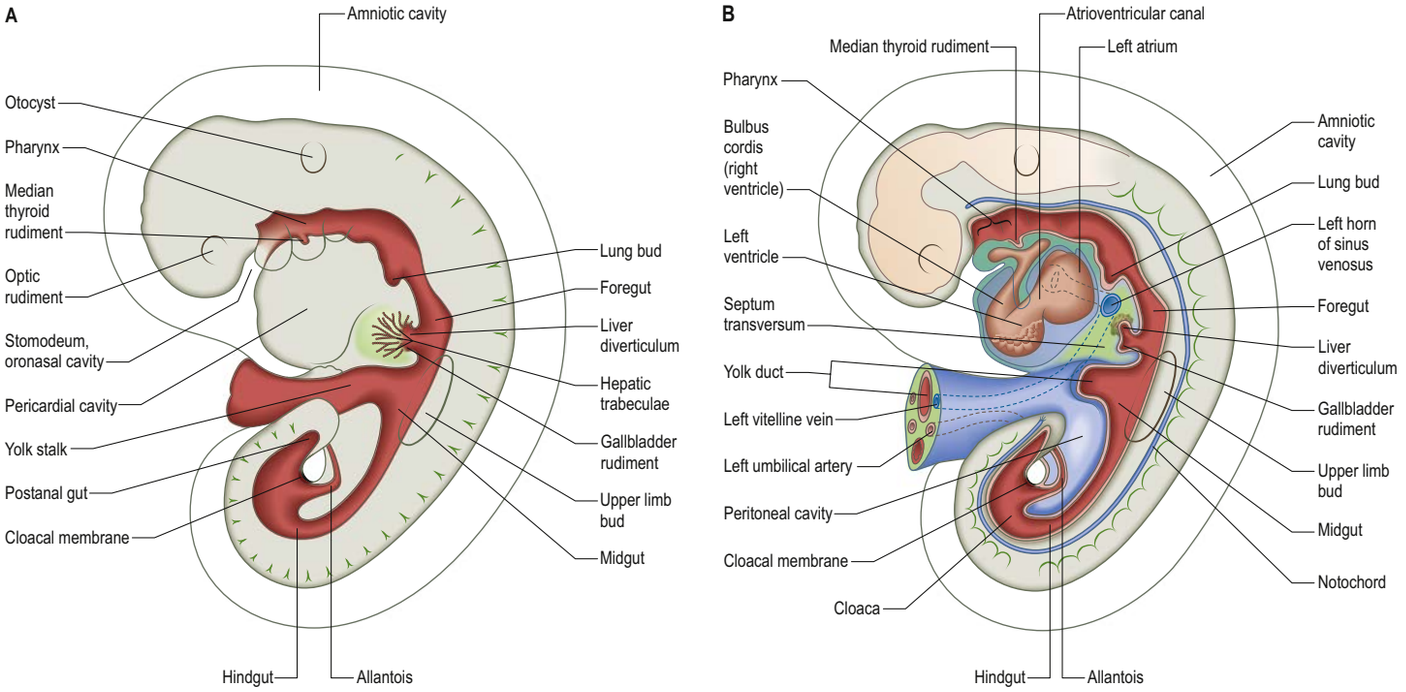

Fig. 21.2 A, The developing gut of a human embryo at stage 12. (Pharyngeal development is followed further in Fig. 17.19). **B**, Reconstruction of the gut and its outgrowths in median section. The brain is shown in outline but the spinal cord has been omitted. The heart is shown in perspective, and the left horn of the sinus venosus is cut just medial to the entrance of the common cardinal vein (see Figs 13.8A-B, 13.17). The somites are indicated in outline.

and left pneumatoenteric recesses (see Fig. 21.7), the relation of the ventral aspect of the middle third of the oesophagus to the oblique sinus of the pericardium, and the relation of its lateral walls in the lower thorax to the mediastinal pleura. All the foregoing are secondary extensions from the primary coelom.

The oesophageal mucosa consists of two layers of cells by stage 15, but the proliferation of the mucosa does not occlude the lumen at any time. The mucosa becomes ciliated at 10 postfertilization weeks, and stratified squamous epithelium is present after postmenstrual week 20; occasionally, patches of ciliated epithelium may be present at birth. Circular muscle can be seen at stage 15 but longitudinal muscle has not been identified until stage 21. Neuroblasts can be demonstrated in the early stages; the myenteric plexuses have cholinesterase activity by 9.5 postfertilization weeks and ganglion cells are differentiated by 13 postfertilization weeks. It has been suggested that the oesophagus is capable of peristalsis in the first trimester. Pharyngeal phase swallowing activity has been identified from 11 postmenstrual weeks on ultrasound examination; oesophageal motor function is well developed by 26 postmenstrual weeks (Neu 2012, Jadcherla et al 2015). The volume of amniotic fluid ingested increases during the third trimester to more than 500 ml/day.

Oesophagus at birth

At birth, the oesophagus extends 8–10 cm from the cricoid cartilage to the gastric cardiac orifice. It starts and ends one to two vertebrae, respectively, higher than in the adult, extending from between the fourth to the sixth cervical vertebra to the level of the ninth thoracic vertebra (see Fig. 23.15). Its average diameter is 5 mm and it possesses the constrictions seen in the adult. The narrowest constriction is at its junction with the pharynx, where the inferior pharyngeal constrictor functions to constrict the lumen; this region may be easily traumatized with instruments or catheters. In the neonate, the mucosa may contain scattered areas of ciliated columnar epithelium but these disappear soon after birth. Complex swallowing and oesophageal reflexes are present in the full-term neonate (Ch. 14). A coordinated relaxation of the upper oesophageal sphincter is followed sequentially by oesophageal peristalsis and relaxation of the lower oesophageal sphincter (Jadcherla 2016). Air or liquid can be distinguished in the oesophagus and result in different swallowing patterns. Maturational changes are seen in the lower oesophageal sphincter relaxation reflex in the postnatal development of preterm infants (Jadcherla et al 2015). In term and preterm infants, transient lower oesophageal sphincter relaxations, unrelated to swallowing, permit gastro-oesophageal reflux resulting in frequent regurgitation of food in the newborn period, with a peak prevalence at 4 postnatal months, declining thereafter (Neu 2012).

Stomach

The stomach can be recognized, at stage 13, as a fusiform dilation cranial to the wide opening of the midgut into the yolk sac (see Fig. 21.3). By stage 14 this opening has narrowed into a tubular vitelline intestinal duct, which will lose its connection with the digestive tube. At this time, the stomach is median in position and separated cranially from the pericardium by the septum transversum (see Fig. 21.5A), which extends caudally on to the cranial side of the vitelline intestinal duct and ventrally to the somatopleure. Dorsally, the stomach is related to the aorta and connected to the body wall by a short dorsal mesentery, the dorsal mesogastrium, formed by the medial walls of the pleuroperitoneal canals and intervening splanchnopleuric mesenchyme (see Figs 21.5B, 21.6). The latter is directly continuous with the dorsal mesentery (mesenteron) of almost all of the remainder of the intestine, except its caudal short segment.

The characteristic gastric curvatures are already recognizable in human embryos during stages 15–16. Growth is more active along the dorsal border of the viscus; its convexity markedly increases and the rudimentary fundus appears. Because of more rapid growth along the dorsal border, the pyloric end of the stomach turns ventrally and the concave lesser curvature becomes apparent (see Figs 21.3, 21.6). The stomach is now displaced to the left of the median plane and becomes physically rotated, such that its original right surface becomes dorsal and its left surface becomes ventral. Accordingly, the right vagus nerve is distributed mainly to the dorsal, and the left vagus mainly to the ventral, surfaces of the stomach. The dorsal mesogastrium increases in depth and becomes folded on itself. The ventral mesogastrium becomes more coronal than sagittal. The pancreaticoenteric recess (see Fig. 21.7B(ii)), until this point conventionally described as a simple depression on the right side of the dorsal mesogastrium, becomes dorsal to the stomach and excavates downwards and to the left between the folded layers: it may now be termed the inferior recess of the bursa omentalis. To summarize, the stomach has undergone relative morphological movements, traditionally referred to as two 'rotations'. The first is 90° clockwise, about a longitudinal axis viewed from the cranial end; the second is 90° clockwise, about a dorsoventral axis viewed ventrally. The displacement, morphological changes and apparent 'rotation' of the stomach have been attributed to differential growth changes of the stomach itself; extension of the pancreaticoenteric recess with changes in its mesenchymal walls; and pressure, particularly that exerted by the rapidly growing liver. Whether the 'rotations', which are conventionally used to aid understanding, occur only in the axes described is unclear; differential regional growth and some 'rotation' in the transverse plane have also been invoked. The angula insura and the cardia of the stomach

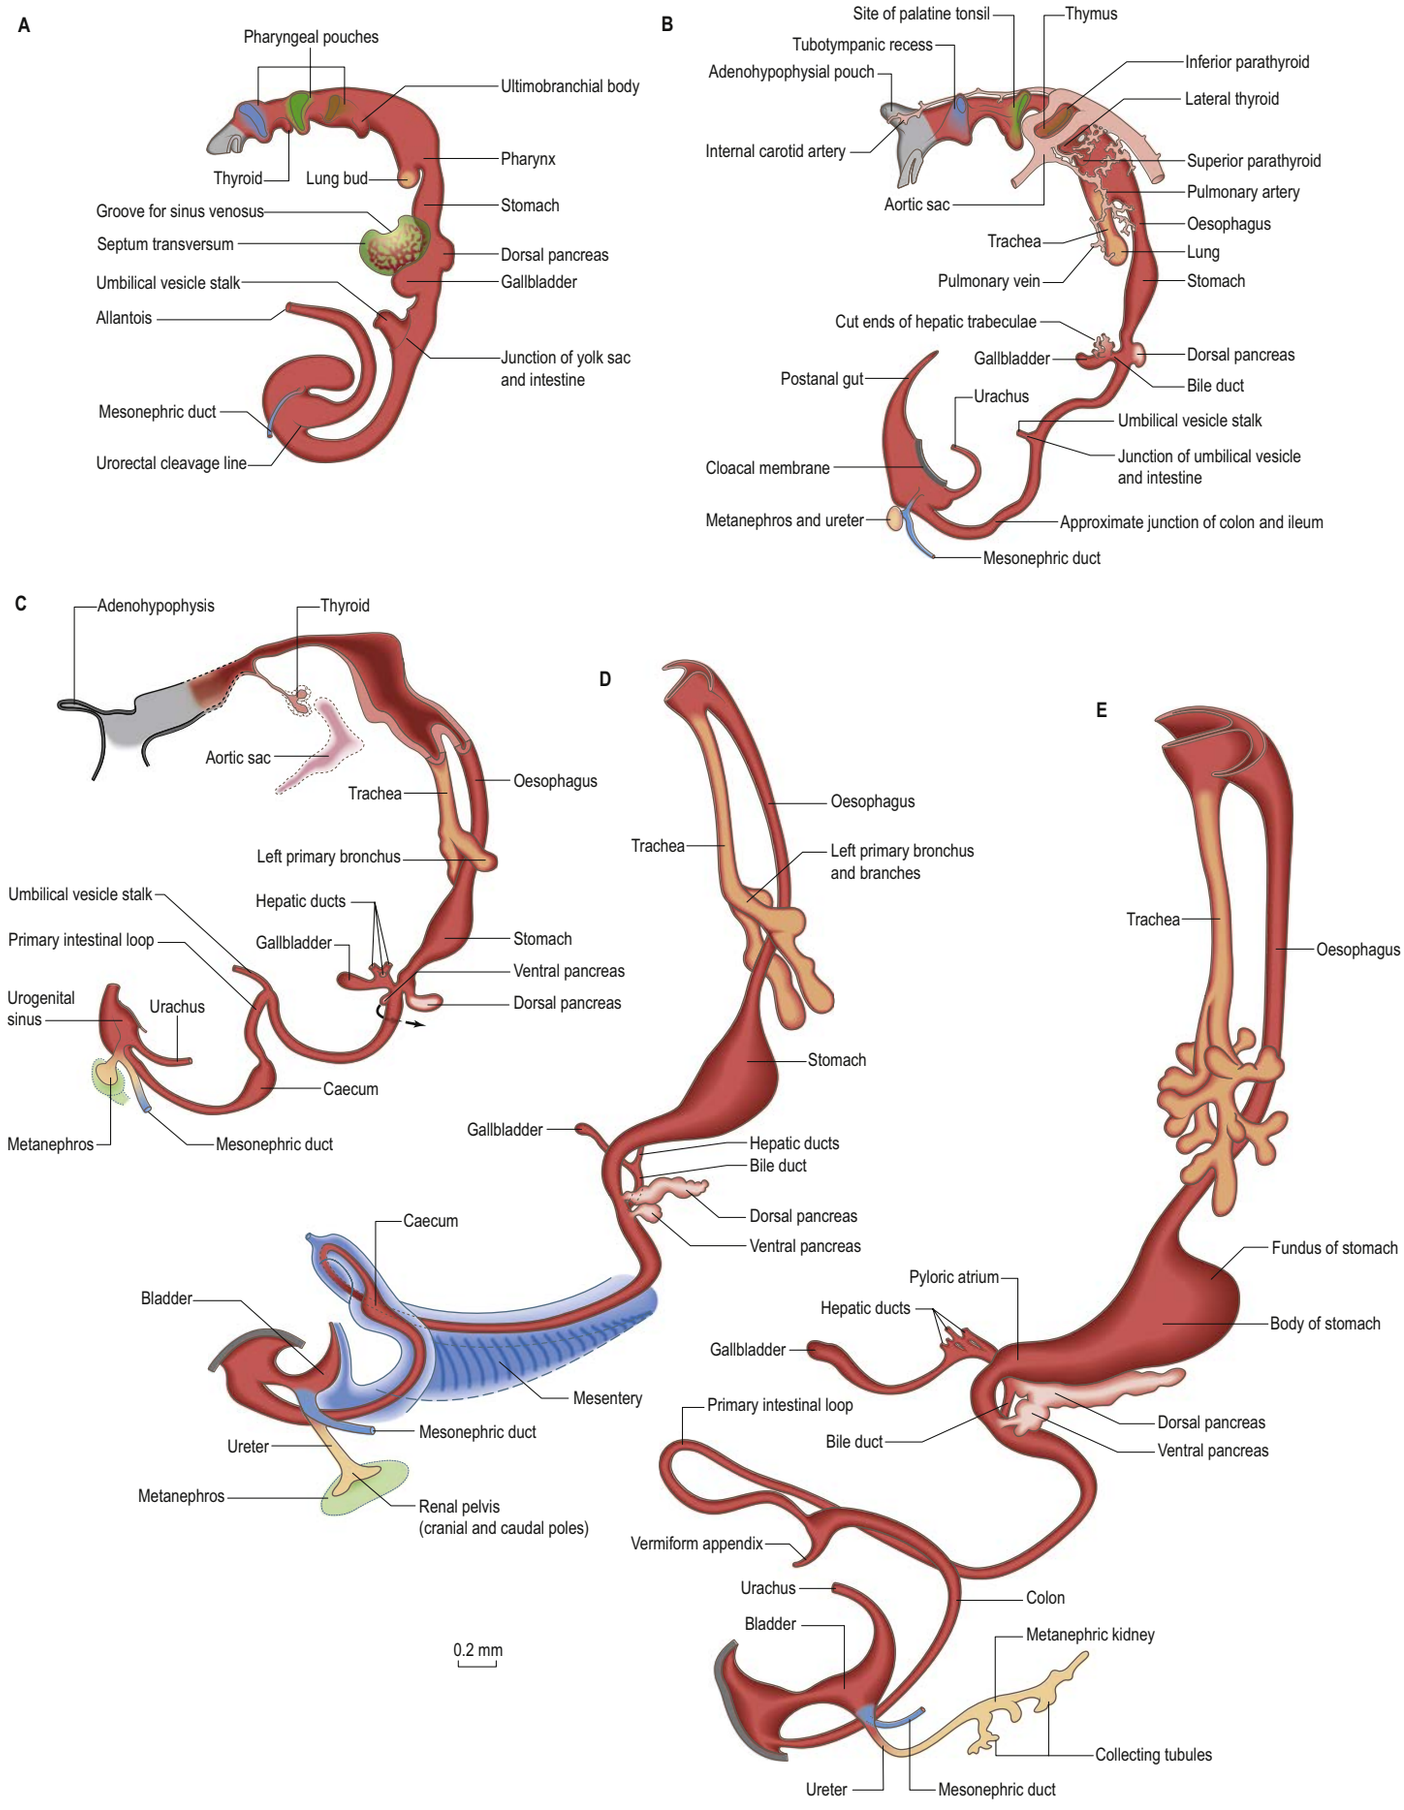

Fig. 21.3 The shape of the endodermal epithelium of the gut at succeeding stages. The scale is constant, illustrating the enormous growth of the gut over a 13-day period. **A**, Stage 13. **B**, Stage 14. **C**, Stage 15. **D**, Stage 16. **E**, Stage 17. Note the separation of the respiratory diverticulum; the elongation of the foregut and expansion of the stomach; the formation of the hepatic and pancreatic diverticula; the lengthening of the midgut loop, which protrudes into the umbilical cord; and the separation of the cloaca into enteric and allantoic portions. (Modified from O'Rahilly R, Müller F 1987 Developmental Stages in Human Embryos. Carnegie Institution of Washington. Pub 637.)

can be seen in stage 18 and the fundus, body and pylorus are evident at stage 20 (Kaigai et al 2014).

Mucosa

Mucosal and submucosal development can be seen in postfertilization weeks 8–9. No villi form in the stomach, unlike in the small intestine; instead, glandular pits can be seen in the body and fundus. These develop in the pylorus and cardia by postfertilization weeks 10–11, when parietal cells can be demonstrated. Although the embryo generally matures in a proximo-distal direction, gastric glands form slightly later than villi in the midgut. Murine embryos show a sharp boundary between the mucosal epithelium of the stomach and the first duodenal crypt. It is suggested that repression of the determination of the stomach endodermal epithelium until a later time, when instructive signals from the surrounding mesenchyme specify a glandular rather than villous mucosal fate, could be part of the patterning of the pylorus and the first part of the duodenum (Li et al 2009).

Chief cells can be identified after postfertilization weeks 12–13, although pepsinogen has not been demonstrated until term (40 postmenstrual weeks). Mucous neck cells actively produce mucus from 16 postmenstrual weeks. Acid secretion has not been demonstrated in the fetal stomach before 32 postmenstrual weeks, however, preterm infants from 26 postmenstrual weeks onwards, are able to secrete acid soon after birth. Intrinsic factor, also from parietal cells, has been detected after postfertilization week 11; it increases during postmenstrual weeks 14–15, at which time the pylorus, which contains more parietal cells than it does in the adult, also contains a relatively larger quantity of intrinsic factor. The significance of the early production of intrinsic factor and the late production of acid by the parietal cells is not known. Gastrin-producing cells have been demonstrated in the antrum between postmenstrual weeks 19 and 20, and gastrin levels have been measured in cord blood and in the plasma at term. Cord serum contains gastrin levels 2–3 times higher than those in maternal serum. Smooth muscle cells of the muscularis mucosae are first visible by 14 postmenstrual weeks and this layer is well defined by 22 postmenstrual weeks.

Muscularis

The muscularis externa can initially be seen at 10 postmenstrual weeks, when neural plexuses are developing in the body and fundus. At postmenstrual week 16, the oblique muscle layer can be seen and by postmenstrual week 26 all three muscularis externa layers are present. The pyloric musculature is thicker than that of the rest of the stomach; its layers develop within the same timescale as those in the fundus, cardia and body (Pangtey et al 2017).

Serosa

The serosa of the stomach is derived from the splanchnopleuric coelomic epithelium. No part of this serosa undergoes absorption. The original left side of the gastric serosa faces the greater sac; the right side faces the lesser sac.

Stomach at birth

The stomach exhibits fetal characteristics until just after birth, when the initiation of pulmonary ventilation, the reflexes of coughing and swallowing, and crying cause the ingestion of large amounts of air and liquid. Once postnatal swallowing has started, the stomach expands to four or five times its contracted state, and shifts its relative position accommodating the status of expansion and contraction of the other abdominal viscera, and to the position of the body. Gastric emptying is slower in the preterm infant than in the term infant (Jadcherla and Berseth 2012). In the neonate, the anterior surface of the stomach is generally covered by the left lobe of the liver, which extends nearly as far as the spleen (see Fig. 23.14B). Only a small portion of the greater curvature of the stomach is visible anteriorly. The capacity of the stomach is 30–35 ml in the full-term neonate, rising to 75 ml in the second postnatal week and 100 ml by the fourth postnatal week (adult capacity is, on average, 1000 ml). The mucosa and submucosa are relatively thicker than in the adult; however, the muscularis is only moderately developed and peristalsis is not coordinated. At birth, gastric acid secretion is low, which means that gastric pH is high for the first 12 postnatal hours. It falls rapidly with the onset of gastric acid secretion, usually after the first feed. Acid secretion usually remains low for the first 10 postnatal days. Gastric emptying and transit times are delayed in the neonate.

Duodenum

The duodenum develops from the caudal part of the foregut and the cranial part of the midgut. A ventral mesoduodenum, which is continuous cranially with the ventral mesogastrium, is attached only to the foregut portion. Posteriorly, the duodenum has a thick dorsal mesoduodenum, which is continuous with the dorsal mesogastrium cranially and the dorsal mesentery of the midgut caudally. Anteriorly, the extreme caudal edge of the ventral mesentery of the foregut extends on to the short initial segment of the duodenum. The liver arises as a diverticulum from the ventral surface of the duodenum at the foregut–midgut junction, i.e. where the midgut is continuous with the yolk sac wall (the cranial intestinal portal). The ventral pancreatic bud also arises from this diverticulum. The dorsal pancreatic bud evaginates posteriorly into the dorsal mesoduodenum slightly more cranially than the hepatic diverticulum. The rotation, differential growth, and cavitations related to the developing stomach and omenta cause corresponding movements in the duodenum, which forms a loop directed to the right, with its original right side now adjacent to the posterior abdominal wall (see Fig. 21.6). This shift is compounded by the migration of the bile duct and ventral pancreatic duct around the duodenal wall. Their origin shifts until it reaches the medial wall of the second part of the fully formed duodenum; the bile duct passes posteriorly to the duodenum and travels in the free edge of the ventral duodenum and ventral mesogastrium. Local adherence of part of the duodenal serosa and the parietal peritoneum result in almost the whole of the duodenum, other than a short initial segment, becoming sessile.

Foregut anomalies

Available with the *Gray's Anatomy* e-book.

Special glands of the postpharyngeal foregut

Pancreas

The pancreas develops from two evaginations of the foregut that fuse to form a single organ. A dorsal pancreatic bud can be seen in stage 13 embryos as a thickening of the endodermal tube that proliferates into the dorsal mesogastrium (see Fig. 21.3; **Fig. 21.4**). A ventral pancreatic bud evaginates in close proximity to the liver primordium but cannot be clearly identified until stage 14, when it appears as an evagination of the bile duct itself. At stage 16 differential growth of the wall of the duodenum results in movement of the ventral pancreatic bud and the bile duct to the right side and, ultimately, to a dorsal position. It is not clear whether there is a corresponding shift of mesenchyme during this rotation. However, the ventral pancreatic bud and the bile duct rotate from a position within the ventral mesogastrium (ventral mesoduodenum) to one in the dorsal mesogastrium (dorsal mesoduodenum), which is destined to become fixed on to the posterior abdominal wall. By stage 17 the ventral and dorsal pancreatic buds have fused, although the origin of the ventral bud from the bile duct is still obvious. Three-dimensional reconstruction of the ventral and dorsal pancreatic buds has confirmed that the dorsal pancreatic bud forms the anterior part of the head, the body and the tail of the pancreas, and the ventral pancreatic bud forms the posterior part of the head and the posterior part of the uncinate process. The ventral pancreatic bud does not form all of the uncinate process (Collins 2002a).

The developing pancreatic ducts usually fuse in such a way that most of the dorsal duct drains into the proximal part of the ventral duct (see Figs 21.3–21.4). The proximal portion of the dorsal duct usually persists as an accessory duct. The fusion of the ducts takes place late in development or in the postnatal period; 85% of infants have patent accessory ducts, as compared to 40% of adults. Fusion may not occur in 10% of individuals, in which case separate drainage into the duodenum is maintained: so-called pancreatic divisum (pancreas divisum). Failure of the ventral pancreatic diverticulum to migrate will result in an anular pancreas, which may constrict the duodenum locally.

Developmental movements of the pancreas in the dorsal mesoduodenum and dorsal mesogastrium are considered below (see p. 338).

Cellular development of the pancreas

The early specification of pancreatic endoderm requires the proximity of the notochord to the dorsal endoderm, which locally represses the expression of Shh transcription factor. Endoderm caudal to the pancreatic region does not respond to notochordal signals. The ventral pancreatic endoderm does not seem to undergo the same induction. Expression of pancreatic duodenal homeobox 1 transcription factor (PDX-1) is seen in the developing endodermal epithelial cells and in

Oesophageal atresia is one of the more common obstructive conditions of the alimentary tract and may be indicated by polyhydramnios. It may be related to trachea-oesophageal fistulae or other associations of vertebral defects, anal atresia, cardiac defects, renal and limb anomalies (VACTERL) (Ch. 20). Infantile hypertrophic pyloric stenosis has a prevalence of 2/1000 live births, with male sex and a family history being the most common associations. It presents between 3 to 8 postnatal weeks with projectile vomiting of milk feeds. Risk factors are first born, caesarean section delivery, preterm birth, formula feeding in the neonatal period; exclusive breast-feeding is noted to be protective (Zhu et al 2017). No clear aetiology has been found, however the transition from a fetal gut receiving only amniotic fluid, with immature parietal cell function and neutral gastric pH, plus slow maturation of gastrin feedback mechanisms, is suggested to contribute to acid over secretion which stimulates pyloric sphincter hypertrophy (Rogers 2015). Duodenal atresia is a developmental defect found in 1 in 5000 live births (Whittle 1999). It may be associated with an anular pancreas, which may compress the duodenum externally (20% of duodenal atresia), or with anomalies of the bile duct. In 40–60% of cases, the atresia is complete and pancreatic tissue fills the lumen. The condition can be diagnosed on abdominal X-ray and ultrasound examination, which reveal a typical double bubble appearance, caused by fluid antenatally and air postnatally enlarging the stomach and the proximal duodenum. Polyhydramnios is invariably present and often is the indication for the scan. Duodenal atresia commonly occurs with other developmental defects, e.g. cardiac and skeletal anomalies, and in Down's syndrome.

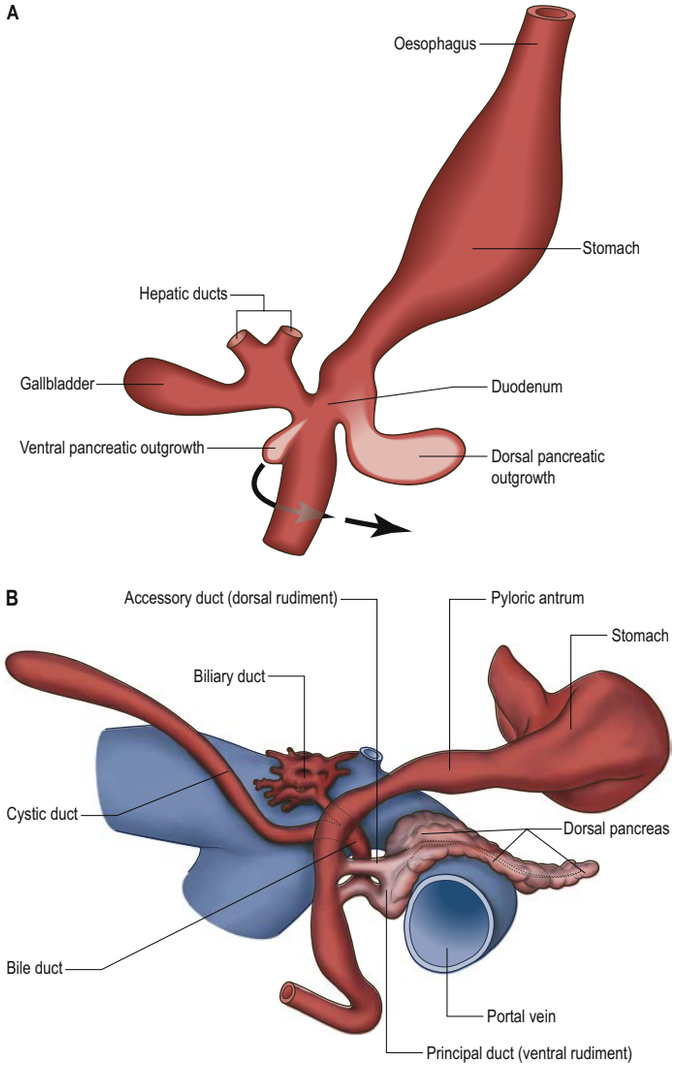

Fig. 21.4 Development of the pancreas in a human embryo. **A**, Stage 14: lateral view. **B**, Stage 17: ventral view.

the maturing postnatal pancreas (Hayes et al 2016, Byrnes et al 2018). Pancreatic mesenchyme is derived from two regions. The mesenchyme that surrounds the dorsal pancreatic bud proliferates from the splanchnopleuric coelomic epithelium of the medial walls of the pericardioperitoneal canals, whereas the ventral pancreatic bud is invested by septum transversum mesenchyme and by mesenchyme derived from the lower ventral walls of the pericardioperitoneal canals.

The primitive endodermal ductal epithelium provides the stem cell population for all the secretory cells of the pancreas. Initially, endocrine cells are located in the duct walls or in buds developing from them; later, they accumulate in pancreatic islets. The remaining primitive duct cells will differentiate into definitive ductal cells. In the fetus, they develop microvilli and cilia but lack the lateral interdigitations seen in the adult. Branches of the main duct become interlobular ductules, which terminate as blind-ending acini or as tubular, acinar elements.

The ductal branching pattern and acinar structure of the pancreas are determined by the pancreatic mesenchyme derived from the coelomic epithelium (Landsman et al 2011, Byrnes et al 2018). This mesenchyme gives rise to connective tissue between the ducts, which, in the fetus, appears to be important in stimulating pancreatic proliferation and maintaining the relative proportions of acinar, α and β cells during development. It also provides cell lines for smooth muscle within the pancreas. Angiogenic mesenchyme invades the developing gland to produce blood and lymphatic vessels. Mouse pancreas endoderm grown in culture without coelomic epithelium does not show normal branching morphogenesis and exhibits higher endocrine/acinar pancreatic markers (Guo et al 2014).

The process of islet differentiation is divided into two phases (Collins 2002a). Phase I, characterized by proliferation of polyhormonal cells, occurs from postmenstrual week 9 to week 15. Phase II, characterized by differentiation of monohormonal cells, is seen from postmenstrual week 16 onwards. The β cells, producing insulin and amylin, differentiate first, followed by α cells, which produce glucagon. The δ cells, which produce somatostatin, are seen after 30 postmenstrual weeks. The dorsal bud gives rise mostly to α cells, and the ventral bud to most of the pancreatic polypeptide-producing cells. The β cells develop from the duct epithelium throughout development and into the neonatal period. Later, in postmenstrual weeks 10–15, some of the primitive ducts differentiate into acinar cells, in which zymogen granules or acinar cell markers can be detected at 12–16 postmenstrual weeks.

The role of the medial coelomic walls of the lower ends of the pleuroperitoneal canals in pancreatic development has other interesting aspects, beyond that of a proliferative epithelium. This specific portion of coelomic epithelium forms tight junctions with adjacent cells and a basement membrane with the underlying mesenchyme, suggesting that it may function as a barrier preventing loss of intrapancreatic morphogens outwards and spread of extrapancreatic morphogens, e.g. from the mesenchyme surrounding the aorta, inwards, maintaining a boundary function between adjacent viscera (Guo et al 2014). This has been demonstrated *in vitro* using mouse embryonic tissue. Developing pancreatic and lung buds from which the coelomic epithelium had been removed fused into a single chimeric tissue mass, whereas no fusion occurred if the coelomic epithelium remained intact. When pancreas without coelomic epithelium was co-cultured with pancreas with intact coelomic epithelium, the epithelium engulfed both explants, extending over the entire surface, forming a larger pancreas. This is reminiscent of the process of dorsal and ventral pancreatic bud fusion. Fusion does not occur in co-culture of lung and pancreatic buds, or two pancreatic buds, when they are surrounded by the relevant coelomic epithelia (Guo et al 2014). This suggests that the maturing coelomic epithelium creates region-specific barriers between portions of gut and its evaginations with two distinct functions: maintenance of local internal environments which express specific and different morphogenetic molecules and maintenance of a barrier, ensuring lack of fusion, between closely apposed regions of gut and developing derived viscera.

Pancreas at birth

The pancreas in the neonate has all of the normal subdivisions of the adult. The pancreatic head is proportionately large in the newborn and there is a smooth continuation between the body and the tail. The inferior border of the head of the pancreas is found at the level of the second lumbar vertebra. The body and tail pass cranially and to the left, and the tail is in contact with the spleen.

Liver

The liver develops from an endodermal evagination of the foregut and from septum transversum mesenchyme, which is derived from the proliferating coelomic epithelium in the protocardiac region. The development of the liver is intimately related to the development of the heart. The vitelline veins, succeeded by the umbilical veins passing to the sinus venosus, are disrupted by the enlarging septum transversum to form a hepatic plexus, the forerunner of the hepatic sinusoids. (See Collins (2002b) for a detailed account of hepatic development.)

Early liver development

As the head fold and early intraembryonic coelom form, the ventral parietal wall of the pericardial cavity gives rise to populations of cells termed precardiac or cardiac mesenchyme. Hepatic endoderm is induced to proliferate by this mesenchyme, although all portions of the early heart tube, truncus arteriosus, atria, ventricle, both endocardium and myocardium, have hepatic induction potency that is tissue-specific but not species-specific. As the heart and foregut become separated by the accumulation of the cardiac mesenchyme, the mesenchyme itself is renamed septum transversum. It is seen as a ventral mass, caudal to the heart, which passes dorsally on each side of the developing gut to join the mesenchyme proliferating from the walls of the pericardioperitoneal canals. The majority of the cells within the septum transversum are destined to become hepatic mesenchyme. For details of the molecular signalling of early hepatic development, see Lemaigre (2009), Gordillo et al (2015).

In the stage 11 embryo, the hepatic endoderm is located at the superior boundary of the rostral intestinal portal. By stage 12 the hepatic endodermal primordium is directed ventrally and begins to proliferate as a diverticulum. There are two parts: a caudal part, which will produce the cystic duct and gallbladder; and a cranial part, which forms the liver biliary system (see Fig. 21.3; **Fig. 21.5A**). The cells start to express liver-specific molecular markers and glycogen storage.

The basal lamina around the cranial portion of the hepatic diverticulum is progressively disrupted and individual epithelial cells migrate

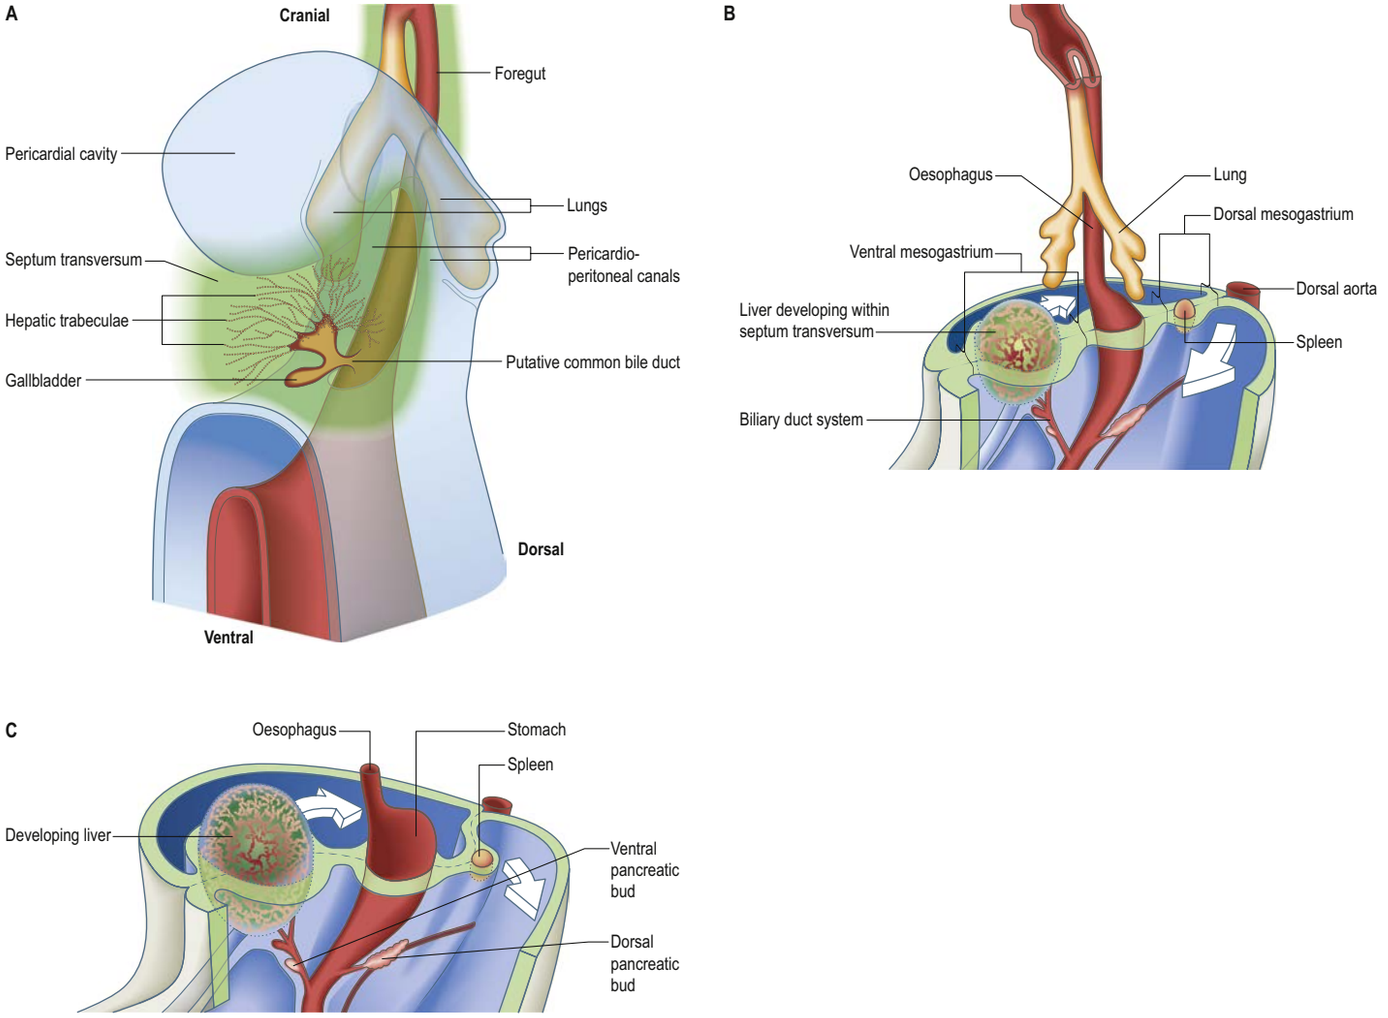

Fig. 21.5 Early development of the liver and the supra-umbilical peritoneal cavities. **A**, The hepatic endodermal primordium proliferates ventrally into the septum transversum mesenchyme. The endodermal cells forming the hepatic trabeculae will become hepatocytes; the septum transversum mesenchymal cells will become the endothelium of the liver sinusoids and early blood cells. The developing lung buds can be seen expanding into the pericardioperitoneal cavities. **B**, The septum transversum mesenchyme and the stomach become enclosed by the right and left pericardioperitoneal canals (shown on transverse section). The apposition of the medial pericardioperitoneal walls forms the dorsal and ventral mesogastria. The proximity of the lung buds to the developing stomach can be seen. The pleural and supra-umbilical peritoneal cavities are transiently, and bilaterally, symmetric above the umbilicus. **C**, The lower border of the ventral mesogastrium denotes the connection between the supra-umbilical peritoneal cavities: pleuroperitoneal canals, which can be identified by the position of the ventral pancreatic bud and common bile duct. The white arrows in **B** and **C** indicate the direction of movement of the dorsal and ventral mesogastria.

into the surrounding septum transversum mesenchyme. The previously smooth contour of the diverticulum merges into columnar extensions of endoderm, the epithelial trabeculae, which stimulate the hepatic mesenchymal cells to form blood islands and endothelium. The advance of the endodermal epithelial cells promotes the conversion of progressively more hepatic mesenchyme into endothelium and blood cells, and only a little remains to form the scanty liver capsule and interlobular connective tissue. This invasion by the hepatic epithelium is completed in stage 13, when it approaches the caudal surface of the pericardial cavity from which it is separated by only a thin lamina of mesenchyme that will give rise to part of the respiratory diaphragm.

During this early phase of development, the liver is far more highly vascularized than the rest of the gut. The hepatic capillary plexus is connected bilaterally with the right and left vitelline veins. Dorsolaterally, these veins empty by multiple channels into enlarged hepatocardiac channels, that lead to the right and left horns of the sinus venosus (see Fig. 13.20); usually, the channel on the right side is more developed. Both left and right channels bulge into the pericardioperitoneal canals, forming sites for the exchange of fluid from the coelom into the vascular channels. The ingrowths of hepatic tissue in these regions are sometimes referred to as the left and right horns of the liver.

The liver remains proportionately large during its development and constitutes a sizeable organ dorsal to the heart at stage 14, then more caudally placed by stage 16. By this stage, hepatic ducts can be seen separating the hepatic epithelium from the extrahepatic biliary system, but, even at stage 17, the ducts do not penetrate far into the liver. The definitive arrangement of the portal and hepatic veins becomes established over stages 18–20. The quadrate and caudate lobes become identifiable in stages 16 and 17 (Hikspoors et al 2017).

Maturation of the liver

The cellular maturation of hepatocytes and hepatic sinusoids corresponds to a complex cell sorting of early endodermal epithelial hepatoblasts, which differentiate into cholangiocytes and hepatocytes, angiogenic mesenchyme from the heart and developing gut which becomes organized into hepatic sinusoids, and septum transversum mesenchymal cells which give rise to the fibroblastic populations, and are thought to control the patterning of liver development with the angiogenic mesenchyme. The cellular arrangements within the liver are complex with sheets of epithelial hepatocytes, with apical biliary canaliculi between adjacent cells, arranged adjacent to sinusoids conveying portal and arterial blood to central veins. Epithelial hepatocytes do not secrete a continuous basal lamina but are able to interact with the endothelium of the sinusoids without direct contact via shared basal lamina proteins. The vascular perfusion and generated shear stress through the developing liver induces the proliferation of hepatocytes both *in vivo* and *in vitro* (Beckwitt et al 2018, Lorenz et al 2018). Specific white blood cells, Kupffer cells, migrate later into the liver sinusoids. The usual functions of the liver in the production of plasma proteins and metabolism of nutrients is undertaken by the placenta; fetal hepatocytes are glycolytic and have low mitochondrial activity.

After stage 19, EryD cells (definitive erythrocytes), part of the second wave of haemopoiesis, are seen within the liver; their terminal maturation by enucleation occurs from postfertilization week 11 (Van Handel et al 2010) (Ch. 13). The third wave of erythrocyte production, from haemopoietic stem cells in a number of regions (including the placental stroma and aorta-gonad-mesonephros region), seeds precursor cells to the liver, thymus and bone marrow, and subsequently give rise to all blood lineages. Although the liver has been considered a main site of haemopoiesis, a study at 15–16 postmenstrual weeks found that fewer lymphocytes were present in the liver than in abdominal lymph nodes (Hwang et al 2014). In a comparison of adult and fetal patterns of gene expression in the liver, haemopoietic genes had low expression at 20–22 postmenstrual weeks, perhaps because by this time blood cell production is established in the bone marrow (Huse et al 2015).

At the end of the first trimester the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right (see Figs 23.14D–E and Figs 23.15B–E). It remains relatively larger than in the adult throughout fetal life. The increase in fetal liver volume is linear between 18–30 postmenstrual weeks, with no sex differences. In diabetic mothers, fetal liver volume is increased by 20% or more, and it is also enlarged in fetuses with trisomy 21. In cases of fetal growth restriction, liver volume is decreased (Szpinda et al 2015).

Development of intrahepatic biliary ducts

The development of the intrahepatic biliary ducts follows the branching pattern of the portal vein radicles (Collins 2002b). The cranial hepatic diverticulum gives rise to the liver hepatoblasts, the intrahepatic large bile ducts (right and left hepatic ducts, segmental ducts, area ducts and their first branches) and the small bile ducts (septal bile ducts, interlobular ducts and bile ductules). The portal and hepatic veins arise together from the vitelline veins. Early in development, the accumulation of mesenchyme around these veins is similar, whereas later mesenchyme increases around the portal veins; this accumulation is a prerequisite for bile duct development. Primitive hepatoblasts surround the portal vein branches and associated mesenchyme, and form a sleeve of cells termed the ductal plate. Individual cells of the ductal plate are termed cholangiocytes. Local hepatoblasts that are adjacent to the cholangiocytes arrange themselves to delineate a bile duct lumen and then also switch to a cholangiocyte lineage (Lemaigre 2009). As the bile ducts develop, angiogenic mesenchymal cells form blood vessels that connect to the hepatic artery from postfertilization week 10. Thus, the portal triads are patterned by the portal vein radicles, which initially induce bile duct formation and then artery formation. The development of the biliary system extends from the hilum to the periphery. Anomalies of the biliary tree are associated with abnormalities of the branching pattern of the portal vein. The developing bile ducts remain patent throughout development (Tan and Moscoso 1994).

Development of extrahepatic biliary ducts

The caudal part of the hepatic endodermal diverticulum forms the extrahepatic biliary system, the common hepatic duct, gallbladder, cystic duct and common bile duct.

The bile duct, which originated from the ventral wall of the foregut (now duodenum), migrates with the ventral pancreatic bud, first to the right and then dorsomedially into the dorsal mesoduodenum. The right and left hepatic ducts arise from the cranial end of the common hepatic duct from postfertilization week 12.

Liver and biliary ducts at birth

In the neonate, the liver constitutes 4% of the body weight, compared to 2.5–3.5% in adults. It is in contact with the greater part of the respiratory diaphragm and extends below the costal arch anteriorly, and, in some cases, to within 1 cm of the iliac crest posteriorly. The left lobe covers much of the anterior surface of the stomach and constitutes nearly one-third of the liver (see Fig. 23.14A). Fetal liver haemopoiesis ceases before birth, whereas enzymatic and synthetic functions are not completely mature at birth. Hepatocytes remain a heterogeneous population with different gene expressions and metabolic functions within different hepatic lobule locations: metabolic zonation becomes fully established after birth (Lemaigre 2009).

In the neonate, the gallbladder has a smaller peritoneal surface than in the adult, and its fundus often does not extend to the liver margin. It is generally embedded in the liver and, in some cases, may be covered by bands of liver. After the second year, the gallbladder assumes the relative size it has in the adult. Normal sonographic measurements of liver and biliary ducts for neonates and infants is given in Zale (2018).

Atresia of the extrahepatic bile ducts in neonates occurs alone or in conjunction with a range of other anomalies, including situs inversus, malrotation, polysplenia and cardiac defects. In such cases, the intrahepatic bile ducts have a mature tubular shape but also show features of ductal plate malformation. Biliary atresia is seen more commonly in males (Zale 2018). Elevated bile acids in infants with biliary atresia has been reported and that postnatal biliary duct inflammatory process may be involved (Davenport 2016).

MIDGUT

The midgut forms the third and fourth parts of the duodenum, jejunum, ileum and two-thirds of the way along the transverse colon; its development produces most of the small, and a portion of the large, intestine. In amniote embryos the midgut, which is connected to a narrowing vitelline intestinal duct to the yolk sac, forms a loop which projects away from the body ventrally, with a proximal cranial limb and a distal caudal limb; in mammals it enters the extraembryonic coelom. The usual explanation for this movement is that rotation of the loop can only occur out of the abdominal cavity, however, studies have shown that biomechanical transduction may promote gut lengthening, and suggest that the formation of the complex secondary and tertiary loops are controlled by genetic regulation. Experimental studies in chick embryo have indicated that the mechanical tension transmitted by the lengthening vitelline duct and the arteries passing to it along the dorsal mesentery, drive the proliferation and elongation of the midgut loop. In the absence of tension gut did not grow, i.e. there was no increase in volume or cell number (Chevalier et al 2018). The differential contribution of the endodermal core, the surrounding mesenchyme, or the outer coelomic epithelial layer which is continuous with the dorsal mesentery, remains to be elucidated.

In human embryos at stages 10–11 the midgut extends from the cranial to the caudal intestinal portals and communicates directly with the yolk sac over its entire length: it has a dorsal wall, but the lateral walls have not yet formed. By stage 12 the connection with the yolk sac has narrowed, such that the midgut has ventral walls cranially and caudally. This connection is reduced to a yolk stalk containing the vitello-intestinal duct during stage 13, at which time the yolk sac appears as a sphere in front of the embryo. Dorsal to the midgut, the splanchnopleuric coelomic epithelia converge, and form the dorsal mesentery with intervening mesenchyme. Ventrolaterally, the intraembryonic coelom is in wide communication with the extraembryonic coelom. At stage 14 the midgut has increased in length more than the axial length of the embryonic body and, with elongation of the dorsal mesentery, it bulges ventrally, deviating from the median plane (see Fig. 21.3).

The following description focuses on the movements of the elongating endodermal epithelial tube, surrounding splanchnopleuric mesenchyme and outer coelomic epithelium. For the later consequences of these movements, focusing on the coelomic epithelium and the fates of the elongating mesenteries relative to the dorsal wall of the developing peritoneal cavity, see p. 338. There is consequently some repetition in these two accounts.

Primary intestinal (midgut) loop

Formation of primary, secondary and tertiary looping of the midgut has been studied in human embryos to determine which parts of the process may be genetically determined and to provide 3D measurements of the movements of the midgut (Soffers et al 2015, Ueda et al 2016). The midgut starts to loop ventrally during stage 14 when the cranial end is level with somites 11–12 (this corresponds to putative thoracic vertebral levels 4–6), and the caudal end with somites 17–18 (putative thoracic vertebral levels 10–11). The caecal bud can be discerned on the lower limb of the loop, caudal to the yolk stalk (which arises from the apex or summit of the loop). The embryonic body is slightly helical at this time, so that the caudal portion of the embryo is more likely to be to the right of the head, and the midgut loop is midsagittal, following the helical body axis. The vitelline veins and the vitelline artery are landmarks for the apex of the midgut loop at stage 14, but from stage 16 the remaining proximal part of the artery gives rise to the superior mesenteric artery. The root of this vessel descends from somite level 13 to 19 (from putative thoracic vertebral levels T6 to T12).

The longest (dorsoventral) portion of the dorsal mesentery is at the level of the yolk stalk: there is less relative lengthening near the caudal end of the duodenum or the cranial half of the colon. When midgut length has increased sufficiently to extend the apex of the loop into the umbilical coelom, the proximal, cranial limb has moved to the right and the distal, caudal limb to the left relative to the midline (see Fig. 21.3C). This relative position is approximately maintained

so long as the protrusion persists, during which time the proximal limb that forms the small intestine elongates even further. It becomes coiled developing secondary loops in a strict spatiotemporal pattern during postfertilization weeks 6–7, and its adjacent mesentery adopts a pleated appearance. Tertiary loops form after the end of postfertilization week 8 when there is an acceleration of the longitudinal growth of this part of the midgut. The origin of the root of the mesentery is initially both median and vertical, while, at its intestinal attachment, it is elongated like a ruffle and folded along a horizontal zone. The distal, colic, part of the loop elongates less rapidly and has no tendency to become coiled. Between stages 16 and 23, the crown–rump length of the embryo increases 3.6 times. The increase in relative length of the gut over this time shows that the duodenum is 3.5 times longer, the large intestinal part of the midgut loop is 8 times longer, and the small intestinal part of the loop 20 times longer (Ueda et al 2016). By 10 postfertilization weeks the peritoneal cavity has enlarged and the relative size of the liver and mesonephroi is much less. The re-entry of the gut occurs rapidly, the umbilical ring being sufficiently large to permit multiple loops to return, and in a particular sequence. The proximal loop returns first, with the jejunum mainly on the left and the ileum mainly on the right of the subhepatic abdominal cavity. As they re-enter the abdominal cavity, the coils of jejunum and ileum slide inwards over the right aspect of the descending mesocolon, and so displace the putative descending colon to the left. The transverse colon passes superiorly to the origin of the root of the mesentery (**Fig. 21.6**). The caecum is the last to re-enter and, at first, lies on coils of ileum on the right. Later development of the colon leads to its elongation and to the establishment of the hepatic and splenic flexures. Timetables for intestinal rotation in staged human embryos is given by Kim et al (2003), Soffers et al (2015), Ueda et al (2016).

The development of the midgut has been described and taught for many years in terms of a rotation of the gut around a dorsoventral axis of some 300°, anticlockwise viewed from the ventral aspect. This concept has recently been challenged. Soffers et al (2015) and Hikspoors et al (2019) reviewed the movement of the midgut using computer generated reconstructions of staged human embryos. They found that several factors contribute to the relative movements of the midgut loop: the helical disposition of the early embryonic body; the extreme longitudinal growth of portions of the midgut loop (the small intestine growth is double that of the colon); the descent of the origins of the cranial and caudal limits of the loop together with the origins of the vessels remained in the loop axis. While the midgut is in the umbilical coelom, secondary loops develop (excluding the intra-abdominal duodenojejunal loop) at three places along the midgut (proximal jejunal, distal jejunal and ileocaecum). Tertiary looping also occurs in these sites although with no predictable pattern of distribution. Resolution of the physiological herniation of the midgut, without any growth of the dorsal mesentery, is achieved once the dorsoventral depth of the abdomen increases, by proximodistal sequential movement of the extra-abdominal loops in a 'slide and stack' manner. This conclusion was supported by the observation of intermediate stages where only secondary, or secondary and tertiary, loops of small intestine had returned. The distal ileum and caecum enter the abdomen by sliding from the umbilical orifice to the lower-right abdominal cavity.

Umbilical cord

During the embryonic stages the umbilical cord is formed as the amniotic cavity expands and amnion encases the connecting stalk, allantois and embedded umbilical vessels caudally, and the extraembryonic coelom surrounding the vitelline duct and vessels cranially (Figs 9.10, 10.10). From stage 14 the umbilical cord occupies all of the ventral body wall between the pericardial bulge and the developing external genitalia, with similar linear dimensions as the heart; by stage 16 it is proportionally smaller than, and distinguishable from the thorax; at stage 23 it forms about one quarter of the ventral abdominal wall. Caudally, there is no infraumbilical region before stage 15; it becomes apparent by 9 postfertilization weeks. Somatic (hypaxial) mesenchyme, that will form the ventral body wall musculature, migrates into the somatopleuric mesenchyme and passes ventrally towards the midline and the lateral borders of the umbilical cord (Mekonen et al 2015). A portion of the extraembryonic coelom (chorionic cavity), the umbilical coelom, remains in the forming umbilical cord into which the lengthening midgut loop protrudes. The midgut loop returns to the abdominal cavity at about 10 postfertilization weeks, and the umbilical coelom remains in the cord for at least one week longer (Soffers et al 2015). The following changes to the maturing cord then occur: the vitellointestinal duct and vessels involute; the cranial end of the allantois becomes thinned and its lumen partially obliterated, forming the urachus. The mesenchymal core of the umbilical cord is derived by coalescence of somatopleuric amniotic mesenchyme, splanchnopleuric vitellointestinal (yolk sac) mesenchyme and splanchnopleuric allantoic (connecting stalk) mesenchyme. These various layers become fused and are gradually transformed into the viscid, mucoid, connective tissue (Wharton's jelly) that characterizes the more mature cord. The changes in the circulatory system result in a large, cranially orientated, left umbilical vein (the right umbilical vein regresses), and two caudally orientated, spirally disposed umbilical arteries (see Fig. 13.25). There is a clear distinction between skin, derived from ectoderm and underlying somatopleuric mesenchyme, and the tissues within the umbilical cord. After birth all tissues within the umbilical cord undergo involution and the cord itself will detach from the skin, regardless of its dimensions.

Anomalies of midgut rotation

Available with the *Gray's Anatomy* e-book.

Maturation of the small intestine

Mucosa

The exact timing of the cellular morphogenesis of the gut is difficult to establish, especially as it undergoes a proximodistal gradient in maturation. Developmental differences between parts of the small intestine or colon have not yet been correlated with age. The endodermal cells of the small intestine proliferate and form pseudostratified layers exhibiting interkinetic nuclear migration with mitotic figures. The formation of villi occurs in a proximodistal progression from the duodenum to the ileocaecal junction in Turing-like pattern formation (Ch. 11). It is not clear how vilification is eventually suppressed in the future colon. For details of the comparative development of the interactions between epithelial endoderm and the local splanchnic mesenchyme see Walton et al (2018). In the human, blunt projections of the endoderm form in the duodenum and proximal jejunum from postfertilization week 7; these developing villi increase in length until, in the duodenum, the lumen becomes difficult to discern. The concept of occlusion of the lumen and subsequent recanalization, described in many accounts of development, is not supported by the cytodifferentiation that occurs in the gut epithelia, challenging the belief that secondary recanalization of the gut lumen occurs (Grosse et al 2011). By 9 postfertilization weeks, the duodenum, jejunum and proximal ileum have villi, and the remaining distal portion of ileum develops villi by 11 postfertilization weeks. The villi are covered by a simple epithelium. Primitive crypts, epithelial downgrowths into the mesenchyme between the villi, appear during postfertilization weeks 10–12, and similarly follow a craniocaudal progression. Brunner's glands are present in the duodenum from postmenstrual week 15 and the muscularis mucosa can be seen in the small intestine from postmenstrual week 18.

Whereas mitotic figures are initially seen throughout the pseudostratified endodermal layer of the small intestine prior to villus formation, by 10–12 postfertilization weeks they are limited to the intervillous regions and the developing crypts. It is believed that an 'adult' turnover of cells may exist when rounded-up cells can be observed at the villus tips, in position for exfoliation. The absorptive enterocytes have microvilli at their apical borders before postfertilization week 9. An apical tubular system appears at this time, and is composed of deep invaginations of the apical plasma membrane and membrane-bound vesicles and tubules; many lysosomal elements (meconium corpuscles) appear in the apical cytoplasm. These latter features are more developed in the ileum than jejunum, are most prominent at 16 postmenstrual weeks, and diminish by 21 postmenstrual weeks. There are abundant deposits of glycogen in the fetal epithelial cells, and it has been suggested that, prior to the appearance of hepatic glycogen, the intestinal epithelium serves as a major glycogen store. Goblet cells are present in small numbers by postfertilization week 8, Paneth cells differentiate at the base of the crypts from postfertilization week 11, and enteroendocrine cells appear between postfertilization weeks 9–11. M cells (membrane or microfold cells) are present from about 14 postmenstrual weeks.

Intestinal subepithelial myofibroblasts have been described within the villus cores and adjacent to the intervillous space at the base of the crypts from postmenstrual week 21. They are arranged as a syncytium between the epithelium and the muscularis mucosae, where they

If the midgut loop fails to return to the abdominal cavity at the appropriate time, a number of ventral defects can result. Failure of obliteration of the vitellointestinal duct connecting the midgut to the yolk sac produces Meckel's diverticulum. This may present as a short segment of vitelline duct attached to the original ventral side of the ileum; it may remain attached to the umbilicus as a fistula; or it may remain as a ligamentous attachment to the umbilicus. The position and configuration of the duodenal loop are of particular importance in children. The normal duodenal loop has a U-shaped configuration. The suspensory ligament of the duodenum (ligament of Treitz) is usually found to the left of the body of the first or second lumbar vertebral body after normal gut rotation; any other position of this ligament may indicate some degree of gut malrotation. On barium studies, the duodenojejunal flexure should, thus, lie to the left of the upper lumbar spine at the level of the pylorus.

If the caecum has remained in the right upper quadrant, it may become fixed in that position by peritoneal attachments passing to the right, the so-called Ladd's bands. These may compress the underlying duodenum and give rise to duodenal stenosis. The high positioning of the caecum close to the duodenal jejunal flexure, in some cases, in the midline, is associated with later development of small intestinal volvulus.

An umbilical hernia occurs when loops of gut protrude into a widened umbilical cord at term. The degree of protuberance may increase when the infant cries, which raises the intra-abdominal pressure; these hernias usually resolve without treatment. Larger anomalies can be detected on routine antenatal ultrasound examination.

Exomphalos is a ventral wall defect with midline herniation of the gut into the base of the umbilical cord. It is frequently associated with genetic and chromosomal anomalies. Herniated viscera are covered by the visceral peritoneum, and parietal peritoneum lines the amniotic covering of the umbilical cord externally. The omphalocele so formed ranges in size from a large umbilical hernia to a very large mass containing most of the visceral organs. Even after the exomphalos has been repaired, these babies will still have a deficient anterior abdominal wall.

Gastroschisis is a paraumbilical defect (usually to the right) of the anterior abdominal wall associated with evisceration of the abdominal organs into the amniotic cavity. The organs are not enclosed in membranes which means that gastroschisis can be detected by prenatal ultrasonography and differentiated from exomphalos (see Fig. 23.6B). Gastroschisis has increased in incidence worldwide over the past 25 years, from 0.1 : 10,000 to 1.0 : 10,000 in developed countries and from 3.0 : 10,000 to 5.0 : 10,000 in underdeveloped countries (Campbell and Copel 2018). Women younger than 25 years of age have 2–3 times higher risk, and since the mid-1990s the incidence in women under 20 years of age has increased from 8 : 10,000 to 18 : 10,000. Low socioeconomic status and vasoactive drug use are risk factors in this population (Wolf 2018). Gastroschisis is not regarded as a genetic condition, although familial occurrences have been reported. It is not usually associated with other visceral anomalies. A number of proposed mechanisms have been suggested, initially periumbilical ischaemia, caused by vascular compromise of either the umbilical vein or arteries; anomalous development of the somatopleuric mesenchyme of the ventral body wall, similar to that in ectopia cordis and cloacal exstrophy; other scenarios permitting coils of intestine to enter the amniotic cavity, rather than stay in contact only with the extraembryonic coelomic fluid within the chorionic cavity and umbilical coelom, include amniotic membrane rupture, possibly at the base of the umbilical ring (Wolf 2018). Nearly all cases of gastroschisis are associated with elevated levels of maternal serum alpha-fetoprotein, which prior to ultrasound screening was the sole indicator of the condition (Campbell and Copel 2018). Oligohydramnios is a common association.

Congenital volvulus arises if the midgut loop does not rotate appropriately. A number of types of this condition are identified. Left-sided colon occurs if the midgut loop has not rotated at all; mixed rotation results in the caecum lying inferior to the pylorus; and failure of appropriate attachment of the peritoneum may result in the small intestine being attached at only two points on the posterior abdominal wall. All of these arrangements lead to a risk of volvulus, which may result in necrosis of the gut. The identification of intestinal malrotation can be made by contrast radiography investigation. However, ultrasonography has the advantage of showing the position of the superior mesenteric vein and artery. The vein should lie to the right of the artery. Most cases of volvulus will show inversion of this normal relationship but malrotation can occur with apparently normally related vessels, particularly in malrotation with bowel obstruction due to Ladd's bands and not volvulus.

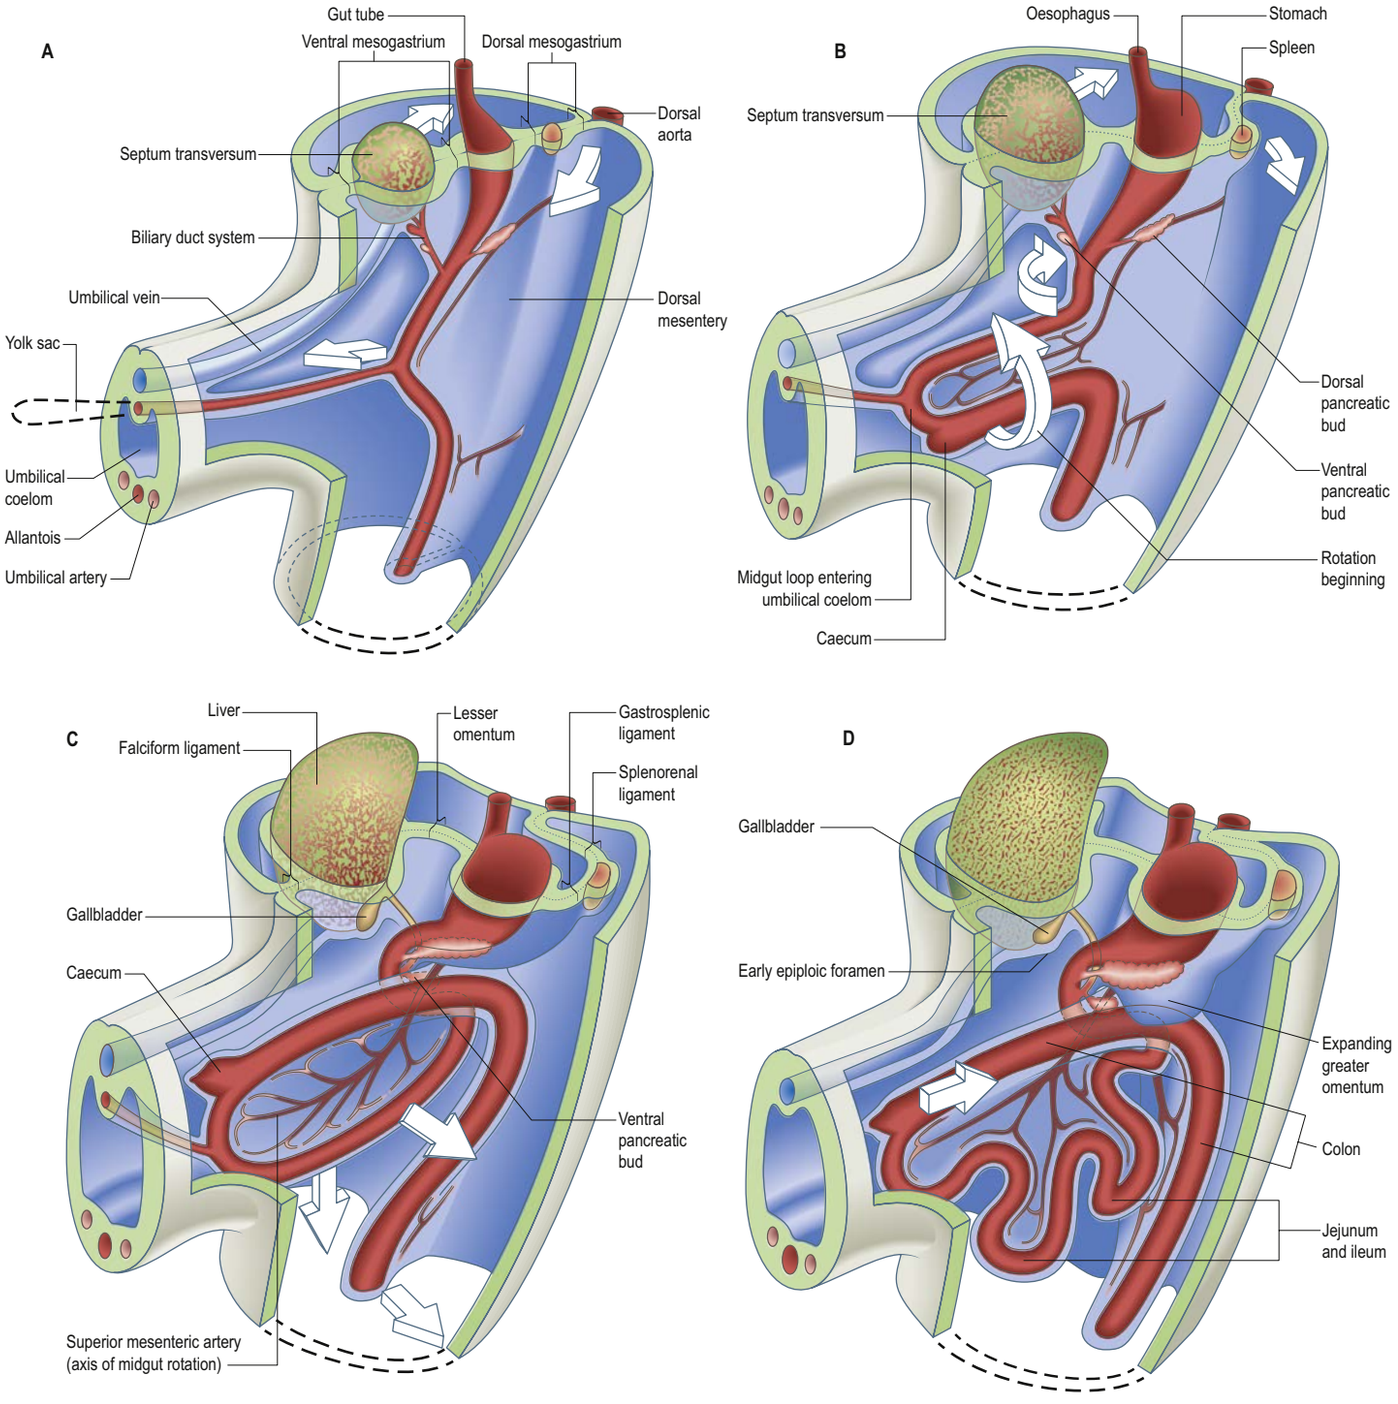

Fig. 21.6 The major developmental sequences of the subdiaphragmatic gut, associated major glands, peritoneum and mesenteries: left anterolateral aspect. The developmental sequence spans the period from stage 14 when the midgut starts to loop ventrally to postmenstrual weeks 10–12 when it returns to the abdominal cavity: it assumes its final disposition between postmenstrual weeks 16–20. **A–B**, The top white arrows show the relative movements of the dorsal and ventral mesogastria that result in the longitudinal rotation of the stomach and limited entry to the lesser sac (see also Fig. 21.5). **C–D**, The lower white arrows associated with the midgut indicate the relative movements and rotation of the midgut loop within the umbilical coelom, and as it returns to the abdominal cavity.

Continued

contribute to the extracellular matrix. They demonstrate α-smooth muscle actin (SMA) expression (McLin et al 2009). It is not clear whether these cells derive from splanchnopleuric mesenchyme fibroblasts, smooth muscle precursors or neural crest. They migrate from the crypts to the villous axis in a manner similar to enterocytes.

Meconium can be detected in the lumen of the intestine by 16 postmenstrual weeks. It is derived from swallowed amniotic fluid, which contains vernix and cellular debris, salivary, biliary, pancreatic and intestinal secretions, and sloughed enterocytes. As the mixture passes along the gut, water and solutes are removed and cellular debris and proteins concentrated. Meconium contains enzymes from the pancreas and proximal intestine in higher concentrations in preterm than in full-term babies.

Muscularis layer

The muscularis layer is derived from the splanchnopleuric mesenchyme, as it is in other parts of the gut. Smooth muscle myoblasts can be identified by expression of α-SMA, with longitudinal muscle seen from 12 postfertilization weeks. At 26–30 postmenstrual weeks, the gut shows contractions without regular periodicity; from 30–33 postmenstrual weeks, repetitive groups of regular contractions have been seen in preterm neonates.

Serosa

The small intestine possesses only a dorsal mesentery. The movement of the root of this mesentery, and the extensive lengthening of its enteric

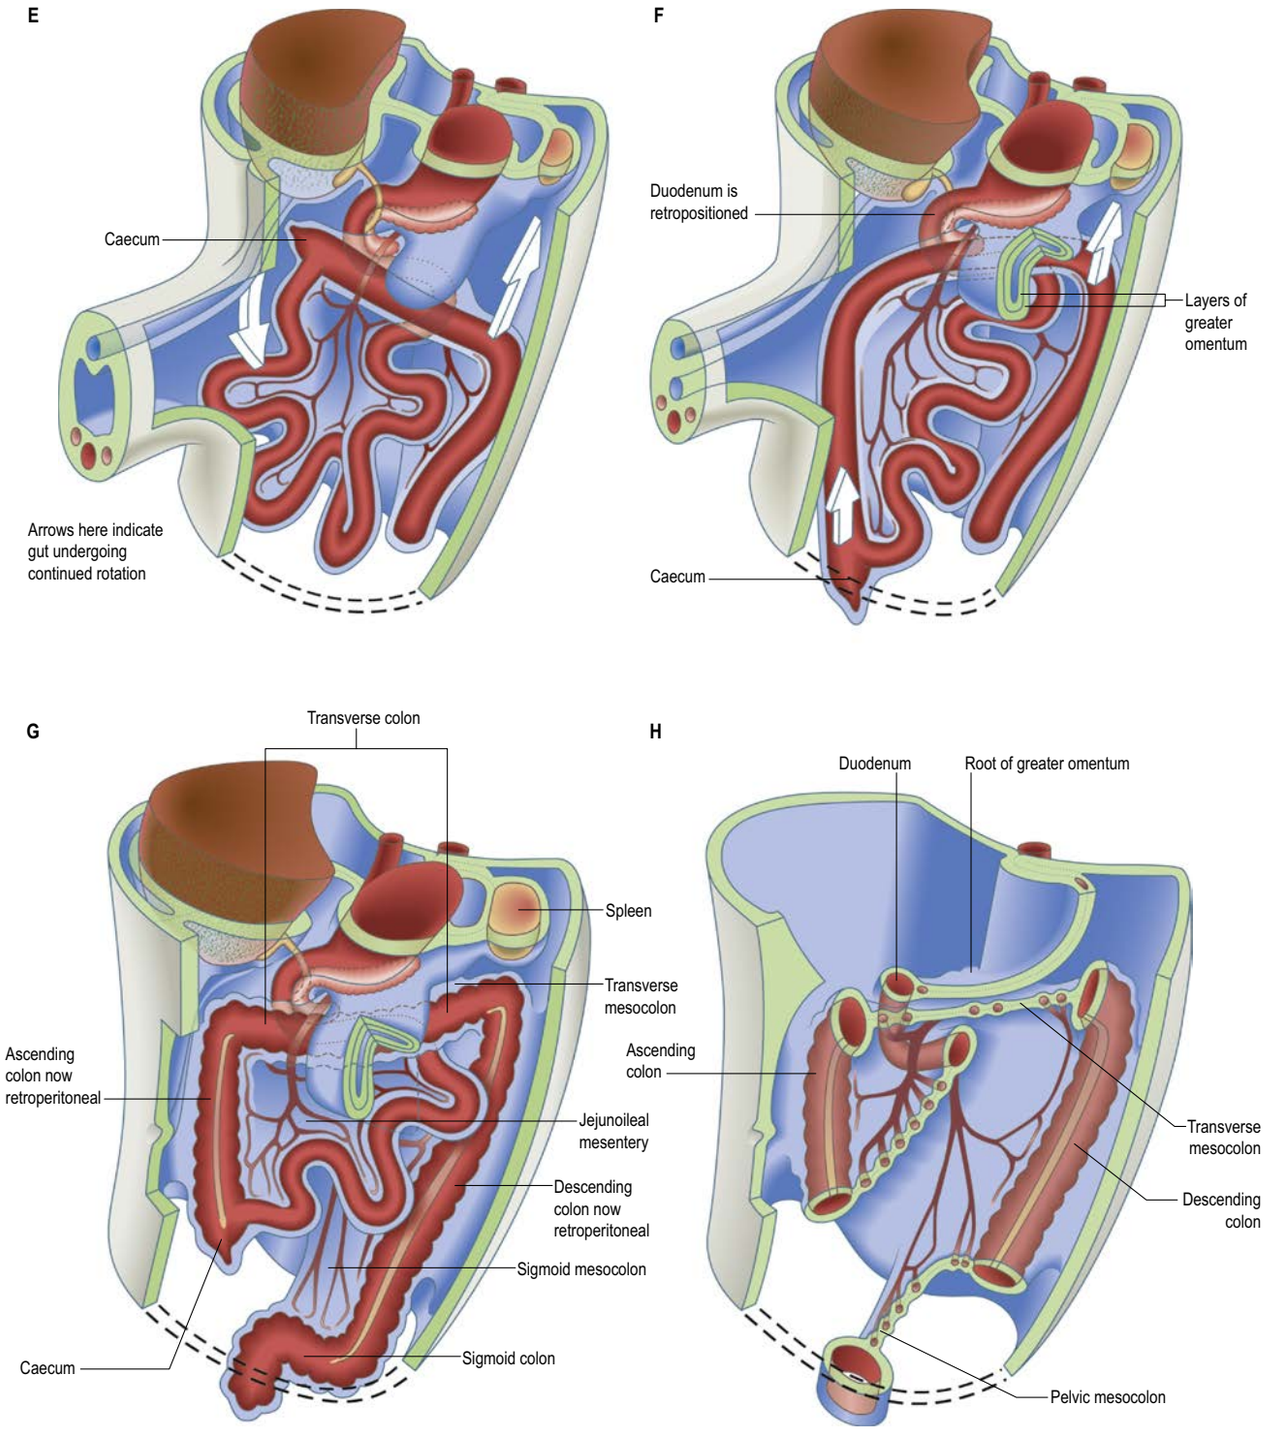

Fig. 21.6, Cont'd E–F, The lower white arrows associated with the midgut indicate the relative movements and rotation of the midgut loop within the umbilical coelom, and as it returns to the abdominal cavity. **G–H**, The approximate disposition in the adult abdomen of the gut (**G**) and the mesenteric roots, showing their lines of attachment and principal contained vessels (**H**).

border in order to match the longitudinal growth of the gut, reflect the spiralizing of the midgut loop in the umbilical coelom (see p. 338).

Small intestine at birth

The radial patterning of the small intestine is completed before birth, with differentiation of the crypt–villous axis. Specification of the space between villi, crypt depth and villous length is a dynamic process dependent on the establishment of the intestinal microbiota (see Postnatal development of the gut, p. 340). In the full-term neonate, the small intestine forms an oval-shaped mass with its greater diameter transversely orientated in the abdomen, rather than vertically as in the adult. The mass of the small intestine inferior to the umbilicus is compressed by the urinary bladder, which is anterior at this point. The small intestine is 300–350 cm long at birth and its width, when empty, is 1–1.5 cm. The ratio between the length of the small and large intestines at birth is similar to the adult ratio. Mucosal villi are present throughout the small intestine, however, some epithelial differentiation is incomplete. The muscularis is very thin, particularly the longitudinal layer, and there is little elastic tissue in the wall. There are few or no circular folds in the small intestine, and the jejunum and ileum have little fat in their mesentery.

PRIMITIVE HINDGUT

Just as the foregut has an extensive ventral endodermal diverticulum that contributes to a system separate from the gut, so, too, the hindgut has a ventral diverticulum, the allantois, that is destined for urogenital system development. However, unlike the respiratory diverticulum of the foregut, the allantois is formed very early in development, prior even to formation of the embryonic endoderm and tail-folding. With

the reorganization of the caudal region of the embryo at stage 10, part of the allantois is drawn into the body cavity. The early embryonic hindgut thus consists of a dorsal tubular region extending from the caudal intestinal portal to the cloacal membrane, and a ventral blind-ending allantois extending from the cloacal region into the connecting stalk. The slightly dilated cavity, lined by endoderm, that cranially receives the enteric hindgut proper and the root of the allantoenteric diverticulum is termed the endodermal cloaca. It is closed ventrally by the cloacal membrane (endoderm opposed to proctodeal ectoderm), and it also has, transiently, a small recess of endoderm in the root of the tail, the postanal gut. As elsewhere, the hindgut, allantois and endodermal cloaca are encased in splanchnopleuric mesenchyme. Proliferation of the mesenchyme and endoderm in the angle of the junction of hindgut and allantois produces a urorectal septum from stage 15 (see Fig. 22.4B). Continued proliferation of the urorectal septum and elongation of the endodermal structures move the endodermal epithelium towards the cloacal membrane, with which it fuses centrally, separating the presumptive rectum and upper anal canal (dorsally) from the presumptive urinary bladder and urogenital sinus (ventrally) (see Fig. 22.4C). The cloacal membrane is thus divided into anal (dorsal) and urogenital (ventral) membranes. The nodal centre of division is the site of the future perineal body, the functional centre of the perineum. For details of the formation of the urorectal septum in human embryos see Kruepunga et al (2018).

There are few studies on the complex development of the caudal regions of the embryonic and fetal body. The skeletal and neural elements, and the lower sphincters of the enteric and urogenital systems, develop subsequent to secondary neurulation processes, within the embryonic caudal eminence. The autonomic and somatic neurological control in this region postnatally is comparable to that of the aerodigestive pharynx, even though the derivation, interactions and maturation of the caudal neural crest cells may be very different.

Enteric hindgut

The development of the large intestine, whether derived from mid- or hindgut, seems to be similar. The proximal end of the colon can be identified initially at stage 15, when an enlargement of a local portion of gut on the caudal limb of the midgut loop defines the developing caecum. An evagination of the distal portion of the caecum forms the vermiform appendix at stage 17 (see Fig. 21.3E). Apart from the embryonic studies of Streeter (1942), there is little information about the development of the large intestine in humans. The early endodermal lining of the colon is pseudostratified with interkinetic nuclear migration and mitoses in the layer. A series of longitudinal folds arise initially at the rectum and caecum, and later in the regions of colon between these two points. The folds segment into villi, with new villi forming between. The developing mucosa invaginates into the underlying mesenchyme between the villi to form glands that increase in number by splitting longitudinally from the base upwards. The villi gradually diminish in size and are absent by the time of birth.

Maturation of the large intestine

The similarity of development of the small and large intestines is further mirrored in their cytological differentiation. From 11 postfertilization weeks, dipeptidase activity in the colon as well as in the small intestine is seen. Throughout preterm development, meconium corpuscles are seen in the colon and in the small intestine; they are believed to be the phagocytosed remains of neighbouring cells that have died as a result of programmed cell death. Between 17 and 24 postmenstrual weeks, fetuses express fewer genes in the colon than adults, but like adults, there is a differential expression of genes between ascending and descending colon (Glebov et al 2003). There is little direct evidence of colonic function in the human fetus.

Mucosa

The absorption of glucose and amino acids does not take place through the colonic mucosa in adult life, but there is evidence of direct absorption of these nutrients during development. At birth, the normal cycle of bile acids is not mature. In the adult, bile is secreted by the liver, stored in the gallbladder and then secreted into the intestine, where it is absorbed by the jejunum and ileum. In the fetus and neonate, the transport of bile acids by an active process from the ileum does not occur, and so bile salts pass on into the colon. In the adult, the presence of bile salts in the colon stimulates the secretion of water and electrolytes, which results in diarrhoeal syndrome; however, the fetal and neonatal colon seems protected from this effect. The colon is not considered a site of significant nutrient absorption in the adult, and yet neonates are unable to assimilate the full lactose load of a normal breast feed from the small intestine and a large proportion of it may be absorbed from the colon. Thus, it appears that the colon fulfils a slightly different role in the preterm and neonatal period, conserving nutrient absorption and minimizing fluid loss until the neonate has adjusted to extrauterine life, oral feeding and the establishment of the symbiotic bacterial flora (see Postnatal development of the gut, p. 340).

Muscularis

The muscularis is present and functioning by the eighth postfertilization week, when peristaltic waves have been observed. The specific orientation of the longitudinal muscle layer into taeniae coli occurs in the 11–12 postfertilization weeks, when haustra appear. The enteric nerves are present in Meissner's and Auerbach's plexuses at 8 and 12 weeks postfertilization, respectively; there is a craniocaudal migration of neurones into the gut wall. A normal distribution of ganglion cells has been noted in preterm babies of 24 postmenstrual weeks, although there is a region devoid of ganglia just above the anal valves. Anomalous migration of neural crest cells to the gut may give rise to Hirschsprung's disease (see p. 334). Puborectalis appears in stage 22–23 embryos, following opening of the anal membrane.

Serosa

The development of the serosa of the intestine is considered with the development of the peritoneal cavity (see below).

Colon at birth

In the full-term (notional 40 postmenstrual weeks) neonate, the colon is typically 66 cm long and averages 1 cm in width. The caecum is relatively smaller than in the adult and it tapers into the vermiform appendix. The ascending colon is shorter in the neonate, reflecting the shorter lumbar region. The transverse colon is relatively long, whereas the descending colon is short, although twice the length of the ascending colon (see Fig. 23.14B). The sigmoid colon may be as long as the transverse colon; it often touches the inferior part of the anterior body wall on the left and, in some neonates, part of the sigmoid colon lies in the right iliac fossa. The muscularis, including the taeniae coli, is poorly developed in the colon, as it is in the small intestine. Appendices, epiploicae and haustra are not present, and so the colon has a smooth external appearance: haustra appear within the first 6 months. This means that the small and large intestines cannot be differentiated by standard radiological views. The rectum is relatively long and its junction with the anal canal forms at nearly a right-angle.

Anal canal

In stage 14 a small part of the hindgut, the postanal gut, projects caudally beyond the anal membrane (see Fig. 21.3B), but it usually disappears by the end of stage 15. Mesenchymal proliferation occurs around the rim of the ectodermal aspect of the anal membrane, which thus comes to lie at the bottom of a depression, the proctodeum (see Fig. 22.7E). With the absorption and disappearance of the anal membrane, the anorectum communicates with the exterior. The lower part of the anal canal is formed from the proctodeal ectoderm and underlying mesenchyme, but its upper part is lined by endoderm: the line of union corresponds with the edges of the anal valves. The dual origin of the anal canal is reflected in its innervation, in that the endodermal portion is innervated by autonomic nerves, and the ectodermal proctodeum is innervated by spinal nerves. The external anal sphincter has an origin from the myoblasts which migrate into the lower limb and then return to the external genital region (Chs 19, 22) (Valasek et al 2005). The anatomy of the terminal portions of the muscularis externa, adventitia, perineal body and the external anal sphincter in the fetus has been explored Wu et al (2018).

Anal canal at birth

Imperforate anus is a term that has been used to describe many different anorectal anomalies. The most common is anal agenesis, which is found in almost half of all cases of imperforate anus. The condition is usually associated with a fistula, which opens into the vulva (females) or into the urethra (males). It is rare for the anal membrane to fail to

perforate. The condition cannot reliably be diagnosed prenatally by ultrasound diagnosis, and it may be confused with Hirschsprung's disease (see below) and colonic atresia. The prognosis is good for low lesions of the anal canal. In all cases, the principal concern is the degree of bowel and urinary control and, in some cases, sexual function, which is compromised by the condition. Anorectal anomalies may be indicators of other anomalies, e.g. those forming the 'VATER' syndrome (Vertebral, Anal, Tracheo-oEsophageal and Renal anomalies).

Blood supply to the gut

The development of the blood supply to the gut and the changes that occur in the formation of the portal circulation are given in Chapter 13. Three midline arteries, the coeliac trunk, superior and inferior mesenteric arteries supply the fore, mid- and hindgut, respectively: they travel in the intermesenteric space of the associated mesenteries, where they arborize.

Enteric nervous system

Enteric neurones are derived from cranial (vagal) neural crest cells at somite levels 1–7 and from level 28 onwards (see Fig. 14.20). Glial cells associated with the gut have been identified as arising from similar levels. Migrating vagal neural crest cells reach the midgut by postfertilization week 5 and the entire length of the gut is colonized by stages 18–20. Sacral neural crest cells migrate ventrally and invade the gut via the dorsal mesentery (see Fig. 14.6A). It is thought that the vagal and sacral neural crest cells have intrinsic differences in their ability to colonize the gut. The local splanchnopleuric mesenchyme patterns the crest cells, such that those that enter the gut layers attain an enteric fate, whereas those that remain outside the gut become committed as parasympathetic postganglionic neurones. The enteric neurones also migrate to the pancreas. Maturation of the myenteric plexus follows a craniocaudal progression, with enteric neurones differentiating into intrinsic primary afferent neurones, motor neurones and interneurons (Rao and Gerson 2018). The submucosal plexus arises from centripetally migrating cells from the myenteric plexus 2–3 days later (Burns et al 2009). Interstitial cells of Cajal are derived from splanchnopleuric mesenchymal cells that interact with the wavefront of migrating chains of neural crest cells along the gut. These cells express a proto-oncogene, *c-kit*, that can be identified in the gut at the end of the embryonic period along a rostrocaudal gradient. Five subtypes have been identified: the subtype ICC-MP has a pacemaker role throughout the gut, generating and propagating electrical slow waves; subtype ICC-SMP also has a pacemaker role in the colon (Radenkovic et al 2018). There is evidence that mucosal enteric glial cells, which move into the mucosa after birth, interact with the colonizing intestinal flora, suggesting a microbiota-driven homeostatic mechanism for gut function (Kabouridis et al 2015).

Hirschsprung's disease

Available with the *Gray's Anatomy* e-book

Gut-associated lymphoid tissue (GALT)

Individual lymphocytes appear in the lamina propria of the gut from about postmenstrual week 14–16, and lymphoid aggregates, Peyer's patches, can be seen from postmenstrual week 19; it is not clear whether these cells migrate in from distant sources or differentiate from the investing mesenchyme (Hoorweg and Cupedo 2008). The endodermal epithelium overlying the lymphoid aggregates is often distorted into a dome shape. The cells within the dome are a mixed population of enterocytes, endocrine cells, goblet cells and M cells. The latter are specialized to provide a mechanism for the transport of microorganisms and intact macromolecules across the epithelium to the intraepithelial space and lamina propria. They have been observed in the fetus by 17 postmenstrual weeks and it is believed that they are formed by a specialized epithelial–mesenchymal interaction of the endoderm and underlying lymphoid-type mesenchyme.

There are similarly specialized epithelial cells between the enterocytes. Intraepithelial leukocytes typically account for 15% of the epithelial cells of the gut in the adult. They have been observed at postfertilization week 11, with a distribution of 2–3 intraepithelial leukocytes per 100 gut epithelial cells. Both T and B lymphocytes have been described in the developing gut wall. For an account of the development of human innate lymphoid cells, consult Juelke and Romagnani (2016). Neonatal gut maturation continues postnatally when the gut microbiome becomes established (see Postnatal development of the gut, p. 340).

PERITONEAL CAVITY

The early development of the intraembryonic coelom, which gives rise to the peritoneal cavity, is described in Chapter 10. Figure 12.2 shows a scheme of the shape of the early peritoneal cavity and indicates the mesenchymal populations derived from its epithelial walls. Initially, the peritoneal cavity associated with the lower end of the foregut has separate right and left components: the pleuroperitoneal canals (see Fig. 21.1). At the level of the midgut, these canals join a confluent cavity surrounding the developing gut, which transitorily is in communication with the extraembryonic coelom.

The description of the development of the peritoneal cavity that follows pertains to changes that occur as a consequence of the differential growth of the gut.

Peritoneum

Peritoneum arises from the terminal differentiation of the intraembryonic coelomic walls. Initially, the intraembryonic coelomic epithelium is a pseudostratified germinal layer from which cellular progeny with different fates arise in specific sites and at specific developmental times. The portion that will give rise to the peritoneum is derived from the lower parts of the pericardioperitoneal canals, and the somatopleure and splanchnopleure associated with the lower foregut, midgut and hindgut to the future rectum (see Figs 21.1, 12.2). The proliferative splanchnopleuric epithelium of these regions of coelomic wall produces splanchnic mesenchymal cell populations that form the laminae propriae of the mucosa and submucosa, the smooth muscle in the muscularis of the gut, and the lamina propria and epithelium of the visceral peritoneum (the serosa of the gut wall). The somatopleuric epithelium gives rise to the lamina propria and epithelium of the parietal peritoneum and the underlying body wall adjacent to the ectoderm.

The coelom wall has not been a topic of specific interest in the past, however, it apparently possesses remarkable characteristics in early development. Its proliferation gives rise to mesenchymal cell populations for all gastrointestinal glands and the connective tissues of the lateral and ventral body walls. At the junction of splanchopleure and somatopleure, it contributes epithelial and mesenchymal populations to the suprarenal glands, the urinary and reproductive tracts, the gonads and the spleen (Ariza et al 2016). Most importantly for gut development, it forms an active barrier in the developing abdomen that maintains the integrity of, and separates, the developing viscera, functions that are continued by the fully developed peritoneum (Guo et al 2014). Its particular role(s) in the development of the respiratory diaphragm and the early expansions of the pleural and peritoneal cavities are as yet uncertain. Above the forming respiratory diaphragm, this putative mesothelial layer is involved in expanding the caudodorsal regions of the pleural cavities, where the somatopleuric mesenchyme of the body wall is excavated dorsal to the developing suprarenal glands, degenerating mesonephric ridges and gonads. Beneath the respiratory diaphragm it drives the development of the upper parts of the forming peritoneal cavity and the transitory formation of peritoneal cul de sacs that pass into the thorax. The most caudal parts of the coelomic wall evaginate bilaterally to create passages for, and the peritoneal coverings of, the testes, as they descend and move out of the abdominal cavity.

As the gut grows, splanchnic mesenchyme accumulates around the inner endodermal epithelium and the whole unit generally moves ventrally. There is a concomitant enlargement of the caudal ends of the developing pericardioperitoneal (pleuroperitoneal) canals and developing peritoneal cavity adjacent to the midgut. The medial walls of the intraembryonic coelom move closer and there is a relative decrease in the mesenchyme between them. The regions where the medial portions of the intraembryonic coelom come together are termed mesenteries. They are composed of two layers of splanchnopleuric coelom wall with intervening mesenchyme, and contain the neurovascular structures that pass to and from the gut. At the caudal ends of the pleuroperitoneal canals, the gut has both ventral and dorsal mesenteries, whereas, caudal to this, there is only a dorsal mesentery that extends from the third part of the duodenum to the rectum (see Fig. 21.6; **Fig. 21.7**). The arrangement of an (endodermal) epithelial tube, surrounded by splanchnopleuric mesenchyme, enclosed with a further layer of (splanchnopleuric) epithelium, permits the development of differential, regional, biomechanical tension and compressive forces along the gut and mesentery. These biomechanical forces produce a growth pattern termed buckling morphogenesis (Chevalier et al 2018). Loose loops of gut are the result of a decrease in differential growth, i.e. equal contributions of the

Hirschsprung's disease (commonly called megacolon) is usually characterized by an aganglionic portion of gut that does not display peristalsis, and a dilated segment of structurally normal colon proximal to this site. Histologically, there is either an absence or a reduction in the number of ganglia and postganglionic neurones in the myenteric plexus of the affected segment of gut; postganglionic innervation of the muscle layers is also often defective. It is believed that the condition is caused by a failure of neural crest cells to colonize the gut wall appropriately (Gershon 2010). A variable length of large intestine may be affected; the lower and mid-rectum are the most common sites but, in severe cases, the rectum, sigmoid, descending and even proximal colon can be aganglionic. Occasionally, aganglionosis affects only a very short length of rectum proximal to the anorectal junction and the degree of functional obstruction is minimal; in these cases of 'ultra-short-segment Hirschsprung's disease', clinical anomalies arise later in life. Infants with Hirschsprung's disease show delay in the passage of meconium, constipation, vomiting and abdominal distension. Culture of enteric nervous system cells derived from patients with Hirschsprung's disease have been shown to support development of enteric nerves in an aganglionic portion of gut from the same patient, indicating that the colonic tissue is still permissive for enteric neurone development and that postnatal enteric nervous system derived cells are still competent to respond (Rollo et al 2016). Suction rectal biopsy is used for histological confirmation of aganglionosis in 90% of neonates. The main surgical procedure in the UK for left-sided disease is the primary pull-through within 3 postnatal months; there is still variation in surgical practice for right-sided Hirschsprung's disease (Bradnock and Walker 2011).

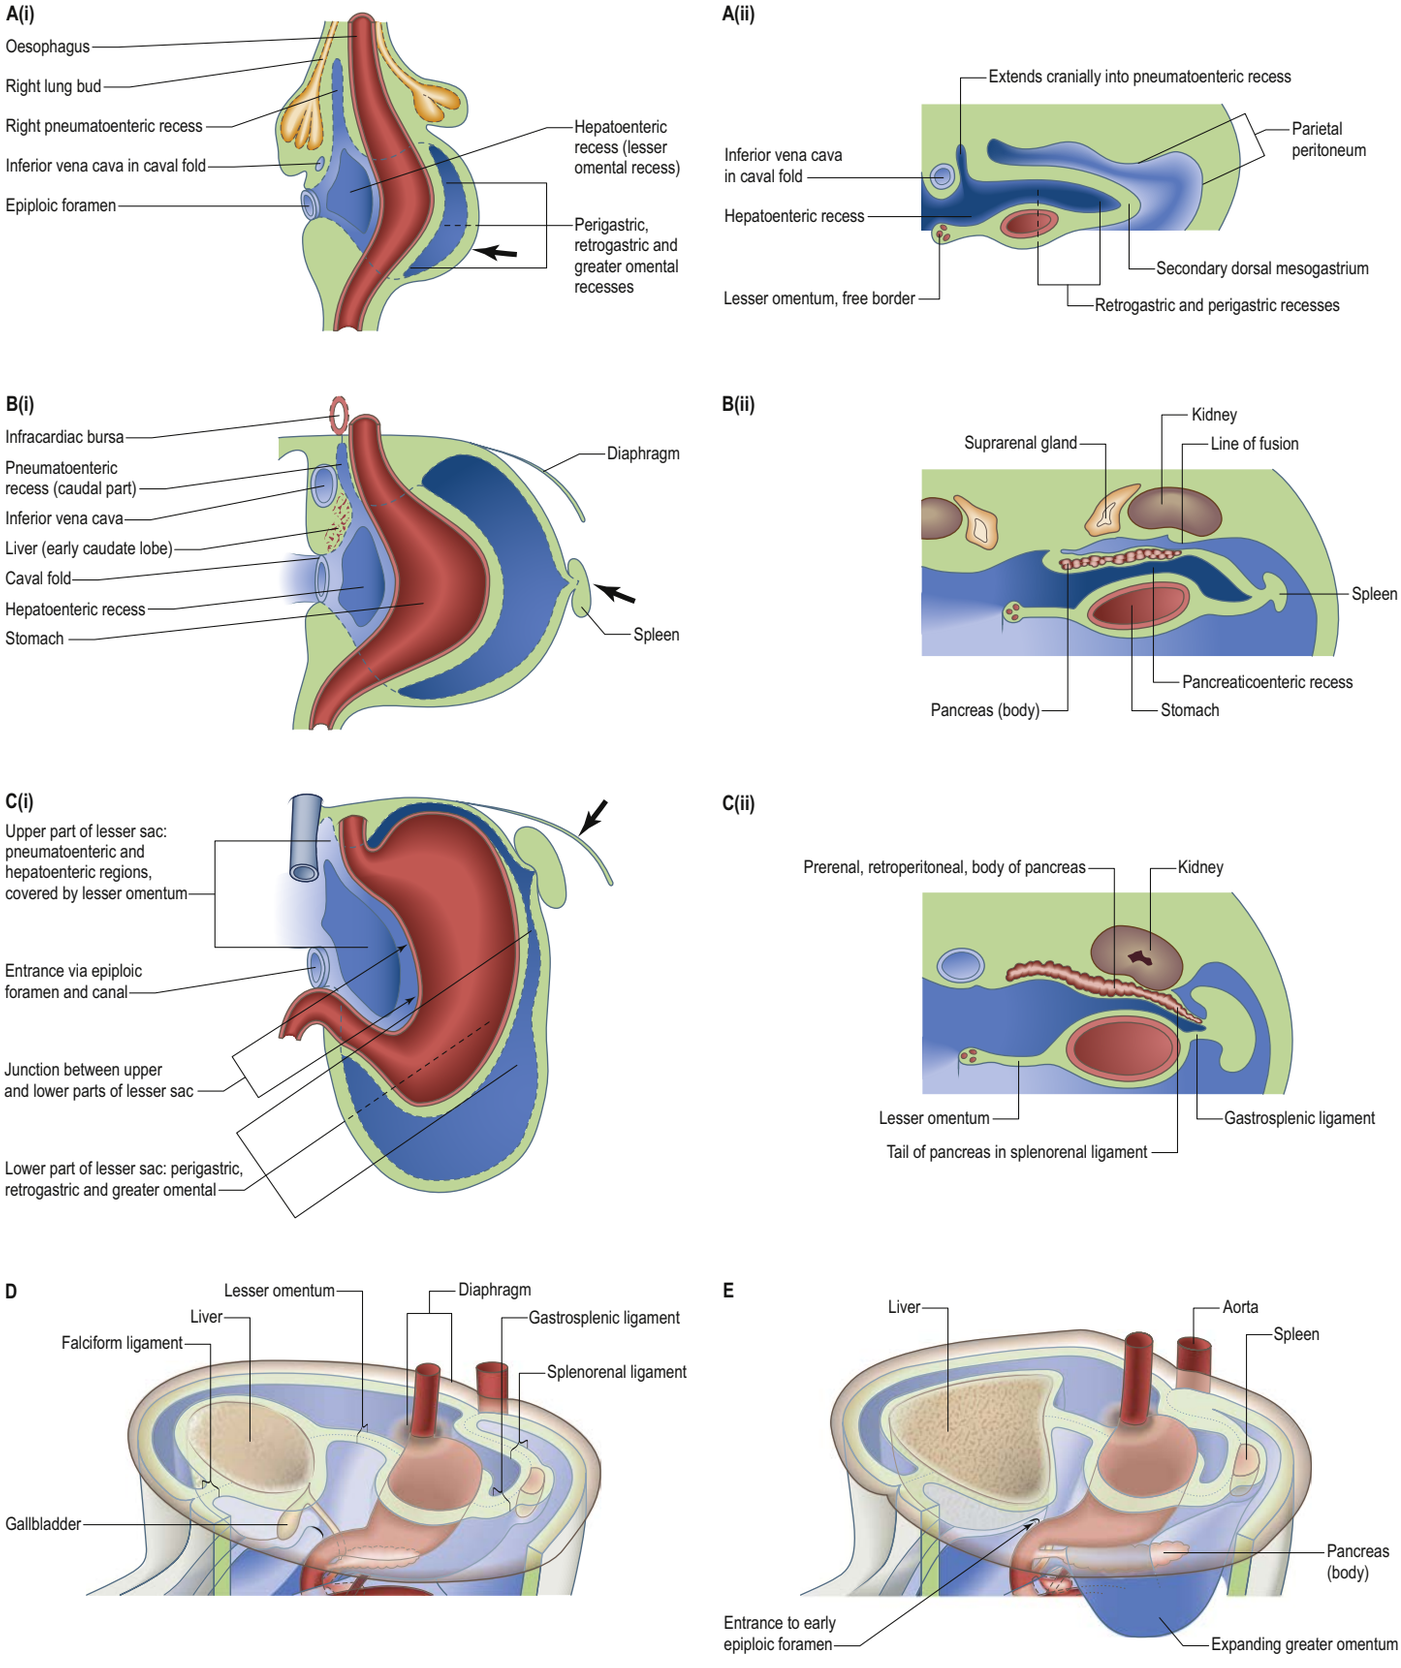

Fig. 21.7 A–C, Stages of development of the subdiaphragmatic foregut and the right and left pericardioperitoneal/pleuroperitoneal canals, with particular reference to the terminal oesophagus, stomach, duodenum, spleen, the lesser sac of the peritoneum and the omenta, seen in semicoronal section (left column) and transverse section at the levels indicated by the arrows (right column). **D–E**, The lesser sac and dorsal and ventral mesogastria.

increase in the endodermal tube radius and matched growth of the mesentery; tight gut coils result from an increase in differential growth, i.e. lengthening of the endodermal epithelium and surrounding mesenchyme with reduction in the elongation of the dorsal mesentery (Nerurkar et al 2017).

The mechanisms of midgut gut and dorsal mesentery protrusion from the developing abdomen, and the subsequent return and specific disposition of the gut in the abdominal cavity into regions termed intra-abdominal and retroperitoneal, does not align with observed adult pathology, and has led to a re-examination of the processes involved (Dodds et al 1986). Dodds et al (1986) suggested that the midgut could be conceptualized as a retroperitoneal organ, similar to the mesonephroi and gonads, regardless of how far its linear elongation and that of the dorsal mesentery changed its relative position. The

process of fusion of specific apposed peritoneal surfaces, when part or the whole of the mesentery lies against the dorsal parietal peritoneum, has also been challenged (Dodds et al 1986, Coffey et al 2016, Haaga and Di Lorenzo 2017).

The proliferating coelomic walls undergo differential determination according to their position to become a mesothelium. Mesothelial cells mostly differentiate into simple squamous cells, however in a few specific places more complex phenotypes are seen. Cuboidal cells covering the respiratory diaphragm form specialized mesothelial:lymphatic endothelial units, with lacunae (about 120 μm wide) and smaller stomata (20 μm in size). These enable particulate matter (equivalent to the stomata size) to be absorbed from the supramesocolic compartment. Mesothelial cells express cytokines and may have an antigen presentation function (Isaza-Restrepo et al 2018). Although pleural mesothelia are described as simple squamous cells, they display stomata on their pleural surface, but at less density than on the peritoneal side. This difference between the mesothelial cells either side of the respiratory diaphragm may permit peritoneal fluid to enter the pleural space, whereas passage from the pleural space to the peritoneum does not occur (Haaga and Di Lorenzo 2017). This might be the reason for some cases of right-sided hydrothorax in patients undergoing peritoneal dialysis (identified by pleural fluid high glucose levels), although other causes have been suggested, including small diaphragmatic herniae, unspecified pleuroperitoneal communication, and remnants of the pneumatoenteric recess and the infracardiac bursa (Gagnon and Daniels 2004).

Mesenteries of the developing gut

The alimentary tube, from the respiratory diaphragm to the start of the rectum, initially possesses a sagittal dorsal mesentery. Its line of continuity with the dorsal parietal peritoneum (i.e. its 'root' or 'line of reflection') is, initially, also midline. Although all of the gut and its derived glands are associated with mesenteries, the nomenclature for some portions of the gut and glands is different. Thus, the mesenteries of the stomach (initially termed mesogastria) are called omenta and the reflections of peritoneum around the liver, which develop from a confluence of splanchnopleuric, somatopleuric and septum transversum-derived portions, are called ligaments.

The movements of the developing viscera within the peritoneal cavity occur with associated movements of the mesothelia that surround them. The descriptions of peritoneal cavity development that follow are thus describing a sequence of changes that affect a complex space and its boundaries.

Foregut mesenteries

The cervicothoracic oesophagus develops between the pericardioperitoneal canals. It is encased in prevertebral, retrotracheal and retrocardiac mesenchyme. As the pericardioperitoneal canals expand with the developing lung buds, and the respiratory diaphragm forms immediately below them, the oesophagus has no true dorsal or ventral mesentery at this level. At superior and intermediate thoracic levels, parts of the lateral aspects of the oesophagus are closely related to the secondary, mediastinal, parietal pleura. In the lower thorax, the oesophagus inclines ventrally. The dorsocaudally sloping midline mesenchyme between oesophageal and aortic orifices may be homologized with part of a dorsal meso-oesophagus, and is used in that context in descriptions of respiratory diaphragmatic development. A ventral midline mesenchymal region may also be considered to be a derivative of a ventral meso-oesophagus; however, this region is more usually thought of as septum transversum.

From the respiratory diaphragm to the future hepatopancreatic duodenal papilla, the abdominal foregut has a ventral mesentery. This extends from the ventrolateral margins of the abdominal oesophagus and as yet 'unrotated' primitive stomach and proximal duodenum, cranially to the future respiratory diaphragm and ventrally to the ventral abdominal wall at the level of the cranial rim of the umbilical cord. Caudally, between umbilicus and duodenum, it presents a crescentic free border (Figs 21.5–21.6).

The ventral and dorsal foregut mesenteries are relatively extensive compared with the slender endodermal tubes they encase. The endodermal epithelium of the stomach and duodenum does not rotate relative to its investing mesenchyme. The rotation includes the coelomic epithelial walls of the pericardioperitoneal canals, and dorsally where these layers come together, the elongating dorsal mesogastrium and the much shorter dorsal mesoduodenum. A ventral mesogastrium can be seen when the distance between the stomach and liver increases.

Consequences of rotation of the stomach

A number of processes occur concurrently, which, conceptually, can be visualized as the movement of the right pleuroperitoneal canal to a position posterior to the stomach, such that its communication with the remainder of the peritoneal cavity is reduced. These processes include the differential growth of the walls of the stomach, the formation and specific local extension of the omenta (dorsal and ventral mesogastria), and the growth of the liver and, particularly, of the vessels and ducts that enter and leave the liver.

Whereas the dorsal mesogastrium takes origin from the posterior body wall in the midline, its connection to the greater curvature of the stomach, which lengthens as the stomach grows, becomes directed to the left as the stomach undergoes its first rotation. With the second rotation, a portion of the dorsal mesogastrium now faces caudally (see Fig. 21.6). The ventral mesogastrium remains as a double layer of coelomic epithelium, which encloses mesenchyme and forms the lesser omentum (see Fig. 21.7).

These developments permit stomach expansion both anteriorly and posteriorly when food is ingested, and free movement of peristalsis. The right pleuroperitoneal canal forms a discrete region of the peritoneal cavity, the lesser sac and the remaining left pleuroperitoneal canal and the remainder of the peritoneal cavity form the greater sac. The entrance to the original right pleuroperitoneal canal (lesser sac) becomes reduced in size. It is called the epiploic foramen, foramen of Winslow, or the aditus of the omental bursa (bursa omentalis).

Early stages of lesser sac development

The lesser sac is first indicated by the appearance of multiple clefts in the para-oesophageal mesenchyme on both left and right aspects of the oesophagus. Although they may become confluent, the left clefts are transitory and soon atrophy. The right clefts merge to form the right pneumatoenteric recess that extends from the oesophageal end of the lesser curvature of the stomach as far as the caudal aspect of the right lung bud. At its gastric end, it communicates with the general peritoneal cavity and lies ventrolateral to the gut, while more rostrally it lies directly lateral to the oesophagus. It is not, as commonly stated, a simple progressive excavation of the right side of the dorsal mesogastrium. The right pneumatoenteric recess undergoes further extension, subdivision and modification (see Fig. 21.7A(i), B(i)). From its caudal end, a second process of cleft and cavity formation occurs, which produces the hepatoenteric recess. This thins and expands the splanchnopleure between the liver and the stomach and proximal duodenum, and reaches the respiratory diaphragm (see Fig. 21.7A(i), C(i)). The resulting mesenteric sheet is the lesser omentum. It is derived, cranially to caudally, from the small meso-oesophagus; the much larger ventral mesogastrium, and the most caudal free border is from the ventral mesoduodenum. As differential growth of the duodenum occurs, the biliary duct is repositioned and the duodenum is sessile. The duodenal attachment of the free border and a continuous neighbouring strip of the lesser omentum become confined to the upper border of a short segment of its superior part. The contrasting growth and positioning of its attached viscera cause the free border to change gradually from the horizontal to the vertical. It carries the bile duct, portal vein and hepatic artery, and its hepatic end is reflected around the porta hepatis. An alternative name for this part of the lesser omentum is the hepatoduodenal ligament; it forms the anterior wall of the epiploic foramen. The floor of the foramen is the initial segment of the superior part of the duodenum, its posterior wall is the peritoneum covering the immediately subhepatic part of the inferior vena cava, and its roof the caudate process of the liver. The major part of the lesser omentum from the lesser gastric curvature passes in an approximately coronal plane to reach the floor of the increasingly deep groove for the ductus venosus on the hepatic dorsum; this part is sometimes called the hepatogastric ligament.

Ligaments of the liver

The liver appears precociously large during development. Thus, the liver mass projects into the abdominal cavity with equal growth on the two sides of the peritoneal cavity. The ligaments associated with the liver develop from the ventral mesogastrium, which passes from the foregut to the ventral abdominal wall, down to the cranial rim of the intestinal portal, and from the reflections of peritoneum from the liver to the respiratory diaphragm.

The medial portions of the proliferating coelomic epithelial walls producing splanchnopleuric mesenchyme, plus the septum transversum mesenchyme and developing liver, constitute the early ventral mesogastrium (see Fig. 21.5). The mesenchyme between these layers is continuous superiorly with the septum transversum mesenchyme of the future respiratory diaphragm. The coelomic epithelial layers of the ventral mesogastrium almost touch ventrally and dorsally to the liver, and are separated by a slender layer of mesenchyme. They form the falciform ligament and the lesser omentum, respectively, and where

they are in contact with the liver directly, they form visceral peritoneum (see Fig. 21.7D).

When the respiratory diaphragm is formed above the liver (Ch. 20), local cavities coalesce and open into the general coelomic cavity as extensions of the greater and lesser sacs. In this way, almost all the ventrosuperior, visceral and some of the posterior aspects of the liver become peritonealized. The process of extending the greater sac continues over the right lobe and stops when the future superior and inferior layers of the coronary ligament and the right triangular ligament are defined. Those, plus a medial boundary provided by an extension of the lesser sac, enclose the 'bare area' of the liver, where loose areolar tissue of septum transversum origin persists. Later in development, the left lobe becomes relatively smaller than the right, and this presumably accounts for the smaller size of the left triangular ligament.

Where the superior layers of the coronary and left triangular ligaments meet, they continue as a (trilaminar) ventral mesentery attached to the ventrosuperior aspects of the liver. The somewhat arched umbilicohepatic free caudal border carries the left umbilical vein. As the ventral body wall develops, this falciform ligament, which initially attaches to the early cranial intestinal portal, is drawn to the diminishing cranial rim of the umbilicus. It may be considered as the final ventral part of the ventral mesogastrium, although its free border has a ventral mesoduodenal origin. Its passage to the ventral body wall becomes increasingly oblique, curved and falciform as the umbilicus becomes more defined.

In the early embryo, the connection between the pericardioperitoneal canals is directly across the ventral surface of the cranial midgut, immediately caudal to the developing primitive ventral mesogastrium (see Fig. 21.1). By stage 14 passage from one side of the falciform ligament to the other means passing either below the greatly enlarged liver, or the curved lower edge of the falciform ligament, or the lesser omentum. The position of the falciform ligament is of clinical interest in the neonate in diagnosing pneumoperitoneum because it is silhouetted by air on abdominal X-rays.

Caval fold

The caval fold is a developing linear eminence, protruding from the dorsal wall of the pleuroperitoneal canal, produced bilaterally by morphological changes in the position of the common cardinal veins, the horns of the sinus venosus, and formation of the rostral portions of the vena cava (Ch. 13). It has divergent rostral and caudal ends. Rostrally, it becomes continuous lateromedially with the root of the developing lung bud and pleural coelom, the uppermost portion of the septum transversum mesenchyme, and the retrocardiac mediastinal mesenchyme. Caudally, it forms an arch with dorsal and ventral horns. The dorsal horn merges with the primitive dorsal mesentery of the developing heart and the mesonephric ridge and associated gonad and suprarenal (adrenal) glands developing on the dorsal walls of the intraembryonic coelom. The ventral horn is confluent with the dorsal surface of the septum transversum mesenchyme.

Thus, the caval fold is a zone where intestinal, mesenteric, intermediate, hepatic, pericardial, pulmonary and mediastinal mesenchymes meet and blend. It provides a mesenchymal route for the upper abdominal, transdiaphragmatic and transpericardial parts of the inferior vena cava, and it is also prominent in the development of parts of the liver, the lesser sac of peritoneum, and certain mesenteries. The left fold regresses whereas the right fold enlarges rapidly (see Fig. 21.7A(i), A(ii)).

The pneumatoenteric recess continues to expand to the right into the substance of the caval fold. It stops near the left margin of the hepatic part of the inferior vena cava, which remains extraperitoneal and crosses the base of the now roughly triangular bare area of the liver and this new expanded line of reflection. With closure of the pleuroperitoneal canals, the rostral part of the right pneumatoenteric recess is sequestered by the respiratory diaphragm but often persists as a small serous sac in the right pulmonary ligament. The remaining caval fold mesenchyme to the left of the inferior vena cava – which forms the right wall of the upper part of the lesser sac – becomes completely invaded by embryonic hepatic tissue and is transformed into the caudate lobe of the liver. This smooth, vertically elongated mass projects into the cavity of the lesser sac; both its posterior and much of its anterior surfaces become peritonealized as a result of the increasing depth of the groove for the ductus venosus and the attachment of the lesser omentum to its floor.

Later stages of lesser sac development

The lower (inferior) part of the lesser sac can be first seen in stage 15 embryos; the early pneumatoenteric and hepatoenteric recesses are well established. Progressive differential gastric growth produces an elliptical transverse sectional profile, with a right-sided lesser curvature, which corresponds to the original ventral border of the gastric tube. The lesser omental gastric part of the ventral mesogastrium remains attached to this border. The greater curvature of the stomach is a new, rapidly expanding, region; its convex profile projects mainly to the left, but also cranially and caudally (see Fig. 21.7A(i), B(i), C(i)). The original dorsal border of the gastric tube now traverses the dorsal aspect of the expanding rudiment, curving along a line near the lesser curvature. The primitive dorsal mesogastrium is transiently attached to it, and blends with the thick layer of compound gastric mesenchyme clothing the posterior aspect and greater curvature of the miniature stomach. Because of its thickness, the mesenchyme projects rostrally, caudally and, particularly, to the left, beyond the 'new' greater curvature of the endodermal lining of the stomach.

The processes already described in relation to the ventral mesenteries now supervene. Multiple clefts appear at various loci in the mesenchyme, with local mesenchymal to epithelial transition. The groups of clefts rapidly coalesce to form transiently isolated closed spaces, which soon join with each other and with the preformed upper part of the lesser sac; the newly formed epithelia join the coelomic epithelium. In sequence, the initial loci occur in the compound posterior gastric mesenchyme nearer the lesser curvature and along its zone of blending with the primitive dorsal mesogastrium; in the dorsal mesoduodenum; and independently, in the caudal rim, where greater curvature mesenchyme and dorsal mesogastrium blend. As these cavities become confluent and their 'reniform' expansion follows, matches and then exceeds that of the gastric greater curvature, there are several major sequelae. The primitive dorsal mesogastrium increases in area by intrinsic growth, and, as cavitation proceeds, by incorporating substantial contributions from the dorsal lamella separated by cleavage of the posterior gastric mesenchyme. It becomes the secondary dorsal mesogastrium and its gastric attachment changes progressively (see Fig. 21.7A(ii)). It may be regarded as a set of somewhat spiral lines, longitudinally disposed, that move with time to the left, from near the lesser curvature, towards and finally reaching the definitive greater curvature. The parietal mesogastrial and (cleaving) mesoduodenal attachments remain in the dorsal midline for a time, but they later undergo profound changes. With the confluence of the cavities that collectively form the lower part of the lesser sac, its communication with the upper part (which corresponds to the lesser gastric curvature and right and left gastropancreatic folds) becomes better defined. Ventral to the lower part of the cavity, post-cleavage splanchnopleure covers the posteroinferior surface of the stomach and a short proximal segment of the duodenum. This ventral wall is continued beyond the greater curvature and duodenum as the splanchnopleuric strip of visceral attachment of the secondary dorsal mesogastrium and mesoduodenum. The radial width of the strip is relatively short cranially (gastric fundus) and gradually increases along the descending left part of the greater curvature. It is longest throughout the remaining perimeter of the greater curvature as far as the duodenum; this prominent part shows continued marginal (caudoventral and lateral) growth with extended internal cavitation (its walls constitute the expanding greater omentum; see Fig. 21.6H). The margins of the cavity of the inferior part of the lesser sac are limited by the reflexed edges of the ventrally placed strata derived from the secondary dorsal mesogastrium just described. These converge to form the splanchnopleuric dorsal wall, which is initially 'free' throughout, except at its midline dorsal root. At roughly mid-gastric levels, the pancreatic rudiment grows obliquely encased in this dorsal wall; its tail ultimately reaches the left limit of the lesser sac at the level of the junction between gastric fundus and body (see Fig. 21.7C(ii)).

Greater omentum

The greater omentum continues to grow, both laterally and, particularly, caudoventrally. It covers and is closely applied to the transverse mesocolon, transverse colon and inframesocolic and infracolic coils of small intestine (see Fig. 21.6D–G). At this stage, the quadrilaminar nature of the dependent part of the greater omentum is most easily appreciated. Mesenteries may be considered trilaminar: they possess two mesothelial surfaces derived from splanchnopleuric coelomic epithelium 'sandwiching' splanchnopleuric mesenchyme between them. In the greater omentum, the gastric serosa covering its posteroinferior surface (single mesothelium) and the anterosuperior serosa (single mesothelium) converge to meet at the greater curvature and initial segment of the duodenum, with intervening mesenchyme. The resulting mesentery continues caudoventrally as the 'descending' trilaminar stratum of the omentum. This, on reaching the omental margins, is reflexed and now passes craniodorsally to its parietal root as the 'ascending' posterior, trilaminar stratum. The descending and ascending layers are, initially, in fairly close contact caudally, but are separated by a fine, fluid-containing,

cleft-like extension of the lower part of the lesser sac. The posterior mesothelium of the posterior stratum makes equally close contact with the anterosuperior surface of the transverse colon, starting at the taenia omentalis, and with its transverse mesocolon.

Maturation of the lesser sac

At this stage, and subsequently, it is convenient to designate the lower part of the lesser sac as consisting of three subregions: retrogastric, perigastric and greater omental (see Fig. 21.7C(ii)). The names are self-explanatory but their confines are all modified by various factors. Two phenomena are particularly prominent: namely, gastric 'descent' relative to the liver, and adherence of peritoneal layers ultimately giving altered lines of reflection, and loss of parts of cavities.

After the first trimester, hepatic growth, particularly of the left lobe, diminishes and the whole organ fits into the upper region of the enlarging abdomen. Meanwhile, the stomach elongates and some descent occurs, despite its relatively fixed cranial and caudal ends. This produces the angular flexure of the stomach, that persists postnatally. The concavity of the lesser curvature is now directed more precisely to the right, and the lesser omentum is more exactly coronal and its free border vertical. Ventral to the liver, the free border of the falciform ligament passes steeply craniodorsally from umbilicus to liver (see disposition in the neonate in Figs 23.14 and 23.15A, D).

The mesenchymal dorsal wall of the lower part of the lesser sac has, up to this point, retained its original dorsal midline root. The mesenchymal cores of the mesenteries become thinner, and are termed fascial sheaths and septa. Overlying areas of mesentery then adhere to the original dorsal coelomic wall, by ways as yet unknown. Where sheets adhere, they remain surgically separable and no vascular anastomoses develop across the interzone.

Above the pancreas, the original left leaf of the dorsal mesoduodenum and greater omentum becomes closely applied to the original left dorsal coelomic wall covering the lower parts of the respiratory diaphragm, much of the left suprarenal gland, the ventromedial part of the upper pole of the left kidney, the initial part of the abdominal aorta, the coeliac trunk and its branches, and other vessels, nerves and lymphatics. Their peritoneal surfaces adhere.

This process is repeated at the level of the developing pancreas which is now extending into the layers of the dorsal mesoduodenum and greater omentum. As the pancreas grows dorsally, and then to the left as the mesenteries themselves move, the whole surface of the pancreas is covered by splanchnopleuric mesenchyme and developing peritoneum, except where peritoneal lines of reflection exist. The left leaf of the dorsal mesoduodenum/greater omentum becomes closely applied and adheres to the left dorsal coelomic wall covering all the posterior abdominal wall structures it crosses, but at a lower level than that described above, i.e. inferior vena cava, abdominal aorta, splenic vein, superior mesenteric vessels, inferior mesenteric vein, portal vein, left renal vessels, the caudal pole of the left suprarenal gland, a broad ventral band on the left kidney and developing muscles of the dorsal abdominal wall (see Fig. 21.7A(ii), B(ii), C(ii)). The pancreas is now sessile. The original right leaf of the dorsal mesoduodenum/greater omentum becomes the peritoneum covering the upper left part of its head, neck and the anterosuperior part of the pancreatic body forms the central part of the dorsal wall of the lesser sac. The pancreatic tail remains peritonealized by a persisting part of the secondary dorsal mesogastrium as it curves from the ventral aspect of the left kidney towards the hilum of the spleen. The infracolic parts of the pancreas are covered with greater sac peritoneum. In the greater omental subregion of the lower part of the lesser sac, two contrasting forms of mesenteric adhesion occur. The posterior 'returning' stratum of the omentum undergoes partial adhesion with the peritoneum of the transverse colon at the taenia omentalis and with its mesocolon. The layers remain surgically separable; no anastomosis occurs between omental and colic vessels.

The original dorsal midline attachment of the foregut dorsal mesentery is profoundly altered during the development of the lesser sac and its associated viscera. However, despite the extensive areas of adhesion, virtually the whole of the gastric greater curvature (other than a small suboesophageal area) and its topographical continuation (the inferior border of the first 2–3 cm of the duodenum) retain true mesenteric derivatives of the secondary dorsal mesogastrium and its continuation, the dorsal mesoduodenum. Although regional names are used to assist identification and description, it is important to emphasize that they are all merely subregions of one continuous sheet.

The upper (oesophagophrenic) part of the lesser omentum arches across the respiratory diaphragm. As this mesentery approaches the oesophageal hiatus, its epithelial laminae diverge, skirting the margins of the hiatus. They then descend for a limited distance and with variable inclination, to enclose reciprocally shaped areas on the dorsum of the gastric fundus and respiratory diaphragm. The area may be roughly triangular to quadrangular. It contains mesenchyme that becomes areolar tissue, and constitutes the bare area of the stomach or, when large, the left extraperitoneal space. Its right lower angle is the base of the left gastropancreatic fold, and its left lower angle reconstitutes the mesentery. The root of the latter arches downwards and to the left across the respiratory diaphragm and suprarenal gland, and gives the gastrophrenic ligament to the gastric fundus. It continues to arch across the ventral surface of the upper part of the left kidney, and its layers part to receive the pancreatic tail; they initially extend to the hilum of the spleen as the splenorenal ligament (see Figs 21.6C, 21.7D). The left half of this trilaminar 'ligament' provides an almost complete mesenchymal and peritoneal tunic for the developing spleen. It then reunites with its fellow at the opposite rim of the splenic hilum, and continues to the next part of the gastric greater curvature as the gastrosplenic ligament. The remaining part (perhaps two-thirds) of the gastric greater curvature and its short duodenal extension provide attachment for the anterior, 'descending', stratum of the greater omentum. Its returning, posterior, stratum continues to its parietal root (which extends from the inferior limit assigned to the splenorenal ligament), and curves caudally and to the right along the anterior border of the body of the pancreas, immediately cranial to the line of attachment of the transverse mesocolon. Crossing the neck of the pancreas, the same curve is followed for a few centimetres on to its head, the omental root then sharply recurves cranially and to the left, to reach the inferior border of the duodenum. Thus it reaches that part of the lesser sac provided by cleavage of the dorsal mesoduodenum from the greater sac. It enters the epiploic foramen, traverses the epiploic canal between the caudate hepatic process and proximal duodenum, then crosses the right gastropancreatic fold, and descends behind the proximal duodenum to enter the right marginal strip enclosed by the greater omentum.

Peritoneum associated with the midgut loop and hindgut

The midgut and hindgut have no ventral mesentery; thus, the early pleural and supra-umbilical peritoneal cavities are, initially and transiently, bilaterally symmetric above the umbilicus. Below the umbilicus, the peritoneal cavity is freely continuous across the midline ventral to the gut (see Fig. 21.5A). It is convenient to consider the mesenteries of the small and large intestine after rotation when the principal growth patterns have been achieved, and the developing pancreas is sessile. Studies of the adult parietal peritoneum, driven by surgical resection of the mesocolon, have led to the view that apposed layers of developing peritoneum adhere in some manner rather than involute dorsally, and that the final differentiation of the dorsal mesentery is of an organ in its own right, continuous from the duodenojejunal flexure to the mesorectum, as it is in the embryo (Dodds et al 1986, Sehgal and Coffey 2014, Byrnes et al 2019). The trilaminar layer of the dorsal mesentery is highlighted by consideration of the intermesenteric space; this refers to the early splanchopleuric mesenchymal layer which transmits autonomic nerves, blood and lymphatic vessels to the gut. Dodds et al (1986) considered that the endodermal epithelial gut was also part of the intermesenteric domain and could be regarded as an extraperitoneal structure. Communication between intermesenteric and the original retroperitoneal mesenchyme is via aortic and caval vessels which supply both regions. Histological examination of regions of mesenteric adhesion has shown, as predicted by Toldt in the nineteenth century, that the original (visceral) left side of the mesentery is joined to the dorsal parietal coelomic wall with a layer termed Toldt's fascia intervening (Coffey et al 2016). These sites have been termed fascial planes (Sehgal and Coffey 2014).

Although understanding the movements and sites of adhesion of the midgut dorsal mesentery is challenging, adding this to earlier, ventral layering of the dorsal mesoduodenum and greater omentum as the pancreas develops, is particularly thought-provoking. However, it does explain the many previously described retroperitoneal planes. The compartments of the retroperitoneum and the final position of the dorsal mesentery of the midgut in the infracolic compartments and the regions of adult parietal peritoneal reflection, are described in Chapters 61 and 62. In the infracolic regions, three original layers of coelomic wall form the peritoneum medial to the ascending and descending colon: the original right and left dorsal coelomic walls and both layers of the mesocolon after its rotation and final disposition. The original right leaf of the mesocolon adheres to the original dorsal coelomic walls, with Toldt's fascia intervening; the left leaf of the mesocolon is uppermost and faces the peritoneal cavity.

Mesenteric relative movements at the junction of the distal end of the foregut and beginning of the midgut are more complex and the exact fate of the overlying layers is not known. The layers over the part

of the duodenum facing the lesser sac are: the left dorsal coelomic wall which adheres to the left leaf of the dorsal mesoduodenum/greater omentum; the right leaf of the dorsal mesoduodenum/greater omentum which becomes the peritoneum covering central dorsal wall of the lesser sac, covering the upper left part of its head, neck and the anterosuperior part of the body of the pancreas. The layers over the lower parts of the duodenum are more complex. The dorsal mesoduodenal layers are covered with portions of peritoneum facing the right infracolic compartment, so are part of the midgut mesocolon. Dodds et al (1986) described the layers in this region, from dorsal to ventral, as primary left dorsal peritoneum; fused leaves of the right mesoduodenum with the pancreas in the so-called pancreaticoduodenal space; left leaf mesoduodenum; right leaf mesocolon; left leaf mesocolon. The importance of understanding these early mesenteric movements was predicted some years ago and they are now informing surgical approaches to gut resection, especially in complete mesocolic excision for colon cancer (Coffey et al 2015, Zhu et al 2016). However, over the years many different terms have been applied to these epithelial and mesenchyme tissues and their final juxtapositions. Hopefully the most pertinent terms will be retained and used and eventually correlated to histological studies on the mechanisms of mesothelial adherence (Lian et al 2019).

Small intestine

Most of the duodenal loop encircles the head of the pancreas and is sessile with peritoneum noted covering its ventral and convex aspects. Areas not covered are a short initial segment of the superior (first) part, which is more completely peritonealized because it gives attachment to the right margins of the greater and lesser omenta; the sites where the transverse colon is closely apposed to the descending (second) part, or where the latter is crossed by the root of the transverse mesocolon; and the sites where the mesentery crosses the transverse (third) part, and descends across the ascending (fourth) part from its upper extremity at the duodenojejunal flexure.

From a mesenteric standpoint, the succeeding small intestine, from the duodenojejunal flexure to the ileocaecal junction, undergoes less modification of its embryonic form than other gut regions. Its early dorsal mesentery is a continuous, single (but structurally trilaminar) sheet, with a midline dorsal attachment (line of reflection) that becomes an oblique narrow band from the left aspect of the second lumbar vertebra to the cranial aspect of the right sacroiliac joint.

Ascending colon

The caecum and vermiform appendix arise as a diverticulum from the antimesenteric border of the caudal limb of the midgut loop and consequently the caecum does not possess a primitive mesocaecum. These regions of the gut undergo long periods of growth, often asymmetric, and their final positions, dimensions and general topography show considerable variation. The vermiform appendix is almost wholly clothed with visceral peritoneum, derived from the diverging layers of its rather diminutive mesoappendix. The latter should perhaps be regarded as a direct derivative of the primitive dorsal mesentery, and a similar status for the vascular fold of the caecum should be considered.

The colonic gut retains its primitive dorsal mesentery, the mesocolon, until the differential growth, rotation and circumabdominal displacement of this part of the gut nears completion. Its original root is still vertical in the dorsal midline, although the mesocolon diverges from it widely as an incomplete, flattened pyramid, to reach its colonic border at the future taenia mesocolica. During postmenstrual weeks 16–20, substantial areas of the primitive mesocolon adhere to the dorsal coelomic wall. In this way, some colonic segments become sessile while others have a shorter mesocolon with an often profoundly altered parietal line of attachment. The mesocolon of the transverse and sigmoid segments normally persists, while the ascending colon, right (hepatic) flexure and descending colon become sessile; the ascending or descending, or both, colonic segments may also retain a mesocolon, which varies from a localized 'fold' to a complete mesocolon. When sessile, the ventral, medial and lateral aspects of the ascending or descending colon are clothed with peritoneum, and the protrusion of the viscus produces medial and lateral peritoneal paracolic gutters on each side. This form of apposition to underlying structures proceeds from the ascending colon to include the right colic (hepatic) flexure, and from there it continues ventro-inferiorly to the left, so involving the right-sided initial segment of the transverse colon.

Transverse colon

The right extremity of the transverse colon is sessile, and is separated by fibro-areolar tissue from the ventral aspect of the descending (second) part of the duodenum and the corresponding aspect of most of the head of the pancreas. The remainder of the transverse colon, up to and including the left (splenic) colic flexure, is almost completely peritonealized by the diverging layers of the transverse mesocolon. The root of the latter reaches the neck and whole extent of the ventral border of the body of the pancreas. The long axis of the definitive pancreas lies obliquely. The splenic colonic flexure is considerably more rostral than the hepatic flexure and, consequently, the root of the mesocolon curves obliquely upwards as it crosses the upper abdomen from right to left. As it expands, the posteroinferior (descending) wall of the greater omental part of the lesser sac gradually covers, and then adheres to the transverse mesocolon and its contained colon, finally projecting beyond the latter. Craniocaudal adhesion now occurs between the omental wall and the pericolonic and mesocolonic layers.

Descending colon

The left colic flexure receives much of its peritoneal covering from the left extremity of the transverse mesocolon. It is also often connected to the parietal peritoneum of the respiratory diaphragm over the 10th and 11th ribs by a phrenicocolic ligament. The latter sometimes blends with a presplenic fold that radiates from the gastrosplenic ligament. The descending colon becomes sessile. The process of adhesion of both ascending and descending mesocolons starts laterally and progresses medially.

Sigmoid colon

The sigmoid colon is most variable in its length and disposition. It retains its dorsal mesocolon, but the initial midline dorsal attachment of its root is considerably modified in its definitive state.

Rectum

The rectum develops from the dorsal region of the early cloaca. The urorectal septum, a localized region of proliferating coelomic epithelium and underlying mesenchyme grows caudally towards the cloacal membrane, and concomitantly enlarges the intraembryonic coelom in a caudal direction (see Figs 21.1, 22.4). By stage 15 the cloaca is divided into enteric hindgut and urogenital sinus, and the cloacal membrane is divided into urogenital and anal parts (Ch. 22). Urorectal septal growth generates different populations of splanchnopleuric mesenchyme that contribute to the lower portions of the enteric hindgut and urethra. The overlying coelomic epithelium covers the dorsal and ventral borders of an extending peritoneal pouch until, at stages 18–20, the caudal region, where these layers are confluent, approaches mesenchyme surrounding the developing levator ani muscle. After this time the lower part of the pouch is found just caudal to the insertion of the mesonephric ducts into the urogenital sinus; segmental levels 31–32 (S2–S3). Between stages 20–23, mesenchymal proliferation increases above the levator ani muscle, and from about 11 postmenstrual weeks onwards the deepest point of the prerectal peritoneal pouch is located in the plane through S3 and the symphysis pubis (Kruepunga et al 2018). The reflection of the peritoneum in female and male neonates is shown in Figs 22.9–22.10. The proximal third of the rectum is covered by peritoneum ventrolaterally, the middle third only on its ventral surface, where it forms the posterior wall of the rectovesical or rectouterine pouch. The remaining rectum and anal canal are extraperitoneal.

Dorsal to the rectum the early splanchnopleuric mesenchyme is sometimes called the dorsal mesorectum, but this is a misnomer. With progressive skeletal development, it is reduced to a woven fibroareolar sheet that displays patterned variations in thickness and fibre orientation. The sheet is closely applied to the ventral concavity of the sacrum and coccyx, and encloses numerous fibromuscular and neurovascular elements.

The interactions between the tissue populations in this caudal body region have not yet been elucidated. Apposition and fusion of the coelomic walls between the developing rectum and urinary bladder and urethra had been suggested to account for the surgically separable fibrous stratum between these structures. However, Silver (1952) concluded that there was no direct evidence that the peritoneum contributed to the rectovesical septum in male fetuses, a view supported by Kraima et al (2015). It is likely that the patterning of the uroseptum mesenchyme is complex; this cell population is involved in interactions with ectodermal and endodermal epithelia, and the development of the external genitalia and external sphincters, which derive from the ventral muscle mass which initially migrates into the lower limb and then returns to the perineal region (Valasek et al 2005). Histological examination of rectogenital mesenchyme in fetuses from 10 to 37 postmenstrual weeks shows development of condensations of collagen, longitudinal smooth muscle and parasympathetic and sensory nerve fibres; a role in the sensory input from local sphincters is suggested (Aigner et al 2014, Kraima et al 2015). The rectogenital mesenchyme is

adherent to and continuous with the ventral mesorectal fascia in the fetus; this is suggested to be the site of a surgical plane in the adult, identified in total mesorectal excision (Heald 1988, 2013, Kraima et al 2015, Sahnan et al 2018).

Peritoneal cavity at birth

The fully formed peritoneal cavity, although complex topographically, remains a single cavity with numerous intercommunicating regions, pouches and recesses (see Fig. 23.14A–E). The only small peritoneal sacs to separate completely from the main cavity are the infracardiac bursa and the tunica vaginalis testis.

In fetal life, the cavity between the anterior descending and posterior ascending layers of the greater omentum extend to the internal aspect of the caudal and lateral edges of the omentum. Postnatally, a slow but progressive adhesion of the internal surfaces occurs, with obliteration of the most dependent part of the cavity; this proceeds rostrally and, when mature, the cavity does not usually extend appreciably beyond the transverse colon. Adhesion between the posterior leaf of the greater omentum and the originally right, but now cranial leaf of the transverse mesocolon, is completed when the transverse colon attains its final position.

In the neonate, the peritoneal cavity is ovoid and fairly shallow from anterior to posterior, because the bilateral posterior extensions on each side of the vertebral column, which are prominent in the adult, are not present. Two factors lead to the protuberance of the anterior abdominal wall in the neonate and infant. The respiratory diaphragm is flatter in the newborn, which produces a caudal displacement of the viscera. The pelvic cavity is very small in the neonate, which means that organs that are normally pelvic in the adult, i.e. urinary bladder, ovaries and uterus, all extend superiorly into the abdomen (see Figs 22.9–22.10). The pelvic cavity is joined to the abdominal cavity at less of an acute angle in the neonate because there is no lumbar vertebral curve and only a slight sacral curve.

The peritoneal attachments are similar to the adult. However, the greater omentum is relatively small; its constituent layers of peritoneum may not be completely adherent, and it does not extend much below the level of the umbilicus. Generally, the relative length of the mesentery of the small intestine and of the transverse and sigmoid mesocolons is greater than in the adult, whereas the area of adherence of the ascending and descending colons is relatively smaller. The peritoneal mesenteries and omenta contain little fat.

SPLEEN

Although the spleen is not in any way related to enteric or overall mesenteric gut development, it develops within the layers of the dorsal mesogastrium. It appears during stages 15–17 as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end (see Figs 21.6–21.7). The proliferating cells invade the underlying angiogenic mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas, that soon fuse to form a lobulated spleen of dual origin, i.e. from dorsal mesogastrium mesenchyme derived from the coelomic epithelium and from angiogenic mesenchyme derived from developing mesenteric blood vessels. Experimental studies in mouse embryos suggest that neural crest cells also invade the spleen via the splenic vessels and give rise to astrocyte-like glial cell populations (Barlow-Anacker et al 2017).

The splenic vascular reticulum is well developed by the end of stage 23 and contains numerous closely spaced, thin-walled, vascular loops and immature reticulocytes. From about 11 postfertilization weeks, the development of the spleen has been described in four stages: stage 0 has erythrocyte precursors, few macrophages and fewer lymphocytes; in stage I, lymphocytes begin colonization and arterial vascular lobules are seen; in stage II, T and B lymphocytes form periarteriolar clusters with B cells aggregated around the peripheral branches of splenic arterioles and T cells centrally; in stage III, before birth, the lobular arrangement is no longer discernible (Steiniger et al 2007). By postmenstrual weeks 15–16, lymphocytes have been found in the mesenteric lymph nodes, but far fewer than those found in the liver and spleen (Hwang et al 2014).

From postmenstrual week 17, α-SMA-positive reticulum cells are found around arterioles. These increase in number and form a reticular framework from 20–23 postmenstrual weeks, when a primitive white pulp can be observed around arterioles. By 24 postmenstrual weeks, T and B lymphocytes become segregated; T cells are found within the SMA-positive reticular framework, and B cells aggregate close to the periarticular lymphoid sheath, where they form lymphoid follicles (Satoh et al 2009).

Changes to the position of the developing spleen are driven by the expansion of the right pleuroperitoneal canal to the left, and the consequent lengthening of the dorsal mesogastrium and its movements caused by stomach rotation. The dorsal mesogastrium becomes the splenorenal ligament (from the dorsal abdominal wall to the spleen) and the gastrosplenic ligament (from the spleen to the stomach) (see Fig. 21.6). There is some adhesion between the original left dorsal coelomic wall and the left leaf of the dorsal mesogastrium, although this does not extend as far as the spleen. The earlier lobulated character of the spleen disappears, but is indicated by the presence of notches on its upper border in the adult.

At birth the spleen weighs, on average, 13 g. It doubles its weight in the first postnatal year and triples it by the end of the third year. The spleen displays various developmental anomalies, including complete agenesis, multiple spleens or polysplenia, isolated small additional spleniculi and persistent lobulation. Asplenia and polysplenia are associated with other anomalies, especially those involving the cardiac and pulmonary systems. For details of the anatomical variation of the spleen, see Varga et al (2018).

Ultrasound antenatal imaging of the fetal abdomen

The abdominal circumference, routinely estimated at 20 postmenstrual weeks, is calculated from the anteroposterior diameter and the transverse abdominal diameter perpendicular to it, taken at the widest part of the abdomen. The section usually includes one entire rib and the stomach cavity (termed stomach bubble) and can be confirmed on the left side of the body (see Fig. 23.5G). Anteriorly, the connection of the umbilical cord can be confirmed (see Fig. 23.5H). Anomalies of the anterior body wall, exomphalos and gastroschisis, are readily detected. In exomphalos, a mass of peritoneal organs herniate through the base of the umbilical ring; in gastroschisis, loops of small intestine and colon float free in the amniotic fluid (see Fig. 23.6B) (Ionescu et al 2014).

POSTNATAL DEVELOPMENT OF THE GUT

Postnatal maturation of the gut is dependent on the establishment of an intestinal microbiota, which, in turn, is affected by term age, mode of delivery, type of feeding and any medical interventions. In cases of chorioamnionitis, preterm infants ingest bacterial products from the amniotic fluid: it has been suggested that this may be associated with preterm labour (Neu and Mai 2012). Chorioamnionitis is associated with an increased risk of necrotizing enterocolitis in preterm infants (Kallapur et al 2014). The prevalence of necrotizing enterocolitis is about 7% in infants delivered at 32 postmenstrual weeks with a birthweight between 500–1500 g. It develops after postnatal week 2, and is characterized by intestinal inflammation, systemic inflammatory response syndrome and multiorgan system failure. There is feeding intolerance, abdominal distention, and pneumatosis is seen on abdominal X-ray, showing intramural gas. It is thought to be caused by genetic predisposition, imbalanced microvascular tone, intestinal immaturity and abnormal microbial intestinal colonization (Sharma et al 2012).

Normal, term vaginal delivery establishes the initial colonization of the neonatal gut with maternal vaginal and intestinal flora. Two-way interactions between enteric microbes in a biofilm within the luminal glycocalyx of enterocytes modify intestinal permeability, increase T and B lymphocyte numbers within the mucosal lamina propria and mesenteric lymph nodes, and stimulate postnatal immune development (Martin et al 2012, Patel et al 2012, Vaarala 2012, Wynn and Neu 2012, Gritz and Bhandari 2015). Delivery by caesarean section results in the establishment of skin microbiota, different intestinal microbes and low microbiota diversity. Failure to develop an appropriate dynamic microbiota is thought to be associated with allergic and inflammatory conditions in later life (Wynn and Neu 2012). (For further reading, see Neu and Mai (2012), Bäckhed et al (2015), Rodríguez et al (2015), Dzidic et al 2018.)

The onset of feeding also contributes to gut maturity. Breast milk, considered an 'active fluid', is complex and unique, containing a range of growth factors, cytokines, chemokines and stem cells (Fanos et al 2017, Bardanzellu et al 2018). It also contains a range of breast-derived and blood derived cells which pass to the infant. Milk leukocyte composition is highest in colostrum and decreases in transition and mature milk; these maternal cells can move from the infant gut to lymph nodes, spleen and liver; an increase in breast milk leukocytes is seen when the infant has an infection, suggesting a dynamic interaction within the mother–infant dyad (Ch. 14, p. 233) (Witkowska-Zimny and Kaminska-El-Hassan 2017). Breast milk is a source of epidermal growth factor, which promotes postnatal mucosal development, helps mucosal repair, and affects the production of immunoglobulin A (IgA) in the gut mucosa (Vaarala 2012). Breast milk also contains a microbiome of about 50 different genera, contributing to the bacterial populations the neonate ingests during vaginal delivery. Sialylated human milk oligosaccharides can induce transcription responses in the intestinal microbiota, indicating the interactive nature of establishing the gut microbiome and gut maturation (Bardanzellu et al 2018). Breast feeding is associated with reduction in postnatal necrotizing enterocolitis and sepsis.

Undernutrition leads to villous atrophy: in the preterm infant, parenteral nutrition is associated with changes in intestinal structure and function that may lead to increased intestinal permeability. Antibiotic therapy within the neonatal period can lead to changes in, and the establishment of, the normal intestinal microbiota (Martin et al 2012). The normal pattern of microbiome formation is disrupted in children with undernutrition causing stunting. Human milk oligosaccharides are not absorbed in the proximal gut, but function as prebiotics for bacterial strains, enhancing gut barrier function and protecting against enteropathogen infection. Sialic acid-containing oligosaccharides are especially important for postnatal neural and musculoskeletal development: their levels are 20 times higher in human milk than bovine milk, suggesting that their use in formula milk supplementation would improve growth outcomes in undernourished infants and children (Charbonneau et al 2016).

The first passage of faeces of the newborn is termed meconium. This dark, sticky, viscid substance is formed from the passage of amniotic fluid, sloughed mucosal cells, digestive enzymes and bile salts along the fetal gut. Meconium becomes increasingly solid as gestation advances but does not usually pass out of the fetal body while *in utero*. Fetal distress produced by anoxia may induce the premature defecation of meconium into the amniotic fluid, with the risk of its inhalation. At birth, the colon contains 60–200 g of meconium. The majority of neonates defecate within the first 24 hours after birth. Delayed passage of stool beyond this time is associated with Hirschsprung's disease (see p. 334.e1) or imperforate anus. The normal passage of meconium continues for the first 2 or 3 days after birth, and is followed by a transition to faecal stools by postnatal day 7.

CHAPTER 22

Development of the urogenital system

DEVELOPMENT OF THE POSTERIOR COELOM WALL

From stage 11 (29–30 days postfertilization; see Fig. 23.3 for comparison of postfertilzation days and the clinical scale of postmenstrual weeks) the dorsal region of the wall of the intraembryonic coelom is composed of a mesenchymal population termed intermediate mesenchyme. Predictive fates of epiblast cells that transform to mesenchyme on ingression through the primitive streak show temporally specified induction of cells that ingress later than those that form the lateral halves of the somites and earlier than mesoblast forming the lateral plate, and become epithelial coelomic wall at the end of their migration (see Fig. 10.3). The rostral limit of the intermediate mesenchymal population, in stage 10 embryos, is lateral to somite 6. It lengthens caudally during development, and is sited (in the folded embryo) at the junction between the splanchnopleuric mesenchyme (surrounding the gut medially) and the somatopleuric mesenchyme (subjacent to the ectoderm laterally). Ultimately it blends with splanchnopleuric mesenchyme around the cloaca (**Fig. 22.1**). After the early migration of mesoblast, further intermediate mesenchyme is formed by proliferation of the overlying coelomic epithelial wall to give a ventrally projecting urogenital ridge (previously termed the nephrogenic cord). Interaction between the coelomic epithelium and its mesenchymal progeny give rise, in a rostro-caudal progression, to the kidneys, suprarenal glands, gonads and reproductive ducts.

URINARY SYSTEM

In lower vertebrates, intermediate mesenchyme typically develops serial, segmental, epithelial diverticula termed nephrotomes. Each nephrotome encloses a cavity, the nephrocele, which communicates with the coelom through a peritoneal funnel, the nephrostome (**Fig. 22.2**). The dorsal wall of a nephrotome evaginates as a nephric tubule. The dorsal tips of the cranial nephric tubules bend caudally and fuse to form a longitudinal primary excretory duct, which grows caudally and curves ventrally to open into the cloaca. The more caudally placed, and therefore chronologically later, tubules open secondarily into this duct or into tubular outgrowths from it. Glomeruli, specific arrangements of capillaries and overlying coelomic epithelium, arise from the ventral wall of the nephrocele (internal glomeruli) or the coelomic wall adjacent to the peritoneal funnels (coelomic or external glomeruli), or in both situations (see Fig. 22.2). External glomeruli, composed of recognizable podocytes, facing the intraembryonic coelom, and the lateral openings of ciliated peritoneal funnels, have been described in turtle embryos (Collins 1990): it is doubtful whether external glomeruli develop in human embryos.

The renal excretory system is described as forming from three organs, the pronephros, mesonephros and metanephros, which succeed each other in time and space, such that the last to develop is retained as the permanent kidney (see Figs 22.1–22.2). It is difficult to provide reliable criteria by which to distinguish these stages or to define their precise limits in human embryos. Much of the knowledge on development of the meso- and meta-nephros comes from experimental studies of mouse embryos and more recently from *in vitro* study of human stem cell-derived kidney organoids. Although kidney development is evolutionarily conserved in mammals, there are significant heterochronic differences between murine and human development that make direct extrapolation between the species unwise; similarly, extrapolation of *in vitro* conditions to *in vivo* development should be treated with caution.

Pronephros

A pronephros is present in human embryos only as clusters of cells in the most cranial portions of the urogenital ridge (see Figs 22.1–22.2).

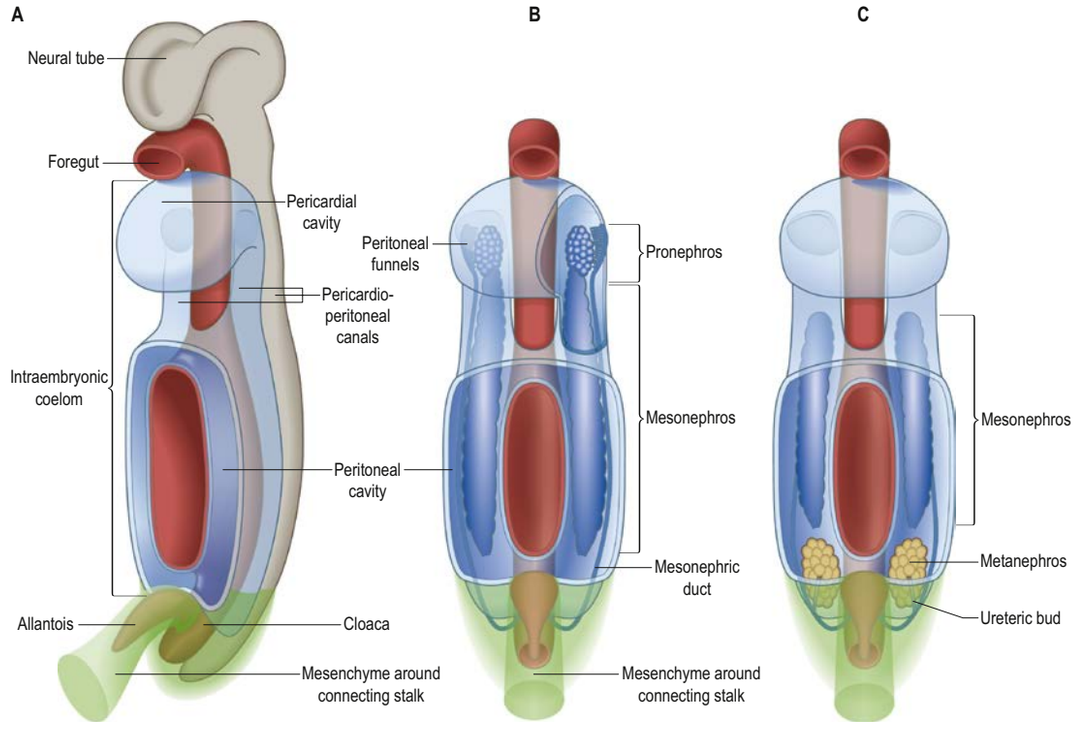

Fig. 22.1 **A**, The major epithelial populations within a stage 11 embryo, viewed from a ventrolateral position. **B**, The position of pronephros and mesonephros on the posterior thoracic and abdominal walls. **C**, The position of mesonephros and metanephros.

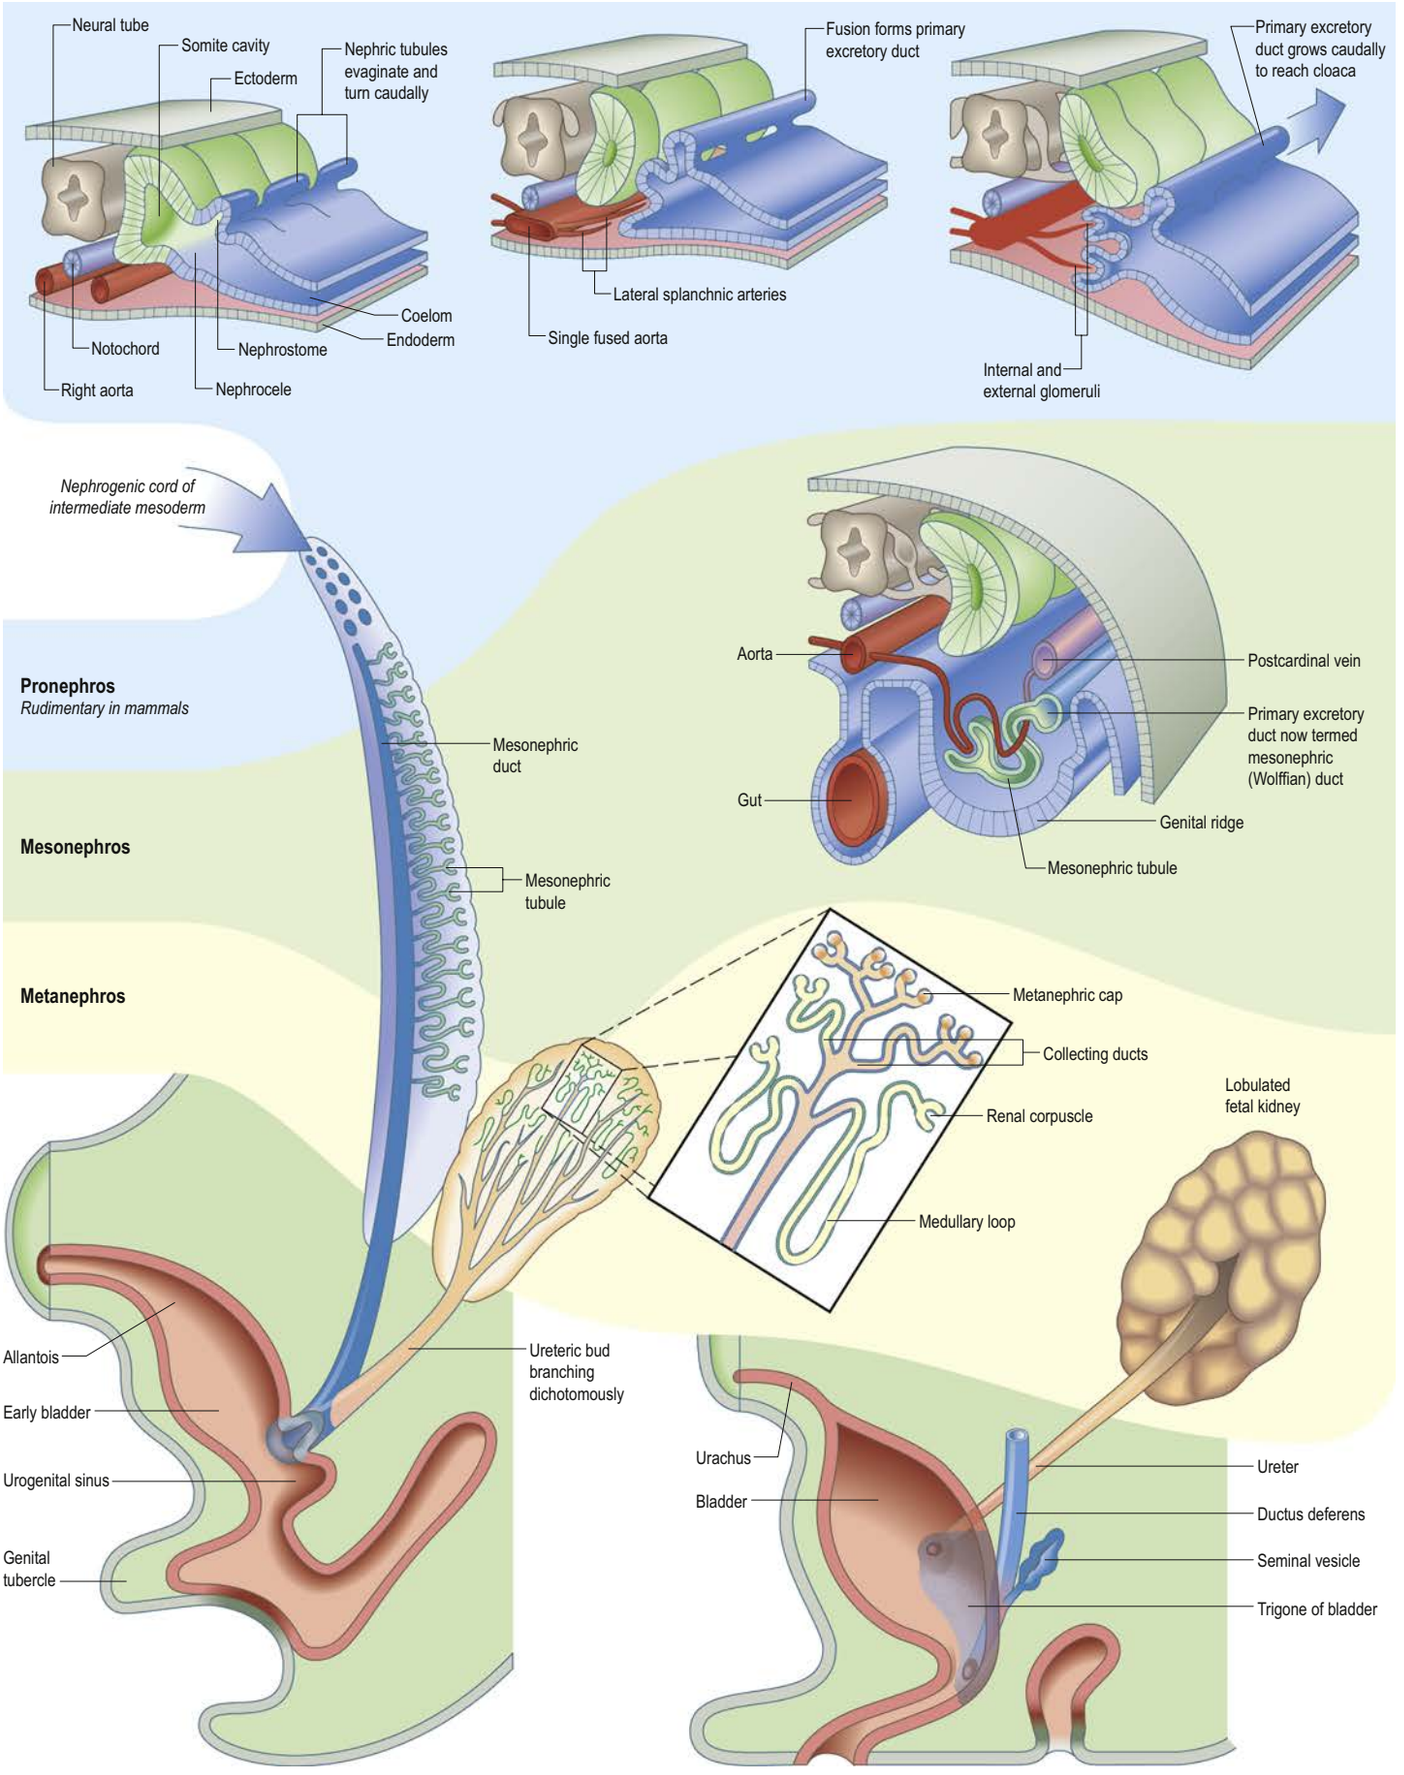

Fig. 22.2 The principal features of the primitive vertebrate nephric system for comparison with the development of the human nephric system. A considerable period of embryonic and fetal life has necessarily been compressed into a single diagram. (Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd ed. London: Pitman Medical & Scientific.)

More caudally, similar groups of cells appear and become vesicular. The dorsal ends of the most caudal of the vesicles join a primary excretory duct. Their central ends are connected with the coelomic epithelium by cellular strands that probably represent rudimentary peritoneal funnels. Glomeruli do not develop in association with these cranially situated nephric tubules, which ultimately disappear.

Primary excretory duct

In stage 11 embryos of approximately 14 somites, a primary excretory duct can be seen as a solid rod of cells in the dorsal part of the urogenital ridge. Its cranial end is about the level of somite 9 and its caudal tip merges with the undifferentiated mesenchyme of the ridge. It differentiates before any nephric tubules and, when the latter appear, it is at first unconnected with them. In older embryos, the duct has lengthened and its caudal end becomes detached from the urogenital ridge to lie beneath the ectoderm. From this level, it grows caudally, independent of the nephrogenic mesenchyme, and then curves ventrally to reach the wall of the cloaca. The lumen develops progressively from its caudal end to form a true duct, which opens into the cloaca in stage 12 embryos.

Mesonephros

From stage 12 mesonephric tubules, which develop from the intermediate (now nephrogenic) mesenchyme between somite levels 8 and 20, begin to connect to the primary excretory duct, which is now renamed the mesonephric duct. More caudally, a continuous ridge of nephrogenic mesenchyme extends to the level of somite 24. The mesonephric tubules (nephrons) are not metameric and there may be two or more mesonephric tubules opposite each somite.

Within the mesonephros, each tubule first appears as a condensation of mesenchyme cells that epithelialize and form a vesicle. One end of the vesicle grows towards and opens into the mesonephric duct, while the other dilates and invaginates. The outer stratum forms the glomerular capsule, while the inner cells differentiate into mesonephric podocytes that clothe the invaginating capillaries to form a glomerulus. The capillaries are supplied with blood through lateral branches of the aorta. It has been estimated that 70–80 mesonephric tubules and a corresponding number of glomeruli develop. However, these tubules are not all present at the same time: it is rare to find more than 30–40 in an individual embryo because the cranial tubules and glomeruli develop and atrophy before those situated more caudally have developed.

By stage 17 each mesonephros is an elongated, spindle-shaped organ that projects into the coelomic cavity, one on each side of the dorsal mesentery, from the level of the septum transversum to the third lumbar segment. This whole projection is called the mesonephric ridge, mesonephros or Wolffian body (see Fig. 22.1B–C; **Fig. 22.3**). It develops subregions, and the suprarenal gland and gonad develop on its medial surface. There are striking similarities in structure between the mesonephros and the permanent kidney or metanephros, but the mesonephric nephrons lack a segment that corresponds to the descending limb of the loop of Henle. The mesonephros is believed to produce urine by stage 17. A detailed comparison of the development and function of the mesonephros and metanephros in staged human embryos is not available.

In stage 18 embryos the mesonephric ridge extends cranially to about the level of rib 9. In both sexes, the cranial end of the mesonephros atrophies. In stage 19 embryos a mesonephros is found only in the first three lumbar segments, although it may still possess as many as 26 tubules. The most cranial one or two tubules persist as rostral aberrant ductules (see Fig. 22.13); the succeeding five or six tubules develop into either the efferent ductules of the testis and lobules of the head of the epididymis (male), or the tubules of the epoophoron (female); the caudal tubules form the caudal aberrant ductules and the paradidymis (male), or the paroophoron (female).

Mesonephric duct

Once mesonephric nephrons connect to the primary excretory duct, it is renamed the mesonephric duct. This runs caudally in the lateral part of the urogenital ridge, and projects into the cavity of the coelom in the substance of a mesonephric fold at the caudal end of the ridge (see Fig. 22.3). As the mesonephric ducts from each side approach the urogenital sinus (see below) the two mesonephric folds fuse, forming a transverse partition across the cavity of the pelvis, somewhat inappropriately called the genital cord (see Fig. 22.3). The insertion of the mesonephric duct into the urogenital sinus occurs at stage 13 and remains associated with segmental levels 31–32 (S2–S3) as the embryo lengthens

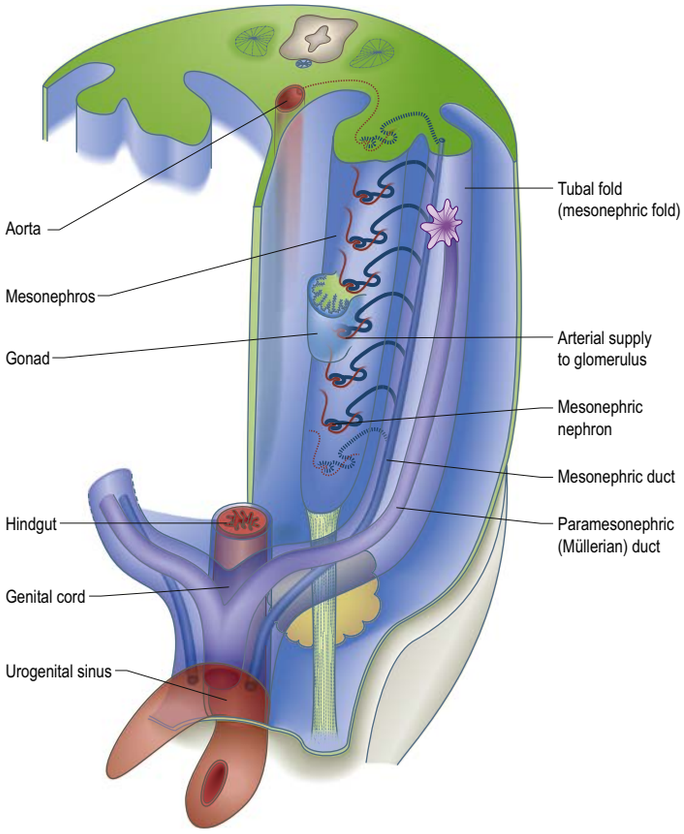

Fig. 22.3 The relative positions of the mesonephros and early gonad in the abdomen in the ambisexual stage of development. The mesonephric and paramesonephric ducts run within the tubal fold to the urogenital sinus.

(Kruepunga et al 2018). In the male, the mesonephric duct itself becomes the canal of the epididymis, ductus deferens and ejaculatory duct, whereas it involutes in the female.

Urogenital sinus and allantois

The early cloaca consists of a dorsal, tubular, enteric hindgut region extending from the caudal intestinal portal to the cloacal membrane, and a ventral, blind-ending allantois extending from the connecting stalk. It is a slightly dilated cavity, lined by endoderm (Fig. 22.1). The allantois and enteric hindgut portions of the cloaca are separated, from stage 15, by the proliferation of the urorectal septum, a partition of mesenchyme and endodermal cloacal wall in the angle of the junction of enteric hindgut and allantois (**Fig. 22.4**; see Fig. 22.7). Molecular markers of the urorectal septum mesenchyme, also termed the intercloacal mesenchyme, include *Six1* and *Six2* (Wang et al 2011, 2013). The endodermal epithelium beneath the mesenchyme of the urorectal septum moves towards the cloacal membrane and fuses centrally, separating the intraembryonic urogenital sinus and extraembryonic allantois (ventrally), bounded now by a urogenital membrane, from the presumptive rectum and upper anal canal (dorsally), bounded by the anal membrane (Kruepunga et al 2018). Both membranes break down during stages 18–20. The urogenital sinus is continuous cranially with the allantoic duct within the connecting stalk. During development it forms the vesico-urethral canal with a middle, narrow channel, the pelvic portion, and a caudal, deep, phallic section that is open to the amniotic cavity. It receives the mesonephric and paramesonephric ducts and will become the urinary bladder and urethra (Fig. 22.4A).

Metanephros

The pronephros and mesonephros are linear structures. They both contain stacks of tubules distributed along the craniocaudal axis of the embryo, an arrangement that results in the production of hypotonic urine in the embryo and fetus. In the mesonephric kidney, development proceeds in a craniocaudal progression, and cranial nephrons degenerate before caudal ones are produced. In the metanephric kidney, development is patterned radially such that the outer cortex is the last part to be formed, and nephrons are arranged concentrically with the loops

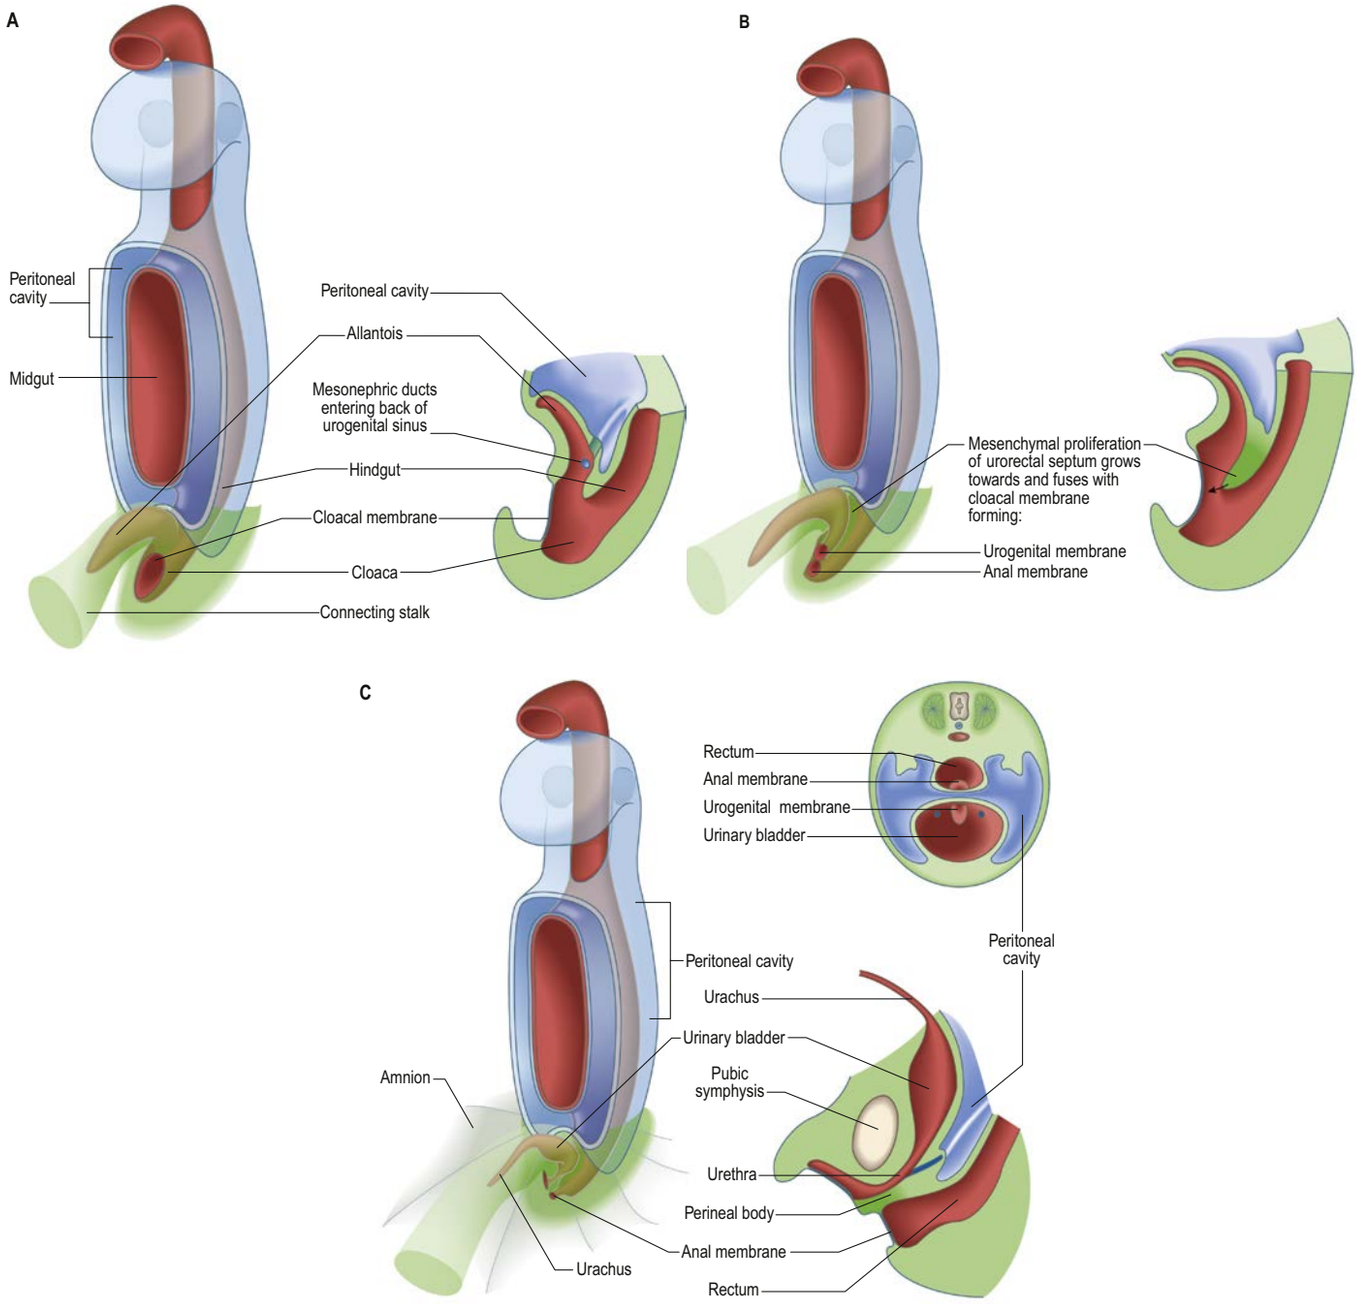

Fig. 22.4 The division of the hindgut into urinary and enteric parts: left ventrolateral view of the intraembryonic coelom and corresponding midsagittal sections. **A**, The early cloaca. **B**, Proliferation of the urorectal septum. **C**, Complete separation of the urethra and anal canal, and position of the perineal body.

of Henle directed towards the renal pelvis. This arrangement allows different concentration gradients to develop within the metanephric kidney and results in the production of hypertonic urine.

The metanephric kidney develops from three sources from stage 13. An evagination of the mesonephric duct, the ureteric bud, and a local condensation of mesenchyme, the metanephric blastema, form the nephric structures (**Fig. 22.5**). Angiogenic mesenchyme migrates into the metanephric blastema slightly later to produce the glomeruli and vasa recta. It is possible that an intact nerve supply is also required for metanephric kidney induction. A range of intra- and extracellular factors potentially involved in metanephric development have been discussed (Kanwar et al 2004).

The following interactions occur sequentially in the development of the metanephric kidney (see Fig. 22.5). Although the timing of human development differs from that in other mammalian species that have been described, similar growth and transcription factors are thought to underpin kidney development (Davidson 2009, Batchelder et al 2010, Faa et al 2012, Chai et al 2013). The ureteric bud bifurcates when it comes into contact with the metanephric blastema in response to extracellular matrix molecules synthesized by the mesenchyme. Both chondroitin sulphate proteoglycan synthesis and chondroitin sulphate glycosaminoglycan processing are necessary for branching of the ureteric bud. The proximal part of the ureteric bud elongates to form the developing ureter and the first generation of branches form the major and minor calyces of the renal pelvis (see Fig. 22.6). Further ureteric branches form the collecting ducts and as they elongate the metanephric mesenchyme condenses adjacent to each of them. An adhesion molecule, syndecan, can be detected between the mesenchymal cells in the condensate. The cells switch off expression of neural cell adhesion molecule (N-CAM), fibronectin and collagen I, and start to synthesize liver cell adhesion molecule (L-CAM; also called E cadherin) and the basal lamina constituents, laminin and collagen IV. The mesenchymal clusters are thus converted to small groups of epithelial cells that undergo complex morphogenetic changes. Each epithelial group elongates, initially forming a comma-shaped, and then an S-shaped, body, with a dilated sac at its proximal end and an elongating distal end that subsequently fuses with a collecting duct (see Fig. 22.5). Each dilated sac invaginates to form a cup: the outer cells become parietal, glomerular capsule cells, and the inner ones become visceral, epithelial podocytes. The podocytes develop in close proximity to the angiogenic

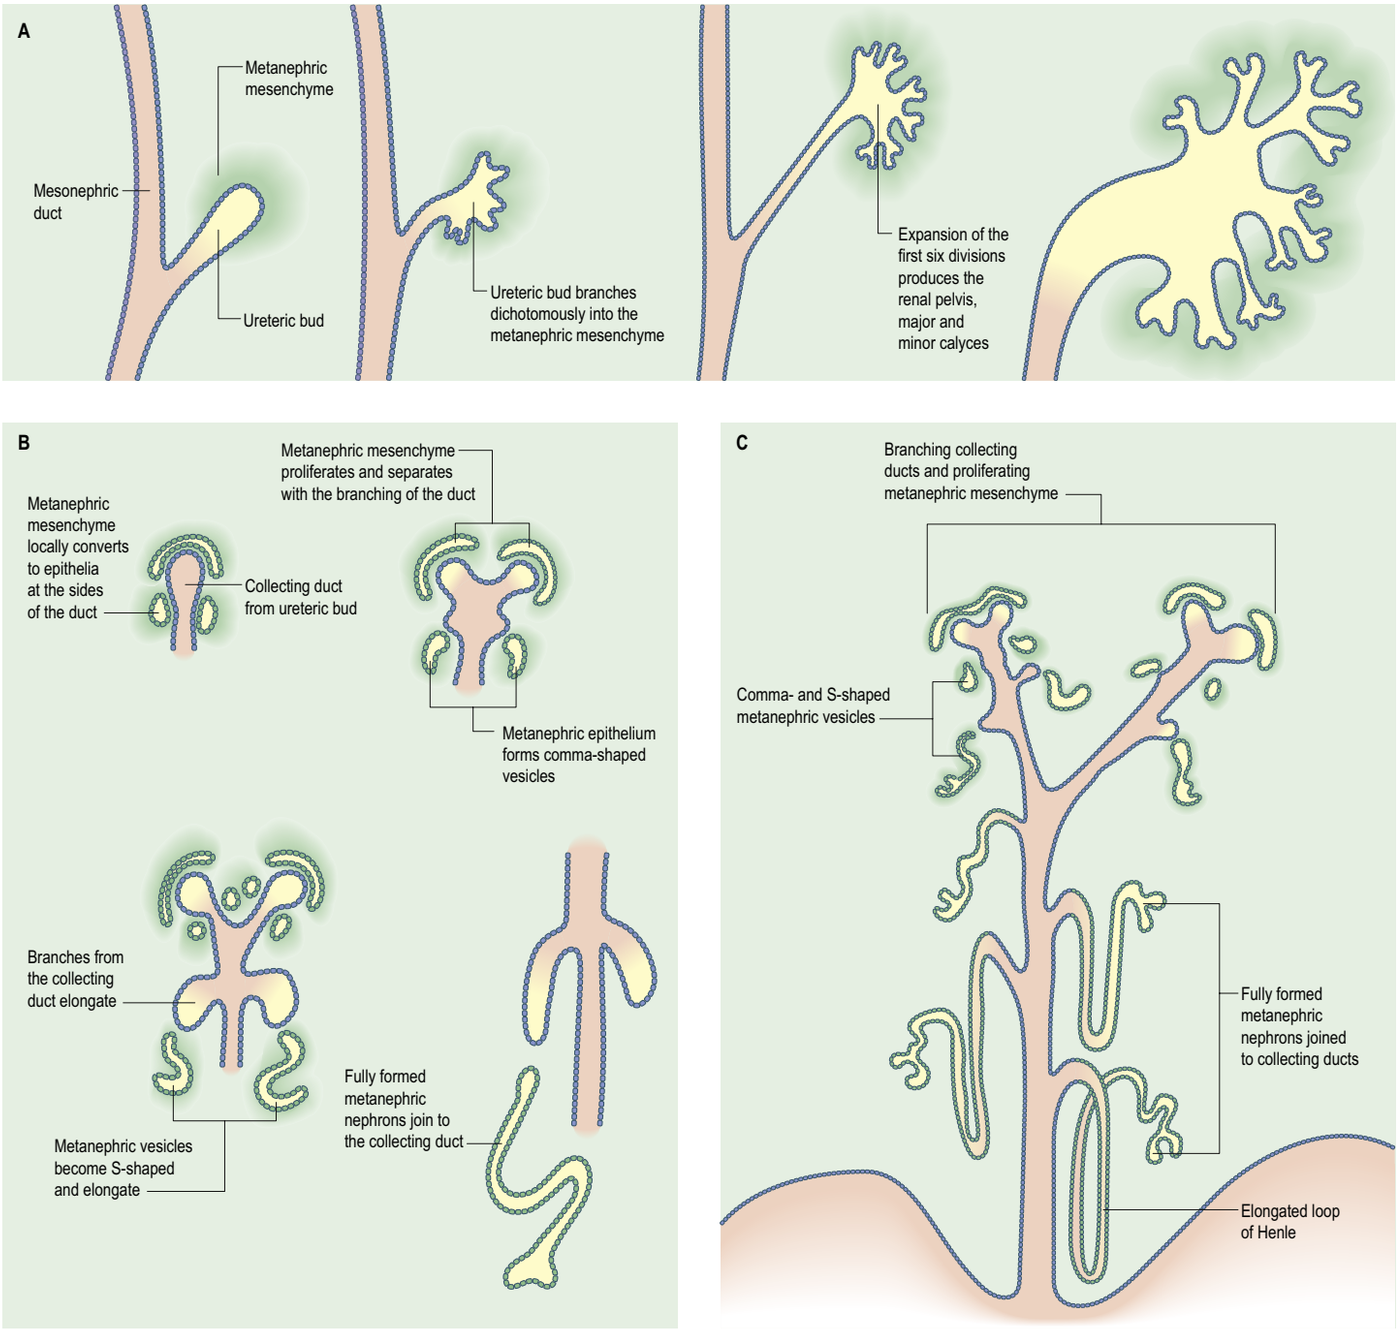

Fig. 22.5 An overview of metanephric kidney development. **A**, The ureteric bud arises from the mesonephric duct. The metanephric mesenchyme proliferates and separates with each subdivision of the ureteric bud. **B**, The metanephric mesenchyme converts to epithelia, forming comma- and S-shaped vesicles, which become metanephric nephrons. **C**, All stages of metanephric development are present concurrently. The most recently formed nephrons are on the outer aspect of the kidney.

mesenchyme of invading capillaries which give rise to the endothelial and mesangial cells of the glomerulus. Both cell lines contribute to components of the glomerular basement membrane. The direct mutual support of two epithelial layers, rather than support of an epithelium by an underlying lamina propria, is unusual and seen only in the lung and brain (see Fig. 11.2). Podocytes and endothelial cells contribute to the generation of mutual basal laminal proteins and the formation of the glomerular basement membrane. The isoforms of type IV collagen within this layer follow a specific programme of maturation as the filtration of macromolecules from the plasma becomes restricted. Platelet-derived growth factor (PDGF) β-chain and the PDGF receptor β-subunit (PDGFR β) have been detected between stage 23 and the end of the first trimester; PDGF β-chain has been localized in the dilated epithelial sac during its comma- and S-shaped stages and PDGFR β is expressed in the undifferentiated metanephric blastema, vascular structures and interstitial cells. Both PDGF β-chain and PDGFR β are expressed by mesangial cells, which may promote further mesangial cell proliferation. Innervation is also necessary for metanephric development: nephrogenesis is completely blocked if developing kidney rudiments are incubated with antisense oligonucleotides that neutralize nerve growth factor receptor (NGF-R) mRNA. With continuing elongation of the collecting ducts and adjacent coalescence of mesenchymal cells, all stages of nephron differentiation can be seen concurrently (see Fig. 22.5C). A number of genes involved in the development of the renal medulla and vasa recta in the mouse have been identified (Song and Yosypiv 2012).

Metanephric mesenchyme will develop successfully *in vitro*, which makes experimental perturbation of non-human kidney development comparatively easy to evaluate. Early experimental studies demonstrated that other mesenchymal populations, and spinal cord, were able to induce ureteric bud division and metanephric development. Culture of hiPSC along a kidney lineage has resulted in the generation of nephron progenitor cells and kidney organoids which are being used to study aspects of podocyte development (Shamin et al 2016, Hale et al 2018). Time-lapse study of cultured mouse embryonic kidney has shown that the original branching morphogenesis of the collecting ducts (from the ureteric bud) changes during maturation such that the branching point moved centripetally. This may promote elongation of outer cortical collecting ducts, resulting in a renal pattern rather than

one that would result from repeated dichotomous branching morphogenesis. Biomechanical factors generated by the outer renal capsule may contribute to these temporal specifications of epithelial mesenchymal interactions (Lindström et al 2015).

Fetal kidney maturation

Nephrons are added to the metanephric kidney throughout the fetal period with different temporal patterning. The earliest ureteric bud branches are absorbed into the renal pelvis so that an average of 44 collecting ducts open into 8 papillae. After the 13th to 15th branching, several metanephric mesenchymal to epithelial transformations can occur along adjacent collecting ducts, forming arcades of juxtaglomerular nephrons in the inner renal cortex. The mid and outer renal cortices are induced by collecting tubules that elongate towards the renal capsule. Addition of new nephrons in the outermost cortex occurs by metanephric mesenchymal induction at collecting duct tips, at a constant average of 83 μm from the inner side of the renal capsule, with only two layers of mesenchyme intervening (Minuth 2018). This subcapsular region of the developing kidney is called the nephrogenic zone. It contains angiogenic mesenchymal populations forming embryonic blood vessels, which means that the tissues are at lower oxygen tension than more central regions where endothelial glomeruli are established. It has been suggested, on the basis of animal experimentation, that increased oxygen tension promotes glomerular differentiation, whereas low oxygen tension maintains stem cell populations and continued developmental interactions (Rymer et al 2014). The addition of new nephrons normally ceases after postmenstrual week 38, although the mechanism is not known (Minuth 2018). Nephrogenesis has been reported as complete by postmenstrual week 34, presumably in fetuses with appropriate weight (Solhaug and Jose 2017). Mature renal capsules contain a constant number and proportion of podocytes relative to other glomerular cell types, whether formed early or later between postmenstrual weeks 20 and 40 (Ryan et al 2018).

The metanephric kidney is lobulated throughout fetal life, but this condition usually disappears during the first year after birth (see Fig. 22.8). Varying degrees of lobulation occasionally persist throughout life.

The growth of left and right kidneys is well matched during development: fetal kidney volume increases most during the second trimester in both sexes. Male fetuses show greater values for renal volume than female fetuses from the third trimester onwards (Geelhoed et al 2009). In neonates and infants, total renal blood flow is determined by clearance of *p*-aminohippurate (PAH), which measures effective renal plasma flow (ERPF); flow correlates with postmenstrual age. ERPF increases in infants born preterm from 20 ml/min/1.73m^2 (the latter unit is a standard measure of body surface area) at postmenstrual week 30, to 45 ml (same units) at postmenstrual week 35 and 83 ml at postmenstrual week 40. In full-term infants, during postnatal months 1–3, ERPF increases to 300 ml/min/1.73 m^2 and thereafter reaches values of 650 ml/min/1.73 m^2 by postnatal months 12–24. The full-term neonatal kidney has a greater percentage of blood flow to inner cortical and medullary areas than the adult kidney (Solhaug and Jose 2017).

At delivery of preterm and low birth weight babies nephrogenesis is still active. It has been shown to continue for up to 3 postnatal weeks in experimental non-hominids, however, there is evidence of nephrogenic perturbation resulting in oligonephropathy in 8–24% of preterm deliveries (Minuth 2017). Dilated Bowman's space and shrunken glomerular tufts have been identified in the outer renal cortex. It may be that the general increase in oxygen tension after birth causes rapid differentiation of all formed nephrons but inhibition of further development of immature outer cortical mesenchymal populations. Kidney weight is lower in infants with low (< −2 SDs) birth weight, reflecting a decreased number of nephrons. This relative smaller kidney size continues into early childhood and may be a factor in adult kidney pathology (Geelhoed et al 2009). Preterm neonates achieve a similar estimated glomerular filtration rate as term neonates soon after birth, possibly by glomerular hyperfiltration in the nephrons present (Kandasamy et al 2018).

Endocrine development of the kidney

The kidney functions not only as an excretory organ, but also as an endocrine organ, secreting hormones that are concerned with renal haemodynamics. Before birth, homeostasis is controlled by the placenta. The fetal kidney produces amniotic fluid. The kidneys of premature babies of less than 36 postmenstrual weeks are immature and contain incompletely differentiated cortical nephrons that compromise their ability to maintain homeostasis. Problems of immaturity are further compounded by the effects of hypoxia and asphyxia, which modify renal hormones.

Renal hormones include the renin–angiotensin system, renal prostaglandins, the kallikrein–kinin system and renal dopamine. Renin is found in the smooth muscle cells of arterioles, interlobular arteries and branches of the renal artery, and has also been described in the distal convoluted tubule cells. Renal dopamine is produced (mainly) by the enzymatic conversion of L-dopa to dopamine in the early segments of the proximal convoluted tubule, and is also sourced locally from dopaminergic nerves. Other renal hormones include an antihypertensive lipid produced in the interstitial cells of the renal medulla, and, possibly, histamine and serotonin. Growth factors produced by human embryonic kidney cells include erythropoietin and interleukin β (which stimulate megakaryocyte maturation) and transforming growth factor-β. For reviews of the various factors in this aspect of kidney development see Yosypiv (2009) and Kurtzeborn et al (2018). Prostaglandins may be important in the fetus in the regulation of renal blood flow (Solhaug and Jose 2017).

Ascent of the kidney

The metanephric kidney is initially sacral, but as the ureteric outgrowth lengthens and the body curvature diminishes, it becomes positioned progressively more cranially. The metanephric pelvis lies on a level with the fourth lumbar vertebra at about stage 18 (Hikspoors et al 2015). During this period the ascending kidney receives its blood supply sequentially from arteries in its immediate neighbourhood, i.e. the middle sacral and common iliac arteries. The definitive renal artery is not recognizable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries. Additional renal arteries are relatively common, and may enter at the hilum or at the upper or lower pole; they also represent persistent mesonephric arteries.

Ureter

At first, the distal end of the ureter is connected to the dorsomedial aspect of the mesonephric duct but, as a result of differential growth, this connection comes to lie lateral to the duct. The wall of the early ureter is initially highly permeable. Its lumen later becomes obliterated and is subsequently recanalized. Both of these processes begin in intermediate portions of the ureter and proceed cranially and caudally. Recanalization is not associated with metanephric function, but perhaps reflects the rapid elongation of the ureter as the embryo grows. Two fusiform enlargements appear at the lumbar and pelvic levels of the ureter at 5 and 9 months, respectively (the pelvic enlargement is inconstant). As a result, the ureter shows a constriction at its proximal end (pelviureteric region) and another as it crosses the pelvic brim. A third narrowing is always present at its distal end and is related to the growth of the bladder wall. Ureteric smooth muscle differentiation occurs from the ureterovesical junction to the ureteropelvic junction. The processes that occur during the development of typical and atypical smooth muscle cells that generate ureteric peristaltic waves are unknown. Interstitial cells of Cajal-like cells have been identified in mouse embryos before ureteric pacemaker activity first occurs (Rassouly and Lu 2013).

Urinary bladder

The urinary bladder develops from the cranial vesico-urethral canal, which is continuous above with the allantoic duct (see Fig. 22.4; **Figs 22.6–22.7**). The mesonephric ducts open into the urogenital sinus during stage 13. The ureters develop as branches of the mesonephric ducts, which gain their own access to the developing bladder, and their orifices open separately into the bladder on the lateral side of the opening of the mesonephric ducts during stage 17. Later, the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens into that part of the urogenital sinus that subsequently becomes the prostatic urethra (Kruepunga et al 2018) (see Fig. 22.6E). The remainder of the vesico-urethral canal forms the body of the bladder and urethra, and its apex is prolonged to the umbilicus as a narrow canal, the urachus.

For many years, it was believed that the absorption of the mesonephric ducts into the urogenital sinus contributed a mesodermal epithelium into the endodermal bladder, limited to the trigone and the dorsal wall of the proximal half of the prostatic urethra extending to the opening of the prostatic utricle and ejaculatory ducts, or its female homologue, the whole female urethral dorsal wall. Studies on transgenic mice have demonstrated that the region of the combined ducts close to the urogenital sinus, referred to as the common nephric duct, undergoes local apoptosis as a part of the normal development of the trigone region of the bladder and the establishment of separate entry

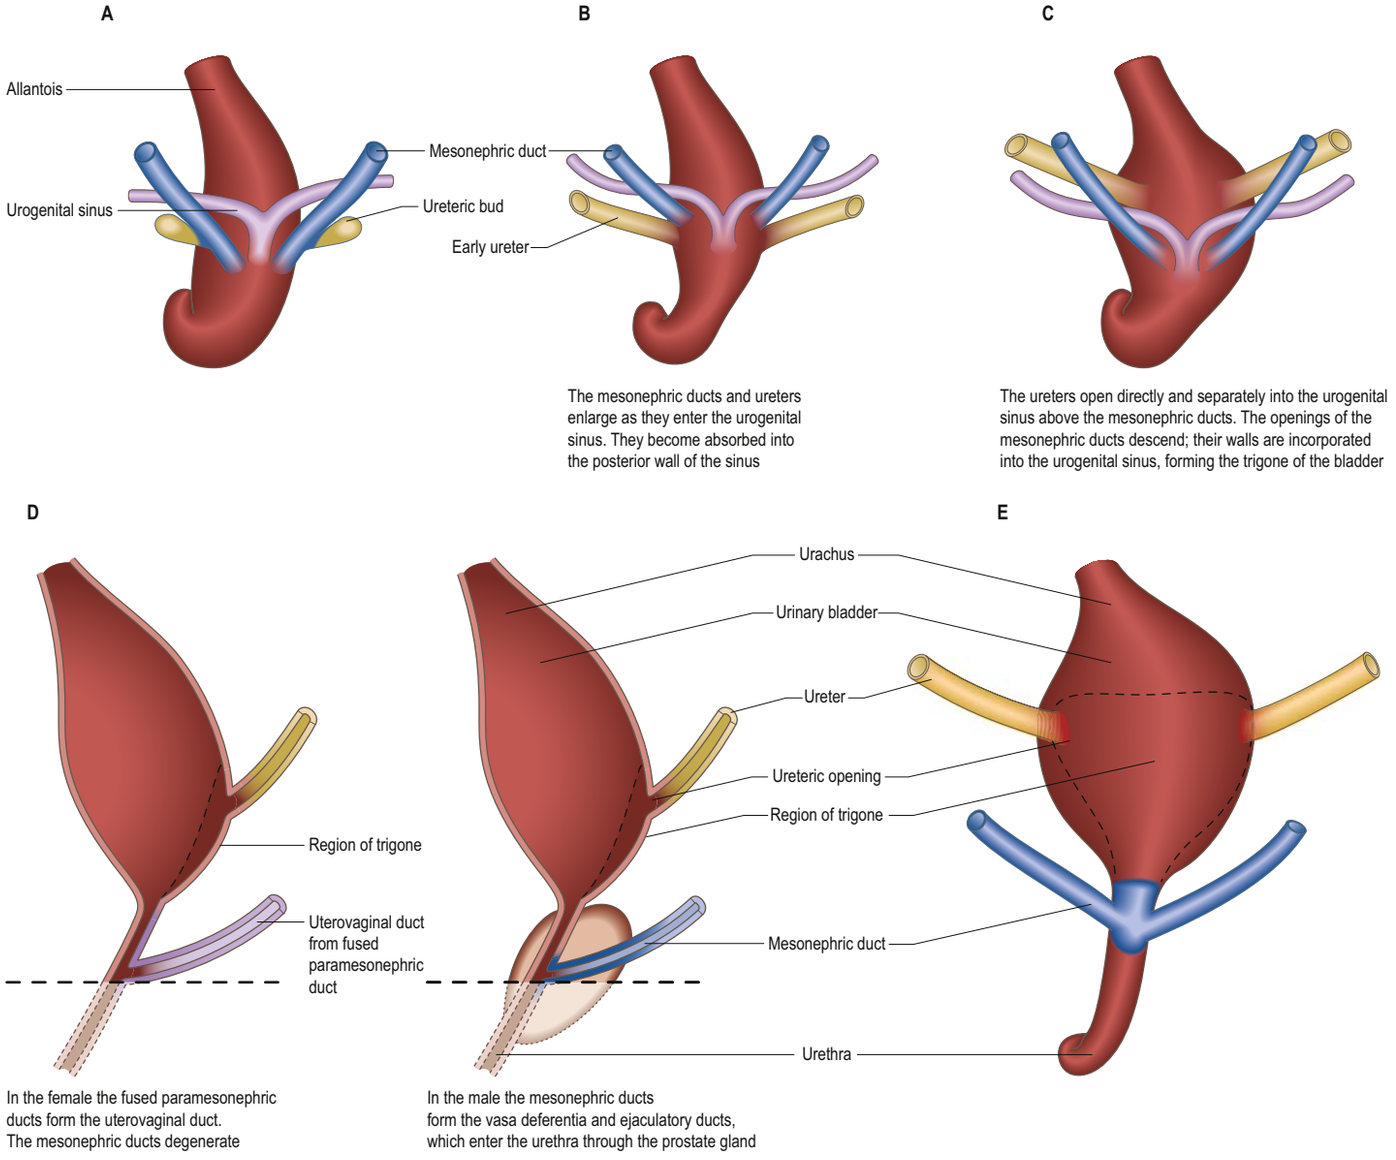

Fig. 22.6 The development of the urinary part of the urogenital sinus and formation of the trigone of the bladder. **A–C**, **E**, Posterior views. **D**, Male and female, median sagittal sections. (Based on Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

points for the ureters and mesonephric ducts (Mendelsohn 2009). Retinoic acid is required for ureteric insertion into the urogenital sinus (Batourina et al 2005). There is no mesodermal epithelial contribution to the bladder at the trigone. This is supported by the observation that *in vitro*, combination of fetal urogenital sinus mesenchyme with epithelial mesoderm or endoderm produces different outcomes. Tissue recombined with endoderm gives rise to prostatic epithelium, whereas the same mesenchyme combined with epithelial mesoderm forms seminal gland epithelium. Trigone epithelium differentiates into prostatic epithelium, confirming an endoderm lineage (Tanaka et al 2010).

The previous mechanism for trigone development also suggested that the muscle in that region was derived from the ureter and contributed to the valve-like entry point that prevents urinary reflux. Studies have now shown that the ureter passes through a tunnel in the bladder wall in parallel with blood vessels and that a tunnel forms even in the absence of ureters (Viana et al 2007). Study of smooth muscle progenitors shows that the bulk of the trigone is derived from bladder muscle (detrusor); there is a limited contribution from ureteric longitudinal smooth muscle fibres at the lateral edges. Eponymous muscular tissues such as Mercier's bar (between the ureteric orifices) and Bell's muscle (extending caudally from the ureteric orifices to the apex of the trigone) that were previously thought to arise from the ureter, have been shown to be derived from urinary bladder muscle (Viana et al 2007).

Differentiation of the bladder mucosal epithelium to transitional epithelium can be seen from about postmenstrual week 10 (Rassouly and Lu 2013). Urothelium develops from both the original mesonephric duct epithelium of the ureteric bud and the endodermal epithelium of the urogenital sinus which becomes the bladder, and in places it is responsive to different local osmolarity. The cells express uroplakin, which is thought to be involved in signalling during the epithelial/mesenchyme interactions that are involved in urinary tract development. The differentiation of the urothelium is a significant element in the development of the blood–urine barrier; genetic modification of uroplakin genes suggests their perturbation is associated with the development of congenital anomalies of the urinary tract (Carpenter and McHugh 2017).

Bladder filling and emptying cycles are required for normal bladder remodelling during fetal development; in this process, detrusor smooth muscle cells undergo cyclical apoptosis and proliferation. Mechanical stretching promotes proliferation. Bladders in which the fluid is diverted do not show this cycle, and do not enlarge or undergo normal remodelling. The detrusor stops growing, producing a low-volume, low-compliance bladder, although the serosal connective tissues continue to expand (Wei et al 2012). As yet, there is little information on the development of bladder interstitial cells of Cajal, which are present within detrusor, bladder microvessels and the mucosal lamina propria (Johnston et al 2010).

Ultrasound antenatal imaging of the urinary system

The fetal bladder may be identified by ultrasound examination at postmenstrual weeks 9–11 in transverse and sagittal section. Filling and emptying over a 30–45 minute cycle can be demonstrated. The absence

of a bladder image at postmenstrual week 13 or later is considered abnormal. At postmenstrual week 20, the kidneys are best visualized in a section of the abdomen caudal to that used for abdominal circumference estimation. The diameter of the renal pelvis is reported in the anterior posterior view; 7 mm or less is considered normal around postmenstrual week 20 (To and Pereira 2015).

The routine use of ultrasound as an aid to *in utero* diagnosis of anomalies has revealed a prevalence of 1–2 abnormal fetuses per 1000 ultrasound procedures, of which 20–30% are anomalies of the genitourinary tract, detectable as early as postmenstrual weeks 12–15. The decision to be made after such a finding is by no means clear. Urinary obstruction is considered an abnormality, yet transient modest obstruction is considered normal during canalization of the urinary tract, and has been reported in 10–20% of fetuses in the third trimester. A delay in canalization, or in the rupture of the cloacal membrane, can produce a dilation. Similarly, the closure of the urachus at postmenstrual week 32 may be associated with high-resistance outflow for the system, which again produces transient obstruction. Distension of the fetal bladder, which may indicate lower urinary tract obstruction, affects 2.2/10,000 births, more commonly in males (Hodges et al 2009, Dias et al 2014). Over half of such cases are caused by the development of posterior urethral valves (a congenitally obstructing posterior urethral membrane); there may also be a dilated posterior urethra and thickened bladder wall

Urinary system at birth

The kidneys function early in development and produce the amniotic fluid that surrounds the fetus. At full-term (postmenstrual week 40), the two kidneys weigh approximately 23 g and the lobulated appearance of fetal kidneys is still present (**Fig. 22.8**; see Fig. 23.14C). Addition of new cortical nephrons continues in the first few months of postnatal life, and after this time, general growth of the glomeruli and tubules results in the disappearance of lobulation. The renal blood flow is lower in the neonate; adult values are attained by the end of the first year. The glomerular filtration rate at birth is approximately 30% of the adult value, which is attained by 3–5 months of age.

The neonatal urinary bladder is egg-shaped and the larger end is directed downwards and backwards (**Figs 22.9–22.10**; see Figs 23.14A, F–I). Although described as an abdominal organ, nearly one-half of the neonatal bladder lies below a line drawn from the promontory of the sacrum to the upper edge of the pubic symphysis, i.e. within the cavity of the true pelvis. From the bladder neck, the bladder extends anteriorly and slightly upwards in close contact with the pubis, until it reaches the ventral abdominal wall. The apex of the contracted bladder, which has a distinct interureteric fold, lies at a point midway between the pubis and the umbilicus. When the bladder is filled with urine, the apex may extend up to the level of the umbilicus: pressure on the lower abdominal wall will express urine from an infant bladder. The bladder remains connected to the umbilicus by the obliterated remains of the urachus (see Figs 22.19 and 23.15A), and so stimulation of the umbilicus can initiate micturition in babies. The elongated shape of the bladder in neonates means that the ureters are correspondingly reduced in length and they lack a pelvic portion. The bladder does not gain its adult, pelvic, position until about the sixth year.

Urine can be aspirated from the neonatal bladder into a sterile syringe, via a needle inserted through the abdominal wall about 2 cm above the pubic symphysis. The success rate of this procedure is improved by the use of ultrasound scanning to visualize urine in the bladder prior to insertion of the needle (O'Callaghan and McDougall 1987).

SUPRARENAL GLANDS

The suprarenal (adrenal) gland is first seen in the human embryo at stage 14 as a specific proliferative region of the coelomic epithelium on the ventromedial surface of the urogenital ridge. Cells pass into the underlying mesenchyme between the root of the dorsal mesogastrium and the mesonephros (see Fig. 14.6A). The proliferating tissue extends from the level of the thoracic segments 6–12, and is soon disorganized dorsomedially by invasion of neural crest cells from somite levels 18–24 (see Fig. 14.20) that form the suprarenal medulla, and by the development of venous sinusoids. The latter are joined by capillaries that arise from adjacent mesonephric arteries and penetrate the cortex in a radial manner. By stage 18, the suprarenal gland is larger than the adjacent degenerating mesonephros and the developing, cranially ascending, metanephros. It remains larger than the metanephros (which touches it by stage 20), but as metanephric growth continues the suprarenal gland becomes relatively smaller by postmenstrual week 10 (see relative size at postmenstrual week 14 in Fig. 23.14F–I). As the suprarenal gland grows it is the most cranial viscus related to the developing pleuroperitoneal membrane (which contributes to the respiratory diaphragm). Initially this membrane is located on the ventral side of the suprarenal gland, gonad and mesonephros, but as the body wall is excavated during the formation of the costodiaphragmatic recess, the pleuroperitoneal membrane and associated mesenchyme become dorsal to the suprarenal gland and degenerating mesonephros during stages 16–17 (Hayashi et al 2011).

When proliferation of the coelomic epithelium stops, the cortex is enveloped ventrally, and later dorsally, by a mesenchymal capsule derived from the dorsolateral mesonephros. The subcapsular nests of cortical cells are the rudiments of the zona glomerulosa and they proliferate cords of cells that pass deeply between the capillaries and sinusoids. The cells in these cords degenerate in an erratic fashion as they pass towards the medulla; they become granular, eosinophilic and ultimately they autolyse. These cords of cells constitute the fetal cortex, which undergoes rapid involution during the first 2 postnatal years. Molecular aspects of the development of the early and fetal suprarenal gland have been reviewed (Ross and Louw 2015, Lotfi et al 2018). A comparison of the proteome of the embryonic and postnatal suprarenal gland in the rat has revealed expression of more proteins in later development and postnatal life (Dihazi et al 2015).

Functional, if not morphological zones, have been described in the fetal suprarenal gland from postmenstrual week 12. Cortisol is produced by the end of the first trimester and the gland is highly active throughout the second trimester. Early steroid synthesis provides substrates for placental oestrogen production: fetal steroid concentrations do not change after postmenstrual week 12. The fetal suprarenal gland does not produce aldosterone during the second trimester, suggesting that salt-wasting disorders, frequently seen in extreme preterm infants, may occur because of this limited early capacity for aldosterone production. Maternal smoking affects fetal suprarenal function and the development of the HPA axis, with reported alterations of placental function, reduced cortisol levels and response to stress in the first postnatal month (Johnston et al 2018).

Ultrasound examination of the suprarenal gland

A range of anthropometric studies have been published to aid identification of abnormal growth. These include fetal suprarenal gland length, recorded at 4-week intervals from postmenstrual week 15; nomograms showing linear growth of the gland between postmenstrual weeks 16 and 24; reference ranges of fetal suprarenal gland and fetal zone volumes between postmenstrual weeks 24 and 38, generated from 3D ultrasound examination (van Vuuren et al 2012, Jamigorn and Phupong 2017, Helfer et al 2017).

Suprarenal glands at birth

The suprarenal glands are large throughout development and are still relatively very large at birth (see Figs 22.8, 23.14C), constituting 0.2% of the entire body weight, compared with 0.01% in the adult. The left gland is heavier and larger than the right, as it is in the adult. At term, each gland usually weighs 4 g and the average weight of the two glands is 9 g (average in the adult is 7–12 g). Estimation of the suprarenal gland volume can provide an estimate of fetal weight; a volume of greater than 420 mm^3/kg is relevant in predicting preterm birth within 5 days of measurement (Turan et al 2007, Turan et al 2012). The glands shrink to normal infantile size within the first 2 weeks of postnatal life,. The average weight of both glands is 5 g by the end of postnatal week 2, and 4 g by 3 postnatal months; gland birth weight is not regained until puberty. This rapid involution of the glands occurs regardless of age at delivery: it is thought that parturition is the stimulus for suprarenal involution (Ben-David et al 2007). The cortex of the suprarenal gland is thicker than in the adult and the medulla of the gland is small. With normal involution, the fetal zone cells of the postnatal gland become smaller and they assume the appearance and organization typical of zona fasciculata.

Developmental anomalies of the suprarenal gland

The most common anomaly of suprarenal gland development is congenital hyperplasia (also termed congenital adrenal hyperplasia) occurring in 1 : 5000 to 1 : 15,000 births. The condition is caused by a group of autosomal recessive disorders, in which there are deficiencies in enzymes required for the synthesis of cortisol. In 90% of cases, the cause is deficiency of the enzyme 21-hydroxylase, producing an accumulation of 17-hydroxyprogesterone, which is converted to androgens. Mutations in the *CYP21A2* gene, on chromosome 6p, is found in 90–95% of affected individuals. The levels of androgens increase in this condition by several hundred times, causing female embryos and fetuses to undergo external genital masculinization ranging from clitoral hypertrophy to the formation of a phallus and scrotum. Postnatal management includes, if required, deferring gender assignment and establishment of the genetic sex of within 48 hours of delivery and monitoring serum electrolyte levels, blood glucose and blood pressure levels; 67–75% of these individuals will have salt wasting due to lack of aldosterone secretion (Rink 2016). In male embryos, the enzyme levels of 21-hydroxylase do not cause any changes in external genitalia. Suprarenal cortical growth and the molecular underpinning of anomalies has been reported (Lotfi et al 2018).

REPRODUCTIVE SYSTEM

Development of the reproductive organs from the intermediate mesenchyme starts from stage 14 (32–34 days postfertilization, see Fig. 23.3 for comparison of postfertilization days and the clinical scale of postmenstrual weeks), about 10 days later than the urinary system. Bilateral paramesonephric (Müllerian) ducts develop alongside the mesonephric ducts, and the midportion of each mesonephros undergoes thickening to form the gonadal ridge. Although the primordial germ cells are delineated very early in development, they are sequestered in the extraembryonic tissues until the gonadal ridge is ready to receive them. It was thought that development to one or other sexual phenotype occurred after migration of the primordial germ cells to the indifferent gonads. However, it is now recognized that the development of male or female gonads, genital ducts and external genitalia is far more complicated, and is the result of a complex interplay between genetic expression, timing of development and the influence of sex hormones. As development proceeds, a significant proportion of early embryonic urinary tissue is incorporated into the reproductive tracts, especially in the male. The earliest stage of reproductive development, prior to the arrival of the primordial germ cells into the gonad, is termed the indifferent or ambisexual stage.

Early gonadal development (ambisexual or indifferent stage)

Essentially, four different cell lineages contribute to the gonads. Cells are derived from: proliferating coelomic epithelium on the medial side of the mesonephros; underlying mesonephric mesenchyme; invading angiogenic mesenchyme already present in the mesonephros; and primordial germ cells that arise from the epiblast very early in development and later migrate from the allantoic wall.

The formation of the gonads is first indicated by the appearance of an area of thickened coelomic epithelium on the medial side of the mesonephric ridge in stage 16 (**Figs 22.12–22.13**; see Fig. 22.16). Elsewhere on the surface of the ridge, the coelomic epithelium is one or two cells thick, but over this gonadal area it becomes multilayered. Thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the renal corpuscles of the

Congenital anomalies of the kidney and urinary tract are relatively common (3–6% of live births). For further reading about the genetic, epigenetic and *in utero* environmental factors in the pathogenesis of non-syndromic forms of human congenital anomalies of the kidney and urinary tract (CAKUT), see Yosypiv (2012) and Capone et al (2017).

Renal agenesis is the absence of one or both kidneys. In unilateral renal agenesis, the remaining kidney exhibits compensatory hypertrophy and produces a nearly normal functional mass of renal tissue. Atresia of the ureter during development causes a non-functional multicystic dysplastic kidney, thought to be secondary to urinary obstruction while the tubules are still forming. Problems with kidney ascent can result in a pelvic kidney. Alternatively, the kidneys may fuse together at their caudal poles, producing a horseshoe kidney that cannot ascend out of the pelvic cavity because the inferior mesenteric artery prevents its further migration. A duplex kidney arises when two ureteric buds meet the metanephros; it is characterized by two pelvicalyceal systems and is associated with ureterocele, ectopic insertion of the ureter and vesico-ureteric reflux.

It was thought that renal cysts arose from clumps of vesicular cells that persisted when the tips of branches from the ureteric diverticulum failed to fuse with metanephrogenic cap tissue. It is now believed that they are wide dilations of a part of otherwise continuous nephrons. In most cases, autosomal dominant polycystic kidney disease results from mutations of *PKD1* or *PKD2* genes, which are expressed in human embryos from postfertilization weeks 5–6 within the mesonephros and later the metanephros (Chauvet et al 2002). In this condition, the cystic dilation may affect any part of the nephron, from Bowman's capsule to collecting tubules. Less common is infantile cystic renal disease, inherited as a recessive trait, in which the proximal and distal tubules are dilated to some degree but the collecting ducts are grossly affected.

Anomalies of the ventral body wall caudal to the umbilicus, especially with inappropriate siting of the genital tubercle, can result in exstrophy of the bladder (**Fig. 22.11**) (Suzuki et al 2009, Williams 2013). In this condition, the urorectal septum (internal) is associated with the genital tubercle (external), which means that the urogenital and anal membranes are widely separated. When the urogenital membrane involutes, the posterior surface of the bladder is exposed to the ventral abdominal wall. The lower part of the abdominal wall is therefore occupied by an irregularly oval area, covered with mucous membrane, onto which the two ureters open. The periphery of this extroverted area, which is covered by urothelium, becomes continuous with the skin. The innervation of the underlying detrusor muscle seems to be normal, but the muscle has a decreased number of smooth muscle cells and an increased amount of collagen, which means that the bladder may have reduced contractile performance after reconstruction (Johal et al 2019). Bladder exstrophy is a complex condition involving the development of the pelvis, cloaca, urorectal septum, urogenital sinus, urethral plate, external genital tissues and all of the associated autonomic and somatic nerves supplying the region. For further reading about exstrophy–epispadias complex, its genetics, presentation and surgical repair, see Gearhart and Mathews (2016). Absence of the bladder, low insertion of the umbilical cord and bony pelvic anomalies on routine antenatal ultrasound examination would suggest the presence of bladder exstrophy in a fetus, however, it has been reported that only 25% of those neonates born with this condition were diagnosed antenatally. Its postnatal repair is exceedingly complex and has not been completely successful in establishing continence and a bladder capable of voluntary voiding. The accumulated experience of those surgical units undertaking these reconstructions provide hope for improved patient outcomes in the future (Dickson 2014).

Amniotic fluid is a dynamic fluid medium that changes throughout development (Ch. 9). The volume of amniotic fluid is used as an indicator of renal function but does not reflect fetal urinary output until the second trimester. Although variation in the amount of amniotic fluid may suggest anomalies of either the gut or the kidneys, it is not always possible to correlate even severe oligohydramnios (too little amniotic fluid) with renal dysfunction. There is an important relationship between the volume of amniotic fluid, lung development and maturity: oligohydramnios has been shown to be associated with pulmonary hypoplasia (Ch. 20).

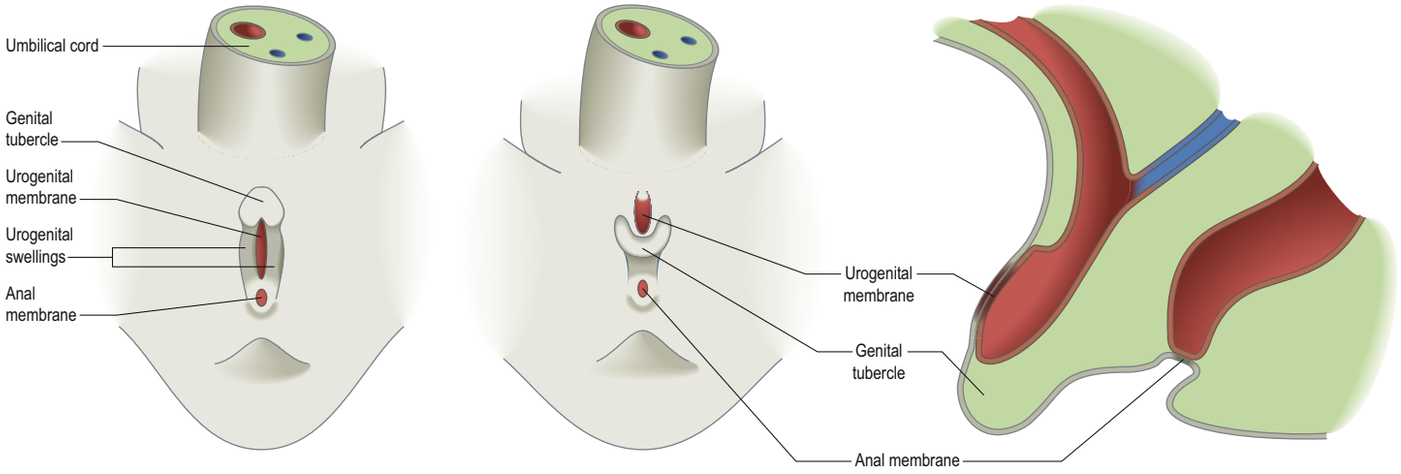

Fig. 22.11 Bladder exstrophy. Misalignment of the genital tubercle and urogenital swellings with the urogenital membrane during early development results in subsequent malposition of the bladder, urethra and associated sphincters. The disappearance of the urogenital membrane exposes the posterior wall of the bladder, and the urethral opening is on the superior side of the penis or clitoris. (Redrawn from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Volume 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

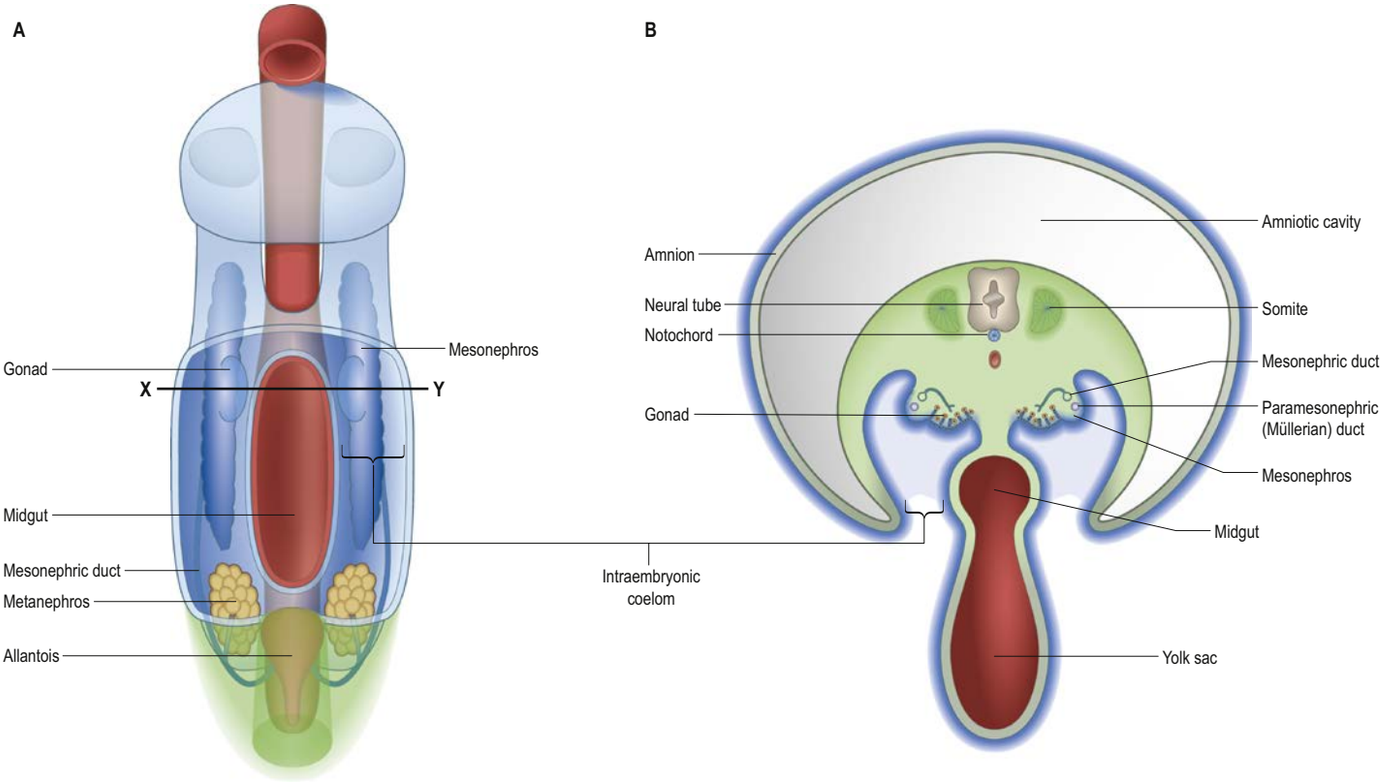

Fig. 22.12 A, The position of the gonads on the posterior abdominal wall, anteromedial to the mesonephros. **B**, A transverse section of figure **A**, through the line X–Y.

mesonephros in a dorsolateral direction, and forms a projection into the coelomic cavity: the gonadal ridge. Surface depressions form along the limits of the ridge, which is thus connected to the mesonephros by a broad mesentery, the mesogenitale. In this way, the mesonephric ridge becomes subdivided into a lateral part, the tubal fold, containing the mesonephric and paramesonephric ducts, and a medial part, the gonadal fold. The tubal fold also contains the nephric tubules and glomeruli at its base (see Fig. 22.3).

The ambisexual gonad possesses no sexually differentiating feature. From stage 16, the proliferating coelomic epithelium forms a number of cellular epithelial cords (sometimes called primary sex cords), separated by mesenchyme. The cords remain at the periphery of the primordium and form a cortex. Proliferation and labyrinthine cellular condensation of the mesonephric mesenchyme, including angiogenic mesenchyme, produce a central medulla. In both sexes the epithelial cells derived from the coelomic epithelium are destined to be the cell populations that support the primordial germ cells and contribute to the gonad–blood barrier. Some of the intervening mesenchyme cells have a later role in hormone production.

Reproductive ducts

The paramesonephric, Müllerian, ducts develop in embryos of both sexes, but become dominant in the development of the female reproductive system. They are not detectable until stage 16. Each begins as a linear invagination of the coelomic epithelium, the paramesonephric groove, on the lateral aspect of the mesonephric ridge near its cranial end. The blind caudal end continues to grow caudally into the substance of the ridge as a solid rod of cells that becomes canalized as it lengthens. Throughout the extent of the mesonephros, it is lateral to the mesonephric duct, which acts as a guide for it. The paramesonephric duct reaches the caudal end of the mesonephros, turns medially and crosses ventral to the mesonephric duct to enter the genital cord, where it bends caudally in close apposition with its fellow from the opposite side (see Fig. 22.13). The two ducts reach the dorsal wall of the urogenital sinus during stage 23 and their blind ends produce an elevation called the Müllerian or sinus tubercle (see Figs 22.7F, 22.19).

At the end of the indifferent stage, each paramesonephric duct consists of vertical cranial and caudal parts and an intermediate horizontal region. The mesonephric ducts course caudally, medial to the paramesonephric ducts, and both duct systems open into the urogenital sinus. The genital ducts possess an external coelomic epithelial covering; a smooth muscle muscularis, derived from underlying mesenchyme; and an internal mucosa, derived from either the mesonephric duct or from the invaginated tube of coelomic epithelium that forms the paramesonephic duct. The layers are invaded by angiogenic mesenchyme and by nerves.

Reproductive ducts in the female: uterine tubes, uterus, cervix

In the female, the mesonephric duct is vestigial. Cranially, it becomes the longitudinal duct of the epoophoron, and caudally it is referred to as Gartner's duct (**Table 22.1**). The cranial part of the paramesonephric ducts forms the uterine tubes, and the original coelomic invagination remains as the pelvic opening of the tube. The fimbriae become defined as the cranial end of the mesonephros degenerates. The caudal vertical parts of the two ducts fuse with each other during stage 23 to form the uterovaginal primordium (**Fig. 22.14**) that gives rise to the lower part of the uterus; as it enlarges, it takes in the horizontal parts to form the fundus and most of the body of the adult uterus. The stroma of the endometrium and the uterine musculature develop from the surrounding mesenchyme of the genital cord.

Failure of fusion of the two paramesonephric ducts can lead to a range of anomalies summarized in **Fig. 22.15**. These fusions can also contribute to anomalies of vaginal development. The fetal female reproductive tract is affected by maternal hormones and undergoes some enlargement in the fetus. The endocervical glands are active before birth and the cervical canal is usually filled with mucus.

At birth, the uterine tubes are relatively short and wide, the uterus is relatively large, 2.5–5 cm long (average 3.5 cm), 2 cm wide between the uterine tubes, and a little over 1 cm thick (see Figs 22.9, 23.14C, 23.15A). The body of the uterus is smaller than the uterine cervix, which forms two-thirds or more of the length. The isthmus between the body and the cervix is absent. The position of the uterus in the pelvic cavity depends, to a great extent, on the state of the bladder anteriorly and the rectum posteriorly. If the bladder contains only a small amount of urine, the uterus may be anteverted but it is often in a direct line with the vagina (see Figs 22.9, 22.19). The uterus subsequently involutes to about one-third of its length and more than half of its weight; it does not regain its neonatal size and weight until puberty.

Vagina

At approximately postmenstrual week 12, an endodermal epithelial proliferation, the sinuvaginal bulb, arises from the dorsal wall of the urogenital sinus in the region of the sinus tubercle. Its proliferation

TABLE 22.1 Homologies of the parts of the urogenital system in male and female

Gonad	Testis	Ovary
Gubernacular cord	Gubernaculum testis	Ovarian and round ligaments
Mesonephros (Wolffian body)	Appendix epididymis (?)	Appendices vesiculosae (?)
	Efferent ductules	Epoophoron
	Lobules of epididymis	
	Paradidymis	Paroophoron
	Aberrant ductules	
Mesonephric duct (Wolffian duct)	Duct of epididymis	Duct of epoophoron (Gartner's duct)
	Ductus (vas) deferens	
	Ejaculatory duct	
	Part of bladder and prostatic urethra	Part of bladder and urethra
Paramesonephric (Müllerian) duct	Appendix testis	Uterine tube
		Uterus
	Prostatic utricle	Vagina (?)
Allantoic duct	Urachus	Urachus
Cloaca:		
Dorsal part	Rectum and upper part of anal canal	Rectum and upper part of anal canal
Ventral part	Most of bladder	Most of bladder and urethra
	Part of prostatic urethra	
Urogenital sinus	Prostatic urethra distal to utricle	
	Bulbourethral glands	Greater vestibular glands
	Rest of urethra to glans	Vestibule
Genital folds	Ventral penis	Labia minora
Genital tubercle	Penis	Clitoris
	Urethra in glans	

produces a column of cells, the vaginal plate, flattened anteroposteriorly, encased within caudal splanchnopleure, that will eventually become the fibromuscular wall of the vagina, cervix and body of the uterus. This uterovaginal primordium results in elongation of the female reproductive tract, causing the caudal tip of the fused paramesonephric ducts to be displaced cranially (see Figs 22.7F, 22.14B). The origin of the sinuvaginal bulb marks the site of the future hymen. Anomalies of paramesonephric duct fusion can produce related vaginal anomalies (see Fig. 22.15).

The following sequence of events occurs between postmenstrual weeks 14–22: the exact timing of each part will vary in individual fetuses. The vaginal plate enlarges into a cylindrical structure that is gradually canalized through its whole extent, the process starting from its caudal end and extending cranially. The lower end grows caudally and approaches the developing vestibule. The vaginal lumen is complete around postmenstrual week 19 and continuous with the exterior about one week later. The boundary of the origin of the vaginal mucosa has been defined in the mouse, but there are significant heterochronic differences between murine and human development (Kurita 2010, 2011). A series of studies have demonstrated the differential expression of *PAX2* and *FOXA1* genes in the human female reproductive tract (Robboy et al 2017, Cunha, Robboy et al 2018a). Coelomic-derived paramesonephric ducts express *PAX2* along their length, whereas vaginal plate expresses *FOXA1*, an endodermal epithelial gene noted in the hindgut and urogenital sinus. At about postmenstrual week 19, *PAX2* is expressed at the lower end of the uterovaginal canal in the uterus, cervix and future vaginal fornices. By about postmenstrual week 22, the fornices and exocervix express *FOXA1*: the transition of expression is sited in the endocervical canal. The surrounding mesenchyme instructively induces the extent of vaginal epithelial differentiation.

In early fetal life the epithelium of the uterine tubes, uterus and cervix is simple columnar, with some ciliated cells. Stratified squamous epithelium is seen in the vagina at about postmenstrual week 19, and by about postmenstrual week 22, the vaginal mucosa is folded and the epithelium thickened in response to oestrogenic stimulation. This hypertrophy continues throughout the later months of fetal life under the influence of placental and maternal hormones (see Fig. 22.22). The

vaginal epithelium assumes the inactive form of childhood after the period of mini-puberty (see p. 364).

In the neonate, the vagina is 2.5–3.5 cm long and 1.5 cm wide at the fornices, and the uterine cervix extends into the vagina for about 1 cm (Crelin 1969). The posterior vaginal wall is longer than the anterior wall, giving the vagina a distinct curve (see Figs 22.9, 22.19, 23.15A). The cavity is filled with longitudinal columns covered with a thick layer of cornified, stratified, squamous epithelium: these cells slough off after birth, when the effect exerted by maternal hormones is removed.

The orifice of the vagina is surrounded by the hymen, a thick, elliptical ring of connective tissue. During childhood, the hymen becomes a membranous fold along the posterior margin of the vaginal lumen: should the fold form a complete diaphragm across the vaginal lumen, it is termed an imperforate hymenal membrane.

Reproductive ducts in the male: epididymis, ductus deferens, seminal glands (vesicles)

In the male, most of the paramesonephric ducts atrophy (see Fig. 22.13) under the influence of anti-Müllerian hormone (AMH; also called Müllerian inhibiting substance, or MIS), which is released into the mesonephric duct by the Sertoli cells of the testis. It is thought that the epithelial cells of the paramesonephric duct initially undergo apoptosis, and that once the epithelial cells no longer secrete a basal lamina, the remaining ductal epithelial cells transform into mesenchyme that remains in the vicinity of the involuting duct (Allard et al 2000). Vestigial remnants of the paramesonephric ducts are most likely to persist cranially and/or caudally, at the limits of the local exocrine effects of AMH. A vestige of the cranial end of the duct persists as the appendix testis (see Figs 22.13, 22.19; see Table 22.1). The fused caudal ends of the two ducts are connected to the wall of the urogenital sinus by a solid utricular cord of cells that soon merges with a proliferation of sinus epithelium, the sinu-utricular cord, that is similar to, but less extensive than, the sinus proliferation in the female. The proliferating epithelium is claimed to be an intermingling of the endoderm of the urogenital sinus with the lining epithelia of the mesonephric and paramesonephric ducts, which have extended on to the surface of the sinus tubercle. As the sinu-utricular cord grows, so the utricular cord recedes from the tubercle. In the second half of fetal life, the composite cord acquires a lumen and becomes dilated to form the prostatic utricle, the lining of which consists of hyperplastic stratified squamous epithelium. The sinus tubercle becomes the colliculus seminalis.

The main reproductive ducts in the male are derived from the mesonephric ducts, which persist under the action of androgens that are probably secreted down the ducts themselves, and are subsumed into the male reproductive system as the metanephric kidney develops. The mesonephric duct gives rise to the canal of the epididymis, ductus (vas) deferens and ejaculatory duct. It is possible that the extensive lengthening and coiling of the epididymis is a local example of buckling morphogenesis produced by biomechanical tension in the surrounding tissues (Hirashima 2014). The seminal gland and the ampulla of the ductus deferens appear as a common swelling at the end of the mesonephric duct during the end of the third and into the fourth months. Their appearance coincides with degeneration of the paramesonephric ducts, although no causal relation between the two events has been established. Separation into two rudiments occurs at about 125 mm crown–heel length. The seminal gland elongates, its duct is delineated and hollow diverticula bud from its wall. Around postmenstrual weeks 22–23, the growth rate of both vesicle and ampulla is greatly increased. Fig. 22.10 shows the position of the ampulla of the ductus deferens in the neonate, possibly in response to increased secretion of prolactin by the fetal or maternal hypophysis, or to the effects of placental hormones. The tubules of the prostate show a similar increase in growth rate at this time.

Primordial germ cells

The primordial germ cells are formed very early from the epiblast (see Fig. 10.3). They are larger (12–20 μm in diameter) than most somatic cells, and are characterized by vesicular nuclei with well-defined nuclear membranes, and by a tendency to retain yolk inclusions long after these have disappeared from somatic cells. It is not yet clear whether the primordial germ cells are derived from particular blastomeres during cleavage, if they constitute a clonal line from a single blastomere, or if they are the product of a progressive concentration of the nucleus of the fertilized ovum by unequal partition at successive mitoses. Primordial germ cells spend the early stages of development within the extraembryonic tissues near the end of the primitive streak and in the connecting stalk (see Fig. 10.4E). In this situation, they are away from the inductive influences to which the majority of the somatic cells are subjected during early development.

Primordial germ cells can be identified in human embryos in stage 11, when the number of cells is probably not more than 20–30. When the tail fold has formed, they appear within the endoderm and the splanchnopleuric mesenchyme and epithelium of the hindgut, as well as in the adjoining region of the wall of the yolk sac. They migrate dorsocranially in the mesentery, by amoeboid movements and by growth displacement, and pass around the dorsal angles of the coelom (medial coelomic bays) to reach the genital ridges from stage 15 (see Fig. 22.16). It is believed that the genital ridges exert long-range effects on the migrating primordial germ cells, in terms of controlling their direction of migration and supporting the primordial germ-cell population. Primordial germ cells contact each other via long processes and retain cytoplasmic bridges when they divide. They are usually in close proximity to somatic cells, which may modify the local environment, forming junctional complexes with them. The surface of primordial germ cells displays binding sites for extracellular matrix macromolecules. A range of molecular markers associated with the migration and proliferation of primordial germ cells has been described (Soto-Suazo and Zorn 2005, Runyan et al 2006, De Felici 2013). Single-cell RNA-Seq analysis has identified the range of genes and transcription factors expressed in the first and second trimester by human primordial germ cells and their associated somatic cells (Li et al 2017).

Primordial germ cells proliferate both during and after migration to the mesonephric ridges. Cells that do not complete this migration mainly degenerate, but if they survive, they can give rise to germ cell tumours, usually in the midline (Runyan et al 2006). After segregation, when they are sometimes termed primary gonocytes, or spermatogonia and oogonia in male and female respectively, they divide to form secondary gonocytes.

Development of the gonads

Gonads in both sexes arise from local interactions along the medial side of the mesonephros, between proliferating dorsal coelomic wall epithelium and the underlying mesonephric mesenchyme and mesonephric nephrons (see Fig. 22.12). Primordial germ cells migrate into this region and are sequestered within the epithelial populations in different ways in male and female. The factors that lead to formation of either testis or ovary are described below and in **Fig. 22.16**.

Testis

The testis develops in the middle portion of the gonadal ridge, but unlike the ovary does not retain any local remnants from the cranial or caudal parts.

The proliferating coelomic epithelial cells contribute to lengthening epithelial cords which invade the underlying mesenchyme. They become determined as Sertoli cells (also called sustenocytes) and form the walls of the seminiferous tubules encroaching on and uniting with a medullary network of mesonephric mesenchyme which forms the rete testis (see Figs 22.13, 22.16). Sertoli cells proliferate throughout fetal and early postnatal life (see mini puberty, p. 364) and perhaps again at the initiation of puberty (Sharpe et al 2003); once dividing ceases the cells mature and cannot be reactivated. Primordial germ cells are incorporated into the early cords and between the dividing Sertoli cells. The number of Sertoli cells produced at this early time determines the maximal limit of adult sperm production, as each Sertoli cell can only support a fixed number of proliferating primordial germ cells (Sharpe et al 2003). Because developing and maturing spermatogonia make up the bulk of the adult testis, the number of Sertoli cells is a major determinant of the size to which the testes will grow (factors that impair the process of spermatogenesis, resulting in the loss of primordial germ cells, will also affect testicular size). Variation in Sertoli cell number is probably the most important factor in accounting for the enormous variation in sperm counts between individual males, whether fertile or infertile. Indeed, the available data for adult males indicate that Sertoli cell numbers vary across a 50-fold range (Sharpe et al 2003). Although some of this variation may result from attrition of Sertoli cell numbers because of ageing, the major differences in Sertoli cell numbers will have been determined by events in fetal life and/or childhood, with parental epigenetic effects also contributing (Sharpe 2010). In mammals, the testis–blood barrier is formed by tight junctions between adjoining Sertoli cell at the basal region of the seminiferous tubule adjacent to the epithelial basal lamina and actin-rich adherens junctions termed ectoplasmic specializations (Wen et al 2018): it is not yet known when this occurs in humans. Early blood vessels form between the seminiferous tubules and appear to form around clusters of Leydig cells.

The interstitial cells of the testis are derived from mesenchyme and, possibly, also from coelomic epithelial cells that do not become incorporated into the tubules. Among other cell lines, they form the embryonic

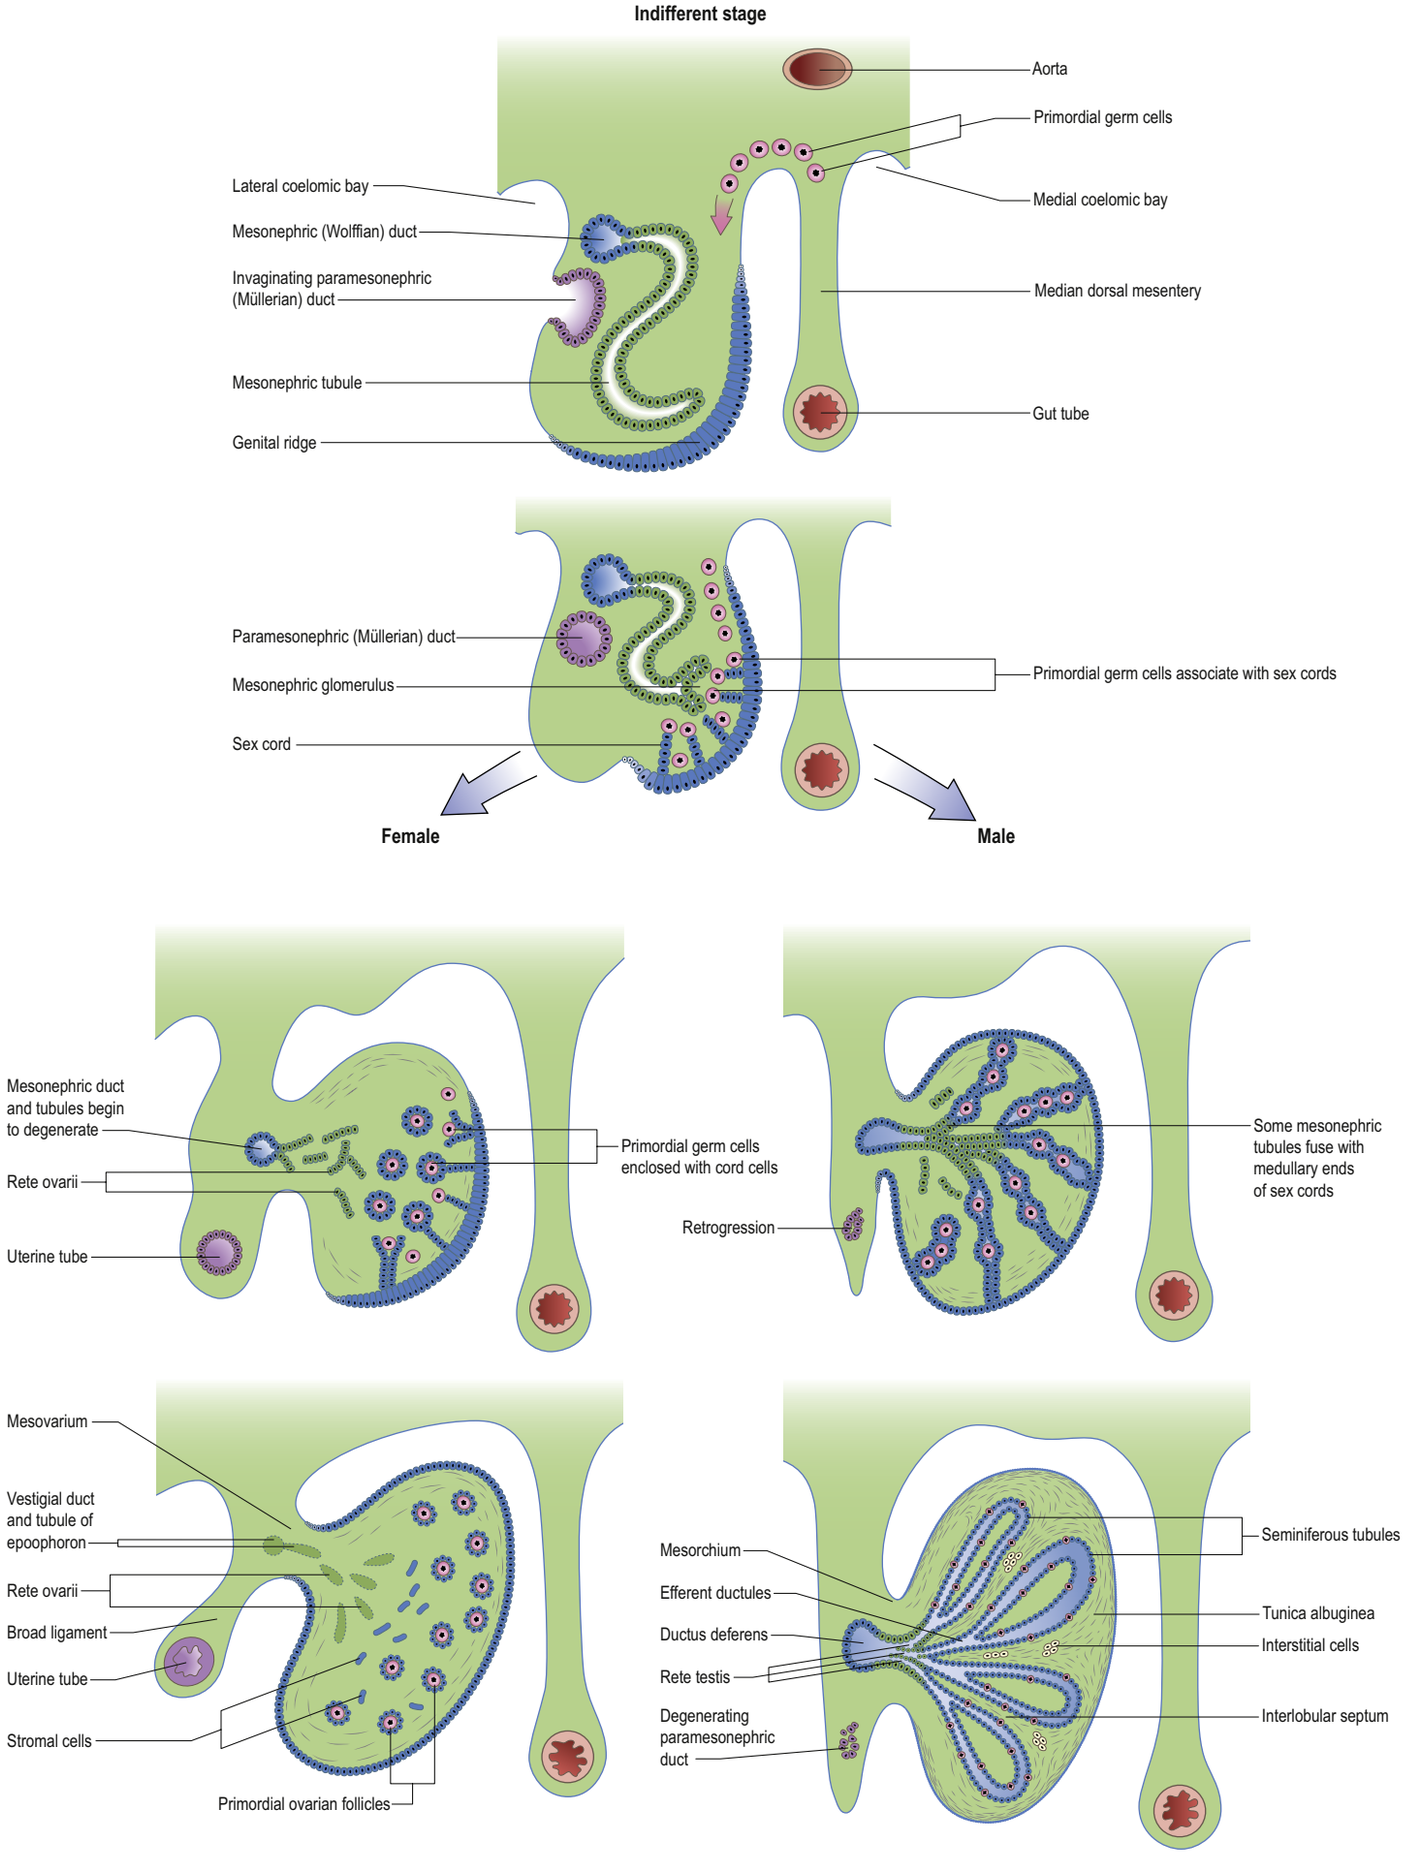

Fig. 22.16 The development of the gonads and associated ducts, as seen in transverse section, to show the fate of the primordial germ cells, mesonephric duct and tubules, and paramesonephric duct in males and females. (Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd ed. London: Pitman Medical & Scientific.)

and fetal cells of Leydig, which secrete testosterone and insulin-like factor 3 (INSL3), and peritubular myoid cells (smooth muscle cells), which surround the seminiferous tubules. Leydig cell numbers increase until postnatal month 3 and then decrease. The tunica albuginea of the testis form from a later migration of mesenchyme beneath the coelomic epithelium.

The channels of the rete testis become connected to the glomerular capsules of persisting mesonephric nephrons. Ultimately the 5–12 most cranial persisting mesonephric tubules form a connection to the mesonephric duct. They become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive 'ureter' of the mesonephros, becomes the canal of the epididymis and the ductus deferens of the testis. The seminiferous tubules do not acquire lumina until postmenstrual weeks 25–28; the tubules of the testicular rete become canalized somewhat earlier.

Developmental anomalies of the testis

All testicular cell lines and their developmental processes can contribute to anomalous development and limited fertility, e.g. genetic changes to the Y chromosome (Colaco and Modi 2018), imbalance of the genes required to ensure sufficient Sertoli and Leydig cell differentiation (She and Yang 2017), disorders of development and descent of the male reproductive tract (Hadziselimovic 2017). Although all of these factors are operating concordantly, disorders of descent of the male reproductive tract is considered below. Anomalies of the testis, e.g. gonadal dysgenesis and small testes, are important risk factors for the later development of testicular germ cell cancer. Testicular carcinoma-in-situ (CIS) cells arise from primordial germ cells that have failed to complete differentiation into spermatogenic germ cells (Rajpert-De Meyts 2006). The condition is seen in young males (95% of cases affect 15- to 45-year-old males) caused by activation of premalignant cells. The incidence of testicular germ cell cancer has increased over the past 60 years and appears to be caused by environmental/lifestyle causes rather than genetic factors. Risk of testicular germ cell cancers in migrant males is comparable to their original country of origin, whereas the risk to children born in a country to which their parents have emigrated is the same as in that country. The development of fewer Sertoli cells during fetal and early postnatal life and at the initiation of puberty directly affects the number of spermatogenic germ cells that the testis can support.

In the relatively recent past, prospective, well-standardized studies undertaken across Europe have documented a fall in sperm counts of around 40–50% (1% per year over the last 50 years); 15–20% of young males have an abnormally low sperm count (less than 20 million sperm per ml based on WHO standards); and only 5–15% of the sperm produced can be classified as normal (depending on the strictness of the criteria of normality used) (Cooper et al 2010, Sharpe 2010). Although this dramatic decrease is obviously manifest only in adulthood, as is the case with testicular cancer, there is growing evidence that it may reflect impaired testicular development during fetal or childhood life (Lobo et al 2019). Imbalance between the genes promoting or suppressing Sertoli/follicle cells and Leydig/theca cells that extends throughout fetal and postnatal life is noted in disorders of sex development, leading to male to female or female to male transition. These related factors, together with cryptorchidism (see below), are considered part of a testicular dysgenesis syndrome promoted by environmental factors, including exhaust fumes, smoking, parental obesity and epigenetic effects, seen particularly in Western countries (Sharpe 2010).

Ovary

The ovary develops from the middle part of the gonadal ridge: the cranial part becomes the suspensory ligament of the ovary (infundibulopelvic fold of peritoneum), and the caudal part is incorporated into the ovarian ligament.

Cellular development of the ovary occurs slightly later than the testis (see Figs 22.13, 22.16). Few, if any, epithelial cords from the proliferating coelomic epithelium invade the underlying mesenchyme. The majority of epithelial cells remain in the cortex separated by fine septa of undifferentiated mesenchyme. An ovarian rete condenses in the medullary mesenchyme and may temporarily join mesonephric glomeruli, but any connection subsequently regresses; mesenchyme and developing blood vessels form the ovarian stroma which will give rise to future thecal cells. The cortical epithelial clusters become determined as follicle cells and surround the primordial germ cells (now identified as primary oocytes) that have entered the prophase of the first meiotic division. Primary oocytes are derived from a mitotic division of the primordial germ cells (naked oogonia). Flattened epithelial follicle cells (also termed pregranulosa cells) coalesce around them producing primordial follicles from about postmenstrual week 13. Placental-derived oestrogens promote an increase in primordial follicle development after postmenstrual weeks 14–15, when about 100,000 are present; this number increases to 680,000 by postmenstrual week 34 when some of these follicles mature. The pool of primordial follicles remains stable until postnatal month 8 (Lanciotti et al 2018).

Further development of ovarian follicles in the fetus, neonate and after puberty includes the specification of a blood–follicle barrier that proteins/peptides, sugars, electrolytes and ions in fluid must cross to access the follicular antrum from the theca (Rodgers and Irving-Rodgers 2010, Siu and Cheng 2012). The barrier is composed of the surrounding endothelial cells (joined by tight and adhesion junctions and an underlying basal lamina), the thecal interstitium, the follicular basement membrane, and the membrana granulosa. The permselectivity of the subendothelial basal lamina and the follicular basement membrane differ, possibly because some of the extracellular matrix components of the follicular basement membrane change during primordial, primary and pre-antral stages (Siu and Cheng 2012). From the pre-antral stage of follicle development to maturity, those cells closest to the oocyte are termed granulosa cells.

There are temporospatial changes within the developing ovary. Neurotropins and their receptors have been shown to be expressed within the fetal ovary between postmenstrual weeks 13 and 21. NT4 is localized initially in epithelioid cells mingled with oogonia, then within oogonial mRNA, and finally in the primordial follicle cells, with lesser expression in the enclosed oocytes (Anderson et al 2002).

Expression of p450c17, a steroidogenic enzyme involved in the production of androgens, has been shown in the human fetal ovary during the second and third trimesters (Cole et al 2006). Its temporospatial expression showed a movement from the cortex to the medulla, with its presence in primary interstitial cells in the cortex from postmenstrual weeks 14 to 23, but not in hilus interstitial cells. Between postmenstrual weeks 27 and 33, few cells stained for p450c17, but there was an increase after postmenstrual week 33 in theca interstitial cells associated with pre-antral follicles. Positive-staining hilar interstitial cells were rarely seen before postmenstrual week 33. The temporospatial expression was similar in anencephalic fetuses of the same age, indicating that anterior pituitary function is not regulating this maturation. A possible role for insulin in regulating fetal ovary androgen production has been suggested. Overexpression of interstitial androgen production is a component in the pathophysiology of polycystic ovary syndrome (Cole et al 2006).

Sex determination in the embryo

It was believed that the gonads were indifferent or ambisexual until the arrival of the primordial germ cells in the gonadal ridge, at which point the sex of the embryo was 'turned on' by the presence of the male or female germ cells. However, embryos in which the genital ridges are devoid of germ cells may still undergo otherwise normal testis development. It is not clear if the germ cells are necessary for ovarian determination. They are required for the proper organization and differentiation of the ovary, and their absence results in the development of 'streak gonads', where only lines of follicular cells can be seen, as in Turner's syndrome.

The processes of sex determination and differentiation involve interacting pathways of gene activity that lead to the total patterning of the embryo as either male or female.

In the current, generally accepted, model of sex determination in humans, the female pathway is considered to be the 'set-up' programme, i.e. the course of events that will occur unless development is diverted into the testicular pathway, a process triggered by the presence of a Y chromosome. The resulting cellular changes convert the indifferent gonad into a testis, which then produces three key hormones (AMH, INSL3 and testosterone) that collectively induce masculinization of the fetus and acquisition of male secondary sexual characteristics.

The possession of a Y chromosome is usually associated with a male developmental pathway. Deletion mapping of the Y chromosome in a class of XX males arising from abnormal X–Y interchange at meiosis showed that the male-determining region of the chromosome was a conserved sequence located near its tip, termed the testis-determining factor (TDF). This sequence contains a gene that is the 'master switch' which programmes the direction of sexual development, the so-called *SRY* gene (sex-determining region on the Y chromosome). The human *SRY* gene is a single exon on Yp that encodes a protein of 204 amino acids with a conserved DNA-binding domain (Colaco and Modi 2018). The *SRY* gene acts initially within the epithelial cords of cells derived from the coelomic epithelium of the ambisexual gonad. These cells can potentially differentiate into either Sertoli or follicle (granulosa) cells, the supporting cells for the germ cells in the testis and ovary,

respectively. Studies indicate that *SRY* initiates testis formation from the indifferent gonad by directing the development of supporting-cell precursors as Sertoli rather than follicle cells (Albrecht and Eicher 2001, She and Yang 2017). *SRY* gene expression is initiated in humans at postfertilization day 41; it reaches maximal expression after this time and is thereafter maintained at a low level throughout fetal, postnatal and adult life (She and Yang 2017). The expression is seen first in cells designated as pre-Sertoli, located centrally in the developing gonad, and then later in the cranial and caudal poles. Once the developmental pathway of Sertoli cells has been initiated, the differentiation of the other cell types in the testicular pathway follows: Leydig cells subsequently appear, and the connective tissue becomes organized into a male pattern. The germ cells are also affected by this environment. When they arrive, they become enclosed within the Sertoli cells, do not enter meiosis and continue to proliferate (which is characteristic of spermatogenesis), instead of ceasing proliferation and entering meiosis and meiotic arrest, as occurs in the ovary. Thus, the development of male characteristics follows the expression of *SRY*: female characteristics develop in its absence.

Studies of XY individuals with sex reversal (i.e. XY females) and corresponding gene knockout studies in mice have established that *SRY* initiates testis development by inducing the expression of another gene, *SOX9* (SRY-like HMG-box protein 9): its expression in the absence of *SRY* is sufficient for male determination. A multi-step cascade of gene expression changes essentially reinforce SOX9 expression and consolidate development along the male pathway; the genes involved include *WT1* (Wilm's tumour gene), *GATA4* (GATA-binding protein 4), *FGF9* (fibroblast growth factor 9) and *DAX-1* (orphan nuclear receptor DAX-1) (Biason-Lauber 2010, Munger et al 2013). This cascade also actively represses expression of genes that promote development along the female pathway, including *RSPO1* (R-spondin 1), *WNT4* (Wingless-type MMTV integration site family member 4) and *FOXL2* (Forkhead box L2). Activation of the female cascade of gene expression actively suppresses expression of SOX9 and/or other genes in the 'male cascade'. Development of either a testis or an ovary therefore results from a balance between activation and repression of sexually dimorphic genes: inactivating mutations in any of these genes, or their aberrant expression in the wrong sex fetus, has the potential to interfere, partially or completely, with normal gonad formation and thus with downstream sexual development (Biason-Lauber 2010, Munger et al 2013).

Gene expression balance is required throughout development and adult life. In early development, high *FGF9* and low *WNT4* is seen in the XY gonad, whereas low *FGF*9 and high *WNT4* is seen in the XX gonad. In later development and throughout life, FOXL2 and DMRT1 (doublesex and mac-3 related transcription factor 1) interact: DMRT1 antagonizes FOX12 to maintain postnatal testis differentiation, and FOXL2 suppresses DMRT1 to ensure adult ovarian differentiation. *DMRT1* is found on chromosome 9, its deletion is correlated with XY male to female sex reversal (Huang et al 2017). *Foxl2* deletion in adult mouse ovary switches theca cells to Leydig-like cells and follicle (granulosa) cells to Sertoli-like cells. For details of the delicate balance of these factors and the maintenance of adult gonadal differentiation see She and Yang (2017)

Subsequent development of the male phenotype requires fetal secretion of testosterone, AMH and INSL3. Of these, testosterone is the most important, because it has body-wide effects, both on the developing reproductive system/genitalia and on numerous other organs/tissues, including the brain. The development of the appropriate cytoplasmic testosterone-binding receptor protein (the androgen receptor) is also important. Sertoli cells synthesize AMH, which causes the regression of the Müllerian ducts, and Leydig cells produce testosterone, which promotes the development of the mesonephric ducts, sets into process the development of male external genitalia, and sensitizes other tissues to testosterone. Absence of a functional androgen receptor, as occurs in the complete androgen insensitivity syndrome (CAIS), results in XY individuals who have testes and degenerated Müllerian ducts, but cannot respond to the circulating testosterone produced by their testes and therefore develop female secondary sexual characteristics.

Descent of the gonads

The gonads develop on the posterior abdominal wall bilaterally along the central portion of the mesonephros. This region receives a rich blood supply that is directed to the gonads as the mesonephros involutes. Both gonads descend, the testis to lie outside the abdominal cavity, and the ovary to the pelvis, and they both retain their early blood supply from the dorsal aorta.

Descent of the testis

The mechanism of testicular descent remains poorly understood (Barthold and Ivell 2018). It is conventionally described in two phases, transabdominal and inguinoscrotal, that are regulated by distinct morphological and endocrine factors (Barteczko and Jacob 2000).

Transabdominal phase

Each testis initially lies on the dorsal abdominal wall. As it enlarges, its cranial end degenerates and the remaining organ therefore occupies a more caudal position. It is attached to the mesonephric fold by the mesorchium (the mesogenitale of the undifferentiated gonad), a fold of the coelomic wall and underlying mesenchyme that contains the testicular vessels and nerves. It also acquires a secondary attachment to the ventral abdominal wall that has a considerable influence on its subsequent movements. At the point where the mesonephric fold bends medially to form the genital cord (see Fig. 22.3), each testis becomes connected to the lower part of the ventral abdominal wall by an inguinal fold of coelomic wall that covers a mesenchymal cord, the gubernaculum or genito-inguinal ligament (see Figs 22.3, 22.13; **Fig. 22.17**). Traditionally, regardless of sex, the proximal end of the gubernaculum has been described as extending from the lower end of the developing gonad, attached either to the mesonephric duct or to the caudal pole of the developing epididymis (Hadziselimovic 2017). The distal end of the gubernaculum seems to align to the inguinal part of the milk line that extends from the axilla to the femoral region (see Fig. 53.27). It has been suggested that this line corresponds to the original lateral edge of the embryo that expresses the apical ectodermal ridges and mesenchymal progress zones of the upper and lower limbs (Hutson 2013, Hutson et al 2014).

Up to about postmenstrual week 12, the gubernaculum in male and female embryos is similar, but then production of the non-androgenic hormone insulin-like 3 (INSL3) from Leydig cells stimulates enlargement (known as the 'swelling reaction') of the gubernaculum in males. This serves to anchor the fetal testis near the future inguinal canal as the abdominal cavity enlarges between postmenstrual weeks 12–15. By comparison, the gubernaculum in females remains thin and subsequently develops into the round ligament (see Table 22.1; p. 359). The cranial attachment of the urogenital ridge, known as the cranial suspensory ligament, regresses in males under the action of androgens. Subtle changes in Leydig cell dysfunction and changes in INSL3 production may occur in cryptorchidism (Barthold and Ivell 2018).

After postfertilization week 12 the midgut loop returns to the abdomen and the ventral abdominal wall inferior to the umbilical cord lengthens. As each umbilical artery runs ventrally from the dorsal to the ventral wall, it pulls up a falciform peritoneal fold, which forms the medial boundary of a peritoneal fossa, the saccus vaginalis of lateral inguinal fossa, into which each testis projects.

Inguinoscrotal phase

Gonadotropin releasing hormone and altering levels of FGF signalling are essential for testicular descent. The caudal end of the gubernaculum is initially associated with a specific portion of the milk line of the abdominal wall around which the future inguinal canal is formed by differentiating abdominal wall muscles. An interaction with the mammary line ectoderm and underlying mesenchyme may trigger gubernacular meristematic growth similar to that seen in the progress zone of the limb bud. Between postmenstrual weeks 25 and 35, the male gubernaculum begins to bulge out from the abdominal muscles and elongate across the pubis and into the scrotum (see Fig. 22.17). A specific evagination of the coelomic wall continuous with the peritoneal cavity, the processus vaginalis, extends into the gubernaculum, hollowing it out so that the proximal part is divided into a crescentic parietal layer within which the cremaster muscle develops, and a central column attached to the epididymis. Elongation of the soft, gelatinous end of the gubernaculum, which, in the early stage, is formed mainly of hyaluronic acid, is controlled by androgens. The exact mechanisms mediating gubernacular growth in humans are still unclear (Barthold and Ivell 2018). In rodent models, there is good evidence that androgens cause sexual dimorphism of the sensory branches of the genitofemoral nerve, which supplies the gubernaculum, the developing cremaster muscle within it, and part of the scrotum. The genital branch of the nerve releases calcitonin gene-related peptide (CGRP), which stimulates growth of the gubernacular tip along a chemotactic gradient to the scrotum.

The testis remains in apposition with the deep inguinal ring, held by the gubernaculum during postmenstrual weeks 13–24 (Barteczko and Jacob 2000). From postmenstrual week 35, the extracellular matrix of the gubernaculum is resorbed and it forms a fibrous attachment to the inside of the scrotum. Testis descent during the inguinoscrotal phase occurs relatively rapidly over postmenstrual weeks 25–28, the left testis usually descending ahead of the right. Intra-abdominal pressure acting

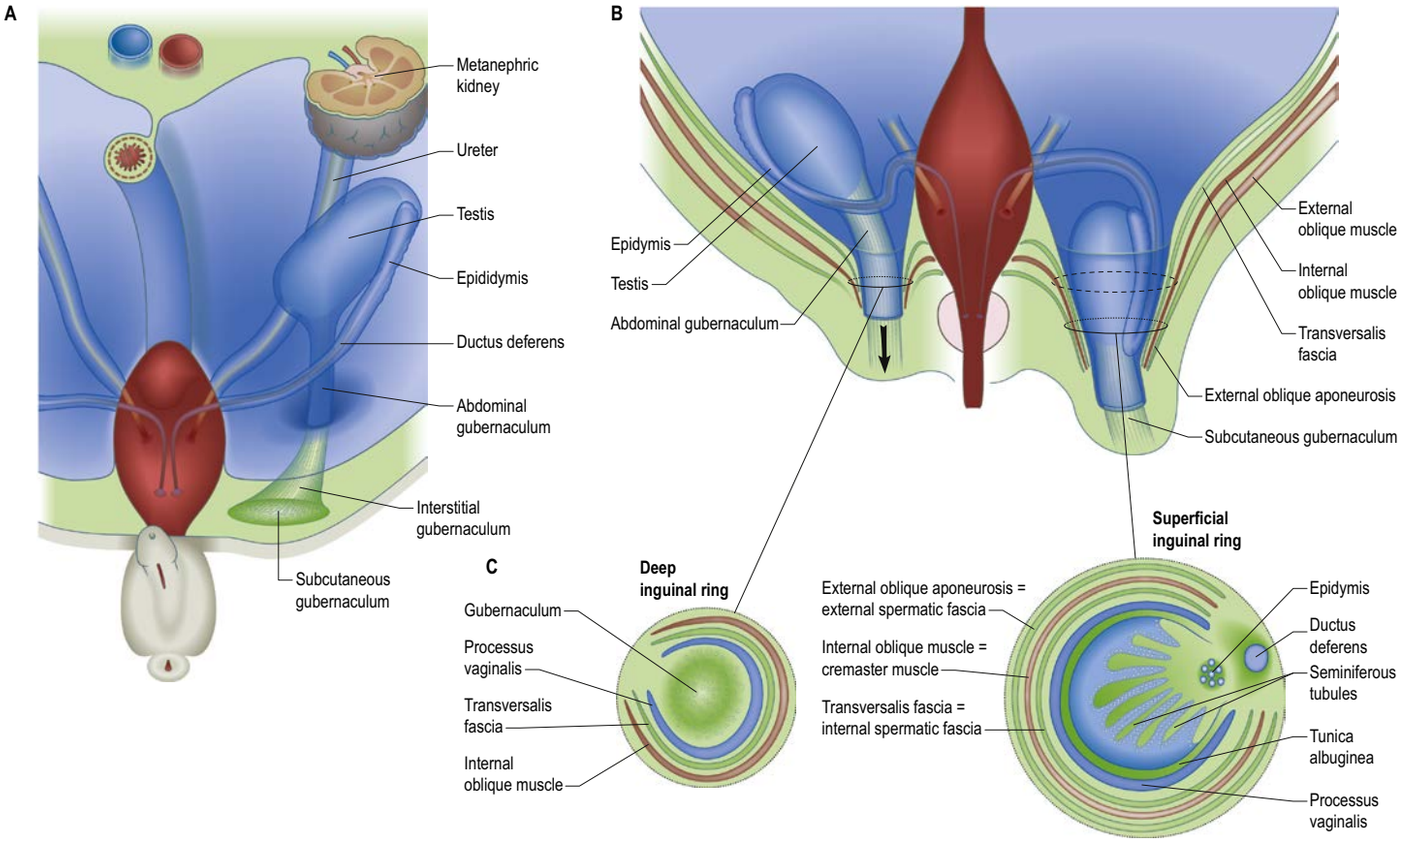

Fig. 22.17 The descent of the testis. The testis is retroperitoneal throughout development. It becomes obliquely orientated during abdominal descent. **A**, The gubernaculum attached to the lower part of the testis has an abdominal part covered with developing peritoneum, an interstitial part and a distal end embedded in the ventral abdominal wall at the site of the future inguinal canal. **B**, The gubernaculum swells, becoming similar in width to the testis. The distal-most portion of the gubernaculum bulges into abdominal wall muscles and grows 3–5 cm over the superior pubic ramus and into the scrotum. A crescentic column of peritoneum, the processus vaginalis, develops in the expanding gubernaculum. **C**, The testis gains a crescentic covering of visceral and parietal peritoneum (which forms the tunica vaginalis) and muscle and connective tissue layers as it passes through the deep and superficial inguinal rings. The coverings remain around the ductus deferens, whereas the proximal processus vaginalis normally becomes obliterated by postnatal week 3. (Based on data from Barteczko KJ, Jacob MI 2000 The testicular descent in human. Origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei and gonadal ligaments. *Adv Anat Embryol Cell Biol* 156:III–X, 1–98.)

through the patent processus vaginalis likely contributes to this migration (Hutson 2012).

Although testis descent may not be complete in preterm infants, over 95% of term (postmenstrual week 40) neonates have descended testes. After descent the processus vaginalis remains patent for 2 weeks in nearly 70% of male infants; it is partially obliterated in 80% of male infants by postnatal week 3, the left side before the right. The distal processus vaginalis (with visceral and parietal layers derived from the coelomic wall) persists as the tunica vaginalis, a satellite peritoneal cavity around the testis that becomes firmly attached to the surrounding scrotum within a few weeks. Obliteration of the proximal processus vaginalis is controlled by androgens, indirectly via CGRP released from the genitofemoral nerve. Both exogenous CGRP and hepatocyte growth factor can cause obliteration *in vitro* of the processus vaginalis in hernial sacs excised from babies with indirect inguinal hernia.

Persistent patency of the processus vaginalis leads to indirect inguinal hernia (widely patent and allowing prolapse of bowel), or hydrocele (narrow patency permitting only intraperitoneal fluid to trickle down into the tunica vaginalis). During obliteration, fluid may trickle only part of the way down the processus vaginalis to produce an encysted hydrocele of the cord. This is a relatively common but transient state and usually resolves completely within a few weeks by further obliteration. The spermatic cord, scrotum, seminal glands and adjacent ampullae of the ductus deferens are all relatively large in the neonate, reflecting perinatal androgen exposure.

In aberrant testicular descent, the testis may remain in the abdomen, although this is thought to be uncommon because the hormonal and morphological features of the transabdominal phase are relatively simple. By contrast, the indirect endocrine regulation and complex migratory process of the gubernaculum during the inguinoscrotal phase is frequently abnormal: the testis lies in the inguinal or pubic region in 2–5% of neonates. Rarely, the testis may lie in the perineum, in the upper part of the thigh or at the root of the penis. Causes may be deficient prenatal and postnatal androgens, a mislocated genitofemoral nerve or inadequate CGRP production from the nerve. Testes that have descended may not remain within the scrotum if the spermatic cord does not double its length between birth and puberty (Hutson 2013). The aetiology of acquired undescended testes is probably linked to that of hydrocele and hernia.

Descent of the ovary

The relative movements of the ovary are less extensive than those of the testis and are not hormonally regulated. Like the testis, the ovary ultimately reaches a lower level than it occupies in the early months of fetal life, but it does not leave the pelvis to enter the inguinal canal, except in certain anomalies. The ovary is connected to the medial aspect of the mesonephric fold by the mesovarium (homologous with the mesorchium), and to the ventral abdominal wall by the inguinal fold (see Fig. 22.13; **Fig. 22.18**). A mesenchymatous gubernaculum develops in this fold but, as it traverses the mesonephric fold, it acquires an additional attachment to the lateral margin of the uterus near the entrance of the uterine tube. Its lower part, caudal to this uterine attachment, becomes the round ligament of the uterus, and the part cranial to the attachment becomes the ovarian ligament. Collectively, these structures are homologous with the gubernaculum testis in the male (**Fig. 22.19**). This new uterine attachment may be correlated with the restricted ovarian descent. Initially, the ovary is attached to the medial side of the mesonephric fold but, in accordance with the manner in which the two mesonephric folds form the genital cord, it is finally connected to the posterior layer of the broad ligament of the uterus. The gubernacula thus develop in the female, unlike in the male, as bilateral fibrous bands or ligaments in the absence of INSL3. They do not extend into the labia majora, but end in the connective tissue just external to the external ring of the inguinal canal: in the absence of androgens, there is no migratory phase analogous to inguinoscrotal migration in the male. The saccus vaginalis is present in the female. Its prolongation into the inguinal canal (the canal of Nuck) is normally completely obliterated, but may remain patent and form the sac of a potential indirect inguinal hernia.

Cryptorchidism is common in neonates, with a prevalence of 2–9% of all boys (Barthold and Ivell 2018, Chen et al 2018). Cryptorchidism used to be considered a relatively minor birth defect that was corrected surgically sometime during childhood. It is now considered to be a symptom of testicular dysgenesis syndrome, a spectrum that includes hypospadias, impaired semen quality and testicular germ cell cancer; it is associated with low birth weight; maternal smoking and gestational diabetes (Toppari et al 2014, Hadziselimovic 2017). Since the number of spermatogonia decreases rapidly in undescended testes, orchidopexy is now undertaken between 6–9 months of postnatal life. Further delay results in impaired testicular catch-up growth in boys: even with early orchidopexy, men with bilateral undescended testes are six times more likely to be infertile (Lee and Shortliffe 2014). The finding that males with unilateral cryptorchidism are 25 times more likely to develop azoospermia than normal males supports the premise that this is a bilateral disease. Lower levels of testosterone, AMH and inhibin B were found in male infants (about 2 postnatal years) with bilateral cryptorchidism, compared to control male infants (Hamdi et al 2017). It has been suggested that cryptorchidism and neurodevelopmental disorders may share genetic risk factors or that individual *in utero* or early postnatal risk factors may be common precursors for both cryptorchidism and neurodevelopmental disorders (Chen et al 2018).

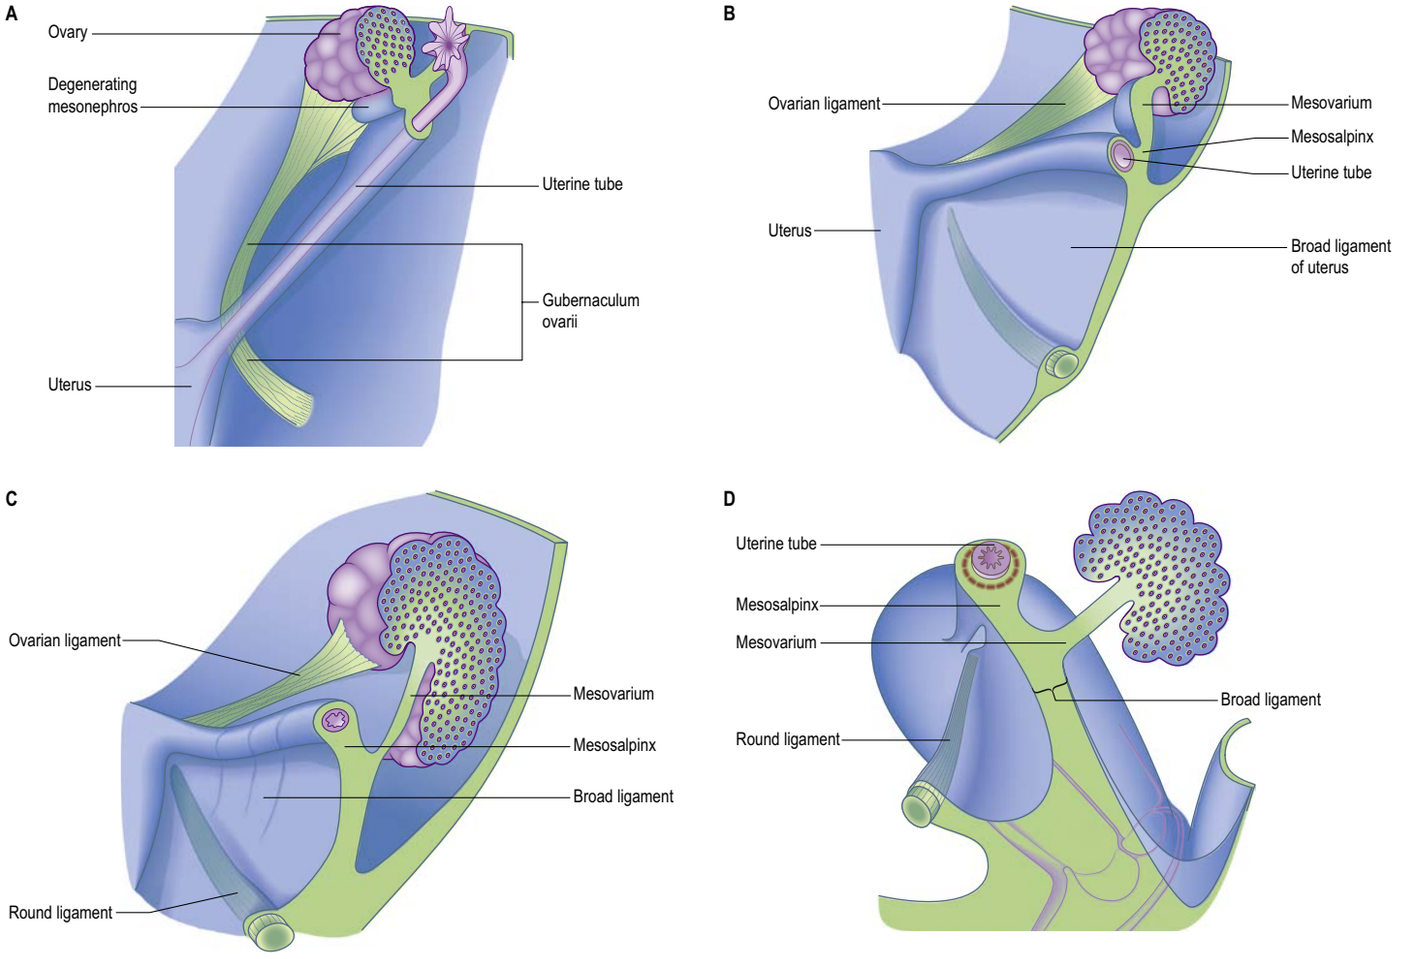

Fig. 22.18 The descent of the ovary. **A**, An early developing left ovary and uterine tube. **B**, The start of posterior movement of the ovary. **C**, The left ovary in its definitive posterior position. **D**, A sagittal section of the ligaments associated with the ovary, viewed from a left lateral position.

In the term neonate (postmenstrual week 40), the ovaries lie in the lower part of the iliac fossae. The long axis of the ovary is almost vertical. It becomes temporarily horizontal during descent, but regains the vertical when it reaches the ovarian fossa. The ovaries complete their descent into the ovarian fossae in early childhood. Thus, at birth, the ovary and the lateral end of the corresponding uterine tube lie above the pelvic brim. They do not sink into the lesser pelvis until the latter enlarges sufficiently to contain both of them and the other pelvic viscera, including the bladder. Neonatal ovaries are 1–3.6 mm long (Stranzinger and Strouse 2008) and their combined weight at birth is 0.3 g, which is relatively large, and much larger than the combined weight of the testes (see Figs 22.9, 23.14C). The ovaries double in weight during the first 6 postnatal weeks. They bear surface furrows that disappear during postnatal months 2–3. All of the primary oocytes for the reproductive life of a female are present in her ovaries by the end postmenstrual week 12. Of the 7 million primary oocytes estimated to be present at about postmenstrual week 20, 1 million remain at birth and 40,000 by puberty and only 400 are ovulated during reproductive life.

Cloaca

The cloaca is the region at the caudal end of the primitive hindgut that is continuous with the allantois (see Figs 22.4, 22.7). The allantois, a blind-ending ventral diverticulum, passes into the connecting stalk of the early embryo prior to tail-folding and is drawn into the body cavity after stage 10. In subsequent stages the distal extension within the connecting stalk is termed the allantoic duct, and the proximal end that later passes into the forming umbilical cord is termed the urachus. The cloacal cavity is slightly dilated and lined with endoderm. It is initially connected dorsocranially to the enteric hindgut, ventrally to the allantois and ventrocaudally is in contact with overlying ectoderm at the cloacal membrane. It receives and contains fluid from the mesonephric kidneys until the cloacal membrane breaks down and the cloacal and amniotic cavities become confluent. Proliferation of mesenchyme at the angle of the junction of the hindgut and allantois produces the urorectal septum (intercloacal mesenchyme), which shows passive caudal expansion with embryonic growth, promoting the movement of the endodermal epithelium towards the cloacal membrane (Fig. 22.20). The cloacal membrane becomes separated into a presumptive rectum and anal canal dorsally, and a presumptive urinary bladder and urogenital sinus ventrally, and the cloacal membrane is divided into anal and urogenital parts, respectively. The nodal centre of division is the site of the future perineal body. The urogenital sinus receives the mesonephric and paramesonephric ducts. The genes involved in mouse embryo cloacal division and the morphogenetic movements of human cloacal division have been reported (Matsumaru et al 2015, Kruepunga et al 2018).

The development of the cloaca, the lower ends of the reproductive ducts and the external genitalia is complex, and associated with mesenchymal populations derived from secondary neurulation. The cranial and dorsal areas of the cloaca show less growth and enlargement than the ventrocaudal area, which matches overall embryonic growth between stages 14 and 23, when the embryonic body straightens and the region of ventral body wall between the cloaca and umbilicus lengthens. There are also regional differences in growth of the surrounding mesenchymal populations, accumulation of extracellular matrix and extent of cell apoptosis. Ventrally, during stage 14, there is concomitant expansion of the genital tubercle and increase in length of the cloacal membrane. The middle portion of the cloacal membrane, formed by close apposition of internal endoderm and external ectoderm breaks down during stage 18 (Kruepunga et al 2018).

Pelvic floor

The pelvic floor consists of the ligamentous supports of the cervix, and the pelvic and urogenital diaphragms. The muscles control

From a morphological perspective, the underlying mechanism of some cloacal malformations may be due to the balance of regional cloacal change: too little or absent regression of the dorsal area of the cloaca may result in its persistence, with the anal opening becoming positioned more ventrally on the perineum, whereas too much regression may lead to stenosis or atresia of the anorectal junction and insufficient development of the internal anal sphincter (Kruepunga et al 2018). Bladder exstrophy is considered with urinary tract malformations (see Fig. 22.11). Cloacal malformations include the exstrophy–epispadias complex and the range of disorders of sex development; associated genital tract anomalies are common, with paramesonephric duct duplication in 40% of those affected (see Fig. 22.15) (Rintala 2016). The broad grouping of cloacal anomalies covers persistent urogenital sinus, anorectal malformations and ambiguous external genitalia. Persistent urogenital sinus is frequently seen with congenital adrenal hyperplasia; it can occur with normal and ambiguous external genitalia. The position of the resulting confluence of urethra and vagina relative to the bladder neck is important for future surgical management; one single common urogenital sinus channel opens on the perineum and anterior displacement of the anus may be seen. In persistent cloacal anomalies confluence of genital, urinary and intestinal paths form an isolated single perineal opening (Rink 2016). Antenatal ultrasound findings of transient fetal ascites and decreased amniotic fluid have been noted from postmenstrual week 19 in cloacal anomalies, and are thought to be due to blocked urine outlet via the vagina (hydrocolpos) and secondary retrograde flow of urine through the uterus and uterine tubes to the peritoneal cavity. Hydronephrosis is common, related to the hydrocolpos and consequent compression of the bladder neck by the distended vagina (Rink 2016). Cloacal anomalies are associated with risk of renal impairment and may ultimately need renal transplant (Gupta et al 2014).

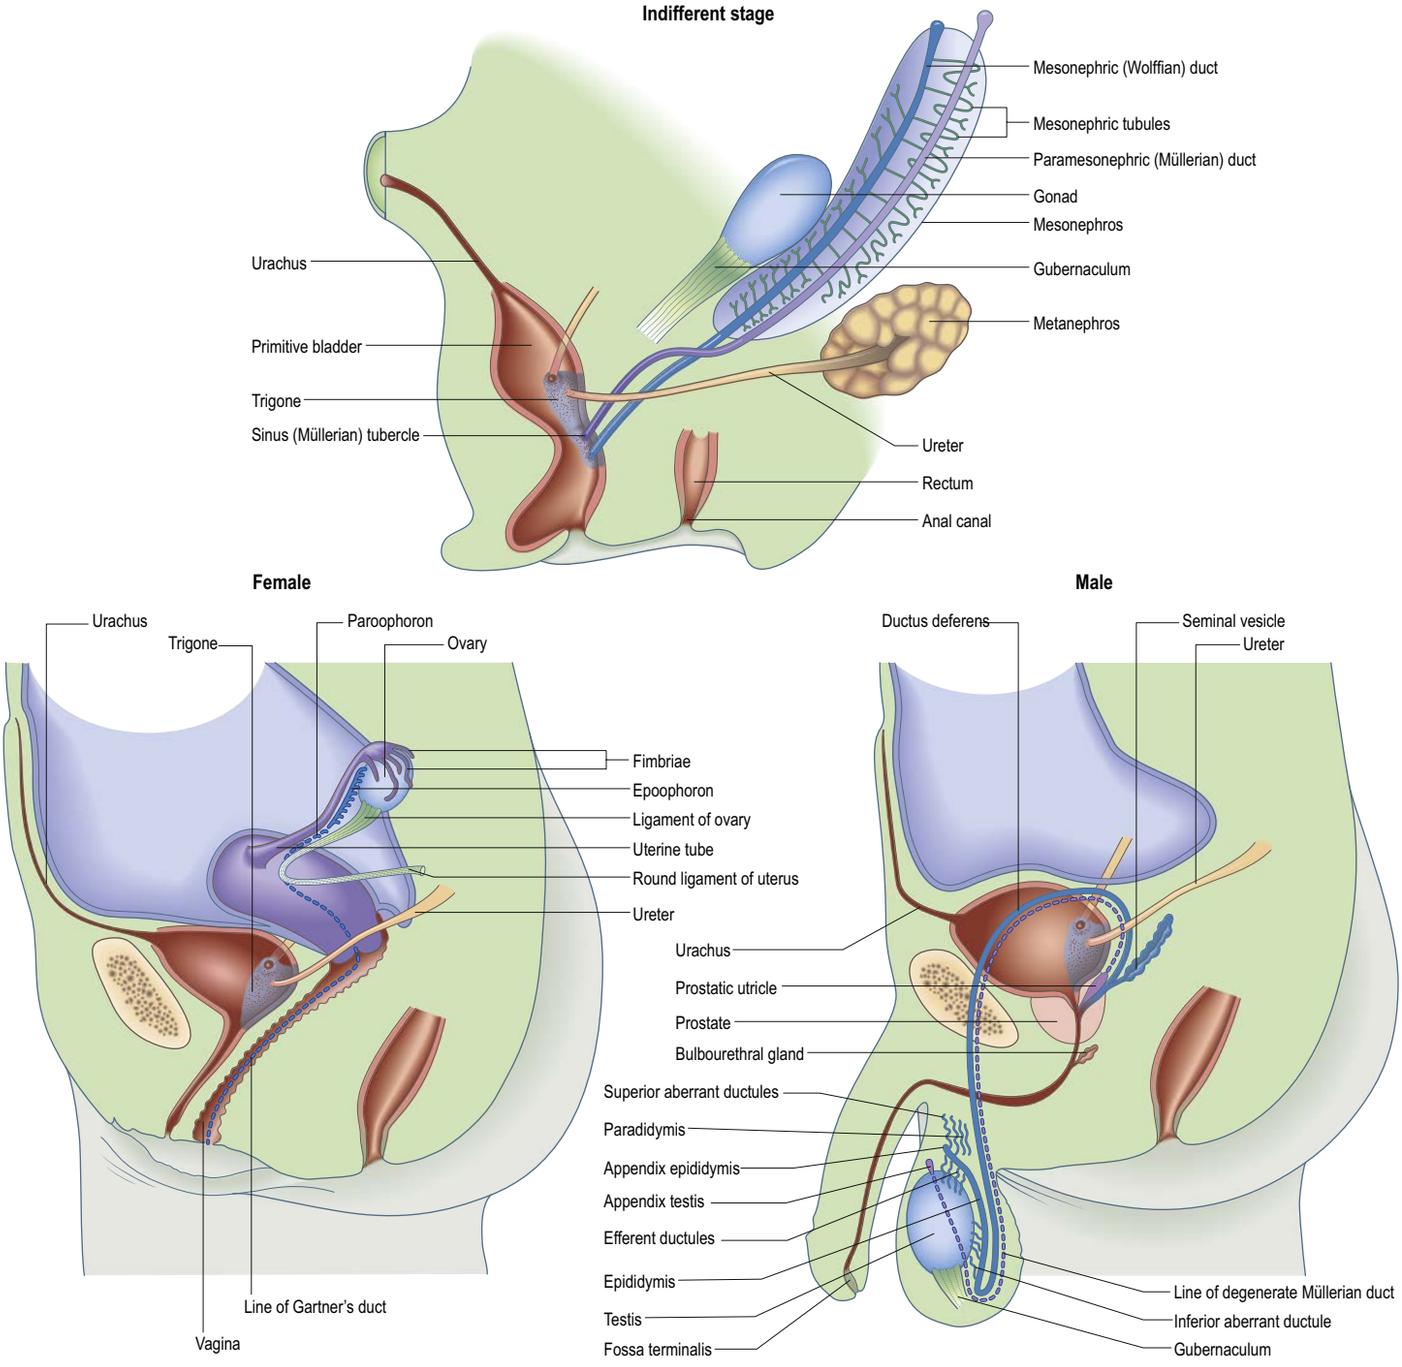

Fig. 22.19 The development of the urogenital system from the indifferent stage to the definitive male and female states. (Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd ed. London: Pitman Medical & Scientific.)

enteric and urinary sphincter mechanisms and vascular erectile tissues. The striated muscle is derived initially from individual muscle precursor cells from the ventrolateral edge of dermomyotomes adjacent to the lower limb that enter the lower limb and divide into dorsal and ventral muscle masses. The cells of the ventral mass divide again and a population migrate from the limb ventrally towards the genital tubercle (Valasek et al 2005). A migratory interaction present in other body regions has been identified in avian and murine embryos, where migratory cloacal muscle cells expressing surface CXCR4 respond to SDF-1 guiding cues expressed in cloacal tissues (Rehimi et al 2010). Although these myoblasts are derived from muscle precursor cells that migrate into the lower limb, they are later patterned by similar developmental signalling as that of trunk body wall muscles into four layers: subcutaneous, external, internal and transverse (Hall et al 2017). The muscle precursor cells give rise to the external urethral and anal sphincters, bulbospongiosus, ischiocavernosus and levator ani muscles. Striated muscle fibres can be seen from postmenstrual week 15, as can the smooth muscle of the urethral sphincter. Puborectalis appears following opening of the anal membrane.

Urethra

The urethra arises from a ventral elongation of the lower end of the urogenital sinus. It is derived, as are the prostate gland and vagina, from endodermal epithelium and local urogenital mesenchyme. Between stages 18 and 23 a solid proliferation of the endodermal epithelium forms the urethral plate which later canalizes and opens to form a urethral groove. Once the cloacal membrane proper thins and ruptures, the urethral groove is in contact with amniotic fluid. For details of the early development of the cloaca and growth of the urethral plate see Kruepunga et al (2018).

In the male, the prostatic urethra proximal to the orifice of the prostatic utricle is derived from the vesico-urethral part of the cloaca and the incorporated caudal ends of the mesonephric ducts. The remainder of the urethra is derived from the urethral groove and its later incorporation by movements of the urethral folds into the shaft of the penis as far as the glans (see Fig. 22.20). It had always been thought that the distal urethra was formed by invaginating ectoderm, however, studies have shown that the urethral plate in the glans is canalized without forming a urethral groove, and that it expresses *FOXA1*,

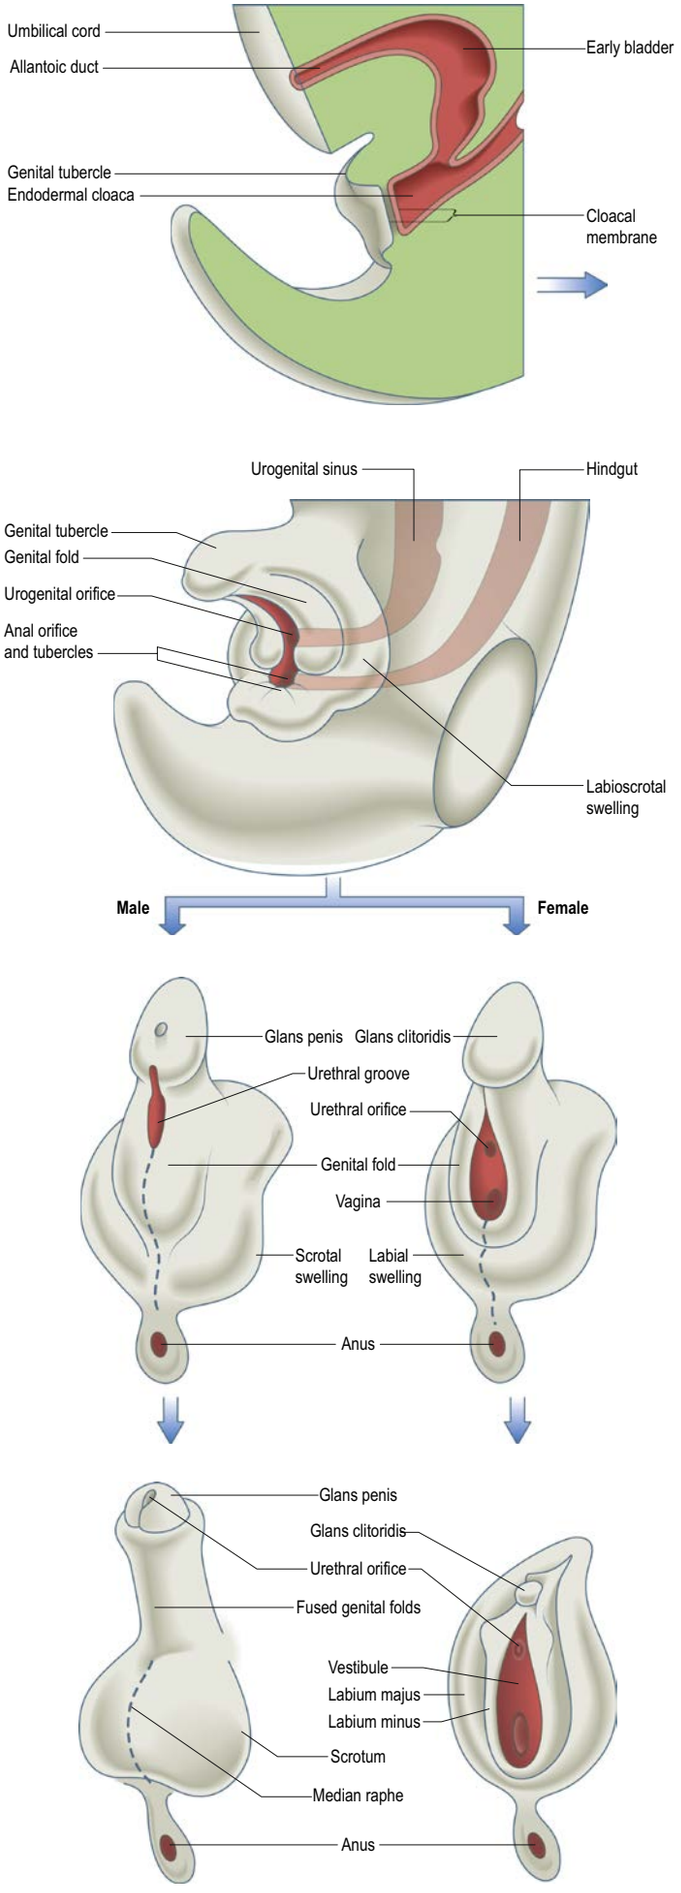

Fig. 22.20 The development of the external genitalia from the indifferent stage to the definitive male and female states.

specific for endodermal epithelium, to the distal meatus (Liu et al 2018, Baskin et al 2018). This endodermal epithelium also expresses cytokeratin 7 and uroplakin, markers of developing and mature urothelium.

In the female, the urethra is derived entirely from the vesico-urethral region of the cloaca, including the dorsal region derived from the mesonephric ducts. It is homologous with the part of the prostatic urethra proximal to the orifices of the prostatic utricle and the ejaculatory ducts. The region of the early urethra remains open to form the vestibule, into which the definitive urethra and vagina open (see Fig. 22.20). It is thought that these regions are invaded by ectoderm because they are innervated by somatic nerves.

The urethral sphincter first forms as a mesenchymal condensation around the urethra in stage 18 embryos, after division of the cloaca. The mesenchyme proliferates and becomes defined at the bladder neck after stage 23, and along the anterior part of the urethra by about postmenstrual week 13. The muscle fibres differentiate after postnatal week 15, at which time both smooth and striated fibres are present. In females, there is continuity between the smooth muscle of the bladder and urethral wall. In males, the muscle fibres are less abundant because of the local development of the prostate. Striated muscle fibres form around the smooth muscle, initially in the anterior wall of the urethra, and later encircle the smooth muscle layer. The striated muscle originates from ventral mass, lower limb myoblasts that, having entered the lower limb, then migrate to the perineal region. In the mouse embryo the myoblasts form levator ani (Valasek et al 2005). The smooth and striated components of the urethral sphincter are closely related, but there is no mixing of fibres as occurs in the anorectal sphincter.

Developmental anomalies of the urethra

Prostate gland

The prostate gland arises during postmenstrual weeks 11–12 from interactions between the urogenital sinus mesenchyme associated with the mesonephric and paramesonephric ducts and the endoderm of the proximal part of the urethra. This region has been termed the Müllerian duct–urogenital sinus junction (Cai 2008). Five stages of prostatic development have been demonstrated in rodent embryos and human fetuses, each typical for an evaginating gland (Cunha et al 2018b). The endodermal urogenital epithelium surrounding the developing urethra thickens and 14–20 solid buds arise around the whole circumference of the tube, mainly on its lateral aspects and excluding the dorsal wall above the utricular plate. The buds elongate and branch into the urogenital mesenchyme, showing some differentiation into luminal and basal cells as the lumen extends. They give rise to the outer glandular zone of the prostate. Later they will complete their secretory differentiation. Smooth muscle cells are seen in the urogenital mesenchyme at about postmenstrual week 20.

In human fetuses the original entry point of the two mesonephric ducts and the (midline joined) paramesonephric ducts into the urogenital sinus produces a region of mixed epithelial derivation. An evagination of each mesonephric duct, now the ductus deferens, gives rise to the seminal glands, and thereafter it is the caudal continuation, the ejaculatory duct, that enters the developing urethra. In the embryo, the entry of the paramesonephric ducts into the urogenital sinus initiates the endodermal proliferation of the sinuvaginal bulb which will grow cranially as the vaginal plate in the female. The caudal-most remnants of the paramesonephric ducts, which involute under the effects of AMH in the male, remain as the prostatic utricle, a structure sometimes termed the male vagina (Puppo and Puppo 2016). These entry points produce an elongated dorsal prominence, the seminal colliculus (verumontanum). This has been shown, by its epithelial expression of FOXA1, to be derived from the urogenital sinus, although it patchily expresses PAX2, the gene expressed by the epithelium of the mesonephric and paramesonephric ducts (Cunha et al 2018a). Anomalous fusion and/or growth of the different tissue populations that meet at the verumontanum may result in protruberance of tissue into the urethra; the biomechanical effects of bladder filling and emptying might elongate this tissue, producing the sail-like fold(s) arising from the verumontanum that are seen in cases of posterior urethral valves. These can be identified on ultrasound examination during the second and third trimesters and are associated with hydro-ureteronephrosis (Hodges et al 2009, Siebert et al 2013).

The developing prostate gland is affected by the local hormonal environment: in response to increased androgens, experimental recombination of female vaginal mesenchyme can direct endodermal epithelium to

Urethral defects are common in the male. Epispadias is a defect in the dorsal wall of the urethra on the glans of the penis, penile shaft, or at the junction of the penis with the ventral (anterior) abdominal wall. Isolated male epispadias is rare (1 in 117,000 males); this anomaly is considered to be a less severe form of exstrophy of the bladder (Gearhart and Mathews 2016). Hypospadias is more common (1 in 250 births), with the urethral meatal opening anywhere along the line of fusion of the urogenital folds and scrotum. The incidence of hypospadias at distal sites along the penis is 94%, but also occurs in the midshaft (4%) and proximal shaft (1%). In more severe cases, the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. The prevalence of hypospadias has increased and it is thought to be part of testicular dysgenesis syndrome. Congenital penile curvature (chordee), both dorsal or ventral, with an orthotopic meatus, is frequently associated with hypospadias and is thought to be linked to anomalous distribution of smooth muscle fibres in the dartos muscle. This condition becomes more evident after puberty (Haroun 2018).

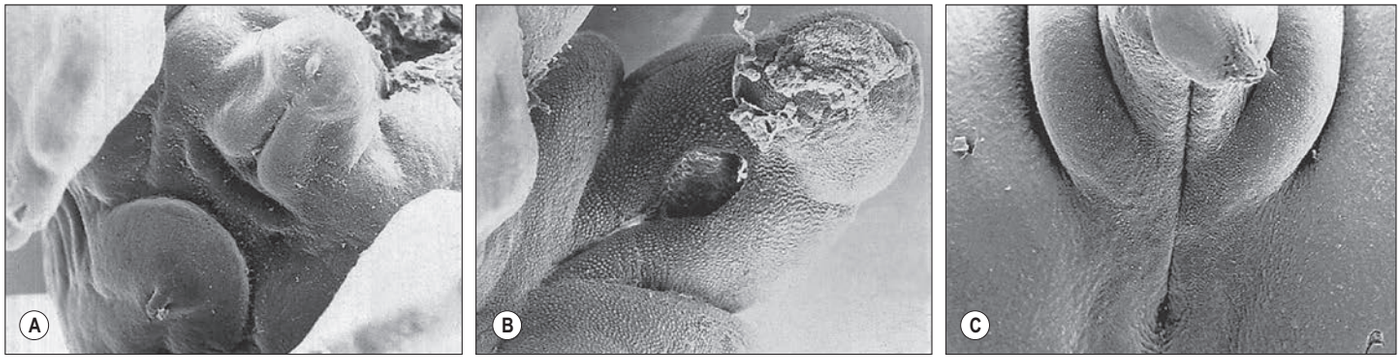

Fig. 22.21 Scanning electron micrographs of early human external genitalia. **A**, The indifferent stage in a human embryo about stage 18. **B**, A human female embryo about postmenstrual week 12. The genital folds are not fused. **C**, A human male embryo at about postmenstrual week 12. Fusion of the genital folds has occurred. (Photographs by P Collins.)

form prostate gland (Cai 2008). In the male, the early surge in androgens at postmenstrual weeks 8–10 is associated with endodermal proliferation; mesenchymal proliferation occurs later from about postmenstrual week 12, when maternal oestrogen levels increase (Cai 2008).

Similar outgrowths occur in the female but remain rudimentary in the absence of androgenic stimulation.

The bulbourethral glands in the male, and the greater vestibular glands in the female, arise as diverticula from the epithelial lining of the urogenital sinus.

External genitalia

Patterning of the external genitalia may be achieved by mechanisms similar to those that pattern the face and limb. In the cranial region, neural crest mesenchyme makes an important contribution to the organization of the pharyngeal arches and the regions around the pharyngeal constrictors and the upper oesophageal sphincter. Neural crest also arises from the tail-bud region, specifically from a population of cells termed the caudoneural hinge, which share the same molecular markers as the primitive node. The neural tube at this level is derived from a mesenchymal to epithelial transformation of caudoneural hinge cells that form a cylinder. Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction. It is not known whether neuronal neural crest arising from secondary neurulation processes contributes to the caudal interface between endoderm and ectoderm. Many of the genes controlling external genital development have been identified (Kojima et al 2010, Blaschko et al 2012).

The external genitalia, like the gonads, pass through an indifferent state before distinguishing sexual characters appear (see Fig. 22.20). From stage 13, primordia of the external genitalia, composed of underlying proliferating mesenchyme covered with ectoderm, arise around the cloacal membrane, between the primitive umbilical cord and the caudal limit of the embryo. During stage 15, the cloacal membrane is divided by the urorectal septum into a cranial urogenital membrane and a caudal anal membrane (see Fig. 22.4). Local ectodermal–mesenchymal interactions give rise to the anal sphincter, which will develop even without the presence of the anal canal: the skeletal muscle is derived from a portion of the ventral muscle mass that initially migrates into the lower limb and then moves to the perineal region (Valasek et al 2005, Rehimi et al 2010). These myoblasts will give rise to the bulbospongiosus and ischiocavernosus muscles. A surface elevation, produced by underlying pericloacal mesenchyme, the genital tubercle, appears at the cranial end of the urogenital membrane and two lateral ridges, the genital or urethral folds, form each side of the membrane (Wang et al 2013) (see Fig. 22.20). The genital tubercle forms a distinct primordium that will become the glans of either the penis or the clitoris. Elongation of the genital folds and urogenital membrane produces a primitive phallus. As this structure grows, it is described as having a cranial surface analogous to the dorsum of the penis, and a caudal surface analogous to the perineal surface in both sexes (Isaacson et al 2018). The urogenital sinus contiguous with the internal aspect of the urogenital membrane, becomes attenuated within the elongating phallus, forming the primitive urethra. The urogenital membrane breaks down at about stage 19, allowing communication of ectoderm and endoderm at the edges of the disrupted membrane and continuity of the urogenital sinus with the amniotic cavity. Urine can escape from the urinary tract from this time. The endodermal layer of the attenuated distal portion of the urogenital sinus, which is now displayed on the caudal aspect of the phallus, is termed the urethral plate (male) and vestibular plate (female). While these changes are in progress, two labioscrotal (genital) swellings appear, one on each side of the base of the phallus, and extend caudally, separated from the genital folds by distinct grooves (see Fig. 22.20; **Fig. 22.21**). Homologies of the parts of the urogenital system are shown in Table 22.1.

As a general rule, epithelium that can be touched easily and has a somatic innervation, is derived from ectoderm. In the buccal cavity and pharynx, the ectoderm/endoderm boundary is a zone towards the posterior third of the tongue, and touch here usually elicits the gag reflex. In the anal canal, the outer portion, distal to the anal valves, is derived from ectoderm and has a somatic innervation, whereas the epithelium proximal to the valves is derived from endoderm and has an autonomic and visceral afferent innervation. The urethral meatus and vagina, although derived from endoderm, have a somatic innervation at the vestibule and so must be part of an ectodermal/endodermal boundary zone in this region.

Male genitalia

The growth of male external characteristics is stimulated by androgens regardless of the genetic sex. The male phallus enlarges to form the penis. As mesenchyme proliferates within the genital folds, the urethral plate sinks into the body of the phallus, forming a primary urethral groove. The genital folds meet proximally in a transverse ridge immediately ventral to the anal membrane. The genital swellings meet each other ventral to the anus and unite to form the scrotum (see Fig. 22.20). The genital folds fuse with each other from behind forwards, enclosing the phallic part of the urogenital sinus behind to form the bulb of the urethra, and closing the definitive urethral groove in front to form the greater part of the spongiose urethra (Shen et al 2016). Fusion of the folds results in the formation of a median raphe and occurs in such a way that the lining of the postglandular urethra is formed by closure of the urethral groove. Thus, as the phallus lengthens, the urogenital orifice is carried onwards until it reaches the base of the glans at the apex of the penis. Within the glans the urethral plate canalizes directly to the urethral meatus. Expression of FOXA1, cytokeratin 7 and uroplakin confirm the entire endodermal origin of the human penile urethra (Liu et al 2018).

The glans and shaft of the penis are recognizable by the end of the first trimester. Development of the prepuce can be seen by postmenstrual week 14, when the primary external orifice of the urethra is still at the base of the glans. A ridge consisting of a mesenchymal core covered by epithelium appears proximal to the neck of the penis and extends forwards over the glans (Isaacson et al 2018, Liu et al 2018). A solid lamella of epithelium deep to this ridge extends backwards to the base of the glans. The ventral extremities of the ridge curve backwards to become continuous with the genital folds at the margins of the urethral orifice. As the urethral folds meet to form the terminal part of the urethra, the ventral horns of the ridge fuse to form the frenulum. The epithelial lamella breaks down over the dorsum and sides of the glans to form the preputial sac, and thus free the prepuce from the surface of the glans. Thereafter, the prepuce grows as a free fold of skin, which covers the terminal part of the glans. Although the prepuce and glans begin to separate from postmenstrual weeks 17–20, they may still be joined at birth. The preputial sac may not be complete until 6–12 postnatal months or more after birth and, even then, the presence of some connecting strands may still interfere with the retractability of the prepuce (Liu et al 2018).

The mesenchymal core of the phallus is comparatively undifferentiated up to stage 17, with the blastemata of the corpora cavernosa

becoming defined after stage 23. Myoblasts forming the bulbospongiosus and ischiocavernosus muscles are derived from lower limb myoblasts (Valasek et al 2005). Nerves are present in the differentiating mesenchyme from about stage 21. Despite containing less smooth muscle and elastic tissue than the adult, the neonatal penis is capable of erection.

The scrotum is formed by proliferation of the genital swellings that fuse across the midline covering the base of the penis. The testes descend into the scrotum prior to birth. The gelatinous matrix of the gubernaculum is then resorbed and the tunica vaginalis becomes adherent to the connective tissue of the scrotum. In the male neonate (postmenstrual week 40), the scrotum has a broad base that does not narrow until after the first year. The septum (i.e. the mesenchyme remaining between the tunica vaginalis on each side) and the walls of the scrotum are both relatively thicker than in adults.

There is evidence that in certain tissues, e.g. urogenital sinus and genital swellings, testosterone is converted into 5α-dihydrotestosterone. In XY individuals with a genetic deficiency of the enzyme responsible for this conversion, not only functioning testes but also female external genitalia, with an enlarged clitoris and a small vaginal pouch, are present, suggesting that external genital development is under the control of 5α-dihydrotestosterone (Kang et al 2014). Such individuals are often raised as girls; however, at puberty the external genitalia become responsive to testosterone, causing masculinization at this time.

Female genitalia

The female phallus becomes the clitoris. The vestibular plate forms a vestibular groove, but there is no midline fusion process and the vestibular groove remains open. The genital swellings remain separate as the labia majora and the genital folds remain separate as the labia minora (see Fig. 22.20). The perineal orifice of the original urogenital sinus is retained as the cleft between the labia minora, and the urethra and vagina open above it. The prepuce of the clitoris develops in the same way as its male homologue. By about postmenstrual week 16, female external genitalia can no longer be masculinized by androgens. In the female neonate (postmenstrual week 40), the distal end of the round ligament of the uterus, the gubernaculum ovarii, ends just outside the external inguinal ring and the labia majora are united by a posterior labial commissure.

Disorders of sex development

The acquisition of appropriate gonads, reproductive ducts, external genital structures and appropriate gender identity occurs through a myriad of complex processes, both local and systemic. Anomalous developmental processes, leading to differences in sex chromosomes, gonadal structure and position, retention of ductal homologues, androgen insensitivity, androgen excess, and ambivalent external genitalia requiring gender assignment, were previously described as intersexual conditions or hermaphrodism. Such terminology is nonspecific, confusing and perceived as potentially pejorative by affected individuals. Advances in the identification of molecular genetic causes of such conditions have led to proposed changes to describe them as 'disorders of sex development' (DSD): congenital conditions in which development of chromosomal, gonadal or anatomical sex is atypical (Lee et al 2006). The range of anomalous development and its management by multidisciplinary teams, as well as by the affected family, are comprehensively covered by Arboleda and Vilain (2014).

Maturation of the reproductive organs, mini-puberty and puberty

This paper considers the importance of Sertoli cell development and the future sperm count of adult males.

Early morphological changes in the developing gonads and ducts are affected by secretion of placental hormones. The functional development of the hypothalamus and pituitary gland is seen towards the end of the embryonic period: LH and FSH are synthesized from about postmenstrual week 9 and appear in fetal serum from postmenstrual weeks 12–14. In males up to postmenstrual week 12, placental hCG induces the differentiation of Leydig cells which secrete testosterone at a peak level similar to adults. In females, the majority of oestrogen is produced by the placenta and primordial ovarian follicles form when fetal circulating oestrogen levels are high, most rapidly after postmenstrual weeks 14–15.

Fetal pituitary secretion of GnRH peaks in mid-gestation and decreases towards birth. It is suppressed toward term by placental oestrogen secretion, which suppresses the fetal HPG axis. Serum LH and FSH are not related to GnRH mid-gestation, but are induced by it after postmenstrual weeks 30–31. Low production of LH and FSH in males coincides with the first maturation of seminiferous tubules, and high production in females coincides with the first maturation of primary ovarian, and growing antral follicles (Lanciotti et al 2018).

At birth, the level of oestradiol in cord blood is high: LH and FSH are undetectable in females and FSH levels are very low in males because of the inhibitory effects of this placental hormone. The concentration in cord blood depends on the age (postmenstrual weeks) and mode of delivery. Circulating placental hormone levels fall in the first few postnatal days. GnRH begins to rise after postnatal days 6–10 when the neonatal HPG axis is re-initiated. In males, LH level increases 10 times within a few minutes of delivery and there is a concomitant rise in testosterone that lasts about 12 hours.

Mini-puberty is the period from birth to about postnatal month 6, when changes in pituitary hormones and consequent changes in the gonads (that affect future growth) occur (Rey 2014, Hadziselimovic 2017, Lanciotti et al 2018). The changing patterns of hormones in male and female fetuses and early neonates is shown in **Fig. 22.22**.

In males Sertoli cells continue to proliferate in the first month after birth, but there is no spermatogenesis because they do not express androgen receptors. They secrete inhibin B that peaks at postnatal months 3–6 and remains elevated until postnatal month 15. Secretion of AMH is highest at postnatal month 3 and then declines to remain stable in childhood until puberty, when it declines to adult levels (3–4% of infant level). The number of Leydig cells increases until postnatal month 3 and then decreases.

In females, the labia minora, clitoris and labia majora are relatively enlarged, reflecting the effects of placental oestrogens. Levels of oestradiol increase after the first postnatal week and remain high up to 6 postnatal months, with fluctuations in the first months. During this time, some ovarian follicles mature to antral stages and some atrophy. Further development of the follicles produces a marked rise in AMH levels, secreted by granulosa cells, at postnatal month 3. The pool of primordial follicles remains stable until postnatal month 8 at which time the majority undergo atresia. The remaining follicles resume development after puberty, completing oocyte first meiotic division shortly before ovulation. The granulosa cells at this time enlarge and multiply to form the stratum granulosum; they are surrounded by thecal cells that differentiate from the stroma.

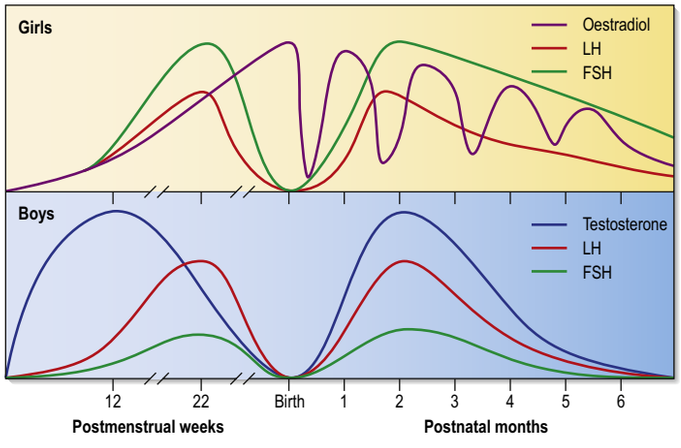

Fig. 22.22 Patterns of fetal and postnatal hormones during mini-puberty. LH, luteinizing hormone; FSH, follicle stimulating hormone. (With permission from Lanciotti L, Cofini M, Leonardi A et al 2018 Up-to-date review about minipuberty and overview of hypothalamic–-pituitary–gonadal axis activation in fetal and neonatal life. Front Endocrinol (Lausanne) 9:410.)

Most term neonates of both sexes have palpable breast tissue, larger and persisting longer in females, that reflects the high level of oestradiol in cord blood. Mammary gland diameter gradually decreases in both sexes, until postnatal month 6 in boys and over a longer time in girls, reflecting endogenous oestrogen activity (Fig. 22.22). Uterine length increases primarily during pregnancy under the influence of the hormones that cross the placental barrier. It is relatively longest at day 7 in full-term babies, then steadily involutes towards postnatal month 3, remains fairly unchanged until the second year, and does not regain its neonatal size and weight until puberty. In males, the penis and scrotum are relatively large; penile length, which is correlated with serum testosterone level, increases from birth to 3 years of age, with the highest growth velocity between birth and postnatal month 3. Testicular volume increases from birth to postnatal months 5–6, reflecting the proliferation of Sertoli cells, and then decreases from about postnatal month 9. It has been suggested that transient activation of the HPG axis causes early germ cells to differentiate into adult dark (Ad) spermatogonia, the future adult reservoir of stem cells, from postnatal month 3 (Hadziselimovic 2017).

In preterm babies the postnatal HPG axis activation is stronger and more prolonged than in full-term babies. In males, the testosterone levels are higher, with a significant difference to full-term babies at postnatal month 6. Preterm males have faster penile and testicular growth. In females the levels LH and FSH are higher, the FSH level possibly reflecting less ovarian follicle development. Antral follicles can be seen postnatally and there are increases in AMH and oestradiol from granulosa cells. The intensity of postnatal hormonal stimulation in preterm babies can cause ovarian hyperstimulation syndrome, which is self-limiting. In neonates with fetal growth restriction, males show reduced testicular volume and testosterone concentration in adult life, leading to infertility; females show adrenal and ovarian hyperandrogenism, with precocious pubarche and reduced ovulation rate, associated with lower insulin sensitivity (Lanciotti et al 2018).

Puberty is the term given to describe the time at which changes in HPG axis, gonads, reproductive organs and secondary sexual characteristics occur, along with the adolescent growth spurt (Ch. 23). The sequence of events, which is much less variable than the age at which they take place, is shown in **Fig. 22.23**. Normal puberty can be regarded as a process of innate maturation that can be modified by nutrition and stress. There is a secular trend toward early puberty in many developed and developing countries linked to the secular trend of greater adult height: faster growth in childhood/juvenile phases is associated with earlier age at puberty. The earliest change associated with puberty is the onset of sleep-related LH pulses that occur earlier in girls than boys; rising oestradiol levels reflect primary follicle recruitment in girls; rising testosterone levels in boys reflect increasing Leydig cell activity and proliferation of Sertoli cells (Ellison and Reiches 2012). Chondrocyte proliferation is stimulated in the growth plates of growing bones (Jee and Baron 2016). Androgen secretion by the suprarenal gland stimulates growth of pubic and axillary hair in both sexes, appearing earlier in girls. Body composition changes as a consequence of gonadal steroid production; oestradiol stimulates adipose tissue growth in girls particularly in the breasts and gluteofemoral region, whereas in boys, testosterone inhibits adipose tissue growth and stimulates muscle anabolism (Ellison and Reiches 2012).

The uterus and vagina develop simultaneously with the breasts. Menarche occurs after the peak of the height spurt; onset is more closely related to radiological than to chronological age. It has been suggested that the menarche occurs as a critical weight of 50 kg is attained. Sports and excessive restriction of diet, both of which may reduce weight below this level, can cause amenorrhoea in females who were previously menstruating normally. Tall girls reach sexual maturity earlier than short ones, but girls with a late adolescent growth spurt and later puberty are ultimately taller on the average than those who pass through the menarche early. A girl who has begun to menstruate can be predicted to grow a further 7.5 cm at most. Menarche marks a definitive stage of uterine development but does not mean attainment of full reproductive function: many of the early menstrual cycles may not involve ovulation.

Testis growth in boys reflects seminiferous tubule development and Sertoli cell proliferation. The volume of the testes may be estimated: the average adult volume is 20 ml, and a volume of 6 ml indicates that puberty has started. Later, the penis, prostate and seminal glands begin to enlarge. Increased testosterone levels produced by the Leydig cells of the testes promote changes in the larynx, skin and distribution of bodily hair.

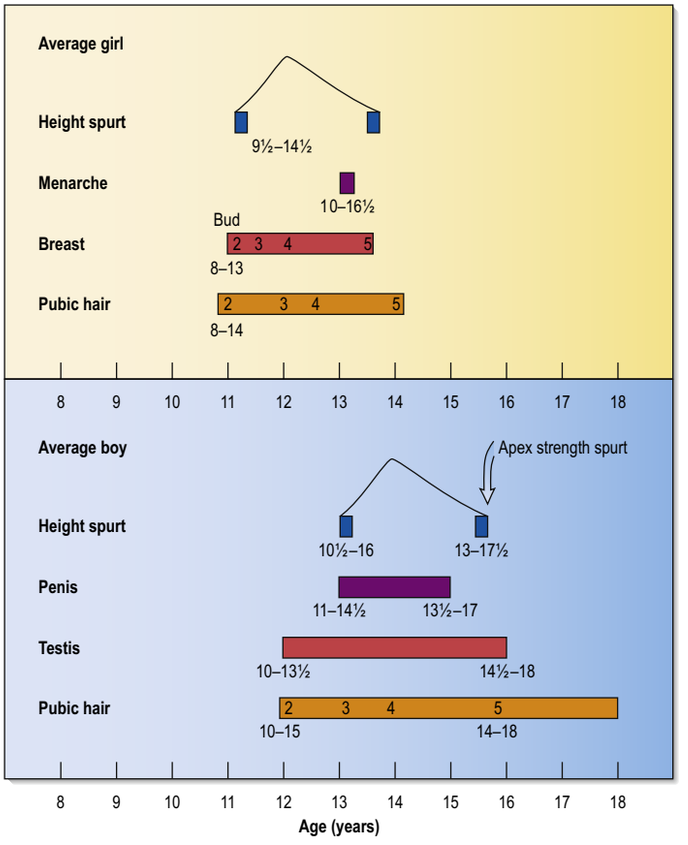

Fig. 22.23 The average ages at which maturation events occur in adolescent girls and boys. The figures beneath the bars indicate the range of ages within which each event may begin and end. Figures within the bars indicate the developmental stage. The velocity of the strength spurt peaks later than the height spurt in boys, associated with testosterone and growth hormone levels. It is appreciated that the assessment and interpretation of the strength spurt during puberty is complex (De Ste Croix 2007). (Modified with permission from Tanner JM 1962 Growth at Adolescence, 2nd ed. Oxford: Blackwell Publishing.)

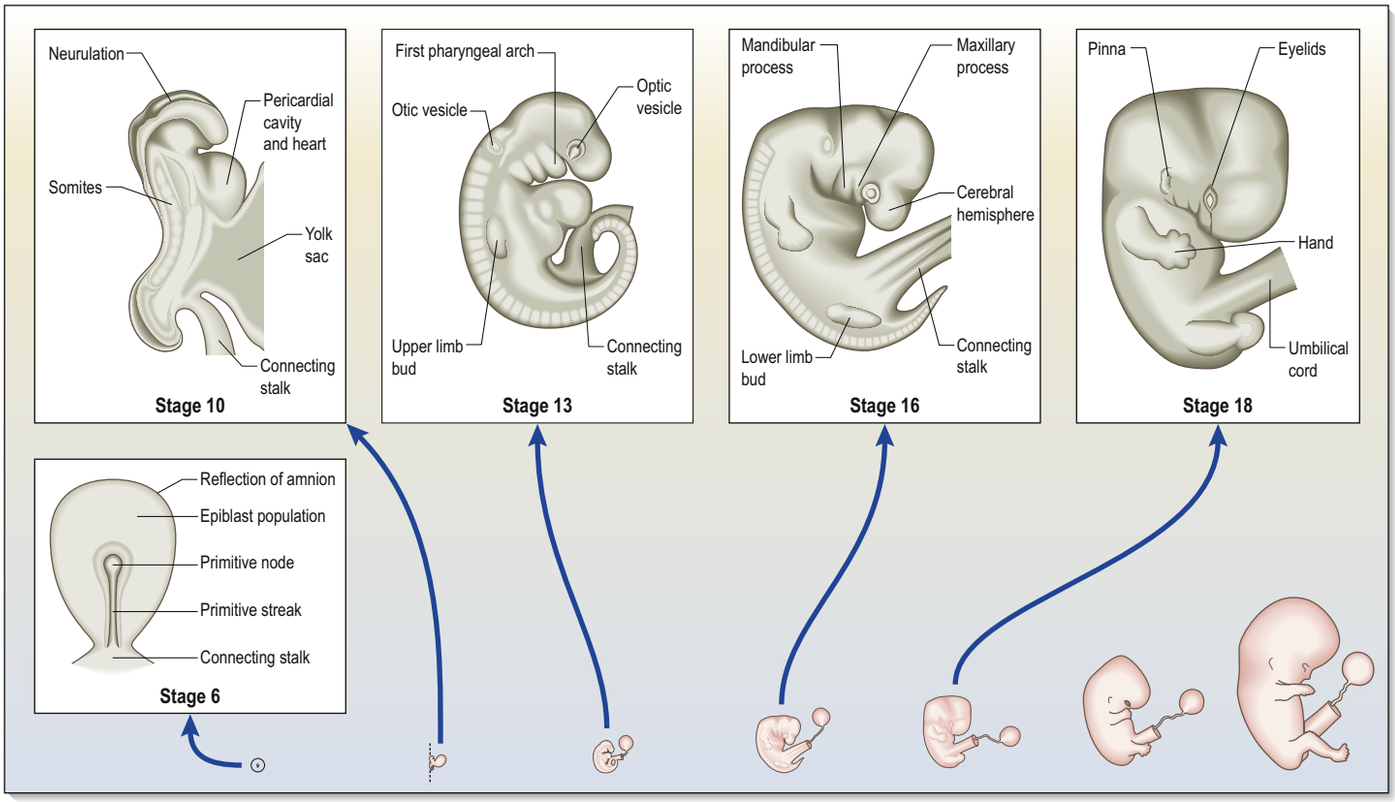
CHAPTER 23

Pre- and postnatal growth and the neonate



PRENATAL STAGES

Development of a human from fertilization to delivery at 'full term' averages 266 postfertilization days, or 9.5 lunar months (28 day units). It has long been customary to compute the length of a pregnancy, whether in a normal birth or an abortion, from the first day of the last menstrual period of the mother but, as ovulation usually occurs near the fourteenth day of a menstrual cycle, this 'menstrual age' is an overestimate of developmental age of about 2 weeks. Estimated in this manner, pregnancy averages 280 days from the last menstrual period or 10 lunar months (40 weeks).

The development of a human from fertilization to birth is divided into two periods: embryonic and fetal. The absolute size of an embryo or fetus does not afford a reliable indication of either its chronological age or the stage of its structural organization, even though graphs based on large numbers of observations have been constructed to provide averages. All such data suffer from the difficulty of timing the moment of conception in humans; *in vitro* fertilization techniques now accurately time the start of embryonic life (Ch. 8).

The embryonic period was graded or classified into developmental stages or 'horizons', on the basis of the internal and external features of approximately 600 sectioned embryos, by Streeter (1942, 1945, 1948). These sections formed the basis of the Carnegie system of staging. Streeter's work and its continuation by O'Rahilly and Müller (1987), provided, and continues to provide, a sound foundation for embryonic study and a means of comparing stages of human development with those of the animals routinely used for experimental study, namely the chick, mouse and rat.

The postfertilization developmental events in embryonic stages 1–10 are shown in detail in Fig. 8.1. The stages up to stage 5 are concerned with implantation of the blastocyst. The external appearance of representative stages from stage 6 to stage 23, correlated with the greatest length in millimetres and approximate age in days is shown in **Fig. 23.1**. Estimations of embryonic length from fixed histological specimens may be 1–5 mm less than their equivalent *in vivo* estimates, reflecting the shrinkage caused by the preparative procedures used in embryological studies. O'Rahilly and Müller (2000, 2010) revised some of the ages that had previously been assigned to early Carnegie embryonic stages, pointing out that interembryonic variation might be greater than had been thought and that, consequently, some ages might have been underestimated. They noted that, as a guide, the age of an embryo could reasonably be estimated from the embryonic length within the range 3–30 mm, by adding 29 to the length. Recent use of ultrasound for the examination

Embryonic stage	6	10	13	16	18	20	23
Size (mm)	0.4	1.5–3	4–6	8–11	13–17	21–23	28–30
Approximate age (days)	16–18	26–29	30–33	35–40	41–45	46–50	53–58

Fig. 23.1 The external appearance and size of embryos between stages 6 and 23. Early in development, external features are used to describe the stage, e.g. somites, pharyngeal arches or limb buds. (Adapted with permission from Pandya P, Oepkes D, Sebire N et al (eds) Fetal Medicine: Basic Science and Clinical Practice, 3rd ed. Elsevier. Copyright 2020.)

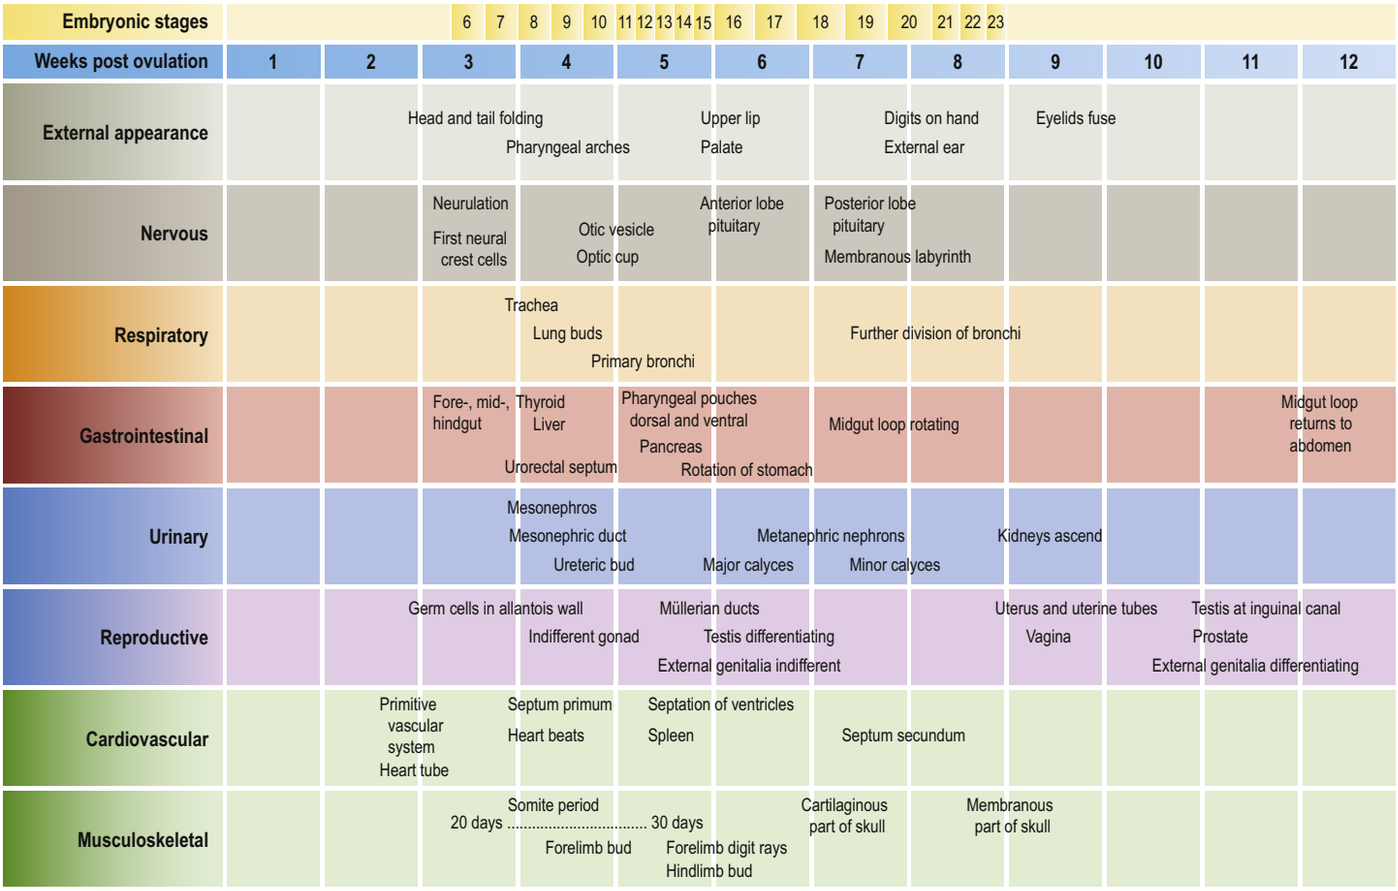


Fig. 23.2 A timetable of development of the body systems. The development of individual systems can be seen progressing from left to right. Embryonic stages and weeks of development are shown. Embryonic stages are associated with external and internal morphological features rather than embryonic length. To identify the systems and organs at risk at any time of development, follow a vertical progression from top to bottom.

of human embryos and fetuses *in utero* has confirmed much of the staging data. However, assigning embryos to a particular stage and the estimated length of days that that stage encompasses remains subject to error. The revisions of age to particular stages given by O'Rahilly and Müller (2010) are followed as closely as possible in what follows.

Obvious external features provide some guidance to the changes occurring within embryos during successive stages. Somite number is related to early embryonic stages; once the number of somites is too great to count with accuracy, the degree of development of the pharyngeal arches is often used. External staging becomes more obvious when the limb buds appear. The upper limb bud is clearly visible at stage 13 (approximately 31–33 days post fertilization) and the acquisition of a distal paddle on the upper limb bud is characteristic by stage 16 (approximately 37–38 days post fertilization). At stage 18 (approximately 42–44 days post fertilization) the lower limb bud has a distal paddle, whereas the upper limb bud has digit rays that are beginning to separate. By stage 23 (approximately 53–58 days post fertilization) the embryo has a head that is almost erect and rounded, and eyelids are beginning to form. The limbs look far more in proportion and fingers and toes are separate. At this stage the external genitalia are well developed, although they may not be sufficiently developed for the accurate determination of the sex.

Stages of embryonic development include all aspects of internal and external morphogenetic change that occur within the embryo during that stage. They are used to convey a snapshot of the status of the development of all body systems within a particular timeframe. Fig. 23.2 gives an overview of the changes in the main body systems over time and also shows the systems and organs at risk at any specific developmental time and the range of anomalies caused by teratogenic insult at a particular time. Historically, the onset of bone marrow formation in the humerus in stage 23 was used by Streeter to indicate the end of the embryonic period and the beginning of the fetal period of prenatal life, after 53–58 days (about 8 weeks) postfertilization. Fig. 23.3 shows embryonic stages 10–23 correlated to postfertilization days of development alongside postmenstrual weeks. The 'term' of a pregnancy, i.e. its completion resulting in delivery, is considered clinically normal between 37 and 42 weeks.

In obstetric practice, the period of pregnancy is divided into thirds, termed trimesters. Within this time scale, starting from the last menstrual period, the fetal period commences during the end of the first trimester (Fig. 23.4). Neonates delivered before 37 weeks are called preterm (or premature); those delivered after 42 weeks are post-term. The use of postmenstrual weeks as a timescale for development has now been extended to those fetuses that are delivered before their predicted 'term'. This terminology removes the ambiguous use of 'gestation','gestational age' or 'gestational weeks', and helpfully standardizes the terminology in studies that continue to document growth postnatally to 64 postmenstrual weeks (the equivalent of 6 postnatal months for a full-term infant born at 40 weeks). Some studies have used the term 'corrected age' for follow-up studies on preterm infants, calculated by subtracting the number of weeks born before 40 weeks' gestation from the chronological age. It is of note that this method is now standardizing 40 weeks as 'term' and it is worth considering if all studies of term babies should have their age similarly adjusted if they were born at 38, 39 or 41 weeks.

The period from postmenstrual week 24 and up to 7 days after birth is termed the perinatal period (see Fig. 23.4). In the UK fetuses that are delivered and die before postmenstrual week 24 are considered to be miscarriages of pregnancy, although technological advances in neonatal care assist the delivery and support of infants younger than postmenstrual week 24. The neonatal period is considered to extend from birth to 28 days postnatally; the early neonatal period extends from birth to 7 days and the late neonatal period from 7 to 28 days.

Ultrasound staging

The predicted date of full term and delivery is revised after routine ultrasound examination of the fetus. Early ultrasound estimation of fetal age increases the rate of reported preterm delivery (delivery at <37 weeks) compared with estimation based only on the date of the last menstrual period, possibly because delayed ovulation is more frequent than early ovulation (Yang et al 2002).

The difficulty of correlating the appearance of a chorionic sac, embryo or fetus on an ultrasound scan, with age during the first trimester is related

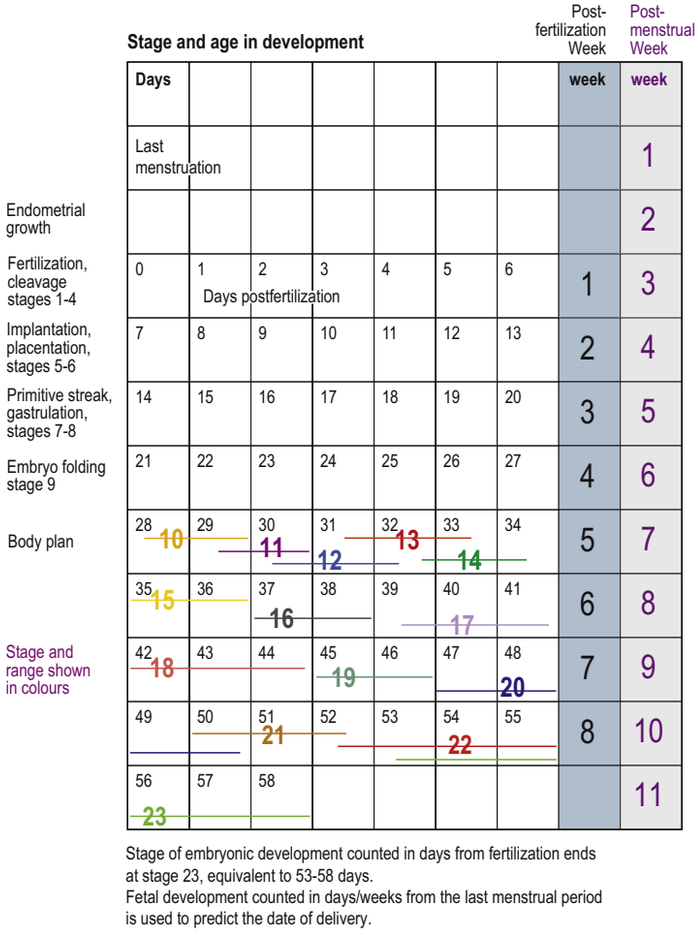

Fig. 23.3 Stages of embryonic development according to O'Rahilly and Müller (2010) correlated with age in postfertilization days. Embryonic stages are based on internal and external morphogenetic change within the duration of a stage. Some stages span only 2 days and others up to 6 days. The clinical estimation of pregnancy is given in postmenstrual weeks for comparison. Note that fertilization occurs at the beginning of week 3 in this system. (Adapted with permission from Pandya P, Oepkes D, Sebire N et al (eds) Fetal Medicine: Basic Science and Clinical Practice, 3rd ed. Elsevier. Copyright 2020.)

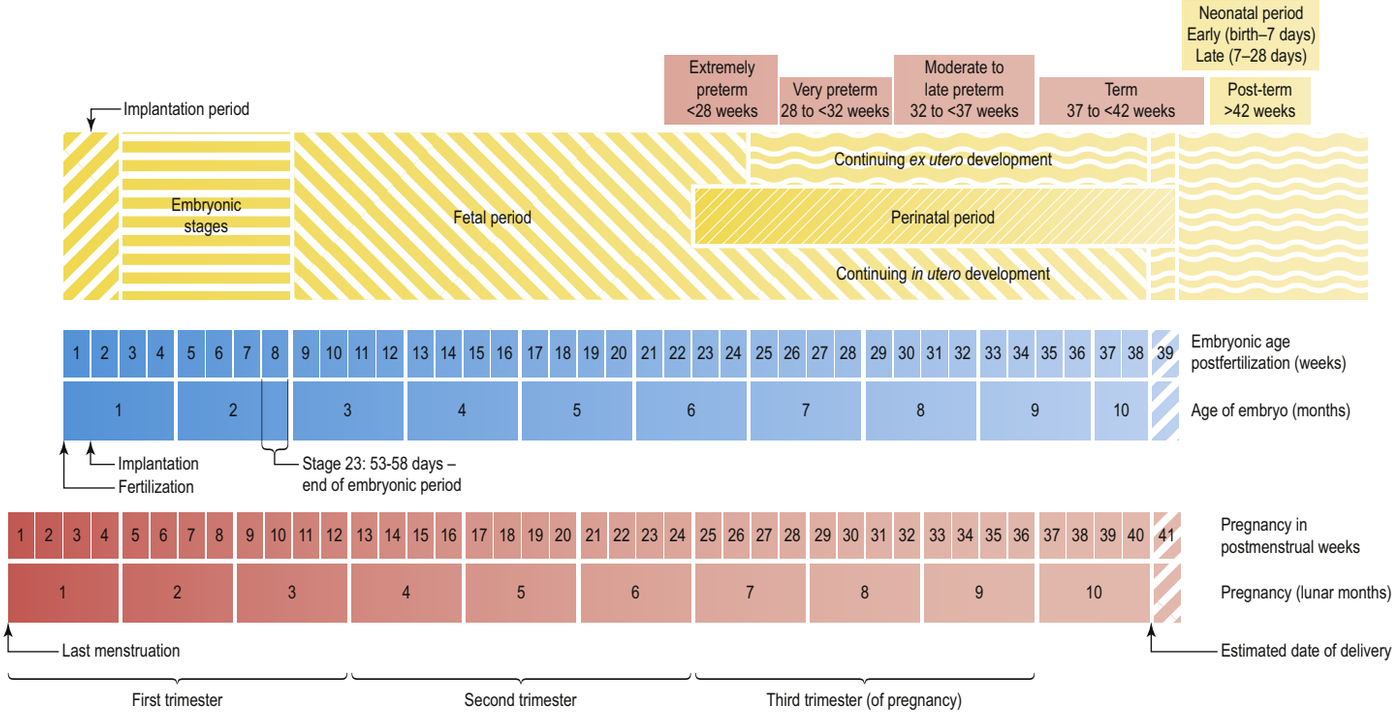

Fig. 23.4 The two timescales used to depict human development. Embryonic development, in the upper scale, is counted in days from fertilization according to O'Rahilly and Müller (2010). Throughout this book, embryonic development is based on this scale. The clinical estimation of pregnancy is counted from the last menstrual period and is shown on the lower scale; throughout this book, fetal ages are described in postmenstrual weeks. Note that there is a 2-week discrepancy between these scales. The perinatal period is very long because it includes all preterm deliveries.

to the specificity of reporting the age. An age reported as within a specific postmenstrual week, e.g. week 12, will cover a period of 6 days (12 weeks 0 days up to 12 weeks 6 days, now noted as 12w0d and 12w6d). It is recommended that sonographic estimation of age should be given as postmenstrual weeks and days (i.e. 12 weeks indicates 12w0d) (Galan et al 2008).

First trimester scan

An early ultrasound scan will detect implantation and viability of the embryo once a heartbeat is detected, confirm multiple pregnancy and estimate the date of delivery. Cardiac activity can be identified by the sixth postmenstrual week (Galan et al 2008); note in Fig. 23.2 that this corresponds to approximately stage 10 (28–29 postfertilization days). Crown–rump length measurement, i.e. the greatest distance between the vertex of the skull and the ischial tuberosities, with the fetus in the natural curved position, is the most accurate predictor of the postmenstrual age of the embryo during the first trimester (Galan et al 2008). Greatest length exclusive of the lower limbs is independent of fixed points and thus simpler to measure, and was recommended by O'Rahilly and Müller (2000); it is generally taken to be the sitting height in postnatal life. Nuchal translucency is measured between 10 and 14 weeks to diagnose trisomy 21. The development of three-dimensional ultrasound scanning has enabled early detection of many anomalies that were previously diagnosed in the second trimester, including anencephaly, hydrocephalus and encephalocele (Pretorius et al 2014). Normograms of fetal spine growth constructed for a Taiwan population showed mean spine length increasing linearly between 11 and 14 weeks (Cheng et al 2010) and a tendency for spinal extension as early as 11 weeks.

Second trimester scan

Routine scanning at 18–20 postmenstrual weeks is used to confirm the delivery date and assess not only the position of the placenta but also the presence of fetal anomalies that would require special intervention following delivery, such as cardiac defects, lung immaturity, renal agenesis, polyhydramnios and defects of the anterior abdominal wall (gastroschisis and exomphalos). Estimations are made of the following: biparietal skull diameter, taken through a plane of section that traverses the third ventricle and thalami; head circumference through a plane that traverses the third ventricle and thalami plus the cavum septi pellucidi anteriorly and the tentorial hiatus posteriorly; abdominal circumference through a plane where the transverse diameter of the liver is greatest, the appearance of the lower ribs is symmetric and the junction of the left and right portal veins is identified; and femoral length, which measures the ossified portions of the diaphysis and metaphyses (**Fig. 23.5**). Between 15 and 28 postmenstrual weeks, the biparietal diameter is the most accurate index of fetal age and the expected date of delivery. Other measurements that may also be taken include the transverse cerebellar diameter and foot length. The amount and type of fetal movement, breathing movements and visceral functions, exemplified by bladder emptying, peristaltic action and colonic echogenicity, are noted. Gender can be identified later in development but this information is not always routinely passed on to parents. Three- and four-dimensional ultrasound scans are now routinely constructed (**Video 23.1**). For assessment of fetal wellbeing from ultrasound examination see Benson and Doubilet (2018).

Managing fetal anomalies

An outcome of routine ultrasound examination of embryos and fetuses for anomalies may be a change to the perinatal management, i.e. to the time, method and place of delivery of the fetus, or the parents may choose to terminate the pregnancy to minimize concerns about fetal and neonatal suffering and long-term disability. Termination may be chosen for severe, untreatable inherited metabolic disorders (e.g. Tay–Sachs disease), severe chromosomal anomalies (e.g. trisomy 13), lethal bone dysplasias, lethal anomalies such as anencephaly and other extreme neurological defects, and bilateral renal agenesis (Cass 2011). Improvements in prenatal screening and diagnosis have led to an overall increase in the prevalence of reported birth defects and overall lower perinatal mortality rates, reflecting increased early terminations of pregnancy (Cass 2011).

Magnetic resonance imaging

Advances in prenatal ultrafast magnetic resonance imaging (MRI) now provide further ways to detect fetal anomalies, capturing particularly clear images (Sepulveda et al 2012) (**Fig. 23.6**). For this reason, MRI is considered a useful adjunct to ultrasound imaging at 20–22 postmenstrual weeks because it enables better management planning for known or suspected anomalies (Reddy et al 2014).

Fetal surgery

The use of routine ultrasound examination and MRI of fetuses has led to the development of a number of prenatal surgical interventions: e.g. to correct placental or membrane anomalies resulting in twin-to-twin transfusion and the production of amniotic bands (Deprest et al 2014); or to offer improved outcomes for meningomyelocele on the basis that the neural tissue may become secondarily damaged by exposure to amniotic fluid and mechanical traumatic injury during gestation (Adzick 2013, Cohen et al 2014, Danzer and Johnson 2014). Other conditions have also been treated prenatally with limited improvement in mortality. Congenital diaphragmatic hernia has been treated by percutaneous fetoscopic endoluminal tracheal occlusion from 25 to 33 postmenstrual weeks to prevent loss of lung fluid and enhance lung growth (Deprest et al 2004). Fetal airway patency has also been preserved during birth through perinatal *ex utero* intrapartum (EXIT) treatment, where a portion of the fetus is delivered through a hysterectomy incision for surgery while the fetus remains attached to the uteroplacental circulation, and the fetus is subsequently completely delivered after the airway procedure is completed (Deprest et al 2014).

GROWTH

The changes with age seen in the fetal period are part of a continuum termed growth, which extends postnatally to adulthood. Growth, which describes the velocity of change in size, has distinct phases. It is most rapid in utero, slower but relatively rapid in infancy, steady in childhood, rapid again during adolescence and thereafter very slow as adulthood is approached. It is measured throughout these periods, in a similar manner to that used for embryonic staging, i.e. by documenting increments in height and weight over time. Both genetic and environmental influences operate in exactly the same way as in earlier stages, with one or the other being dominant at any time point. Individual genetic potential can be fully realized at any stage of growth when environmental effects are neutral; conversely, negative environmental conditions and consequent epigenetic changes can prevent an individual from reaching their full growth potential.

Growth is documented in charts that portray different attributes of growth optimally for different end users, e.g. paediatricians, midwives, health visitors, endocrinologists, researchers etc. The recorded data is subject to detailed and specific statistical methodologies that ensure any graphs presented show smooth curves and are easy to follow. Specific terminology indicates the methodology used when collecting and presenting the data. A *longitudinal study* shows the successive measurement of individuals taken for the entire period of growth. A *cross-sectional study* collects measurements from different individuals and means (with their standard deviation – SD) are calculated for each time point, sometimes also for each sex.

A cross-sectional collection of weight or height from an adult population would produce a graph with a normal distribution with the mean measurement at the highest point. To display the change in weight and height in children, growth charts are presented with the weight or height plotted against time plus standard deviations each side of the mean (1SD, 2SD and 3SD), shown also as lines. Growth charts can also be constructed to show centiles (calculated from the mean and SD), so that the 50th centile (also known as the median), in the midpoint of the distribution, is flanked by lines showing the 3rd, 10th, 25th, 75th, 90th and 97th centiles. The charts are different because SD lines are delineated equally each side of the mean, whereas centiles are more widely spaced above the median than below. Both types of chart are often colloquially termed growth curves (Cole 2003, 2012).

The data from longitudinal and cross-sectional studies can be used to plot the increments in height or weight from one age to the next. This produces a *velocity curve*, which reflects a child's state at any particular time much better than the growth curve, in which each point is dependent on the preceding one. The oldest published longitudinal study, still of great value today, was made by Count Philibert de Montbeillard on his son (**Fig. 23.7**). Comparison of the charts show clearly that although height increases over 18 years, the growth velocity decreases from birth onwards, with an acceleration between 13–15 years, during the adolescent growth spurt. Height and the corresponding growth velocity for the first 22 months of life, compiled from cross-sectional data is shown in **Fig. 23.8**.

The time at which data for growth charts were collected is important because secular change is now very apparent between older and more recent charts. Many of the growth charts acknowledged in the literature are based on meticulous studies from the 1940s and 1950s. They illustrate the reference weight and height for children born between or after the World Wars and later when food rationing was still in operation in the UK. They also reflect the social mores of those times when men were usually fed first, followed by the children, and women were fed last, factors that undoubtedly affected the growth of children at that time and the fetuses of low weight mothers.

Cross-sectional growth charts are particularly important in the management of public health issues, e.g. summarizing and comparing the nutritional status of different groups of children to explore the potential effects of socioeconomic status on growth. In this case the applicability of the chart to an individual child is less important. However, the

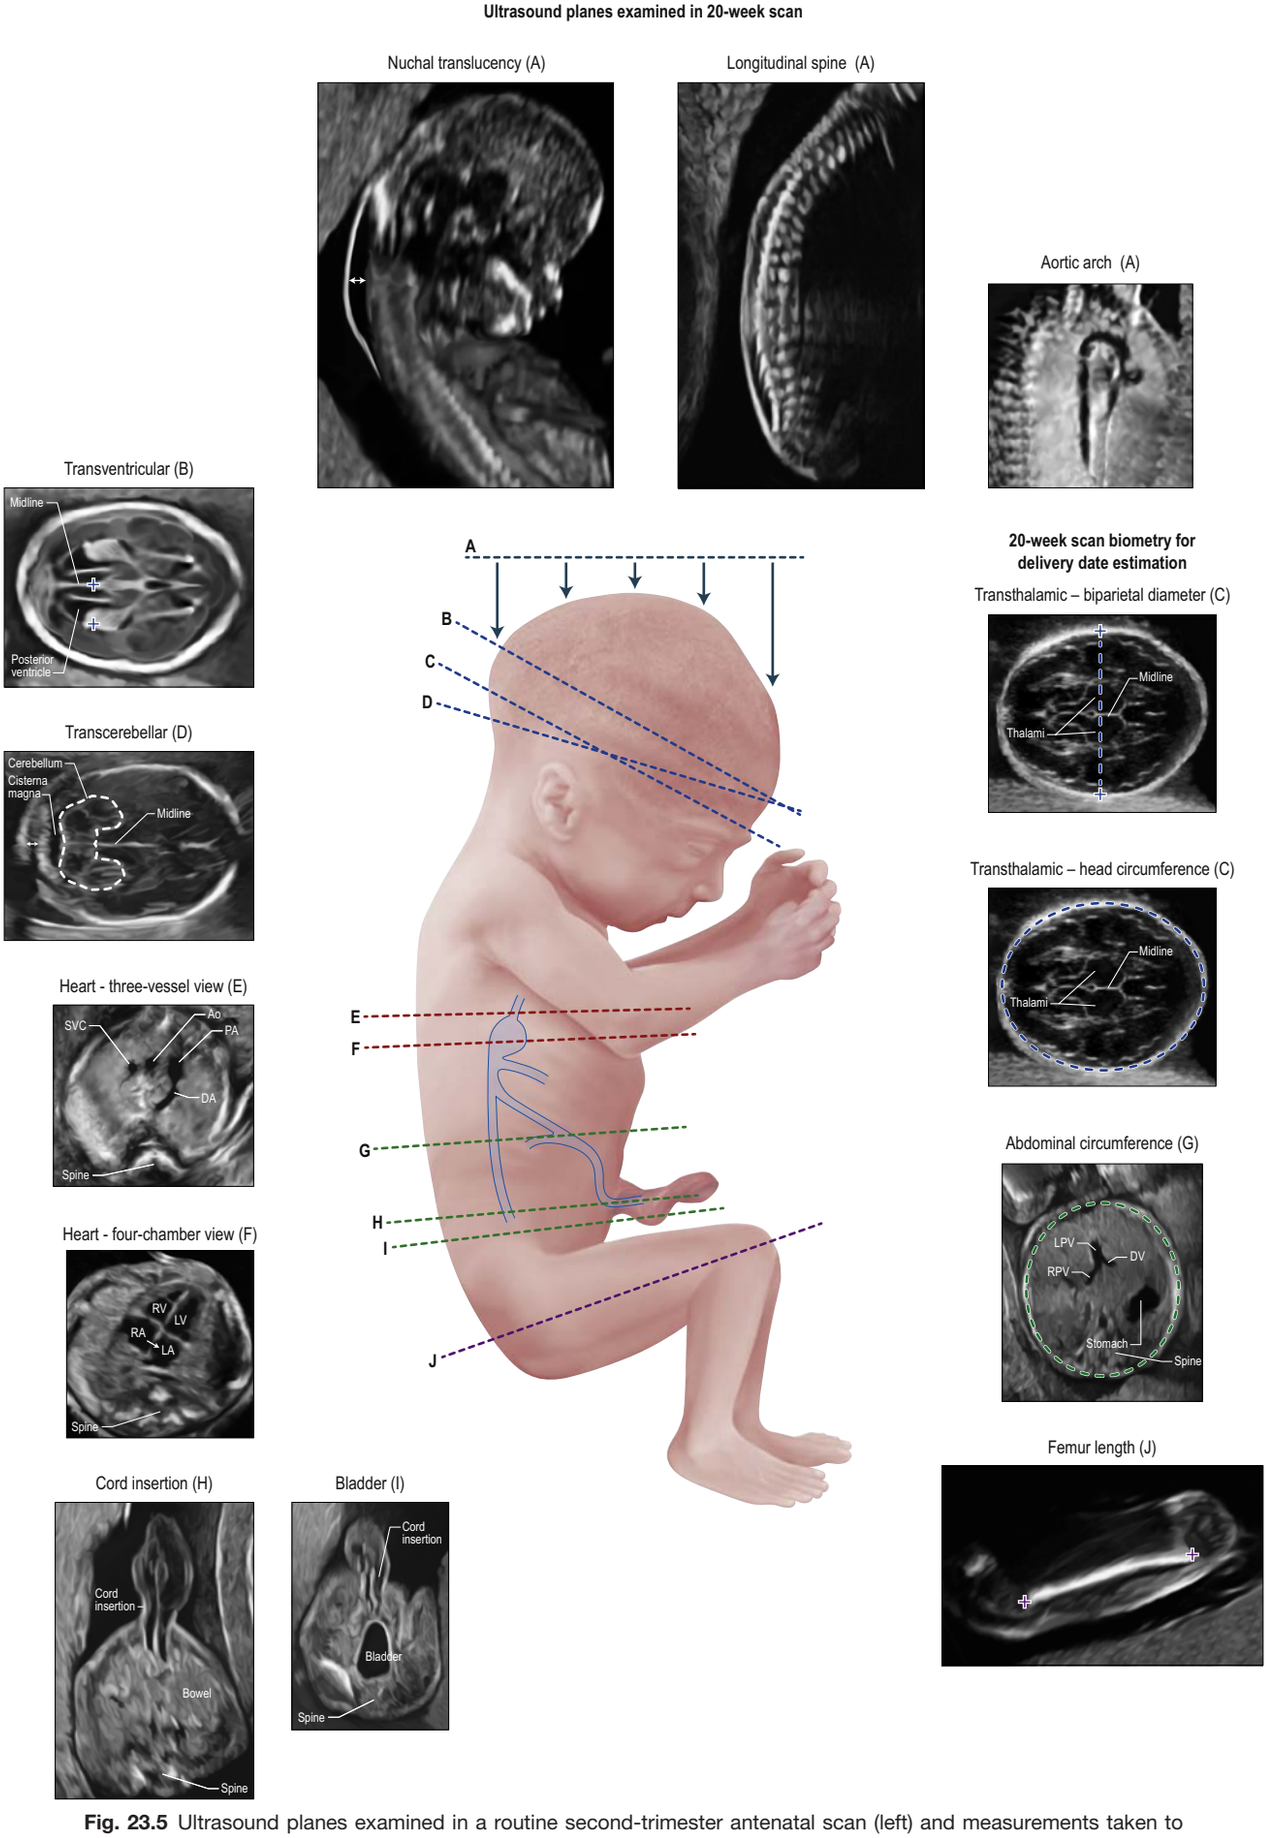

Fig. 23.5 Ultrasound planes examined in a routine second-trimester antenatal scan (left) and measurements taken to predict the estimated date of delivery (right). The top three images are in the sagittal plane (A). The other planes are transverse, apart from J, which is longitudinal. Abbreviations: Ao, aorta; DA, ductus arteriosus; DV, ductus venosus; LA, left atrium; LPV, left portal vein; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPV, right portal vein; RV, right ventricle; SVC, superior vena cava.

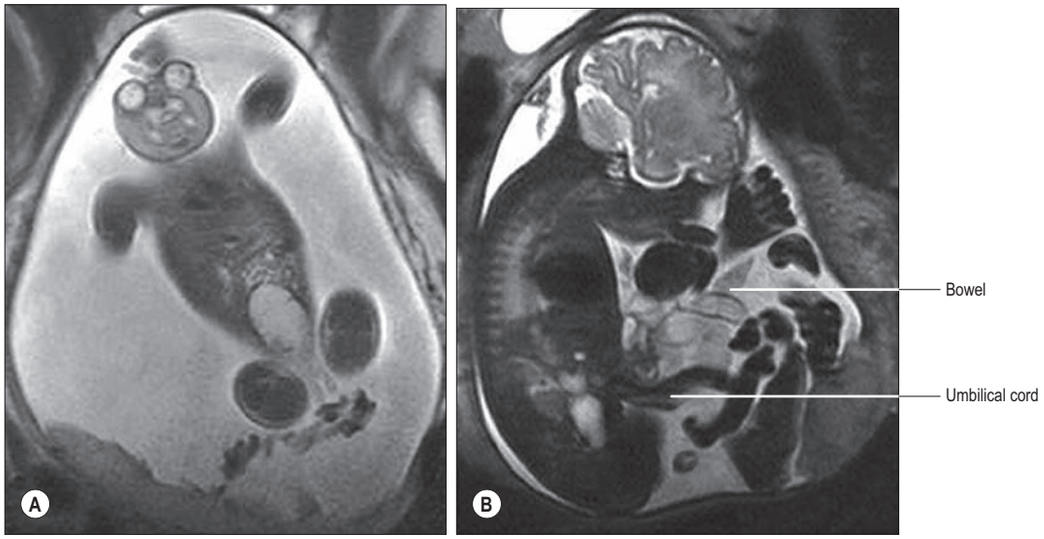

Fig. 23.6 MRI scans of fetal anomalies. **A**, Polyhydramnios may arise as a result of oesophageal compression, impaired swallowing and lack of absorption of amniotic fluid from the gut. **B**, Gastroschisis with loops of bowel in the extracellular coelom (chorionic cavity) and normal insertion of the umbilical cord. (With permission from Sepulveda W, Ximenes R, Wong AE et al 2012 Fetal magnetic resonance imaging and three-dimensional ultrasound in clinical practice: applications in prenatal diagnosis. Best Pract Res Clin Obstet Gynaecol 26:593–624.)

Fetal growth velocity has been computed from estimated fetal weight standards for singleton pregnancies undergoing ultrasound scans at 10w0d–13w6d, 16–22, 24–29, 30–33, 34–37 and 38–41 postmenstrual weeks (Grantz et al 2018). Mean EFW growth velocity at 16, 20, 30 and 35 postmenstrual weeks was 29 g/wk, 59 g/wk, 175 g/wk and 215 g/wk, with growth velocity peaking at 35 weeks (Grantz et al 2018) (**Fig. 23.11**). Considering the anthropometric measurements in this study, the average BPD growth velocity peaks at 13 postmenstrual weeks with a second slight acceleration from 19–22 weeks. Head circumference average growth velocity peaks at 14 weeks with a second acceleration from 19–21 weeks. Both decrease in growth velocity after this time. Average growth velocities for femoral and humeral length peak at about 15 weeks and then steadily decline. Abdominal circumference average growth velocity increases until 16 postmenstrual weeks, with a second acceleration from 27–31 weeks, after which growth velocity steadily declines up to 40 weeks (**Fig. 23.12A–D**).

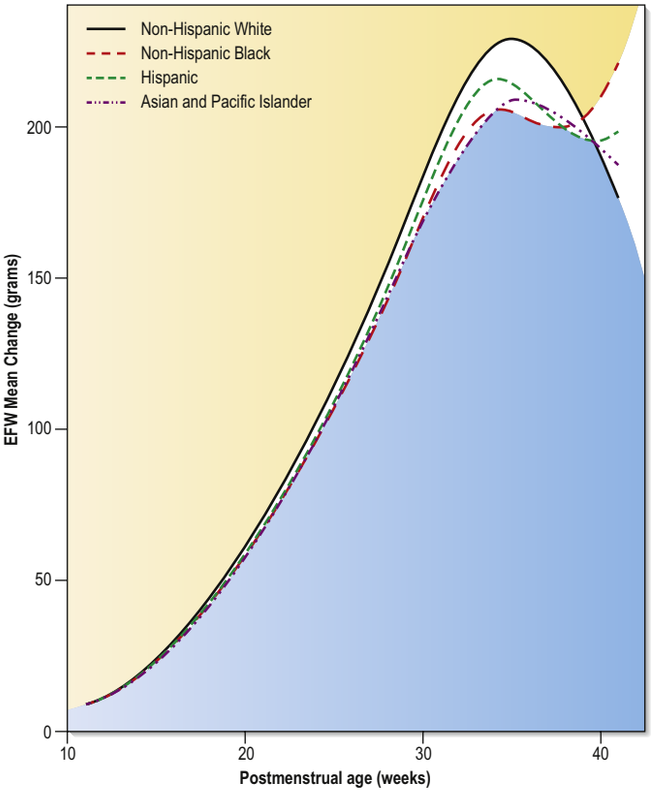

Fig. 23.11 Velocity of estimated fetal growth over postmenstrual weeks. (Data from Grantz et al 2018.)

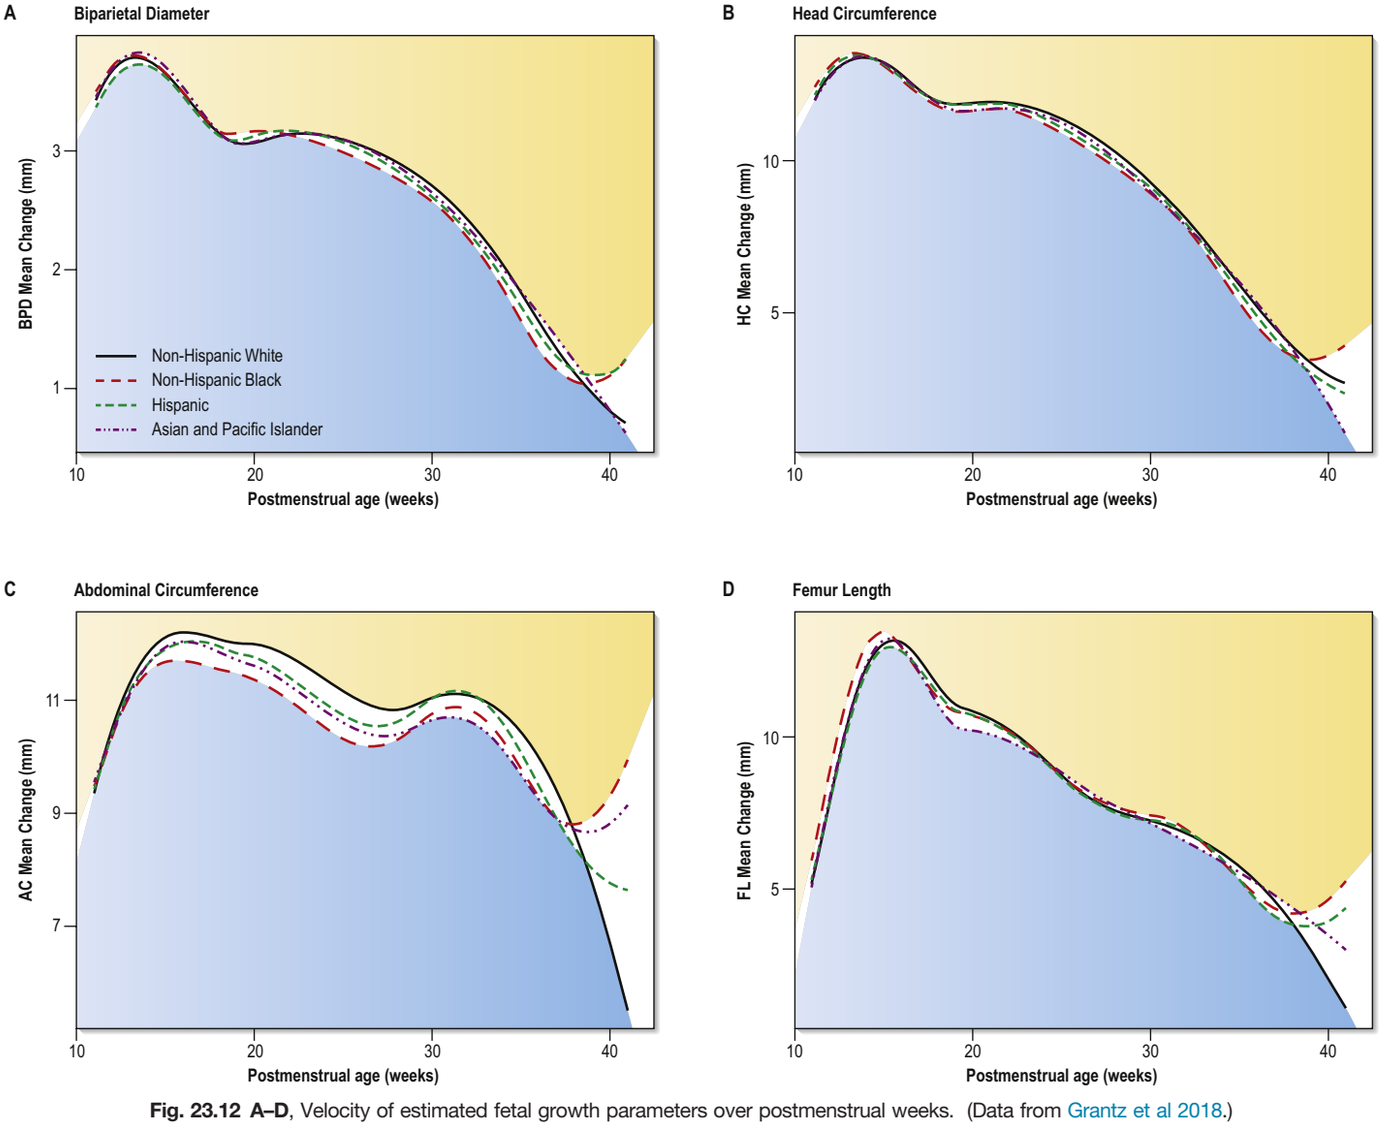

Fig. 23.12 A–D, Velocity of estimated fetal growth parameters over postmenstrual weeks. (Data from Grantz et al 2018.)

There is a correlation between short maternal stature and macrosomia; macrosomic fetuses are at risk of shoulder dystocia and brachial plexus injuries during vaginal delivery. Adiposity at birth is related to obesity and metabolic dysfunction in childhood, which may be perpetuated through adulthood in an ongoing cycle through the generations (Catalano and Hauguel-De Mouzon 2011, Poston 2012). A range of risk factors for pre-, peri- and postnatal issues in maternal obesity is given in McGuire et al (2010).

Stillbirth

Stillbirth is classified as antepartum death occurring before the initiation of labour or intrapartum death occurring during labour and delivery. It is estimated that by 28 postmenstrual weeks approximately 1 in 250 pregnancies will result in a stillbirth in high-income countries and 1 in 22 pregnancies in low- and middle-income countries (Hirst et al 2018). Maternal age of 40 years or older doubled the risk of stillbirth compared to mothers aged 18–25 years. The epidemiology of neonatal mortality in Europe and the UK is presented in Macfarlane and Mugford (2012).

Assisted reproductive technique effects

A range of assisted reproductive techniques (ART) (Ch. 8) have been used and developed over the last 40 years and account for about 2% of births annually in Europe and America (Ginod et al 2018). It is becoming apparent that the mode of conception influences the epigenetic imprinting of offspring and that ARTs affect fetal growth kinetics, postnatal growth and adult risk of pathology. ART-conceived fetuses show higher CRL and EFW than reference charts during the first and second trimesters, but decelerated growth from the second trimester onwards with increased risk of low birth weight mortality (Fleming et al 2018, Ginod et al 2018).

TRANSITION TO EXTRAUTERINE LIFE

The sudden release of a fetus into a gaseous environment of varying temperature, with full gravity and a range of microorganisms, promotes the rapid maturation of some systems and the compensatory growth of others (in terms of responses to the effect of gravity, enteral feeding and exposure to microorganisms, respectively). Maturational processes involving local interactions and pattern formation still drive development at local and body-system levels in preterm infants. For details of the cardiovascular changes at birth see Chapter 13.

The type of birth, whether for preterm or term delivery, confers developmental outcomes on the neonate that affect its subsequent growth. Caesarean section for preterm delivery appears not to be associated with improved neonatal outcomes but is associated with increased risk of respiratory distress syndrome due to slower postnatal movement of fluid out of the lungs (Bellini et al 2006, Bhatta and Keriakos 2011, Werner et al 2012). The dramatic rise of this delivery method is not necessarily driven by improved neonatal outcomes because caesarean section has been shown to increase the odds of developing asthma and type 1 diabetes in later life by 20%. Meta-analyses indicate that the endocrine milieu during caesarean section may lead to epigenetic effects on hepatic and metabolic function and so affect immune function in adult life, leading, in some instances, to food allergy and obesity (Steer and Modi 2009, Hyde and Modi 2012, Song et al 2013).

Prior to birth, the gut is exposed to hundreds of proteins, metabolites and cytokines that are swallowed in amniotic fluid, and there is some evidence for the presence of bacterial species in amniotic fluid prior to delivery. Establishment of the gut microbiota by exposure to maternal vaginal and colonic bacteria during vaginal delivery leads to normal maturation of the gut wall. Gut colonization in preterm infants is delayed (Cilieborg et al 2012). Infants born via caesarean section may have primary gut flora disturbance for up to 6 months after birth and associated delay in postnatal immune development (Neu and Rushing 2011, Neu and Mai 2012, Matamoros et al 2013).

Preterm neonate

The way in which birth at a particular postmenstrual week of delivery has been classified into preterm birth age has been more complex than might be thought. The WHO has subdivided preterm birth into the categories of postmenstrual weeks *in utero*: extremely preterm <28 weeks; very preterm 28–32 weeks; late preterm 32–<37 weeks (Howson et al 2012). Term pregnancy has been defined as within the postmenstrual weeks period 37 completed weeks to less than 42 completed weeks; early term delivery 37–38 weeks; full term 38–40 weeks and post-term >42 weeks (Quinn et al 2016). Because the processes involved in initiating parturition are so complex, Villar et al (2012) recommend that five components should be included in any consideration of preterm birth: significant maternal conditions present before delivery; significant fetal conditions present before delivery; presence of placental pathological conditions; signs of the initiation of parturition; and the type of delivery. These factors involved in the pathogenesis of spontaneous preterm birth are discussed in Buhimschi and Norman (2014). Infection of the decidua, amniotic fluid, amnion or chorion, and clinical and subclinical chorioamnionitis have been reported in approximately 50% of preterm births (Maltepe and Penn 2018) (Ch. 9), whereas sterile inflammation occurs normally in the decidua, myometrium and cervix prior to parturition (Mesiano 2019). In 2010 more than 10% of all births were premature world-wide (Simhan et al 2014), the majority in south Asia and sub-Saharan Africa. In the United States, more than 70% of preterm births occurred between 34 and 36 postmenstrual weeks and 16% of preterm births occurred before 32 postmenstrual weeks (Simhan et al 2014). Preterm birth is the most frequent cause of infant mortality and accounts for one-third of infant deaths (for details of the risk factors for preterm birth see Simhan et al (2014)).

Previously, low birth weight fetuses and neonates were grouped statistically with preterm birth infants, however, improvement in sonographic estimation of fetal age means that perinatal and infant morbidities, which vary according to maturity and weight, can be addressed separately. A new definition of preterm birth syndrome has been proposed in publications from the Global Alliance to Prevent Prematurity and Stillbirth, which includes all births (live births, stillbirths and pregnancy terminations) occurring from 16w0d to 38w6d (Villar et al 2012, Kramer et al 2012, Buhimschi and Norman 2014). The rationale for the early time is because pathologies occurring between 16 and 20 weeks also affect later gestation; the rationale for the later time because births between 37 and 39 weeks are associated with greater morbidity than births after 39 weeks. The definition aims to consider early delivery and not disturbances of growth (see p. 371). The definition is based on a clinical phenotype of: (a) one or more conditions of the mother, placenta, or fetus; (b) the presence or absence of signs of parturition; (c) the pathway to delivery (spontaneous or caregiver initiated). The Global Alliance to Prevent Prematurity and Stillbirths recommends the use of this definition world-wide and acknowledges that its use will initially lead to higher reported rates.

It was previously assumed that the trajectories for extrauterine growth of preterm neonates would mimic that of intrauterine growth of fetuses matched for gestational age and of neonatal birth weights. The Preterm Postnatal follow-up study of the INTERGROWTH-21st Project has highlighted the differences between weight and head circumference of preterm infants and the WHO Child Growth Standards for term neonates (Villar et al 2015). The prospective studies within the INTERGROWTH project collected data from heathy women, with reliable menstrual dates and confirmatory ultrasound scan dating. Singleton pregnancies born preterm between 26 and 37 postmenstrual weeks were followed. The infants were breastfed or bottle-fed maternal milk daily, initially by nasogastric tube if required. Any neonates with congenital anomalies or with birth weights less than the 3rd centile were excluded, thus these growth charts are standards of postnatal growth of healthy infants, delivered earlier than expected. The charts plot postnatal growth up to 64 postmenstrual weeks, at which time the growth trajectories are similar to the WHO Child Growth Standards for term neonates (**Fig. 23.13**).

Full-term neonate

Details of the relative positions of the viscera and the skeleton in a full-term neonate are shown in **Figs 23.14–23.16**. The newborn infant is not a miniature adult, and extremely preterm infants are not the same as full-term infants.

Just as there are differences in the anatomical relationships of structures between the 40 postmenstrual week neonate, child and adult, there are major differences between 20 postmenstrual week and 40 postmenstrual week fetuses. The study of fetal anatomy at 20, 25, 30 and 35 weeks is vital for the investigative and life-saving procedures carried out on preterm infants today.

At birth, neonatal weight reflects the maternal environment, the number of conceptuses, the sex of the baby and the parity of the mother. Generally, full-term female babies are lighter than full-term males, twins are lighter than singletons, and later children tend to be heavier than the first born. The 10th to 90th centile ranges for the weight of a full-term infant at parturition can be seen in Fig. 23.10 (Stirnemann et al 2017). Body water accounts for 75–80% of this weight and a further 15–28% is composed of adipose tissue. Heavier babies have greater fat mass that can contribute to 46% of the variance in birth weight, although the relationship between lean mass and fat mass is not clear; heavier babies have thicker skinfolds (a measurement of fat mass) proportional to their size (Pomeroy et al 2014).

The establishment of enteral feeding has profound effects on early postnatal maturation. Human breast milk contains many bioactive substances that enhance gut maturity. It improves gastric emptying, encourages the growth of the microbiome and contains a range of proteins, including large amounts of secretory immunoglobulin A and cytokines (e.g. interleukin (IL)-10) (Jakaitis and Denning 2014). Feeding preterm infants human milk is associated with less feeding intolerance and is thought to provide protection against diabetes and obesity in later life (Valentine and Morrow 2012). Metabolomic studies on human milk fed to preterm and full-term neonates have shown that preterm milk contains higher concentrations of proteins and amino acids, and that the fatty acid content is higher in colostrum from mothers with neonates lower than the 20th centile for weight. The metabolome of milk from preterm delivered mothers achieves a similar composition to full-term delivered mothers by 5–7 postnatal weeks (Bardanzellu et al 2018). The rate of growth of infants fed breast milk for the first 6 months of postnatal life is different to that of formula-fed infants. Delivery of low-weight preterm babies, followed by parenteral feeding with no enteral nutrition, disrupts normal gut maturation and may lead to necrotizing enterocolitis (Wynn and Neu 2012, Neu and Pammi 2017). However, a balance with the gut microbiome is necessary; although full-term neonates born in tropical countries have similar villous height to those born in temperate climates, villous length in the small intestine shortens within 2–12 months of birth as a consequence of tropical enteropathy (Ramakrishna et al 2006). Human milk oligosaccharides, which are not absorbed in the proximal gut, are thought to act as probiotics by establishing interactions with the early gut microbiome so that specific bacterial species, able to metabolize sialylated breast milk oligosaccharides, can flourish, enhance gut barrier function and limit the expansion of enteropathogens (Charnonneau et al 2016). The physiological effects and importance of maternal–infant dyad interactions in establishing healthy postnatal life are complex and only now being investigated.

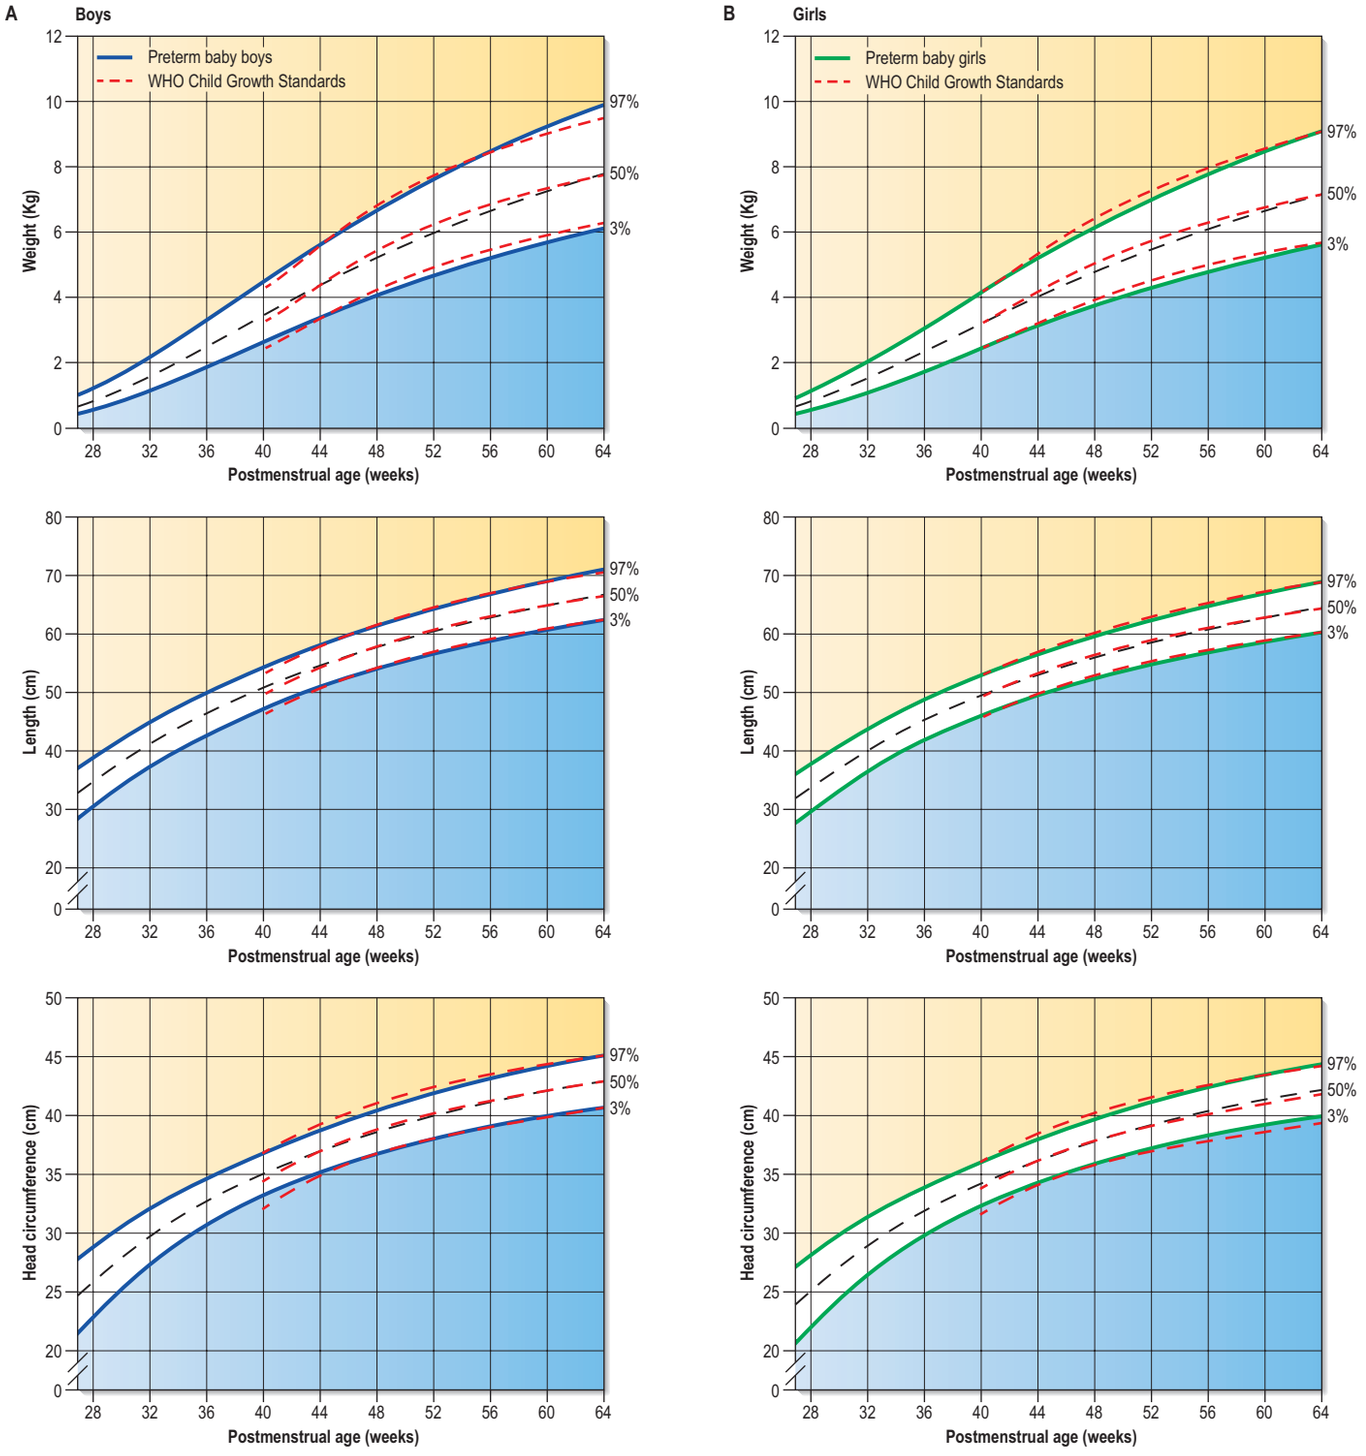

Fig. 23.13 Preterm delivered infant growth rate (red dotted lines) over a continuing scale shown in postmenstrual weeks, compared with INTERGROWTH-21st Newborn Size Standards for weight, height and head circumference in (**A**) boys (blue lines) and (**B**) girls (green lines). The trajectory for extrauterine growth of preterm infants does not match the intrauterine growth of fetuses or attain the levels of full-term (postmenstrual week 40) neonates. Growth trajectories are similar by the equivalent of postmenstrual week 64. (Data from Villar et al 2015.)

Different birth phenotypes have been correlated with different pathological sequelae. Infants who are thin at birth, with a low ponderal index (weight/length^3), tend to develop a combination of insulin resistance, hypertension, type 2 diabetes and lipid disorders, whereas those who are short in relation to head size tend to develop hypertension and high plasma fibrinogen concentrations. These associations have been reported in low weight babies, rather than in those born prematurely. Some babies of average weight also develop cardiovascular pathology; they are either thin at birth and small in relation to the size of their placenta, or of average weight but short in relation to head size and have below average weight gain during the first year (Barker et al 1993). For more views on this concept consult Godfrey and Barker (2000), Ross and Beal (2008) and Kelishadi and Poursafa (2014).

Post-term neonate

Post-term delivery has been reported to affect the subsequent growth of boys more than girls. It is estimated that 8.1% of all live births in Europe and 5.6% of live births in the United States are born post-term (Beltrand et al 2012). In a Swedish study, post-term boys were heavier and longer than term boys at birth, although with similar ponderal indices. Post-term boys showed weight velocity changes and had higher BMIs than term boys by 3 years of age. There were no differences in weight gain throughout childhood in post-term and term girls. By 16 years post-term and term boys had similar height, but post-term boys were heavier. The rate of obesity (BMI >95th centile for age; BMI >85th centile for age) was 29% and 47% respectively in post-term boys and 7% and 13% respectively for term boys (Beltrand et al 2012).

The female genital tract is shown on the right of the body, and the male tract is shown on the left. (D–K, *continued online*)

Infancy and childhood

Preadult life is divided into five stages (Bogin 2012). Term delivery is considered normal between postmenstrual weeks 37 and 40. Postnatal growth is now described to 64 postmenstrual weeks to facilitate examination of the growth trajectories of preterm infants. The normal neonatal period can be defined as the first 28 postnatal days, 40–44 postmenstrual weeks. It is followed by infancy, which commences at postmenstrual week 45 and ends at about 36 postnatal months. During infancy weaning occurs and deciduous tooth eruption is seen. The WHO define infancy as ending at 12 postnatal months and the CDC have the subdivision of toddler extending from 1 to 3 years of age. Childhood extends from 3 to 7 years; there a midgrowth spurt, and eruption of the first permanent incisor and molar teeth. A human juvenile period begins at about 7 years of age; this ends in girls at about 10 years and in boys at about 12 years. Juveniles are prepubertal and in

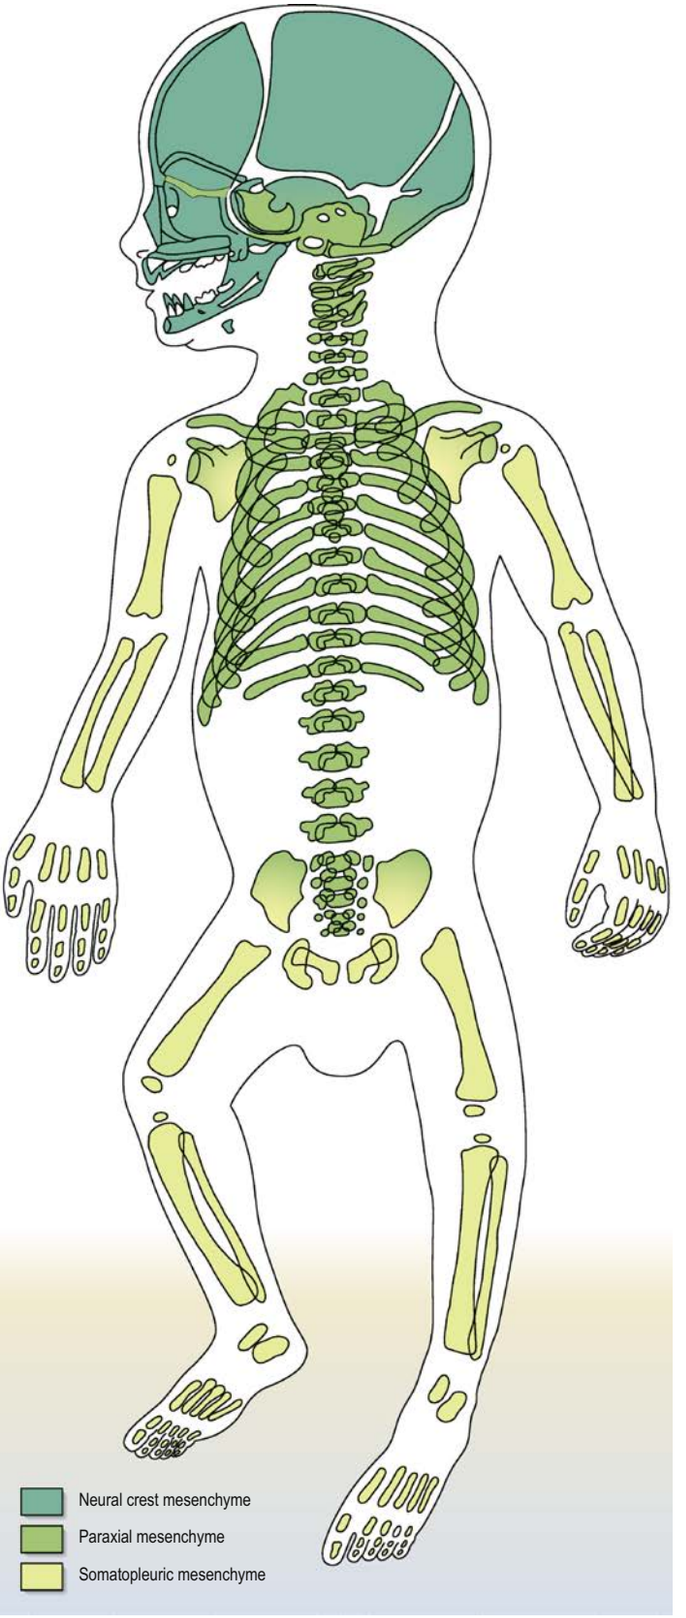

Fig. 23.16 The extent of the ossified skeleton in a full-term neonate. Note the derivation of the parts of the skeleton: the skull is derived from paraxial mesenchyme and neural crest mesenchyme; the axial skeleton, vertebrae and ribs are derived from paraxial mesenchyme; and the skeletal elements in the limbs are derived from somatopleuric mesenchyme, which forms the limb buds.

many industrialized nations the juvenile stage coincides with entry into traditional formal education.

After birth, there is a general decrease in total body water but a relative increase in intracellular fluid. Normally, a newborn loses about 10% of its birth weight by 3–4 days postnatally as a result of loss of excess extracellular fluid: by the end of the first year, total body water makes up 60% of the body weight. Growth in weight usually reaches its peak velocity after birth. Birth weight normally triples by the end of the first year, and quadruples by the end of the second year. Infants that have been breastfed for longer have slower weight growth velocities in the first months of life and their peak weight growth velocity occurs at

a later age (Regnault and Gillman 2014). The peak velocity for length is reached at about 4 postnatal months (see Fig. 23.7). Body length increases from a neonatal range of 48–53 cm to about 75 cm during the first year after birth, by 12–13 cm in the second year and by 5–6 cm each year thereafter until puberty.

Hormonal changes that affect early postnatal life and subsequent growth rates in infants occur from birth to 6 postnatal months. This period has been termed mini-puberty (Ch. 22). It is associated with the rapid decrease of circulating placental hormones in the neonate and the activation of the HPG axis. The early surge in circulating testosterone in males during the first postnatal months influences somatic and adipose development in childhood. The growth velocity in weight and BMI at 8 postnatal weeks in boys is faster than girls; this corresponds to the time when median testosterone levels approach pubertal male values (Lanciotti et al 2018).

In 2006 the WHO published growth charts from birth to 5 years and 5–19 years compiled from children considered to be growing under optimal environmental conditions, i.e. they were breastfed, raised in environments that minimized poor diets and infection, and had non-smoking mothers. UK reference growth charts for boys and girls aged 2–18 years were published in 2012 by the Royal College of Paediatrics and Child Health (**Fig. 23.17**). Similar growth charts have been published for specified regions around the world, addressing racial and ethnic differences (Mansourian et al 2012, Khadilkar and Khadilkar 2015, Barzin et al 2018). As an example, Khadilkar and Khadilkar (2015) stress the importance of updating growth reference charts in countries experiencing major secular change in nutritional status and an increasing incidence of obesity. Compared to previous Indian growth charts, the revised charts show that Indian boys and girls are taller at all ages than they were 7 years ago. Using WHO guidelines, Khadilkar and Khadilkar lowered the weight centiles in comparison to previous charts which had included affluent children. The revised Indian Academy of Pediatrics charts are now considered more appropriate for use with Asian children. At birth South Asian children are among the lightest with a 'thin-fat' phenotype, i.e. small abdominal viscera, low muscle mass, and a relatively large proportion of body fat (Fairley et al 2013). Lower birth weight and fast early growth in Asian populations, both in Asia and in the UK, led to increased adiposity and increased cardiometabolic risk with a lower BMI (West et al 2013).

The pattern of postnatal growth in children is considered to be predictable: deviation from these patterns suggests growth disorders. Measurement of linear growth (supine length in infants and height in children) and growth velocity (as assessed from sequential height charts) show that linear growth velocity is most rapid in infancy, averaging 15 cm/year in the first two years. Children who grow in an environment that does not constrain their growth exhibit a pattern of growth that is mainly parallel to a particular centile, a phenomenon that has been termed homeorhesis or canalization (following the same imaginary 'canal' on the growth chart). Two-thirds of infants cross centile channels on linear growth curves (Cuttler 2016). After deviation from a centile (e.g. as a consequence of chronic disease in childhood, or the adolescent growth spurt), most children return to the same centile position in adulthood, a finding that suggests that this pattern is genetically determined within individuals (Cameron and Bogin 2012). Upward crossing of 2 centile lines in the first 6 months of life is more predictive of later obesity than upward centile crossing in any other 6-month interval in the first two years of postnatal life (Regnault and Gillman 2014).

From infancy to puberty the velocity of linear growth averages about 6 cm/year (Cuttler 2016). A target height, the child's genetic potential, can be predicted by the midparental height plus 6.5 cm for boys and minus 6.5 cm for girls. (Mid-parental height is the average of both parents' heights, plotted on the height centile chart at age 18 years after adjustment for sex). Syndrome-specific growth charts have been developed for aneuploidy and genetic anomalies that cause differences in the growth trajectory of children to adulthood, although there are few new growth charts for short stature children. For growth charts for Down's syndrome consult Styles et al (2002) for UK data and Zemel et al (2015) for US data. For growth charts for Turner syndrome consult Lyon et al (1985) for UK data and Isojima et al (2010) for Japanese data.

Infants and children with chronic diseases and recurrent infections fail to achieve the genetic growth potential. 'Catch-up growth' describes growth above the normal rate expected for the specific age, seen on recovery from such conditions. It may restore the child to their original canal (channel) on the growth chart; if the disorder extends for many years and into puberty, it may not be completed. Information concerning individual growth may be retained as a memory in the epiphysial plates of long bones and in the chondrocyte resting zone and seems to influence structural and functional catch up in the epiphysial plate (Cuttler 2016).

Changes in weight during childhood can be secondary to changes in body water, muscle mass, total lean body mass and fat: weight is not synonymous with fat. Body mass index (BMI, weight/height^2) can be calculated for children. Body fat increases from about 15% to 25% by 6 months of age and decreases to about 15% by 5 years. Weaning is usually initiated after the first 6 months of postnatal life (equivalent to 64 postmenstrual weeks); there is high risk of growth delay during this process that may affect weight. By 5 years of age the sex difference in body fat is about 2% increasing to 6% by 10 years. Although growth velocity plateaus between 5 and 10 years, a mid-growth or juvenile growth spurt is seen between 6 and 8 years in both sexes. It is small in terms of height, but larger for weight and skinfolds and has been attributed to an increase in adrenal androgenic hormone secretion (Lejarraga 2012).

Low weight in infancy and childhood at a given age may result in stunting, i.e. linear growth restriction (short height for age), or wasting, i.e. low weight for height (low BMI for age or reflecting recent weight loss). In neonates, these examples of alterations in growth are considered to be two different phenotypes with different timing, duration of causal insult and different prognoses (Victora et al 2015). Although the proportion of undernourished and underweight children declined globally from 25% in 1990 to 15% in 2015, it increased by about one-third in sub-Saharan Africa between 1990 and 2015. One-third of all undernourished children globally are now in sub-Saharan Africa, 39% of those stunted and 10% wasted (Akombi et al 2017).

Adolescence and adulthood

The juvenile period ends when puberty commences. Puberty is a short time period when there is a dramatic increase in sex hormone secretions and reactivation of the CNS for sexual development. It precedes adolescence, a developmental stage of 5–10 years during which there is a growth spurt in height and weight, eruption of the remaining permanent teeth, development of secondary sexual characteristics and sociosexual maturation (Bogin 2012). Humans seem to be the only species to have a quiescent interval between the rapid growth that takes place after birth and the adolescent growth spurt, a pattern of growth termed the Infancy/Childhood/Puberty (ICP) growth model (Stevens et al 2013). It has been suggested that this quiescent interval allows the acquisition of language, cultural inheritance and complex socialization before individuals pass through puberty and become sexually active. A neotenous heterochronic shift in the transcription of specific genes in the prefrontal cortex occurs in humans from early adolescence and corresponds to a period of substantial cortical reorganization that may be associated with the development of cognitive skills (Somel et al 2009).

Development-related gene expression correlates with three phases of human growth (infancy/early childhood; childhood/puberty; final height) in a development-dependent manner in human tissues (Stevens et al 2013) (**Fig. 23.18**). The outcomes of the Human Genome Project have been linked to anthropomorphic traits in meta-analyses of genome-wide association data that have identified genetic variants at hundreds of loci relevant to growth in pre-puberty, puberty and adulthood, particularly those associated with childhood and adult obesity (Genome-wide Investigation of ANThropometric measures – GIANT). Genome-wide association studies have shown genetic loci linking pubertal timing, height and growth with childhood obesity and genes involved with increases in BMI (Cousminer et al 2013, Locke et al 2015).

It is thought that the return to long bone growth seen in adolescence is a specifically human event (Stevens et al 2013). The adolescent growth spurt occurs at different times for different individuals, which means that nearly all children will cross centiles on reference charts of cross-sectional data. In an 'early developer', the height-for-age curve rises before that of their peers and levels off early. In a 'late developer', growth appears to slow but then accelerates and so their height-for-age curve rises after their peers have either ceased or nearly ceased growing (Cameron 2012). The increase in the growth velocity occurs between 10.5 and 11 years in girls, and 12.5 and 13 years in boys (**Fig. 23.19**; see Fig. 23.17). In both sexes, this spurt lasts for 2–2.5 years. Girls gain about 16 cm in height during the spurt, with a peak velocity at 12 years of age. Boys gain about 20 cm in height (mostly by growth of the trunk), with a peak velocity at 14 years of age, during which time they may be growing at the rate of 10 cm a year.

Growth in height continues at a slower rate after the adolescent growth spurt. Noticeable growth is said to stop at 18 years in females

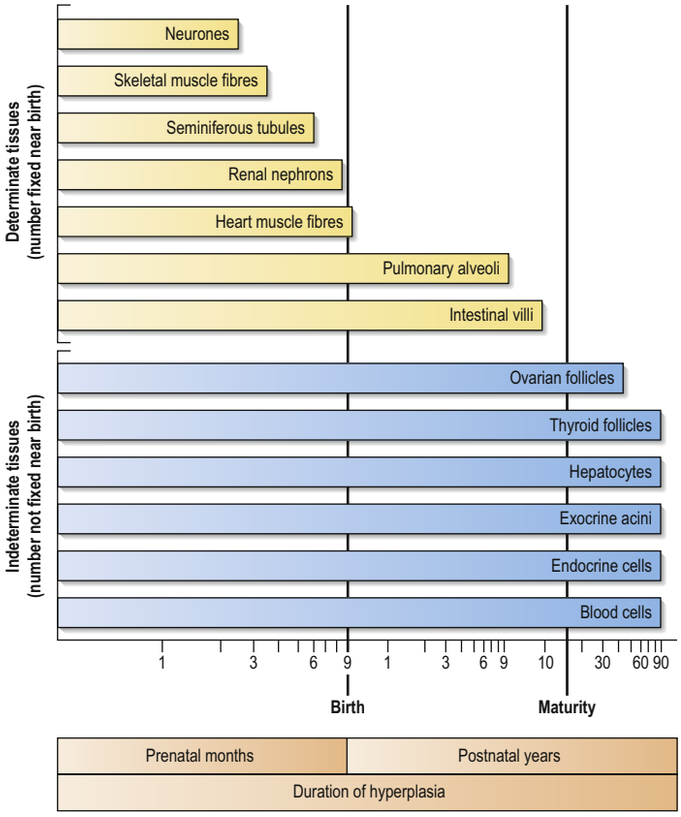

Fig. 23.20 The duration of multiplicative growth for various human tissues.

and 20 years in males; longitudinal studies have indicated an average figure of 16.25 years (females) and 17.75 years (males) with a normal variation of ± 2 years (Harrison et al 1964). Bone age is suggested to be a better predictor of pubertal milestones than chronological age (Cuttler et al 2016). A bone age of 11 years in boys and of 12 years in girls corresponds to the onset of puberty; menarche in girls occurs at a mean skeletal age of about 13 years. Second metacarpal length has been used to assess the impact of regional nutrition on development (Moro and Covino 2018).

Weight gain is more variable in the juvenile stage and adolescence. The onset of puberty is reported to be earlier in obese girls, although obesity *per se* does not affect the age of menarche (Li et al 2017). Juvenile weight increases by 2.25–2.75 kg annually until the adolescent growth spurt, when boys may add 20 kg to their weight and girls 16 kg. The peak velocity for weight gain lags behind the peak velocity for height by about 3 months. Body weight does not reach adult values until sometime after adult height is attained. Apart from the expected change in growth velocity that occurs during adolescence, it is now apparent that taller child height is prospectively associated with an elevated risk of obesity (Johnson et al 2012, Van Dommelen 2014) and that early attainment of peak height velocity may increase the risks for chronic disease in adulthood life (Regnault and Gillman 2014).

Longitudinal studies suggest that adult height peaks at the end of the third decade of life and declines with increasing velocity from the end of the fourth decade (Leon et al 1995). In a 10-year longitudinal study in England of individuals mostly aged over 55 years, physical stature declined by an annual rate of 0.08–0.10% for males and 0.12–0.14% for females, which would be a 2–4 cm reduction in height over the life course: reductions in height loss occurred simultaneously with deteriorating health (Fernihough and McGovern 2015).

INTEGRATION OF TYPES OF GROWTH DURING DEVELOPMENT AND LIFE

The complex interaction between maternal and paternal genes from the earliest stages of development has been likened to a 'parental conflict' for maternal resources. Parentally imprinted genes are only a small proportion of the genome but are important in blastocyst implantation, placentation and developmental growth rates. For example, changes in some individuals to the 11p15 domain affects the future expression of Insulin-like Growth Factor 2 (*IGF2*) gene (if paternally imprinted) or the negative growth regulator *PHLDA2* gene (if maternally imprinted); both conditions affect growth regulation and trajectory in early development (Moore et al 2015) (Ch. 8). Generally, paternally expressed genes enhance growth and maternally expressed genes suppress growth, the latter via genetic processes that prevent offspring becoming too large to be delivered normally because of obstructed labour (Butler 2009). Parental and neonatal phenotype and the prenatal environment may also affect the sexes differently; male fetuses grow faster and to a larger size and may place a greater demand on maternal physiology in stressful environments (Pomeroy et al 2015).

The various types of growth in the later prenatal months and in the postnatal period occur in differing patterns and at different rates. Under physiological conditions it appears that growth and duration of pregnancy are inversely related, with fast-growing fetuses delivering early and slower-growing fetuses having a longer time *in utero* (Kiserud and Johnsen 2009). High growth velocity at 16–22 weeks increases the likelihood for preterm birth (Lampl et al 2009). These differences in the rates of fetal growth affect the accuracy of estimations of fetal age.

The extent of tissue growth in an organ depends on the specific duration of multiplicative growth for the cell types contained within the organ (**Fig. 23.20**). Different cell populations complete their initial developmental proliferation and become differentiated at different times; the final stage of differentiation is usually the cessation of cell division.

Growth of a body can be described in two ways: isometric and allometric. Isometric growth implies a progressive proportional increase in all organs and systems with time; it does not occur in the developing embryo, which displays differential rates of growth. Allometric growth describes the differences in the relative rates of growth between one part of the body and another, and is most clearly seen in the changes in body proportion between fetuses, neonates, children and adults. Between 6 and 7 weeks after fertilization, the head is nearly one-half of the total embryonic length; it subsequently grows proportionally more slowly and it is one-quarter of the entire length at birth. During childhood, this pattern of growth continues with lengthening of the torso and limbs; in adults, the head is one-eighth of the total length of the body and lower limb length is the equivalent of four head lengths (**Fig. 23.21**). Relative limb length at birth is not associated with birth weight and growth-restricted fetuses show little difference in limb proportion. The limbs undergo accelerated

Global estimates of the numbers of adults who are overweight or obese in adult life exceed the numbers of adults who do not have sufficient food (Mascie-Taylor and Goto 2007). Some of the consequences of the high prevalence of obesity in adults on future generational growth are now apparent. Oocyte maturation in obese women is affected by higher circulating concentrations of inflammatory cytokines: these oocytes are smaller, influencing periconception quality. Elevated BMI in men is associated with altered seminal fluid composition, sperm anomalies and decreased motility (Fleming et al 2018). Approximately one-third of adults of reproductive age (20–39 years) were obese in 2015–2016 in the United States (Hales et al 2017), with an annual increase of 2% (Adibi and Zhao 2017). It has been suggested that placental metabolism buffers the lipid environment of the obese mother, limiting lipotoxic effects on the fetus by placental lipid storage (Calabuig-Navarro et al 2017).

The Fetal Origins of Adult Disease hypothesis correlated low birth weight with increased adult risk of cardiovascular diseases; due to fetal anticipation of a similar future *ex utero* environment to that *in utero* followed by a childhood obesogenic environment (Barker 2013). The adaptations of this process to fetuses and children of obese parents are still to be investigated.

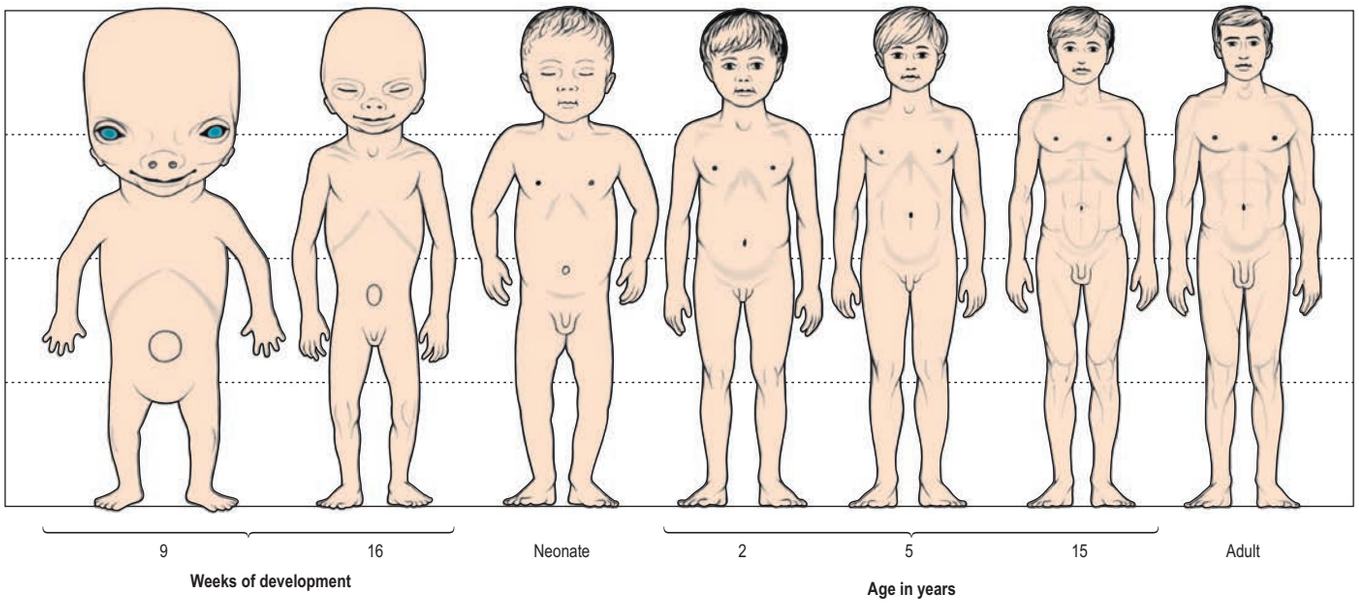

Fig. 23.21 Allometric growth in humans. The head is very large in proportion to the rest of the body during the embryonic period. After this time, the head grows more slowly than the torso and limbs and, by adulthood, the head is only one-eighth of the body length.

postnatal growth relative to the head and trunk and distal limb segment length is especially sensitive to the postnatal environment (Pomeroy et al 2014). Undernutrition between 7 and 8 years of age causes relatively short legs in adults; adults with short stature caused by relatively short legs appear to be at greater risk for coronary heart disease and diabetes than those adults with longer legs (Bogin 2012, Pomeroy et al 2014). Growth of the liver, spleen, kidneys, skeletal and muscular tissues generally follows pre- and postnatal growth curves given for the entire body, whereas other tissues have very different growth rates. The brain, skull, lymphoid tissues and reproductive organs all show differing growth rates during childhood and adolescence (Kappelou et al 2006) (**Fig. 23.22**).

Differential bone growth rates during puberty can lead to temporal-specific associated pathology. For example, 30% of childhood fractures affect the radius, mostly the distal metaphysis, during the pubertal growth spurt, but the incidence of these fractures decreases rapidly thereafter (Rauch 2012). Local differential rates of bone growth are seen in bone growth plates, peripheral and central trabecular bone, and in bone remodelling. During prepubertal growth, the distal radial growth plate adds about 9 mm to the length of the radius per year and the spaces between the peripheral trabeculae are filled with mineralized bone. It has been suggested that incomplete trabecular coalescence during this rapid growth, and not bone remodelling (which takes at least 6 months to complete), leads to lower bone mineral density (especially in boys) and higher local metaphysial cortical porosity (Wang et al 2010, Rauch 2012).

Final adult height is determined by the time at which the epiphysial growth plates fuse and appears to be controlled by a mechanism within the growth plate itself rather than by a systemic mechanism (Baron et al 2015, Jee and Baron 2016). The length of the proliferative columns of chondrocytes within growth plates is correlated with the length of the limbs in mammals, and is longer in longer limb bones: the sensitivity of growth plates changes during development (Bogin 2012). Over the juvenile and pubertal time periods chondroblast number decreases, and the rate of cell division and extent of cell hypertrophy diminishes; the process is termed growth plate senescence. When chondroblast proliferation ceases, the growth plate is resorbed and replaced by bone. Growth velocity, which is at the equivalent of 82 cm/year from postmenstrual weeks 12 to 40, decreases linearly from birth to about 5 cm/year just before the onset of puberty. During puberty a growth spurt is driven by oestrogen and androgens and followed by further linear growth velocity decrease until cessation of chondrogenesis at the growth plate. Growth plates are sensitive to oestrogen which accelerates the loss of chondrocyte progenitor cells in the growth plate; early exposure to oestrogens, as in precocious puberty, causes early epiphysial fusion. Inflammatory illness and malnutrition in children slow linear growth and the rate of growth plate senescence: if the condition resolves, the growth plates function at a more rapid rate resulting in catch-up growth (Jee and Baron 2016). Skeletal dysplasias affecting stature are thought to reflect the molecular balance of the variable spatial and temporal expression of skeletal genes (Baron et al 2015).

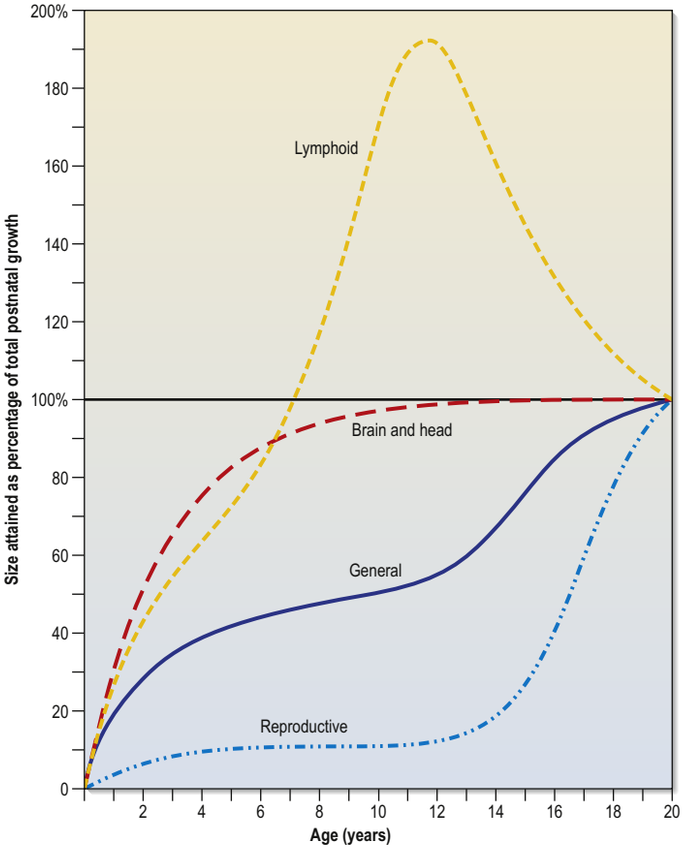

Fig. 23.22 Growth curves of different tissues, regions of the body and systems. Note that the growth of lymphoid tissue, thymus, lymph nodes and intestinal lymph masses decreases after puberty. (Adapted with permission from Tanner JM 1962 Growth at Adolescence, 2nd ed. Oxford: Blackwell Publishing.)

COMMENTARY

2.1

Head–trunk interface in the vertebrate embryo

Shigeru Kuratani

The vertebrate body is characterized by the possession of an overt head. However, the definition of 'head' in this context is enigmatic because the boundary between the head and trunk is not always self-evident. The head is usually defined as the rostral region of the vertebrate body where the brain, various sensory organs and a well-developed oral apparatus are located, but this definition can vary according to morphological context (reviewed by Kuratani 2019).

In the vertebrate embryo, the head is composed of various germ-layer derivatives. Head-specific mesodermal components include the head mesoderm in the paraxial domain, and the pharyngeal arch mesoderm in the ventrolateral domain of the pharyngula. The endoderm develops into the pharynx and the segmental pharyngeal pouches, and further head-specific ectodermal components include ectodermal placodes and populations of cranial neural crest cells (**Fig. 2.1.1A**). These head-specific components are distinct from those of the trunk, such as the unsegmented lateral plate, pharyngeal endoderm, segmented somites and trunk neural crest (TNC; see Fig. 2.1.1A).

During early embryogenesis, cranial neural crest cells migrate under the epidermis to form the ectomesenchyme, which comprises three distinct neural crest cell populations (these are, from rostral to caudal: trigeminal, hyoid and circumpharyngeal).

Dorsal migration of cranial neural crest cells is permitted by the absence of somites, which also allows the cranial neural crest cells to adhere selectively to rhombomeres 2, 4 and 6 and to the posterior region of the hindbrain, thus prefiguring the morphology of the trigeminal (V), facial (VII), glossopharyngeal (IX) and vagus (X) cranial nerves (i.e., the branchiomeric nerves that innervate pharyngeal arches). The morphological pattern of these nerves is different from that of the spinal nerves in the trunk, the precursors of which are segmented by somites.

Ventrally, the cranial neural crest cells migrate into the pharyngeal pouches, where they come into contact with the epibranchial placodes (primordia of the inferior ganglia of the branchiomeric nerves) (**Fig. 2.1.1B**). The cranial neural crest cells also migrate ventrally to fill the pharyngeal arches and craniofacial region, thereby establishing the (pseudo-)segmental organization (branchiomeres and rhombomeres) of the branchiomeric cranial nerves, pharyngeal arches and hindbrain.

The posterior boundary of the head mesoderm (at roughly the position of the otic vesicle) does not line up with the caudal-most pharyngeal arch, and so the posterior boundary of the cranial neural crest cell distribution forms an S-shape (see Fig. 2.1.1). This boundary was first recognized by Froriep (1885), who interpreted it as representing the interface between the somatic and visceral parts of the body (see Figs 17.7, 18.12). Developmentally, the interface coincides with the first few somites and lateral plates (Kuratani 1997). In other words, there is a domain in the vertebrate pharyngula (a stage in embryonic development after head and tail folding with a specified body plan, about stage 11 in human embryos, see Chapter 12) where somites and pharyngeal arches coexist at the same rostrocaudal level. This means that the somites in this domain – the suprapharyngeal somites (see Fig. 2.1.1A) – develop in a unique environment, surrounded both by cells that are unique to the head and by cells that are unique to the trunk.

During the evolutionary process, the shoulder girdle developed as the posterior-most part of the dermal shield of the head of jawless vertebrates; it arises during embryogenesis along the S-shaped head–trunk interface. In jawed vertebrates, the shoulder girdle began to move away from the head, eventually resulting in the formation of an aperture (Trinajstic et al 2013), around which several unique structures that also develop along the head–trunk interface – including the hypobranchial muscles (including the muscles of the tongue and geniohyoid and infrahyoid), vagus, hypoglossal (occipitospinal) and accessory nerves and cucullaris (trapezius and sternocleidomastoid) muscles – then form and elongate to produce the neck (**Fig. 2.1.1C**). Some somite-derived muscles are also referred to as 'neck muscles' because their connective tissues are, in part, derived from cranial neural crest cells, unlike most other postcranial skeletal muscles, the connective tissues of which are mesodermal in origin. The developmental and morphological characteristics of the cucullaris muscles remain to be elucidated (reviewed by Tada and Kuratani 2015).

The neck is particularly conspicuous in amniotes, whose hearts are shifted posteriorly (Hirasawa et al 2016). In this context, the neck can be defined as the domain between the head and the shoulder girdle, where, during embryogenesis, the posterior-most part of the ectomesenchyme contributes to organogenesis, including that of the connective tissues of the neck muscles (Noden 1983, Matsuoka et al 2005, Nagashima et al 2016; reviewed by Hirasawa and Kuratani 2015). It is important to note that the neck has partially lost its trunk-like nature, not only with respect to the distribution of cranial neural crest cells, but also because of the disappearance of the coelom, as seen in the head. Furthermore, the neck muscles are not considered to be hypaxial skeletal muscles because they are not located in the lateral body wall (see Fig. 2.1.1C).

The head–trunk interface is not present in non-vertebrate chordates such as amphioxi and tunicates. In cyclostomes (modern jawless vertebrates), lamprey and hagfish embryos both show an S-shaped interface between the prospective head and trunk, but the hagfish embryo shows an additional caudal shift of the posterior half of the pharynx. The hagfish hypoglossal nerve violates the head–trunk interface and has lost the typical shape of this nerve in vertebrates: this peculiar morphology is assumed to be a derived condition (Oisi et al 2015, Kuratani et al 2019). Despite these differences, the cyclostome hypobranchial muscles are coextensive with the pharynx, thereby being a prototype of the human neck. Thus, the head–trunk interface appears to have been already obtained by the latest common vertebrate ancestor. This interface can be seen as a synapomorphy that defines vertebrates as a unique group among chordates with a clearly differentiated head and trunk (Irie et al 2018).

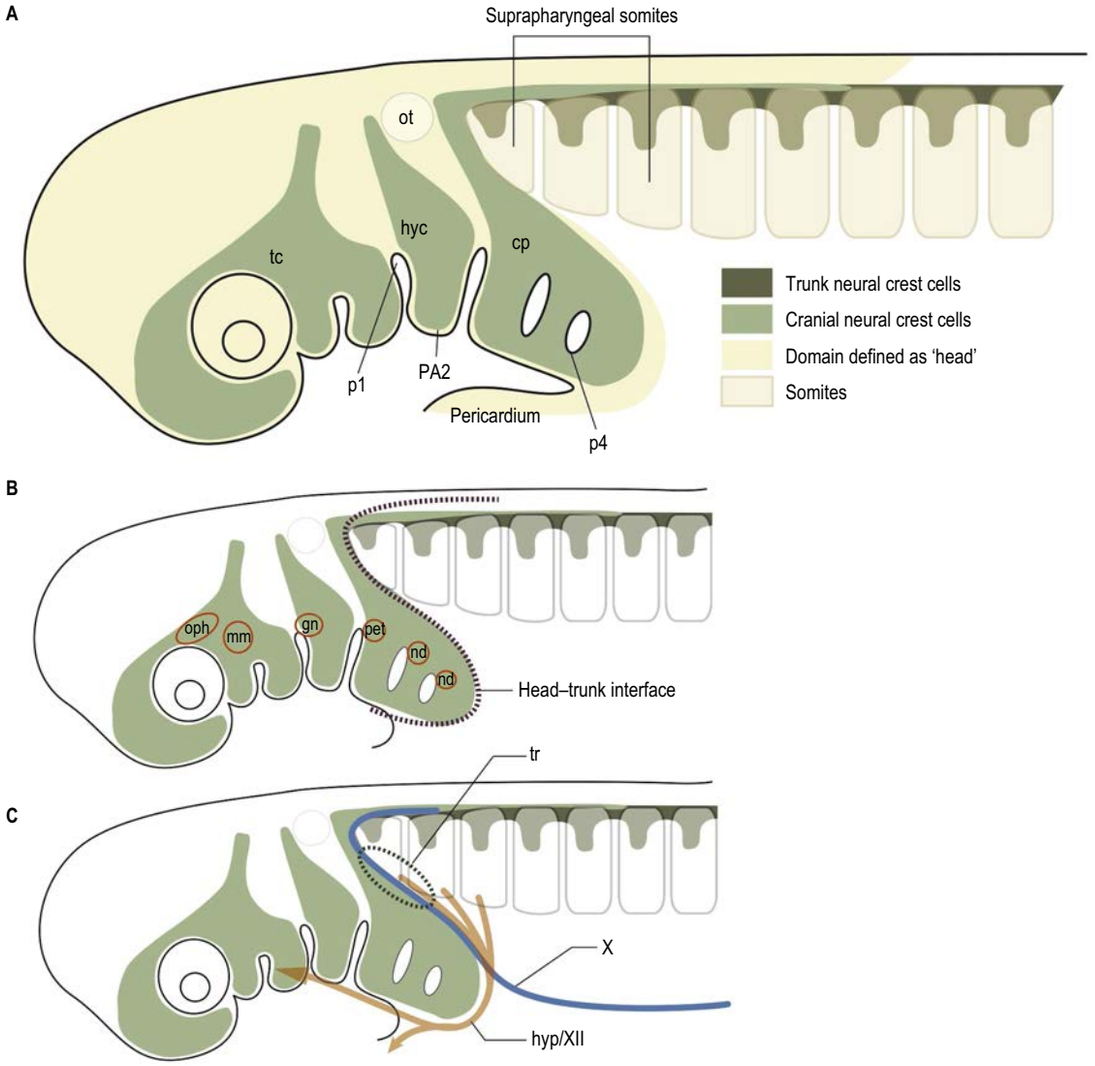

Fig. 2.1.1 The head–trunk interface in the vertebrate embryo. **A**, The ectomesenchyme that fills the pharyngeal arches and craniofacial region of the vertebrate embryo comprises three distinct cell populations of cranial neural crest cells: trigeminal (tc), hyoid (hyc) and circumpharyngeal (cp). In contrast, the TNC cell population is divided segmentally by somites that reflect the basic vertebrate body plan. The head is defined by the distribution of cranial neural crest cells. The suprapharyngeal somites are ventrally associated not with the lateral plate but with the pharyngeal arches and will form the occipital bones and hypobranchial muscles. **B**, The head–trunk interface (purple dotted line) and sensory ganglionic placodes (red circles). **C**, The vagus nerve (X), hypoglossal nerve (XII) and hypobranchial muscle primordium (hyp) follow the head–trunk interface. The trapezius muscle anlage (tr) also develops along the head–trunk interface. Other abbreviations: gn, geniculate placode; mm, maxillomandibular placode; nd, nodose placode; oph, ophthalmic placode; ot, otic vesicle; p1–p4, pharyngeal pouches or slits; PA2, second pharyngeal (hyoid) arch; pet, petrosal placode. CHAPTER
24

Overview of the nervous system

The human nervous system is the most complex product of evolution. The activity of its billions of neurones constitutes the physical basis of sensory experience, motor behaviour, consciousness and self-awareness. Research to elucidate the mechanisms that underlie these functions is one of the most active areas of contemporary biology and medicine and is essential for the future treatment and prevention of neurological and psychiatric disorders.

The nervous system has two major divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord. The PNS consists of the cranial and spinal nerves and their peripheral ganglia and ramifications. It is composed mainly of the axons of sensory and motor neurones that pass between the CNS and the body. The autonomic nervous system (ANS) consists of neurones located within both the CNS and PNS which control secretory glands and smooth and cardiac muscle. It is subdivided into sympathetic and parasympathetic components and is concerned primarily with control of the internal environment. Neurones in the wall of the gastrointestinal tract form the enteric nervous system (ENS) and are capable of sustaining local reflex activity that is independent of the CNS.

CENTRAL NERVOUS SYSTEM

The brain and spinal cord (see Fig. 47.1A) contain the great majority of neuronal cell bodies in the nervous system. In many parts of the CNS, neuronal cell bodies are grouped together and are, more or less, segregated from axons. The generic term for such collections of cell bodies is grey matter. Small aggregations of neuronal cell bodies, which usually share common connections and functional roles, are termed nuclei. Neuronal dendrites and synaptic interactions are mostly confined to grey matter. Axons tend to be grouped together to form white matter, so named because axons are often ensheathed in myelin, which confers a paler coloration on the tissue. Axons that pass between similar origins or destinations within the CNS tend to run together in defined pathways, or tracts. These often cross the midline (decussate), which means that one half of the body is, in many respects, controlled by, and sends information to, the opposite side of the brain.

Some groups of neurones in the spinal cord and brainstem that subserve similar functions are organized into longitudinal columns. The neurones in these columns may be concentrated into discrete, discontinuous nuclei in some areas, e.g. the cranial nerve nuclei of the brainstem, or they may form more or less continuous longitudinal bands, as in much of the spinal cord (**Fig. 24.1**). Efferent neurones constitute three such columns. The axons of motor neurones in the somatic motor column innervate muscles derived from head somites. The two other columns are related to specialized features of head morphology: neurones in the branchial motor column innervate muscles derived from the wall of the embryonic pharynx (branchial muscles) and the visceral motor column supplies preganglionic parasympathetic fibres to exocrine glands and visceral smooth muscle. Four longitudinal cell columns are related to sensory functions. The general somatic sensory column essentially deals with general sensory information from the head; special somatic sensory neurones are related to the special senses and receive vestibular and auditory input; general visceral sensory neurones deal with information from widespread and varied visceral sensory endings; special visceral sensory neurones are related to the special sense of taste.

The spinal cord and brain communicate with the rest of the body via the spinal and cranial nerves, respectively. These nerves contain afferent fibres that bring information into the CNS from sensory receptors, and efferent fibres that convey instructions from the CNS to peripheral effector organs. The spinal cord and brainstem can control many aspects of bodily function by reflex action mediated via interconnections of varying complexity between the afferent and efferent components of the spinal and cranial nerves. Numerous descending connections from the brain may modulate this activity. Afferent input to the spinal cord and brainstem is channelled into various ascending pathways, some of which eventually impinge upon the cerebral cortex, conferring conscious awareness.

To provide the energy required by constant neuronal activity, the CNS has a high metabolic rate and a rich blood supply (Ch. 26). A blood–brain barrier controls the neuronal environment and restricts the types of substance that can pass from the blood stream into nervous tissue.

Spinal cord

The spinal cord lies within the vertebral column, in the upper two-thirds of the vertebral canal, and is continuous rostrally with the medulla oblongata of the brainstem. For the most part, the spinal cord receives afferent input from, and controls the functions of, the trunk and limbs. Afferent and efferent connections between the periphery and the spinal cord travel in 31 pairs of segmentally arranged spinal nerves that are attached to the cord as a linear series of dorsal and ventral rootlets. Adjacent groups of rootlets unite to form dorsal and ventral roots that combine to form the spinal nerves proper (**Fig. 24.2**). Dorsal and ventral roots are functionally distinct: dorsal roots carry primary afferent nerve fibres from neuronal cell bodies located in dorsal root ganglia, whereas ventral roots carry efferent fibres from neuronal cell bodies located in the spinal grey matter.

Internally, the spinal cord consists of a central core of grey matter surrounded by white matter. The grey matter is configured in a characteristic H, or butterfly, shape that has projections known as dorsal (posterior) and ventral (anterior) horns (**Fig. 24.3**). In general, neurones situated in the dorsal horn are primarily concerned with sensory functions whilst those in the ventral horn are mostly associated with motor activities. At thoracic and upper lumbar levels of the spinal cord a small lateral horn is additionally present, marking the location of the cell bodies of preganglionic sympathetic neurones. The central canal, a vestigial component of the ventricular system, lies at the centre of the spinal grey matter and runs the length of the cord. The white matter of the spinal cord consists of ascending and descending tracts that link spinal cord segments to one another and the spinal cord to the brain.

Brain

The brain receives information from, and controls the activities of, the trunk and limbs, mainly via connections with the spinal cord. It also possesses 12 pairs of cranial nerves through which it communicates with structures that are mostly in the head and neck.

The brain is divided into major regions on the basis of ontogenetic growth and phylogenetic principles (**Figs 24.4–24.6**). Ascending in sequence from the spinal cord, the principal divisions are the rhombencephalon (hindbrain), mesencephalon (midbrain) and prosencephalon (forebrain).

The rhombencephalon is subdivided into the myelencephalon or medulla oblongata, metencephalon or pons, and the cerebellum. The medulla oblongata, pons and midbrain are collectively referred to as the brainstem: it lies upon the basal portions of the occipital and sphenoid bones (clivus). The medulla oblongata is the most caudal part of the brainstem and is continuous with the spinal cord below the level of the foramen magnum. The pons lies rostral to the medulla and is distinguished by a mass of transverse nerve fibres that connect it to the cerebellum. The midbrain is a short segment of brainstem, rostral to the pons. The cerebellum consists of paired hemispheres united by a median vermis: it lies within the posterior cranial fossa, dorsal to the pons, medulla and caudal midbrain, with all of which it has numerous fibre connections.

The prosencephalon is subdivided into the diencephalon and the telencephalon. The diencephalon equates mostly to the thalamus and hypothalamus, but also includes the smaller epithalamus and

subthalamus. The telencephalon is composed mainly of the cerebral hemisphere or cerebrum. The diencephalon is almost completely embedded in the cerebrum and is, therefore, largely hidden from the exterior. The human cerebrum constitutes the major part of the brain. It occupies the anterior and middle cranial fossae and is directly related to the calvaria. The surface of the cerebral hemisphere is convoluted into a complex pattern of ridges (gyri) and furrows (sulci). Internally, the hemisphere has an outer layer of grey matter, the cerebral cortex,

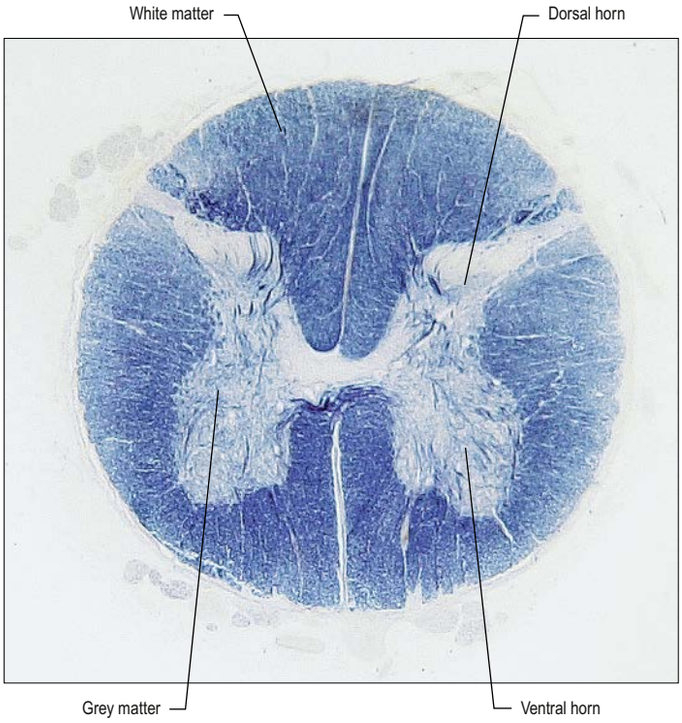

Fig. 24.3 A transverse section through the spinal cord at lumbar level. The section has been stained for nerve fibres, leaving the grey matter relatively unstained. (Figure enhanced by B Crossman.)

beneath which lies a thick mass of white matter (Fig. 24.7). One of the most important components of the cerebral white matter, the internal capsule (see Fig. 24.9), contains nerve fibres that pass to and from the cerebral cortex and lower levels of the neuraxis. Several large nuclei of grey matter, the basal ganglia or basal nuclei, are partly embedded in the subcortical white matter. Nerve fibre connections between corresponding areas on either side of the brain cross the midline within commissures, the largest being the corpus callosum.

During prenatal development, the walls of the neural tube thicken greatly but never completely obliterate the central lumen, which remains in the spinal cord as the vestigial central canal and becomes greatly expanded in the brain to form a series of interconnected cavities or ventricles (Ch. 25). In the forebrain and hindbrain, parts of the roof of the neural tube do not generate nerve cells but become thin, folded sheets of highly vascular secretory tissue, the choroid plexuses which secrete cerebrospinal fluid into the ventricles. The cavity of the rhombencephalon becomes expanded to form the fourth ventricle dorsal to the pons and upper half of the medulla. Caudally, the fourth ventricle is continuous with a canal in the caudal medulla and, through this, with the central canal of the spinal cord. It is continuous with the subarachnoid space through three openings (the foramina of Luschka and of Magendie) and with a narrow channel, the cerebral aqueduct, at its rostral extent. The cerebral aqueduct passes through the midbrain and opens out rostrally into the third ventricle, a narrow, slit-like, midline cavity bounded laterally by the diencephalon. At the rostral end of the third ventricle, a small aperture on each side leads into the large lateral ventricle located within each cerebral hemisphere (see Fig. 24.4C).

Overview of ascending sensory pathways

Sensory modalities are conventionally described as being either special senses or general senses. The special senses are olfaction, vision, taste, hearing and vestibular function: afferent information is encoded by highly specialized sense organs and transmitted to the brain in the olfactory, optic, facial, vestibulocochlear and glossopharyngeal nerves.

The general senses include touch (ranging from light to discriminative), pressure, vibration, pain, thermal sensation and proprioception (perception of posture and movement). Stimuli from the external and internal environments activate a diverse range of receptors in the skin, fascia, viscera, muscles, bones, tendons and joints (Ch. 3). Afferent impulses from the trunk and limbs are conveyed to the spinal cord in spinal nerves, while those from the head are carried to the brain in cranial nerves. The detailed anatomy of the complex pathways by which the various general senses impinge on consciousness levels is better

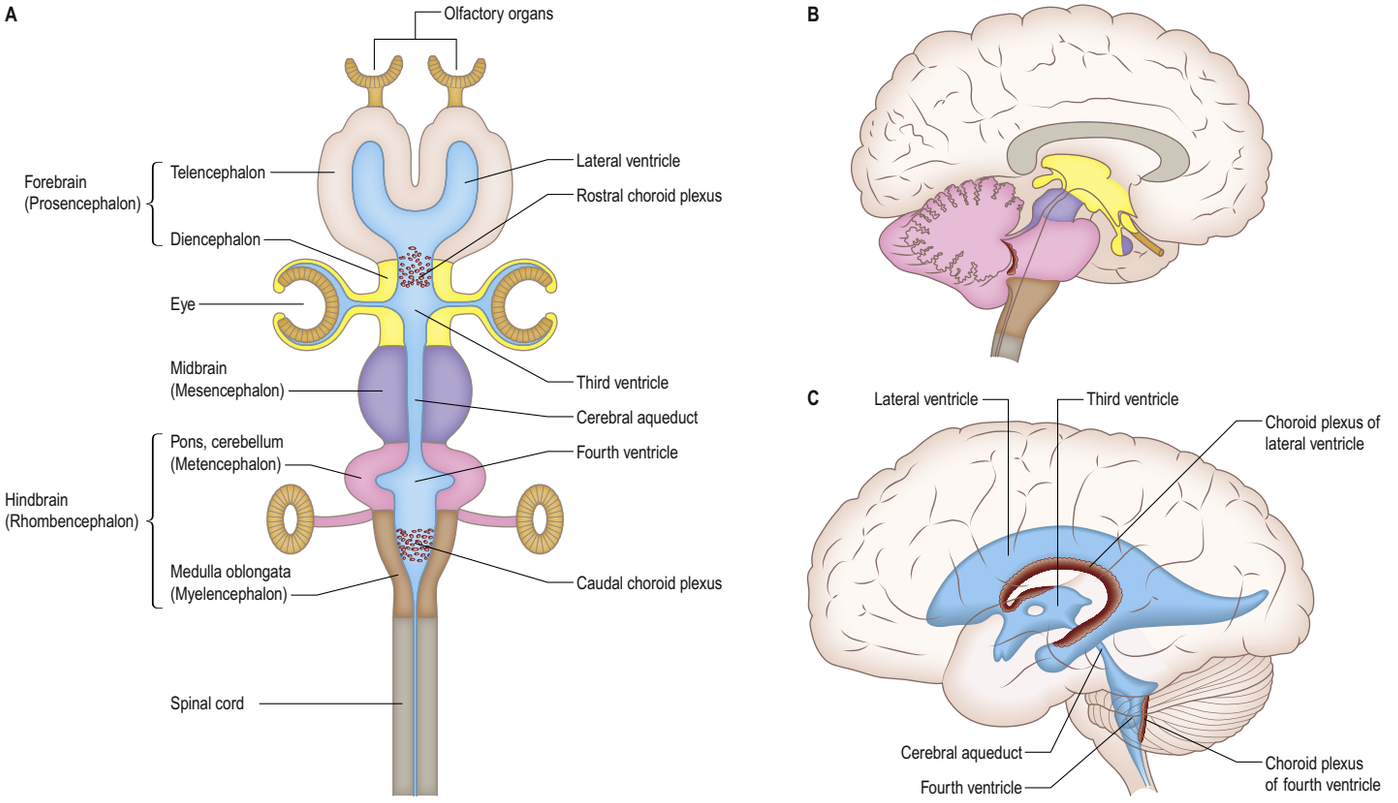

Fig. 24.4 Nomenclature and arrangement of the major divisions of the brain. **A**, The major features of the basic brain plan, including their relationships to the major special sensory organs of the head. **B**, The corresponding regions in the adult brain, seen in sagittal section. **C**, The organization of the ventricular system in the brain.

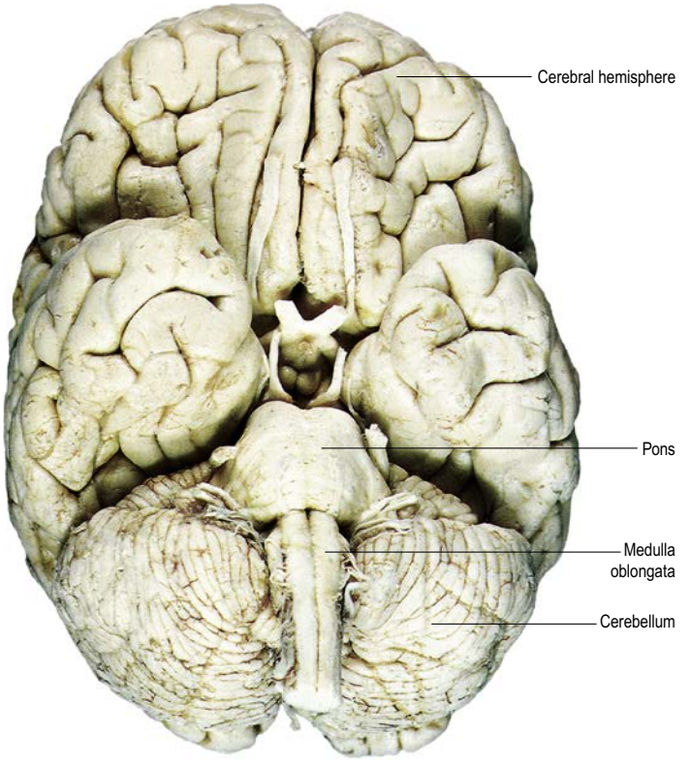

Fig. 24.5 The base of the brain, showing the major divisions and cranial nerves. (Figure enhanced by B Crossman.)

understood by reference to certain common organizational principles. Whilst undoubtedly oversimplified and subject to exceptions, this schema is helpful in emphasizing the essential similarities that exist between the ascending sensory systems.

In essence, ascending sensory projections related to the general senses consist of a sequence of three neurones that extends from peripheral receptor to contralateral cerebral cortex (Fig. 24.8). These are often referred to as primary, secondary and tertiary neurones or first-, second- and third-order neurones. Primary afferents have peripherally located sensory endings and cell bodies that lie in dorsal root ganglia or the sensory ganglia associated with certain cranial nerves. Their axons enter the CNS through spinal or cranial nerves and terminate by synapsing on the cell bodies of ipsilateral second-order neurones, the precise location of which depends upon the modality.

Primary afferent fibres carrying pain, temperature and light touch/pressure information from the trunk and limbs terminate in the dorsal horn of the spinal grey matter, near their point of entry into the spinal cord. Homologous fibres from the head terminate in the spinal nucleus of the trigeminal nerve in the brainstem. The cell bodies of second-order neurones are located in either the dorsal horn or the spinal nucleus of the trigeminal nerve. Their axons decussate and ascend to the ventral posterior nucleus of the contralateral thalamus as the spinothalamic or the trigeminothalamic tract, respectively; they synapse on the cell bodies of third-order neurones in the thalamus. Axons of third-order neurones pass through the internal capsule to reach the cerebral cortex, terminating in the primary somatosensory cortex in the postcentral gyrus of the parietal lobe.

Primary afferent fibres carrying proprioceptive information and fine (discriminative) touch from the trunk and limbs ascend ipsilaterally in the spinal cord as the dorsal columns (fasciculus gracilis and fasciculus cuneatus) and end by synapsing on second-order neurones in the dorsal column nuclei (nucleus gracilis and nucleus cuneatus) of the medulla. Axons of second-order neurones decussate in the medulla and then ascend as the medial lemniscus to the ventral posterior nucleus of the contralateral thalamus, where they synapse on the cell bodies of third-order neurones. Axons of third-order neurones pass through the internal capsule and terminate in the primary somatosensory cortex. A similar homologous projection to the cortex exists for afferents derived from the head, except that primary afferent fibres carrying discriminative touch from the face and oral cavity terminate by synapsing on second-order neurones in the principal sensory nucleus of the trigeminal nerve.

Overview of descending motor pathways

Corticofugal fibres descend through the internal capsule and pass into the brainstem, where many of them terminate in various cranial nerve nuclei and other brainstem nuclei such as the red nucleus, reticular nuclei, and olivary nuclei. The term 'corticobulbar' has been used for many years to describe cortical projections to brainstem nuclei but it is

Fig. 24.6 A sagittal section of the brain. (Figure enhanced by B Crossman.)

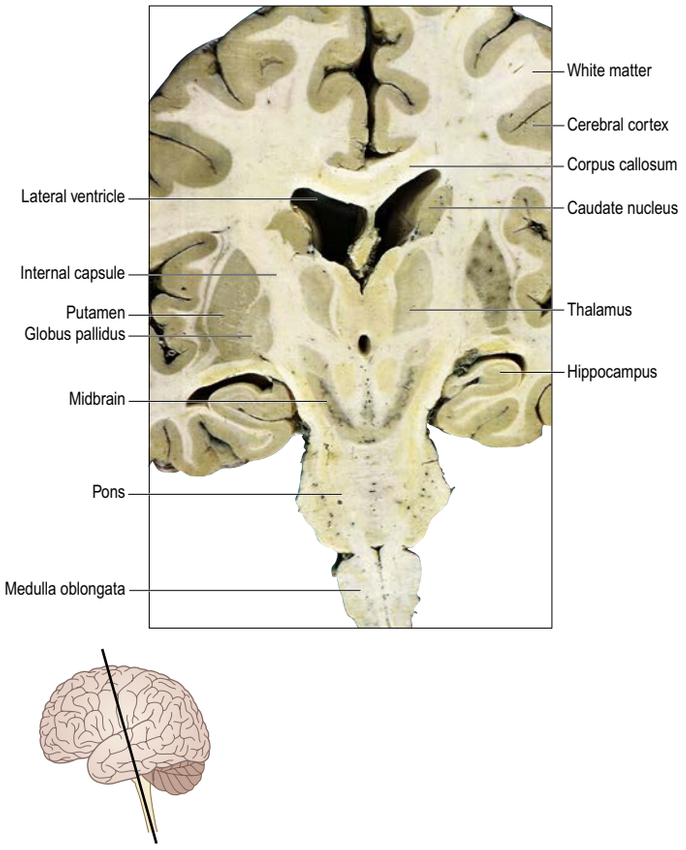

Fig. 24.7 A section through the cerebral hemisphere and brainstem, showing the disposition of grey and white matter, the basal ganglia and the internal capsule. (Dissection by EL Rees; photograph by Kevin Fitzpatrick, London.)

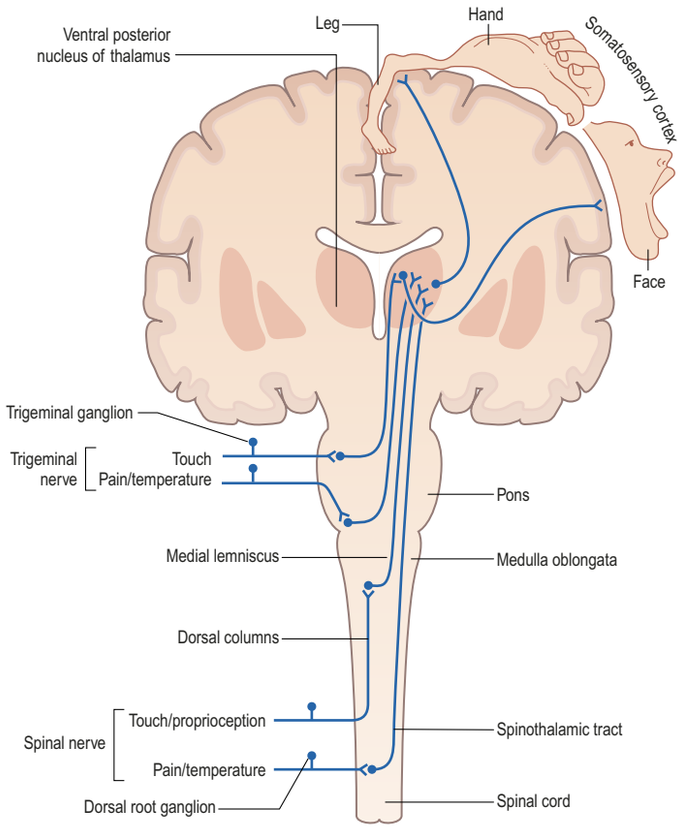

Fig. 24.8 The organization of general sensory pathways showing first-order, second-order and third-order neurones.

a misnomer. The suffix 'bulbar' is derived from 'bulb', an archaic name for the medulla oblongata. The term 'corticonuclear' is, therefore, more accurate to describe these connections although the term 'bulb' is still used (e.g. pseudobulbar palsy).

Corticospinal (pyramidal tract) fibres originate from widespread regions of the cerebral cortex, including the primary motor cortex of the frontal lobe where the contralateral half of the body is represented in a detailed somatotopic fashion. The fibres descend throughout the length of the brainstem and the majority then cross to the contralateral side in the decussation of the pyramids in the ventral medulla. Thereafter, the majority of fibres continue caudally as the lateral corticospinal tract of the spinal cord and terminate in association with interneurones and motor neurones of the spinal grey matter (Fig. 24.9). The principal function of the corticonuclear and corticospinal tracts is the control of fine, fractionated movements, particularly of those parts of the body where delicate muscular control is required. These tracts are particularly important in speech (corticonuclear fibres) and movements of the hands (corticospinal fibres).

The concept of 'upper' and 'lower' motor neurones is fundamental in clinical neurology because the motor signs and symptoms of damage to each category are different and are indicative of the anatomical site of the lesion. Lower motor neurones are the alpha motor neurones located in the brainstem and spinal cord that innervate the extrafusal muscle fibres of skeletal muscle. The term upper motor neurones refers collectively to all the descending pathways that impinge upon the activity of lower motor neurones but, in clinical parlance, the term is often equated with the corticonuclear and corticospinal tracts. The terms upper and lower motor neurone lesion are used clinically to distinguish, for example, between the effects of a stroke in the internal capsule (a typical upper motor neurone lesion) and those of motor neurone disease (a typical lower motor neurone lesion).

Lower motor neurone lesions cause paralysis or paresis of specific muscles because the affected muscles have lost their direct innervation. There is also loss or reduction of tendon reflex activity and reduced muscle tone. Spontaneous muscular contractions (fasciculation) occur and affected muscles atrophy over time. Upper motor neurone lesions cause paralysis or paresis of movements as a result of loss of higher control. There is increased tendon reflex activity and increased muscle

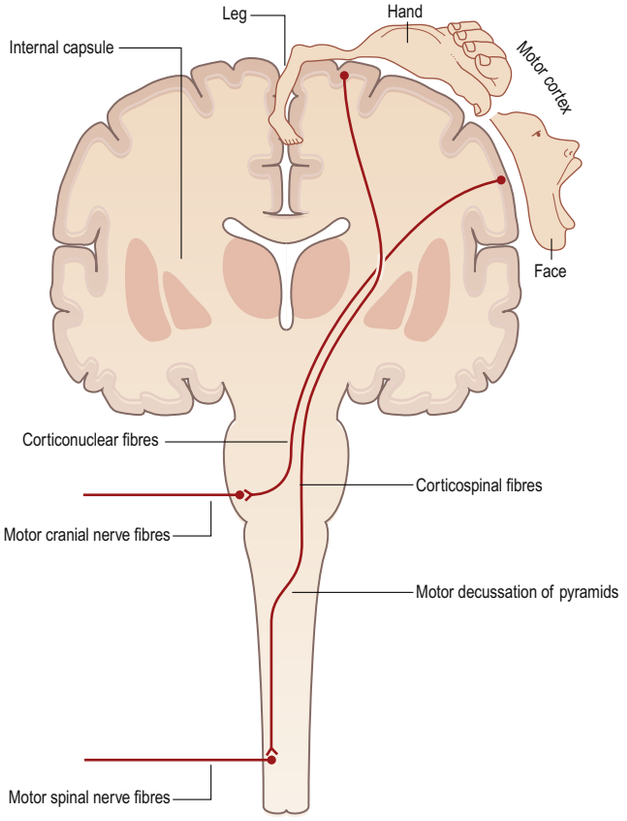

Fig. 24.9 The corticospinal and corticonuclear tracts.

tone, but no muscle atrophy. The combination of paralysis, increased tendon reflex activity and hypertonia is referred to as spasticity. A positive plantar (Babinski) reflex is present with corticospinal lesions.

The pathophysiology underlying the symptoms of upper motor neurone lesions is complex. This is because many descending pathways other than the corticonuclear and corticospinal tracts that also influence lower motor neurone activity may be compromised to varying extents, depending on the site of a lesion. These pathways include corticofugal projections to the brainstem that traverse the internal capsule (e.g. corticoreticular and corticopontine fibres), and numerous pathways that originate within the brainstem itself (e.g. reticulospinal and vestibulospinal tracts): their involvement is believed to be important in the pathophysiological mechanisms that underlie the generation of spasticity. Pure corticospinal tract lesions are exceedingly rare in humans because corticospinal tract fibres lie in close relationship to other pathways throughout most of their course: when they occur, they are believed to cause specific deficits in delicate, fractionated movements and to induce a positive plantar reflex.

Two other major systems that contribute to the control of movement are the basal ganglia (basal nuclei) and the cerebellum. The basal ganglia are a group of large subcortical nuclei, the major components being the caudate nucleus, putamen and globus pallidus (see Fig. 24.7; Ch. 31). These structures have important connections with the cerebral cortex, certain nuclei of the thalamus and subthalamus, and with the brainstem. They appear to be involved in the selection of appropriate behavioural patterns/movements and the suppression of inappropriate ones. Disorders of the basal ganglia cause either too little movement (akinesia) or abnormal involuntary movements (dyskinesias), as well as tremor and abnormalities of muscle tone (Crossman and Neary 2019). The basal ganglia are sometimes described as being part of the so-called 'extrapyramidal system'. This somewhat archaic term was introduced to distinguish between the effects of basal ganglia disease and those of damage to the 'pyramidal' (corticospinal) system. However, the progressive elucidation of the anatomy of the basal ganglia and of the pathophysiology of motor disorders has revealed the close functional interrelationship between the two 'systems', and has rendered the terms that distinguish them largely obsolete (Brodal 1981). The cerebellum (Ch. 29) has rich connections with the brainstem, particularly the reticular and vestibular nuclei, and with the thalamus. It is concerned with the coordination of movement: cerebellar disorders cause ataxia, intention tremor and hypotonia.

PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system (PNS) is composed mainly of spinal nerves, cranial nerves, their ganglia and their ramifications that carry afferent and efferent neurones between the CNS and the rest of the body. It also includes the peripheral part of the autonomic nervous system (ANS), notably the sympathetic trunks and ganglia, and the enteric nervous system (ENS), composed of plexuses of nerve fibres and cell bodies in the wall of the gastrointestinal tract.

Spinal nerves

Spinal nerves are the means by which the CNS receives information from, and controls the activities of, the trunk and limbs. Spinal nerves are considered in detail elsewhere on a regional basis (Sections 4–9).

There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal) and these contain a mixture of sensory and motor fibres. They originate from the spinal cord in a continuous series of dorsal and ventral nerve rootlets. Adjacent groups of rootlets fuse to form dorsal and ventral roots, which then merge to form the spinal nerves proper. The dorsal roots of spinal nerves contain afferent nerve fibres from neuronal cell bodies located in dorsal root ganglia. The ventral roots of spinal nerves contain efferent fibres from motor neurones (somatic and autonomic) located in the spinal grey matter.

Spinal nerves leave the vertebral canal via their corresponding intervertebral foramina and each divides into a large ventral (anterior) ramus and a smaller dorsal (posterior) ramus. In general terms, ventral rami innervate the limbs and the muscles and skin of the anterolateral trunk: the nerve fibres serving the upper and lower limbs are redistributed within the brachial and the lumbar and lumbosacral plexuses, respectively. Dorsal rami innervate the post-vertebral (intrinsic) muscles and skin of the back.

Cranial nerves

Cranial nerves are the means by which the brain receives information from, and controls the activities of, the head and neck and the thoracic and (most of) the abdominal viscera. The component fibres, their route of exit from the cranial cavity, their subsequent peripheral course and the distribution and functions of the cranial nerves are considered in detail elsewhere on a regional basis.

There are 12 pairs of cranial nerves that are individually named and numbered (Roman numerals) in a rostrocaudal sequence (**Table 24.1**). Unlike spinal nerves, only some cranial nerves are mixed in function, and carry both sensory and motor fibres; some others are purely sensory or motor. The first cranial nerve (I; olfactory) has an ancient lineage and is derived from the forerunner of the cerebral hemisphere. It retains this unique position through the connections of the olfactory bulb, and is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus. The areas of cerebral cortex receiving olfactory input have a primitive cellular organization and are an integral part of the limbic system, which is concerned with the emotional aspects of behaviour. The second cranial nerve (II; optic) consists of the axons of second-order visual neurones and these terminate in the thalamus. Most of the component fibres of the other 10 pairs of cranial nerves originate from, or terminate in, named cranial nerve nuclei in the brainstem.

Dermatomes and myotomes

The sensory fibres in individual spinal and cranial nerves have characteristic, but often overlapping, peripheral (cutaneous) distributions. As far as the innervation of the body surface is concerned, the area of skin that is supplied by a particular spinal or cranial nerve is referred to as a dermatome (Greenberg 2003), and the areas of skin supplied by named peripheral nerves are often referred to as the peripheral nerve field (or cutaneous nerve distribution) of that nerve. There is marked overlap between dermatomes of adjacent spinal nerves, particularly for the segments least affected by development of the limbs, i.e. the second thoracic to the first lumbar segments (Ladak et al 2013). In some regions, e.g. the upper anterior thoracic wall, the cutaneous nerves that supply adjoining areas are not derived from consecutive spinal nerves and in these instances

TABLE 24.1 Summary of cranial nerves

No.	Name	Components	Cells of origin	Main central connections	Exit from skull	Distribution and function
I	Olfactory	Special somatic afferent	Olfactory receptor cells in nasal mucosa	To olfactory bulb, anterior perforated substance, piriform cortex	Foramina of cribriform plate	Olfaction
II	Optic	Special somatic afferent	Ganglion cells of retina	To lateral geniculate nucleus of thalamus, pretectal area of midbrain	Optic canal	Vision
III	Oculomotor	Somatic efferent	Oculomotor nucleus	From visual cortical areas, medial longitudinal fasciculus	Superior orbital fissure	Motor to medial rectus, inferior rectus, superior rectus, inferior oblique, levator palpebrae superioris
III	Oculomotor	General visceral efferent	Edinger–Westphal nucleus	From pretectal area of midbrain	Superior orbital fissure	Parasympathetic to sphincter pupillae and ciliary muscles, via ciliary ganglion, mediating pupillary constriction and accommodation
IV	Trochlear	Somatic efferent	Trochlear nucleus	From visual cortical areas, medial longitudinal fasciculus	Superior orbital fissure	Motor to superior oblique
Trigeminal division:						
V	Ophthalmic (V_1)	General somatic afferent	Trigeminal (semilunar) ganglion	To trigeminal sensory nucleus	Superior orbital fissure	Sensation from forehead, scalp, eyelids, nose and eye, including conjunctiva
	Maxillary (V_2)	General somatic afferent	Trigeminal (semilunar) ganglion	To trigeminal sensory nucleus	Foramen rotundum	Sensation from mid-face, lower eyelid, nasal cavity and paranasal sinuses, upper lip, maxillary teeth and palate
	Mandibular (V_3)	General somatic afferent	Trigeminal (semilunar) ganglion	To trigeminal sensory nucleus	Foramen ovale	Sensation from lower face and scalp, tongue and floor of mouth, mandibular teeth and part of external ear
		General somatic afferent	Mesencephalic part of trigeminal sensory nucleus	To trigeminal sensory nucleus, cerebellum	Foramen ovale	Proprioception from muscles of mastication, temporomandibular joint
	Mandibular (V_3)	Branchial (special visceral) efferent	Trigeminal motor nucleus	From precentral gyrus	Foramen ovale	Motor to muscles of mastication (temporalis, masseter, medial and lateral pterygoids), tensor tympani
VI	Abducens	Somatic efferent	Abducens nucleus	From visual cortical areas, medial longitudinal fasciculus	Superior orbital fissure	Motor to lateral rectus
VII	Facial	General somatic afferent	Geniculate ganglion	To trigeminal sensory nucleus, cerebellum	Internal acoustic meatus	Sensation from part of tympanic membrane, external acoustic meatus and skin behind pinna. Proprioception from facial muscles
VII	Facial	Special visceral afferent	Geniculate ganglion	To nucleus solitarius	Internal acoustic meatus	Taste from anterior two-thirds of tongue
VII	Facial	General visceral efferent	Superior salivatory nucleus	From olfactory areas, nucleus solitarius	Internal acoustic meatus	Parasympathetic to lacrimal gland and mucous membrane of nasal and oral cavities (via pterygopalatine ganglion) and submandibular and sublingual salivary glands (via submandibular ganglion) causing secretion and vasodilation
VII	Facial	Branchial (special visceral) efferent	Facial nucleus	From precentral gyrus	Internal acoustic meatus	Motor to 'muscles of facial expression', stapedius, posterior belly of digastric and stylohyoid
VIII	Vestibulocochlear					
	Vestibular division	Special somatic afferent	Vestibular ganglion	To vestibular nuclei, cerebellum	Internal acoustic meatus	Sensations of equilibrium and motion
	Cochlear division	Special somatic afferent	Spiral ganglion	To cochlear nuclei	Internal acoustic meatus	Hearing
IX	Glossopharyngeal	General somatic afferent	Glossopharyngeal ganglia	To trigeminal sensory nucleus	Jugular foramen	General sensation from posterior one-third of tongue, oropharynx and middle ear
IX	Glossopharyngeal	General visceral afferent	Glossopharyngeal ganglia	To nucleus solitarius	Jugular foramen	Sensory from carotid body (chemoreceptors) and carotid sinus (baroreceptors)
IX	Glossopharyngeal	Special visceral afferent	Glossopharyngeal ganglia	To nucleus solitarius	Jugular foramen	Taste from posterior one-third of tongue
IX	Glossopharyngeal	General visceral efferent	Inferior salivatory nucleus	From olfactory areas, nucleus solitarius	Jugular foramen	Parasympathetic to parotid salivary gland (via otic ganglion), causing secretion and vasodilation
IX	Glossopharyngeal	Branchial (special visceral) efferent	Nucleus ambiguus	From precentral gyrus	Jugular foramen	Motor to stylopharyngeus
X	Vagus	General somatic afferent	Superior (jugular) ganglion	To trigeminal sensory nucleus	Jugular foramen	General sensation from pharynx, larynx, trachea, oesophagus, part of auricle and external auditory meatus
X	Vagus	General visceral afferent	Inferior (nodose) ganglion	To nucleus solitarius	Jugular foramen	Sensory from thoracic and abdominal viscera Sensory from aortic arch (baroreceptors) and aortic bodies (chemoreceptors)
X	Vagus	General visceral efferent	Dorsal motor nucleus of vagus	From hypothalamus, nucleus solitarius	Jugular foramen	Parasympathetic to glands and smooth muscle in the pharynx, larynx, thoracic and abdominal viscera
X	Vagus	Branchial (special visceral) efferent	Nucleus ambiguus	From precentral gyrus, sensory nuclei of brainstem	Jugular foramen	Motor to pharyngeal, external laryngeal and oesophageal striated muscles
XI	*Accessory					
	Cranial root	*Branchial (special visceral) efferent*	*Nucleus ambiguus*	*From precentral gyrus, sensory nuclei of brainstem*	*Jugular foramen*	*Motor to muscles of soft palate and intrinsic muscles of larynx (distributed via vagus)*
	Spinal root	Branchial (special visceral) efferent	Spinal cord segments C1–C5	From precentral gyrus	Jugular foramen	Motor to sternocleidomastoid and trapezius
XII	Hypoglossal	Somatic efferent	Hypoglossal nucleus	From precentral gyrus	Hypoglossal canal	Motor to all intrinsic and extrinsic muscles of the tongue, except palatoglossus

- Somatic efferent
- General visceral efferent
- Branchial (special visceral) efferent

*The existence of a 'cranial root' of the accessory nerve, with its cell bodies in the nucleus ambiguus and a distribution as given in the table is controversial. There is a view that the 'spinal root' of the accessory nerve should be regarded as the accessory nerve proper (sometimes called the 'spinal accessory nerve') and that the vagus nerve supplies all but one of the muscles of the soft palate and all of the intrinsic muscles of the larynx.

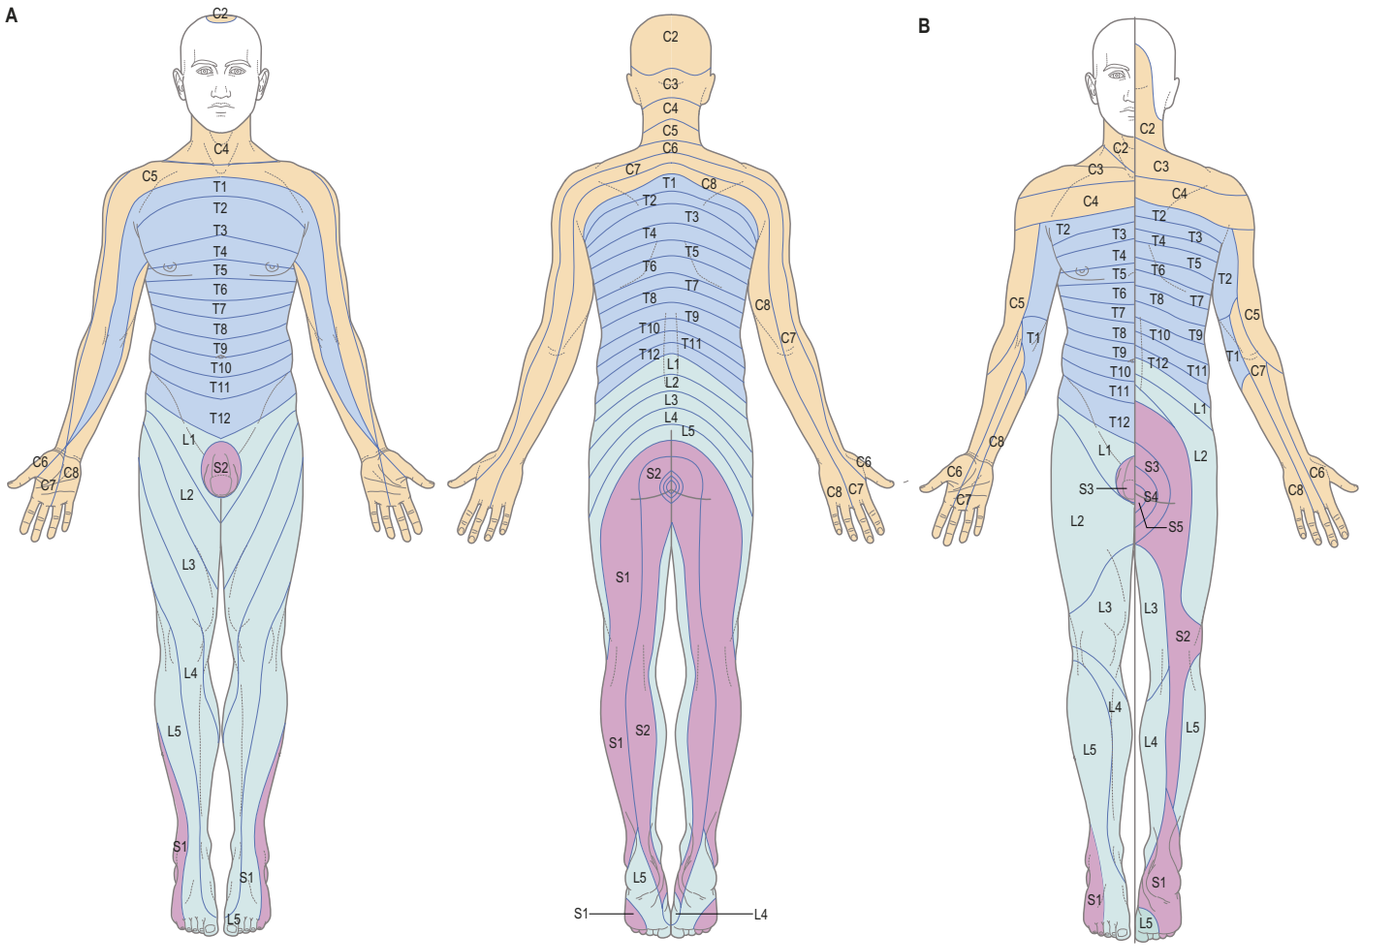

Fig. 24.10 Typical dermatome maps, illustrating some of the variations reported by different authors. **A**, Dermatome map based on Keegan JJ, Garrett FD 1948 The segmental distribution of the cutaneous nerves in the limbs of man. Anat Rec 102:409–39. Mainly used in literature in the USA. **B**, Dermatome map based on Moffat DB 1993 Lecture Notes on Anatomy, 2nd ed. Oxford: Blackwell Scientific. Mainly used in literature in the UK.

the overlap between dermatomes is minimal; these boundaries give more reliable and clinically useful borders (Apok et al 2011). Maps of dermatome distribution are useful in clinical neurology as a guide to identify the location of pathology in patients with peripheral sensory deficits, but it is important to remember that they are approximations. Dermatome maps are somewhat inconsistently reported by different authors, reflecting the fact that the maps are composites that have been compiled to a large extent by clinical observations on patients with cranial or spinal nerve pathology, and also that considerable normal individual variation exists (**Fig. 24.10**) (Lee et al 2008). Common to all published maps are areas of sensory overlap along borders of contiguous spinal nerves and axial lines where non-contiguous spinal nerves meet, and across which very little or no sensory overlap occurs. Detailed dermatome maps are described on a regional basis. The motor axons of individual spinal and cranial nerves tend to innervate anatomically and functionally related groups of skeletal muscles, referred to as myotomes.

AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system represents the visceral component of the nervous system. It consists of neurones located within both the CNS and the PNS that are concerned with the control of the internal environment, through the innervation of secretory glands and cardiac and smooth muscle. Its functions are closely integrated with those of the somatic nervous system.

Visceral efferent pathways differ from their somatic equivalents because they are interrupted by peripheral synapses, which means that there is a sequence of at least two neurones between the CNS and the target structure: these are referred to as preganglionic and postganglionic neurones, respectively (**Fig. 24.11**). The somata of preganglionic neurones are located in the visceral efferent nuclei of the brainstem and in the lateral horn of the spinal cord. Their axons, which are usually finely myelinated, exit from the CNS in certain cranial and spinal nerves, and then pass to peripheral ganglia, where they synapse on postganglionic neurones. The axons of postganglionic neurones are usually unmyelinated. Postganglionic neurones are more numerous than preganglionic ones; one preganglionic neurone may synapse with 15–20 postganglionic neurones, which permits the wide distribution of many autonomic effects.

The autonomic nervous system is traditionally divided into two major parts: sympathetic and parasympathetic. Structures innervated by the autonomic nervous system generally receive both sympathetic and parasympathetic fibres. Neurones intrinsic to the gastrointestinal tract are regarded as a third, or enteric, division.

Two long-held dogmas are that the sympathetic and parasympathetic nervous systems are functionally antagonistic. A better concept is that the two systems constitute an integrated system for the coordinated neural regulation of visceral and homeostatic functions. In general, sympathetic activity results in the constriction of cutaneous arteries (increasing blood supply to the heart, muscles and brain), cardiac acceleration, an increase in blood pressure, contraction of sphincters and depression of peristalsis, all of which mobilize body energy stores for dealing with increased activity. Parasympathetic activity results in cardiac slowing and an increase in intestinal glandular and peristaltic activities, which may be considered to conserve body energy stores.

The classical concept of autonomic neurotransmission holds that preganglionic sympathetic and pre-and postganglionic parasympathetic neurones are cholinergic and postganglionic sympathetic neurones are mainly noradrenergic. The discovery of neurones that use neither acetylcholine nor noradrenaline as their primary transmitter, and the recognition of a multiplicity of substances in autonomic nerves that fulfil the criteria for a neurotransmitter or neuromodulator, greatly complicated neuropharmacological concepts of the autonomic nervous system (Burnstock 2013).

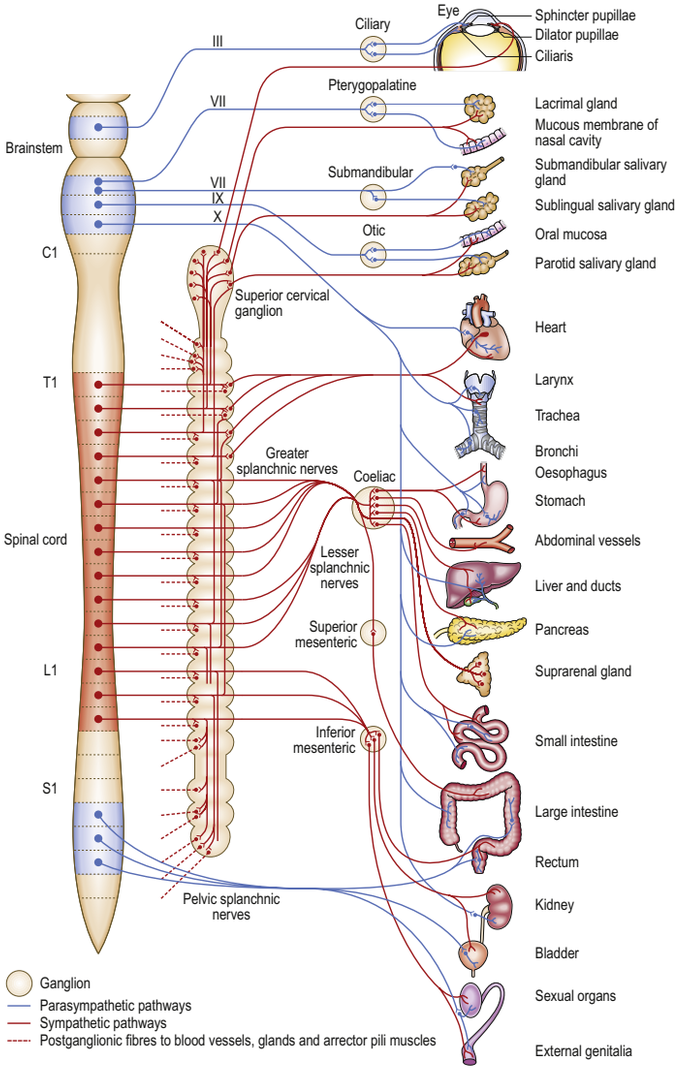

Fig. 24.11 Efferent pathways of the autonomic nervous system.

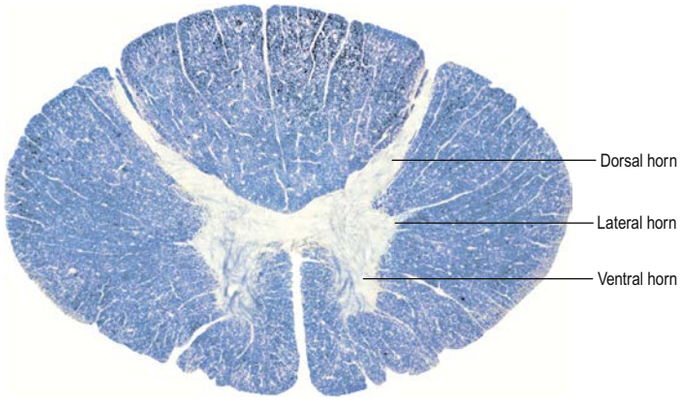

Fig. 24.12 A transverse section through the thoracic spinal cord. Preganglionic sympathetic neurones are located in the lateral horn. (Figure enhanced by B Crossman.)

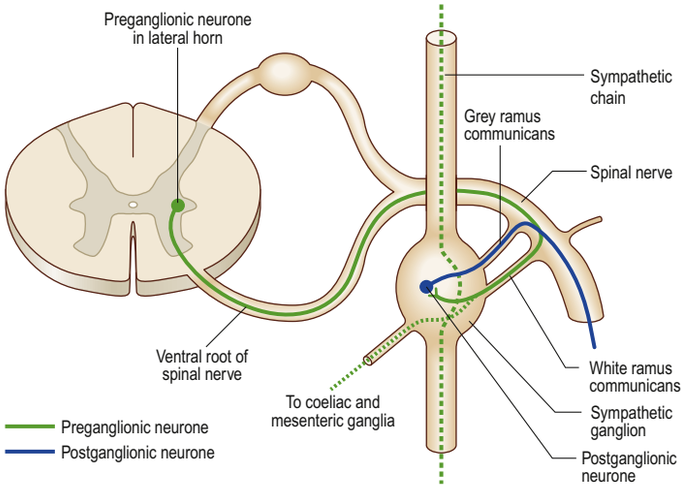

Fig. 24.13 Outflow from preganglionic sympathetic neurones in the lateral horn of the spinal cord. Preganglionic axons may synapse on a postganglionic neurone in a sympathetic ganglion at the same segmental level, or may pass into the sympathetic chain to synapse on a postganglionic neurone in a more rostral or caudal sympathetic ganglion, or may pass to a ganglion in an autonomic plexus in the abdominal cavity, e.g. the coeliac ganglion.

Sympathetic nervous system

The sympathetic system has a much wider distribution than the parasympathetic system. It innervates all sweat glands and arrector pili muscles, the muscular walls of many blood vessels, the heart, lungs and respiratory trees, the abdominopelvic viscera, the muscles of the iris and the non-striated muscle of the eyelids, oesophagus and urogenital tract.

The cell bodies of preganglionic sympathetic neurones are located in the lateral horn of the spinal grey matter of all thoracic segments and the upper two or three lumbar segments (Fig. 24.12). The cell bodies of postganglionic sympathetic neurones are located in the paravertebral sympathetic trunk or a more peripheral plexus (e.g. coeliac plexus). The sympathetic trunk is a ganglionated cord that extends on either side of the vertebral column from the cranial base to the sacrococcygeal junction. The ganglia are joined to spinal nerves by short connecting nerves, the white and grey rami communicantes (Fig. 24.13).

In the neck, the sympathetic trunks lie posterior to the carotid sheath and anterior to the transverse processes of the cervical vertebrae. In the thorax, the trunks are anterior to the heads of the ribs, in the abdomen they lie anterolateral to the bodies of the lumbar vertebrae, and in the pelvis they are anterior to the sacrum and medial to the anterior sacral foramina. The two trunks meet in a single, median, terminal ganglion, the ganglion impar, at the level of the sacrococcygeal junction. Cervical sympathetic ganglia are usually reduced to three, superior, middle and inferior, by fusion. The internal carotid nerve, a continuation of the sympathetic trunk, issues from the cranial pole of the superior cervical ganglion and accompanies the internal carotid artery through its canal into the cranial cavity. There are between 10 and 12 (usually 11) thoracic ganglia, 4 lumbar ganglia, and 4 or 5 ganglia in the sacral region.

Preganglionic axons are myelinated, with diameters of 1.5–4 μm, and join the sympathetic trunk through the white rami communicantes. On reaching the trunk, the axons behave in one of several ways (see Fig. 24.13). They can synapse with neurones in the nearest ganglion, or traverse the nearest ganglion and ascend or descend in the sympathetic trunk to end in another ganglion. A preganglionic fibre can terminate in a single ganglion or, through collateral branches, synapse with neurones in several ganglia. Preganglionic fibres may traverse the nearest ganglion, ascend or descend and, without synapsing, emerge in one of the medially directed branches of the sympathetic trunk to synapse in the ganglia of autonomic plexuses (mainly situated in the midline, e.g. around the coeliac and mesenteric arteries). More than one preganglionic fibre may synapse with a single postganglionic neurone. Uniquely, the suprarenal gland is innervated directly by preganglionic sympathetic neurones that traverse the sympathetic trunk and coeliac ganglion without synapsing.

The cell bodies of postganglionic sympathetic neurones are located in the ganglia of the sympathetic trunk or in ganglia in more peripheral plexuses. Postganglionic axons are unmyelinated and are distributed to target organs in various ways. Those from a ganglion in the sympathetic trunk may return to the spinal nerve of preganglionic origin through a grey ramus communicans (which usually joins the nerve just proximal to the white ramus communicans), and they are then distributed through ventral and dorsal spinal rami to blood vessels, sweat glands, hairs, etc., in their zone of supply. Segmental areas vary in extent and overlap considerably and the extent of innervation of different effector systems, e.g. vasomotor, sudomotor, etc. by a particular nerve may not be the same. Alternatively, postganglionic fibres may pass direct to

particular viscera, or innervate adjacent blood vessels, or pass along them externally to their peripheral distribution. They may ascend or descend before leaving the sympathetic trunk as described above. Many fibres are distributed along arteries and ducts as plexuses to distant effectors.

Postganglionic sympathetic fibres that return to the spinal nerves are vasoconstrictor to blood vessels, secretomotor to sweat glands and motor to the arrector pili muscles within their dermatomes. Those that accompany the motor nerves to voluntary muscles are probably only dilatory. Most, if not all, peripheral nerves contain postganglionic sympathetic fibres. Those reaching the viscera are concerned with general vasoconstriction, bronchial and bronchiolar dilation, modification of glandular secretion, pupillary dilation, inhibition of gastrointestinal muscle contraction, etc. A single preganglionic fibre probably synapses with the postganglionic neurones in only one effector system, which means that effects such as sudomotor and vasomotor actions can be separate.

Parasympathetic nervous system

Preganglionic parasympathetic neuronal cell bodies are located in certain cranial nerve nuclei of the brainstem and in the lateral horn (intermediolateral column) of the second to fourth sacral segments of the spinal cord. Efferent fibres, which are myelinated, emerge from the CNS only in the oculomotor, facial, glossopharyngeal and vagus nerves, and in the second to fourth sacral spinal nerves. Preganglionic parasympathetic neurones are cholinergic.

The cell bodies of postganglionic parasympathetic neurones are mostly sited distant from the CNS, either in discrete ganglia located near the structures they innervate, or dispersed in the walls of viscera. In the cranial part of the parasympathetic system, four small peripheral ganglia (ciliary, pterygopalatine, submandibular and otic) are all described on a regional basis. These are efferent parasympathetic ganglia, unlike the trigeminal, facial, glossopharyngeal and vagal sensory ganglia, all of which are concerned exclusively with afferent impulses and contain the cell bodies of sensory neurones. The cranial parasympathetic ganglia are also traversed by afferent fibres, postganglionic sympathetic fibres and, in the case of the otic ganglion, by branchial efferent fibres, but none of these fibres synapse in the ganglia. Postganglionic parasympathetic fibres are usually unmyelinated and shorter than their counterparts in the sympathetic system because the ganglia in which the parasympathetic fibres synapse are either in or near the viscera they supply. Postganglionic parasympathetic neurones are cholinergic.

Enteric nervous system and intrinsic neurones

Many peripheral autonomic ganglia contain neurones derived from the neural crest during embryonic development that are anatomically distinct from classical sympathetic and parasympathetic neurones. Connections between these intrinsic neurones allow them to sustain and modulate visceral activities by local reflex mechanisms. The enteric nervous system consists of many millions of neurones and enteric glial cells grouped into ganglionated plexuses lying in the wall of the gastrointestinal tract; ganglia containing neuronal cell bodies and glia are connected by bundles of axons to form myenteric and submucous plexuses that extend from the oesophagus to the anal sphincter (see Fig. 59.9). This intrinsic circuitry mediates numerous reflex functions including the contractions of the muscular coats of the gastrointestinal tract, secretion of gastric acid, intestinal transport of water and electrolytes, and the regulation of mucosal blood flow (Poole and Furness 2012). Although complex interactions occur between the enteric and sympathetic and parasympathetic nervous systems, the enteric nervous system is capable of sustaining local reflex activity independent of the CNS.

Since intrinsic neurones survive after section of the extrinsic sympathetic and parasympathetic nerves, organs that are transplanted are not truly denervated. Separation from their autonomic input often has no obvious impact on the non-striated muscle or glands innervated by autonomic fibres; contraction may be unaffected and no structural changes ensue. This has been variously attributed to the continued activity of local plexuses or to the intrinsic activity of visceral muscle. In some important instances, however, denervation does result in cessation of activity, e.g. in sweat glands, pilomotor muscle, orbital non-striated muscle and the suprarenal medulla.

Visceral afferent pathways

Visceral afferent pathways in many ways resemble somatic afferent pathways. The peripheral processes of visceral afferents run through autonomic ganglia or plexuses, and possibly through somatic nerves. Their central processes accompany somatic afferent fibres through cranial nerves or dorsal spinal roots into the CNS, where they establish connections that mediate autonomic reflexes and visceral sensation.

General visceral afferent fibres from the viscera and blood vessels accompany their efferent counterparts, and are the peripheral processes of neuronal cell bodies located in the sensory ganglia of some cranial nerves and in dorsal root ganglia. They travel in the vagus, glossopharyngeal and possibly other cranial nerves; the second to fourth sacral spinal nerves, distributed with the pelvic splanchnic nerves; and thoracic and upper lumbar spinal nerves, distributed through rami communicantes and alongside the efferent sympathetic innervation of viscera and blood vessels.

The cell bodies of vagal general visceral afferent fibres are in the superior and inferior vagal ganglia. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls where, acting synergistically with glossopharyngeal visceral afferents in the pharynx, they are concerned with swallowing reflexes. Vagal afferents are also believed to innervate the thyroid and parathyroid glands. In the heart, vagal afferents innervate the walls of the great vessels, the aortic bodies and pressor receptors, where they are stimulated by raised intravascular pressure. In the lungs they are distributed via the pulmonary plexuses. They supply bronchial mucosa, where they are probably involved in cough reflexes; bronchial muscle, where they encircle myocytes and end in tendrils that are sometimes regarded as muscle spindles and which are believed to be stimulated by change in the length of myocytes; interalveolar connective tissue, where their knob-like endings, together with terminals on myocytes, may evoke Hering–Breuer reflexes; the adventitia of pulmonary arteries, where they may be pressor receptors; and the intima of pulmonary veins, where they may be chemoreceptors. Vagal visceral afferent fibres also end in the gastric and intestinal walls, digestive glands and the kidneys. Fibres ending in the gastrointestinal tract and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

The cell bodies of glossopharyngeal general visceral afferents are in the glossopharyngeal ganglia. Their peripheral processes innervate the posterior lingual region, the palatine tonsils and the oropharynx, but they do not innervate taste buds. They also innervate receptors sensitive to tension and changes in the chemical composition of the blood in the carotid sinus and the carotid body: impulses from these receptors are essential to the integrity of circulatory and respiratory reflexes.

Visceral afferents that enter the spinal cord through spinal nerve roots terminate in the spinal grey matter. Almost all the central processes of vagal and glossopharyngeal afferent fibres end in the nucleus tractus solitarius of the medulla. About 5% of the vagal afferents project directly to, and terminate in, the upper cervical spinal cord (C1–C2), where they are believed to contribute to referred sensations, as well as to propriospinal mechanisms of nociceptive modulation. Visceral afferents establish connections within the CNS that mediate autonomic reflexes. They probably also mediate visceral sensations such as hunger, nausea, sexual excitement and vesical distension, etc. Visceral pain fibres may follow these routes. Although viscera are insensitive to cutting, crushing or burning, excessive tension in smooth muscle and some pathological conditions produce visceral pain. In visceral disease, vague pain may be felt near the viscus itself (visceral pain) or in a cutaneous area or other tissue from which somatic afferents enter spinal segments that also receive afferents from the viscus, a phenomenon known as referred pain. If inflammation spreads from a diseased viscus to the adjacent parietal serosa (e.g. the peritoneum), somatic afferents will be stimulated, causing local somatic pain, which is commonly spasmodic. Referred pain is often associated with local cutaneous tenderness. For further reading on visceral pain, see Bielefeldt and Gebhart (2013).

Afferent fibres in pelvic splanchnic nerves innervate pelvic viscera and the distal part of the large intestine. Vesical receptors are widespread; those in muscle strata are associated with thickly myelinated fibres and are believed to be stretch receptors, possibly activated by contraction. Pain fibres from the bladder and proximal urethra travel in both the pelvic splanchnic nerves and the inferior hypogastric plexus, hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their cell bodies in ganglia on the lower thoracic and

upper lumbar dorsal spinal roots. Lesions of the cauda equina abolish pain from vesical overdistension; hypogastric section is ineffective. Pain fibres from the uterus traverse the hypogastric plexus and lumbar splanchnic nerves to reach their cell bodies in the lowest thoracic and upper lumbar spinal ganglia; hypogastric division may relieve dysmenorrhoea. Afferents from the uterine cervix traverse the pelvic splanchnic nerves to reach their cell bodies in the upper sacral spinal ganglia; stretching the cervix uteri causes pain but cauterization and biopsy excisions do not.

In general, afferent fibres that accompany pre- and postganglionic sympathetic fibres have a segmental arrangement and end in spinal cord segments from which preganglionic fibres innervate the region or viscus concerned. General visceral afferents entering thoracic and upper lumbar spinal segments are largely concerned with pain. Nociceptive impulses from the pharynx, oesophagus, stomach, intestines, kidneys, ureter, gallbladder and bile ducts seem to be carried in sympathetic pathways. Cardiac nociceptive impulses enter the spinal cord in the first to fifth thoracic spinal nerves, mainly via the middle and inferior cardiac nerves; some fibres pass directly to the spinal nerves. Peripherally, the fibres pass through the cardiac plexuses and along the coronary arteries. Myocardial anoxia may evoke symptoms of angina pectoris in which pain is typically presternal, and is also referred to much of the left chest, and radiates to the left shoulder, the medial aspect of the left arm, along the left side of the neck to the jaw and occiput, and down to the epigastrium. Cardiac afferents carried in vagal cardiac branches are concerned with the reflex depression of cardiac activity. Ureteric pain fibres, also running with sympathetic fibres, are presumably involved in the agonizing renal colic that follows obstruction by calculi. Afferent fibres from the testis and ovary run through the corresponding plexuses to neuronal call bodies in the tenth and eleventh thoracic dorsal root ganglia.

Some of the primary afferent neurones that innervate the gut, lungs, heart and blood vessels, also appear to have an efferent function in that they release transmitters from their peripheral endings during the axon reflex. The primary substances released in this way are substance P, calcitonin gene-related peptide (CGRP) and ATP. These act on target cells to produce vasodilation, increased venular permeability, changes in smooth muscle contractility, degranulation of mast cells and a variety of effects on leukocytes and fibroblasts, a process collectively known as 'peripheral neurogenic inflammation'. The local release of such substances may play a trophic role in the maintenance of tissue integrity and repair in response to injury (for further reading, see Xanthos and Sandkühler (2014)).

Paraganglia

Paraganglia are extra-suprarenal aggregations of neuroepithelial cells. They are all derived from the neural crest and all synthesize and store catecholamines (Fig. 24.14). Paraganglia can be divided into two broad categories, non-chromaffin and chromaffin. Non-chromaffin paraganglia are related to the parasympathetic system, particularly in the head and neck, where they tend to be associated with the glossopharyngeal or vagus nerves (carotid body, promontory of the middle ear, tunica adventitia of the jugular bulb, facial canal, ganglion nodosum, larynx). Chromaffin paraganglia are connected with the orthosympathetic system (in the sympathetic ganglia of various viscera and a variety of thoracolumbar para-aortic retroperitoneal sites). Small paraganglia have also been reported incidentally in the urinary bladder, prostate, gallbladder, splenic capsule and mesosigmoid. Their functions differ with location: some cells act as interneurones, others as sources of neuroendocrine secretion. Paraganglionic catecholamine release occurs mainly in response to chemical rather than to neural stimuli. Extra-suprarenal chromaffin tissue is prominent in the fetus, and acts as the main source of catecholamines while the suprarenal medulla is immature. Although many paraganglia degenerate soon after birth, others persist into adulthood, often as microscopic paraganglia.

Paraganglia are well vascularized and their secretory cells are usually close to one or more fenestrated capillaries. Most have a sympathetic innervation and act as endocrine organs, e.g. suprarenal medullary chromaffin cells. Those associated with the parasympathetic system probably have activities on local nerve endings, e.g. the carotid body. Paraganglia produce regulatory peptides, particularly enkephalins, and store them as cytoplasmic granules until stimulated to release them. Their secretions may exert a local paracrine action on nearby cells, in addition to having remote endocrine effects.

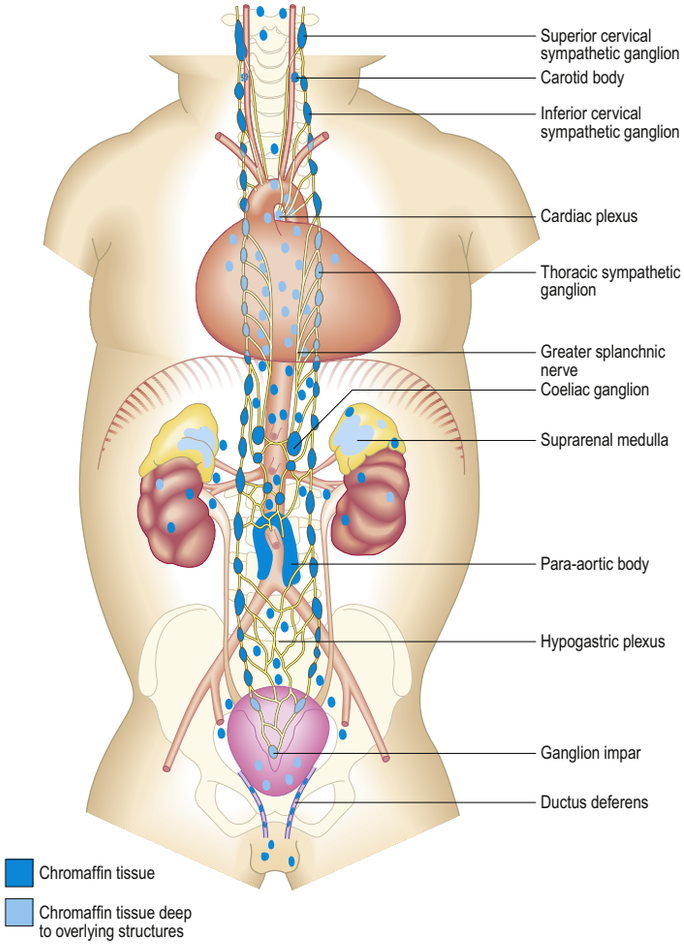

Fig. 24.14 The principal aggregations of 'classic' chromaffin tissue in the human neonate. The aggregates in pale blue lie deep to overlying structures.

Paragangliomas have been found in practically every site in which normal paraganglia are known to occur; carotid body paragangliomas are the most common and important group of extra-suprarenal paragangliomas (accounting for approximately 60% of head and neck paragangliomas). For further reading, see Rosai (2011) and Lack and Wieneke (2014).

SURFACE ANATOMY

The surface positions of cerebral structures, meningeal arteries and dural venous sinuses may be approximated via a number of standardized reference lines and planes. The midsagittal nasion–inion line curves around the sagittal plane of the skull from the nasion anteriorly to the inion posteriorly (Fig. 24.15). Reid's baseline (Frankfurt plane) passes through the inferior margin of the orbit and the superior margin of the external acoustic meatus (porion). The infraorbitomeatal line passes from the inferior margin of the orbit and through the centre of the external acoustic meatus (auricular point). The preauricular/condylar line passes through the preauricular point/mandibular condyle and sits perpendicular to the infraorbitomeatal line.

Cerebral sulci and lobes

The central sulcus (Rolandic fissure) and lateral sulcus (Sylvian fissure) of the cerebral hemispheres can be landmarked via the cranium using multiple methods, the most common being that developed by Taylor and Haughton (Fig. 24.16) (Taylor and Haughton 1900, Taylor et al 1980). Analysis of these methods has shown them to be accurate to within a few millimetres (Reis et al 2011). Using Taylor–Haughton craniometric lines, the lateral sulcus sits on the frontozygomatic (Sylvian) line, which passes from the frontozygomatic suture to a point 75% the way along the nasion–inion midsagittal line. The lateral sulcus extends posteroinferiorly from the Sylvian point, which

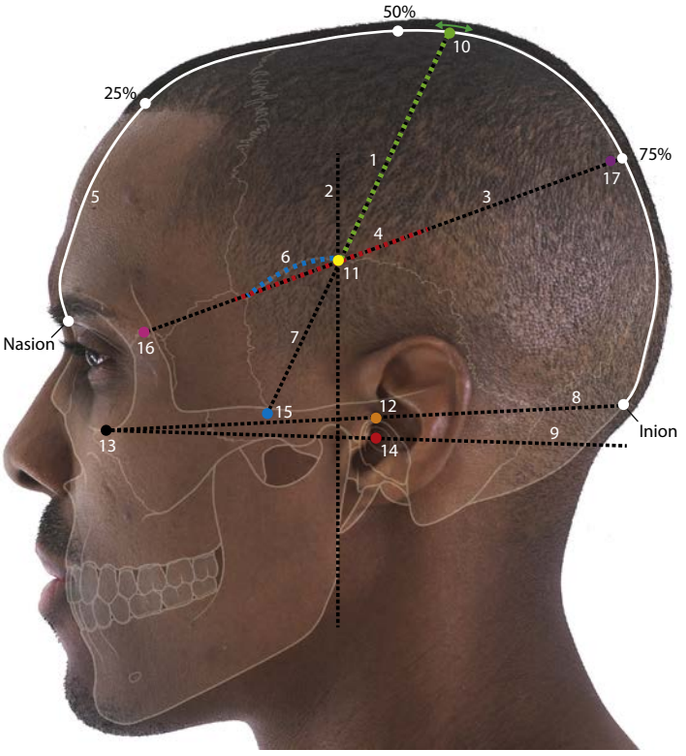

Fig. 24.15 Cranial reference lines, craniometric points and cerebral sulci. Key: 1, Rolandic line/central sulcus (green line); 2, pre-auricular/mandibular condylar line orientated perpendicular to the infra-orbitomeatal line; 3, frontozygomatic/Sylvian line passing from the frontozygomatic suture (16) to a point 75% of the way along the nasion–inion midsagittal line; 4, lateral sulcus/Sylvian fissure (red line); 5, nasion–inion midsagittal line; 6, lateral sulcus/Sylvian fissure alternative location (blue line): aligns anteriorly with the anterior part of the squamosal suture in a zone from 2.5 cm to 4.0 cm anterior to the external acoustic meatus; 7, line from the superior Rolandic point (green dot) to the midpoint of the zygomatic arch (15, blue dot); 8, Reid's baseline/Frankfurt plane; 9, infra-orbitomeatal line; 10 (green dot), superior Rolandic point located 2 ± 1 cm (green arrow) posterior to the midpoint of the nasion–inion line (at the 53–55% point of the nasion–inion line); 11 (yellow dot), inferior Rolandic point; 12 (orange dot), porion; 13 (black dot), lowest point of inferior orbital margin; 14 (red dot), auricular point; 15 (blue dot), midpoint of zygomatic arch; 16 (pink dot), frontozygomatic suture; 17 (purple dot), superior extent of the parieto-occipital sulcus. is located in the region of the pterion, about 3 cm posterior to the zygomatic process of the frontal bone, to a vertical line passing through the apex (tip) of the mastoid process. The lateral sulcus has also been shown to align with the anterior part of the squamosal suture in a zone located from 2.5 cm to 4.0 cm anterior to the external acoustic meatus (Rahmah et al 2011). The position of the central sulcus is approximated via a line passing from the superior Rolandic point, situated within 2 ± 1 cm posterior to the midpoint of the nasion–inion midsagittal line (Mirjalili et al 2012), to the inferior Rolandic point, situated at the intersection of the frontozygomatic line with the pre-auricular/condylar line. The position of the superior Rolandic point may vary between sides and individuals (Hamasaki et al 2012). Alternatively, the position of the central sulcus can be approximated using a line passing from the superior Rolandic point to the midpoint of the zygomatic arch, with the central sulcus ending at the point of intersection of this line with the frontozygomatic line (Rhoton 2002). The superior extent of the parieto-occipital sulcus sits at the point of intersection of the frontozygomatic line and the 75% point on the nasion–inion line. The approximate positions of the lobes of the brain, and of the precentral and postcentral gyri, can be determined following localization of the central, lateral and parieto-occipital sulci (see Fig. 24.16).

Dural venous sinuses

The superior sagittal sinus passes along the nasion–inion midsagittal line on the inner surface of the calvaria (**Fig. 24.17**) (Reis et al 2015). It may deviate either side of the midsagittal plane/superior sagittal suture by up to 11 mm, but is more commonly to the right (Tubbs et al 2001, Samadian et al 2011, Reis et al 2015). The confluence of the dural venous sinuses sits mainly to the upper right side of the inion on the inner surface of the occipital bone (Sheng et al 2012). The course of the transverse sinus has been shown to vary widely and no single plane or surface marking can be used to predict its route accurately (Sheng et al 2012). The position of the lower border of the proximal transverse sinus is best approximated via the insertion of semispinalis capitis into the cranium (Tubbs et al 2000). The asterion, found at the junction of the lambdoid, occipitomastoid and parieto-mastoid sutures, sits over the junction between the transverse and sigmoid sinuses in 81% of subjects, inferior to it in 15% and superior to it in 4% (Sheng et al 2012).

Middle meningeal artery

The surface positions of the anterior and posterior branches of the middle meningeal artery can be determined relative to cranial landmarks (see Fig. 33.8A).

Vertebral column, spinal cord and meninges

The surface positions of the termination of the spinal cord and dural sac can be mapped relative to the vertebrae and their spinous processes (see Figs 46.81–46.82).

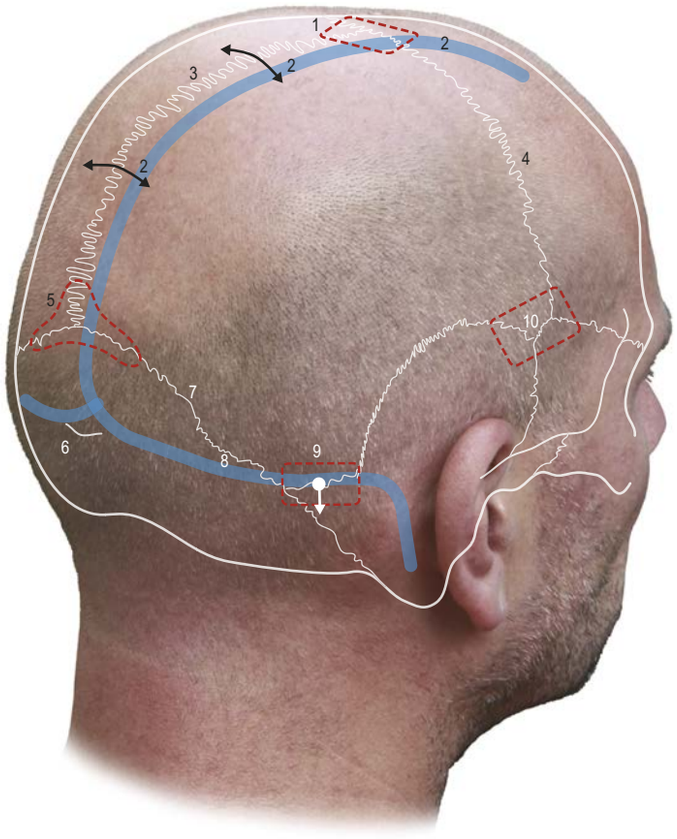

Fig. 24.17 Cranial suture joints, fontanelles and dural venous sinuses. Key: 1, bregma (site of infant anterior fontanelle); 2, superior sagittal sinus: deviates either side of the sagittal suture by up to 11 mm (black arrows), most commonly to the right (as shown); 3, sagittal suture: sits on the nasion–inion midsagittal line; 4, coronal suture; 5, lambda (site of infant posterior fontanelle); 6, inion: normally sits below and to the left of the confluence of the sinuses and just below the level of the internal occipital protruberance; 7, lambdoid suture; 8, transverse sinus; 9, asterion (site of infant posterolateral mastoid fontanelle): commonly sits over (in 81%) or just below (in 15%) the transverse–sigmoid sinus complex (white arrow shows range of positions); 10, pterion (site of infant anterolateral sphenoidal fontanelle). CHAPTER
25

Meninges and ventricular system

The meninges consist of three concentric membranes that envelop the brain and spinal cord, supporting and protecting the delicate tissues they surround. The individual layers, from outside to inside, are the dura mater (pachymeninx), arachnoid mater and pia mater. The dura is an opaque, tough, fibrous coat that incompletely divides the cranial cavity into compartments and accommodates the dural venous sinuses. The arachnoid is much thinner than the dura and is mostly translucent. It loosely surrounds the brain, cranial nerves and vessels and spans fissures and sulci. The pia mater is a transparent, microscopically thin membrane that follows the contours of the brain and is closely adherent to its surface.

The dura is separated from the arachnoid by a narrow subdural space. The arachnoid is separated from the pia by the subarachnoid space, which varies greatly in depth; the larger expanses are termed subarachnoid cisterns. The subarachnoid space contains cerebrospinal fluid (CSF) which is secreted by the choroid plexuses of the cerebroventricular system, circulates within the subarachnoid space and is reabsorbed into the venous system through arachnoid villi associated with the dural venous sinuses.

Cranial and spinal meninges are continuous through the foramen magnum. The cranial meninges are described in this section and the spinal meninges are described in Chapter 47.

DURA MATER

The dura mater is largely acellular and consists mainly of densely packed fascicles of collagen fibres arranged in laminae. The fascicles run in different directions in adjacent laminae, producing a lattice-like appearance that is particularly obvious in the tentorium cerebelli and around the defects or perforations that sometimes occur in the anterior portion of the falx cerebri.

The cranial dura differs from the spinal dura mainly in its relationship to the surrounding bones. It lines the cranial cavity and has an inner, meningeal, layer and an outer, endosteal layer. The two membranes are physically joined only at sites where veins pass from the brain into venous sinuses, e.g. the superior sagittal sinus. There is little histological difference between the layers: both contain fibroblasts, and the endosteal layer also contains osteoblasts. Focal calcification may occur in the falx cerebri and near the superior sagittal sinus. As a general rule, the meningeal layer covers neural tissues. It provides tubular sheaths for the cranial nerves as they pass out through the cranial foramina: the sheaths fuse with the epineurium as the nerves emerge from the skull. The dura fuses with the adventitia of major vessels, such as the internal carotid and vertebral arteries, at sites where they pierce it to enter the cranial cavity. The dural sheath of the optic nerve is continuous with the ocular sclera. The endosteal layer of dura adheres to the internal surfaces of the cranial bones, particularly at the sutures and the cranial base, and around the foramen magnum. It is continuous with the pericranium through the cranial sutures and foramina and with the orbital periosteum through the superior orbital fissure. Fibrous bands pass from the dura into the bones, so that it is difficult to remove the dura from the suture lines in young skulls: as the suture lines fuse, the dura becomes separated from them. The meningeal layer of dura is closely applied to the arachnoid mater over the surface of the brain: the layers are united except where they separate to enclose the venous sinuses that drain blood from the brain.

Extradural haematoma

The anatomical organization of the dura, and its relationships to the major venous sinuses, sutures and blood vessels, are clinically important. Separation of the dura from the cranial bones requires significant force, and consequently happens when high-pressure arterial bleeding takes place into the extradural or epidural space: this can result from damage to any meningeal vessel, commonly following skull fracture. The classic site for such injury is along the course of the middle meningeal artery, where a direct blow causing a fracture of the temporal and/or parietal bones can rupture the artery and cause rapid collection of blood into the extradural space. An extradural haematoma therefore acts as a rapidly expanding intracranial mass lesion that causes acute brain compression and displacement: it is a classic medical emergency that requires immediate diagnosis and surgery through a craniotomy for epidural blood clot evacuation and coagulation of the ruptured vessel (Fig. 25.1).

Dural partitions

The meningeal layer of the dura is reflected inwards to form four septa, the falx cerebri, falx cerebelli, diaphragma sellae and tentorium cerebelli, that partially divide the cranial cavity into compartments.

Falx cerebri

The falx cerebri is a strong, crescent-shaped sheet that lies in the sagittal plane and occupies the longitudinal fissure between the two cerebral hemispheres (Fig. 25.2). The crescent is narrow anteriorly, where the falx is fixed to the crista galli, and broad posteriorly, where it blends with the tentorium cerebelli: the straight sinus runs along this line of attachment to the tentorium (see Fig. 25.2). The anterior part of the falx is thin and may have a number of irregular perforations. Its convex upper margin is attached to the internal cranial surface on each side of the midline, as far posteriorly as the internal occipital protuberance. The superior sagittal sinus runs in a cranial groove within the dura along this margin, and the falx cerebri is attached to the lips of this groove. The lower edge of the falx is free and concave, and contains the inferior sagittal sinus.

Falx cerebelli

The falx cerebelli is a small midline fold of dura mater that lies below the tentorium cerebelli and projects forwards into the posterior cerebellar notch between the cerebellar hemispheres. Its base is directed upwards and is attached to the posterior part of the inferior surface of the tentorium cerebelli in the midline. Its posterior margin contains the occipital sinus and is attached to the internal occipital crest. The lower apex of the falx cerebelli frequently divides into two small folds that disappear at the sides of the foramen magnum.

Diaphragma sellae

The diaphragma sellae is a small, circular, horizontal sheet of dura mater that forms a roof over the sella turcica and covers the pituitary gland (hypophysis). The infundibulum (pituitary stalk) passes into the pituitary fossa through a central opening in the diaphragm: there is wide individual variation in the size of this opening. The diaphragma sellae is an important landmark in pituitary surgery because large pituitary tumours extend above it and may adopt a characteristic dumbbell shape. A trans-sphenoidal approach is currently the preferred option for accessing pituitary tumours, irrespective of whether there is suprasellar extension beyond the diaphragma sellae.

Tentorium cerebelli

The shape of the tentorium cerebelli (see Fig. 25.2B) is reminiscent of a single-poled tent, as its name suggest. It lies between the cerebellum and the occipital lobes of the cerebral hemispheres, and divides the cranial cavity into supratentorial and infratentorial compartments that contain the forebrain and hindbrain, respectively. Its concave anterior edge is free and separated from the dorsum sellae of the sphenoid bone by a large curved hiatus, the tentorial incisure or notch, which is occupied by the midbrain and the anterior part of the superior aspect of the cerebellar vermis. The convex outer limit of the tentorium is attached posteriorly to the lips of the transverse sulci of the occipital bone and

to the posterior inferior angles of the parietal bones, where it encloses the transverse sinuses. Laterally, it is attached to the superior borders of the petrous parts of the temporal bones, where it contains the superior petrosal sinuses. On each side, near the apex of the petrous temporal bone, the lower layer of the tentorium is evaginated anterolaterally under the superior petrosal sinus to form a recess, Meckel's cave, between the endosteal and meningeal dural layers in the middle cranial fossa. The cave is entered by the posterior root of the trigeminal nerve and contains cerebrospinal fluid and the trigeminal ganglion; the evaginated meningeal layer fuses anteriorly with the anterior part of the ganglion.

The arrangement of the dura mater in the central part of the middle cranial fossa is complex. The tentorium forms the medial part of the floor of the middle cranial fossa. On both sides, the rim of the tentorial incisure is attached to the apex of the petrous temporal bone. It continues forwards as a ridge of dura, the anterior petroclinoidal ligament, that is attached to the anterior clinoid process: this ligament marks the junction of the roof and the lateral wall of the cavernous sinus. The periphery of the tentorium cerebelli (attached to the superior border of the petrous temporal bone), crosses under the free border of the tentorial incisure at the apex of the petrous temporal bone, and continues forwards to the posterior clinoid process as a rounded ridge of dura mater, the posterior petroclinoidal ligament. The dural extension between the anterior and posterior petroclinoidal ligaments forms the roof of the cavernous sinus. On either side, it is pierced superiorly by the oculomotor nerve and posteriorly by the trochlear nerve: both nerves proceed anteroinferiorly into the lateral wall of the cavernous sinus.

In the anteromedial part of the middle cranial fossa, the dura ascends as the lateral wall of the cavernous sinus. It reaches the ridge produced by the anterior petroclinoidal ligament and runs medially as the roof of the cavernous sinus, where it is pierced by the internal carotid artery. The interclinoidal ligament, between the anterior and posterior clinoid processes, forms the medial limit of the roof of the cavernous sinus and continues medially with the diaphragma sellae. At, or just below, the opening in the diaphragma for the pituitary stalk, the dura of the diaphragma and the suprasellar arachnoid blend with each other and with the capsule of the pituitary gland: the subarachnoid space does not extend into the sella turcica.

Transtentorial coning

Normally, the arrangement of dural partitions such as the falx cerebri and tentorium cerebelli may help to stabilize the brain within the cranial cavity. However, when there is focal brain swelling or a focal space-occupying lesion within the brain or cranial cavity, mass effect and raised intracranial pressure may cause the brain to herniate under the falx cerebri or, more significantly, through the tentorial incisure. In this case, the medial temporal lobe, and particularly the uncus, will compress the oculomotor nerve, midbrain and the posterior cerebral arteries. This life-threatening event and neurosurgical emergency, occurring in patients with supratentorial space-occupying lesions, is known as transtentorial uncal herniation. Similarly, space-occupying lesions in the smaller infratentorial compartment may cause upward herniation of the cerebellar vermis through the tentorial hiatus (upward transtentorial herniation) or downward herniation of the cerebellar tonsils through the foramen magnum (tonsillar herniation) (see Fig. 28.23); these neurosurgical emergencies require a suboccipital craniectomy.

Innervation of the cranial dura mater

The cranial dura mater is innervated mainly by branches of the three divisions of the trigeminal nerve, the second and third cervical spinal nerves and the cervical sympathetic trunk (**Fig. 25.3**).

Sensory nerve endings are restricted to the dura mater and cerebral blood vessels, and are not found in either the brain itself, or in the arachnoid or pia mater. Stimulation of these nerve endings causes pain, as evidenced during awake craniotomy procedures, and is the basis of certain forms of headache. The density of dural innervation, particularly around the dural venous sinuses, increases during the later part of gestation, peaking at term and subsequently decreasing during the first year of postnatal life (Davidson et al 2012).

Dural venous sinuses

Dural venous sinuses form a complex network of venous channels that drain blood from the brain and cranial bones (**Fig. 25.4**; see Figs 25.2, 26.10–26.11, 26.13). They lie between the endosteal and meningeal layers of dura mater, are lined by endothelium, lack valves and their walls are devoid of muscular tissue (Kılıç and Akakın 2008). They develop initially as venous plexuses and, to a variable degree, most adult sinuses retain that form. Plexiform arrays of small veins adjoin the superior and inferior sagittal and straight sinuses, and, less frequently, the transverse sinuses. Ridges of 'spongy' venous tissue, venous lacunae, often project into the lumina of the superior sagittal and transverse sinuses (Browder and Kaplan 1976, Kaplan and Browder 1976).

The named sinuses are the superior and inferior sagittal, straight, transverse, sigmoid, occipital, cavernous, intercavernous, superior and inferior petrosal, sphenoparietal, basilar and marginal.

Superior sagittal sinus

The superior sagittal sinus runs in the attached convex margin of the falx cerebri. It grooves the internal surface of the frontal bone, the adjacent margins of the two parietal bones and the squamous part of the occipital bone (**Fig. 25.5**; see Figs 25.2, 26.10, 26.11B,C, 26.13).

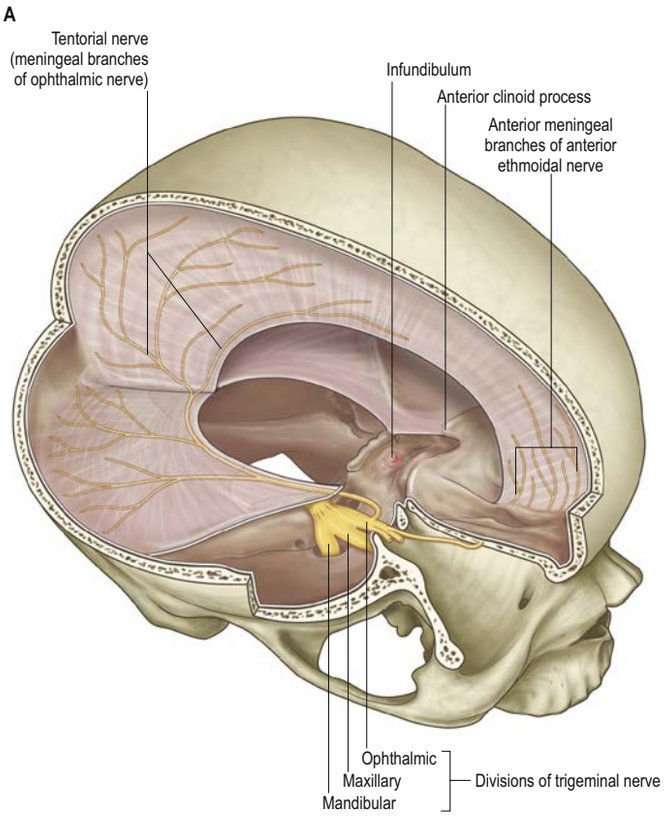

Fig. 25.3 The innervation of the cranial meninges. (**B**, *continued online*)

It begins near the crista galli, a few millimetres posterior to the foramen caecum, and receives primary tributaries from the cortical veins draining the superior part of the frontal, parietal and occipital lobes, and the anterior part of the orbital surface of the frontal lobe. The sinus is triangular in cross-section, with the apex directed downwards, and is continuous with the falx cerebri. Its lumen is invaded in its intermediate third by projections from its dural walls that may divide the lumen into superior and inferior channels. It is narrow anteriorly, and widens gradually to approximately 1 cm in diameter as it runs posteriorly to enter the confluence of the sinuses, situated to one side (usually the right) of the internal occipital protuberance (see Fig. 25.4). (The confluence of the sinuses is also known as the torcular Herophili or the torcula, although the term actually describes the bony gutter in which the confluence lies). At the confluence of the sinuses the superior sagittal sinus usually deviates to become continuous with the right transverse sinus, but also usually connects with the occipital and contralateral transverse sinuses. The size and degree of communication of the channels meeting at the confluence are highly variable; any sinus involved may be duplicated, narrowed or widened near the confluence (see Fig. 26.13B).

There are usually two or three lateral venous lacunae on each side of the midline, named frontal (small), parietal (large) and occipital (intermediate) lacunae; they tend to become confluent in the elderly, producing a single elongated lacuna on each side. Fine fibrous bands cross the lacunae, and numerous arachnoid granulations project into them (**Fig. 25.6**; see Fig. 25.5). The lacunae mainly drain diploic and meningeal veins. The cortical veins typically pass beneath the lacunae on their way to the sinus. The superior anastomotic vein (of Trolard), the largest cortical vein that connects the superficial middle cerebral (Sylvian) vein and the superior sagittal sinus, often runs in the precentral, central or postcentral sulci. Near its posterior end, the superior sagittal sinus receives veins from the pericranium that pass through parietal foramina. Acute and complete thrombosis of the superior sagittal sinus is an extremely severe condition causing acute elevation of the intracranial pressure and herniation. Slow and progressive occlusion of

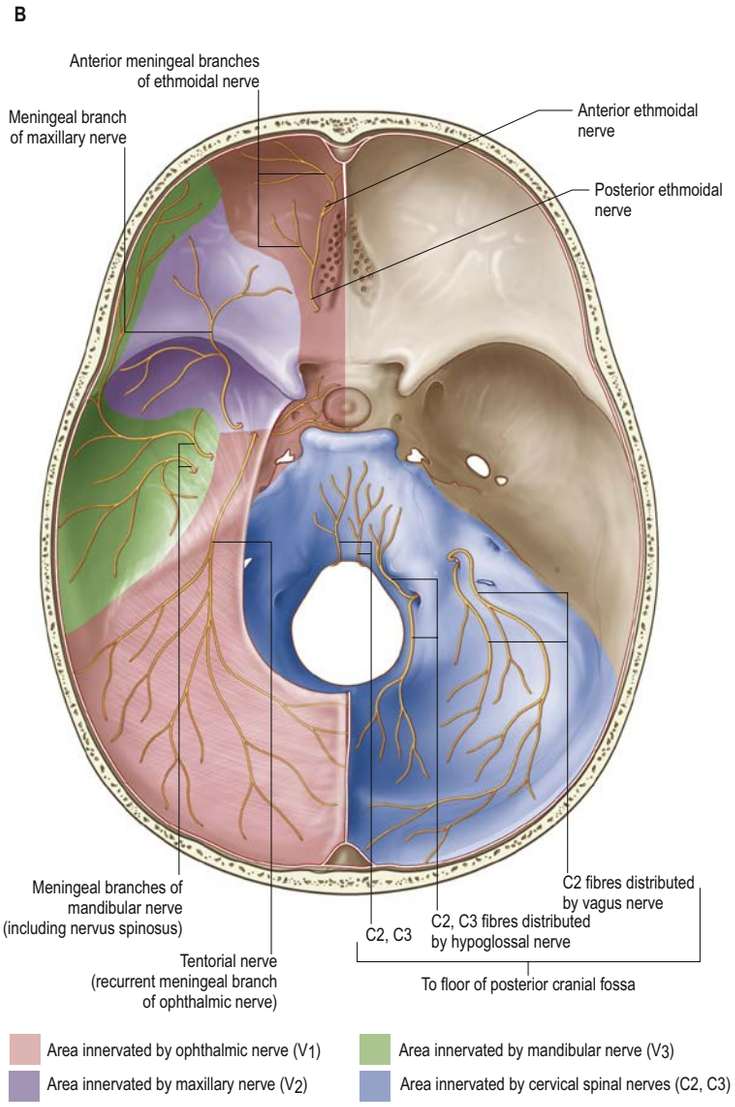

Fig. 25.3, cont'd B, The innervation of the cranial meninges.

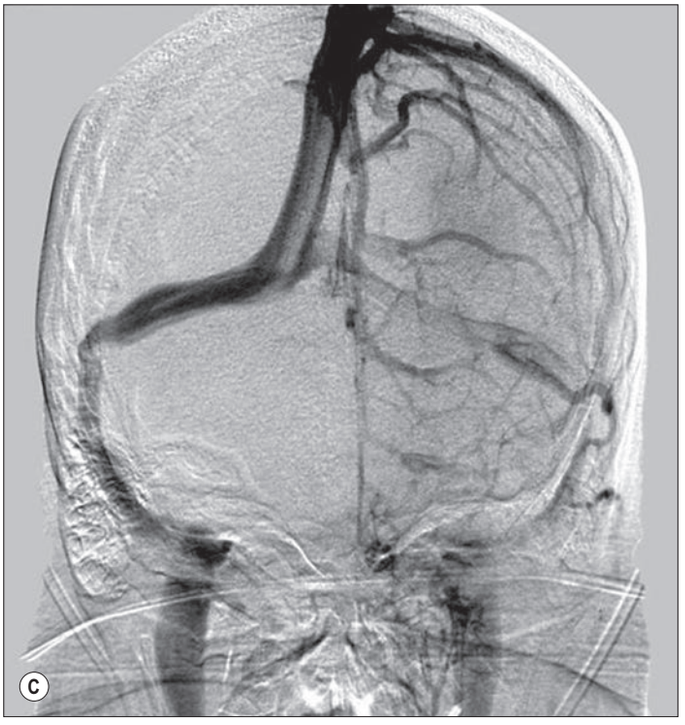

Fig. 25.4, cont'd C, Posterior view; note the asymmetry of the transverse sinuses.

Less well established meningeal branches have been described arising from the vagus and hypoglossal nerves, and possibly from the facial and glossopharyngeal nerves.

In the anterior cranial fossa, the dura is innervated by meningeal branches of the anterior and posterior ethmoidal nerves and anterior filaments of the meningeal rami of the maxillary (nervus meningeus medius) and mandibular (nervus spinosus) divisions of the trigeminal nerve. Nervi meningeus medius and spinosus are largely distributed to the dura of the middle cranial fossa, which also receives filaments from the trigeminal ganglion. The nervus spinosus re-enters the cranium through the foramen spinosum with the middle meningeal artery, and divides into anterior and posterior branches that accompany the main divisions of the artery and supply the dura mater in the middle cranial fossa and, to a lesser extent, the anterior fossa and calvarium. The anterior branch communicates with the meningeal branch of the maxillary nerve. The posterior branch also supplies the mucous lining of the mastoid air cells. The nervus spinosus contains sympathetic postganglionic fibres from the middle meningeal plexus. The nervus tentorii, a recurrent branch of the intracranial portion of the ophthalmic division of the trigeminal nerve, supplies the supratentorial falx cerebri and the tentorium cerebelli. Intraoperative mechanical stimulation of the falx may trigger the trigeminocardiac reflex (Bauer et al 2005). The space between the anterior half of the straight sinus and the medial tentorial notch can be considered a safe surgical area where innervation is scarce, whereas the entire region of the transverse sinus and the posterior half of the straight sinus are densely innervated by the nervus tentorii (Lee et al 2017). The dura in the posterior cranial fossa is innervated by ascending meningeal branches of the upper cervical nerves that enter through the anterior part of the foramen magnum (second and third cervical nerves) and through the hypoglossal canal and jugular foramen (first and second cervical nerves).

Meningeal branches from the vagus nerve apparently originate from the superior vagal ganglion and are distributed to the dura mater in the posterior cranial fossa. Meningeal branches from the hypoglossal nerve leave the nerve in its canal and supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses, and much of the floor and anterior wall of the posterior cranial fossa. These meningeal rami may not contain vagal or hypoglossal fibres but ascending, mixed sensory and sympathetic fibres from the upper cervical nerves and superior cervical sympathetic ganglion. All meningeal nerves contain a postganglionic sympathetic component, either from the superior cervical sympathetic ganglion or by communication with its perivascular intracranial extensions. The role of the autonomic nerve supply of the cranial dura mater is uncertain.

The plexiform nature of the cranial venous sinuses and their wide connections with cerebral and cerebellar veins vary considerably, particularly in earlier years, e.g. in infancy, the falx cerebelli may contain large plexiform channels and venous lacunae that augment the occipital sinus. These variations must be established for each patient by catheter-based angiography, magnetic resonance (MR) venography or computed tomographic (CT) venography, when clinical necessity arises. The existence of arteriovenous shunts has been inferred from the demonstration of a connection between the middle meningeal arteries and the superior sagittal sinus (Browder and Kaplan 1976). Dural arteriovenous fistulae are thought to be acquired lesions that form in an area of thrombosis within a sinus. If the sinus remains completely thrombosed, venous drainage from these lesions takes place through cortical veins: when the sinus remains closed, the elevated pressure within the cortical veins receiving the arterial flow carries the risk of haemorrhage. If the sinus is partially open, venous drainage is usually into the involved sinus.

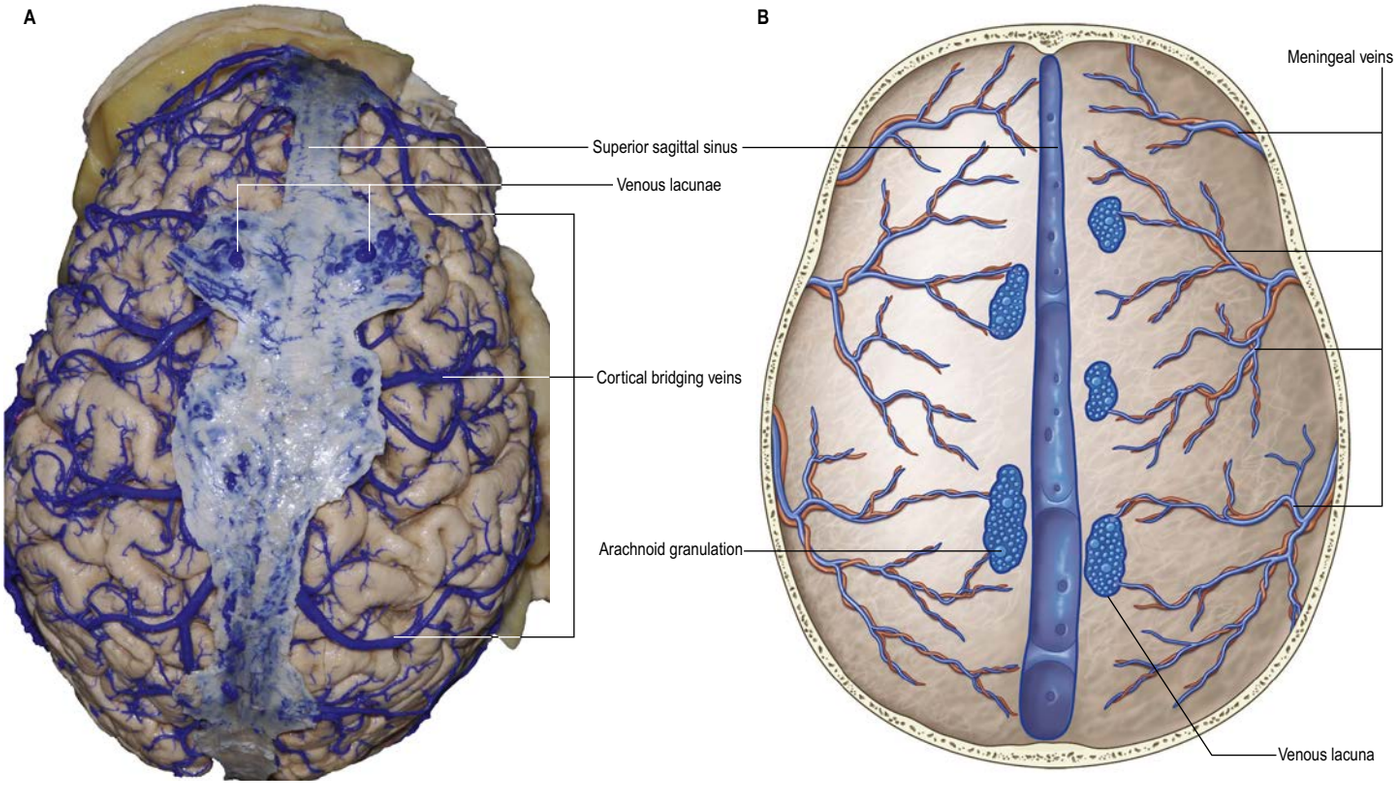

Fig. 25.5 The superior sagittal sinus and venous lacunae. **A**, An anatomical dissection of a silicon-injected specimen. **B**, The superior sagittal sinus opened up after removal of the cranial vault. Note the fibrous bands that cross the sinus from two of the venous lacunae. (A, From the Rhoton Collection.)

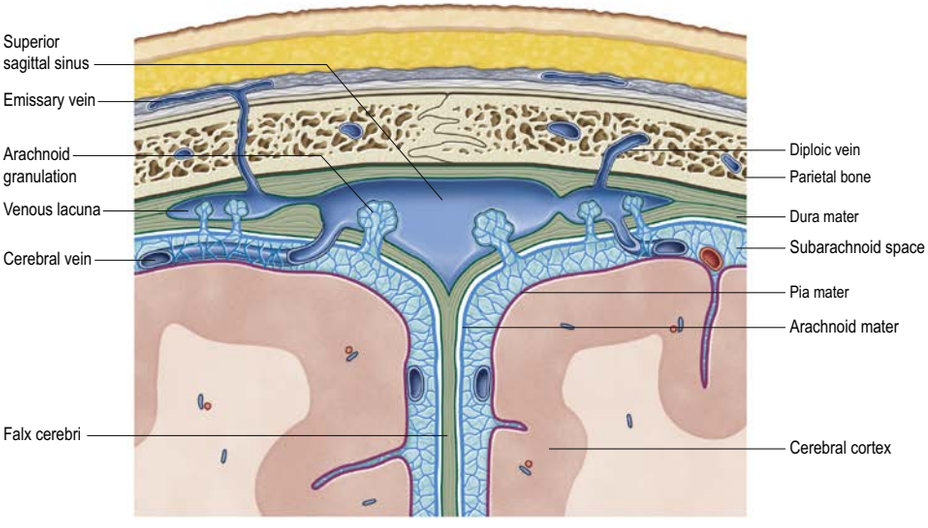

Fig. 25.6 A coronal section through the vertex of the skull to show the relationships between the superior sagittal sinus, meninges and arachnoid granulations. the sinus, as is typical for sagittal meningiomas, may be compensated by the development of collateral venous drainage with no clinical consequences.

Inferior sagittal sinus

The inferior sagittal sinus is located in the posterior half or two-thirds of the free margin of the falx cerebri (see Figs 25.2, 26.11C). It increases in size posteriorly, ends in the straight sinus, and receives veins from the falx and sometimes from the medial surfaces of the cerebral hemispheres (anterior pericallosal veins).

Straight sinus

The straight sinus lies in the junction of the falx cerebri and the tentorium cerebelli (see Figs 25.2, 26.10, 26.11A,C). It runs posteroinferiorly as a continuation of the inferior sagittal sinus and drains into the transverse sinus, most commonly into the left sinus. It is not (or is only tenuously) continuous with the superior sagittal sinus. Its tributaries include the great cerebral vein (of Galen), formed by the convergence of the internal cerebral and basal veins, and some superior cerebellar veins which may drain initially into the medial tentorial sinus (a short sinus within the tentorium).

Transverse sinus

The transverse sinuses are attached to the internal occipital protuberance (see Figs 25.2, 25.4, 26.11, 26.13). They begin at the confluence of the sinuses: one, usually the right, is directly continuous with the superior sagittal sinus, and the other is directly continuous with the straight sinus. The right transverse sinus is typically larger and drains blood from the superficial parts of the brain. The left transverse sinus mainly drains blood from the deep parts of the brain. On each side, the sinuses run in the attached margin of the tentorium cerebelli, first on the squama of the occipital bone, then on the mastoid angle of the parietal bone. Each follows a gentle anterolateral curve, increasing in size as it does so, to the posterolateral part of the petrous temporal bone, where it turns down as a sigmoid sinus that ultimately becomes continuous with the internal jugular vein. The transverse sinuses receive tributaries from the lateral temporal surface and basal surface of the temporal and occipital lobes. The inferior anastomotic vein (of Labbé) is the largest vein that connects the veins of the Sylvian fissure with the transverse sinus. All tributaries of each transverse sinus may drain first into a lateral tentorial sinus. The superior petrosal sinuses drain into the transition between the transverse and sigmoid sinuses on each side (see Figs 25.2, 25.4).

Sigmoid sinus

The sigmoid sinuses are continuations of the transverse sinuses, beginning where these leave the tentorium cerebelli (**Fig. 25.7**; see Figs 25.4, 26.11, 26.13C). Each sigmoid sinus curves inferomedially in a groove on the mastoid process of the temporal bone, crosses the jugular process of the occipital bone and turns forwards to the superior jugular bulb, lying posteriorly in the jugular foramen. Anteriorly, a thin plate of bone separates its upper part from the mastoid antrum and mastoid air cells. The sigmoid sinus is connected with pericranial veins via mastoid and condylar emissary veins. Neurosurgical approaches to the lateral aspect of the posterior fossa (cerebellopontine angle) are classified as retrosigmoid, when the craniectomy is located just behind the sigmoid sinus, and presigmoid, when the mastoid bone in front of the sinus is drilled away to provide a more anterior corridor into the posterior fossa.

Superior petrosal sinus

The superior petrosal sinuses are small, narrow sinuses that drain the cavernous sinus into the transverse sinus on each side (**Figs 25.8–25.9**; see Figs 25.2, 25.4, 26.11A). Each leaves the posterosuperior part of the cavernous sinus and runs posterolaterally in the attached margin of the tentorium cerebelli, crosses superior to the trigeminal nerve to lie in a groove on the superior border of the petrous part of the temporal bone, and ends by joining the transverse sinus at the point where this curves down to become the sigmoid sinus. The superior petrosal sinuses may receive cerebellar and brainstem veins, such as the superior petrosal vein, and, rarely, the inferior cerebral and tympanic veins; they are connected with the inferior petrosal sinuses and the basilar plexus.

Inferior petrosal sinus

The inferior petrosal sinuses drain the cavernous sinus into the internal jugular veins (see Figs 25.4, 26.10, 26.11A). They begin at the posteroinferior aspect of the cavernous sinus and run back in the petroclival fissure (a groove between the petrous part of the temporal bone and the basilar part of the occipital bone). On each side, the inferior petrosal sinus then passes through the anteromedial part of the jugular foramen, accompanied by a meningeal branch of the ascending pharyngeal artery, and descends obliquely backwards to drain into the superior jugular bulb. It sometimes drains via a vein in the hypoglossal canal to the suboccipital vertebral plexus.

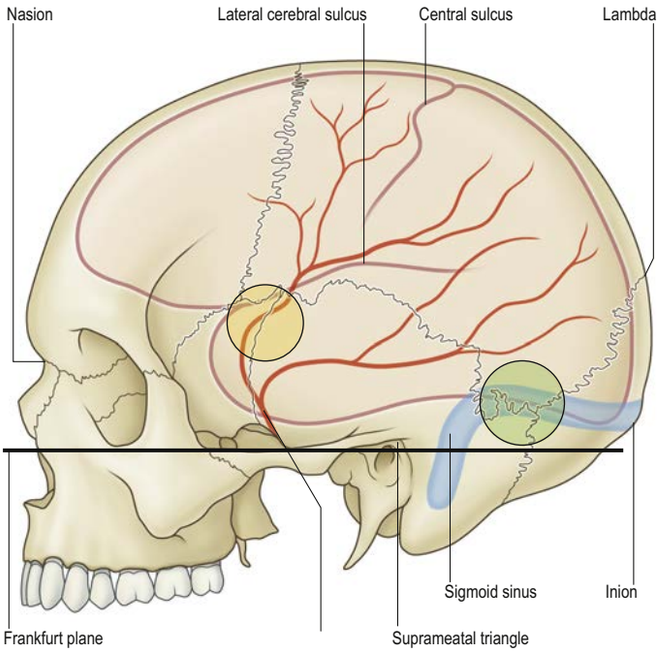

Fig. 25.7 The relations of the brain, the middle meningeal artery and the transverse and sigmoid sinuses to the surface of the skull. The area enclosed in the yellow circle (including the pterion) is used when performing a pterional craniotomy over the frontal branch of the middle meningeal artery and lateral Sylvian fissure; the area enclosed in the green circle is used when performing a retrosigmoid craniotomy extending to the confluence of the transverse and sigmoid sinuses.

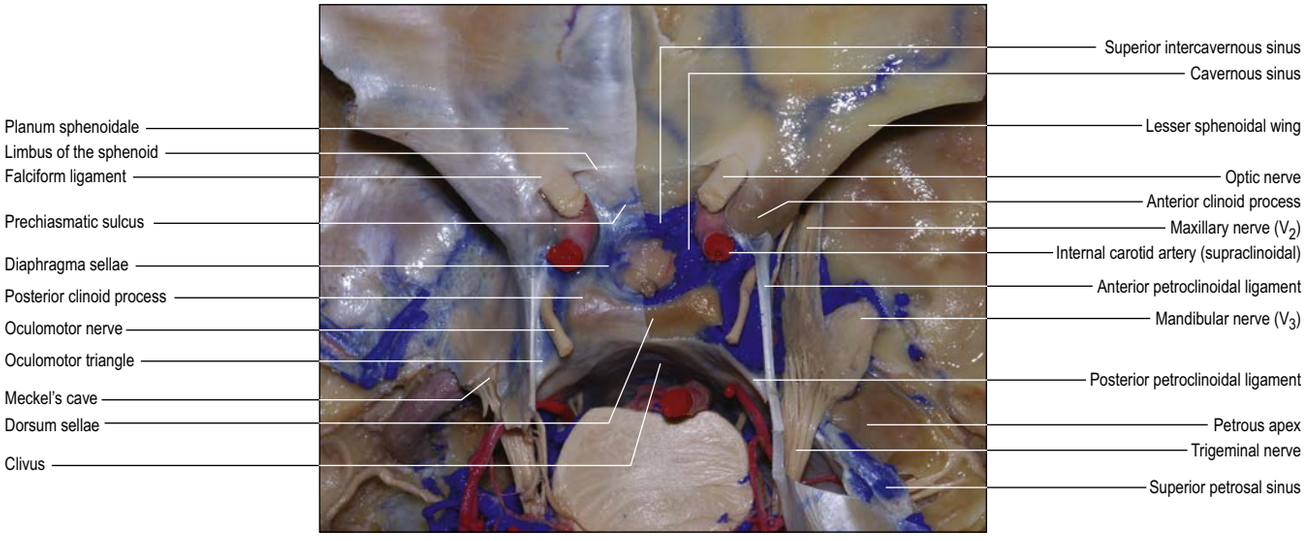

Fig. 25.8 The sellar region and adjacent middle and anterior cranial fossae, viewed from above, in a silicon-injected anatomical specimen. The dura has been removed on the right half of the specimen to show the roof of the cavernous sinus (oculomotor triangle), and the maxillary and mandibular nerves running on the floor of the middle fossa.

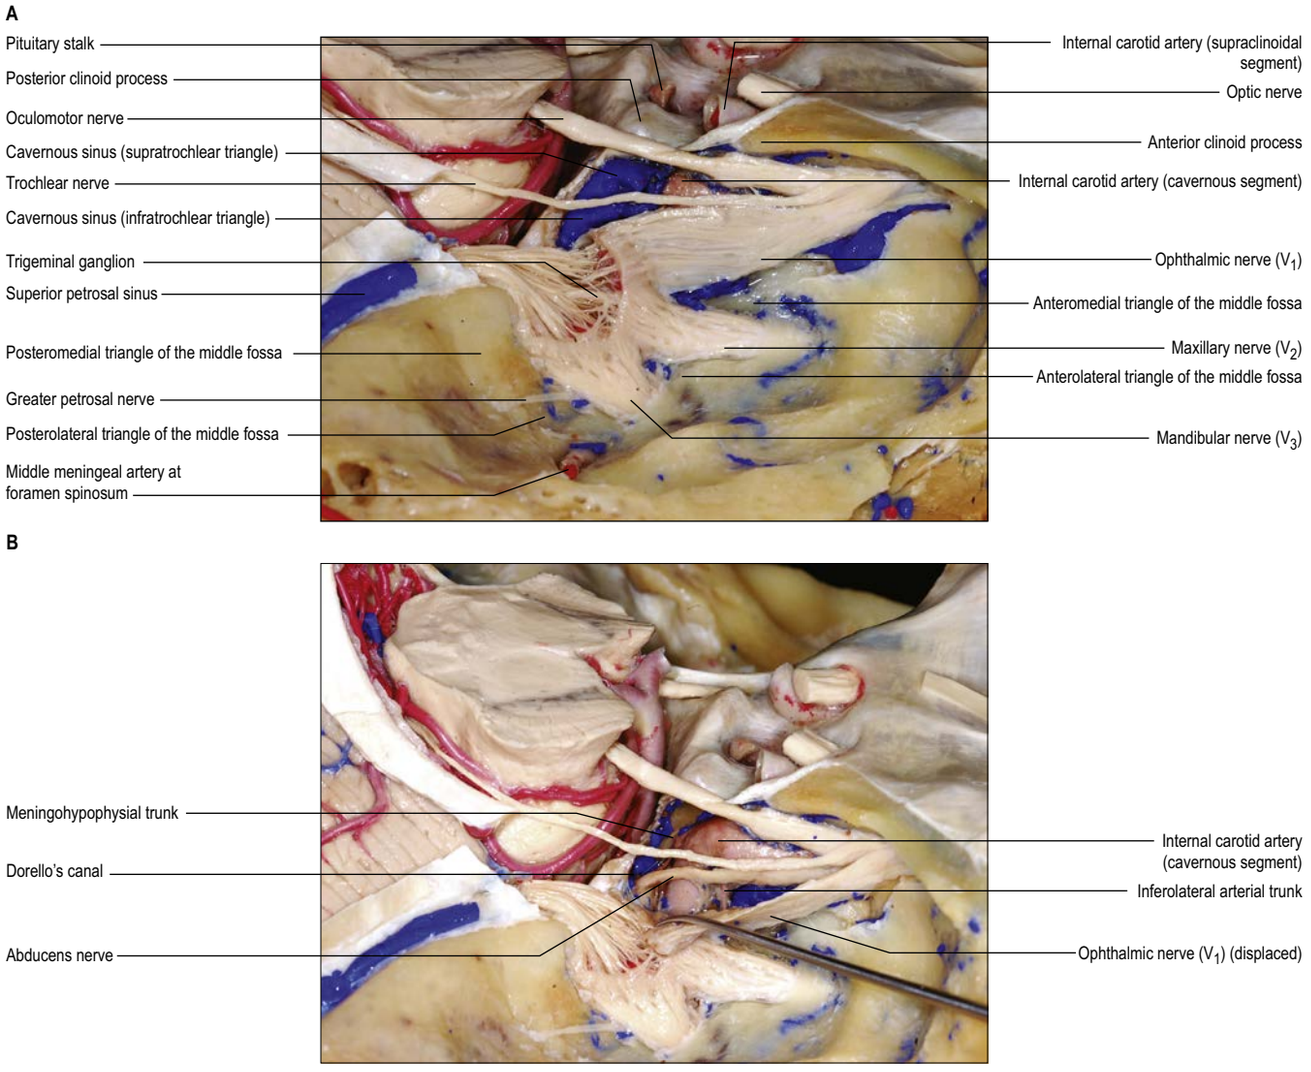

Fig. 25.9 A, A lateral view of the right middle cranial fossa and lateral wall of the cavernous sinus in a silicon-injected anatomical specimen. **B**, The ophthalmic nerve has been retracted inferiorly to show the inside of the cavernous sinus (abducens nerve, internal carotid artery and its branches) through the infratrochlear triangle.

Cavernous sinus

The cavernous sinuses are two large venous plexuses that lie on either side of the body of the sphenoid bone (see Figs 25.4, 26.11A). They extend from the superior orbital fissure to the apex of the petrous temporal bone, with an average length of 2 cm and width of 1 cm. The cavity of the cavernous sinus is formed when the two layers of dura that cover the anterior aspect of the pituitary gland separate from each other at the lateral margin of the sella: the outer (endosteal) layer continues laterally to form the anterior (sphenoidal) wall of the cavernous sinus, and the inner (meningeal) layer remains attached to the pituitary gland and runs back towards the dorsum sellae to form the medial (sellar) wall of the cavernous sinus. The posterior dural wall is posterior to the dorsum sellae and upper clivus, and is shared with the basilar plexus. The lateral wall extends from the superior orbital fissure to the petrous apex, and separates the cavernous sinus from Meckel's cave, which is inferior and posterior to the sinus. The roof of the cavernous sinus is formed by the clinoidal triangle (the dura lining the lower margin of the anterior clinoid process anteriorly), and the oculomotor triangle (the patch of dura between the anterior and posterior clinoids and the petrous apex).

Each sinus contains the cavernous segment of the internal carotid artery which is associated with a perivascular sympathetic plexus. From proximal to distal, the cavernous carotid artery has several portions, named short ascending, posterior genu, horizontal and anterior genu. The anterior genu of the cavernous carotid artery continues as the paraclinoidal segment of the carotid artery, which typically protrudes into the cavity of the sphenoidal sinus. The cavernous carotid gives off two major arterial branches: the meningohypophysial and inferolateral trunks (see Fig. 25.9B). The meningohypophysial trunk typically arises from the posterior genu and gives off the inferior hypophysial, tentorial and dorsal meningeal arteries. The inferolateral trunk arises a few millimetres distal to the meningohypophysial and is distributed around the nerves on the lateral wall of the sinus. (For more detailed descriptions of these branches, including their main variations, see Krisht et al (1994), Reisch et al (1996), Tekdemir et al (1998).)

Several cranial nerves run forwards through the cavernous sinus to enter the orbit via the superior orbital fissure (see Fig. 25.9). The oculomotor and trochlear nerves and the ophthalmic division of the trigeminal nerve all lie in the lateral wall of the sinus. The abducens nerve enters the cavernous sinus by passing inferior to the petrosphenoidal ligament within a dural tunnel (Dorello's canal) just posterior to the short ascending portion of the cavernous carotid artery, and then runs on the inferolateral side of the horizontal portion of the cavernous carotid artery, just medial to the ophthalmic nerve. The space between the trochlear and ophthalmic nerves at the lateral wall of the sinus, known as the infratrochlear or Parkinson's triangle, gives access to the horizontal and posterior genu portions of the cavernous carotid and the meningohypophysial trunk, and the abducens nerve. Unlike the ophthalmic division of the trigeminal nerve, the maxillary division of the trigeminal nerve does not run through the cavernous sinus or its lateral wall, but courses beneath the dura of the middle cranial fossa below the level of the cavernous sinus (Abhinav et al 2017).

Caroticocavernous sinus fistula and cavernous sinus thrombosis

Available with the *Gray's Anatomy* e-book

The inferior petrosal sinuses are often plexiform. Each receives labyrinthine veins via the cochlear canaliculus and the vestibular aqueduct, and tributaries from the medulla oblongata, pons and inferior cerebellar surface. The venous spaces in the sphenopetroclival area, which are filled anteriorly by blood from the cavernous sinus, medially by blood from the basilar plexus, and laterally by blood from the superior petrosal sinus, typically drain into the inferior petrosal sinuses (Iaconetta et al 2003).

Several major venous spaces or compartments can be identified within the sinus in relation to the cavernous carotid artery: superior, posterior, inferior and lateral (Fernandez-Miranda et al 2017, modified from Harris and Rhoton 1976). The superior and inferior ophthalmic veins drain into the inferior space; the basilar plexus and inferior petrosal sinus drain into the posterior space; the superior petrosal sinus opens into the superior space; and the superficial middle cerebral vein, the inferior cerebral veins and the sphenoparietal sinus may drain into the lateral compartment. Veins traversing the emissary sphenoidal foramen, foramen ovale and foramen lacerum and, less frequently, the central retinal vein and frontal tributary of the middle meningeal vein, also drain into the cavernous sinus.

Tumours (meningiomas, haemangiomas, schwannomas) can arise within the cavernous sinus or extend into the cavernous sinus from adjacent regions; typically, these are pituitary adenomas that invade the medial wall of the sinus. Transcranial microsurgical approaches enter the cavernous sinus through the lateral wall (infratrochlear triangle) or roof (oculomotor triangle) of the sinus. Recently introduced endoscopic endonasal approaches facilitate access to the cavernous sinus from its anterior (sphenoidal) and medial (sellar) walls and provide access to the posterior clinoids (Fernandez-Miranda et al 2014). (For more detailed descriptions of the microsurgical anatomy of the cavernous sinus, see Dolenc (1987), Umansky et al (1994), Seoane et al (1998), Yasuda et al (2004), Dolenc and Rogers (2009), Fernandez-Miranda et al (2014, 2017).)

Direct communication between the intracavernous portion of the internal carotid artery and the cavernous sinus, creating a caroticocavernous sinus fistula (CCF), may occur as a result of either severe head trauma or aneurysmal vessel disease. The classic signs are ptosis, proptosis (which may be pulsatile), chemosis, periorbital oedema, and extraocular dysmotility causing diplopia secondary to a combination of third, fourth and sixth cranial nerve palsies. Hypo- or hyperaesthesia in the distribution of the ophthalmic division of the trigeminal nerve and a decreased corneal reflex may also be detected. There may be evidence of dilated, tortuous retinal veins and papilloedema. These changes can cause permanent blindness. CCFs are most commonly treated by passing a catheter up the carotid into the fistula, and then occluding it with dilatable balloons or flexible metal coils. Any spreading infection involving the upper nasal cavities, paranasal sinuses, cheek (especially near the medial canthus), upper lip, anterior nares, or even an upper incisor or canine tooth, may very rarely lead to septic thrombosis of the cavernous sinuses; infected thrombi pass from the facial vein or pterygoid venous complex into the sinus via either ophthalmic veins or emissary veins that enter the cranial cavity through the foramen ovale. This is a critical medical emergency with a high risk of disseminated cerebritis and cerebral venous thrombosis.

Intercavernous sinuses

The two cavernous sinuses are connected by superior, inferior and posterior intercavernous sinuses, and the basilar plexus (see Figs 25.4, 25.8, 26.11A). The superior and posterior intercavernous sinuses lie in the anterior and posterior attached borders of the diaphragma sellae and they thus form a complete circular venous sinus. The inferior intercavernous sinuses are irregular and plexiform in nature, and commonly encountered in a surgical transnasal approach to the pituitary gland. Obliteration of any intercavernous sinus has no clinical consequences because all connections are valveless and the direction of flow in them is reversible.

Basilar venous plexus

The basilar sinus and plexus consist of interconnecting channels between the two layers of dura mater on the clivus (see Figs 25.4, 25.8). The basilar venous plexus interconnects the cavernous sinuses and inferior and superior petrosal sinuses, and joins the internal vertebral venous plexus.

Sphenoparietal sinus

The sphenoparietal sinuses are inconstant dural venous channels that lie under the lesser wings of the sphenoid bone, near their posterior edge (see Figs 25.4, 26.11A,C). Each sinus curves medially to open into the anterior part of the cavernous sinus, and receives small veins from the adjacent dura mater and sometimes from the frontal ramus of the middle meningeal vein. In its middle course, each may also receive connecting rami from the superficial middle cerebral vein, temporal lobe veins and the anterior temporal diploic vein. When these connections are well developed, the sphenoparietal sinus is a large channel. It has been suggested that the term sphenoparietal sinus should be abandoned on the basis that it is not an anatomical entity, but an artificial combination of two independent meningeal vessels, namely the parietal portion of the anterior branch of the middle meningeal veins and the sinus of the lesser wing of the sphenoid (Ruíz et al 2004).

Occipital sinus

The occipital sinus is the smallest of the sinuses and is typically larger in children. It lies in the attached margin of the falx cerebelli (see Fig. 25.4) and is occasionally paired. It starts near the foramen magnum in several small channels, one of which joins the end of the sigmoid sinus and connects with the internal vertebral plexuses. It ends in the confluence of the sinuses.

Marginal sinus

The marginal sinus encircles the foramen magnum. It communicates anteriorly with the basilar plexus and posteriorly with the occipital sinus. It typically drains to the sigmoid sinus or jugular bulb by small sinuses and may connect extracranially to the internal vertebral venous plexus or the paravertebral or deep cervical veins in the suboccipital region.

Emissary veins

Emissary veins traverse cranial apertures and connect intracranial venous sinuses and extracranial veins. Some are relatively constant, others may be absent. These connections are of clinical significance in determining the spread of infection from extracranial foci to venous sinuses, e.g. the spread of infection from the mastoid to the venous sinuses or from the paranasal sinuses to the cavernous sinus, and they may provide alternative drainage pathways in cases of venous sinus thrombosis.

Meningeal arteries and veins and diploic veins

Despite their names, the cranial meningeal arteries are predominantly periosteal (**Fig. 25.10A**). Their main targets are bone and haemopoietic marrow, and only some arterial branches are distributed to the cranial dura mater *per se*.

The branches of the meningeal vessels lie mainly in the endosteal layer of dura. In the anterior cranial fossa, the dura is supplied by the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries and a branch of the middle meningeal artery. In the middle cranial fossa, the dura is supplied by the middle and accessory meningeal branches of the maxillary artery; a branch of the ascending pharyngeal artery (entering via the foramen lacerum); branches of the internal carotid artery; and a recurrent branch of the lacrimal artery. In the posterior fossa, the dura is supplied by meningeal branches of the occipital artery which enter the skull by the jugular and mastoid foramina; the posterior meningeal branches of the vertebral artery; occasional small branches of the ascending pharyngeal artery which enter the skull by the jugular foramen and hypoglossal canal; and dorsal meningeal and tentorial branches from the meningohypophysial trunk. The anatomy of the meningeal arteries explains the vascular supply of tumours arising from the meninges (meningiomas) and the architecture of dural arteriovenous fistulae and malformations. (For detailed information on the surgical anatomy of the meningeal arteries, see Lasjaunias et al (2001), Martins et al (2005).)

Middle meningeal artery

The middle meningeal artery is the largest of the meningeal arteries. It arises from the first part of the maxillary artery in the infratemporal fossa and passes between the roots of the auriculotemporal nerve. It lies lateral to tensor veli palatini, then enters the cranial cavity through the foramen spinosum and runs in an anterolateral groove on the squamous part of the temporal bone, dividing into frontal and parietal branches (see Fig. 25.10A). The larger frontal (anterior) branch crosses the greater wing of the sphenoid and enters a groove or canal in the sphenoidal angle of the parietal bone (the sphenoparietal canal). It divides into branches between the dura mater and cranium, and some branches ascend to the vertex. The parietal (posterior) branch curves back on the squamous temporal bone, reaches the lower border of the parietal bone anterior to its mastoid angle and divides to supply the posterior parts of the dura mater and cranium. These frontal and parietal branches anastomose with their fellows and with the anterior and posterior meningeal arteries.

Ganglionic branches supply the trigeminal ganglion and associated roots. The petrosal branch enters the hiatus for the greater petrosal nerve, supplies the facial nerve, geniculate ganglion and tympanic cavity, and anastomoses with the stylomastoid artery (El Khouly et al 2008). The superior tympanic artery runs in the canal for tensor tympani and supplies the muscle and the mucosa that lines the canal. Temporal branches traverse minute foramina in the greater wing of the sphenoid and anastomose with deep temporal arteries that supply temporalis. An anastomotic branch enters the orbit laterally in the superior orbital fissure, and anastomoses with a recurrent branch of the lacrimal artery; enlargement of this anastomosis is believed to account for the occasional origin of the lacrimal artery from the middle meningeal artery.

Accessory meningeal artery

Available with the *Gray's Anatomy* e-book

Meningeal veins

Meningeal veins begin from plexiform vessels in the dura mater. They drain into efferent vessels in the outer dural layer that connect with lacunae associated with some of the cranial sinuses. They include the middle meningeal and the diploic veins. Intracranial veins also communicate with extracranial vessels via emissary veins.

Middle meningeal vein (sinus)

The frontal (anterior) branch of the middle meningeal vein crosses the floor of the middle cranial fossa, from either the foramen ovale or foramen spinosum, to the pterion, usually in the form of two parallel channels that accompany the middle meningeal artery. The vein subsequently passes cranially along the anterior margin of the parietal squama to empty into the venous lakes of the superior sagittal sinus. As they course under the most lateral aspect of the lesser sphenoidal wing, the anterior branches of the middle meningeal vessels are contained for a short distance within a bony canal, the sphenoparietal canal (of Trolard), which they leave to enter a groove on the internal surface of the parietal squama. The veins lie closer to the bone than the artery, sometimes occupying separate grooves, and are particularly liable to tear in cranial fractures. Before it enters the sphenoparietal canal, the anterior branch of the middle meningeal vein usually connects with the sinus of the lesser sphenoidal wing, which is connected medially with the anterior and superior aspect of the cavernous sinus by a channel that crosses over the superior ophthalmic vein to reach the sinus. The parietal (posterior) trunk of the middle meningeal vein may traverse the foramen spinosum to end in the pterygoid venous plexus. The frontal trunk may also reach this

The following emissary veins have been recognized. A mastoid emissary vein in the mastoid foramen connects the sigmoid sinus with the posterior auricular or occipital veins. A parietal emissary vein in the parietal foramen connects the superior sagittal sinus with the veins of the scalp. The venous plexus of the hypoglossal canal (occasionally a single vein) connects the sigmoid sinus and the internal jugular vein. A supracondylar emissary vein connects the sigmoid sinus and veins in the suboccipital triangle via the posterior condylar canal. A plexus of emissary veins (venous plexus of the foramen ovale) connects the cavernous sinus to the pterygoid plexus via the foramen ovale. Two or three small veins traverse the foramen lacerum and connect the cavernous sinus and the pharyngeal veins and pterygoid plexus. A vein in the emissary sphenoidal foramen (of Vesalius) connects the cavernous sinus with the pharyngeal veins and pterygoid plexus. The internal carotid venous plexus, which passes through the carotid canal, connects the cavernous sinus and the internal jugular vein. A vein may traverse the foramen caecum and connect nasal veins with the superior sagittal sinus. An occipital emissary vein usually connects the confluence of the sinuses with the occipital vein through the occipital protuberance, and also receives the occipital diploic vein. The occipital sinus connects with variably developed veins around the foramen magnum (marginal sinuses) and thus with the vertebral venous plexuses; this pathway provides an alternative venous drainage when the jugular vein is blocked or tied. The ophthalmic veins are potentially emissary because they connect intracranial and extracranial veins. The petrosquamous sinus arises from the dorsolateral portion of the transverse sinus before its confluence with the superior petrosal sinus, courses over the lateral superior surface of the petrous part of the temporal bone, and drains anteroinferiorly into the retromandibular vein and anteromedially into the pterygoid venous plexus. It usually disappears during the development of adult venous patterns in the last three months of prenatal life.

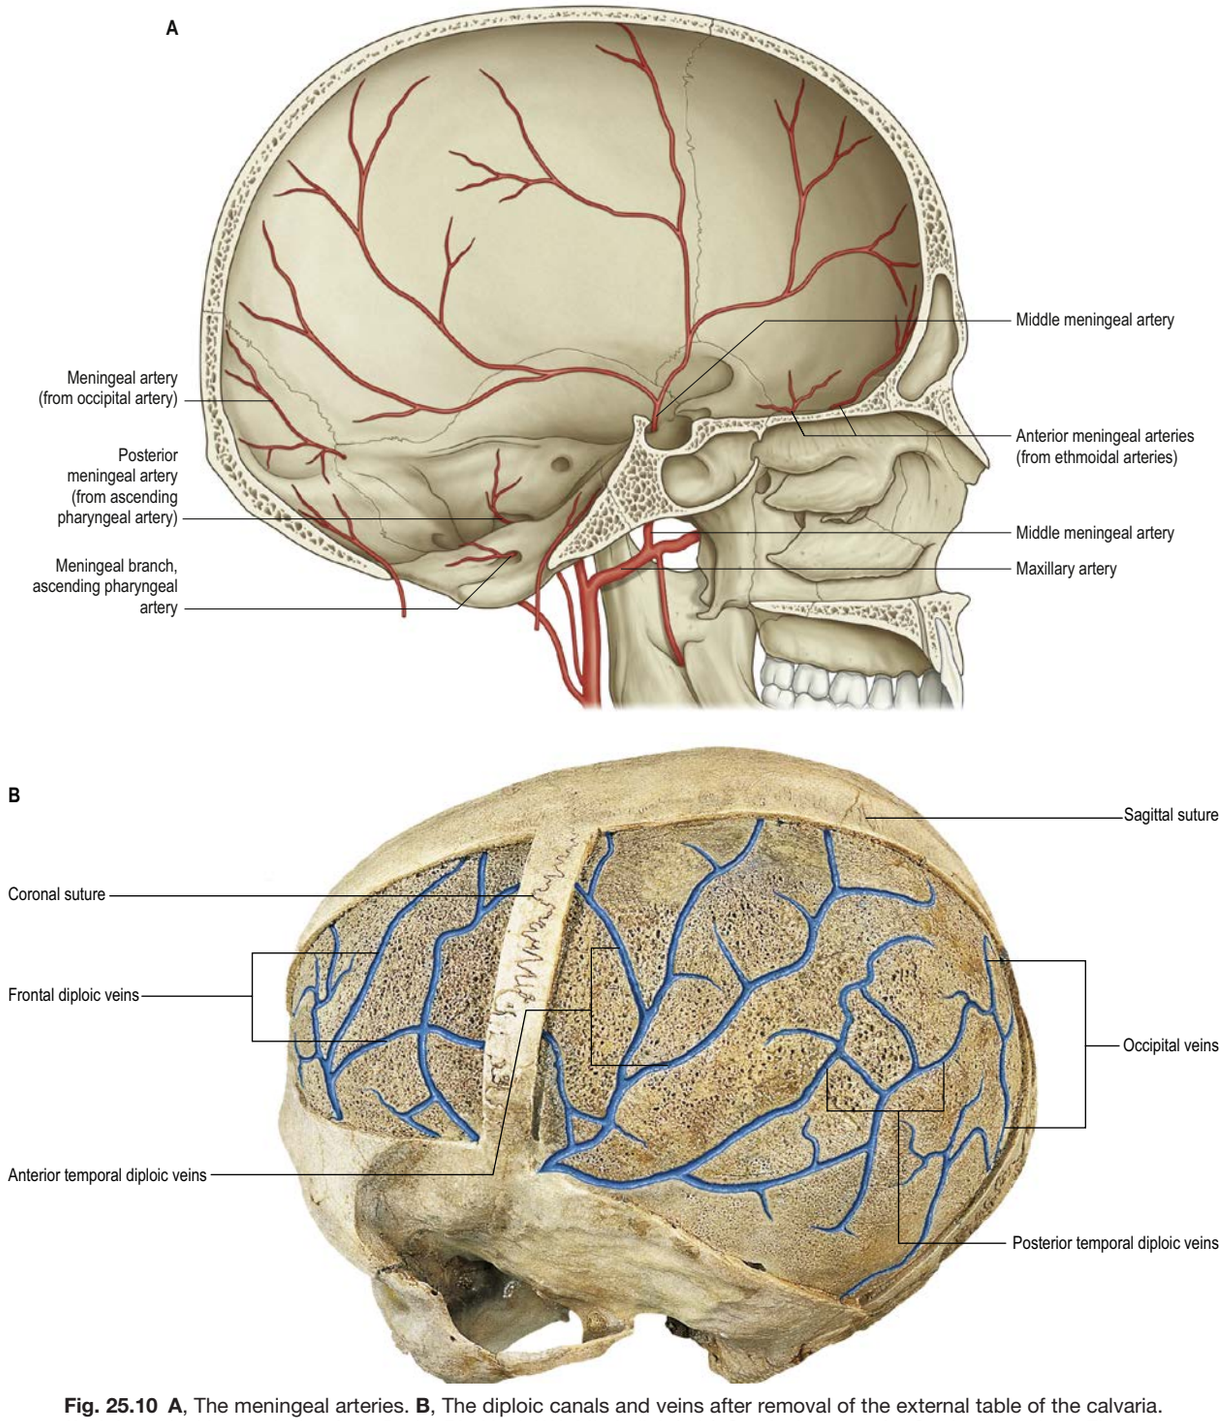

Fig. 25.10 **A**, The meningeal arteries. **B**, The diploic canals and veins after removal of the external table of the calvaria. plexus via the foramen ovale, or it may end in the sphenoparietal or cavernous sinus (see Fig. 25.4). The middle meningeal vein receives meningeal tributaries and small inferior cerebral veins, and connects with the diploic and superficial middle cerebral veins. It frequently bears arachnoid granulations.

Diploic veins

The diploic veins are large, thin-walled vessels that occupy channels in the diploë of the cranial bones (Fig. 25.10B). Four main trunks are usually described: the frontal, anterior and posterior temporal, and occipital diploic veins. The frontal vein opens into the supraorbital vein and the superior sagittal sinus; the anterior temporal vein is confined mainly to the frontal bone, and opens into the sphenoparietal sinus and one of the deep temporal veins through an aperture in the greater wing of the sphenoid; the posterior temporal vein lies in the parietal bone and empties into the transverse sinus either through an opening at the mastoid angle of the parietal bone or through the mastoid foramen; the occipital vein, the largest of the four, is confined to the occipital bone and may open externally into the occipital vein or internally into either the transverse sinus or the confluence of the sinuses.

Sinus pericranii

ARACHNOID AND PIA MATER

The arachnoid mater and the pia mater together are sometimes referred to as the leptomeninges. They are separated by the subarachnoid space and joined by trabeculae. The outer layer of the arachnoid, the dura–arachnoid interface, is formed from five or six layers of cells joined by numerous desmosomes and tight junctions and forms a barrier that normally prevents permeation of CSF through the arachnoid into the

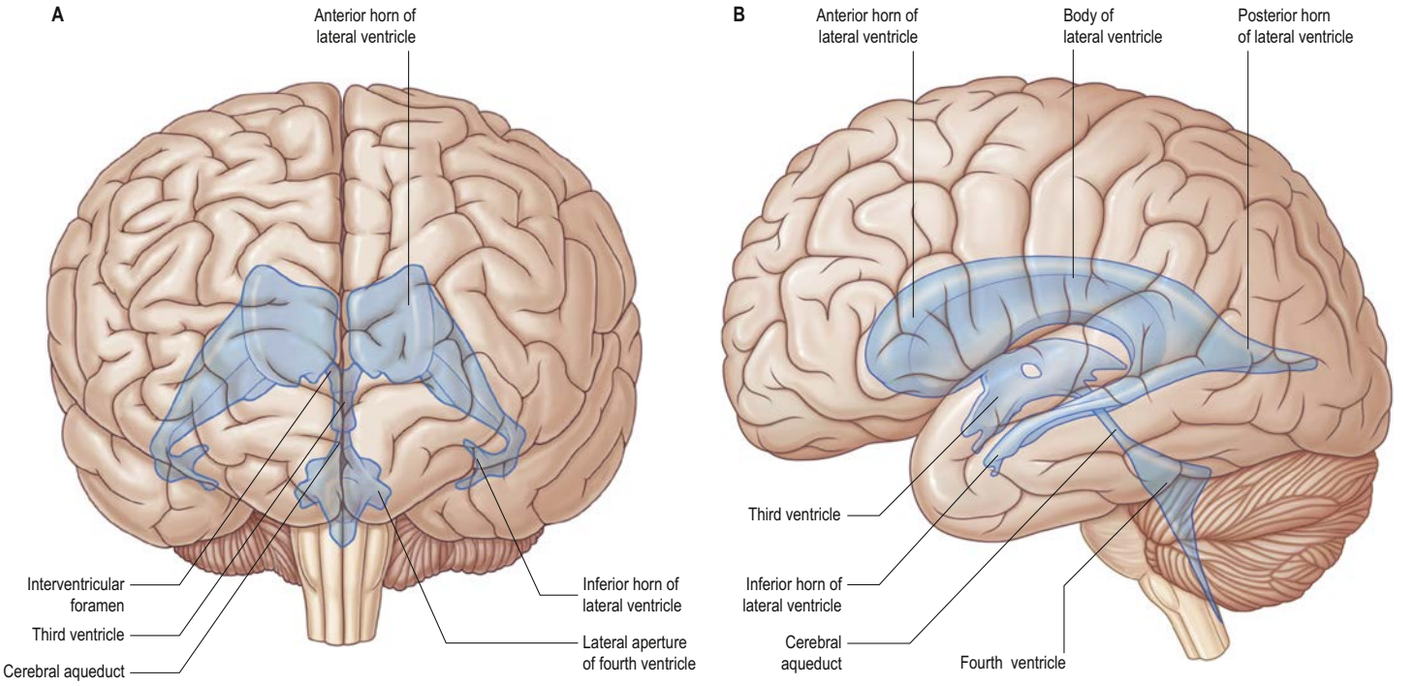

Fig. 25.11 The ventricular system. **A**, Anterior view. **B**, Left lateral view.

subdural space. The central portion of the arachnoid is closely apposed to the outer layer, and is formed from tightly packed polygonal cells joined by desmosomes and gap junctions. The cells are more loosely packed in the inner layer of the arachnoid, where they intermingle with bundles of collagen continuous with the trabeculae that cross the subarachnoid space. The leptomeningeal cells are not surrounded by basement membrane, except where they are in contact with collagen in the inner layers of the arachnoid and on the deep aspects of the pia mater.

The anatomical relationships of the arachnoid and pia differ to some extent in the cerebral and spinal regions. The cerebral part of the arachnoid mater invests the brain loosely: it does not enter the sulci or fissures, other than the interhemispheric and Sylvian fissures, and it coats the superior surface of the pituitary fossa. The arachnoid is easily separated from the dura over the surface of the brain, but it is adherent to the adventitia of the internal carotid and the vertebral arteries where they enter the subarachnoid space. It is reflected onto the surface of blood vessels and cranial nerves in the subarachnoid space: this is the basis for microsurgical subarachnoid dissection to expose brain vessels and cranial nerves. The subarachnoid cisterns are cavities formed by the wide separation of the pia and arachnoid, which is particularly common on the basal aspect of the brain, where the basal cisterns are located. Knowledge of the neural and vascular contents of each of the basal cisterns is of particular value to the neurosurgeon in the planning and execution of intracranial procedures (Yasargil 1984).

Subdural haematoma

Separation of the arachnoid and dura mater requires little physical force, which means that damage to small bridging veins in the space can result in a subdural haematoma after even relatively mild head trauma. In cases of chronic or subacute subdural haematomas, the accumulation is of relatively low pressure and seldom presents as a medical emergency; even sizeable accumulations may be tolerated on a chronic basis with mild or no symptoms, and can be surgically drained through small openings in the skull (burr-holes). In many cases, there is some predisposing factor, such as cerebral atrophy or an increase in the size of the underlying subarachnoid space. In cases of acute subdural haematoma, typically after severe head trauma, there is rapid accumulation of blood in the subdural space which requires emergency neurosurgical drainage through a large craniotomy or craniectomy. The distinction between subdural and extradural haematoma on a CT scan relies on the anatomical features of the clot. Extradural collections tend to be lentiform in shape, reflecting the pressure required to separate the dura and periosteum: they will not pass deep to any major dural sinus and cannot extend along the falx cerebri or tentorium cerebelli. In contrast, acute subdural haematomas tend to be biconcave in shape and often follow the line of the dura along the falx or tentorium (see Fig. 25.1).

TOPOGRAPHY AND RELATIONSHIPS OF THE VENTRICULAR SYSTEM

The cerebral ventricular system consists of a series of interconnecting spaces and channels within the brain (**Figs 25.11–25.12**), which are derived from the central lumen of the embryonic neural tube and the cerebral vesicles to which it gives rise (Ch. 14). Each cerebral hemisphere contains a large lateral ventricle that communicates near its rostral end with the third ventricle via the interventricular foramen (foramen of Monro). The third ventricle is a midline, slit-like cavity lying between the right and left thalamus and hypothalamus. Caudally, the third ventricle is continuous with the cerebral aqueduct. This narrow tube passes through the midbrain and is continuous with the fourth ventricle, a wide cavity lying between the brainstem and cerebellum. The fourth ventricle communicates with the subarachnoid space of the cisterna magna through the foramen of Magendie, and with the cerebellopontine angles through the foramina of Luschka; caudally it is continuous with the vestigial central canal of the spinal cord.

The ventricular system contains cerebrospinal fluid (CSF), which is mostly secreted by the choroid plexuses located within the lateral, third and fourth ventricles.

Lateral ventricle

Viewed from its lateral aspect, the lateral ventricle has a roughly C-shaped profile (see Figs 25.11–25.12; **Fig. 25.13**). The shape is a consequence of the developmental expansion of the frontal, parietal and occipital regions of the cerebral hemisphere that displaces the temporal lobe inferiorly and anteriorly. Both the caudate nucleus and the fornix, which lie in the wall of the ventricle, have adopted a similar morphology, so that the tail of the caudate nucleus encircles the thalamus in a C shape, and the fornix traces the outline of the ventricle forwards to the interventricular foramen.

The lateral ventricle is divided into five parts: the frontal (anterior), occipital (posterior) and temporal (inferior) horns, the body and the atrium (Rhoton 2002).

The frontal horn lies within the frontal lobe. The posterior aspect of the genu and the rostrum of the corpus callosum bound it anteriorly, forming the floor and anterior wall. Its roof is formed by the anterior part of the body of the corpus callosum. The frontal horns of the two ventricles are separated by the septum pellucidum. The coronal profile of the frontal horn is roughly that of a flattened triangle in which the rounded head of the caudate nucleus forms the lateral wall (**Figs 25.14–25.15**). The frontal horn extends posteriorly as far as the interventricular foramen.

Cavum septum pellucidum (CSP) describes a septum pellucidum that has a separation between its two leaflets (septal laminae). The

The accessory meningeal artery may arise from the maxillary artery or the middle meningeal artery. It enters the cranial cavity through the foramen ovale and supplies the trigeminal ganglion, dura mater and bone. Its main distribution is extracranial, principally to medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, the greater wing and pterygoid processes of the sphenoid bone, the mandibular nerve and the otic ganglion. It is sometimes replaced by separate small arteries.

Sinus pericranii is a rare condition involving congenital or acquired anomalous connections between an extracranial blood-filled nodule and an intracranial dural venous sinus via dilated diploic and/or emissary veins of the skull (Sheu et al 2002).

Fig. 25.12 The ventricular system. Copyright 2013.)

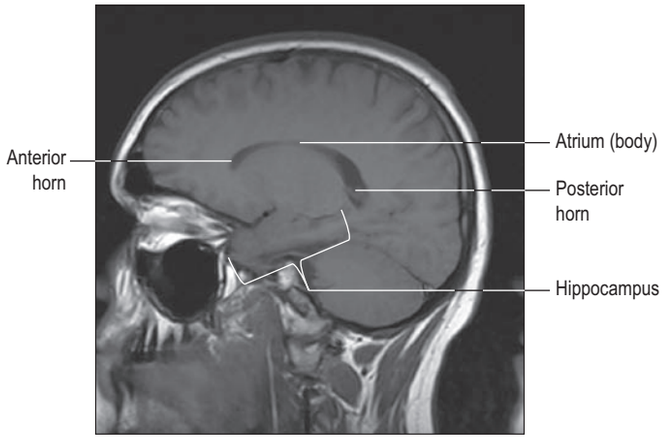

Fig. 25.13 A sagittal T1-weighted MRI, showing the C-shaped profile of the lateral ventricle.

cavity contains cerebrospinal fluid that filters from the ventricles through the septal laminae. The most common type of cavum septum pellucidum is non-communicating, i.e. it is not connected to the ventricular system. Cavum septum pellucidum is present in 100% of fetuses below 36 postmenstrual weeks. Its prevalence gradually decreases with age, being present in approximately 2% of the adult population (Farruggia and Babcock 1981, Nakano et al 1981, Mott et al 1992).

The body of the lateral ventricle lies within the frontal and parietal lobes and extends from the interventricular foramen to the splenium of the corpus callosum, where the septum pellucidum disappears and the corpus callosum and fornix meet. The bodies of the lateral ventricles are separated by the septum pellucidum, which contains the columns of the fornices in its lower edge. The lateral wall of the body of the ventricle is formed by the caudate nucleus superiorly and the thalamus inferiorly. The boundary between the thalamus and caudate nucleus is marked by the thalamostriate sulcus, a groove that is occupied by a fascicle of nerve fibres, the stria terminalis, and by the thalamostriate vein (**Fig. 25.16**; see Fig. 25.14). The inferior limit of the body of the ventricle and its medial wall are formed by the body of the fornix (**Fig. 25.17**; see Fig. 25.14). The fornix is separated from the thalamus by a narrow cleft, the choroidal fissure, along which the choroid plexus in the lateral ventricle is attached. The choroidal fissure extends in a C-shaped arc that starts from the interventricular foramen, runs along the superior, posterior and inferior aspects of the thalamus, and ends at the inferior choroidal point, located in the temporal horn just behind the head of the hippocampus. On either side, the tela choroidea, the membrane in which the choroid plexus arises, is attached to the taeniae (the edges of the thalamus and fornix bordering the choroidal fissure) (Nagata et al 1988).

The body of the lateral ventricle widens posteriorly to become continuous with the occipital and temporal horns at the atrium (collateral trigone). The roof of the atrium is formed by the posterior body and splenium of the corpus callosum. The medial wall is formed by two prominences: an upper prominence, the bulb of the corpus callosum, formed by fibres of the corpus callosum as they sweep posteriorly into the occipital lobe (forceps major); and an inferior prominence, the calcar avis, which overlies the calcarine fissure. The lateral wall is formed by the caudate nucleus as it wraps around the pulvinar of the thalamus and more posteriorly by fibres of the tapetum of the corpus callosum. The anterior wall has a medial part formed by the crus of the fornix, and a lateral part formed by the pulvinar of the thalamus. The floor is formed by the collateral trigone, a bulge that overlies the collateral sulcus. Posteriorly, the atrium is continuous with the occipital horn.

The occipital horn curves posteromedially into the occipital lobe. It is usually diamond-shaped in outline and it varies in size: it can

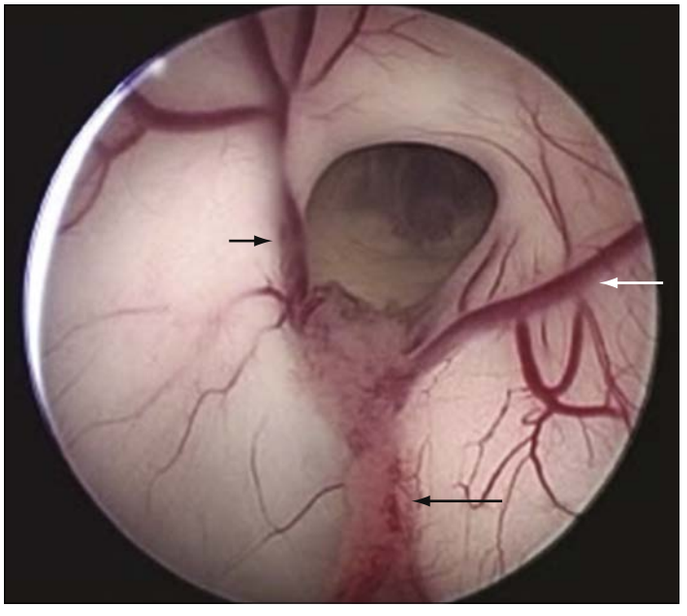

Fig. 25.16 Endoscopic view into the right lateral ventricle. The thalamostriate vein (white arrow) runs along the lateral wall and converges with the anterior septal vein (short black arrow) before converging and entering the foramen of Monro as the internal cerebral vein. The superior choroidal vein (long black arrow) is also seen coursing through the choroid plexus. (With permission from Winn HR (ed) Youmans Neurological Surgery, 6th ed. Elsevier, Saunders. Copyright 2011.)

be almost entirely absent or extend far into the occipital lobe. The two sides are often asymmetric. Fibres of the tapetum of the corpus callosum separate the ventricle from the optic radiation and the inferior fronto-occipital fasciculus, and form the roof and lateral wall of the occipital horn. The medial wall of the occipital horn is formed by fibres of the forceps major superiorly and the calacar avis inferiorly.

The temporal horn extends forwards from the atrium into the temporal lobe. It curves round the posterior aspect of the thalamus (pulvinar), passes downwards and posterolaterally and then curves anteriorly to end behind the amygdala, usually within 2.5 cm of the temporal pole, near the uncus. The roof of the temporal horn is formed by the tapetum of the corpus callosum laterally and by the tail of the caudate nucleus medially (Fig. 25.18). The latter is separated from the inferior surface of the thalamus by the striothalamic sulcus and the stria terminalis, which extend forwards in the roof to terminate in the amygdala at the anterior end of the ventricle. The floor of the temporal horn consists of the hippocampus medially and the collateral eminence, formed by the infolding of the collateral sulcus, laterally. The inferior part of the choroidal fissure, located between the fimbria of the fornix and the inferolateral aspect of the thalamus, lies in the medial wall. The temporal extension of the choroid plexus fills the choroidal fissure, covers the outer surface of the hippocampus and ends at the inferior choroidal point as previously described.

The position of the lateral ventricle relative to the surface of the hemisphere is important in understanding the topographical anatomy of the ventricles (see Fig. 25.11). The frontal horn usually corresponds to the inferior frontal gyrus; the body and atrium project along the precentral and postcentral gyri and inferior parietal lobule; the occipital horn corresponds to the occipital convexity; the temporal horn projects along the superior temporal sulcus.

Third ventricle

The third ventricle is a midline, slit-like cavity derived from the primitive forebrain vesicle (**Figs 25.19–25.20**; see Figs 25.11, 25.17) (Rhoton 2002). The lateral wall of the third ventricle is formed in its upper part by the medial surface of the anterior two-thirds of the thalamus, and in its lower part by the hypothalamus. A faint hypothalamic sulcus extends horizontally on the ventricular wall between the interventricular foramen and the cerebral aqueduct, marking the boundary between the thalamus and hypothalamus. Dorsally, the lateral wall is limited by a ridge covering the stria medullaris thalami. The lateral walls of the third ventricle are commonly joined by an interthalamic adhesion (massa intermedia), a band of grey matter that extends between the two thalami. An interthalamic adhesion is almost always found in humans, more often in females (Orly and Haines 2005). The anterior wall of the third ventricle is formed mainly by the lamina terminalis (see Fig. 25.20). This thin structure stretches from the optic chiasma inferiorly to the rostrum of the corpus callosum superiorly and represents the rostral boundary of the embryonic neural tube. The lamina terminalis forms the roof of a small virtual cavity, the cistern of the lamina terminalis, which lies immediately below the ventricle and is an extension of the interpeduncular cistern. This is clinically important because it contains the anterior communicating artery; aneurysm development and rupture at this site may cause intraventricular haemorrhage through the thin membrane of the lamina terminalis. Superior to the lamina terminalis, the anterior wall of the third ventricle is formed by the diverging columns of the fornices and by the transversely orientated anterior commissure, which crosses the midline. The narrow interventricular foramen is located immediately posterior to the column of the fornix and separates the fornix from the anterior nucleus of the thalamus. A small, angular, optic recess occurs inconsistently at the base of the lamina terminalis just dorsal to, and extending into, the optic chiasma.

In its anterior part, the floor of the third ventricle is formed mainly by hypothalamic structures (**Fig. 25.21**). The thin infundibular recess lies immediately posterior to the optic chiasma and extends into the pituitary stalk. Behind this recess, the tuber cinereum and the mammillary bodies complete the floor of the ventricle posteriorly.

The roof of the third ventricle consists of four layers. The most superior layer is formed by the two fornices (bodies anteriorly and crura posteriorly). The tela choroidea, giving rise to the choroid plexus, form two of the three layers located below the fornices. The choroid plexus extends from the floor of the lateral ventricle through the interventricular foramen into the roof of the third ventricle. The final layer in the roof lies between the two layers of tela choroidea and contains the internal cerebral veins and the medal posterior choroidal arteries (see Fig. 25.17).

The posterior wall of the ventricle is marked by a suprapineal recess, the habenular commissure, a pineal (epiphysial) recess that extends into the pineal stalk, and by the posterior commissure. The ventricle is continuous with the cerebral aqueduct of the midbrain inferior to the posterior commissure (see Fig. 25.20).

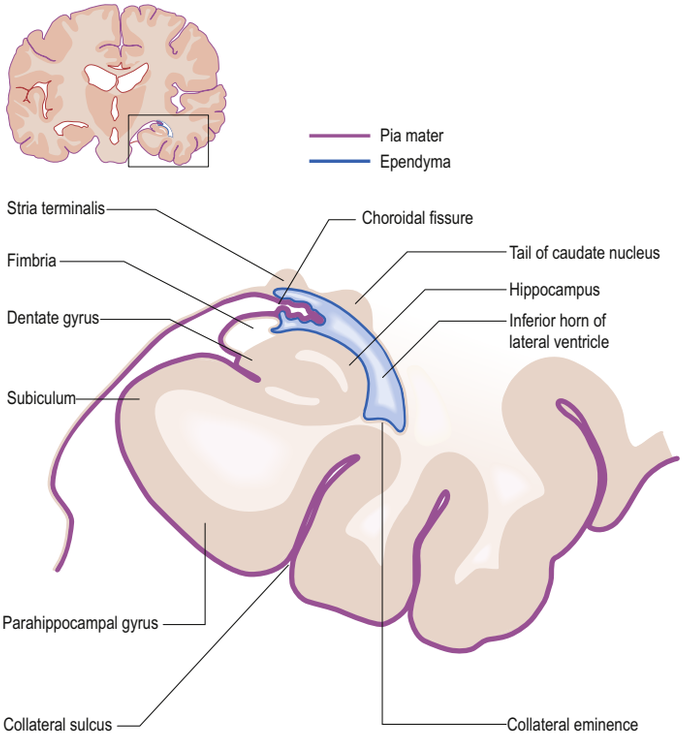

Fig. 25.18 The temporal (inferior) horn of the left lateral ventricle, coronal section.

Cerebral aqueduct

The cerebral aqueduct is a small tube, roughly circular in transverse section and 1–2 mm in diameter. It is commonly described as having a pars anterior, an antrum and a pars posterior, and extends throughout the dorsal quarter of the midbrain in the midline, surrounded by the periaqueductal (central) grey matter (see Fig. 25.20). Rostrally, it commences immediately inferior to the posterior commissure, where it is continuous with the caudal aspect of the third ventricle. Caudally, it is continuous with the lumen of the fourth ventricle at the junction of the midbrain and pons. The superior and inferior colliculi are dorsal to the aqueduct and the midbrain tegmentum is ventral. Primary aqueductal stenosis is a cause of congenital hydrocephalus in newborns.

Fourth ventricle

The fourth ventricle lies between the brainstem and the cerebellum (**Fig. 25.22**; see Figs 25.11, 25.19–25.20, 28.5) (Rhoton 2000). Rostrally, it is continuous with the cerebral aqueduct, and caudally it is continuous with the central canal of the spinal cord. In sagittal section, the fourth ventricle has a characteristic triangular profile; the apex of its tented roof protrudes into the inferior aspect of the cerebellum. The ventricle is at its widest at the level of the pontomedullary junction, where a lateral recess on both sides extends to the lateral border of the brainstem. At this point the lateral apertures of the fourth ventricle (foramina of

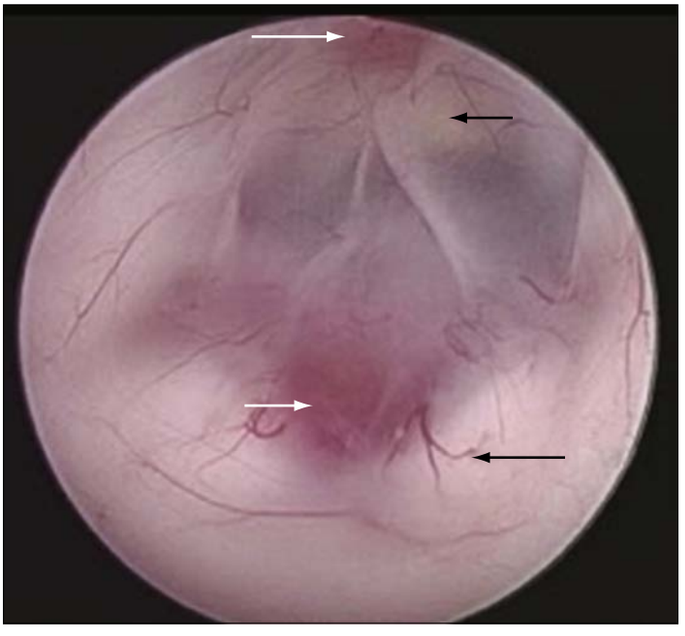

Fig. 25.21 An endoscopic view of the floor of the third ventricle. The ideal spot for fenestration is in the midline, midway between the dorsum sellae (short black arrow) and the basilar artery (short white arrow). The paired mammillary bodies (long black arrow) and the infundibular recess (long white arrow) are also seen. (With permission from Winn HR Youmans Neurological Surgery, 6th ed. Elsevier, Saunders. Copyright 2011.)

Luschka) open into the subarachnoid space at the cerebellopontine angle, behind the upper roots of the glossopharyngeal nerves.

The floor of the fourth ventricle is a shallow diamond-shaped, or rhomboidal, depression (rhomboid fossa) on the dorsal surfaces of the pons and the rostral half of the medulla (see Fig. 25.12). It consists largely of grey matter and contains important cranial nerve nuclei (V–XII). The precise location of some nuclei is discernible from surface features. The floor of the ventricle can be divided into a superior and inferior part: both parts are triangular in shape and are separated by the striae medullares, which have a horizontal course across the floor of the ventricle. The superior triangle is limited laterally by the superior cerebellar peduncles as they converge towards the cerebral aqueduct; its apex is directed superiorly, towards the aqueduct. The inferior triangle is bounded caudally by the gracile and cuneate tubercles, which contain the dorsal column nuclei, and, more rostrally, by the diverging inferior cerebellar peduncles. The apex of the inferior triangle is known as the obex. A longitudinal median sulcus divides the floor of the fourth ventricle into two halves. Each half is itself divided, by an often indistinct sulcus limitans, into a medial region, the medial eminence, and a lateral region, the vestibular area. The vestibular nuclei lie beneath the vestibular area. In the superior part, the medial eminence is represented by the facial colliculus, a small elevation produced by an underlying loop of efferent fibres from the facial nucleus that covers the abducens nucleus. Between the facial colliculus and the vestibular area the sulcus limitans widens into a small depression, the superior fovea. In its upper part, the sulcus limitans constitutes the lateral limit of the floor of the fourth ventricle. Here, a small region of bluish-grey pigmentation denotes the presence of the subjacent locus coeruleus. Caudal to the facial colliculus, at the level of the lateral recess of the ventricle, a variable group of nerve fibre fascicles, the striae medullares, runs transversely across the ventricular floor and passes into the median sulcus. In the inferior part, the medial eminence is represented by the hypoglossal triangle (trigone), which lies over the hypoglossal nucleus. Laterally, the sulcus limitans widens to produce an indistinct inferior fovea. Caudal to the inferior fovea, between the hypoglossal triangle and the vestibular area, the vagal triangle (trigone) covers the dorsal motor nucleus of the vagus. A narrow translucent ridge, the funiculus separans, separated from the gracile tubercle by the small area postrema, crosses below the vagal triangle.

The roof of the fourth ventricle is formed by the superior and inferior medullary veli. The thin superior medullary velum stretches across the ventricle between the converging superior cerebellar peduncles (see Fig. 25.22) and is continuous with the cerebellar white matter. Dorsally, it is covered by the lingula of the superior vermis. The inferior medullary velum is more complex and is mostly composed of a thin sheet, devoid of neural tissue, formed by ventricular ependyma and the pia mater of the tela choroidea. Just inferior to the nodule of the cerebellum, a median aperture, the foramen of Magendie, opens the roof of the fourth ventricle into the cisterna magna. The aperture forms when a membranous structure (Blake's pouch) perforates into the fourth ventricle during early development; persistence of this membrane results in cystic obstruction of the median outlet from the fourth ventricle (Paladini et al 2012).

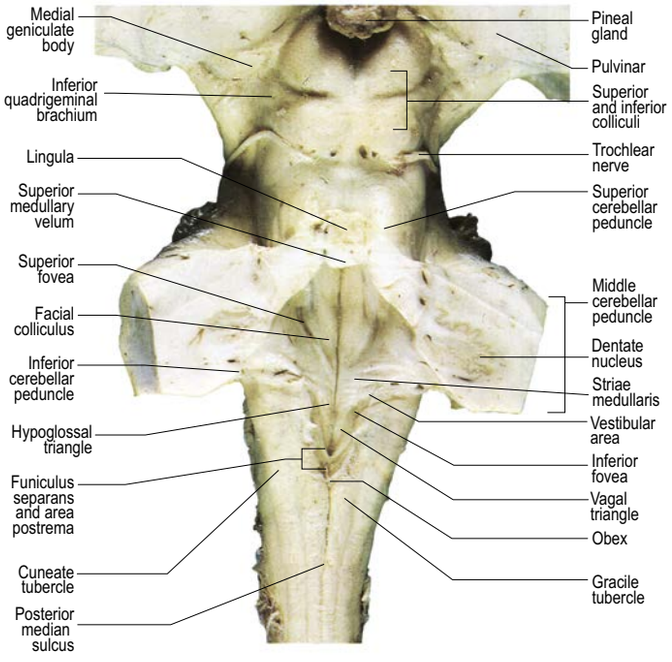

Fig. 25.22 The floor of the fourth ventricle, dorsal aspect of the brainstem.

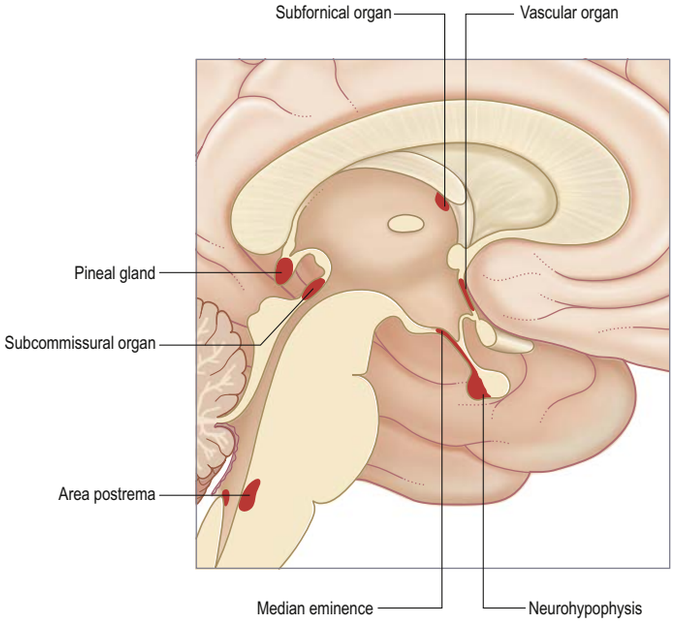

Fig. 25.23 Locations of the circumventricular organs, median sagittal section of the brain.

Circumventricular organs

The walls of the ventricular system are lined with ependymal cells that cover a subependymal layer of glia. At certain midline sites in the ventricular walls, collectively referred to as circumventricular organs, the blood–brain barrier is absent and specialized ependymal cells, tanycytes, are present (Horsburgh and Massoud 2013). The functions of ependyma and tanycytes may include secretion into the CSF; transport of neurochemicals from subjacent neurones, glia or vessels to the CSF; transport of neurochemicals from the CSF to the same subjacent structures; and chemoreception (Rodríguez et al 2005). Adult mammalian neurogenesis occurs in discrete neurogenic sites that are best characterized in the ependymal and subependymal glial cell layers in the subgranular zone of the dentate gyrus and in the subventricular zone (Sanai et al 2004).

The circumventricular organs include the vascular organ (organum vasculosum), subfornical organ, neurohypophysis, median eminence, subcommissural organ, pineal gland and area postrema (**Fig. 25.23**). The vascular organ lies in the lamina terminalis between the optic chiasma and the anterior commissure. Its external zone contains a richly fenestrated vascular plexus that covers glia and a network of nerve fibres. Its major inputs appear to come from the subfornical organ, locus coeruleus and a number of hypothalamic nuclei, and it projects to the median preoptic and supraoptic nuclei. The vascular organ is involved in the regulation of fluid balance and may also have neuroendocrine functions. The subfornical organ lies at the level of the interventricular foramen. It contains many neurones, glial cells and a dense fenestrated capillary plexus, and is covered by flattened ependyma. It is believed to have widespread hypothalamic interconnections and to function in the regulation of fluid balance and thirst.

The neurohypophysis (posterior pituitary) is the site of termination of neurosecretory projections from the supraoptic and paraventricular nuclei of the hypothalamus. Neurones in these nuclei release vasopressin and oxytocin respectively into the capillary bed of the neurohypophysis, where the hormones gain access to the general circulation.

The median eminence contains the terminations of axons of hypothalamic neurosecretory cells. Peptides released from these axons control the hormonal secretions of the anterior pituitary via the pituitary portal system of vessels.

The subcommissural organ lies ventral to and below the posterior commissure, near the inferior wall of the pineal recess. The pineal gland is a small structure, approximately 8 mm in diameter, situated rostrodorsal to the superior colliculus and behind the stria medullaris. It is part of the epithalamus and produces melatonin, a serotonin-derived hormone implicated in the regulation of sleep–wake patterns in both circadian and seasonal cycles.

The area postrema is a bilaterally-paired structure, located at the caudal limit of the floor of the fourth ventricle. It is an important chemoreceptive area that triggers vomiting in response to the presence of emetic substances in the blood. The area postrema, the nucleus of the solitary tract and the dorsal motor nucleus of the vagus, collectively constitute the dorsal vagal complex, the major termination site of vagal afferent nerve fibres.

CHOROID PLEXUS AND CEREBROSPINAL FLUID

Choroid plexus

The vascular pia mater in the roofs of the third and fourth ventricles and in the medial wall of the lateral ventricle along the line of the choroid fissure, is closely apposed to the ependymal lining of the ventricles. It forms the tela choroidea, which gives rise to the highly vascularized choroid plexuses from which CSF is secreted into the lateral, third and fourth ventricles (see Figs 25.14, 25.17–25.18). The body or stroma of the choroid plexus consists of many capillaries, separated from the ventricles by the pia mater and choroid ependymal cells (Strazielle et al 2000).

In the lateral ventricle, the choroid plexus extends anteriorly as far as the interventricular foramen, through which it is continuous, across the third ventricle, with the plexus of the contralateral lateral ventricle. From the interventricular foramen, the plexus passes posteriorly, in contact with the thalamus, curving round its posterior aspect to enter the temporal horn of the lateral ventricle and reaching the hippocampus at the level of the inferior choroidal point (see above: topographical anatomy of the lateral ventricle). Throughout the body of the ventricle, the choroid fissure lies between the fornix superiorly and the thalamus inferiorly (see Fig. 25.17).

In the lateral ventricle, the tela choroidea, has a triangular shape when seen from above. Its apex lies between the interventricular foramina, often indented by the anterior columns of the fornices. Its lateral edges are delimited by the fornix (taeniae fornicis) and the thalamus is attached to the taeniae on either side (taeniae thalami).

The choroid plexus of the third ventricle is attached to the tela choroidea which contributes to the thin roof of the third ventricle as it develops during fetal life. In coronal sections of the cerebral hemispheres, the choroid plexus of the third and lateral ventricles are seen to be continuous.

The choroid plexus of the fourth ventricle is similar in structure to that of the lateral and third ventricles. The roof of the inferior part of the fourth ventricle develops as a thin sheet in which the pia mater is in direct contact with the ependymal lining of the ventricle. This thin sheet, the tela choroidea of the fourth ventricle, lies between the cerebellum and the inferior part of the roof of the ventricle. The choroid plexus of the fourth ventricle is T-shaped, i.e. it has vertical and horizontal limbs; the precise form varies widely from a single vertical limb to an elongated 'T' that extends out through the foramina of Luschka into the cerebellopontine angle. The vertical (longitudinal) limb is double, flanks the midline and is adherent to the roof of the ventricle. The limbs fuse at the superior margin of the median aperture (foramen of Magendie) and are often prolonged onto the ventral aspect of the cerebellar vermis. The horizontal limbs of the plexus project into the lateral recesses of the ventricle. Small tufts of plexus may pass through the lateral apertures (foramina of Luschka) and emerge, still covered by ependyma, in the subarachnoid space of the cerebellopontine angle. The mean thickness of the choroid plexus in the fourth ventricle in children is 2.5 mm (Madhukar et al 2012).

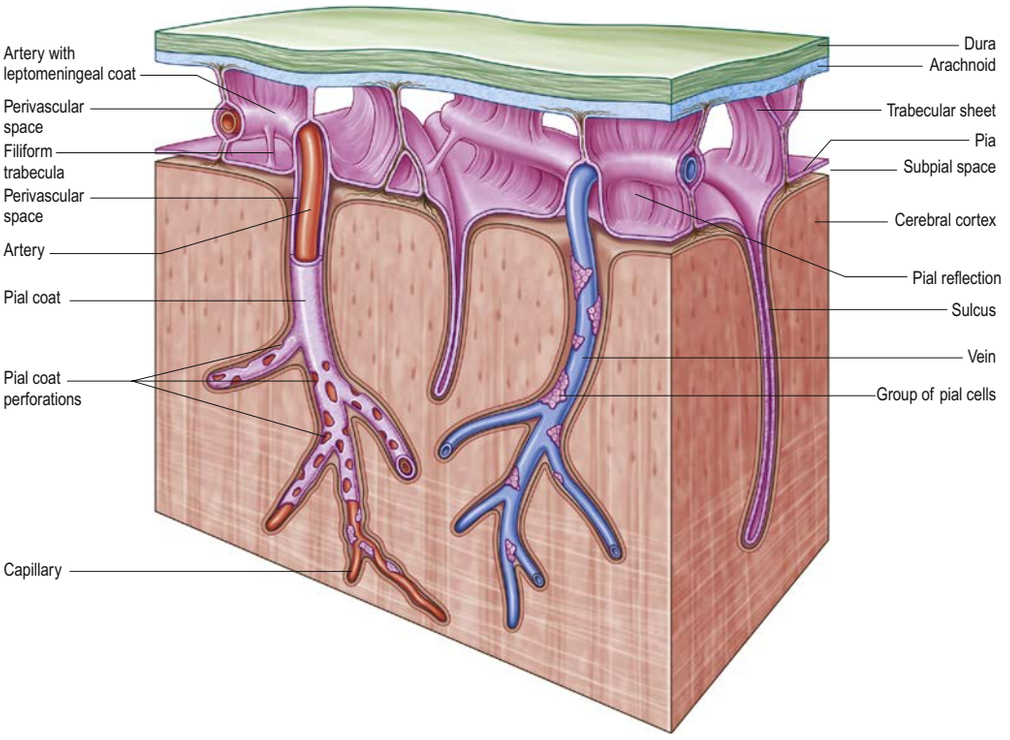

Fig. 25.24 Relationships between the dura mater, the leptomeninges and the blood vessels that enter and leave the cerebral cortex. The subarachnoid space is divided by trabeculae.

The blood supply of the choroid plexus in the tela choroidea of the lateral and third ventricles is usually via a single vessel from the anterior choroidal branch of the internal carotid artery and several choroidal branches of the posterior cerebral artery; the two sets of vessels anastomose to some extent. Capillaries drain into a rich venous plexus served by a single choroidal vein. The blood supply of the choroid plexus of the fourth ventricle is from the inferior cerebellar arteries.

Physiological calcification of the choroid plexus and pineal gland are the most frequently described intracranial calcifications incidentally discovered during head computed tomography (CT) examinations (Doyle and Anderson 2006).

Cerebrospinal fluid

The cerebrospinal fluid (CSF) is a clear, colourless liquid. Normal CSF contains small amounts of protein and differs from blood in its electrolyte content. Different pathologies can be diagnosed by looking at alterations in the composition of the CSF (Deisenhammer et al 2006). CSF is not simply an ultrafiltrate of blood but is actively secreted by the choroid plexuses in the lateral, third and fourth ventricles.

The choroid plexus epithelium constitutes a blood–CSF barrier. Choroid plexus epithelial cells have the characteristics of transport and secretory cells (see Figs 3.19, 3.20); their apical surfaces have microvilli, and their basal surfaces exhibit interdigitations and folding. Tight junctions (occluding junctions, zonulae adherentes) at the apical ends of the cells are permeable to small molecules. Fenestrated capillaries lie just beneath the epithelial cells in the stroma of the choroid plexus. The ependymal lining of the ventricles and the extracellular fluid from the brain parenchyma are additional sources of CSF, but how much each source contributes to CSF production is unclear.

The total volume of CSF in the adult is approximately 150 ml; the volume of the ventricles is about 25 ml. CSF is produced at a rate of 0.3–0.4 ml per minute (20 ml/hour, approximately 500 ml per day), which means that the entire CSF volume is replaced 3–4 times per day.

CSF production in children, as measured by output through external ventricular drainage, increases during infancy, reaching 64% of the output of a 15-year-old child by 2 years of age. There is a logarithmic increase in CSF output with age and body weight (Yasuda et al 2002). Mixing of CSF from different sources within the subarachnoid space is probably assisted by ciliary motion on the ependymal cells lining the ventricles and by arterial pulsations.

Subarachnoid space

The subarachnoid space lies between the arachnoid and the pia mater. It is continuous with the lumen of the fourth ventricle via the median aperture (foramen of Magendie) and the paired lateral apertures (foramina of Luschka). The subarachnoid space contains CSF, the larger arteries and veins that traverse the surface of the brain, and the intracranial or intravertebral portions, respectively of the cranial and spinal nerves.

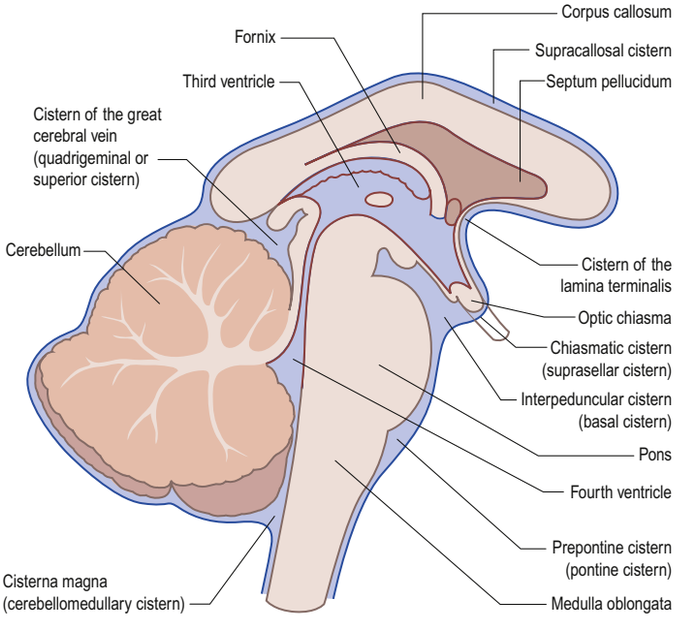

Fig. 25.25 The principal subarachnoid cisterns, sagittal section.

Trabeculae, in the form of sheets or fine filiform structures, each containing a core of collagen, cross the subarachnoid space from the deep layers of the arachnoid mater to the pia mater (Fig. 25.24). The trabeculae are attached to the large blood vessels within the subarachnoid space and may form compartments, particularly in the perivascular regions, thereby possibly facilitating directional flow of CSF through the space. A thin layer of leptomeninges, often only one cell thick, coats the trabeculae, vessels and nerves that cross the subarachnoid space, and fuses with the arachnoid mater at the margins of the exit foramina in the skull and vertebral column.

Arachnoid and pia mater are in close apposition over the convexities of the brain, such as the cortical gyri, whereas concavities are followed by the pia but spanned by the arachnoid. This arrangement produces a subarachnoid space of greatly variable depth that is location-dependent. The more expansive spaces form subarachnoid cisterns (Figs 25.25–25.27), which are continuous with the general subarachnoid space and crossed by long, filamentous trabeculae (Inoue et al 2009).

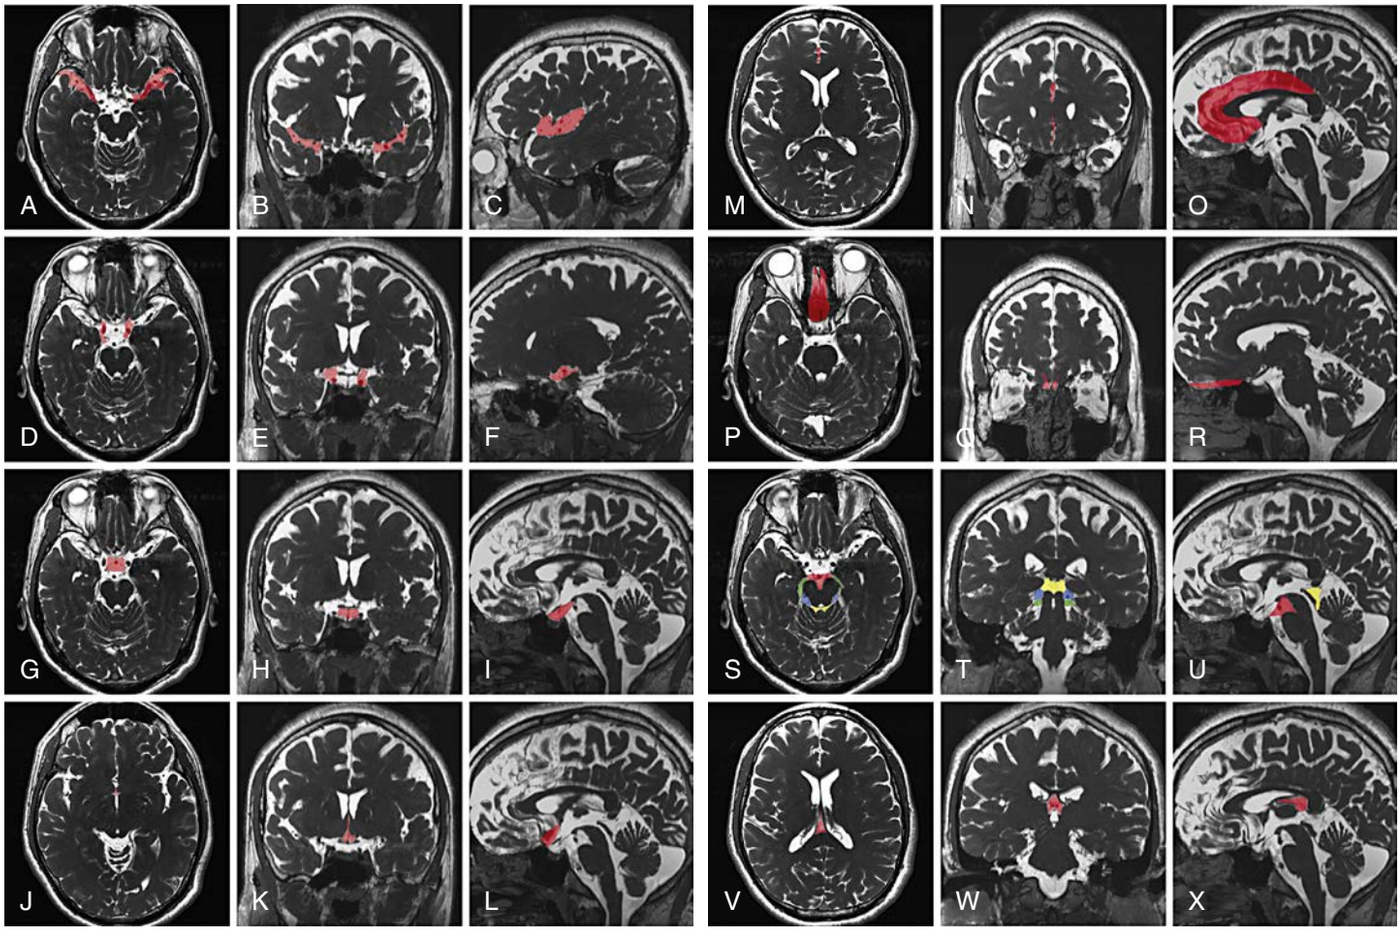

Fig. 25.26 The supratentorial subarachnoid cisterns. FIESTA MR images colour-coded to provide a visual approximation to the borders of the individually named supratentorial cisterns. These images are arrayed so that each row depicts a single cistern, in the axial plane (column 1), coronal plane (column 2) and sagittal plane (column 3). This montage is intended to indicate the general location for each cistern within the 'sea' of multiple confluent CSF spaces around the brain. **A–C**, Paired Sylvian cisterns. **D–F**, Paired carotid cisterns. **G–I**, Midline chiasmatic cistern. **J–L**, Midline cistern of the lamina terminalis. **M–O**, Midline pericallosal cistern. **P–R**, Paired olfactory cisterns. **S–U**, Midline perimesencephalic cistern. **V–X**, Cistern of the velum interpositum. The perimesencephalic cistern is often considered in four portions (**S–U**): midventral interpeduncular fossa (red), paired anterolateral crural cisterns (green), paired posterolateral ambient cisterns (blue) and mid-dorsal quadrigeminal plate (vein of Galen) cistern (yellow). (With permission from Rios JC, Galper MW, Naidich TP Ventricles and intracranial subarachnoid spaces. In: Naidich TP, Castillo M, Cha S et al (eds) Imaging of the Brain. Elsevier, Saunders; Ch. 13, pp. 245–71. Copyright 2013.)

Magnetic resonance imaging with fluid movement-sensitive sequences performed on normal subjects has shown CSF flow to be pulsating and bidirectional between the compartments of the ventricular system, probably with a net flow in a direction towards the fourth ventricle (Yamada et al 2008). The flow of CSF changes at the age of 2 years from an infantile to a mature pattern. The infantile pattern is characterized by flow directed into the ventricular system, and the mature pattern by flow directed out of the ventricles (Bateman and Brown 2012). The route of CSF through the subarachnoid space is even more complex and less understood, and it is debated whether CSF moves mainly over the cerebral convexities or mainly at the cranial base. It is known that CSF is absorbed into the superior sagittal sinus, but also that this site is insufficient to account for all CSF absorption and that this absorption system may only start to operate when CSF pressure is increased. Therefore one or more additional routes of absorption must exist but their precise location, function and mutual contributions to CSF absorption have yet to be clarified (Pollay 2010). Absorption through pial and subarachnoid vessels, across the ependymal ventricular surfaces and pial surfaces and via extracranial lymphatics may all be involved (Zakharov et al 2004).

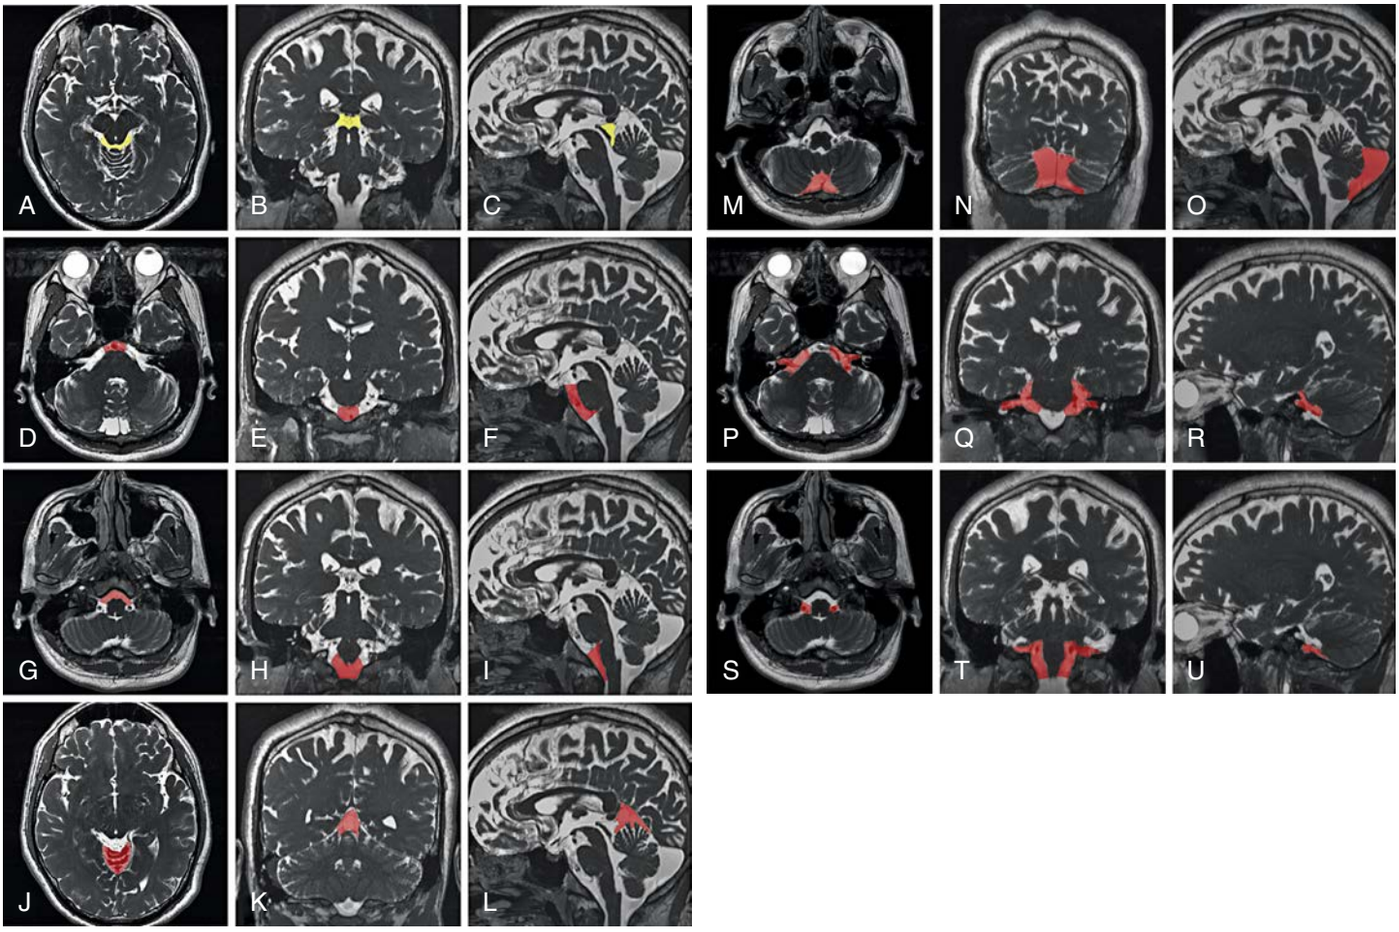

Fig. 25.27 The infratentorial subarachnoid cisterns. FIESTA MR images colour-coded to provide a visual approximation to the borders of the individually named infratentorial cisterns. These images are arrayed so that each row depicts a single cistern, in axial plane (column 1), coronal plane (column 2) and sagittal plane (column 3) images. This montage is intended to indicate the general location for each cistern within the 'sea' of multiple confluent CSF spaces around the brain. **A–C**, Midline quadrigeminal plate (vein of Galen) cistern (yellow). **D–F**, Midline prepontine cistern. **G–I**, Midline premedullary cistern. **J–L**, Midline superior vermian cistern. **M–O**, Midline cisterna magna. **P–R**, Paired cerebellopontine angle cisterns. **S–U**, Paired cerebellomedullary cisterns. (With permission from Rios JC, Galper MW, Naidich TP Ventricles and intracranial subarachnoid spaces. In: Naidich TP, Castillo M, Cha S et al (eds) Imaging of the Brain. Elsevier, Saunders; Ch. 13, pp. 245–71. Copyright 2013.)

The largest cistern, the cisterna magna (cerebellomedullary cistern) is formed where the arachnoid bridges the space between the dorsal aspect of the medulla oblongata and the inferior surface of the cerebellum. The cistern is continuous above with the lumen of the fourth ventricle through its median aperture (foramen of Magendie) and below with the spinal subarachnoid space. It contains the vertebral arteries and the origins of the posterior inferior cerebellar arteries, the glossopharyngeal, vagus, accessory and hypoglossal nerves, and the choroid plexus.

On either side, the paired cerebellopontine cisterns (angle cisterns or cerebellopontine angle cisterns) are situated in the lateral angle between the cerebellum and the pons. They are traversed by the trigeminal, facial and vestibulocochlear nerves, the anterior inferior cerebellar arteries and the superior petrosal veins.

The prepontine cistern (pontine cistern) is an extensive space ventral to the pons, which is continuous inferiorly with the spinal subarachnoid space, posteriorly and laterally with the cerebellopontine cisterns, and rostrally with the interpeduncular cistern. The prepontine cistern contains the origin of the abducens nerve and the basilar artery and its two main branches, the anterior inferior cerebellar and superior cerebellar arteries. The quadrigeminal cistern (superior cistern, vein of Galen cistern, peripineal cistern) lies posterior to the brainstem and third ventricle, and occupies the interval between the splenium of the corpus callosum and the superior cerebellar surface. The great cerebral vein, formed by the union of the basal veins (of Rosenthal) and the internal cerebral veins, traverses this cistern and the pineal gland protrudes into it. It also contains the P3 segments of the posterior cerebral arteries and portions of the medial and lateral posterior choroidal arteries.

The paired ambient cisterns are extensions of the quadrigeminal cistern. On each side, they lie between the parahippocampal and dentate gyri of the temporal lobes laterally and the lateral surface of the midbrain behind the cerebral peduncles medially; they therefore extend laterally and anteriorly around the midbrain on either side to the interpeduncular cistern (basal cistern) (see Fig. 25.26). They are divided into supra- and infra-tentorial compartments and contain the basal vein (of Rosenthal), the P2P segment of the posterior cerebral artery, the superior cerebellar artery and the trochlear nerves.

The paired crural cisterns lie between the posterior borders of the unci and the cerebral peduncles on each side and contain the P2A segments of the posterior cerebral artery and the postoptic part of the anterior choroidal artery. The midline interpeduncular cistern (basal cistern) lies between the two crura cerebri, bordered superiorly and inferiorly by the diencephalic and mesencephalic leaves respectively of Liliequist's membrane. It contains the basilar artery, the origins of the posterior cerebral and posterior thalamo-perforating arteries, the proximal portion of the anterior ponto-mesencephalic vein and the proximal portions of the oculomotor nerves. Anteriorly, the interpeduncular cistern extends to the optic chiasma.

The cistern of the lateral sulcus (Sylvian cistern) is formed by the arachnoid as it bridges the lateral sulcus between the frontal, parietal and temporal opercula and it contains the middle cerebral artery and veins.

Several smaller cisterns have been described. They include the chiasmatic cistern (suprasellar cistern), which is related to the optic chiasma, the cistern of the lamina terminalis and the supracallosal cistern, all of which are extensions of the interpeduncular cistern and contain the anterior cerebral arteries. The subarachnoid space extends through the optic foramina into the orbits, where it is bounded by the sheath of the optic nerve. It is for this reason that a raised intracranial pressure is transmitted to the optic nerve and can be visible on direct examination of the fundus as papilloedema. The sheath of the optic nerve is formed by fusion of the arachnoid mater and dura mater, and surrounds the orbital portion of each optic nerve as far as the back of the globe, where the dura fuses with the sclera of the eyeball. For further reading, see Rios et al (2013).

Arachnoid villi and granulations

Arachnoid villi and granulations (Pacchionian bodies) are focal pouches of arachnoid mater and subarachnoid space that protrude through the walls of the dural venous sinuses, very often close to points where veins enter the sinuses. They are found in the superior sagittal, transverse, superior petrosal and straight sinuses in decreasing frequency and are most prominent along the margins of the great longitudinal fissure, commonly in the lateral lacunae of the superior sagittal sinus.

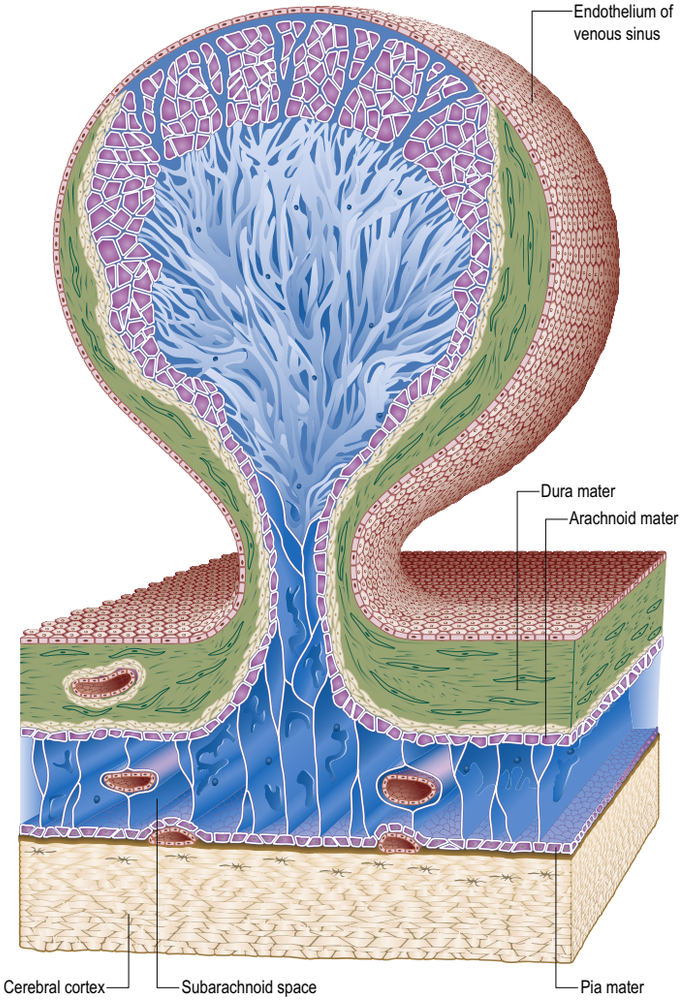

Fig. 25.28 An arachnoid granulation. (Adapted with permission from Kida S, Weller RO 1994 Morphology of CSF drainage pathways in man. In: Raimondi A (ed) Principles of Pediatric Neurosurgery, vol. 4. Berlin: Springer.)

At the base of each arachnoid granulation, a thin neck of arachnoid mater projects through an aperture in the dural covering of a venous sinus and then expands to form a core of collagenous trabeculae and interwoven channels (Fig. 25.28). An apical cap of arachnoid cells, some 150 µm thick, surmounts the core and is attached to the endothelium of the sinus over an area some 300 µm in diameter. The rest of the core of the granulation is separated from the endothelium by a fibrous dural cupula. Channels extend through the cap to reach the subendothelial regions of the granulation. Meningiomas, the most common benign intracranial tumours, arise from arachnoid cap cells.

Arachnoid villi develop during fetal life. At term, the number and complexity of the villi increase. It is generally believed that the fetal and early infantile villi do not fully penetrate the dura, but with maturation they grow in size, achieve penetration through the wall of the venous sinus, and are thereafter referred to as arachnoid granulations. In the elderly, the arachnoid membrane thickens and the arachnoid granulations degenerate and often calcify.

The function of arachnoid granulations is not fully understood, although they are thought to be involved in the reabsorption of CSF. There are observations both to support and to question their role in the absorption of CSF. Their relative paucity in the fetal and early postnatal period strongly suggests the importance of other absorption routes. The degenerative changes in arachnoid granulations in old age could be the substrate for the condition of 'normal pressure hydrocephalus' and for decreased CSF absorption, which could play an important role in degenerative brain diseases of the elderly. An alternative, and not necessarily mutually exclusive, view of arachnoid granulations is that they are involved in dissipating the pressure wave that occurs in the subarachnoid space during arterial systole (caused by the pulsation of the arterial vessels within the space). Since the dural venous sinuses lie within thick, non-compliant dural coverings, pressure changes within them functionally represent the extracranial venous compartment; systolic dilation of the arachnoid granulations would therefore dissipate intracranial pressure changes into the extracranial venous system.

PIA MATER

The pia mater is a delicate membrane that closely invests the surface of the brain and spinal cord, from which it is separated by a microscopic subpial space. It follows the contours of the brain into concavities and the depths of fissures and sulci. In the spinal canal, it contributes to the formation of the dentate ligaments and the filum terminale (Adeeb et al 2013) (see Figs 47.1C, 47.5).

Pia mater is formed from a layer of leptomeningeal cells, often only 1–2 cells thick, in which the cells are joined by desmosomes and gap junctions but few, if any, tight junctions. The cells are continuous with the coating of the subarachnoid trabeculae and separated from the basal lamina of the glia limitans by bundles of collagen, fibroblast-like cells and microscopic vessels that lie in the subpial space (Mercier et al 2002) (see Fig. 25.24).

It was long thought that the subarachnoid space was connected directly with the perivascular spaces (Virchow–Robin spaces) that surround blood vessels in the brain. However, it is now recognized that the pia mater is reflected from the surface of the brain onto the surface of blood vessels in the subarachnoid space, which means that the subarachnoid space is separated by a layer of pia from the subpial and perivascular spaces of the brain (see Fig. 25.24). The pia mater appears to form a regulatory interface between the subarachnoid space and the brain, across which small molecules may diffuse between the interstitial space and the CSF through the perivascular space. This may allow movement of metabolites and could play a role in blood–brain barrier function (Zhang et al 1990).

During development, the pia mater becomes apposed to the ependyma in the roof of the telencephalon and fourth ventricle to form the tela choroidea. It shares a common embryological origin and structural similarity with the arachnoid mater.

CHAPTER 26

Vascular supply and drainage of the brain

The brain is a highly vascular organ, its profuse blood supply characterized by a densely branching arterial network (Kaplan and Ford 1966). It has a high metabolic rate that reflects the energy requirements of constant neural activity. It receives about 15% of the cardiac output and utilizes 25% of the total oxygen consumption of the body. The brain is supplied by two internal carotid arteries and two vertebral arteries that form a complex anastomosis (circulus arteriosus cerebri, circle of Willis) on the base of the brain. Vessels diverge from this anastomosis to supply the various cerebral regions. In general, the internal carotid arteries and the vessels arising from them supply the forebrain, with the exception of the occipital lobe of the cerebral hemisphere, and the vertebral arteries and their branches supply the occipital lobe, the brainstem and the cerebellum. Venous blood from the brain drains into sinuses within the dura mater. Acute interruption of the blood supply to the brain for more than a few minutes causes permanent neurological damage. Such ischaemic strokes, along with intracranial haemorrhage, are major contemporary sources of morbidity and mortality.

ARTERIES OF THE BRAIN

The arterial supply of the brain is derived from the internal carotid and vertebral arteries which lie, together with their proximal branches, within the subarachnoid space at the base of the brain.

Internal carotid artery

The internal carotid arteries (Fig. 26.1) and their major branches (the internal carotid system or 'anterior' circulation) supply blood to the majority of the forebrain (**Video 26.1**). Some parts of the occipital and temporal lobes are supplied by branches of the vertebrobasilar system (see Fig. 26.5).

The internal carotid artery arises from the bifurcation of the common carotid artery, approximately at the level of C4, ascends in the neck (cervical segment) and enters the carotid canal of the temporal bone. Its subsequent course is said to have petrous, cavernous and intracranial parts.

Petrous part

The petrous part of the internal carotid artery ascends in the carotid canal, curves anteromedially and then superomedially above the cartilage that fills the foramen lacerum, and enters the cranial cavity. It lies at first anterior to the cochlea and tympanic cavity, and is separated from the latter and the pharyngotympanic tube by a thin, bony lamella that is cribriform in the young and partly absorbed in old age. Further anteriorly, it is separated from the trigeminal ganglion by the thin roof of the carotid canal, although this is often deficient. The artery is surrounded by a venous plexus and by the carotid autonomic plexus, derived from the internal carotid branch of the superior cervical ganglion. The petrous part of the artery gives rise to two branches. The

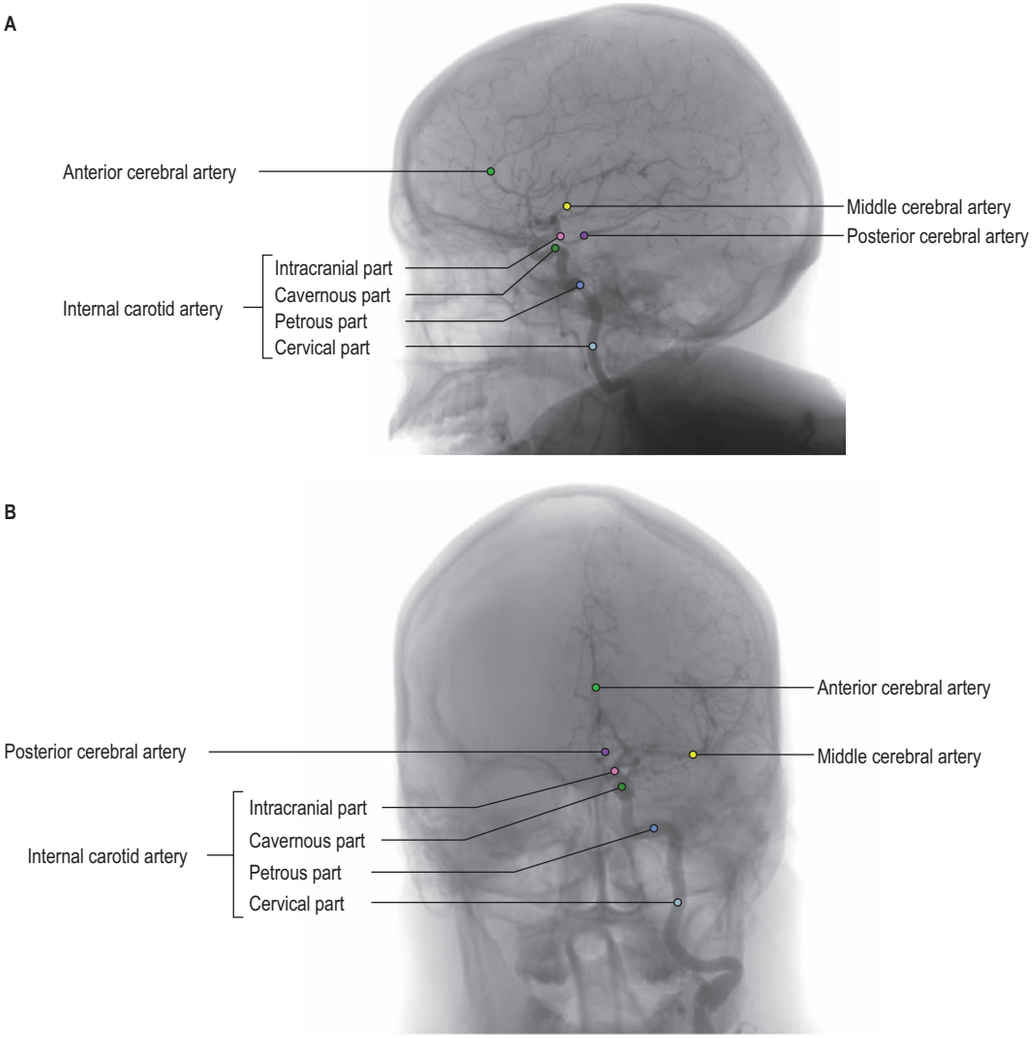

Fig. 26.1 Internal carotid arteriograms (note the perfusion of the posterior cerebral artery due to a fetal posterior communicating artery variant). **A**, Lateral projection. **B**, Towne's projection.

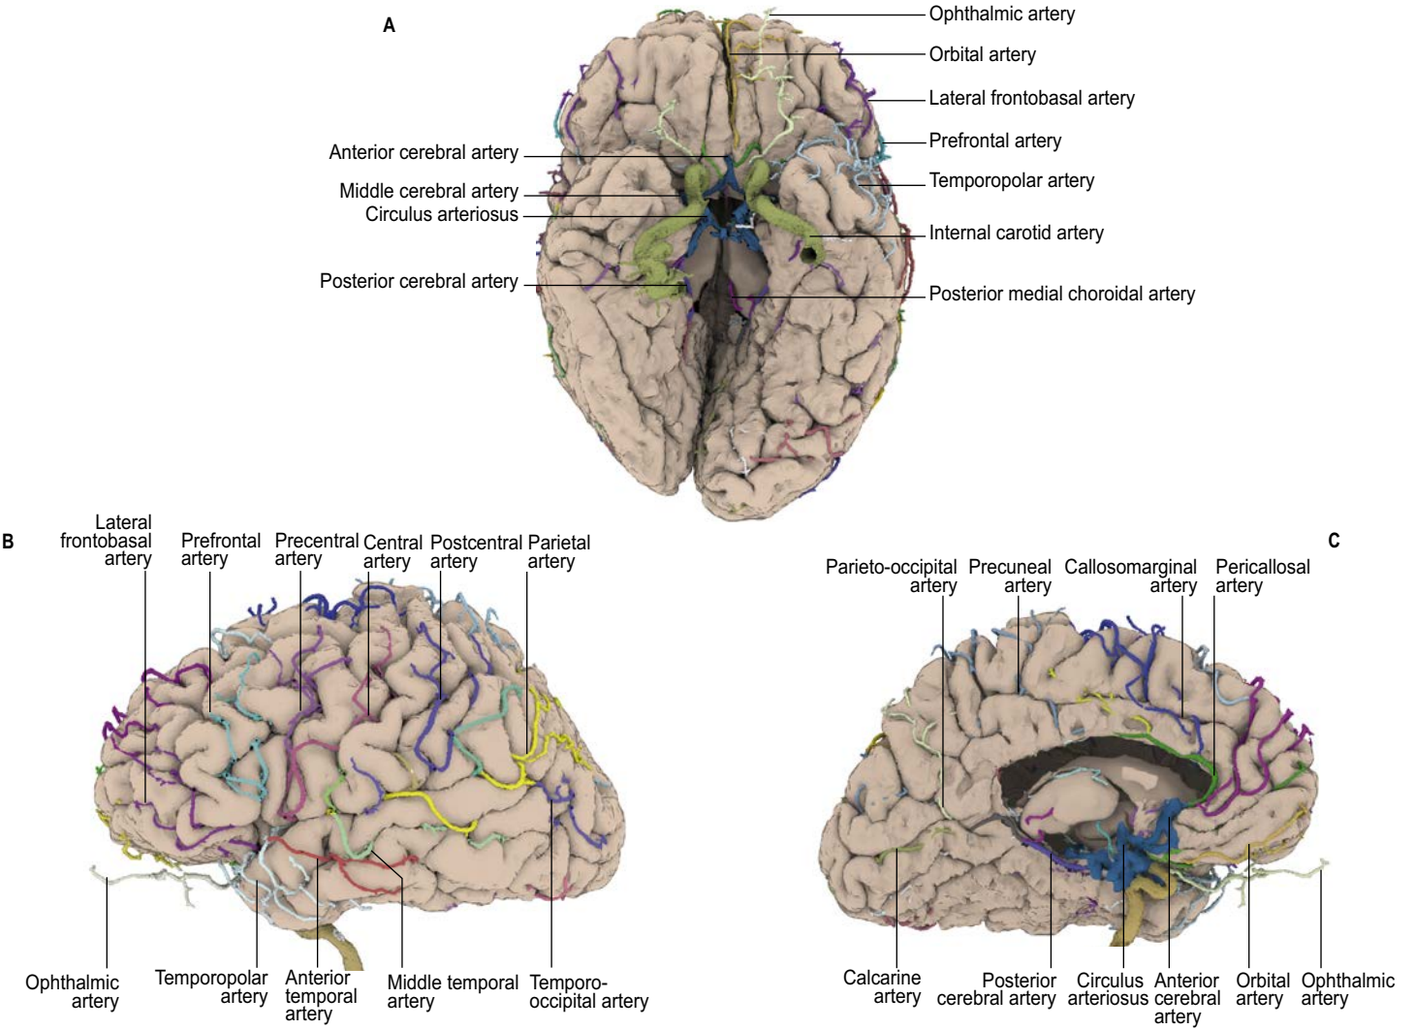

Fig. 26.2 Volumetric reconstruction from real subject data showing the major arteries supplying the basal (**A**), lateral (**B**) and medial (**C**) aspects of the brain.

caroticotympanic artery is a small, occasionally double, vessel that enters the tympanic cavity by a foramen in the carotid canal and anastomoses with the anterior tympanic branch of the maxillary artery and the stylomastoid artery. The pterygoid artery is inconsistent; when present, it enters the pterygoid canal with the nerve of the same name, and anastomoses with a (recurrent) branch of the greater palatine artery.

Cavernous part

The cavernous part of the internal carotid artery ascends to the posterior clinoid process. It turns anteriorly to the side of the body of the sphenoid within the cavernous sinus and then curves superiorly and medial to the anterior clinoid process, to emerge through the dural roof of the sinus. The oculomotor, trochlear, ophthalmic and abducens nerves are lateral to it within the cavernous sinus. The abducens nerve is closely related to the lateral wall of the internal carotid artery, whilst the oculomotor and trochlear nerves are situated in the lateral wall of the cavernous sinus (see Figs 25.8–25.9). This explains the higher risk of abducens nerve injury secondary to pathology such as aneurysms of the cavernous part of the carotid artery. Occasionally, the caroticoclinoid ligament between the anterior and middle clinoid processes becomes ossified, forming a bony ring (caroticoclinoid foramen) around the artery (Ray and Gupta 2006).

The cavernous part of the artery gives off a number of small vessels. Branches supply the trigeminal ganglion, the walls of the cavernous and inferior petrosal sinuses, and the nerves contained therein. A minute meningeal branch passes over the lesser wing of the sphenoid to supply the dura mater and bone in the anterior cranial fossa, and also anastomoses with a meningeal branch of the posterior ethmoidal artery. Numerous small hypophysial branches supply the neurohypophysis, and are of particular importance because they form the pituitary portal system (see Fig. 30.11).

Intracranial part

After piercing the dura mater, the internal carotid artery turns back below the optic nerve to run between it and the oculomotor nerve. It reaches the anterior perforated substance at the medial end of the lateral fissure and terminates by dividing into the anterior and middle cerebral arteries (Fig. 26.2).

Several preterminal vessels leave the cerebral portion of the internal carotid. The ophthalmic artery arises from the anterior part of the internal carotid as it leaves the cavernous sinus, often at the point of piercing the dura, and enters the orbit through the optic canal. The posterior communicating artery (Fig. 26.3) runs back from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral artery (a terminal branch of the basilar artery), thereby contributing to the circulus arteriosus around the interpeduncular fossa. The posterior communicating artery is usually very small. However, sometimes it is so large that the posterior cerebral artery is supplied via the posterior communicating artery rather than from the basilar artery ('fetal posterior communicating artery', Lambert et al 2016); it is often larger on one side only. Small branches from its posterior half pierce the posterior perforated substance together with branches from the posterior cerebral artery. Collectively they supply the medial thalamic surface and the walls of the third ventricle. The anterior choroidal artery leaves the internal carotid just distal to its posterior communicating branch and passes back above the medial part of the uncus. It crosses the optic tract to reach and supply the crus cerebri of the midbrain, then turns laterally, recrosses the optic tract, and gains the lateral side of the lateral geniculate body, which it supplies with several branches. It finally enters the temporal (inferior) horn of the lateral ventricle via the choroidal fissure and ends in the choroid plexus. This small, but important, vessel also contributes to the blood supply of the globus pallidus, caudate nucleus, amygdala, hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, optic radiation, optic tract, hippocampus and the fimbria of the fornix.

The combination of the petrous, cavernous and intracranial parts of the internal carotid artery is called the 'carotid siphon' because of its sigmoid course (see Fig. 26.1 and Video 26.1). However, in infants, the parasellar region of the internal carotid artery does not form a siphon but takes a relatively straight course (Weninger and Muller 1999). The cranial and sympathetic nerves therefore have different topographical relationships with the artery in the infant compared with that found in older children and adults.

The initial millimetres of the intracranial part lie between two rings (proximal and distal rings) of dense connective tissue that surround the carotid artery where the ophthalmic artery usually branches. In cases of surgical clipping of ophthalmic artery aneurysms it is of surgical relevance for neurosurgeons to expose this part of the artery by removing the anterior clinoid process and exposing this segment of the carotid, where there is no venous flow (Video 26.1).

Anterior cerebral artery

The anterior cerebral artery is the smaller of the two terminal branches of the internal carotid (see Fig. 26.3).

Surgical nomenclature divides the vessel into three parts: A1, from the termination of the internal carotid artery to the junction with the anterior communicating artery; A2, from the junction with the anterior communicating artery to the origin of the callosomarginal artery; and A3, distal to the origin of the callosomarginal artery. The A3 segment is also known as the pericallosal artery.

The anterior cerebral artery starts at the medial end of the stem of the lateral fissure. It passes anteromedially above the optic nerve to the great longitudinal fissure where it connects with its contralateral fellow by a short transverse anterior communicating artery. The latter is about 4 mm in length and may be double. It gives off numerous anteromedial central branches that supply the optic chiasma, lamina terminalis, hypothalamus, para-olfactory areas, anterior columns of the fornix and the cingulate gyrus (Fig. 26.2C).

The two anterior cerebral arteries travel together in the great longitudinal fissure. They pass around the curve of the genu of the corpus callosum and then along its upper surface to its posterior end, where they anastomose with posterior cerebral arteries.

The anterior cerebral artery has cortical and central branches. Cortical branches are named according to their distribution. Two or three orbital branches ramify on the orbital surface of the frontal lobe and supply the olfactory cortex, gyrus rectus and medial orbital gyrus. Frontal branches supply the corpus callosum, cingulate gyrus, medial frontal gyrus and paracentral lobule and parietal branches supply the precuneus. The frontal and parietal branches both send twigs over the superomedial border of the hemisphere to supply a strip of territory on the superolateral surface (see Figs 26.2B, 26.4). Cortical branches of the anterior cerebral artery, therefore, supply the areas of the motor and somatosensory cortices that represent the lower limb.

Central branches of the anterior cerebral artery arise from its proximal portion and enter the anterior perforated substance (see Fig. 26.3B) and lamina terminalis. Collectively, they supply the rostrum of the corpus callosum, septum pellucidum, anterior part of the putamen, head of the caudate nucleus and adjacent parts of the internal capsule. Immediately proximal or distal to its junction with the anterior communicating artery, the anterior cerebral artery gives rise to the medial striate artery, which supplies the anterior part of the head of the caudate nucleus and adjacent regions of the putamen and internal capsule (Video 26.1).

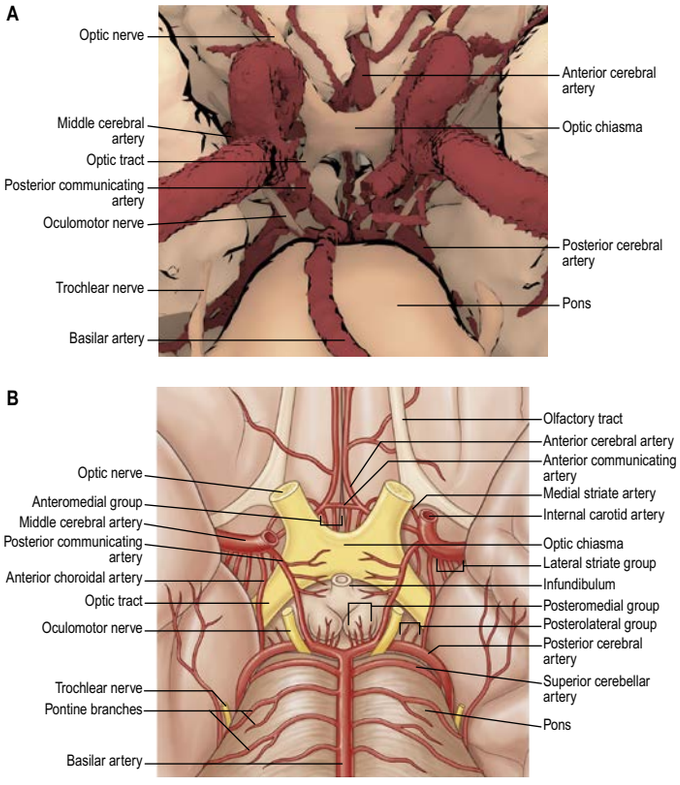

Fig. 26.3 The circulus arteriosus on the base of the brain. **A**, Volumetric reconstruction from real subject data showing the anatomical relations of the circulus arteriosus at the base of the brain. **B**, The distribution of central (perforating or ganglionic) branches.

Middle cerebral artery

The middle cerebral artery is the larger terminal branch of the internal carotid. Surgical nomenclature divides the vessel into four parts: M1 (sphenoidal), from the termination of the internal carotid artery to the bi/trifurcation; M2 (insular), running in the lateral (Sylvian) fissure; M3 (opercular), coming out of the lateral fissure; M4, cortical portions. The middle cerebral artery runs at first in the lateral fissure, then posterosuperiorly on the insula, and divides into branches distributed to the insula and the adjacent lateral cerebral surface (**Fig. 26.4**, see Fig. 26.2).

The middle cerebral artery has cortical and central branches. Cortical branches send orbital vessels to the inferior frontal gyrus and the lateral orbital surface of the frontal lobe. Frontal branches supply the precentral, middle and inferior frontal gyri. Two parietal branches are

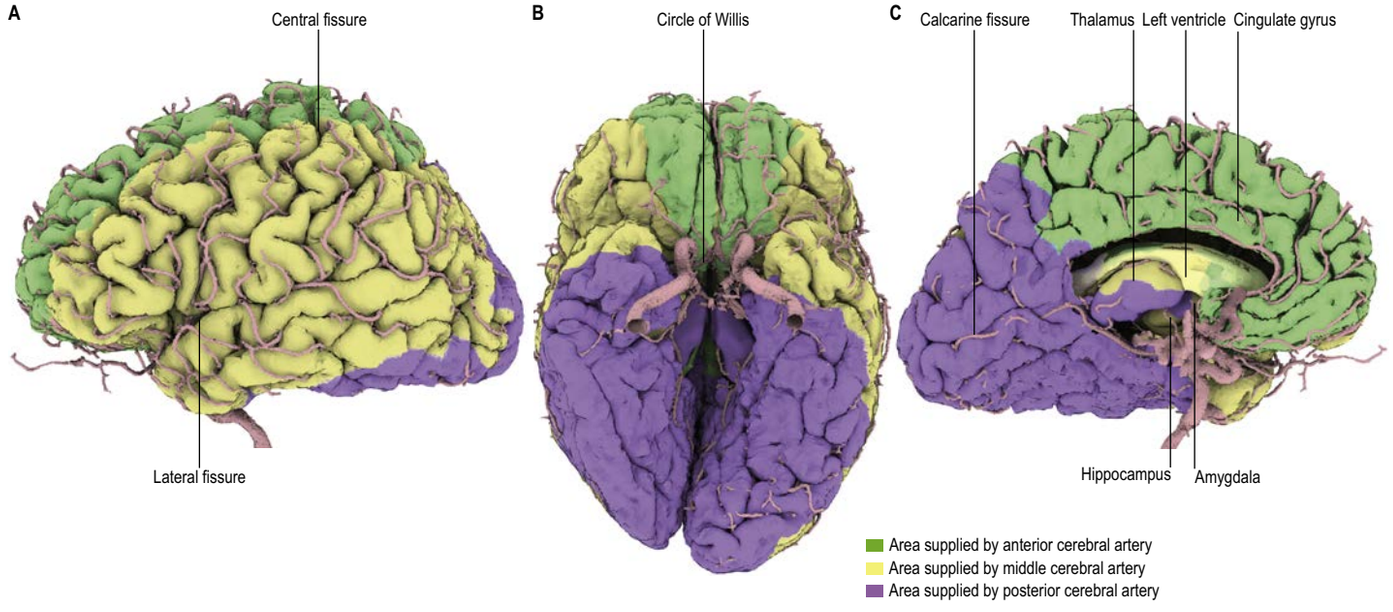

Fig. 26.4 Volumetric reconstruction from real subject data showing the arteries supplying the left cerebral hemisphere. **A**, Lateral surface. **B**, Basal surface. **C**, Medial surface.

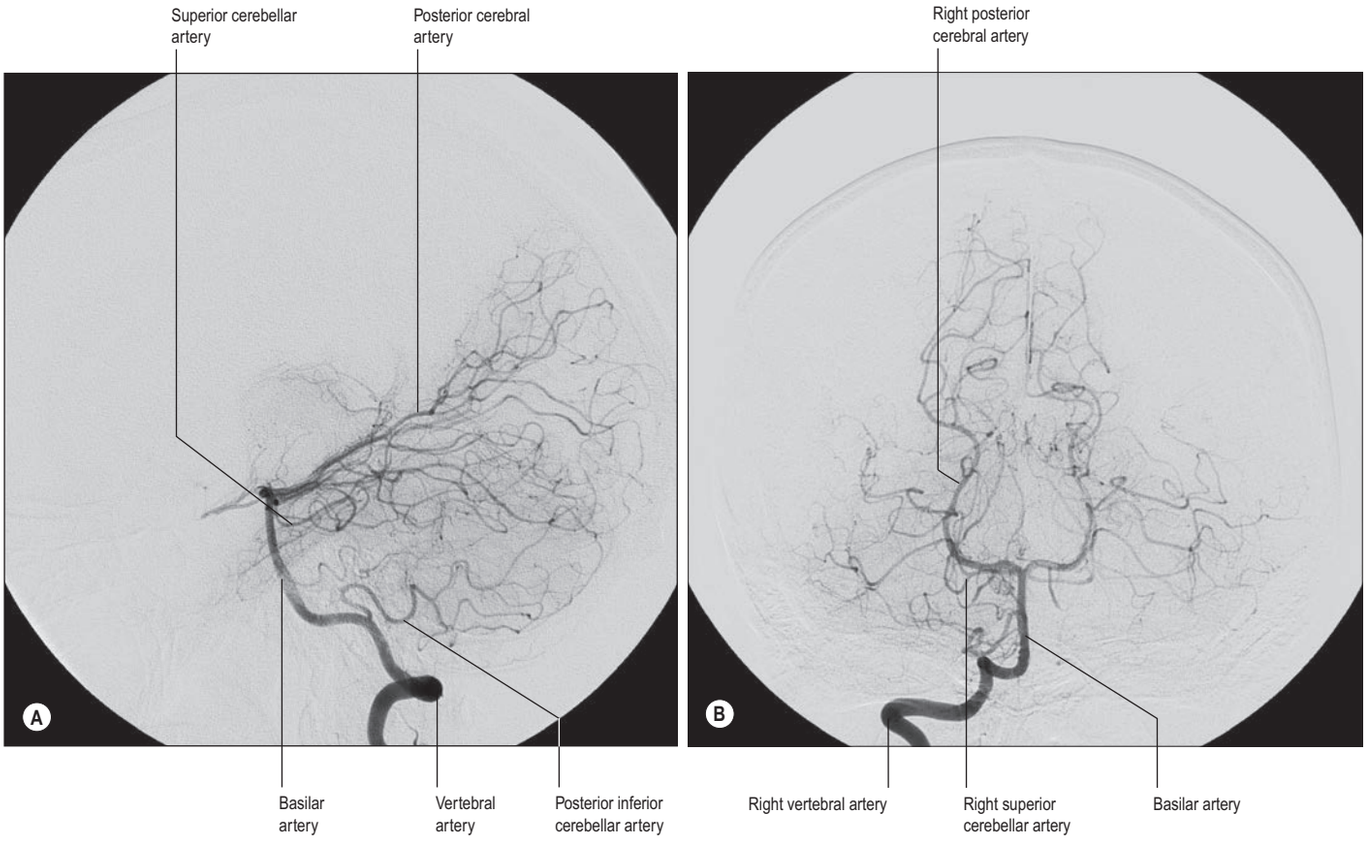

Fig. 26.5 Vertebral arteriograms. **A**, Lateral projection. **B**, Towne's projection.

distributed to the postcentral gyrus, the lower part of the superior parietal lobule and the whole inferior parietal lobule. Two or three temporal branches supply the lateral surface of the temporal lobe. Cortical branches of the middle cerebral artery therefore supply the motor and somatosensory cortices that represent the whole of the body (other than the lower limb), the auditory area and the insula.

Small central branches of the middle cerebral artery, the lateral striate or lenticulostriate arteries, arise at its origin and enter the anterior perforated substance together with the medial striate artery. Lateral striate arteries ascend in the external capsule over the lower lateral aspect of the lentiform complex, then turn medially, traverse the lentiform complex and the internal capsule and extend as far as the caudate nucleus (Video 26.1).

Vertebral artery

The vertebral arteries and their major branches (sometimes referred to as the 'vertebrobasilar system') essentially supply blood to the upper spinal cord, the brainstem and cerebellum, and a significant but variable part of the posterior cerebral hemispheres (Fig. 26.5).

The vertebral arteries are derived from the subclavian arteries, ascend through the neck in the foramina transversaria of the upper six cervical vertebrae and enter the cranial cavity through the foramen magnum, close to the anterolateral aspect of the medulla (see Fig. 35.11). They converge medially as they ascend the medulla and unite to form the midline basilar artery at approximately the level of the junction between the medulla and pons.

One or two meningeal branches arise from the vertebral artery near the foramen magnum, ramify between the bone and dura mater in the posterior cranial fossa, and supply bone, diploë and the falx cerebelli. A small anterior spinal artery arises near the end of the vertebral artery, descends anterior to the medulla oblongata and unites with its fellow from the opposite side at mid-medullary level. The common trunk descends on the ventral midline of the spinal cord, and is reinforced sequentially by small spinal rami from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, which all enter the vertebral canal via intervertebral foramina. Branches from the anterior spinal arteries and the beginning of their common trunk are distributed to the medulla oblongata.

The largest branch of the vertebral artery is the posterior inferior cerebellar artery (see Fig. 26.5A). It arises near the lower end of the olive and then ascends behind the roots of the glossopharyngeal and vagus nerves to reach the inferior border of the pons. Here it curves and descends along the inferolateral border of the fourth ventricle, then turns laterally into the cerebellar vallecula between the hemispheres and divides into medial and lateral branches. The medial branch runs back between the cerebellar hemisphere and inferior vermis, supplying both. The lateral branch supplies the inferior cerebellar surface as far as its lateral border and anastomoses with the anterior inferior and superior cerebellar arteries (branches of the basilar artery). The trunk of the posterior inferior cerebellar artery supplies the medulla oblongata dorsal to the olivary nucleus and lateral to the hypoglossal nucleus and its emerging nerve roots. It also supplies the choroid plexus of the fourth ventricle and sends a branch lateral to the cerebellar tonsil to supply the dentate nucleus. The posterior inferior cerebellar artery is sometimes absent.

A posterior spinal artery usually arises from the posterior inferior cerebellar artery, but may originate directly from the vertebral artery near the medulla oblongata. It passes posteriorly and descends as two branches that lie anterior and posterior to the dorsal roots of the spinal nerves. These are reinforced by spinal twigs from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, all of which reach the vertebral canal via intervertebral foramina and sustain the posterior spinal arteries to the lower spinal levels.

Very small medullary arteries arise from the vertebral artery and its branches and are distributed widely to the medulla oblongata.

Basilar artery

The basilar artery is a large median vessel formed by the union of the vertebral arteries at the junction of the medulla and pons (see Figs 26.3, 26.5). It lies in the pontine cistern and follows a shallow median groove on the ventral pontine surface, extending to the upper border of the pons. It ends by dividing into two posterior cerebral arteries at a variable level behind the dorsum sellae, usually in the interpeduncular cistern.

Numerous small pontine branches arise from the front and sides of the basilar artery along its course and supply the pons. The long and slender labyrinthine (internal auditory) artery has a variable origin. It usually arises from the anterior inferior cerebellar artery, but may arise from the lower part of the basilar artery, the superior cerebellar artery or, occasionally, the posterior inferior cerebellar artery. The labyrinthine artery accompanies the facial and vestibulocochlear nerves into the internal acoustic meatus and is distributed to the internal ear.

The anterior inferior cerebellar artery is given off from the distal part of the basilar artery and runs posterolaterally, usually ventral to the

abducens, facial and vestibulocochlear nerves. It commonly exhibits a loop into the internal acoustic meatus below the nerves; when this occurs, the labyrinthine artery may arise from the loop. The anterior inferior cerebellar artery supplies the inferior cerebellar surface anterolaterally and anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches supply the inferolateral parts of the pons and occasionally also supply the upper medulla oblongata.

The superior cerebellar artery (see Figs 26.3, 26.5) arises near the distal portion of the basilar artery, immediately before the formation of the posterior cerebral arteries. It passes laterally below the oculomotor nerve, which separates it from the posterior cerebral artery, and curves round the cerebral peduncle below the trochlear nerve to gain the superior cerebellar surface. Here it divides into branches that ramify in the pia mater and supply this aspect of the cerebellum, and also anastomose with branches of the inferior cerebellar arteries. The superior cerebellar artery supplies the pons, pineal body, superior medullary velum and tela choroidea of the third ventricle.

Posterior cerebral artery

The paired posterior cerebral arteries are the terminal branches of the basilar artery (see Figs 26.2–26.4). Surgical nomenclature divides the vessel into three parts: P1, from the basilar bifurcation to the junction with the posterior communicating artery; P2, from the junction with the posterior communicating artery to the portion in the perimesencephalic cistern; and P3, the portion that runs in the calcarine fissure.

The posterior cerebral artery is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve and, lateral to the midbrain, by the trochlear nerve. It passes laterally, parallel with the superior cerebellar artery, and receives the posterior communicating artery. It then winds round the cerebral peduncle and reaches the tentorial cerebral surface, where it supplies the temporal and occipital lobes.

The posterior cerebral artery has cortical and central branches. Cortical branches are named according to their distribution. Temporal branches, usually two, are distributed to the uncus and parahippocampal, medial occipitotemporal and lateral occipitotemporal gyri. Occipital branches supply the cuneus, lingual gyrus and posterolateral surface of the occipital lobe. Parieto-occipital branches supply the cuneus and precuneus. The posterior cerebral artery supplies the visual areas of the cerebral cortex and other structures in the visual pathway.

The central branches supply subcortical structures. Several small posteromedial central branches arise from the beginning of the posterior cerebral artery (see Fig. 26.3B) and, together with similar branches from the posterior communicating artery, pierce the posterior perforated substance to supply the anterior thalamus, subthalamus, lateral wall of the third ventricle and globus pallidus. One or more posterior choroidal branches pass over the lateral geniculate body and supply it before entering the posterior part of the temporal horn of the lateral ventricle via the lower part of the choroidal fissure. Branches also curl round the posterior end of the thalamus and pass through the transverse fissure, or go to the choroid plexus of the third ventricle, or traverse the upper choroidal fissure: collectively, these branches supply the choroid plexuses of the third and lateral ventricles and the fornix. Small posterolateral central branches arise from the posterior cerebral artery beyond the cerebral peduncle and supply the peduncle and the posterior thalamus, superior and inferior colliculi, pineal gland and medial geniculate body.

Circulus arteriosus cerebri

The circulus arteriosus cerebri (cerebral arterial circle, circle of Willis) is a large arterial anastomosis that unites the internal carotid and vertebrobasilar systems (see Figs 26.3, 26.5B). It lies in the subarachnoid space within the basal cisterns that surround the optic chiasma and infundibulum. The anterior cerebral arteries are derived from the internal carotid arteries and are linked by a small, but functionally important, anterior communicating artery. Posteriorly, the two posterior cerebral arteries, formed by the division of the basilar artery, are joined to the ipsilateral internal carotid artery by a posterior communicating artery.

There is considerable individual variation in the pattern and calibre of vessels that make up the circulus arteriosus (Puchades-Orts et al 1976). Although a complete circular channel almost always exists, one vessel is usually sufficiently narrowed to reduce its role as a collateral route and the circle is rarely functionally complete. Individual cerebral and communicating arteries may be absent, variably hypoplastic, double or even triple. The haemodynamics of the circle are influenced by variations in the calibre of communicating arteries and in the segments of the anterior and posterior cerebral arteries that lie between their origins and their junctions with the corresponding communicating arteries. The greatest variation in calibre occurs in the posterior communicating artery, which is normally very small, so that only limited flow is possible between the anterior and posterior circulations. Commonly, the diameter of the pre-communicating part of the posterior cerebral artery is larger than that of the posterior communicating artery, which means that the blood supply to the occipital lobes is mainly from the vertebrobasilar system. When the diameter of the pre-communicating part of the posterior cerebral artery is smaller than that of the posterior communicating artery, the blood supply to the occipital lobes is mainly from the internal carotid arteries via the posterior communicating arteries. The primary purpose of the vascular circle is to provide anastomotic channels if one vessel is occluded, but a normal-sized posterior communicating artery cannot usually fulfil this role. Agenesis or hypoplasia of the initial segment of the anterior cerebral artery are more frequent than anomalies in the anterior communicating artery and contribute to defective circulation in about one-third of individuals (Video 26.1).

Central or perforating arteries

Numerous small central (perforating or ganglionic) arteries arise from the circulus arteriosus or from vessels near it (see Fig. 26.3), and many enter the brain through the anterior and posterior perforated substances. Central branches supply nearby structures on or near the base of the brain together with the interior of the cerebral hemisphere, including the internal capsule, basal ganglia and thalamus. These branches form four principal groups (antero- and posteromedial and antero- and posterolateral). Arteries in the anteromedial group arise from the anterior cerebral and anterior communicating arteries, and pass through the medial part of the anterior perforated substance. They supply the optic chiasma, lamina terminalis, anterior, preoptic and supraoptic areas of the hypothalamus, septum, para-olfactory areas, anterior columns of the fornix, cingulate gyrus, rostrum of the corpus callosum and the anterior part of the putamen and the head of the caudate nucleus. Arteries in the posteromedial group arise from the entire length of the posterior communicating artery and from the proximal portion of the posterior cerebral artery. Anteriorly, they supply the hypothalamus and pituitary gland, and the anterior and medial parts of the thalamus via thalamoperforating arteries. Caudally, they supply the mammillary bodies, subthalamus, the lateral wall of the third ventricle, including the medial thalamus, and the globus pallidus. Arteries in the anterolateral group are mainly branches from the proximal part of the middle cerebral artery; they are also known as striate, lateral striate or lenticulostriate arteries. They enter the brain through the anterior perforated substance and supply the posterior striatum, lateral globus pallidus and the anterior limb, genu and posterior limb of the internal capsule. The medial striate artery, derived from the middle or anterior cerebral arteries, supplies the rostral part of the caudate nucleus and putamen, and the anterior limb and genu of the internal capsule. Arteries in the posterolateral group arise from the posterior cerebral artery distal to its junction with the posterior communicating artery, and supply the cerebral peduncle, colliculi, pineal gland and, via thalamogeniculate branches, the posterior thalamus and medial geniculate body.

Regional arteries of the brain

Brainstem

The medulla oblongata is supplied by branches of the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries, which enter along the ventral median fissure and the dorsal median sulcus. Vessels that supply the central substance enter along the rootlets of the glossopharyngeal, vagus and hypoglossal nerves. There is an additional supply via a pial plexus from the same main arteries. The choroid plexus of the fourth ventricle is supplied by the posterior inferior cerebellar arteries. The pons is supplied by the basilar artery and the anterior inferior and superior cerebellar arteries. Direct branches from the basilar artery enter the pons along the basilar sulcus; other vessels enter along the trigeminal, abducens, facial and vestibulocochlear nerves and from the pial plexus. The midbrain is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels that enter on their medial and lateral sides: medial vessels enter the medial side of each crus and also supply the superomedial part of the tegmentum, including the oculomotor nucleus, and lateral vessels supply the lateral part of each crus and the tegmentum. The colliculi are supplied by the posterior cerebral and superior cerebellar arteries. The posterolateral group of central branches of the posterior cerebral artery also supply the crura and the colliculi.

Cerebellum

The cerebellum is supplied by the posterior inferior, anterior inferior and superior cerebellar arteries, which form superficial anastomoses on the cortical surface. Anastomoses between deeper, subcortical, branches have been postulated (Duvernoy et al 1983).

Optic chiasma, tract and radiation

The blood supply to the optic chiasma, tract and radiation is of considerable clinical importance. The chiasma is supplied in part by the anterior cerebral arteries, but its median zone depends upon rami from the internal carotid arteries reaching it via the stalk of the hypophysis. The anterior choroidal and posterior communicating arteries supply the optic tract, and the optic radiation receives blood through deep branches of the middle and posterior cerebral arteries.

Diencephalon

The thalamus is supplied mainly by branches of the posterior communicating, posterior cerebral and basilar arteries (Plets et al 1970). A contribution from the anterior choroidal artery is often noted but this has been disputed. The medial branch of the posterior choroidal artery supplies the posterior commissure, habenular region, pineal gland and medial parts of the thalamus, including the pulvinar. Small central branches, which arise from the circulus arteriosus and its associated vessels, supply the hypothalamus. The pituitary gland is supplied by hypophysial arteries derived from the internal carotid artery, and the anterior cerebral and anterior communicating arteries supply the lamina terminalis. The choroid plexuses of the third and lateral ventricles are supplied by branches of the internal carotid and posterior cerebral arteries.

Basal ganglia

Most of the arterial supply to the basal ganglia comes from the striate arteries, which are branches from the roots of the anterior and middle cerebral arteries that enter the brain through the anterior perforated substance and also supply the internal capsule. The caudate nucleus receives blood additionally from the anterior and posterior choroidal arteries. The posteroinferior part of the lentiform complex is supplied by the thalamostriate branches of the posterior cerebral artery. The anterior choroidal artery, a preterminal branch of the internal carotid artery, contributes to the blood supply of both segments of the globus pallidus and the caudate nucleus. Famously, the ligation of this vessel during a neurosurgical procedure on a patient suffering from Parkinson's disease led to alleviation of the parkinsonian symptoms, presumably as a consequence of infarction of the globus pallidus. This chance observation led to the initiation of pallidal surgery (pallidotomy) for this condition (Ch. 31).

Internal capsule

The internal capsule is supplied by central, or perforating, arteries that arise from the circulus arteriosus and its associated vessels. These include the lateral and medial striate arteries that come from the middle and anterior cerebral arteries and also supply the basal ganglia. The lateral striate arteries supply the anterior limb, genu and much of the posterior limb of the internal capsule and are commonly involved in ischaemic and haemorrhagic stroke; indeed, one of the larger striate branches of the middle cerebral artery is known anachronistically as 'Charcot's artery of cerebral haemorrhage'. The medial striate artery, a branch of the proximal part of either the middle or anterior cerebral arteries, supplies the anterior limb and genu of the internal capsule and the basal ganglia. The anterior choroidal artery also contributes to the supply of the ventral part of the posterior limb and the retrolenticular part of the internal capsule.

Cerebral cortex

The entire blood supply of the cerebral cortex comes from cortical branches of the anterior, middle and posterior cerebral arteries (see Figs 26.2, 26.4, Video 26.1; Duvernoy et al 1981). In general, long branches traverse the cortex and penetrate the subjacent white matter for 3 or 4 cm without communicating. Short branches are confined to the cerebral cortex and form a compact network in the middle zone of the grey matter, whereas the outer and inner zones are sparingly supplied. Although adjacent vessels anastomose on the surface of the brain, they become end arteries as soon as they enter it. In general, superficial anastomoses only occur between microscopic branches of the cerebral arteries, and there is little evidence that they can provide an effective alternative circulation after the occlusion of larger vessels.

The lateral surface of the hemisphere, which includes the territories of the motor and somatosensory cortices (representing the whole of the body apart from the lower limb) and the auditory cortex and language areas, is supplied mainly by the middle cerebral artery. The anterior cerebral artery supplies a strip next to the superomedial border of the hemisphere, as far back as the parieto-occipital sulcus. The occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) are supplied by the posterior cerebral artery.

Medial and inferior surfaces of the hemisphere are supplied by the anterior, middle and posterior cerebral arteries. The area supplied by the anterior cerebral artery is the largest, extending almost to the parieto-occipital sulcus and including the medial part of the orbital surface. The rest of the orbital surface and the temporal pole are supplied by the middle cerebral artery, and the remaining medial and inferior surfaces are supplied by the posterior cerebral artery.

Near the occipital pole, the junctional zone between the territories of the middle and posterior cerebral arteries corresponds to the visual (striate) cortex, which receives information from the macula. When the posterior cerebral artery is occluded, a phenomenon known as 'macular sparing' may occur, where vision with the central part of the retina is preserved. Collateral circulation of blood from branches of the middle cerebral artery into those of the posterior cerebral artery may account for this phenomenon. In some individuals, the middle cerebral artery may directly supply the macular area.

Cerebral blood flow

The brain is devoid of either glucose stores or a means of storing oxygen and is therefore dependent minute-by-minute on an adequate blood supply. It has a high metabolic rate in comparison to other organs, reflecting the metabolic demands of constant neural activity: the blood supply of grey matter is more copious than that of white matter.

Cerebral blood flow in the human brain is approximately $50\,ml\,g^{-1}\,min^{-1}$. Global cerebral blood flow is autoregulated, i.e. it remains constant in normal individuals despite variations in mean arterial blood pressure over a range of 8.7–18.7 kPa (65–140 mmHg). If the blood pressure falls below this range, cerebral blood flow decreases, and if the pressure rises above this range, cerebral blood flow may increase. Arterial and arteriolar intraluminal pressure directly control contraction of intramural muscle, e.g. an increase in arterial pressure causes arterial constriction, and blood flow remains constant.

Although autoregulation normally ensures that global cerebral blood flow remains constant, regional blood flow varies in response to the level of neural activity and local metabolic demand. This has been demonstrated for many brain areas, including the motor and sensory cortical regions, areas involved in convulsive activity and cortical areas involved in complex thought processes. The principal local factors affecting regional blood flow are the local hydrogen ion (H^+) or carbon dioxide concentrations, which cause arterial dilation both by a direct action on the endothelium and through indirect mediators, such as nitric oxide.

Not all substances circulating in arterial blood have access to the brain parenchyma: particulate matter, such as bacteria, is excluded. In general, lipophilic molecules and small molecules, such as oxygen and carbon dioxide, can cross the blood–brain barrier but hydrophilic ones (excluding glucose) cannot. The cellular basis for the blood–brain barrier is discussed in Chapter 3.

Ischaemic stroke

Stroke refers to the clinical syndrome of a rapidly developing focal neurological deficit that is not due to seizure activity. If the cause is lack of, or reduced, blood supply to a portion of the brain, then the term ischaemic stroke (**Fig. 26.6**) is used, as opposed to haemorrhagic stroke, e.g. subarachnoid haemorrhage. The lack of blood flow can be due to pathology in the vessel lumen, such as thrombosis or embolus (common); pathology outside the blood vessel, such as occlusion from the mass effect of a tumour or haematoma (rare); or pathology of the vessel wall, such as inflammatory or infective arteritides (rare). The symptoms and signs of ischaemic stroke depend on the location and extent of the arterial infarction (Bogousslavsky and Caplan 2002). In certain locations, even a small volume stroke can have devastating effects. For example, the internal capsule and most of the adjacent basal

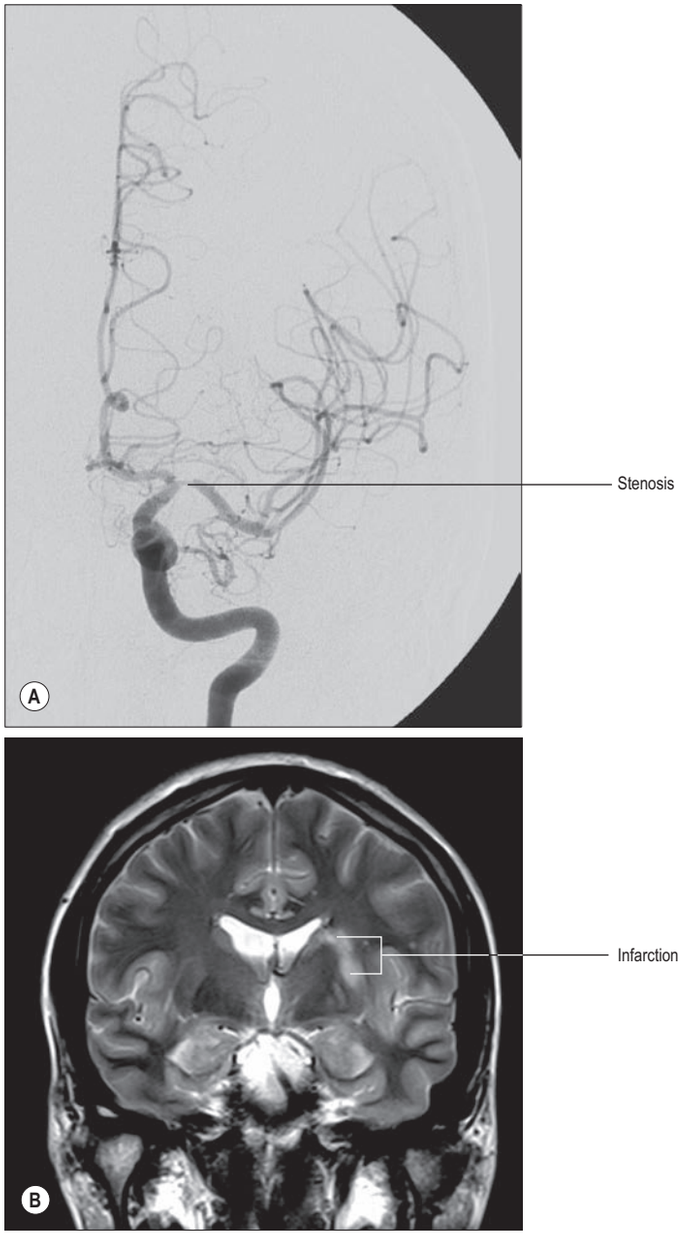

Fig. 26.6 **A**, A frontal projection of a selective catheter angiogram of the left internal carotid artery, showing a focal narrowing at the termination of the left internal carotid artery and the origin of the left middle cerebral artery. **B**, A coronal T2-weighted image of the brain at the level of the basal ganglia. There is an abnormal high signal in the left putamen and adjacent white matter, consistent with infarction. It is likely that the infarction was due to occlusion of small perforating vessels originating in the area of the stenosis and supplying the basal ganglia.

ganglia are supplied by small perforating arteries, common sites for ischaemic stroke. Corticonuclear and corticospinal motor pathways and third-order thalamocortical sensory fibres all pass through the internal capsule, which means that effectively it is the only route connecting the cerebral cortex with other regions of the neuraxis. The neurological deficits that result from stroke in the internal capsule therefore may include contralateral spastic hemiparesis, contralateral hemisensory loss and psychological deficits.

It is possible for a major vessel, such as the internal carotid artery in the neck, to become occluded and for the affected individual to remain asymptomatic, provided that an appropriate flow of blood can be recruited to supply the affected brain region from other sources (collateral supply). The primary role of the circulus arteriosus is to allow for this eventuality by redirecting blood from other sources, such as the contralateral internal carotid artery and vertebrobasilar system. If the circulus arteriosus is complete, two or even three of the four major arteries supplying the brain can be occluded without producing an ischaemic stroke. Unfortunately, the circulus arteriosus is rarely haemodynamically complete and ischaemic stroke often occurs because the collateral supply is inadequate.

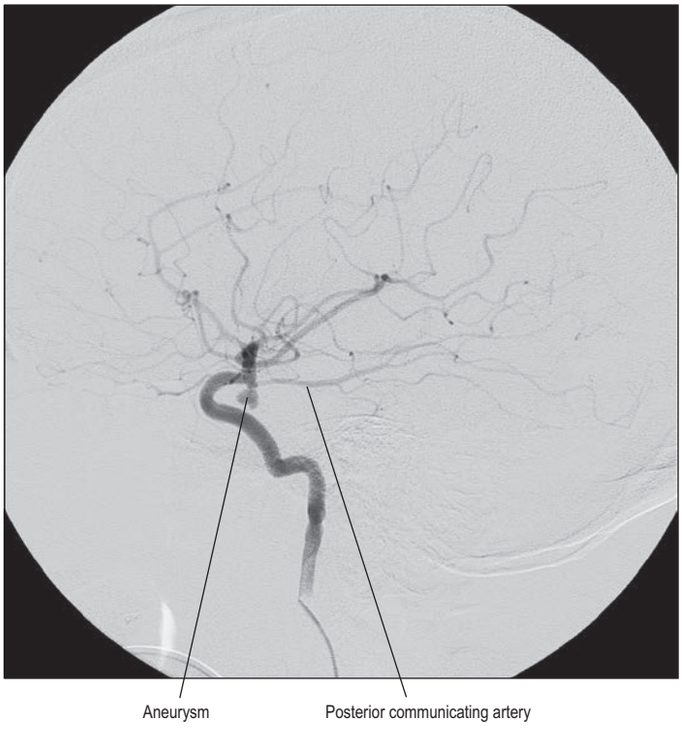

Fig. 26.7 An intra-arterial digital subtraction angiogram of the right internal carotid artery in a patient with a complete right oculomotor nerve palsy, reflecting compression of the nerve by an aneurysm on the posterior communicating artery, lateral projection.

For example, an individual in whom neither anterior nor posterior communicating arteries are patent will suffer an ischaemic stroke if there is occlusion of one internal carotid artery because the proximal anterior and middle cerebral arteries cannot receive collateral flow via the incomplete circulus arteriosus. Some collateral flow may be available from anastomoses between distal branches of the external carotid artery (e.g. middle meningeal artery) but invariably this is not sufficient to supply the whole hemisphere.

Somewhat paradoxically, the more distally an occlusion occurs in the cerebral vasculature, the more likely it is to cause an ischaemic stroke (although the volume of infarcted tissue will be less). This is because the major capacity to form collateralization is proximal, mainly at the circulus arteriosus. For example, an embolus formed in the proximal internal carotid artery may travel to the M1 portion of the ipsilateral middle cerebral artery and occlude the vessel. There is very little scope for collateralization at this site and an ischaemic stroke is unavoidable, unless the embolus can be cleared and flow restored in good time.

Watershed areas Regions of the brain lying at the extreme edges of the major cerebral arterial territories are called watershed areas and are the first to be deprived of sufficient blood flow in the event of cerebral hypoperfusion. Ischaemic infarcts of the cortex and adjacent subcortical white matter in the border zones between these territories are known as watershed, boundary-zone or border-zone infarcts. There is some evidence that a second arterial border zone, the internal arterial border zone, exists within the white matter of the centrum semiovale and corona radiata (between the lenticulostriate perforators and the deep penetrating branches of the distal middle cerebral artery).

Cerebral aneurysms Aneurysms are balloon-like swellings that occur on arteries as a result of defects in the vessel wall. They are most commonly found on the vessels of the circulus arteriosus, particularly at or near the junctions of vessels. Aneurysms on the internal carotid artery near its termination may compress the lateral aspect of the optic chiasma and compromise axons derived from the temporal side of the ipsilateral retina, causing a defect in the nasal visual field. Aneurysms in the vicinity of the oculomotor nerve, e.g. on the posterior communicating artery, superior cerebellar artery or the tip of the basilar artery, can cause damage to the oculomotor nerve by compression (Fig. 26.7).

Subarachnoid haemorrhage Bleeding into the subarachnoid compartment, subarachnoid haemorrhage, is the most common pathology that involves the subarachnoid space (Sengupta and McAllister 1986). There are many causes: in adults, the most common is rupture of an aneurysm of the intracranial vessels that run within the subarachnoid

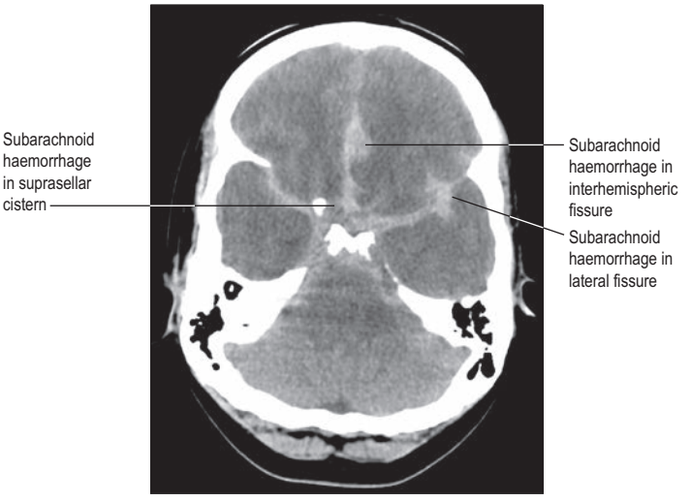

Fig. 26.8 An axial CT image (without intravenous contrast agent) at the level of the posterior clinoid processes. There is abnormally high attenuation in the basal cisterns and subarachnoid space of the interhemispheric fissure, indicating an acute subarachnoid haemorrhage, subsequently shown to be due to a ruptured aneurysm on the anterior communicating artery.

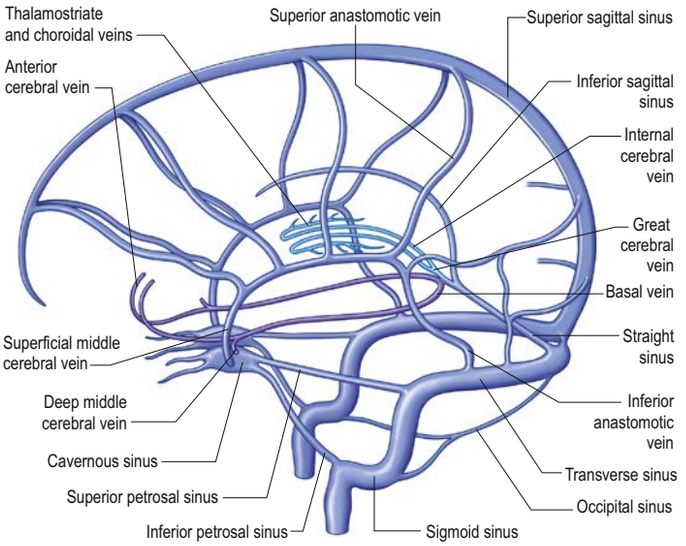

Fig. 26.10 The cerebral venous system showing the principal superficial and deep veins of the brain and their relationship to the dural venous sinuses, viewed from the left side.

space. An individual who has suffered a subarachnoid haemorrhage usually complains of a headache of very sudden onset that is frequently described as being their 'worst ever headache' or 'like being hit on the head with a hammer'. When this is suspected, the first investigation is a CT examination, which has a very high sensitivity for detecting fresh haemorrhage. Blood will be seen in the basal cisterns and entering the depths of the cortical sulci, i.e. delineating the anatomy of the subarachnoid space, a presentation that permits an accurate diagnosis (**Fig. 26.8**). In marked contrast, the spread of blood in a subdural haemorrhage is limited by the arachnoid mater on its deep surface, and the blood therefore remains on the surface of the brain.

Arteriovenous malformations Arteriovenous malformations (AVMs) of the brain are developmental abnormalities of the blood vessels supplying the brain and are thought to occur in 1–2 per 10,000 people. In the normal brain, blood flows from a cerebral artery into a capillary system and then into a draining vein(s). When an AVM is present, arterial blood passes into a tangle (nidus) of abnormal blood vessels that allows passage into the venous system without passing through normal capillaries (**Fig. 26.9**).

VEINS OF THE BRAIN

The venous drainage of the brain occurs through a complex system of deep and superficial veins (Andeweg 1996) devoid of valves and with thin walls that lack muscular tissue. They pierce the arachnoid mater and the inner layer of the dura mater to open into the dural venous sinuses.

Veins of the posterior fossa

The veins of the brainstem form a superficial venous plexus deep to the arteries. Veins of the medulla oblongata drain into the veins of the spinal cord or the adjacent dural venous sinuses, or into variable radicular veins that accompany the last four cranial nerves to either the inferior petrosal or occipital sinuses, or to the superior bulb of the jugular vein. Anterior and posterior median medullary veins may run along the ventral median fissure and dorsal median sulcus to become continuous with the spinal veins in corresponding positions. Pontine veins, which may include a median vein and a lateral vein on each side, drain into the basal vein, cerebellar veins, the petrosal or transverse sinuses or the venous plexus of the foramen ovale. Veins of the midbrain join the great cerebral vein (of Galen) or the basal vein.

The veins of the cerebellum drain mainly into sinuses adjacent to them or, from the superior surface, into the great cerebral vein. The cerebellar veins course on the cerebellar surface, and consist of superior and inferior groups. Superior cerebellar veins run either anteromedially across the superior vermis to the straight sinus or great cerebral vein, or they run laterally to the transverse and superior petrosal sinuses. Inferior cerebellar veins include a small median vessel that runs backwards on the inferior vermis to enter the straight or sigmoid sinus. Laterally coursing vessels join the inferior petrosal and occipital sinuses.

Veins of the cerebral hemisphere

Superficial and deep cerebral veins drain the surfaces and interior of the cerebral hemisphere, respectively (**Figs 26.10–26.11**, Video 26.2). The superficial veins may be divided into superior, middle and inferior groups. Between 8 and 12 superior cerebral veins drain the superolateral and medial surfaces of each hemisphere. They mainly follow the sulci, although some pass across gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface, and then open into the superior sagittal sinus. Superior cerebral veins in the anterior part of the hemisphere join the sinus almost at right angles. The larger posterior veins are directed obliquely forwards, against the direction of flow in the sinus, an arrangement that may resist their collapse when intracranial pressure is raised.

The superficial middle cerebral vein drains most of the lateral surface of the hemisphere and follows the lateral fissure to end in the cavernous sinus. A superior anastomotic vein runs posterosuperiorly between the superficial middle cerebral vein and the superior sagittal sinus, connecting the superior sagittal and cavernous sinuses. An inferior anastomotic vein courses over the temporal lobe and connects the superficial middle cerebral vein to the transverse sinus. The deep middle cerebral vein drains the insular region and joins the anterior cerebral and striate veins to form a basal vein. Regions drained by the anterior cerebral and striate veins correspond approximately to those supplied by the anterior cerebral artery and the central branches that enter the anterior perforated substance. The basal veins pass back alongside the interpeduncular fossa and midbrain, receiving tributaries from this vicinity, and join the great cerebral vein.

Inferior cerebral veins on the orbital surface of the frontal lobe join the superior cerebral veins and thus drain to the superior sagittal sinus. Those on the temporal lobe anastomose with basal veins and middle cerebral veins, and drain to the cavernous, superior petrosal and transverse sinuses.

The basal vein is formed at the anterior perforated substance by the union of several vessels: a small anterior cerebral vein, which accompanies the anterior cerebral artery; a deep middle cerebral vein, which receives tributaries from the insula and neighbouring gyri, and runs in the lateral cerebral fissure; and striate veins, which emerge from the anterior perforated substance. The basal vein passes back round the cerebral peduncle to the great cerebral vein and receives tributaries from the interpeduncular fossa, temporal horn of the lateral ventricle, parahippocampal gyrus and midbrain.

The internal cerebral vein drains the deep parts of the hemisphere and the choroid plexuses of the third and lateral ventricles (**Fig. 26.12**). It is formed behind the column of the fornix, near the interventricular foramen, primarily by union of the thalamostriate and choroidal veins, although numerous smaller veins from surrounding structures also converge here. The thalamostriate vein runs anteriorly, between the caudate nucleus and thalamus, and receives many tributaries from both. The choroidal vein runs a convoluted course along the whole choroid

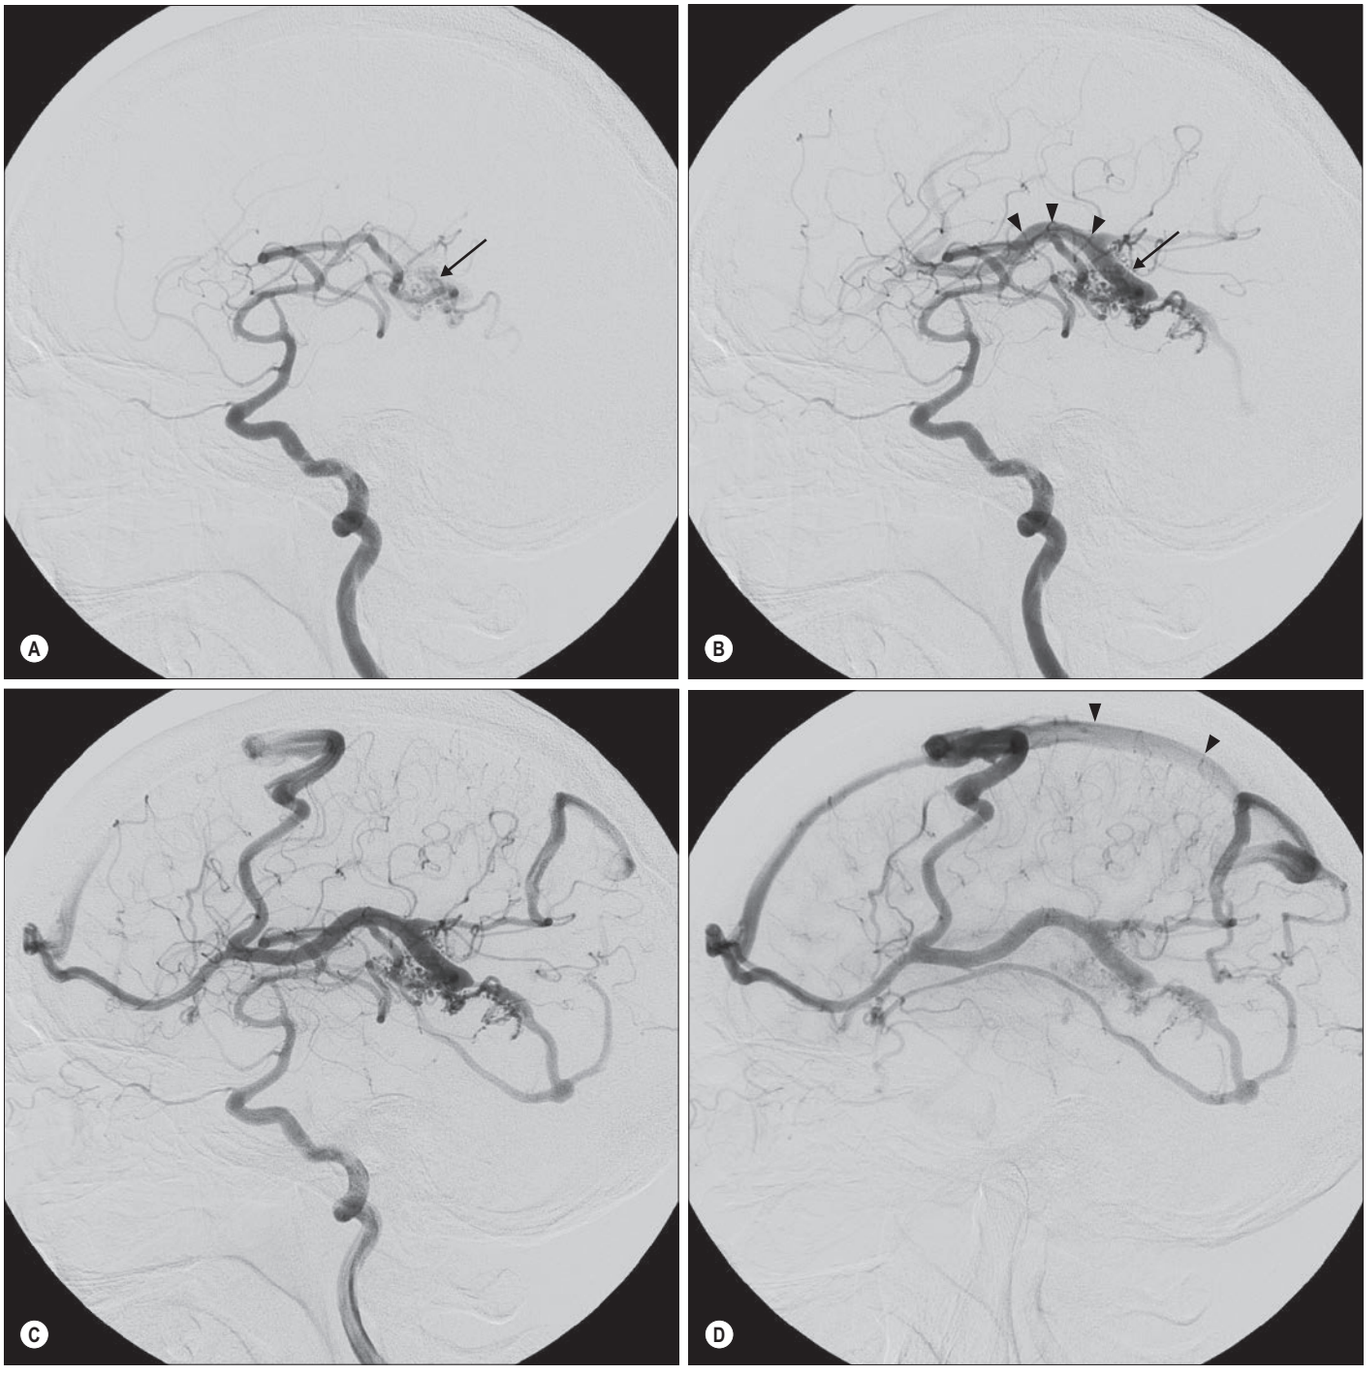

Fig. 26.9 Selective catheter angiograms showing an arteriovenous malformation (AVM) in the left cerebral hemisphere. **A**, Injection of contrast medium into the left internal carotid artery shows the nidus of an AVM being supplied by enlarged posterior branches of the middle cerebral artery (arrow). **B**, An image taken one-third of a second later shows better filling of the nidus (arrow) and early filling of a draining vein (arrowheads). **C**, One second after the original image was taken, abnormally large cortical veins can be seen draining towards the superior sagittal sinus. **D**, Two seconds after the original, the superior sagittal sinus is opacified but the remainder of the dural venous system is not filled with contrast, indicating rapid shunting through the AVM.

As a result, there is often rapid, high-volume blood flow through the nidus, and coupled with abnormal vessel walls, this leads to a high risk of rupture. The resulting haemorrhage from a cerebral AVM is associated with high mortality/morbidity, and recurrent haemorrhages are common in survivors. Not all brain AVMs present with rupture but they may cause headaches, seizures or focal neurological deficits; some brain AVMs are discovered incidentally. There are several treatment options for brain AVMs, including surgical resection, endovascular obliteration and stereotactic radiosurgery. In some circumstances, conservative management is appropriate.

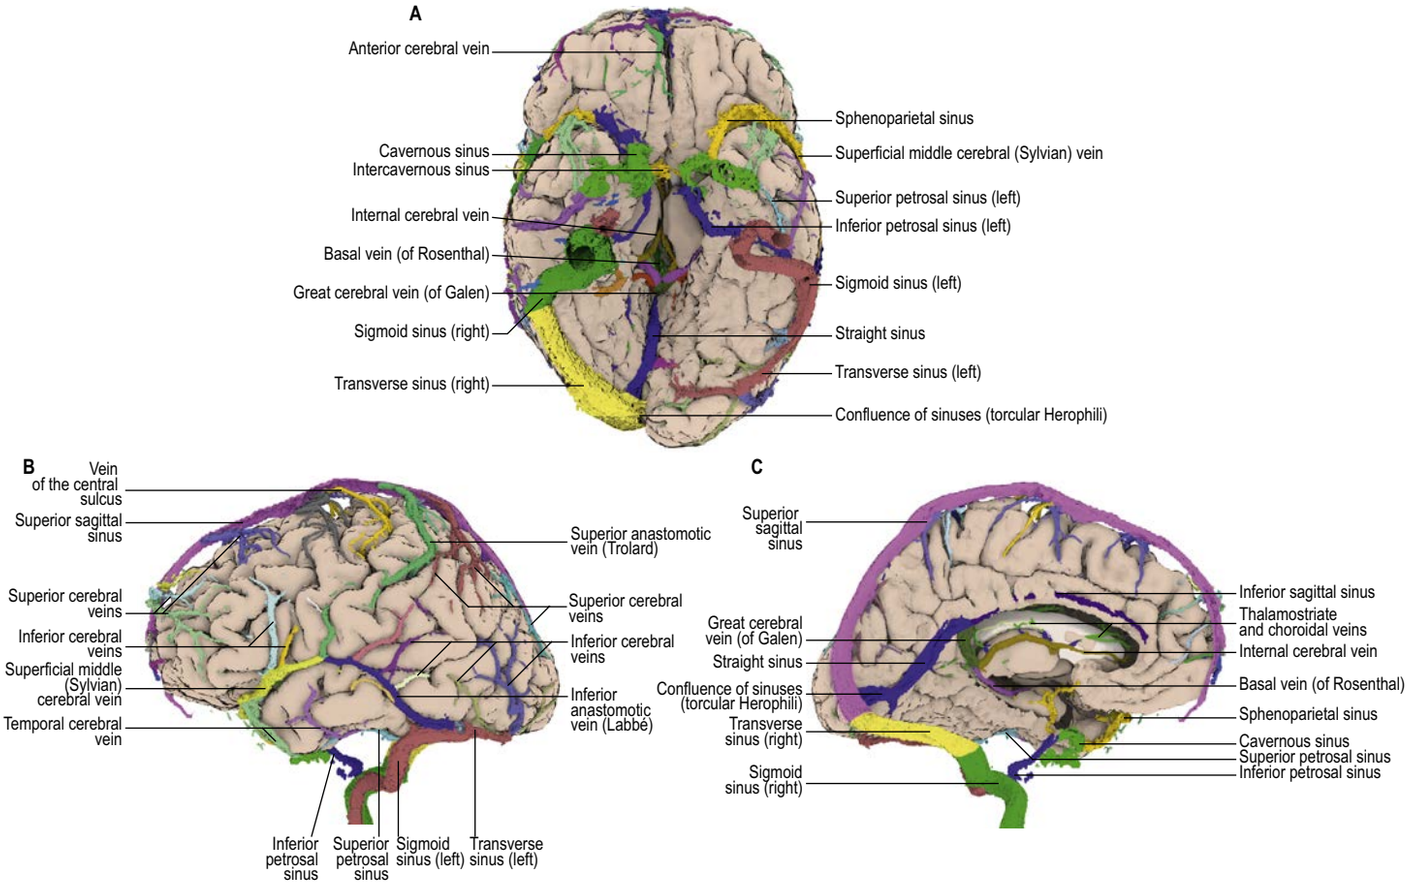

Fig. 26.11 Volumetric reconstruction from real subject data showing the veins and sinuses draining the basal (**A**), lateral (**B**) and medial (**C**) aspects of the brain.

plexus, and receives veins from the hippocampus, fornix, corpus callosum and adjacent structures. After their formation, the two internal cerebral veins travel back parallel to one another beneath the splenium of the corpus callosum, where they unite to form the great cerebral vein (Fig. 26.13). The great cerebral vein is a short median vessel that curves sharply up around the splenium of the corpus callosum and opens into the anterior end of the straight sinus after receiving the right and left basal veins (Video 26.2).

Intracranial venosinus thrombosis One of the most potentially serious pathologies affecting the intracranial venous system is venosinus thrombosis (Fig. 26.14). In this condition, blood clots within the dural sinuses and/or intracranial veins, and the resulting obstruction of venous drainage, may produce life-threatening complications.

In many cases, the cause of the venosinus thrombosis is not found; trauma involving the dural sinuses and infections in the vicinity of the sinuses (e.g. mastoiditis) present significant risk. Conditions that increase the coagulability of the blood, such as the oral contraceptive pill, pregnancy, dehydration and inborn abnormalities of the coagulation pathways, are also risk factors.

Individuals with intracranial venosinus thrombosis at its most severe present moribund, in coma or with major seizure activity, and in these situations the prognosis is poor. The clot within the dural sinuses and/or cortical veins obstructs the drainage of venous blood from the brain and causes venous hypertension. As the pressure in the venous system approaches the arterial pressure, the blood flow perfusing the affected parts of the brain decreases. If it dips below a critical level, the brain tissue will become ischaemic and may die (venous infarction). As the arterial supply to the brain is still present, the infarcted areas of the brain frequently undergo major haemorrhage and this is often the factor that kills the patient.

Clinicians distinguish between thrombosis that affects the 'superficial' and 'deep' venous systems, although they may occur together. Superficial thrombosis usually occurs in the superior sagittal sinus (with or without involvement of the cortical veins). Deep intracranial thrombotic disease usually affects the great cerebral vein and the straight sinus. The parts of the cerebral hemispheres affected are different in the two situations: superficial thrombosis affects the cerebral hemispheres (particularly the white matter) and deep thrombosis affects the thalami and basal ganglia. A common feature is the tendency for bilateral involvement because all of the main draining venous channels are in the midline and accept venous drainage from both hemispheres. If the extent of the intracranial venosinus thrombosis is less severe, or if alternative venous drainage has been accommodated by reasonable collateral channels, the patient may have more modest symptoms such as headaches or visual disturbance. Those symptoms are due to raised intracranial pressure and, if untreated, may become chronic.

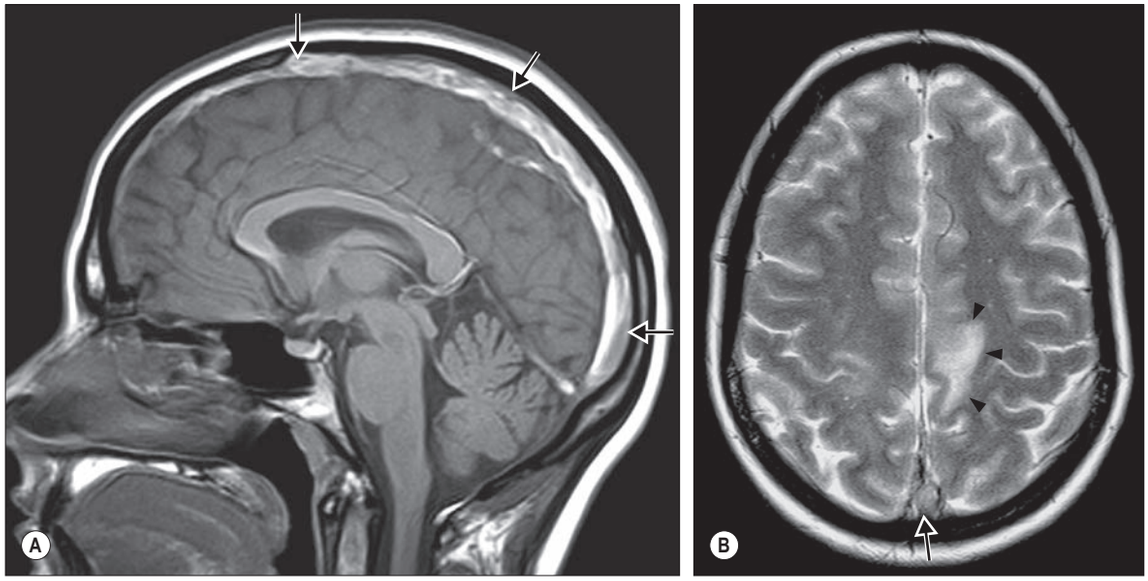

Fig. 26.14 Venosinus thrombosis. Images from a magnetic resonance study in an adult patient with a 6 day history of headache and increasingly severe seizures. **A**, The sagittal T1-weighted image shows abnormal high signal along the course of the superior sagittal sinus (arrows). **B**, The axial T2-weighted image also shows high signal in the enlarged superior sagittal sinus (arrow). This pattern of abnormal signal indicates extensive subacute thrombus in the sinus. There are abnormal high signal changes in the left paracentral lobule (arrowheads), indicating venous infarction, which was shown to be bilateral and haemorrhagic on other images.

CHAPTER 27

Spinal cord

The spinal cord provides innervation for the trunk and limbs via spinal nerves and their peripheral ramifications. It receives primary afferent fibres from peripheral receptors located in widespread somatic and visceral structures, and sends motor axons to skeletal muscle. It also contains the cell bodies of all the preganglionic neurones responsible for the sympathetic innervation of cardiac and smooth muscle and secretory glands, and for the parasympathetic innervation of smooth muscle in the distal part of the hindgut, the pelvic viscera and the erectile tissues of the external genitalia. Many bodily functions are regulated at an unconscious level by intraspinal reflex connections between afferent and efferent neurones. Profuse ascending and descending pathways link the spinal cord with the brain, allowing higher centres to monitor and perceive external and internal stimuli and to modulate and control spinal efferent activity.

EXTERNAL FEATURES AND RELATIONS

The topographical anatomy of the spinal cord in relation to other structures within the vertebral canal is described in more detail in Chapter 47. In brief, the cord begins just below the level of the foramen magnum where it is continuous rostrally with the medulla oblongata. It terminates caudally as the conus medullaris, which narrows into the filum terminale, anchored to the dorsum of the coccyx. The cord is ensheathed by spinal meninges that are continuous with the cranial meninges through the foramen magnum. Although it is approximately circular in cross-section, the diameter of the spinal cord varies according to level; it bears two enlargements, cervical and lumbosacral (**Fig. 27.1**).

The spinal cord is essentially a segmental structure, each of the 31 segments giving rise to bilaterally paired spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal (see Fig. 27.1). The spinal nerves attach to the cord as a linear series of small dorsal and ventral nerve rootlets. Dorsal rootlets contain afferent nerve fibres and ventral rootlets contain efferent fibres (see Fig. 27.1). Groups of adjacent rootlets coalesce to form dorsal or ventral nerve roots that cross the subarachnoid space and unite to form functionally mixed spinal nerves as they exit the vertebral canal through the intervertebral foramina. The dorsal roots bear dorsal root ganglia which contain the cell bodies of primary afferent neurones.

INTERNAL ORGANIZATION

In transverse section, the spinal cord is incompletely divided into symmetrical halves by a dorsal (posterior) median sulcus and septum and a ventral (anterior) median fissure (see Fig. 27.1). The cord consists of an outer layer of white matter and an inner core of grey matter, their relative sizes and configuration varying according to the level. The amount of grey matter reflects the number of neuronal cell bodies present; it is proportionately largest in the cervical and lumbosacral enlargements, which contain the neurones that innervate the upper and lower limbs, respectively (see Fig. 27.1). The absolute amount of white matter is greatest at cervical levels, where ascending tracts increasingly accumulate fibres, and decreases progressively at lower levels as descending tracts shed their fibres.

A diminutive central canal, lined by columnar, ciliated epithelium (ependyma) and containing cerebrospinal fluid (CSF), extends the whole length of the spinal cord, lying in the centre of the spinal grey matter (see Fig. 27.1). Rostrally, the central canal extends into the caudal half of the medulla oblongata and then opens into the fourth ventricle.

Spinal grey matter

In transverse section, the spinal grey matter is often described as being 'butterfly-shaped' or resembling the letter 'H' (see Fig. 27.1). It consists of two dorsal horns, which project dorsolaterally, and two ventral horns, which project ventrolaterally towards the surface. The grey matter that immediately surrounds the central canal and unites the two sides constitutes the dorsal and ventral grey commissures. The dorsal horn is the site of termination of the primary afferent fibres that enter the cord via the dorsal roots of spinal nerves. The tip of the dorsal horn is separated from the dorsolateral surface of the cord by a thin tract (of Lissauer), in which branches of primary afferent fibres ascend and descend for a short distance before terminating in the subjacent grey matter. The ventral horn includes efferent motor neurones; their axons leave the spinal cord in ventral nerve roots. A small lateral or intermediate horn is present at thoracic and upper lumbar levels; it contains the cell bodies of preganglionic sympathetic neurones.

Spinal grey matter (**Fig. 27.2**) is a complex mixture of neuronal cell bodies, their processes and synaptic connections, neuroglia and blood vessels. Neurones in the grey matter are multipolar. They vary in size and features such as the length and the arrangement of their axons and

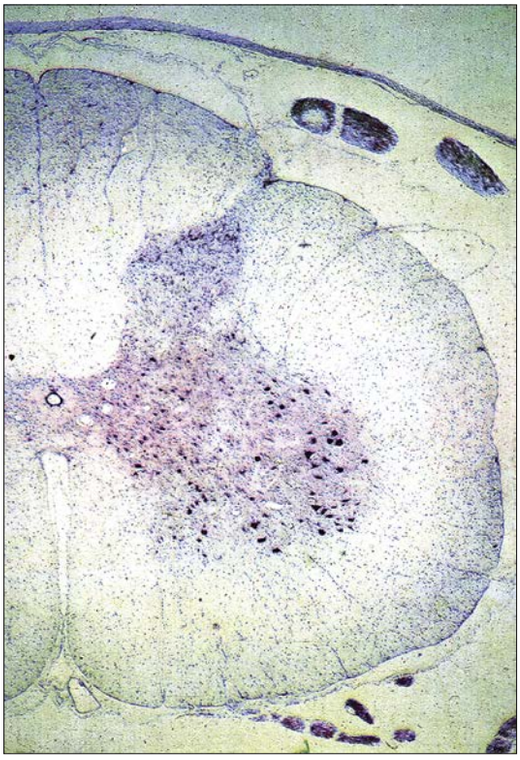

Fig. 27.2 A transverse section of a spinal cord at a mid-lumbar level. Groups of the larger motor neurones in the ventral grey column are prominent. Stained with cresyl fast violet.

dendrites. Neurones may be intrasegmental, i.e. contained within a single segment, or intersegmental, i.e. their ramifications spread through several segments. Research in a number of animal models has demonstrated groups of dorsal and ventral groups of interneurones, each with a characteristic genetic signature, some excitatory and some inhibitory. These different classes of interneurones have been demonstrated to be important for different reflex and locomotor activities (Kiehn 2016).

Neuronal cell groups of the spinal cord

The grey matter of the spinal cord may be divided, on the basis of cytoarchitecture, into nine zones, known as Rexed's laminae, which are numbered sequentially from dorsal to ventral, and an additional area X (**Fig. 27.3B**). The laminae are defined on the basis of neuronal size, shape, cytological features and density. Some of these laminae are equated with cell groupings of particular functional types (see Fig. 27.3B) (Rexed 1952, Mai and Paxinos 2011).

Laminae I–IV correspond to the dorsal part of the dorsal horn, and are the main site of termination of cutaneous primary afferent terminals and their collaterals. Many complex polysynaptic reflex paths (ipsilateral, contralateral, intrasegmental and intersegmental) start from this region, as also do many long ascending tract fibres that pass to higher levels. Lamina I (lamina marginalis) is a very thin layer with an ill-defined boundary at the dorsolateral tip of the dorsal horn. The much larger lamina II consists of densely packed small neurones that are responsible for its dark appearance in Nissl-stained sections. With myelin stains, lamina II is characteristically distinguished from adjacent laminae by the almost total lack of myelinated fibres. Lamina II corresponds approximately to the substantia gelatinosa. Laminae I and II are the primary termination for nociceptive peripheral afferents, and are also targets for descending projections from the cortex, brainstem and hypothalamus involved in modulatory control of these inputs. Lamina III consists of somata that are mostly larger, more variable and less closely packed than those in lamina II: it contains interneurones that transmit tactile and nociceptive afferent inputs to the cells of origin of ascending sensory pathways, including the dorsal columns and spinocervical tract. The ill-defined nucleus proprius of the dorsal horn corresponds to some of the cellular constituents of laminae III and IV. Lamina IV is a thick, loosely packed, heterogeneous zone permeated by fibres. Its neuronal somata vary considerably in size and shape, from small and round, through intermediate and triangular, to very large and stellate (Schoenen and Faull 1990). Laminae IV and V contain projection neurones that give rise to fibres in ascending pathways including the spinocervical and dorsal column pathways.

Laminae V and VI lie at the base of the dorsal horn. They receive most of the terminals of proprioceptive primary afferents, profuse corticospinal projections from the motor and sensory cortices, and input from subcortical levels, suggesting their involvement in the regulation of movement. Lamina V is a thick layer, divisible into a lateral third and medial two-thirds. Both have a mixed cell population but the former contains many prominent somata interlaced by numerous bundles of transverse, dorsoventral and longitudinal fibres. Lamina VI is particularly prominent in the limb enlargements and is mostly concerned with local and propriospinal projections. It has an intensely staining medial third of small, densely packed neurones and a lateral two-thirds containing larger, more loosely packed, triangular or stellate somata.

Lamina VII occupies the region just ventral to lamina VI and extends across the spinal grey matter on each side: this region is known as the intermediate zone throughout the cord. The size of lamina VII varies at different spinal levels. In the cervical and lumbar enlargements, it extends laterally and ventrally throughout the ventral horn, and cell groups of lamina IX neurones are embedded within it. In the thoracic region, lamina VII occupies the intermediate zone and the dorsal part of the ventral horn, and it includes the lateral horn. Lamina VII contains three important nuclear groups: the posterior thoracic nucleus (nucleus thoracis or Clarke's column, **Figs 27.3A,C**), which extends throughout the thoracic and upper lumbar segments and gives rise to the fibres of the dorsal spinocerebellar tract; the intermediolateral nucleus, which is located between T1 and L2 and gives rise to the preganglionic sympathetic fibres; and the intermediomedial nucleus, which extends the full length of the cord and may be involved in the control of visceral motor neurones (see Fig. 27.3).

Lamina VIII spans the base of the ventral horn in the thoracic region but is restricted to the medial aspect of the ventral horn in the cervical and lumbar enlargements. Its neurones display a heterogeneous mixture of sizes and shapes from small to moderately large. Lamina VIII is a mass of propriospinal interneurones. It receives terminals from the adjacent laminae, many commissural fibres from the contralateral lamina VIII, and descending connections from the interstitiospinal, reticulospinal, corticospinal and vestibulospinal tracts and the medial longitudinal fasciculus. The axons from these interneurones influence α motor neurone activity bilaterally, perhaps directly but also by reflex excitation of small γ motor neurones supplying efferent fibres to muscle spindles.

Lamina IX consists of several distinct groups or columns of somatic motor neurones located throughout the ventral horn. In the thoracic cord, these nuclear groups are embedded within lamina VIII, whereas the lamina IX cell groups are embedded within both lamina VII and lamina VIII in the cervical and lumbar enlargements. Lamina IX is a complex array of cells consisting of α and γ motor neurones and many interneurones. The large α motor neurones supply motor end-plates of extrafusal muscle fibres in striated muscle. Recording techniques have demonstrated the existence of tonic and phasic α motor neurones. Tonic α motor neurones have a lower firing rate and lower conduction velocity, and tend to innervate type S muscle units. Phasic α motor neurones have a higher conduction velocity and tend to supply fast twitch motor units, either fast-resistable (FR) or fast-fatigable (FF) types. The smaller γ motor neurones give rise to small-diameter efferent axons (fusimotor fibres), which innervate the intrafusal muscle fibres in muscle spindles. There are several functionally distinct types of γ motor neurone. The 'static' and 'dynamic' responses of muscle spindles have separate controls mediated by static and dynamic fusimotor fibres, which are distributed variously to nuclear chain and nuclear bag fibres (Boyd and Gladden 1985). β-motor neurones innervate both extrafusal and intrafusal fibres which constitute the skeletofusimotor innervation that is particularly prominent in human hand and wrist muscles.

Area X surrounds the central canal and is crossed by the dorsal and ventral grey commissures, which include the axons of commissural interneurones coordinating activity between the two sides of the spinal cord.

The Rexed system provides the classification of neuronal cell groups in the spinal grey matter when considered in transverse section. These cell groups are also organized into longitudinal columns (see Fig. 27.3), some of which have been mentioned already, such as the dorsal (posterior) thoracic nucleus (Clarke's column) and the motor neuronal columns located in different subgroups within lamina IX. There are also columns of neurones in the dorsal horn, including the nucleus proprius. The intermediolateral cell columns in lamina VII provide preganglionic parasympathetic and sympathetic outflows from the cord.

Dorsal horn

The dorsal horn is a major zone of termination of primary afferent fibres that enter the spinal cord through the dorsal roots of spinal nerves. Dorsal

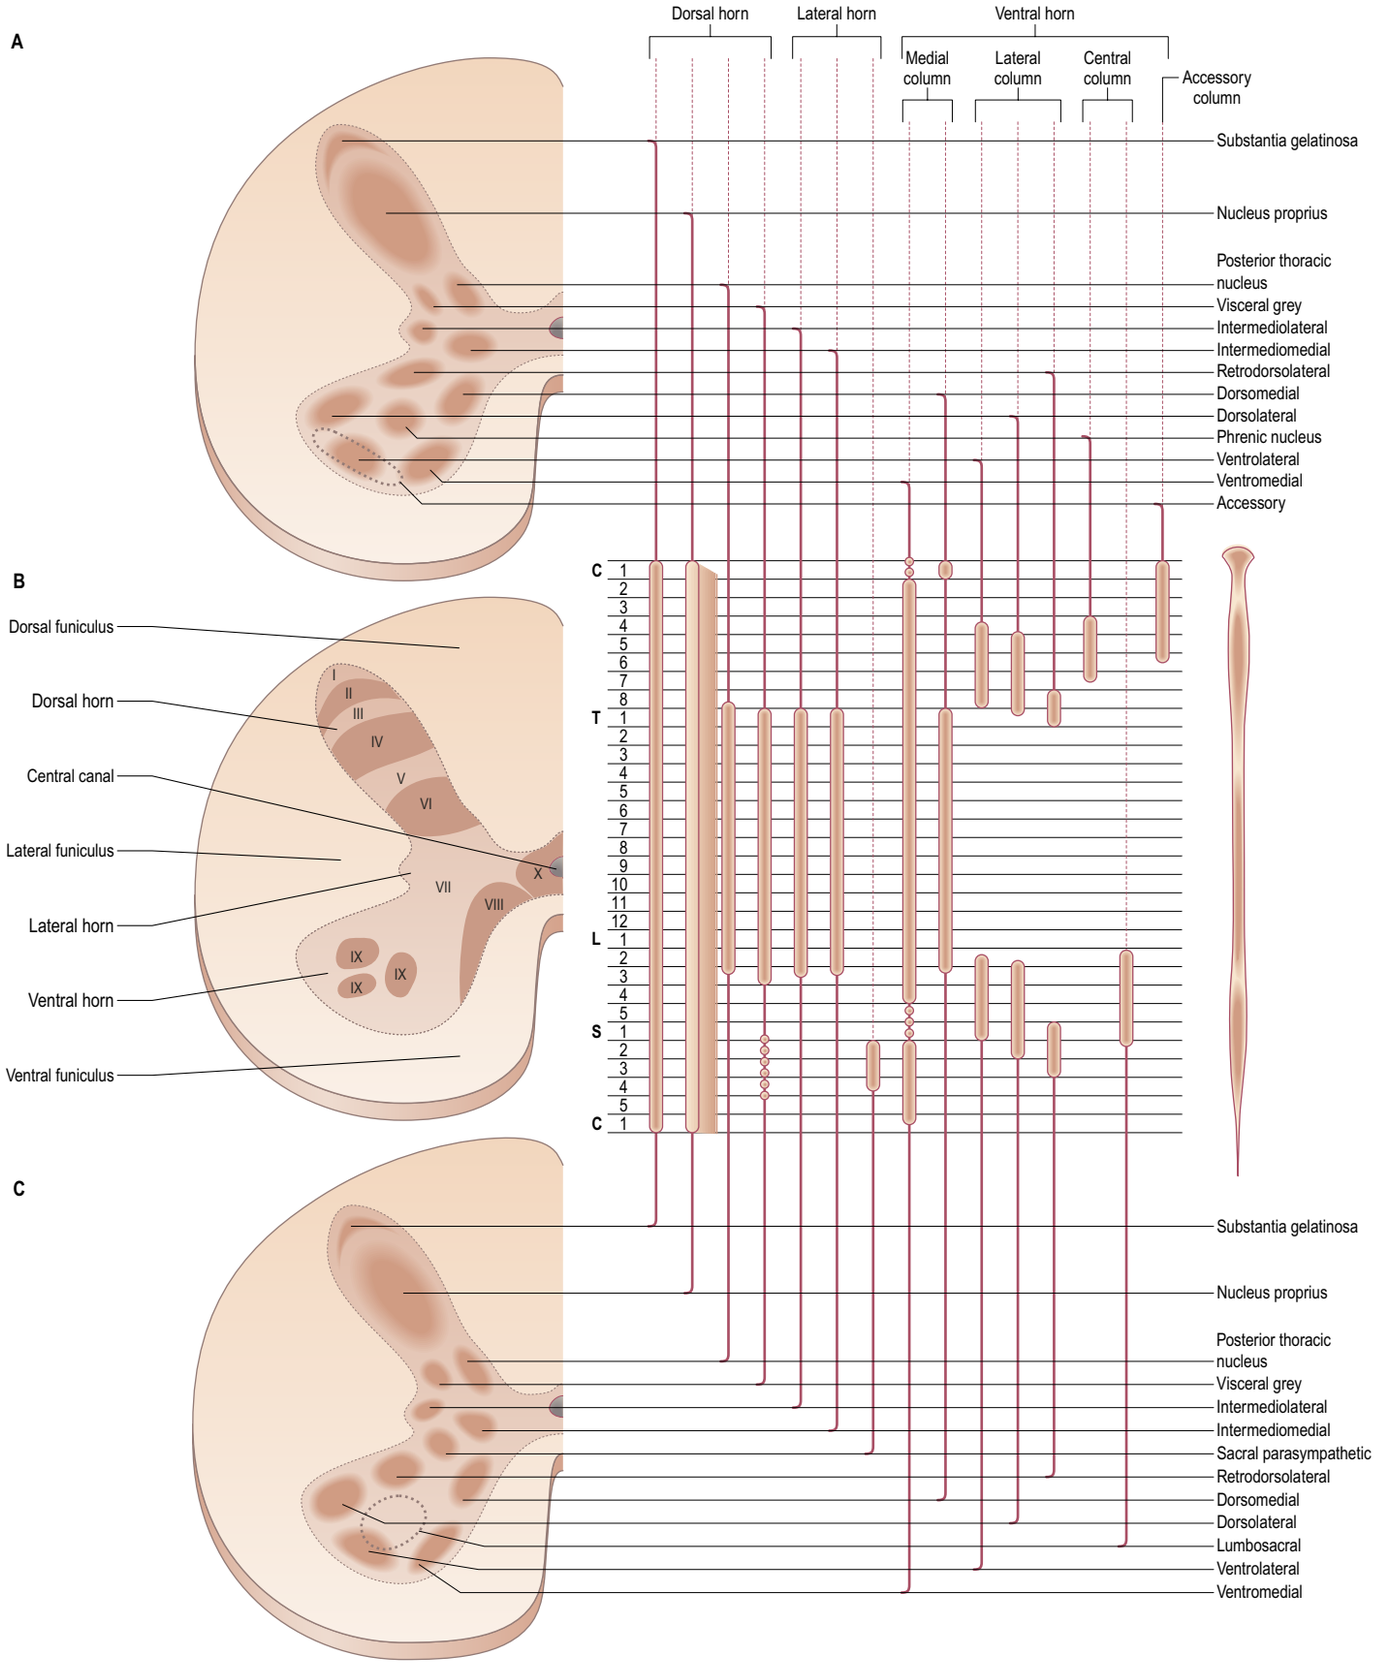

Fig. 27.3 The groups of nerve cells in the grey columns of the spinal cord. The relative positions of these columnar groups and their extent through spinal segments (C: cervical, T: thoracic, L: lumbar, S sacral, C: coccygeal) are indicated. **A** and **C** show the main cell groupings while **B** shows the system of Rexed laminae I–IX, and the white matter distributed in the dorsal, lateral and ventral funiculi. root fibres contain numerous molecules that are either known, or suspected, to fulfil a neurotransmitter or neuromodulator role. These include glutamic acid, substance P, calcitonin gene-related peptide (CGRP), bombesin, vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), somatostatin, dynorphin and angiotensin II (Mai and Paxinos 2011). Dorsal root afferents carry exteroceptive, proprioceptive and interoceptive information. Laminae I–IV are the main cutaneous receptive areas; lamina V receives fine afferents from the skin, muscle and viscera; lamina VI receives proprioceptive and some cutaneous afferents. Most, if not all, primary afferent fibres divide into ascending and descending branches on entering the cord that then travel for variable distances in the tract of Lissauer, near the surface of the cord, and send collaterals into the subjacent grey matter.

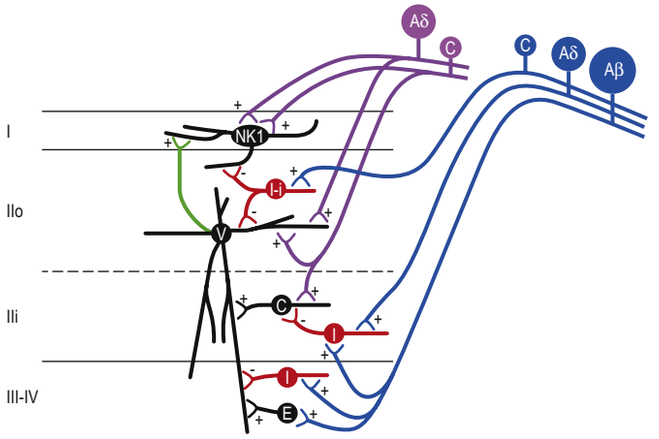

Fig. 27.4 Routes by which noxious (purple) and non-noxious (blue) primary afferent inputs may engage spinothalamic projection neurones in laminae I–IV of the dorsal horn. Nociceptive C and Aδ fibres (purple) activate neurokinin 1 (NK1)-expressing spinothalamic projection neurones of lamina I directly, and through the vertical cells (V) of the outer part of lamina II (IIo) indirectly (green axon). Nociceptive C fibres also activate central cells (C) of lamina II (IIi); the C cells contact, and probably excite, V cells in lamina IIo. Non-nociceptive Aβ fibres (blue) establish monosynaptic connections with local excitatory interneurones (E) of deeper laminae (III–IV), which directly activate V cells. These dorsally directed circuits are the route through which both noxious and non-noxious primary afferent input can engage the projection neurones of lamina I, which results in onward transmission in the spinothalamic tract. The excitatory circuits in the superficial dorsal horn are subject to profound inhibitory control (red), which allows for control of that onward transmission. For example, the majority of the inhibitory neurones (I) in lamina II are islet cells (I-i) and these can be directly engaged by input from low-threshold, mechanoreceptive C fibres (blue). The islet cells in turn establish monosynaptic inhibitory connections with both vertical cells of lamina IIo and NK1 receptor-expressing projection neurones of lamina I. Low-threshold Aδ and Aβ fibres (both in blue) also directly engage inhibitory interneurones in laminae IIi–IV. The latter in turn exert inhibitory control of a variety of excitatory interneurones, including vertical (V) and central (C) cells. According to the gate control theory the Aβ-to-inhibitory cell circuit is presumably responsible for closing the 'gate'. (Adapted with permission from Braz J, Solorzano C, Wang X et al 2014 Transmitting pain and itch messages: a contemporary view of the spinal cord circuits that generate gate control. Neuron 82:522–36.)

The lamina marginalis (lamina I) is a thin lamina of neurones at the dorsolateral tip of the dorsal horn, deep to the tract of Lissauer. Beneath it lies the substantia gelatinosa (laminae II), which is present at all levels and consists mostly of small neurones, with some larger neurones. The substantia gelatinosa receives afferents via the dorsal roots; its neurones give rise to fibres that form the contralateral spinothalamic tract. The large propriospinal neurones of the nucleus proprius lie ventral to the substantia gelatinosa within laminae III and IV and link segments for the mediation of intraspinal coordination (see Fig. 27.3).

The posterior thoracic nucleus can usually be identified from the eighth cervical to the third or fourth lumbar segments. It lies at the base of the dorsal horn within lamina VII, near the dorsal white funiculus, and may project into it. Neurones of the posterior thoracic nucleus vary in size but most are large, especially in the lower thoracic and lumbar segments; some send axons into the dorsal spinocerebellar tracts and some are interneurones.

Local circuitry mediating pain transmission

The gate control theory (GCT) of pain describes a mechanism by which nociceptive input from the skin is modulated ('gated') by local circuits within the dorsal horn and by descending inputs from the brain (Melzack and Wall 1965). According to the GCT, interneurones in the substantia gelatinosa modulate afferent input to spinothalamic tract projection neurones that mediate onward transmission of nociceptive information to the brain. Increased activity in the collaterals of large-calibre non-noxious afferents excite substantia gelatinosa cells, which in turn inhibit the tract cells, i.e. the 'gate' is closed. Activity in small-calibre nociceptive afferents have the opposite effect of inhibiting the substantia gelatinosa interneurones and opening the 'gate' to nociceptive inputs. The main elements in the circuitry by which noxious and non-noxious primary afferent inputs are thought to influence projection neurones within lamina I of the dorsal horn are shown in Fig. 27.4.

Interneurones in laminae I–IV are morphologically, topographically and neurochemically heterogeneous: islet, central, radial and vertical cells have been identified in experimental animal studies. Islet cells are predominantly GABAergic (transmitting or secreting γ-aminobutyric acid); a subset co-express glycine and are presumed to be exclusively inhibitory. Radial and vertical cells are predominantly glutamatergic and presumed to be excitatory, and central cells include both inhibitory and excitatory subsets. All these interneurones can influence the output from spinothalamic projection neurones in lamina I (NK1 in Fig. 27.4). The input from C fibre nociceptors is concentrated in lamina I and lamina II (see Fig. 27.4). Recent evidence has refocused attention on the concept of 'labelled lines' with each sensory modality processed via a fixed path from skin to brain. This applies to noxious heat, cold, noxious mechanical stimulation and pruritogens, at least at the level of the primary afferent input. (For further reading, see Ma (2010), Moayedi and Davis (2013), Todd and Koerber (2013), Zhang et al (2013), Braz et al (2014), Mendell (2014).)

Onward transmission in the lateral spinothalamic tract (see Fig. 27.10) evokes the perception of pain at supraspinal levels, although the activity of spinothalamic tract neurones is modulated by descending projections from the cortex and from a number of brainstem nuclei, which constitute an endogenous analgesic control system. In the mesencephalon, these regions are the periaqueductal grey matter, dorsal raphe nucleus and part of the cuneiform nucleus. Neurones in these sites contain 5-HT (5-hydroxytryptamine, serotonin), GABA, substance P, CCK, neurotensin, enkephalin and dynorphin. The periaqueductal grey matter receives afferents from the frontal, somatosensory and cingulate neocortices, the amygdala, numerous local reticular nuclei and the hypothalamus. Afferents from the latter are separate bundles that carry histamine, luteinizing hormone-releasing hormone (LHRH), vasopressin, oxytocin, adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone (γ-MSH), endorphin and angiotensin II. Some fibres descend from the periaqueductal grey matter to nuclei of the brainstem, while others pass directly to the spinal cord.

In the brainstem, the nucleus raphe magnus and the medial reticular column constitute an important multi-neuromodulation system, involving a number of different neurotransmitters and neuromodulators (see p. 454). Neurones in these sites contain 5-HT, substance P, CCK, thyrotrophin-releasing hormone (TRH), enkephalin and dynorphin; some neurones contain and release two or even three neurotransmitters. Descending corticospinal fibres from somatosensory cortex pass to the nucleus of the spinal tract of the trigeminal nerve and its continuation, the substantia gelatinosa. The latter extends throughout the length of the cord and contains populations of neurones that express many different neuromediators, e.g. GABA, substance P, neurotensin, enkephalin and dynorphin. There is abundant physiological and pharmacological evidence that all of these regions are intimately concerned with the control of nociceptive (and probably other modality) inputs.

Stimulation of forebrain sites, including the periventricular grey matter, the ventral posterolateral nucleus of the thalamus, and the primary sensory (S1) and posterior parietal cortices, inhibit spinothalamic tract neurones. In contrast, some spinothalamic tract neurones are excited by stimulation of the medullary reticular formation and the primary motor cortex, the latter effect probably being mediated by the corticospinal tract.

Lateral horn

The lateral horn is a small lateral projection of grey matter located between the dorsal and ventral horns in lamina VII. It is present from the eighth cervical or first thoracic segment to the second or third lumbar segment. It contains the cell bodies of preganglionic sympathetic neurones that develop in the embryonic cord dorsolateral to the central canal and migrate laterally, forming the intermediolateral cell columns. Their axons travel via ventral spinal roots and white rami communicantes to the sympathetic trunk. A similar cell group is found in the second to fourth sacral segments but, unlike the thoracolumbar lateral cell column, it does not form a visible lateral projection. It has long been regarded as the source of the sacral outflow of parasympathetic preganglionic nerve fibres: there is an alternative view that the sacral autonomic flow may be entirely sympathetic (Ch. 3) (Espinosa-Medina et al 2016, 2017, Horn 2018).

Ventral horn

The ventral horn is formed by laminae VII, VIII and IX. Laminae VII and VIII contribute to the intermediate zone, which is a major target for proprioceptive reflex afferents and descending motor pathways. The

Modern neuroimaging and molecular, genetic and behavioural studies confirm that the experience of pain involves a complex network of responsive brain regions. The somatosensory cortices (S1 and S2) and the insula are thought to encode the sensory features of pain, whereas the prefrontal cortex, components of the limbic system (anterior cingulate cortex, amygdala), the nucleus accumbens and the ventral tegmental area mediate the affective and contextual aspects of pain. Mechanisms underlying 'deep' visceral, muscular, neuropathic and persistent, chronic pain remain even less clear than those mediating cutaneous pain (Devor 2013). Patients with chronic pain may have anatomical alterations within the regions involved in the cognitive and emotional modulation of pain, e.g. the dorsolateral and medial prefrontal cortex, anterior cingulate gyrus and insula (Bushnell et al 2013, Denk et al 2014) and dysregulation of the descending pain modulation systems (Ossipov et al 2014).

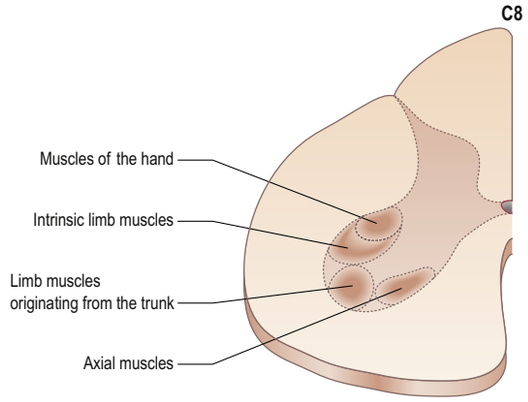

Fig. 27.5 The approximate location of motor neurone groups at the C8 segmental level of the spinal cord.

largest cell bodies in the ventral horn are those of lamina IX α motor neurones, which are multipolar and may range from 25 to 70 μm in diameter. Their axons emerge in ventral roots of spinal nerves to innervate extrafusal fibres in striated skeletal muscles. Large numbers of smaller neurones, 15–25 μm in diameter, are also present: some are γ motor neurones which innervate intrafusal fibres of muscle spindles, and the rest are interneurones. α and γ motor neurones that innervate a given muscle are intermixed and both types utilize acetylcholine as their neurotransmitter.

The motor neurones in lamina IX are organized into two major longitudinal columns, medial and lateral: in transverse section, they form the dorsomedial, ventromedial, dorsolateral and ventrolateral cell groups in the ventral horn (see Fig. 27.3A). The motor neurones of lamina IX are somatotopically organized according to a medial-to-lateral and a dorsal-to-ventral gradient. The basic arrangement is that medial cell groups innervate the axial musculature, and lateral cell groups innervate the muscles of the limbs. Motor neurones innervating flexor muscles are located dorsally and those innervating extensors are located ventrally. The classical work of George Romanes demonstrated further subdivisions of these longitudinally orientated cell groups and the importance of spatial codes in the location of motor neurones innervating particular muscles: motor neurones innervating a specific muscle are located together in longitudinal clusters within the column and have a constant coordinate position within the cord. Clusters of motor neurones innervating synergist muscles form neighbouring groups or 'columels' that conform, in a precise pattern, to the three major rostrocaudal, mediolateral and dorsoventral axes of limb organization. Work in mice suggests that this positional map involves a motor neurone transcriptional network engaging the action of several Hox proteins (Jessel et al 2011).

The medial nuclear group extends throughout the length of the spinal cord. Its neurones innervate epaxial muscle groups and hypaxial muscle groups. Epaxial muscles are extensors of the head and vertebral column and include the erector spinae group: they are innervated by branches of the dorsal primary rami of the spinal nerves. Hypaxial muscles are flexors of the head and vertebral column and include the prevertebral muscles of the neck and the intercostal and anterior abdominal wall muscles: they are innervated by branches of the ventral primary rami. In the medial column, motor neurones supplying epaxial muscles are sited ventral to those that supply hypaxial muscles.

The columns of the lateral nuclear group innervate the rest of the body musculature and their organization presents some segmental variations. In the thoracic region, the lateral group is small and innervates the lateral trunk muscles. In the cervical and lumbosacral enlargements, the lateral nuclear group is greatly enlarged and a number of subgroups may be distinguished, including the ventrolateral (anterolateral), dorsolateral (posterolateral), central and retrodorsolateral (retroposterolateral) groups.

In the cervical and lumbosacral enlargements, the lateral nuclear group innervates muscles of the upper and lower limbs, respectively. The somatotopic organization of the cervical ventral horn includes, clockwise from ventromedial to dorsolateral, α motor neurones to the muscles of the trunk, shoulder girdle, upper arm and lower arm and hand (**Fig. 27.5**). The proximal muscles of the limb are supplied from motor cell groups located more rostrally in the enlargement than those supplying the distal muscles, thus, motor neurones in C5 and C6 innervate shoulder muscles and motor neurones in C8 and T1 innervate the intrinsic muscles of the hand. There is a similar overall arrangement in

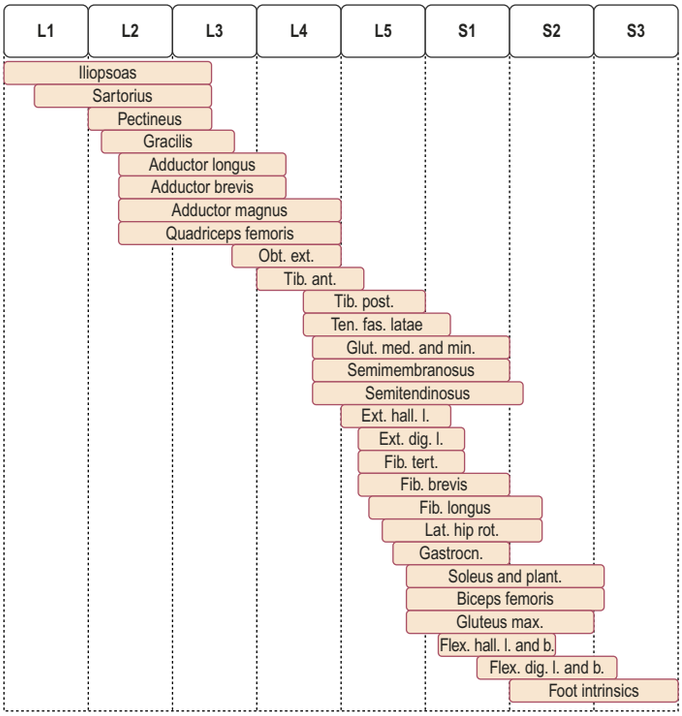

Fig. 27.6 The segmental arrangement of motor neurones innervating muscles of the lower limb. Abbreviations: Obt. ext., obturator externus; Tib. ant., tibialis anterior; Tib. post., tibialis posterior; Ten. fas. latae, tensor fasciae latae; Glut. med. and min., gluteus medius and minimus; Ext. hall. l., extensor hallucis longus; Ext. dig. l., extensor digitorum longus; Fib. tert., fibularis tertius; Fib. brevis, fibularis brevis; Fib. longus, fibularis longus; Lat. hip. rot., lateral hip rotators; Gastrocn., gastrocnemius; Soleus and plant., soleus and plantaris; Gluteus max., gluteus maximus; Flex. hall. l. and b., flexors hallucis longus and brevis; Flex. dig. l. and b., flexors digitorum longus and brevis.

the lumbosacral cord for motor neurones innervating the muscles in the lower limb (**Fig. 27.6**).

Other groups of neurones form a central column and an accessory column that can be identified at the cervical and lumbar levels. The phrenic nucleus, containing the motor neurones that innervate the respiratory diaphragm, forms the central column at the level of the third to fifth cervical segments. The same position is occupied by the lumbosacral nucleus that extends between the second lumbar and second sacral segment; its axons have an unknown distribution.

The spinal nucleus of the accessory nerve contains motor neurones that innervate sternocleidomastoid and trapezius. Described as a curvilinear band of motor neurones extending within the ventral horn from C1/2 to C5/6 (Orhan et al 2009, Saylam et al 2009) in line rostrally with the nucleus ambiguus of the medulla, the spinal nucleus of the accessory nerve is unusual not only for its position between the medial and lateral columns (Routal and Pal 2000) but also for its rootlets exiting the spinal cord just dorsal to the ligamentum denticulatum (Jenny et al 1988). They subsequently combine to form the intraspinal portion of the accessory nerve, which ascends the vertebral canal to enter the posterior cranial fossa via the foramen magnum. The supranuclear innervation of the spinal nucleus of the accessory nerve is uncertain. The bulk of current evidence favours bilateral hemispheric innervation of motor neurones in the rostral spinal nucleus of the accessory nerve (innervating sternocleidomastoid). Opinion varies as to the extent of the ipsilateral input: supranuclear control of the neurones in the caudal spinal nucleus of the accessory nerve (innervating the upper and middle fibres of trapezius) is thought to be predominantly contralateral. This pattern is analogous to the supranuclear innervation of the facial nerve motor nucleus.

The nucleus of Onuf (see Fig. 73.13), which is thought to innervate the perineal striated and sphincter muscles, is a ventrolateral (anterolateral) group of lamina IX in the first and second sacral segments.

The main afferent connections to motor neurones are direct monosynaptic connections from proprioceptive dorsal root afferents in the same or nearby segments; connections from axonal collaterals of dorsal horn and other interneurones, including Renshaw cells (which provide negative feedback control of α-motor neurones) and last-order excitatory and inhibitory interneurones; and direct monosynaptic connections from the vestibulospinal, reticulospinal and corticospinal tracts.

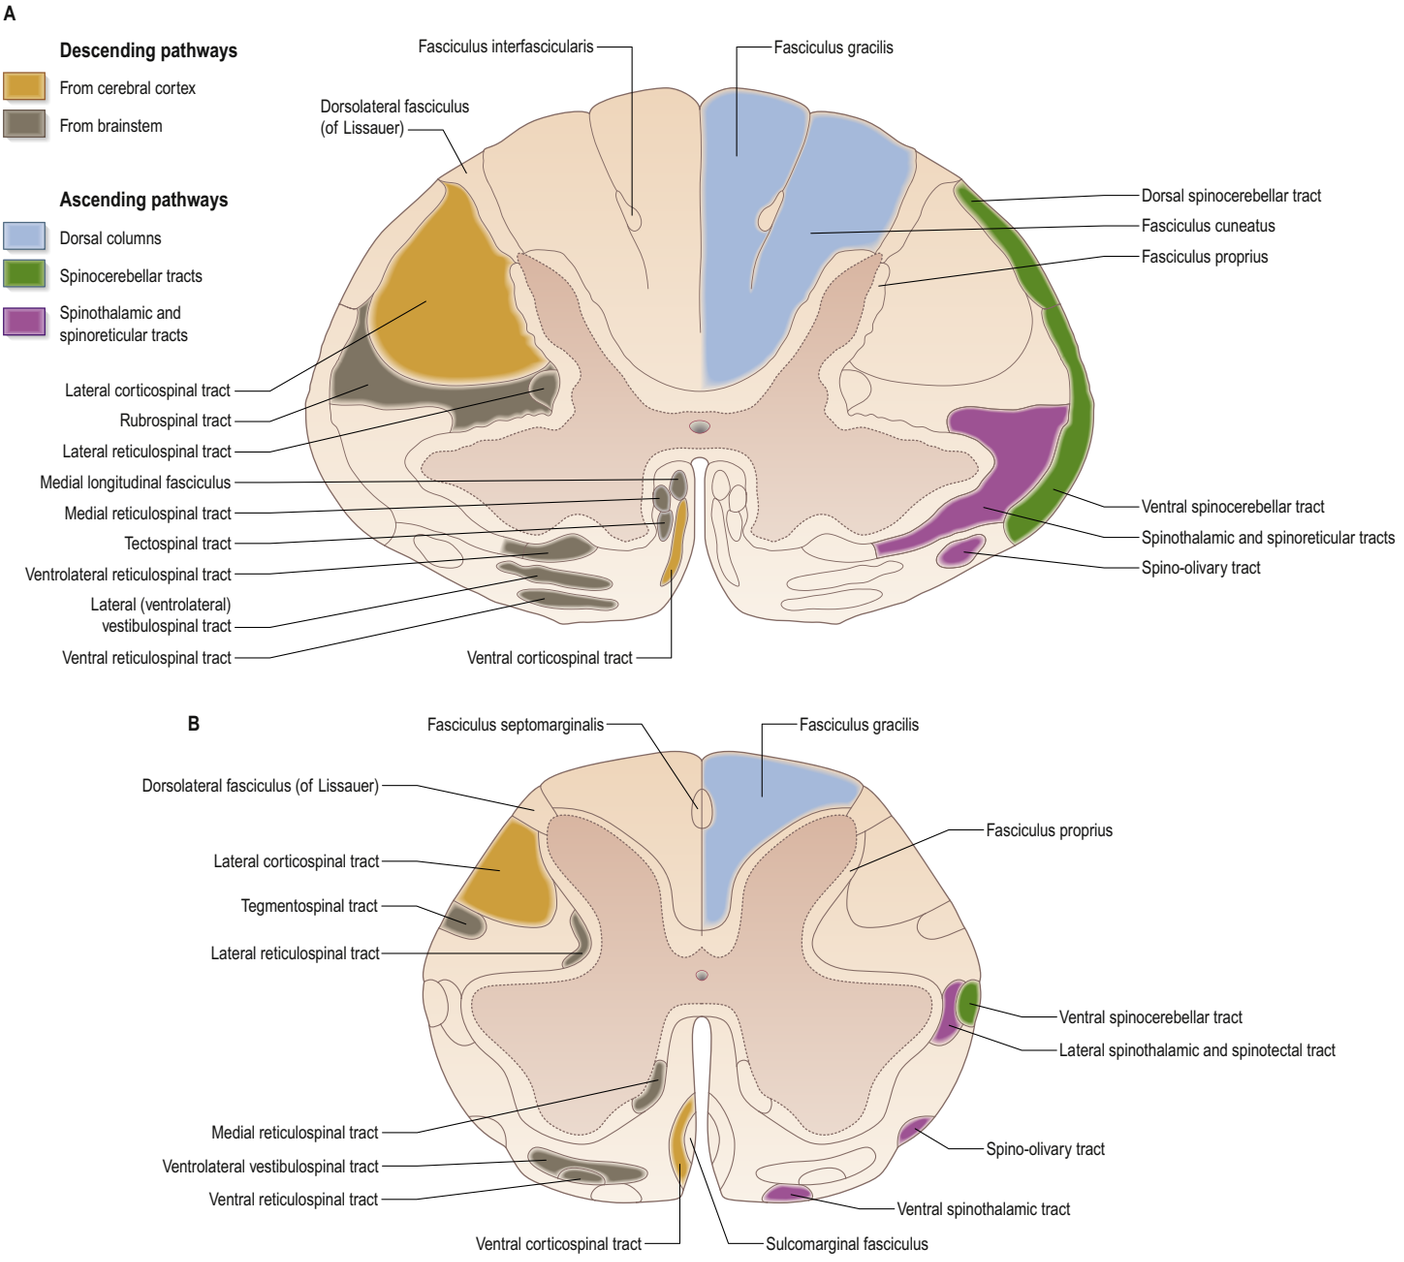

Fig. 27.7 The approximate positions of ascending and descending tracts in the spinal cord at mid-cervical (**A**) and lumbar (**B**) levels.

Spinal white matter

The spinal white matter surrounds the central core of grey matter and consists primarily of longitudinally running nerve fibres. Fibres subserving related functions, or those with common origins or destinations, are generally grouped together anatomically to form tracts (fasciculi), which may be ascending, descending or propriospinal. Ascending tracts carry afferent impulses to supraspinal levels and consist of either primary afferent fibres, which enter the cord via the dorsal roots of spinal nerves, or fibres derived from intrinsic spinal neurones. Descending tracts contain fibres that originate from cell bodies in the cerebral cortex or brainstem nuclei to control the activity of spinal neurones. Propriospinal tracts connect neurones that are localized entirely to the spinal cord and contain both ascending and descending components, collectively mediating intersegmental coordination.

The spinal white matter is conventionally described as being arranged into three large, bilaterally paired masses, the dorsal, lateral and ventral funiculi, each of which contains a number of specific tracts (see Figs 27.1, 27.3B, 27.7). The dorsal funiculus lies between the dorsal horn and the dorsal median septum. The lateral funiculus lies between the dorsal root entry zone and the site where the ventral roots emerge. The ventral funiculus lies between the ventral median fissure and the site where the ventral roots emerge. Narrow dorsal and ventral white commissures run close to the central canal and unite the two halves of the cord.

Fibres in the spinal white matter vary in calibre. Many are small and are either thinly myelinated or unmyelinated. Most regions contain a wide spectrum of fibre diameters, from 1 μm or less to 10 μm. Some tracts typically contain only small fibres, e.g. the dorsolateral tract, fasciculus gracilis and central part of the lateral funiculus. The fasciculus cuneatus, ventral funiculus and peripheral zone of the lateral funiculus all contain many large diameter fibres. The ascending and descending tracts are, to a large extent, discrete and regularly located (**Fig. 27.7**), but significant overlap between adjacent tracts does occur (Parent and Carpenter 1996).

Ascending pathways

Dorsal columns

The dorsal funiculus consists of two large ascending tracts, the fasciculus gracilis and fasciculus cuneatus (see Fig. 27.7; **Fig. 27.8**), which are also known as the dorsal columns. They are separated by a postero-intermediate septum. The dorsal columns contain a high proportion of myelinated fibres carrying proprioceptive (position sense and kinaesthesia), exteroceptive (touch-pressure) and vibratory sensation to higher levels. These fibres come from several sources: the central branches of primary afferent fibres that enter the cord in the dorsal roots of spinal nerves and ascend to the dorsal column nuclei in the medulla oblongata; shorter primary afferent fibres that project to neurones of the posterior thoracic nucleus and other spinal neurones; and axons of secondary

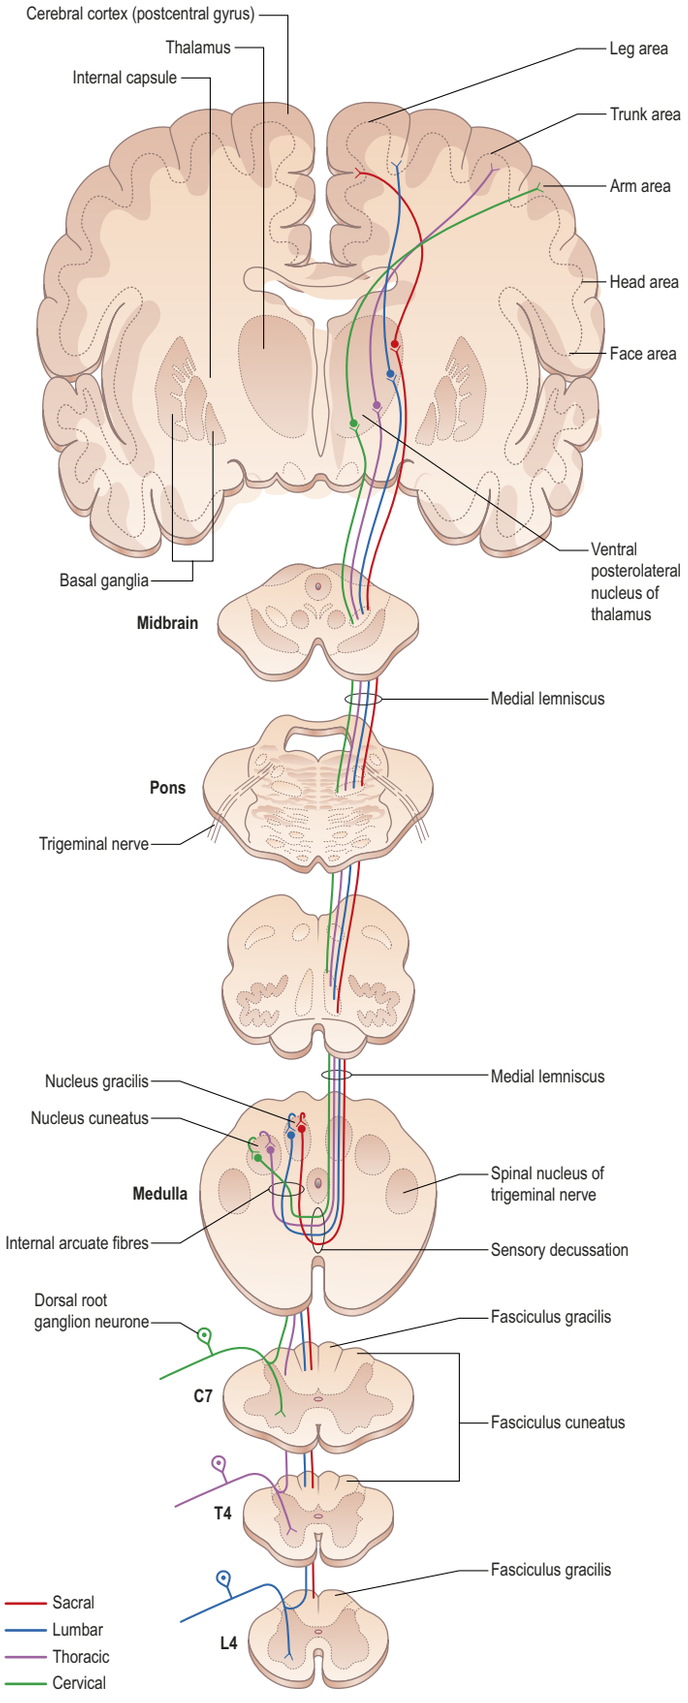

Fig. 27.8 The dorsal columns. Primary afferent fibres from different levels and their associated second- and third-order neurones are depicted in different colours.

neurones of the spinal cord ascending to the dorsal column nuclei. The dorsal columns also contain axons of propriospinal neurones.

The fasciculus gracilis begins at the caudal end of the spinal cord. It contains long ascending branches of primary afferents that enter the cord through ipsilateral dorsal spinal roots and ascending axons of secondary neurones in laminae IV–VI of the ipsilateral dorsal horn. As the fibres ascend, they are joined by axons of successive dorsal roots. Fibres entering in coccygeal and lower sacral regions are shifted medially by successive additions of fibres entering at higher levels.

The fasciculus gracilis lies medial to the fasciculus cuneatus in the upper spinal cord (see Fig. 27.7). At upper cervical levels, the fasciculus gracilis contains a larger proportion of afferents from cutaneous receptors than from deep proprioceptors because many of the latter leave the fasciculus at lower segments to synapse in the posterior thoracic nucleus (Clarke's column). Proprioception from the lower limb mainly reaches the thalamus by relaying in the posterior thoracic nucleus and then again in nucleus Z in the brainstem. Axons of the fasciculus gracilis, from both primary and secondary neurones, terminate in the nucleus gracilis of the dorsal medulla.

The fasciculus cuneatus (see Fig. 27.7) begins at mid-thoracic level and lies lateral to the fasciculus gracilis. It is composed mostly of primary afferent fibres of the upper thoracic and cervical dorsal roots. At upper cervical levels, it contains a large population of afferents from both proprioceptive and cutaneous receptors of the upper limb. Some of its axons arise from secondary neurones in laminae IV–VI of the ipsilateral dorsal horn. Many axons (both primary and secondary) that ascend in the fasciculus cuneatus terminate in the nucleus cuneatus of the dorsal medulla and some also end in the lateral (external or accessory) cuneate nucleus which projects to the cerebellum via the cuneocerebellar pathway.

Many ascending fibres of the fasciculus gracilis and fasciculus cuneatus terminate by synapsing on neurones of the dorsal column nuclei (nucleus gracilis and nucleus cuneatus, respectively) in the medulla oblongata (see Fig. 27.8). (The connections of the dorsal column nuclei are described further with the medulla oblongata in Ch. 28). Axons arising from neurones in the dorsal column nuclei arch ventromedially round the central grey matter of the medulla as internal arcuate fibres (see Fig. 28.7) and decussate in the great sensory decussation to form the medial lemniscus. They ascend to the ventral posterolateral nucleus of the thalamus, from where neurones project to the somatosensory cortex in the postcentral gyrus of the parietal lobe (areas 1, 2 and 3). Some neurones of the dorsal column nuclei form posterior external arcuate fibres that enter the cerebellum.

A high degree of somatotopic organization is preserved as the pathways ascend from the dorsal columns to the primary somatosensory cortex (see Fig. 27.8). The orientation of the somatotopic organization changes at different levels. In the dorsal column nuclei, the lower limb is represented medially in the nucleus gracilis, the upper limb laterally in the nucleus cuneatus, and the trunk in an intermediate position between them. Within the medial lemniscus at the level of the medulla, the lower limb is represented ventral to the trunk and upper limb. This representation rotates at the level of the pons and becomes the reverse of the spinal arrangement. Fibres are also segregated by modality in the dorsal columns: fibres from hair receptors are most superficial, and fibres from tactile and vibratory receptors lie in deeper layers.

Spinocerebellar tracts

The dorsal and ventral spinocerebellar tracts occupy the periphery of the lateral funiculi (see Fig. 27.7; **Fig. 27.9**) and carry proprioceptive and cutaneous information to the cerebellum for the coordination of movement. The dorsal tract has a greater number of large diameter myelinated fibres and more small calibre fibres are present in the ventral tract.

The dorsal spinocerebellar tract lies lateral to the lateral corticospinal tract. Its axons originate ipsilaterally from the larger neurones of the posterior thoracic nucleus located in lamina VII of spinal segments T1–L2. The posterior thoracic nucleus receives input from primary afferents ascending from segments caudal to L2. In the medulla, the dorsal spinocerebellar tract passes through the restiform body and the inferior cerebellar peduncle and terminates ipsilaterally in the rostral and caudal parts of the cerebellar vermis.

The ventral spinocerebellar tract lies lateral to the rubrospinal, spinothalamic and spinoreticular tracts. The cells of origin are in laminae V–VII of the lumbosacral cord and the tract carries proprioceptive information from the lower limb. Unlike the dorsal spinocerebellar tract, most of the axons forming the ventral spinocerebellar tract decussate at their origin and then again before their termination; some remain ipsilateral. The tract begins in the upper lumbar region, ascends through the medulla oblongata to reach the upper pontine level and then descends in the dorsal part of the superior cerebellar peduncle to terminate, mainly contralaterally, in the anterior cerebellar vermis.

The rostral spinocerebellar tract originates from cell groups of the intermediate zone of the contralateral cervical enlargement and is considered to be the upper limb and upper trunk equivalent of the ventral spinocerebellar tract.

Experimental tracing studies in animals have demonstrated a cervicospinocerebellar tract arising from a central cervical nucleus in the upper cervical spinal cord (C1–C4); the central cervical nucleus, possibly Cajal's nucleus intermedius, receives primary afferents from the vestibular labyrinth and muscle afferents from the deep muscles of the neck. A similar pathway may exist in humans where the nucleus intermedius of Cajal receives fibres from only the upper two cervical roots (Marani and Schoen 2005).

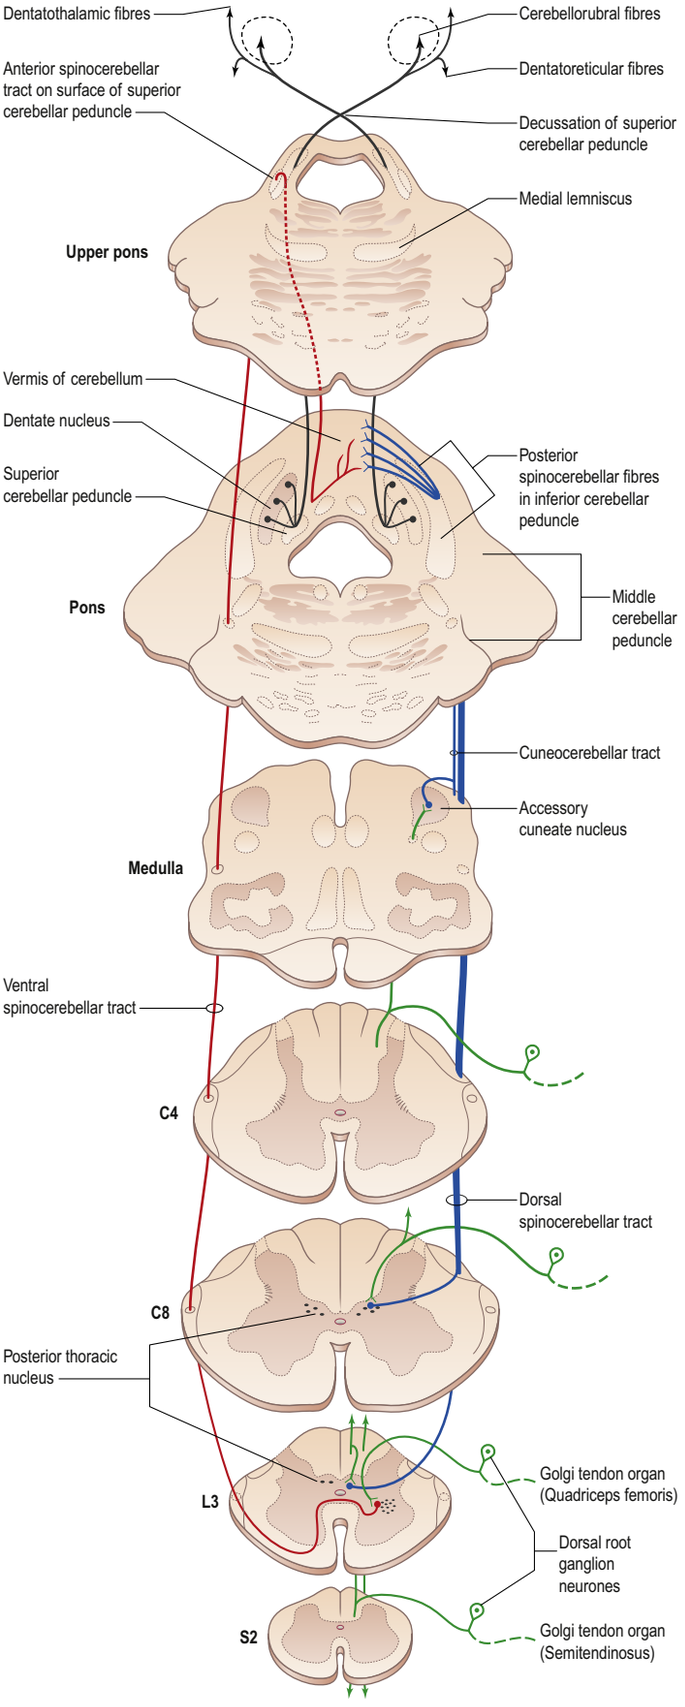

Fig. 27.9 The spinocerebellar tracts. (Adapted with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th ed. Baltimore: Williams and Wilkins.)

The dorsal and ventral spinocerebellar tracts are organized such that fibres from lower spinal segments are most superficial. Both tracts convey proprioceptive and exteroceptive information, but they are functionally different. Neurones of the posterior thoracic nucleus are excited monosynaptically by group Ia and Ib primary afferent fibres (from muscle spindles and tendon organs, respectively) and also by group II muscle afferents and cutaneous touch and pressure afferents. The proprioceptive impulses often arise from a single muscle or from synergistic muscles acting at a common joint. Thus, the dorsal spinocerebellar tract transmits modality-specific and space-specific information that is used in the fine coordination of individual limb muscles. On the other hand, the cells of the ventral tract are activated monosynaptically by Ib afferents and transmit information from large receptive fields that include different segments of a limb. The ventral tract lacks subdivisions for different modalities and transmits information for the coordinated movement and posture of the entire lower limb.

Since the posterior thoracic nucleus diminishes rostrally (see Fig. 27.3) and does not extend above the lowest cervical segment, it follows that the dorsal spinocerebellar tract carries information from the trunk and lower limb. Proprioceptive and exteroceptive information from the upper limb travel in primary afferent fibres of the fasciculus cuneatus. These fibres end somatotopically in the accessory (external or lateral) cuneate nucleus and the adjoining part of the cuneate nucleus situated in the medulla oblongata. Cells of these nuclei give rise to the posterior external arcuate fibres that form the cuneocerebellar tract (see Fig. 27.9), which enters the cerebellum via the ipsilateral inferior cerebellar peduncle. The cells in the accessory cuneate nucleus and the lateral part of the cuneate nucleus are considered to be homologous to the cells in the posterior thoracic nucleus. The cuneocerebellar tract is therefore functionally allied to the dorsal spinocerebellar tract and is its upper limb equivalent.

Axons of all the spinocerebellar tracts and the cuneocerebellar tract form part of the 'mossy-fibre system' and end in the cerebellar cortex in a highly somatotopically and functionally organized pattern (Ch. 29).

Spinothalamic tracts

Some authorities describe two spinothalamic tracts (lateral and ventral) with more or less distinct anatomical locations and functions. However, physiological studies in animals suggest that these tracts may be best considered as a structural and functional continuum. The spinothalamic tracts (see Fig. 27.7) consist of second-order neurones that convey pain, temperature, coarse (non-discriminative) touch and pressure information to the thalamus. The cells of origin lie in a wide range of spinal laminae and are found in all segments of the spinal cord. Fibres decussate in the ventral white commissure to reach the contralateral spinothalamic tract. Pain and temperature fibres do so promptly, within about one segment of their origin, whilst fibres carrying other modalities may ascend for several segments before crossing. Spinothalamic fibres mostly ascend in the white matter of the lateral and ventral funiculi.

The lateral spinothalamic tract (**Fig. 27.10**) is sited in the lateral funiculus, lying medial to the ventral spinocerebellar tract. Clinical evidence indicates that it subserves sensations of pain and temperature. The anterior (ventral) spinothalamic tract (see Fig. 27.10) lies in the ventral funiculus medial to the point of exit of the ventral spinal nerve roots and dorsal to the vestibulospinal tract, which it overlaps: on the basis of clinical evidence, it subserves coarse tactile and pressure modalities.

On reaching the lower brainstem, spinothalamic tract axons separate. Axons in the ventral tract join the medial lemniscus and axons in the lateral tract continue as the spinal lemniscus.

It is claimed that a somatotopic organization of the fibres in the spinothalamic tracts exists throughout their extent. Fibres crossing at any cord level join the deep aspect of those that have already crossed. Somatotopy is maintained throughout the medulla oblongata and pons. In the midbrain, fibres in the spinal lemniscus conveying pain and temperature sensation from the lower limb extend dorsally, while those from the trunk and upper limb are more ventrally placed: both lemnisci ascend to end in the thalamus. The major spinothalamic projections in humans are to the ventral posterolateral nucleus and centrolateral intralaminar nucleus.

Neurones of the spinothalamic tracts

The specific localization of spinothalamic tract cell bodies is poorly documented in humans. In animals, about one-third are localized to the upper three cervical segments, about 20% are located in lower cervical segments, 20% in the thoracic region (mostly in segments T1–T3), 20% in the lumbar region and 10% in the sacrococcygeal cord. Cells are located in laminae I and IV–VIII, the greatest concentration being in laminae VI and VII. Cell bodies giving rise to spinothalamic tract axons are predominantly contralateral, although a relatively small number (10%), mostly in the upper three cervical segments, are ipsilateral.

Neurones of the spinothalamic tracts have varied receptive fields. Specificity of separate types of afferents, as exists in the dorsal column nuclei, is absent in the spinothalamic nuclei; convergence of different

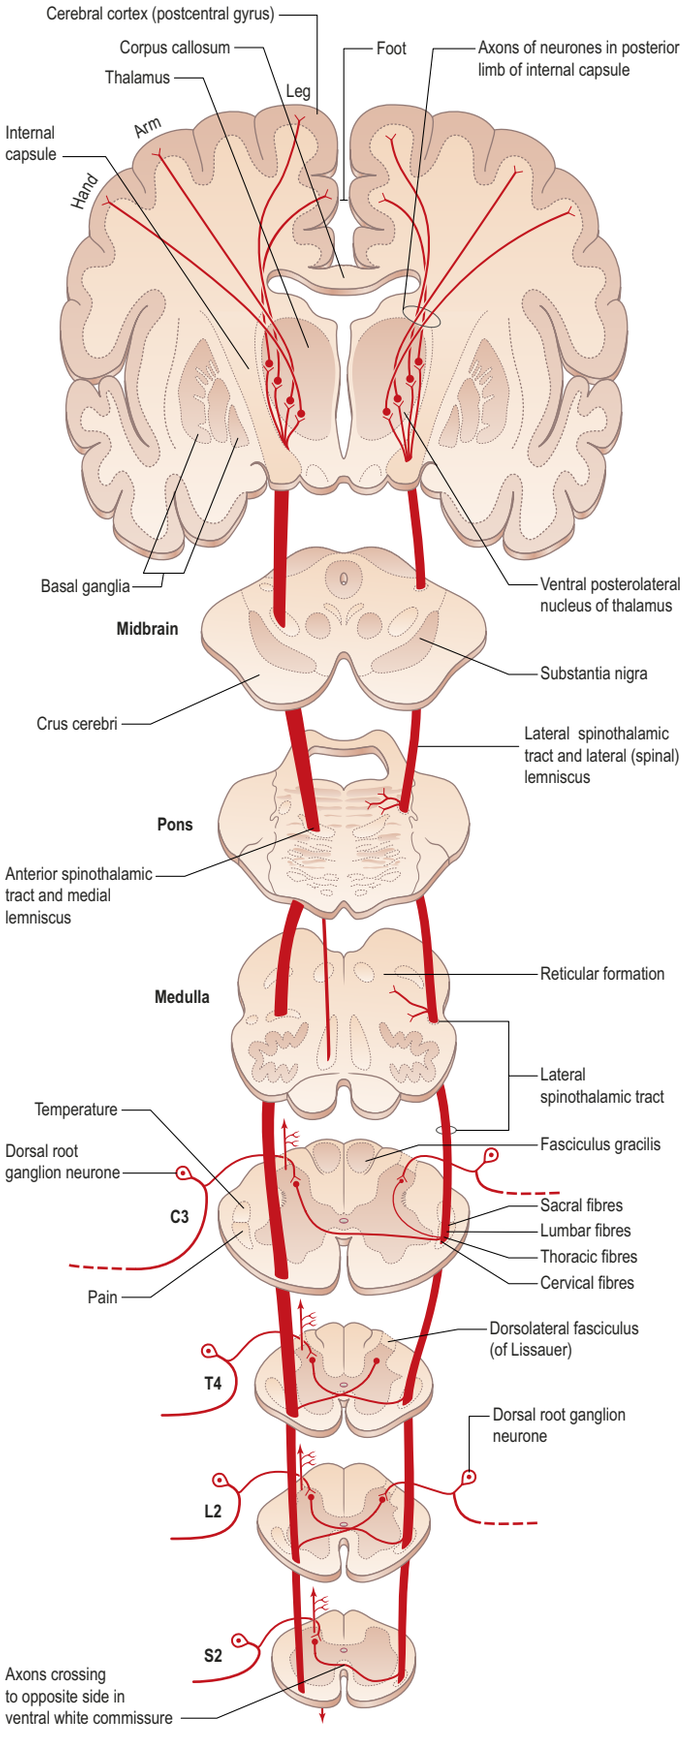

Fig. 27.10 The lateral and ventral (anterior) spinothalamic tracts. (Adapted with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th ed. Baltimore: Williams and Wilkins.)

functional types of afferent fibres onto an individual tract cell is a common feature in the cord. On the basis of laminar site, functional properties, and specific thalamic termination of their axons, spinothalamic tract neurones may be divided into three separate groups: the apical cells of the dorsal horn (lamina I), deep dorsal horn cells (laminae IV–VI), and cells in the ventral horn (laminae VII and VIII). There are species differences and the description above is derived from studies in non-human primates.

Spinoreticular pathway

Spinoreticular fibres are intermingled with those of the spinothalamic tracts and ascend in the ventrolateral quadrant of the spinal cord (see Fig. 27.7, Fig. 27.14). Evidence from animal studies suggests that cells of origin occur at all levels of the spinal cord, particularly in the upper cervical segments. Most neurones are in lamina VII, some are in lamina VIII, and others are in the dorsal horn, especially lamina V. Most axons in the lumbar and cervical enlargements cross the midline; there is a large uncrossed component in cervical regions. Most axons are myelinated. The pattern of anterograde degeneration, in both human postmortem studies and in experimental animals following anterolateral cordotomy, indicates the existence of spinoreticular projections to many nuclei of the medial pontomedullary reticular formation. There is also a projection to the lateral reticular nucleus (a precerebellar relay nucleus). These projections do not appear to be somatotopically organized. Spinoreticular neurones respond to inputs from the skin or deep tissues. Non-noxious cutaneous stimuli may inhibit or excite a particular cell, whereas noxious stimuli are often excitatory. A spino-reticulothalamo-cortical pathway has been proposed as an important route serving pain perception: like other ascending pathways, the tract cells are influenced by descending control. For example, electrical stimulation of the periaqueductal grey matter inhibits the responses of certain spinoreticular cells to input from cardiopulmonary afferents. Stimulation of the reticular formation also alters the activity of spinoreticular neurones.

Spinocervicothalamic pathway

In humans, the lateral cervical nucleus is small and lies in the lateral funiculus, ventrolateral to the dorsal horn in the upper two cervical segments. In some human cord specimens it is not distinctly defined and is possibly incorporated into the dorsal horn. The lateral cervical nucleus receives axons from the spinocervical tract that ascends in the dorsolateral funiculus. The tract cells are found in laminae III–V at all levels of the spinal cord, ipsilateral to the nucleus. Most neurones of the nucleus project to the contralateral thalamus via the medial lemniscus, and some project to the contralateral midbrain. Specific thalamic targets include the ventral posterolateral nucleus and part of the posterior complex. Spinocervical tract neurones respond to hair movement, pressure, pinch and thermal stimuli and to high-threshold muscle input; many also respond to noxious stimuli. Like the tract cells of other ascending pathways, they are under tonic descending inhibitory control.

Descending tracts

Descending pathways to the spinal cord originate primarily from the cerebral cortex and from numerous sites within the brainstem (see Figs 27.11–27.14). They are concerned with the control of movement, muscle tone and posture, the modulation of spinal reflex mechanisms and central pattern generators, and the modulation of transmission of afferent information, including nociceptive input, to higher levels. They also mediate control over spinal autonomic neurones and have long-term trophic functions (Kuypers 1981, Lemon 2008). A generalized scheme of the organization of the descending pathways is given in **Fig. 27.11**.

Corticospinal and corticonuclear tracts

Corticospinal and corticonuclear (corticobulbar) fibres arise from neurones in the cerebral cortex. They project to neurones located in the spinal cord or brainstem, respectively (**Fig. 27.12**). Corticonuclear projections include those to the cells of origin of other descending pathways (such as the reticulospinal tract), to cranial motor nuclei, and to cell groups such as the dorsal column nuclei. The majority of corticospinal and corticonuclear fibres arise from cells situated in the primary motor cortex (area 4), premotor cortex and supplementary motor areas (area 6), and cingulate motor cortex (area 24). A significant contribution comes from cells in the postcentral gyrus (somatosensory cortex; areas 3, 1 and 2) and the adjacent parietal cortex (area 5). In the monkey, 30% of corticospinal fibres arise from area 4, 30% from area

Lamina I cells project to the thalamus. They respond maximally to noxious or thermal cutaneous stimulation and consist mainly of high-threshold but also some wide-dynamic-range units (responding to various different intensities of stimulus). Their receptive fields are usually small, representing a part of a digit or a small area of skin involving several digits. Lamina I spinothalamic tract neurones receive input from Aδ and C fibres, and some respond to convergent input from deep somatic and visceral receptors. Spinothalamic tract cells in the thoracic cord display marked viscero-somatic convergence and so, for example, pain from cardiac disease such as angina or a myocardial infarction is commonly felt as a tightness around the chest wall (referred pain). Lamina I spinothalamic tract neurones project via the lateral spinothalamic tract and terminate preferentially in the ventral posterolateral nucleus of the thalamus, with limited projections to the centrolateral intralaminar and mediodorsal thalamic nuclei. These projections are probably concerned with affective aspects of pain sensation.

The spinothalamic neurones of the deep dorsal horn (laminae IV–VI) are of varied types. In the lumbar cord, for example, 60% are wide-dynamic-range types, 30% are high-threshold and only 10% are low-threshold types. They can accurately code both non-noxious and noxious cutaneous stimuli. Some cells also respond to input from deep somatic and visceral receptors. In the lumbar cord, their receptive fields are small or medium-sized: they are larger than the area of the foot but smaller than the entire leg. In the thoracic cord, the fields of these laminar cells are larger and often include the entire upper limb plus part of the chest. Many of the deep dorsal grey column spinothalamic tract neurones in the thoracic segments receive convergent input from visceral afferent fibres. Spinothalamic axons from laminae IV–VI project via the anterior (ventral) spinothalamic tract either to the ventral posterolateral nucleus or to the centrolateral intralaminar nucleus of the thalamus, and sometimes to both. Units projecting to the ventral posterolateral nucleus receive input from all classes (Aβ, Aδ and C) of cutaneous fibres.

Spinothalamic neurones in the ventral horn (laminae VII and VIII) respond mainly to deep somatic (muscle and joint) stimuli but also to non-noxious and/or noxious cutaneous stimuli. In the thoracic regions of the spinal cord, they also receive convergent input from visceral sources. The majority of these neurones have large, complex receptive fields (often bilateral), which encompass widespread areas of the body. Cells of this group receive input from Aβ, Aδ and C classes of afferent fibres, and many respond to convergent input from receptors of deep structures. This population of neurones contains wide-dynamic-range (25%), high-threshold (63%) and low-threshold (12%) units. Most of the spinothalamic axons from the ventral horn project to the intralaminar nuclei of the thalamus, and these are again related to affective aspects of pain sensation. The wide-dynamic-range type of neurones are particularly effective for discriminating between different intensities of painful stimulation.

The spinomesencephalic pathway consists of a number of tracts ascending from the spinal cord to various regions of the midbrain. It includes the spinotectal tract projecting to the superior colliculus, neurones synapsing in the periaqueductal grey matter, and other spinal cord projections that terminate in the parabrachial nucleus, the pretectal nuclei and the nucleus of Darkschewitsch. Cells of origin are located throughout the length of the spinal cord, particularly in the cervical segments and the lumbosacral enlargement, mostly in lamina I, but they are also present in laminae IV–VIII, where they are concentrated in lamina V. Most are contralateral, but a prominent ipsilateral group is also found at upper cervical levels. Spinomesencephalic fibres are mostly myelinated and ascend in the white matter of the ventrolateral quadrant of the spinal cord, in association with the spinothalamic and spinoreticular tracts.

Spinomesencephalic neurones are of low-threshold, wide-dynamic-range or high-threshold classes. Their receptive fields may be small, or very complex and encompass large surface areas of the body. Many spinomesencephalic cells are nociceptive and are likely to be involved in the motivational–affective component of pain. Electrical stimulation of their site of termination in the periaqueductal grey matter results in severe pain in humans. The cells of the deeper layers of the superior colliculus, where spinotectal fibres synapse, are activated by noxious stimuli.

The spino-olivary tract is described in animals as arising from neurones in the deeper laminae of grey matter. Axons forming the tract cross and then ascend superficially at the junction of the ventral and lateral white funiculi, to end in the dorsal and medial accessory olivary nuclei. The tract carries information from muscle and tendon proprioceptors and from cutaneous receptors. A functionally similar route, the dorsal spino-olivary tract, ascends in the dorsal white funiculi and relays in the dorsal column nuclei to the contralateral inferior olivary nucleus. Information on these tracts in primates is scant, but postmortem evidence following cordotomies in humans has revealed degenerating axonal terminals in the inferior olivary nucleus.

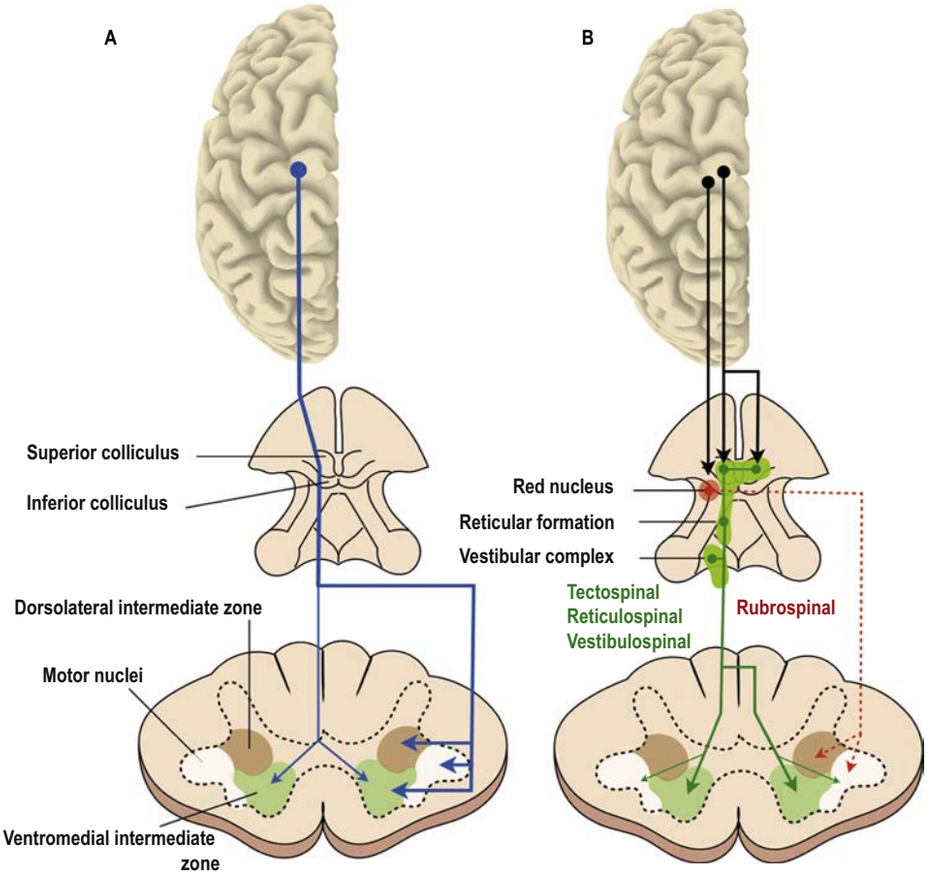

Fig. 27.11 Schematic representation of the main descending pathways. The distribution of fibres belonging to the (**A**) corticospinal system (blue) and (**B**) dorsolateral (red) and ventromedial (green) brainstem pathways, according to the scheme proposed by Kuypers (1981). For simplicity, descending projections from the cortex in **A** and **B** are shown arising from the motor cortex, but in fact they arise from widespread frontal and parietal areas (see text). Some uncrossed fibres in the anterior corticospinal tract terminate bilaterally in the ventromedial intermediate zone (lamina VIII; green shading in spinal sections). The majority of corticospinal fibres decussate and descend in the lateral corticospinal tract, terminating contralaterally in the dorsolateral intermediate zone (lamina VII; brown shading), with some projecting to lamina VIII (green) and many terminating directly on motor neurones innervating the arm and hand (lamina IX; white area). In **B**, ventromedial fibre pathways (reticulospinal, tectospinal, vestibulospinal) are shown in green, arising from the brainstem reticular formation, superior colliculus, and vestibular complex, respectively. These fibres terminate, for the most part, bilaterally in the ventromedial intermediate zone (green shading), but also have direct projections to motor neurones supplying trunk and girdle muscles, and some projections to hand and forearm motor neurones (green arrows extending into lateral lamina IX, white area). The dorsolateral pathways include the rubrospinal tract (red) which arises from the magnocellular red nucleus; its fibres terminate contralaterally in the dorsolateral region of the intermediate zone (brown shading), with some projections to the lateral group of motor nuclei innervating the arm and hand. The existence of a rubrospinal tract in humans has not been established, so the pathway is shown by dashed red lines. All of the nucleii giving rise to brainstem pathways receive significant cortical projections (black). (Adapted with permission from Lemon RN 2008 Descending pathways in motor control Ann Rev Neurosci 31:195–218.)

6 and 40% from the parietal regions. The cells of origin of corticospinal and corticonuclear fibres vary in size according to their cortical origins and are clustered into groups or strips. The largest neurones (giant pyramidal neurones; Betz cells) are located in the primary motor cortex of the precentral gyrus, with most of them located in the leg, and to a lesser extent in the hand/arm area. Each corticospinal neurone has an axon that branches and contacts a number of different target structures at cortical, subcortical and spinal levels.

Corticospinal and corticonuclear fibres descend through the subcortical white matter to enter the genu and posterior limb of the internal capsule. They then pass through the ventral part of the midbrain in the crus cerebri. As they continue caudally through the pons, they are separated from its ventral surface and fragmented into fascicles by transversely running pontocerebellar fibres. Corticopontine fibres, which are far more numerous than corticospinal or other corticonuclear fibres, terminate in the different divisions of the pontine nuclei (see Fig. 29.34). Corticonuclear fibres terminate on cranial nerve and other nuclei of the midbrain, pons and medulla. In the medulla oblongata, the cortical efferent fibres destined for the spinal cord (corticospinal fibres) form a discrete bundle (the pyramid) on the ventral surface of the medulla: the corticospinal tract is therefore also referred to as the pyramidal tract (see Fig. 28.4). Each pyramid contains about a million axons of various diameters: the majority have a diameter of 1–4 μm and are myelinated, approximately 10% have diameters of 5–10 μm and an even smaller number have diameters of 11–22 μm. The largest diameter axons probably arise from the giant pyramidal neurones (Betz cells) of the primary motor cortex. The function of the smallest fibres is unknown.

Just rostral to the spinomedullary junction, approximately 90% of the corticospinal fibres in the pyramid cross the midline in the decussation of the pyramids and continue caudally as the lateral corticospinal tract. About 10% of the fibres continue ipsilaterally as the ventral corticospinal tract and a small fraction descend ipsilaterally in the lateral corticospinal tract. The lateral corticospinal tract (see Fig. 27.12) descends in the lateral funiculus throughout most of the length of the spinal cord until about the fourth sacral segment. It occupies an oval area, ventrolateral to the dorsal horn and medial to the dorsal spinocerebellar tract (see Fig. 27.7). In the lower lumbar and sacral regions, where the dorsal spinocerebellar tract is absent, the lateral corticospinal tract reaches the dorsolateral surface of the cord. Studies in both human and non-human primates show that axons derived from the different cortical areas giving rise to the corticospinal tract (Brodmann's areas 4, 6 etc.) remain separated within the internal capsule, but show increasing overlap as they pass from the crus cerebri to the pyramid and thence into the lateral corticospinal tract where the overlap is complete. As the lateral corticospinal tract descends, approximately 50% of the fibres terminate in the cervical cord, 20% in the thoracic cord and 30% in the lumbosacral cord.

The smaller ventral corticospinal tract descends in the ventral funiculus (see Fig. 27.12). It lies close to the ventral median fissure and is separated from it by the sulcomarginal fasciculus (medial longitudinal fasciculus, medial vestibulospinal tract; see Fig. 27.7). Near their

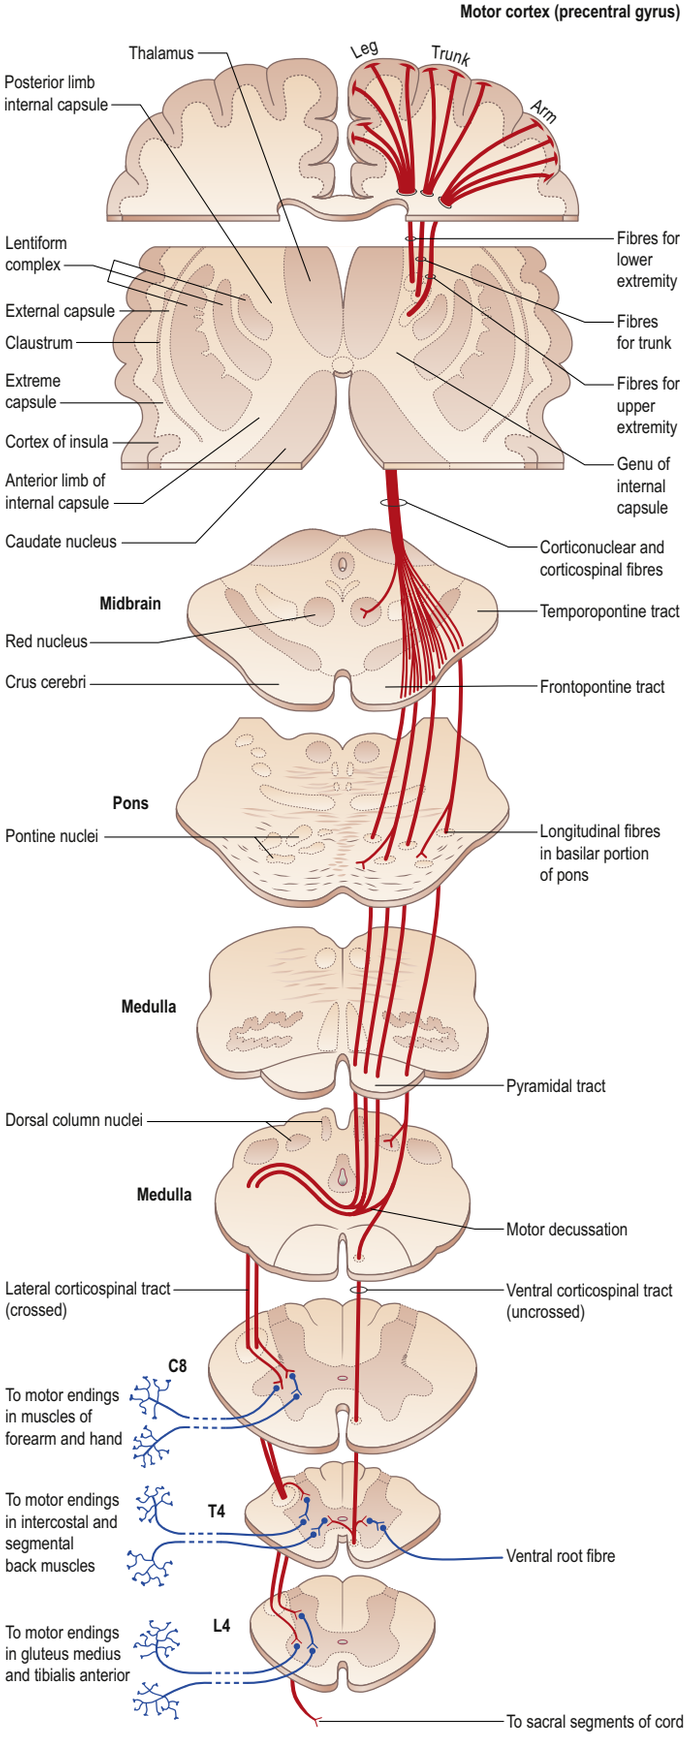

Fig. 27.12 The corticospinal tracts, also showing some of the corticonuclear projections. (Adapted with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th ed. Baltimore: Williams and Wilkins.)

termination, most fibres of the tract cross the midline in the ventral white commissure to synapse on contralateral neurones, which means that the vast majority of corticospinal fibres projecting to the cervical cord, irrespective of the tract in which they descend, terminate in the spinal cord on the side contralateral to their cortical origin. In contrast, some of the corticospinal fibres projecting to the lumbosacral cord have ipsilateral terminations. Corticospinal fibres from the motor areas do not terminate in the dorsal horn.

Modern tractography methods have made it possible to image the course of the human corticospinal tract. Knowledge of the detailed termination of corticospinal fibres is based largely on animal studies, but is supplemented by data from postmortem studies on human brains using anterograde degeneration methods. Corticospinal projections from different cortical areas have different patterns of termination within the spinal grey matter. Most corticospinal fibres projecting to the cervical cord from the motor cortex terminate contralaterally on interneurones in the lateral parts of laminae IV–VI and both lateral and medial parts of lamina VII, which receives the strongest projection (Morecraft et al 2013). Some corticospinal fibres are distributed to lamina VIII bilaterally.

Corticospinal fibres from the motor areas also terminate directly on α motor neurones in lamina IX: these are the cortico-motoneuronal projections (Lemon 2008), which constitute the second largest projection from the motor cortex to the cervical cord (Morecraft et al 2013). The corticospinal tract therefore influences motor neurones both directly and indirectly, via interneurones, and this may involve branches of the same corticospinal axons. As the widespread dendrites of multipolar motor neurones in lamina IX extend into laminae VII and VIII, direct monosynaptic axodendritic contacts can also exist on large α motor neurones in these laminae. Direct terminations on motor neurones are most abundant in the spinal cord enlargements, and particularly in the dorsolateral motor nuclei supplying hand and digit muscles (Schoen 1964, Morecraft et al 2013). There is evidence in both human and monkey cortices for rostral and caudal subdivisions of area 4; most of the direct, cortico-motoneuronal projections originate from the caudal division, referred to as 'new M1' to reflect its more recent evolution (Rathelot and Strick 2009). In contrast, 'old' M1 lacks cortico-motoneuronal projections and its corticospinal fibres influence spinal motor neurones indirectly; it is also the source of major corticonuclear projections to brainstem structures giving rise to descending pathways such as the reticulospinal tract.

Experimental evidence shows that precentral corticospinal neurones influence the activities of both α and γ spinal motor neurones, facilitating flexor muscles and inhibiting extensors, which are the opposite effects to those mediated by lateral vestibulospinal fibres. Evidence from animal studies shows that direct projections from the precentral cortical areas to spinal motor neurones are concerned with highly fractionated, precision movements of the limbs. Accordingly, in primates, precentral corticospinal fibres are mainly distributed to motor neurones supplying the distal limb muscles. Corticospinal projections probably use glutamate or aspartate, often co-localized, as excitatory neurotransmitters.

Corticospinal fibres from parietal sources end mainly in the contralateral dorsal horn, including laminae I–II and the lateral parts of laminae IV–VI, and these fibres are a major source for the presynaptic inhibition of peripheral afferent input. They do not terminate in the ventral horn. Phylogenetically, these fibres may represent the oldest part of the corticospinal system (Kuypers 1981). Axons from the sensory cortex terminate chiefly in laminae IV and V and are concerned with the supraspinal modulation of the transmission of afferent impulses to higher centres, including the motor cortex.

Experimental studies in primates indicate that complete transection of corticospinal fibres at the level of the pyramid (pyramidotomy) results in flaccid paralysis or paresis of the contralateral limbs and loss of independent hand and finger movements. Destruction of human corticospinal fibres at the level of the internal capsule, commonly caused by a cerebral vascular accident or 'stroke', results in a contralateral hemiplegia. The paralysis is initially flaccid but later becomes spastic, and is most marked in the distal muscles of the extremities, especially those concerned with individual movements of the fingers and hand. An abnormally active synergy develops between elbow flexors and shoulder abductors. Associated signs on the paralysed side are: hyperactive deep tendon reflexes; increased tone; the loss of superficial abdominal and cremasteric reflexes; and the appearance of dorsiflexion of the toes (Babinski sign) in response to stroking the sole of the foot. The latter is usually interpreted as pathognomonic of corticospinal damage, but it is not always present in patients with confirmed corticospinal lesions. Moreover, Babinski's sign is normally present in human infants up to about 2 years of age; its subsequent disappearance may reflect the completion of myelination of the corticospinal fibres and/or the establishment of direct cortical connections to lower motor neurones.

It is generally accepted that the sequelae of stroke damage to the internal capsule reflect a combination of negative effects, including weakness and loss of dexterity, and positive effects, in particular

hyperreflexia and hypertonia. The latter are probably due to the involvement of other pathways in addition to the corticospinal tract, including descending cortical projections to the cells of origin of the rubrospinal, vestibulospinal and reticulospinal tracts (Baker 2011, Krakauer and Carmichael 2017).

There are very considerable differences across animal species in the organization and function of the corticospinal system, and these differences are useful in understanding the function of the human corticospinal tract (see Commentary 3.1).

Rubrospinal tract

The rubrospinal tract arises from neurones in the caudal, magnocellular part of the red nucleus, situated in the midbrain tegmentum; see p. 451). This part of the nucleus is very small in humans and contains only a few large neurones. The origin, localization, termination and functions of the rubrospinal tract are poorly defined in humans, and the tract is often referred to as rudimentary. Rubrospinal fibres cross in the ventral tegmental decussation and descend in the lateral funiculus of the cord, where they lie ventral to, and intermingled with, fibres of the lateral corticospinal tract (see Fig. 27.7). In humans, the rubrospinal tract appears to project only to the upper three cervical cord segments: fibres are distributed to the lateral parts of laminae V–VI and the dorsal part of lamina VII of the spinal grey matter. The terminal zones of the tract are similar to those of corticospinal fibres from the motor cortex. In animals, the rubrospinal tract is considered to be part of the group of descending pathways that exert their main influence on muscles of the contralateral extremities. In animals, the effects of rubrospinal fibres on α and γ motor neurones are similar to those of corticospinal fibres, with particularly strong effects on upper limb extensor muscles.

Tectospinal tract

The tectospinal tract arises from neurones in the intermediate and deep layers of the superior colliculus of the midbrain. It crosses ventral to the periaqueductal grey matter in the dorsal tegmental decussation and descends in the medial part of the ventral funiculus of the spinal cord (see Fig. 27.7). Fibres of the tract project only to the upper cervical cord segments, ending in laminae VI–VIII. They make polysynaptic connections with motor neurones serving muscles in the neck, facilitating those that innervate contralateral muscles and inhibiting those that innervate ipsilateral ones. In animals, unilateral electrical stimulation of the superior colliculus causes turning of the head to the contralateral side, an effect mainly mediated through the tectospinal tract. It is speculated that the tectospinal tract is concerned with reflex orientation of the head in response to visual stimuli.

Vestibulospinal tracts

The vestibular nuclear complex lies in the lateral part of the floor of the fourth ventricle, at the level of the pontomedullary junction and gives rise to the lateral and medial vestibulospinal tracts, which are functionally and topographically distinct (**Fig. 27.13**).

The lateral vestibulospinal tract (green in Fig. 27.13) arises from small and large neurones of the lateral vestibular nucleus (Deiters' nucleus). It descends ipsilaterally, initially in the periphery of the ventrolateral spinal white matter, but subsequently migrating into the medial part of the ventral funiculus at lower spinal levels. Fibres of this tract are somatotopically organized: fibres projecting to the cervical, thoracic and lumbosacral segments of the cord arise from neurones in the rostroventral, central and dorsocaudal parts, respectively, of the lateral vestibular nucleus. Lateral vestibulospinal fibres end ipsilaterally, mostly in the medial part of the ventral horn in lamina VIII and the medial part of lamina VII.

The medial vestibulospinal tract (red in Fig. 27.13) arises mainly from neurones in the medial vestibular nucleus, and also from neurones in the inferior and lateral vestibular nuclei. It descends in the medial longitudinal fasciculus into the ventral funiculus of the spinal cord, where it lies close to the midline in the sulcomarginal fasciculus (see Fig. 27.7). Unlike the lateral tract, it contains both crossed and uncrossed fibres, and does not extend beyond the mid-thoracic cord level. Fibres of the medial tract project mainly to the cervical cord segments and end in lamina VIII and the adjacent dorsal part of lamina VII.

The vestibular nuclei exert a strong excitatory influence upon the motor neurones that innervate antigravity muscles (including the epaxial muscles of the vertebral column and the extensor muscles of the lower limbs) by way of the medial and lateral vestibulospinal tracts.

Reticulospinal tracts

The reticulospinal tracts pass from the brainstem reticular formation to the spinal cord, and are for the most part uncrossed (**Fig. 27.14**). The pontine reticulospinal tract (red in Fig. 27.14) originates from the pontine tegmentum. The medullary reticulospinal tract (black in Fig. 27.14) arises from the nucleus gigantocellularis, which lies dorsal to the inferior olivary complex. The terminals of reticulospinal fibres are distributed to lamina VIII, and the central and medial parts of lamina VII of the spinal grey matter. The medullary reticulospinal terminals are more widely distributed, ending additionally in the lateral parts of laminae VI and VII, and also directly on motor neurones. In general, terminations of reticulospinal fibres that originate in the medulla are more dorsally placed than those that originate in the pons, although there is considerable overlap.

Some anatomical texts classify the reticulospinal tracts into medial, ventral and ventrolateral tracts, but this is based mainly on studies in animals (see Fig. 27.7). The course and location of the human reticulospinal tracts are poorly defined: fibres do not form well-defined tracts but are typically scattered throughout the ventral and lateral columns (Nathan et al 1996).

Both α and γ motor neurones are influenced by reticulospinal fibres through polysynaptic and monosynaptic connections. There is

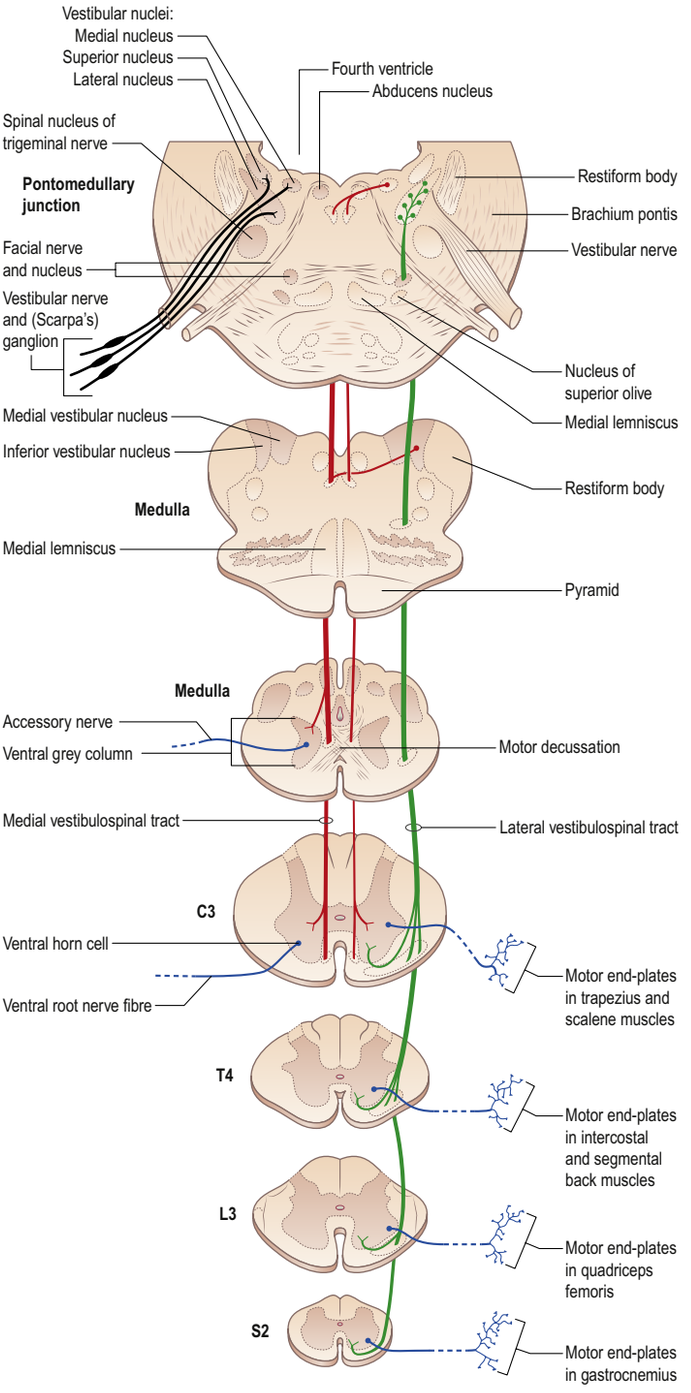

Fig. 27.13 The vestibulospinal tracts. (Adapted with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th ed. Baltimore: Williams and Wilkins.)

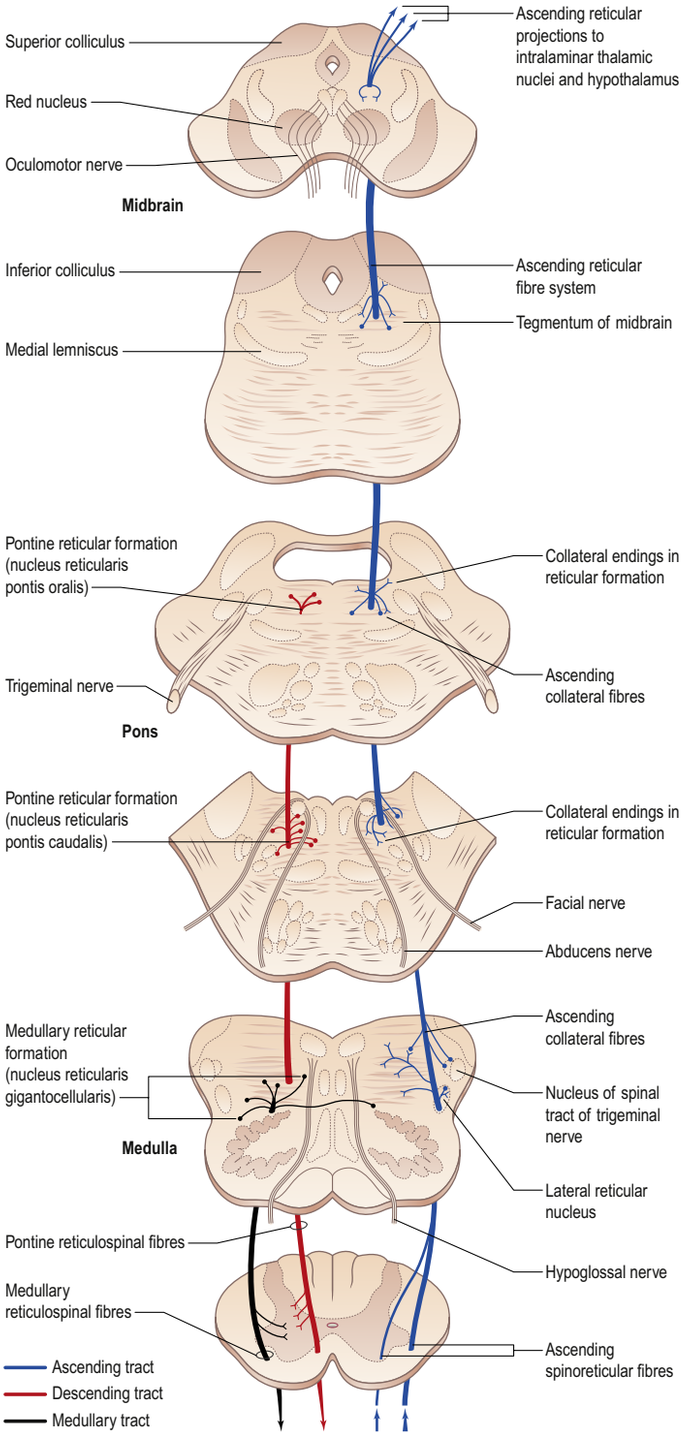

Fig. 27.14 The spinoreticular (blue) and reticulospinal (red, black) tracts. (Adapted with permission from Carpenter MB 1991 Core Text of Neuroanatomy, 4th ed. Baltimore: Williams and Wilkins.)

significant overlap in the termination of reticulospinal and corticospinal projections to segmental interneurones (Lemon 2008, Baker 2011). The pontine reticulospinal tract appears to be tonically active and is excitatory to the antigravity muscles, including the epaxial muscles of the vertebral column and the extensor muscles of the lower limbs. In marked contrast, the medullary reticulospinal tract is inhibitory to antigravity muscles. The cells of origin of the medullary reticulospinal tract receive a dense cortical input from the rostral region of primary motor cortex ('old M1') and premotor cortex. The reticulospinal tracts normally function in a coordinated, balanced fashion to control muscle tone. However, if the descending control from higher centres is lost, such as occurs after a stroke in the internal capsule, then the natural excitability and enhanced connectivity of the ipsilateral pontine reticulospinal tract, combined with the activity of the vestibulospinal tracts, causes the antigravity muscles (upper limb flexors and lower limb extensors) to become hypertonic and hyperreflexic (spasticity), with weakened upper limb extensors (Guyton and Hall 2006, Krakauer and Carmichael 2017). There are also increased excitatory effects on intrinsic hand muscles, probably explaining the crude grasp that persists after corticospinal lesions (Baker 2011).

Interstitiospinal tract

The interstitiospinal tract arises from neurones in the midbrain interstitial nucleus (of Cajal) in the dorsal midbrain and the immediate surrounding area, and descends via the medial longitudinal fasciculus into the ventral funiculus of the spinal cord. Its fibres project, mainly ipsilaterally, as far as lumbosacral levels, and are mostly distributed to the dorsal part of lamina VIII and the dorsally adjoining part of lamina VII. They establish some monosynaptic connections with motor neurones supplying neck muscles, but their main connections are disynaptic with motor neurones supplying limb muscles.

Solitariospinal tract

The solitariospinal tract is a small group of mostly crossed fibres that arises from neurones in the ventrolateral part of the nucleus solitarius of the medulla. Descending in the ventral funiculus and ventral part of the lateral funiculus of the spinal cord, these axons terminate on phrenic motor neurones supplying the respiratory diaphragm and thoracic motor neurones that innervate the intercostal muscles. A pathway with somewhat similar course and terminations to that of the solitariospinal tract originates from the nucleus retroambiguus. Both pathways subserve respiratory activities by driving inspiratory muscles, and some descending axons from the nucleus retroambiguus facilitate expiratory motor neurones. There is clinical evidence that bilateral ventrolateral cordotomy at high cervical levels abolishes rhythmic ventilatory movements.

Hypothalamospinal fibres

Hypothalamospinal fibres exist in animals. They arise from the paraventricular nucleus and other areas of the hypothalamus, and descend ipsilaterally, mainly in the dorsolateral region of the cord, to be distributed to sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. They are also distributed to laminae I and area X in the spinal cord. Descending fibres from the dopaminergic cell group (A11) situated in the caudal hypothalamus innervate sympathetic preganglionic neurones and neurones in the dorsal horn. That similar pathways exist in humans may be inferred from ipsilateral sympathetic deficits (e.g. Horner's syndrome) that follow lesions of the hypothalamus, the lateral tegmental brainstem, or the lateral funiculus of the cord.

Monoaminergic spinal pathways

Monoaminergic cell groups utilize dopamine, adrenaline (epinephrine), noradrenaline (norepinephrine) and 5-HT as neurotransmitters. They are widely and diffusely distributed throughout the brainstem and in the hypothalamus, and do not form well-identified spinal tracts. They project rostrally to many forebrain areas and caudally to the spinal cord, and appear to be concerned with the modulation of sensory transmission and the control of autonomic and somatic motor neuronal activities.

The projections to the spinal cord are highly branched and arise from several sources. Coeruleospinal projections originate from noradrenergic cell groups A4 and A6 in the locus coeruleus complex in the pons and descend via the ventrolateral white matter to innervate all cord segments bilaterally. They end in the dorsal grey matter (laminae IV–VI) and the intermediate zone and ventral horn. They also project extensively to preganglionic parasympathetic neurones in the sacral cord. Descending noradrenergic fibres, which arise from the lateral tegmental cell groups A5 and A7 of the pons, travel in the dorsolateral white matter and are distributed to laminae I–III, particularly to the intermediate zone. Descending fibres from adrenergic cell groups C1 and C3 of the medulla oblongata have been traced into the ventral funiculus of the cord and are extensively distributed to the intermediolateral column. Dopaminergic fibres projecting to the spinal cord travel in the hypothalamospinal pathway.

The raphe nuclei pallidus (B1), obscurus (B2) and magnus (B3) in the brainstem give rise to two serotoninergic descending bundles. The lateral raphe spinal bundle, from B3 neurones, is concerned with the control of nociception. It descends close to the lateral corticospinal tract and ends in the dorsal horn (laminae I, II and V). The ventral bundle, composed mainly of axons from B1 neurones, travels in the medial part of the ventral white column and ends in the ventral horn (laminae VIII and IX). It facilitates extensor and flexor motor neurones. Some descending serotoninergic fibres project to sympathetic preganglionic neurones and are concerned with the central control of cardiovascular function.

Propriospinal pathways

Propriospinal pathways (fasciculi proprii) consist of intrinsic ascending and descending fibres that connect spinal neurones. They contact other neurones within the same segment and/or in more distant segments of the spinal cord and so subserve intrasegmental and intersegmental integration and coordination. The majority of spinal neurones are propriospinal neurones, most of which lie in laminae V–VIII. Propriospinal fibres are mainly concentrated around the margins of the grey matter where they form the fasciculus proprius (see Fig. 27.7), but are also dispersed diffusely in the white matter funiculi.

Tract of Lissauer

The tract of Lissauer (dorsolateral fasciculus) lies between the apex of the dorsal horn and the surface of the spinal cord, where it surrounds the incoming dorsal root fibres (see Fig. 27.7). It is present throughout the spinal cord and is most developed in the upper cervical regions.

The tract consists of small myelinated and unmyelinated axons: many are the branches of primary afferent axons in the lateral bundles of the dorsal roots. These axons bifurcate into ascending and descending branches as they enter the cord. The branches travel in the tract of Lissauer for one or two segments and give off collaterals that terminate on neurones in the dorsal horn. Up to 50% of the tract consists of propriospinal fibres: some are short axons of small substantia gelatinosa neurones which re-enter the dorsal horn and transmit nociceptive information onwards to cells that give rise to sensory ascending pathways.

SPINAL REFLEXES

The intrinsic connections of the spinal cord and brainstem subserve a number of reflexes by which the functions of peripheral structures are modulated in response to afferent information in a relatively automatic and autonomous fashion. The fundamental components of such reflex 'arcs' are an afferent and an efferent neurone, although in all but the simplest of reflexes, interneurones are intercalated between the afferent and efferent components, conferring increased versatility and complexity of reflex responses. Reflexes may be confined to a single cord level (intrasegmental) or involve several cord segments (intersegmental). By their very nature, reflexes are relatively fixed and stereotyped in form, nevertheless, they are strongly influenced and modulated by descending connections. In the case of spinal reflexes, these descending controls come from both the brainstem and the cerebral cortex. Pathology of descending supraspinal pathways is associated with abnormalities of spinal reflex activity that are routinely tested for in neurological examination: reflexes may be absent (areflexia), diminished (hyporeflexia) or exaggerated (hyperreflexia). During development, descending control mechanisms suppress what may be regarded as 'primitive' spinal reflex responses, such as the extensor plantar reflex and the grasp reflex: when the higher control mechanisms become damaged, these reflexes are released and reappear as a sign of central nervous system pathology (e.g. the Babinski reflex).

Muscle stretch reflex

The muscle stretch reflex (also somewhat misleadingly called the tendon reflex or deep tendon reflex) is the mechanism by which stretch applied to a muscle elicits its reflex contraction. It is essential for the maintenance of both muscle tone and an upright stance (via the innervation of the postural muscles of the neck, back and lower limbs). Anatomically it is the simplest of reflexes, mediated by an afferent and an efferent neurone, and it is therefore also known as a monosynaptic stretch reflex or a myotatic reflex. The anulospiral endings of large sensory fibres (group Ia afferents) spiral around the intrafusal muscle fibres of muscle spindles (see Fig. 3.33). The central processes of these afferent axons enter the spinal cord and make excitatory synaptic contact directly onto the α motor neurones that innervate the same muscle (Fig. 27.15). The α motor neurones of antagonistic muscles are simultaneously inhibited via collateral connections to inhibitory interneurones (reciprocal innervation).

Gamma effects on reflex sensitivity

Extrafusal muscle fibres are innervated by α motor neurones. Intrafusal muscle fibres are innervated by γ motor neurones. Activation of different classes of γ motor neurones increases the sensitivity of the intrafusal fibres to either dynamic or static stretch;

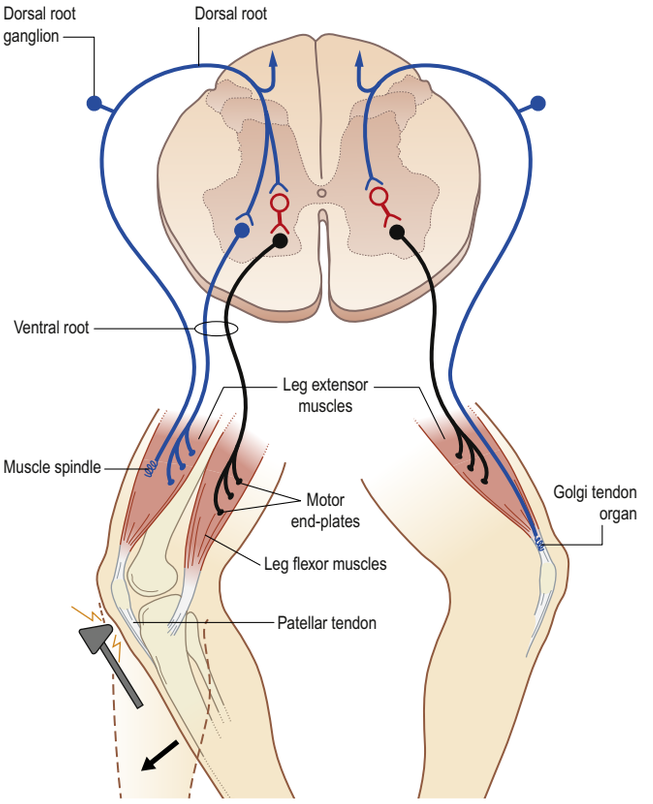

Fig. 27.15 The pathway for the patellar tendon reflex and reciprocal inhibition (left) and autogenic inhibition (right). The inhibitory glycinergic interneurones are represented by the red open cell bodies. (Adapted with permission from Haines D Fundamental Neuroscience for Basic and Clinical Applications, 4th ed. Elsevier, Saunders. Copyright 2013.)

changes in γ activity have a profound effect on the stretch reflex and on muscle tone. Like α motor neurones, γ motor neurones are under the influence of descending pathways from the brainstem and cerebral cortex. Changes in muscle tone and in the activity of the stretch reflex are commonly found in disorders of the central and peripheral nervous systems.

Flexor reflex and crossed extensor reflex

Painful stimulation of the limbs leads to flexion withdrawal, mediated by a polysynaptic reflex in which interneurones link the afferent and efferent neurones (Fig. 27.16). Thus, activation of nociceptive primary afferents indirectly causes activation of limb flexor motor neurones. Collateralization of fibres to nearby spinal segments mediates flexion of a limb at several joints, depending on the intensity of the stimulus. Decussating connections to the contralateral side of the cord activate α motor neurones innervating corresponding extensor muscles, which produces a crossed extensor reflex (Fig. 27.17). In principle, virtually any cutaneous stimulus has the potential to induce a flexor reflex but, other than in the case of noxious stimuli, this response is normally inhibited by descending pathways. When descending influences are lost, even harmless cutaneous stimulation can elicit flexion of the limbs. The Babinski (extensor plantar) reflex, which is generally regarded as pathognomonic of damage to the corticospinal tract, is part of a flexion withdrawal of the lower limb in response to stimulation of the sole of the foot.

Central pattern generators

SPINAL CORD LESIONS

A sound understanding of spinal cord anatomy is vital in making the correct diagnosis (Boxes 27.1–27.5).

Mechanical compression and secondary ischaemic damage to underlying nervous tissue cause surgically relevant spinal cord disease

Box 27.1 Case history 1: Complete transection of the spinal cord

A 29-year-old male fractured his cervical spine after a road traffic accident, leading to transection of the spinal cord at C5. When examined 6 months later, he had paralysis of all four limbs but shoulder abduction and elbow flexion were spared (i.e. all muscles innervated by nerve fibres arising below C5 were paralysed). Tone was increased in the limbs with brisk reflexes and extensor plantar responses (i.e. the weakness was upper motor neurone or pyramidal weakness). He had complete loss of sensation below C5 and a neurogenic bladder.

Box 27.2 Case history 2: Hemisection of the spinal cord giving rise to the Brown–Séquard syndrome

A 20-year-old female presented with a 4-day history of gradually worsening right leg weakness, burning pain and loss of sensation in the left leg. On examination she had pyramidal pattern weakness of the right leg (i.e. hip and knee flexion and ankle dorsiflexion were mainly affected). Tone was increased in the right leg: there were brisk right leg reflexes and a right extensor plantar response (i.e. right pyramidal weakness). There was impaired proprioception in the right leg and reduced pinprick sensation affecting the left leg and side up to the umbilicus.

This case illustrates a Brown–Séquard syndrome resulting from hemisection of the cord caused by a right-sided cord lesion in the thoracic spine. Involvement of the corticospinal tract caused 'pyramidal' weakness below the level of the lesion on the same side as the lesion (because the pyramidal tract predominantly crosses in the medulla). Involvement of the dorsal columns caused impaired proprioception below the level of the lesion on the same side as the lesion (because the fibres in the dorsal columns also cross in the medulla). Involvement of the spinothalamic tract caused loss of pinprick sensation below the lesion on the contralateral side (because the spinothalamic tract crosses the midline soon after entering the cord). The progression of symptoms over several days suggests an inflammatory problem. Magnetic resonance imaging of the cord showed a right-sided area of cord inflammation (myelitis) at T10. The patient had previously had an episode of inflammation affecting the optic nerve (optic neuritis) and the diagnosis was therefore one of multiple sclerosis.

Box 27.3 Case history 3: Anterior (ventral) cord syndrome

A 75-year-old male with diabetes and hypertension presented with sudden onset of weakness and sensory disturbance in both legs. When examined 6 months later, he had a 'pyramidal' weakness of both legs with increased tone, brisk reflexes and extensor plantar responses, and a complete loss of pinprick sensation below T10. Proprioception was normal.

The acute onset suggested a vascular problem and the diagnosis was of an anterior spinal artery infarction. Proprioception was spared because the anterior spinal artery supplies only the anterior cord, whereas the posterior cord, including the dorsal columns, is supplied by the posterior spinal arteries.

Box 27.4 Case history 4: Posterior (dorsal) cord syndrome

A 73-year-old male presented with a 6-month history of unsteadiness on walking. When examined, he had an unsteady gait, a tendency to fall when asked to stand still with his eyes closed (positive Romberg's test), and impaired proprioception in all four limbs. Spinothalamic sensation (pinprick sensation) was intact and his power was normal.

Investigations revealed signal change in the posterior cervical cord on magnetic resonance imaging and his vitamin B_{12} levels were very low. A diagnosis of posterior cord syndrome secondary to B_{12} deficiency was made. Posterior cord syndromes involve the dorsal columns, leading to impaired proprioception. Although not illustrated in this case, B_{12} deficiency sometimes affects the corticospinal tract, causing weakness in the limbs, and may also sometimes affect the peripheral nerves.

Box 27.5 Case history 5: Central cord syndrome

A 20-year-old female presented with a 4-month history of painless injuries to her hands. For example, after gardening she would sometimes come inside and notice later that there were rose thorns sticking into her hands. Examination showed reduced pinprick sensation (spinothalamic sensation) over the upper limbs.

Magnetic resonance imaging of her cervical spine showed a collection of fluid in the centre of the cervical spinal cord (syringomyelia): a diagnosis of central cord syndrome secondary to syringomyelia was made. As spinothalamic tract fibres cross over from the dorsal horn to run in the contralateral spinothalamic tract, they pass very close to the centre of the cord. Central cord syndromes thus initially damage the spinothalamic tracts, resulting in altered pain sensation at the level of the lesion. As the lesion expands to involve the ventral horns, patients may develop lower motor neurone weakness of the upper limbs. They may subsequently experience upper motor neurone problems in the legs if the lesion expands further to involve the corticospinal tracts.

The propriospinal system plays important roles in spinal functions. Most of the descending pathways end on specific subgroups of propriospinal neurones and these, in turn, relay to motor neurones and other spinal neurones. The system mediates all those automatic functions that continue after transection of the spinal cord, e.g. sudomotor and vasomotor activities, and bowel and bladder functions. Propriospinal effects can be detected indirectly in humans and may be particularly important in the recovery of motor function after spinal cord injury (Pierrot-Deseilligny and Burke 2005).

Some propriospinal axons are very short and span only one segment, while others run the entire length of the cord. The shortest axons lie immediately adjacent to the grey matter and the longer ones are situated more peripherally. Propriospinal neurones can be categorized as long, intermediate or short according to the length of their axons. Axons of long propriospinal neurones are distributed throughout the length of the cord, mainly via the ventral and lateral funiculi; their cell bodies are in lamina VIII and the dorsally adjoining part of lamina VII. Axons from the long propriospinal neurones of the cervical cord descend bilaterally, whereas those from the corresponding lumbosacral neurones ascend mainly contralaterally. Most of the fibres are less than 3 μm in diameter and some are the first spinal tract axons to become myelinated. Intermediate propriospinal neurones occupy the central and medial parts of lamina VII and project mainly ipsilaterally. Short propriospinal neurones are found in the lateral parts of laminae V–VIII and their axons run ipsilaterally in the lateral funiculus.

Propriospinal fibres in the different parts of the white funiculi are distributed preferentially to specific regions of the spinal grey matter. In the spinal enlargements, the propriospinal fibres in the dorsolateral funiculus project to the dorsal and lateral parts of the intermediate zone, and to spinal motor neurones that supply distal limb muscles, especially those of the hand and the foot. The propriospinal fibres in the ventral part of the ventrolateral funiculus are distributed to the central and medial parts of lamina VII and to motor neurones of proximal limb and girdle muscles. Other propriospinal fibres run in the medial part of the ventral funiculus and travel mainly to the ventromedial part of the intermediate zone, which characteristically contains long propriospinal neurones, and to motor neurones that innervate axial and girdle muscles.

Research in animals has demonstrated that the spinal cord contains a number of 'central pattern generators' that can generate the rhythmic movements and patterns required for walking, swimming, breathing, scratching etc. These generators are made of multiple interneuronal cell types that collectively form highly interconnected neural circuits. By definition, a central pattern generator can generate motor patterns or rhythms when completely isolated from both descending supraspinal

influences and peripheral afferent input. There is some evidence that a central pattern generator for locomotion exists in the human spinal cord (Minassian et al 2017).

In the mouse, a number of classes of spinal interneurone are thought to constitute the central pattern generator for locomotion. Commissural interneurones that influence contralateral motor neurones play an important role in side-to-side excitation of locomotor muscles. V_0 neurones can be either excitatory or inhibitory and together with the V_3 class of interneurones are responsible for side-to-side alterations in muscle activity. Other classes of interneurones that exert ipsilateral effects include V2a (excitatory) and V1 and V2b (inhibitory) interneurones. Reciprocal inhibition of motor neurones by muscle spindle Ia inputs are all thought to be mediated by either V1 or V2b interneurones (Kiehn 2016).

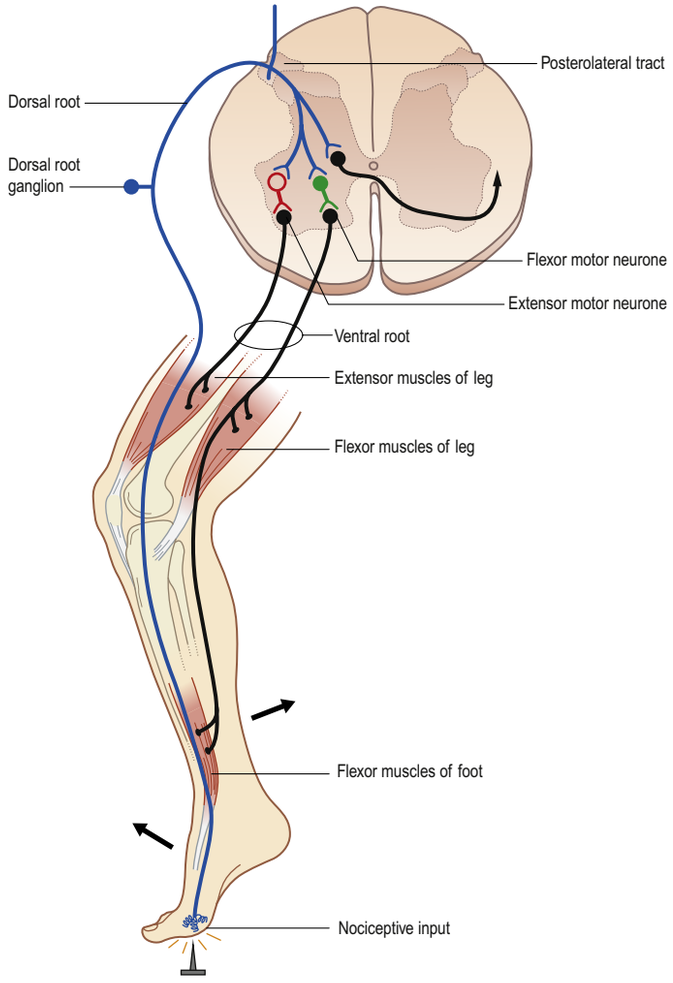

Fig. 27.16 The pathway for the flexor reflex. The inhibitory glycinergic interneurone is represented by the red open cell body and the excitatory glutaminergic interneurone by the green closed cell body. In addition to being involved in reflexes, this nociceptive input is also relayed to higher levels of the neuraxis via the anterolateral system (ascending black fibre). (Adapted with permission from Haines D Fundamental Neuroscience for Basic and Clinical Applications, 4th ed. Elsevier, Saunders. Copyright 2013.)

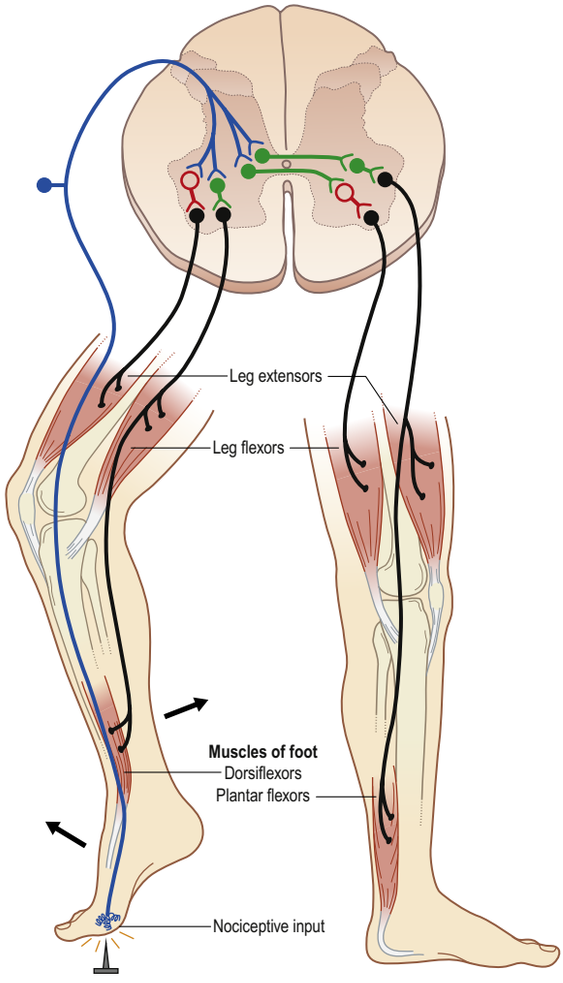

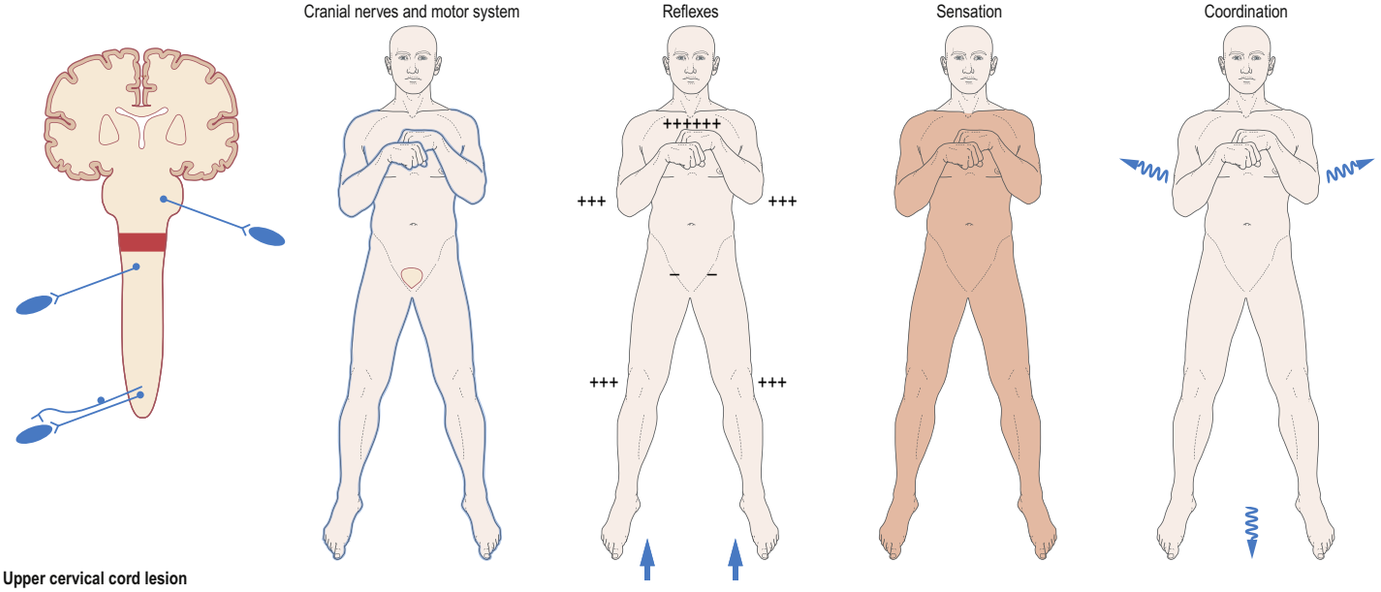

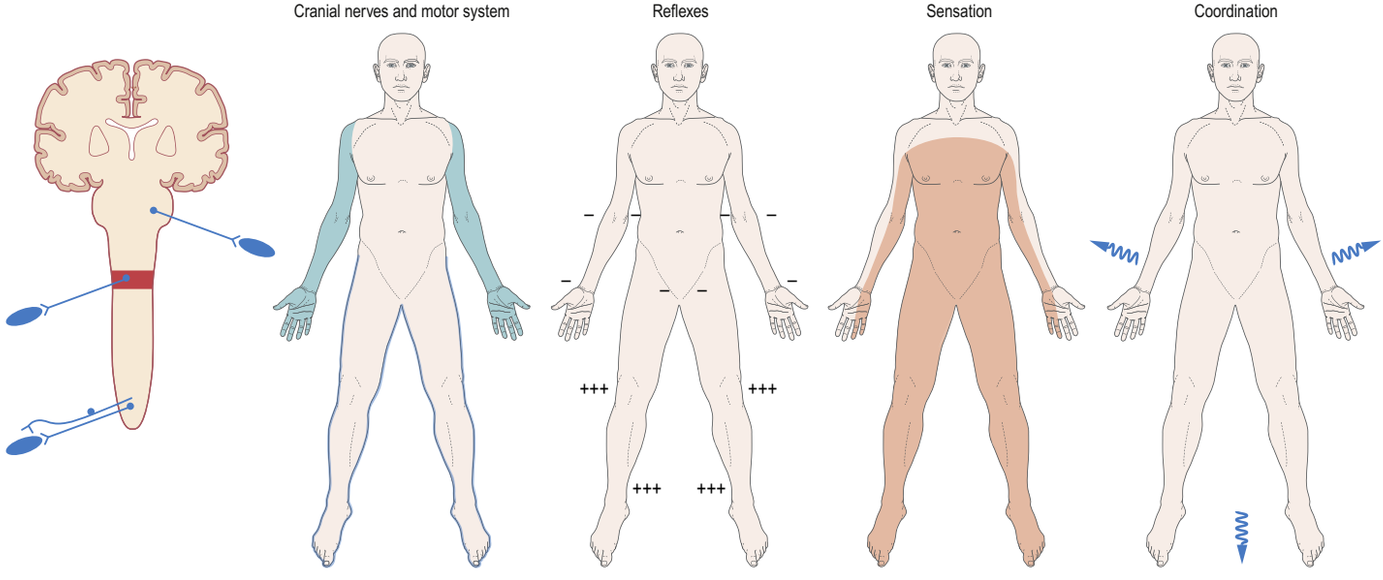

Fig. 27.17 The pathway for the crossed extensor reflex. Glycinergic interneurones (inhibitory) are represented by the open red cell bodies and glutaminergic interneurones (excitatory) by the closed green cell bodies. (myelopathy). The site and the level of damage to the cord determine the particular clinical syndrome, e.g. whether the lesion involves the upper or lower cervical, thoracic or lumbosacral spinal cord. At each of these levels, symptoms and signs are determined by direct destruction of segmental tissue (transversely distributed damage) and disconnection of suprasegmental ascending and descending tracts above and below the level of a lesion (longitudinally distributed damage; **Fig. 27.18**). For example, a lower cervical spinal cord lesion damages the segmental sensory and motor contributions to the nerve roots and to the brachial plexus, causing sensory loss, weakness and wasting of the muscles and loss of tendon reflexes in the upper limbs. Disruption of the ascending sensory pathways in the lateral and dorsal columns of the cervical spinal cord leads to loss of sensation to pain and temperature (lateral spinothalamic tracts) and touch and proprioception (dorsal columns) below the 'sensory level' corresponding to the segment of the spinal cord. Damage to the descending corticospinal tracts in the lateral columns of the spinal cord produces a spastic paraparesis, i.e. increased tone of the muscles, weakness of an upper motor neurone pattern (weakness of extensors more than flexors in the upper limbs; weakness of flexors more than extensors in the lower limbs), exaggerated tendon reflexes and abnormal superficial reflexes, e.g. extensor plantar responses and absent abdominal reflexes. Descending pathways to the bladder are interrupted and this produces a 'neurogenic bladder', characterized by incontinence, frequency, urgency or retention of urine. The same principles apply to lesions at other levels of the spinal cord and these are illustrated in Fig. 27.18.

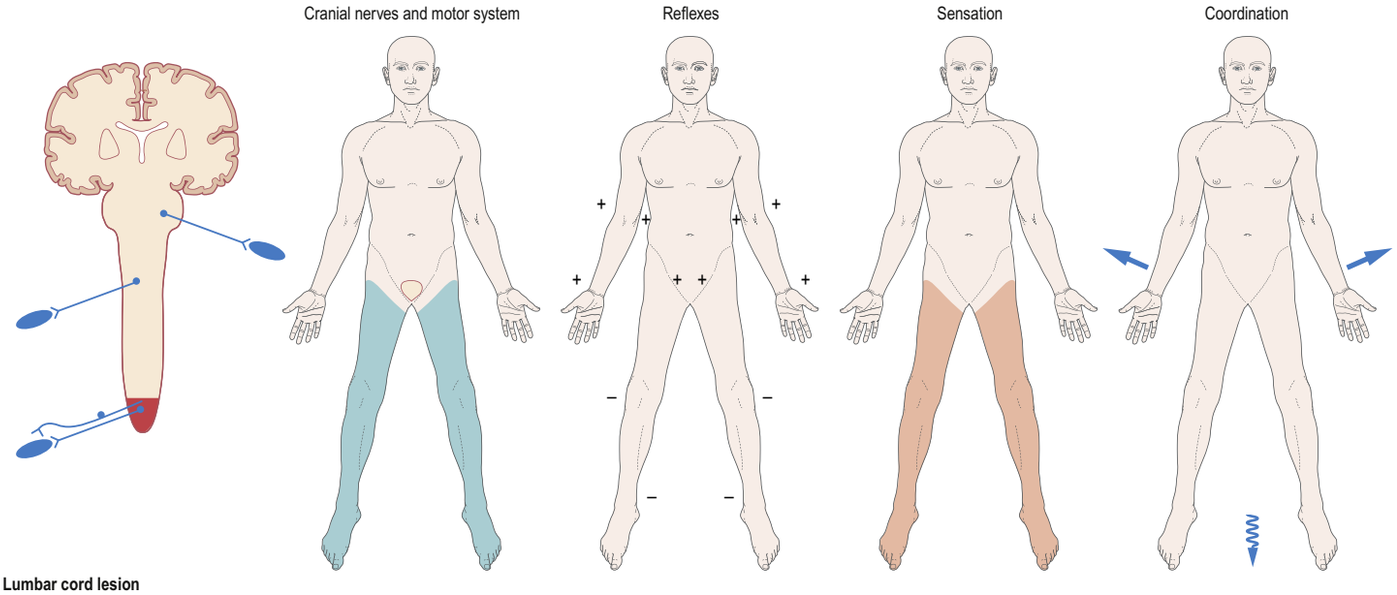
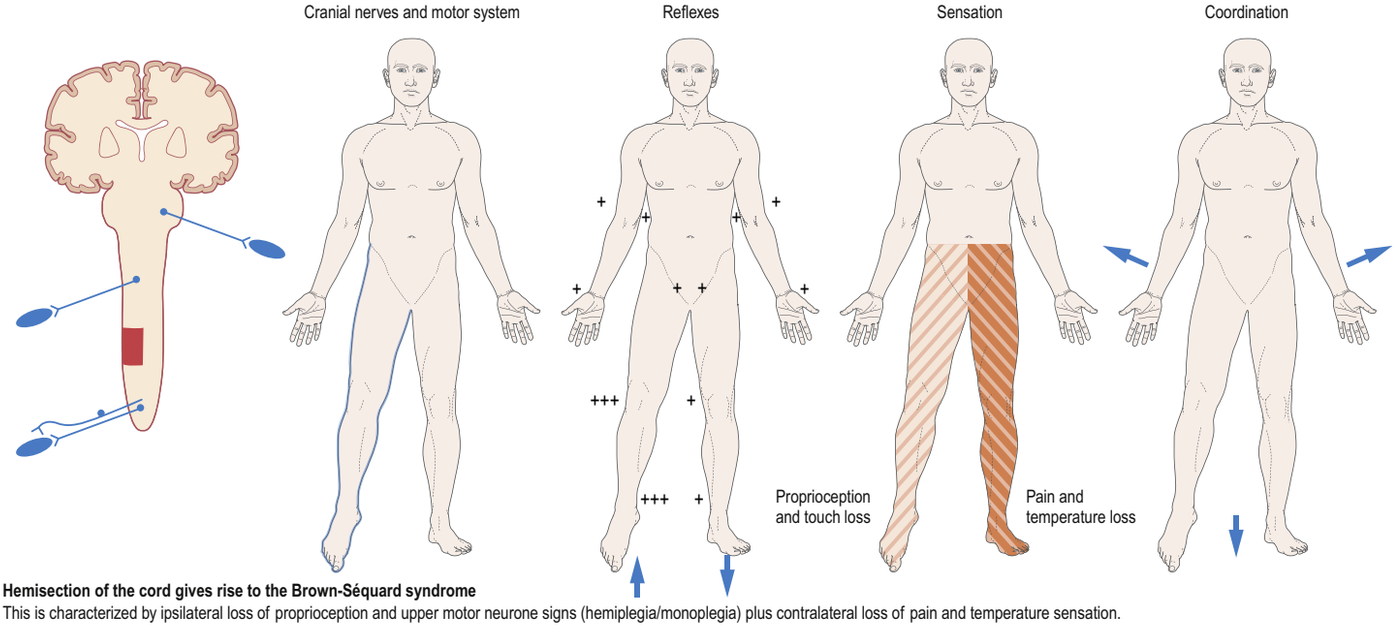
The time course of spinal cord disease is very important in suggesting the likely cause, as the rate of evolution of a disorder varies depending on the aetiology. Disorders with sudden or rapid onset are usually caused by trauma or by a vascular accident (i.e. stroke). When a condition develops over days it is often due to an inflammatory disorder such as multiple sclerosis. Neoplastic lesions such as a spinal cord meningioma often progress over months. Degenerative problems usually progress over months (such as amyotrophic lateral sclerosis or motor neurone disease) or even years (e.g. hereditary spastic paraparesis).

Upper cervical cord lesion
A high cervical cord lesion causes spastic tetraplegia with hyperreflexia, extensor plantar responses (upper motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.



Lower cervical cord lesion
A lower cervical cord lesion causes weakness, wasting and fasciculation of muscles and areflexia of the upper limbs (lower motor neurone lesion). In addition, there is spastic paraparesis, hyperreflexia and extensor plantar responses (upper motor neurone lesion) in the lower limbs, incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.



Thoracic cord lesion
A thoracic cord lesion causes a spastic paraparesis, hyperreflexia and extensor plantar responses (upper motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.

Fig. 27.18 Lesions of the spinal cord. (Adapted with permission from Crossman AR, Neary D Neuroanatomy: An Illustrated Colour Text, 4th ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Lumbar cord lesion
A lumbar cord lesion causes weakness, wasting and fasciculation of muscles, areflexia of the lower limbs (lower motor neurone lesion), incontinence, sensory loss below the level of the lesion and 'sensory' ataxia.

Hemisection of the cord gives rise to the Brown-Séquard syndrome
This is characterized by ipsilateral loss of proprioception and upper motor neurone signs (hemiplegia/monoplegia) plus contralateral loss of pain and temperature sensation.

CHAPTER
28

Brainstem

The brainstem is situated in the posterior cranial fossa, where it faces the clivus and dorsum sellae ventrally and the cisterna magna, fourth ventricle and cerebellum dorsally (**Fig. 28.1**). It is approximately 6–7.5 cm in length and 3–4 cm in width at its widest portion. Its caudal border corresponds to the transverse plane immediately above the exit of the first cervical nerve roots. Its cephalic border is defined by the plane cutting through the caudal edge of the mammillary bodies, optic tracts and the posterior commissure. From caudal to cranial, the brainstem is divided into the medulla oblongata (myelencephalon), pons and midbrain (mesencephalon). The medulla oblongata, pons and midbrain each have a ventral portion (basis) and a dorsal portion (tegmentum): only the midbrain has a third portion, the tectum, dorsal to the tegmentum (**Fig. 28.2**) (Riley 1943, Mai and Paxinos 2012).

The brainstem contains numerous intrinsic neuronal cell bodies and their processes, some of which are the brainstem homologues of spinal cell groups. Some brainstem cell groups are the nuclei of cranial nerves and are concerned with the sensory, motor and autonomic innervation of the head and neck. Others give rise to autonomic (visceromotor) fibres that are distributed widely within the thorax and abdomen via branches of the vagus nerve. The brainstem also contains the reticular formation, a complex and sometimes ill-defined network of neurones that extends throughout its length, and is continuous caudally with its spinal counterpart (Olszewski and Baxter 1954, Haines and Mihailo 2018). Some reticular nuclei are referred to as vital centres because they are concerned with regulation of cardiac and respiratory activities; other parts of the reticular formation are essential for cerebral cortical arousal and the maintenance of consciousness, or are involved in the regulation of muscle tone, posture and reflex activities. The brainstem is the site of origin and/or termination of numerous ascending and descending fibres and is traversed by many others. The anterolateral system (spinal lemniscus), medial lemniscus and the trigeminothalamic tracts all ascend through the brainstem to reach the thalamus. Prominent corticospinal projections descend through the brainstem and corticonuclear projections end within it.

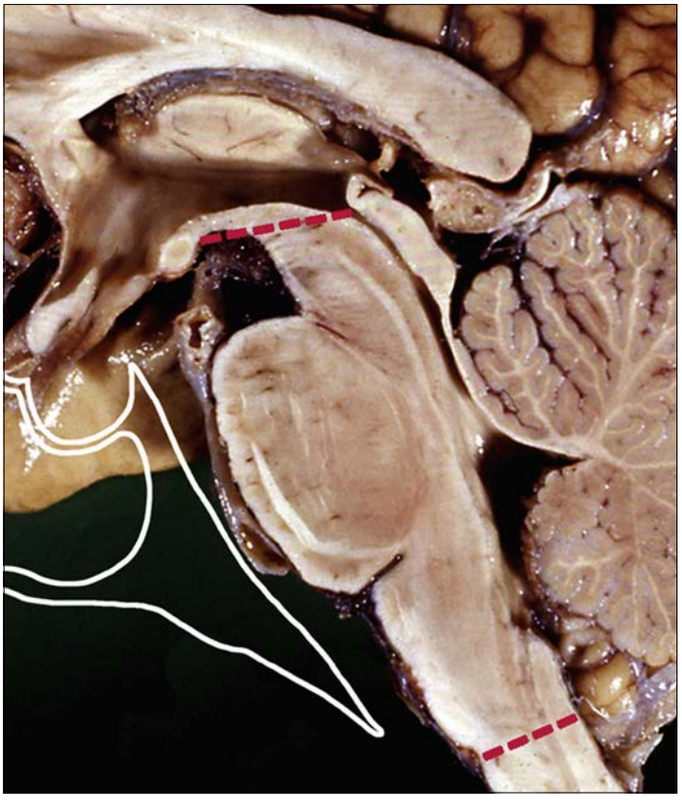

Fig. 28.1 A midline sagittal section through the brainstem delineating the lower and upper borders of the brainstem (dashed red lines) and the relative proportions of the medulla, pons and midbrain. The bony clivus, pituitary fossa and sphenoidal sinus are diagrammed in white.

Because the brainstem is so compact, structurally and functionally, even small lesions can destroy vital centres, disconnect forebrain motor areas from motor neurones in the brainstem and spinal cord, and sever incoming sensory fibres from higher centres of consciousness, perception and cognition. Clinically, irreversible cardiac and respiratory arrest often follows complete destruction of the respiratory and cardiac centres in the medulla. Damage to substantial portions of the reticular system bilaterally may cause coma. Damage to the ventral pons bilaterally may cause the 'locked in' syndrome, where interruption of motor function causes total paralysis and inability to speak, despite maintenance of consciousness. Accurate anatomical knowledge of brainstem anatomy is essential to reach a correct diagnosis and determine proper patient management.

OVERVIEW OF CRANIAL NERVES AND THEIR NUCLEI

The cranial nerves are the routes by which the brain receives information directly from, and controls the functions of, structures that are located mainly, although not exclusively, within the head and neck. All but three of the 12 pairs of cranial nerves are regarded as being attached to the brainstem, the exceptions being the olfactory, optic and accessory nerves.

The 12 pairs of cranial nerves are individually named and are numbered (using Roman numerals) from rostral to caudal, reflecting the order in which they emerge from the brain (see Table 24.1). The olfactory nerve (I) arises from the olfactory epithelium in the nasal cavity (see Fig. 39.13) and terminates directly in cortical and subcortical areas of the frontal and temporal lobes; it is closely associated functionally with the limbic system and is described in that context. The axons of the optic nerve (II) pass into the optic chiasma, where medially positioned axons decussate; all of the axons emerge as the optic tract, which terminates in the lateral geniculate nucleus of the thalamus (the visual pathways are discussed in Chapter 45). The oculomotor (III) and trochlear (IV) nerves arise in, and emerge from the midbrain. The trigeminal nerve (V) emerges from the pons, medial to the middle cerebellar peduncle. The abducens (VI), facial (VII) and vestibulocochlear (VIII) nerves emerge from the brainstem at, or close to, the pontomedullary junction. The glossopharyngeal (IX), vagus (X), cranial accessory (XI_{cr}) and hypoglossal (XII) nerves all emerge from the medulla. The spinal accessory nerve (XI_{sp}) arises from cervical levels C1–C5/C6.

Cranial nerves III–X, XI_{cr} and XII are associated with brainstem cell groupings referred to collectively as the cranial nerve nuclei (**Fig. 28.3**). The latter are either the origin of efferent cranial nerve fibres or the site of termination of cranial nerve or descending cerebral cortical afferents. They are considered to be organized into discontinuous longitudinal cell columns corresponding to columns that may be identified in the embryo.

MEDULLA OBLONGATA

The medulla oblongata (myelencephalon or bulb) is the most caudal part of the brainstem and is demarcated from the pons by a transverse plane that cuts through the transverse pontine sulcus ventrally and the striae medullares on the floor of the fourth ventricle dorsally. It is approximately 2.5–3.5 cm in length, about 1.5 cm wide at the level of the olives, and 2–2.5 cm wide at the greatest expanse of the inferior cerebellar peduncles. The medulla oblongata occupies the anterior space of the low posterior fossa and the foramen magnum: its ventral

The accessory nerve is conventionally described as having a cranial root composed of a variable number of small rootlets that emerge from the postolivary groove of the dorsolateral medulla, caudal to the rootlets of the vagus, and a spinal root composed of fibres derived from the cervical segments of the spinal cord. The cranial rootlets carry axons of motor neurones located in the caudal part of the nucleus ambiguus, and the spinal rootlets carry axons of motor neurones located in a nucleus in the ventral horn of the cervical spinal cord in line with the nucleus ambiguus. The spinal root ascends the vertebral canal and enters the skull via the foramen magnum. The cranial and spinal roots join, either before or within the jugular foramen, and the bundle so formed then divides into internal and external branches on leaving the jugular foramen. The internal branch joins the vagus nerve and its fibres innervate branchiomeric muscles via the pharyngeal and laryngeal branches of the vagus nerve. The external branch descends into the neck to innervate sternocleidomastoid and the upper and middle fibres of trapezius. There is an alternative view that the cranial root is anatomically and functionally part of the vagus nerve, and that the spinal root is the *de facto* accessory nerve. Paradoxically, meticulous cadaveric dissection studies, often undertaken stereomicroscopically, have failed to reach a consensus, finding either no connections between rootlets arising from the dorsolateral medulla and the spinal root of the accessory nerve because the cranial root was absent, or significant variations in the arrangement and size of plexiform connections between the cranial rootlets and the spinal root. Plexiform interconnections between neighbouring cranial nerves are not uncommon and are certainly not confined to the accessory and vagus nerves (Shoja et al 2014); their functional significance is often uncertain. (For further reading, see Krammer et al (1987), Lachman et al (2002), Ryan et al (2007), Wiles et al (2007), Benninger and McNeil (2010), Skinner (2011), Liu et al (2014), Tubbs et al (2014).)

The three columns that are derived from the basal plate of the neural tube are motor in function and include, from ventromedial to dorsolateral, general somatic efferent (GSE), special visceral efferent (SVE) and general visceral efferent (GVE) columns. The four columns derived from the alar plate of the neural tube are sensory in function and include, from ventral to dorsal, general visceral afferent (GVA), special visceral afferent (SVA), general somatic afferent (GSA) and special somatic afferent (SSA) (see Table 24.1 and Ch. 14). In humans, the general and special visceral afferent columns are united into the single nucleus of the solitary tract (Nieuwenhuys et al 2008).

The sensory nucleus of the trigeminal nerve, which extends throughout the length of the brainstem and into the cervical spinal cord, represents a general somatic afferent (GSA) cell column (Olszewski 1950, Haines 2015, Haines and Mihailo 2018). Its principal afferents are carried in the trigeminal nerve. General visceral afferents (GVA) carried by the facial, glossopharyngeal and vagus nerves end in the nucleus solitarius of the medulla. The special somatic afferent (SSA) column corresponds to the vestibular and cochlear nuclei, which are located beneath the vestibular area of the floor of the fourth ventricle.

The general somatic efferent (GSE) cell column consists of four nuclei that lie near the midline and give rise to motor fibres that run in nerves of the same name. From rostral to caudal, these are the oculomotor, trochlear and abducens nuclei, which innervate the extraocular muscles, and the hypoglossal nucleus, which innervates all but one of the muscles of the tongue. The general visceral efferent, or parasympathetic, (GVE) cell column is made up of the Edinger–Westphal preganglionic nucleus of the midbrain, the salivatory nuclei of the pons and the vagal nucleus of the medulla. Cells in the special visceral efferent (SVE) column innervate muscles derived from the branchial arches and lie in the trigeminal motor nucleus, the facial nucleus and the nucleus ambiguus.

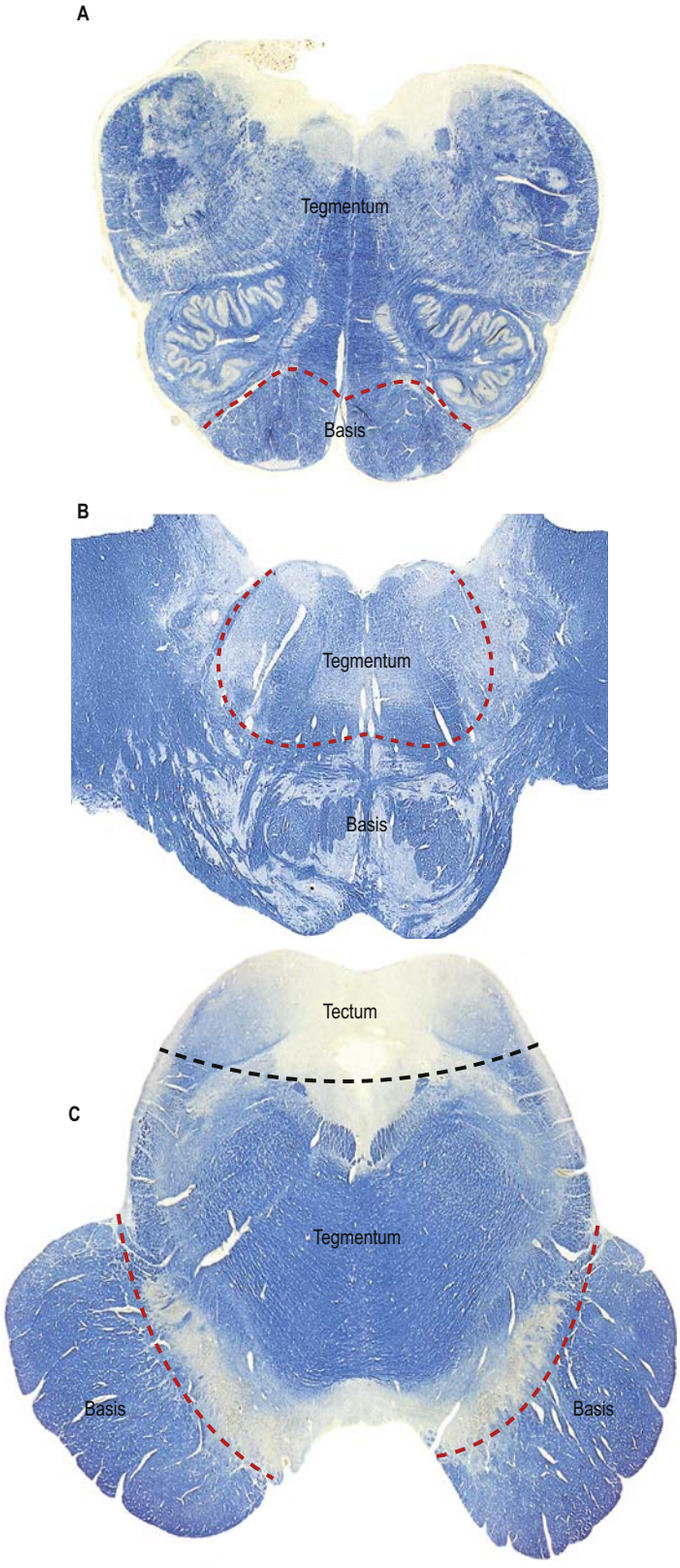

Fig. 28.2 The three ventrodorsal tiers of the brainstem, transverse histological sections prepared using Luxol fast blue stain for myelinated nerve fibres (blue). **A**, Medulla. **B**, Pons. **C**, Midbrain. The demarcation (dashed red lines) between the basis and the tegmentum lies along the dorsal surface of the pyramids in the medulla (**A**), along the ventral surface of the medial lemnisci in the pons (**B**) and along the ventral surface of the substantia nigra in the midbrain (**C**).

surface is separated from the inferior clivus (basilar part of the occipital bone) and apex of the dens by the meninges and occipito-axial ligaments. Dorsally and laterally, the inferior half of the medulla faces the overlying cerebellum and the CSF within the cisterna magna (a subarachnoid cistern between the cerebellar hemispheres). The superior medulla forms the caudal part of the floor of the fourth ventricle. The glossopharyngeal, vagus, (cranial) accessory and hypoglossal nerves either emerge from or enter the medulla.

External features and relations

The ventral and dorsal surfaces of the medulla (Figs 28.4–28.5) possess a longitudinal median fissure and sulcus respectively, which are continuous with their spinal counterparts. Caudally, the ventral (anterior) median fissure is interrupted by the obliquely crossing fascicles of the motor decussation (pyramidal decussation). Rostrally, the fissure ends at the pontine border in a diminutive depression, the foramen caecum. A prominent elongated ridge, the pyramid, which contains descending corticospinal axons, lies immediately lateral to the ventral median fissure. The lateral margin of the pyramid is indicated by a shallow ventrolateral sulcus: the rootlets of the hypoglossal nerve emerge from this sulcus in line with the ventral spinal nerve roots. The abducens nerve emerges at the caudal border of the pons generally in line with the rootlets of the hypoglossal nerve. Caudally, most fibres of the pyramid taper, decussate and enter the lateral funiculus of the spinal cord. The olive forms an oval prominence lateral to the pyramid and the ventrolateral sulcus: it contains the inferior olivary nuclear complex (see Fig. 28.4). Lateral to the olive, the glossopharyngeal and vagus nerves emerge from the brainstem along the posterolateral sulcus, in line with the dorsal spinal nerve roots.

The spinal central canal extends into the caudal half of the medulla, migrating progressively more dorsally until it opens out into the lumen of the fourth ventricle at the obex. This divides the medulla into a caudal closed part, in which the central canal is surrounded by neural tissue, and a rostral open part, in which the central canal opens into the caudal floor or medullary triangle of the fourth ventricle (see Fig. 28.5). The inferior cerebellar peduncles form the lateral walls of the medullary triangle and the striae medullares mark its upper end.

In the closed part of the medulla, a shallow dorsal intermediate sulcus on either side of the dorsal median sulcus that is continuous with its cervical spinal counterpart, indicates the location of the dorsal columns (fasciculi gracilis and cuneatus). The fasciculus gracilis terminates superiorly in the gracile tubercle and the fasciculus cuneatus terminates superiorly in the cuneate tubercle. The restiform body lies dorsolaterally in the medulla, forming a rounded ridge between the caudal part of the fourth ventricle and the glossopharyngeal and vagal rootlets on each side. It contains a wide variety of fibres (dorsal spinocerebellar, cuneocerebellar, olivocerebellar, reticulocerebellar and other cerebellar afferents). The restiform bodies on the two sides diverge and incline to enter the cerebellar hemispheres as the major component of the inferior cerebellar peduncles. Rostrally, in the open portion of the medulla, the dorsal surface of the medulla is demarcated from medial to lateral by the hypoglossal trigone, the sulcus limitans, the vagal trigone, the medullary vestibular area containing portions of the medial and inferior vestibular nuclei, and the dorsal aspect of the inferior cerebellar peduncle. The area postrema lies just inferior to the vagal trigone. The lateral recess of the fourth ventricle opens into the cerebellopontine angle cistern through the lateral aperture of Luschka and conveys a tuft of choroid plexus into the cistern. Inferiorly, the peduncles converge to form a deep 'V', the most caudal point of which, the obex, marks the transition from the fourth ventricle to the central canal of the lower medulla.

Internal organization

Transverse section of the medulla at the level of the motor (pyramidal) decussation

In the inferior medulla, the anatomical configuration typical of the spinal cord is modified to accommodate the intrinsic nuclei and fibres of the brainstem. The continuity between the ventral grey column and central grey matter that is maintained throughout the spinal cord is disturbed by corticospinal fibres crossing in the motor (pyramidal) decussation to reach the contralateral lateral funiculi (Fig. 28.6). As corticospinal fibres leave the anterior funiculi to enter the decussation, the pyramids progressively reduce in volume. At this level, the ventral grey column is subdivided into the supraspinal nucleus (the efferent source of the first cervical nerve and continuous rostrally with the nucleus of the hypoglossal nerve), and the nucleus of the accessory nerve (in line rostrally with the nucleus ambiguus). These nuclei are surrounded by the ventral corticospinal tract medioventrally and the ventral and dorsal spinocerebellar tracts dorsolaterally.

The dorsal grey column is also modified at this level as the nucleus gracilis appears in the ventral part of the fasciculus gracilis. The nucleus gracilis begins caudal to the nucleus cuneatus and both nuclei lie ventral to their corresponding fasciculi. The spinal nucleus and tract of the trigeminal nerve are visible lateral to the dorsal grey

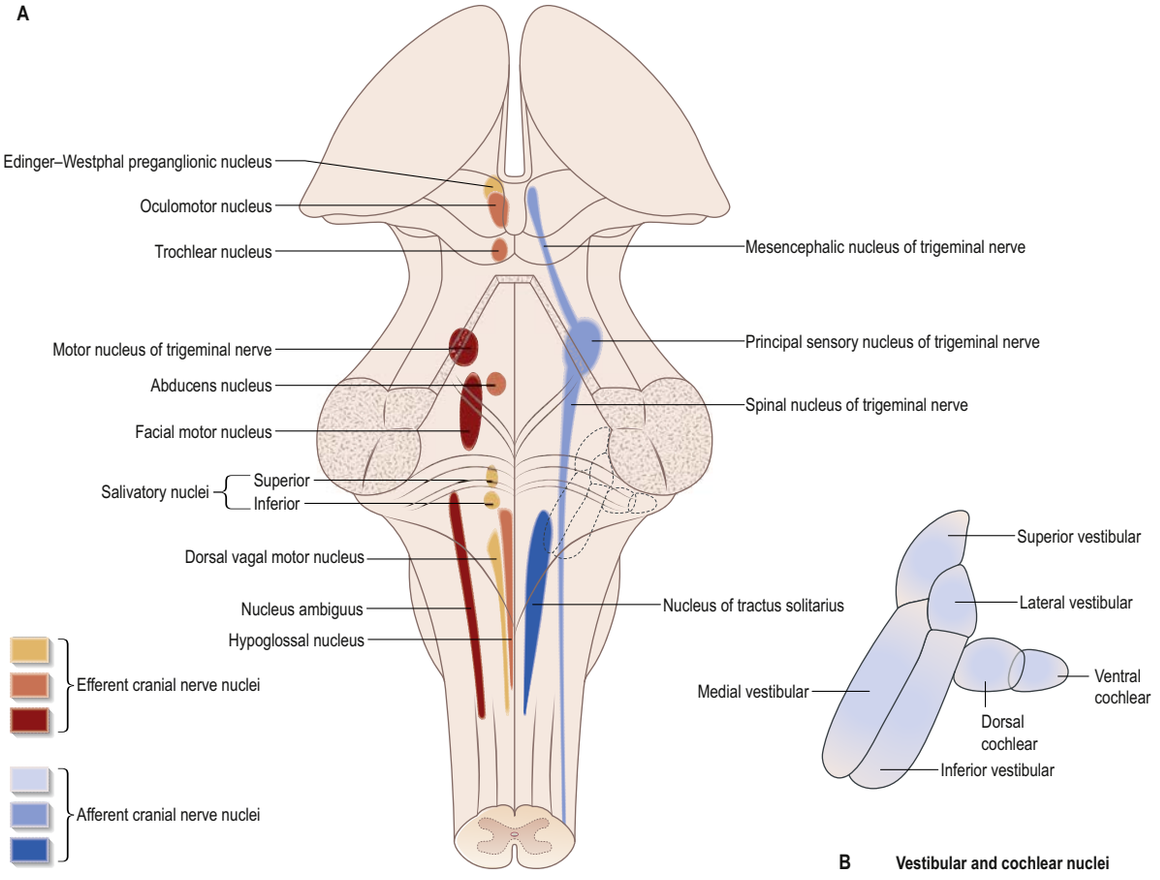

Fig. 28.3 **A**, The cranial nerve nuclei. The components of the vestibular and cochlear nuclei are indicated by the dotted lines. **B**, The components of the vestibular and cochlear nuclei shown in more detail.

columns and are continuous with the substantia gelatinosa and tract of Lissauer of the spinal cord, respectively.

Transverse section of the closed medulla at the level of the sensory decussation of the dorsal column–medial lemniscus system

A transverse section of the closed medulla at the level of the sensory decussation (Fig. 28.7) again displays the dorsal median sulcus, the fasciculus and nucleus gracilis, the dorsal intermediate sulci, and the fasciculus and nucleus cuneatus. First-order afferent fibres contained within the fasciculi gracilis and cuneatus synapse on neurones in their respective nuclei (Millar and Basbaum 1975). Second-order axons emerge from these nuclei as internal arcuate fibres that curve ventrally around the central grey matter toward the midline. Ventral to the central canal, the internal arcuate fibres cross the midline as the sensory decussation and aggregate into the medial lemniscus that ascends from the sensory decussation as a flattened tract near the median raphe. At this level the medial lemniscus lies near the midline, just dorsal to the medial aspect of the pyramid. The inferior olivary complex is just becoming visible lateral to the medial lemniscus and dorsal to the pyramid. The internal arcuate fibres separate the spinal nucleus and tract of the trigeminal nerve from the central grey matter, which is gradually replaced by the inferior tips of the hypoglossal nucleus and the dorsal motor nucleus of the vagus. The fibres of the dorsal spinocerebellar tract now cover over the spinal tract of the trigeminal nerve as they move dorsally. The ventral spinocerebellar tract ascends along the anterolateral surface of the medulla. The reticular formation lies ventromedial to the spinal trigeminal nuclei. The corticospinal tract lies ventrally, and the medial longitudinal fasciculus and the tectospinal tract lie dorsally.

Transverse sections of the medulla at the level of the caudal end of the fourth ventricle and at the level of the striae medullares

The total area of grey matter in the transverse sections through the upper medulla and fourth ventricle is increased by the presence of the nuclei of the vestibulocochlear, glossopharyngeal and vagus nerves dorsally and by the appearance of the inferior olivary nuclear complex, composed of the principal olivary nucleus and the smaller dorsal and medial accessory olivary nuclei (Figs 28.8–28.9). The central canal merges into the fourth ventricle. At this level, the central grey matter forms the floor of the ventricle: from medial to lateral, it contains the hypoglossal nucleus covered by the myelinated dorsal longitudinal fasciculus, the dorsal motor nucleus of the vagus, the salivatory nuclei, the nucleus and tractus solitarius and the caudal ends of the inferior and medial vestibular nuclei. The dorsal and ventral cochlear nuclei lie along the dorsal and lateral contour of the dorsal medulla. The dorsal lateral border is formed by the restiform body that conveys afferent fibres, including the dorsal spinocerebellar and olivocerebellar tracts, to the cerebellum. The spinal trigeminal nucleus and tract, the nucleus ambiguus and the reticular formation lie ventromedial to the restiform body. Further ventrally, the ventral spinocerebellar, lateral spinothalamic and rubrospinal tracts lie along the anterolateral border of the medulla, dorsal to the olivary complex and the pyramid (Nathan and Smith 1982).

The bulge of the olive on the ventrolateral aspect of the medulla is formed by the principal olivary nucleus which receives the descending fibres of the central tegmental tract. The olive is delimited by the pre-olivary sulcus ventrally and retro-olivary sulcus dorsally. The principal olivary nucleus appears as an irregularly crenated 'C-shaped' mass of grey matter with a medially directed hilum. Olivocerebellar fibres emerge from the hilum, course across the full transverse extent of the medulla as olivocerebellar fibres, and aggregate into the major component of the contralateral restiform body (Fig. 28.10). The rootlets of the vestibular nerve emerge inferior to the inferior cerebellar peduncle; the rootlets of the glossopharyngeal, vagus and accessory nerves emerge at the retro-olivary sulcus; the rootlets of the hypoglossal nerve run ventrally between the medial accessory and principal olivary nuclei to emerge at the pre-olivary sulcus, between the olive and the pyramid.

Pathways and nuclei of the medulla

Corticospinal and corticonuclear tracts

The corticospinal and corticonuclear tracts arise in the cerebral hemispheres, traverse the corona radiata and pass through the posterior limb and genu, respectively, of the internal capsule. At the level of the

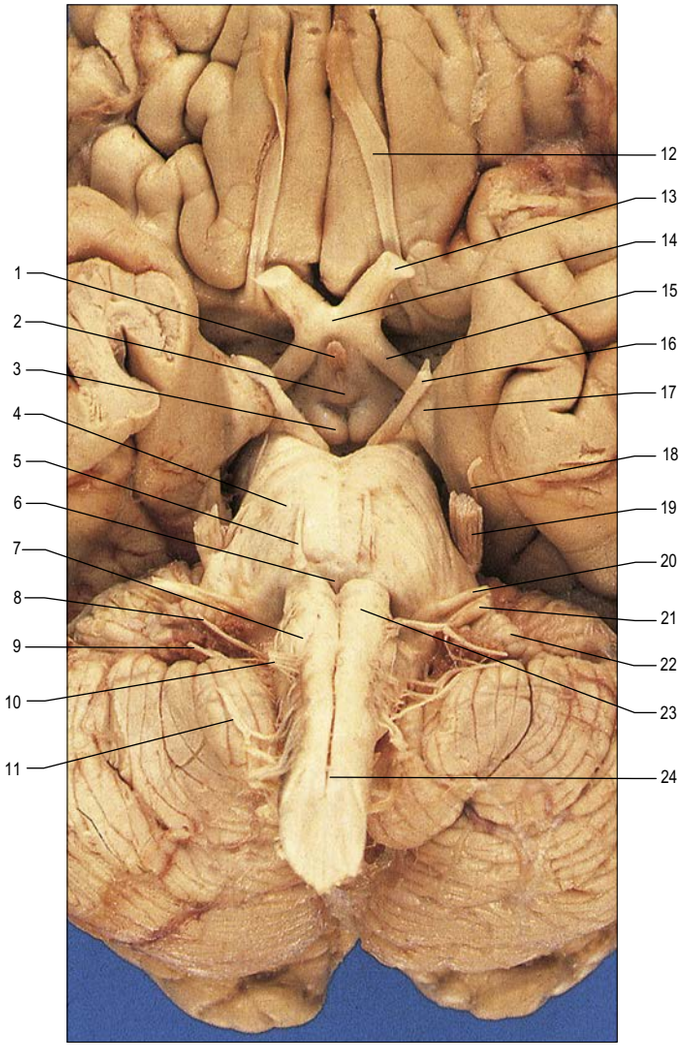

Fig. 28.4 The ventral aspect of the brainstem. Key: 1, infundibulum; 2, tuber cinereum; 3, mammillary body; 4, basilar pons; 5, abducens nerve; 6, foramen caecum; 7, olive; 8, glossopharyngeal nerve; 9, vagus nerve; 10, rootlets of hypoglossal nerve; 11, accessory nerve; 12, olfactory tract; 13, optic nerve; 14, optic chiasma; 15, optic tract; 16, oculomotor nerve; 17, uncus; 18, trochlear nerve; 19, trigeminal nerve; 20, facial nerve; 21, vestibulocochlear nerve; 22, flocculus; 23, pyramid; 24, motor decussation (decussation of pyramids).

cerebral peduncles these fibres assemble into compact tracts that descend through the midbrain, pons and medulla. Corticonuclear fibres terminate within the motor nuclei of the brainstem. In the medulla, the corticonuclear (corticobulbar) fibres project to the nucleus ambiguus and the hypoglossal nucleus: these projections are predominantly contralateral.

The corticospinal tract displays somatotopy at almost all levels of the brainstem: fibres representing the hand descend ventromedially and those representing the foot descend dorsolaterally. Corticospinal fibres continue caudally through the pyramids. Most decussate at this level and pass into the contralateral lateral column of the spinal cord as the crossed lateral corticospinal tract (Nathan et al 1990) (Ch. 27). The majority of corticospinal fibres cross the midline between the central grey matter and the ventral median fissure as the motor (pyramidal) decussation (see Fig. 28.6). Fibres to cervical levels cross first in the rostral part of the decussation, and fibres to lumbosacral levels cross more caudally. The corticospinal fibres that do not decussate here continue caudally into the ipsilateral anterior column of the spinal cord as the ventral corticospinal tract, lying just lateral to the ventral median fissure. Most of these fibres ultimately decussate within each cord segment and cross the ventral white commissure to reach the contralateral ventral horn: a small proportion of corticospinal fibres do not decussate at any level and terminate ipsilaterally.

Dorsal column nuclei and medial lemniscus system

The nuclei gracilis and cuneatus are part of the dorsal column–medial lemniscus pathway that is the major route for discriminative aspects of tactile and proprioceptive sensation (Millar and Basbaum 1975, Haines 2015). Sensory input concerning deformation of skin, movement of hairs, joint movement and vibration is conveyed by the ipsilateral fasciculi gracilis and cuneatus to the secondary neurones of their respective nuclei in the medulla. Afferents from the body inferior to approximately T6 ascend in the fasciculus gracilis to synapse in the nucleus gracilis; afferents from the body rostral to T6 ascend in the fasciculus cuneatus to synapse in the nucleus cuneatus (Miller and Burack 1982). The fibres display a somatotopic organization in the transverse plane: the sacral regions are represented dorsomedially in the nucleus gracilis and cervical regions are represented ventrolaterally in the nucleus cuneatus. The afferent fibres terminate somatotopically in the dorsal column nuclei. Caudal regions of the nuclei receive afferents from the most caudal dorsal root ganglia (i.e. nucleus gracilis from sacral and nucleus cuneatus from mid-thoracic ganglia) and rostral regions receive afferents from the most rostral dorsal root ganglia (i.e. nucleus gracilis from lower thoracic and nucleus cuneatus from cervical ganglia) (Ferraro and Barrera 1935).

A variety of control mechanisms can modulate the transmission of impulses through the dorsal column–medial lemniscus pathway. Descending afferents from the somatosensory cortex reach the nuclei through the corticonuclear tracts, and appear to be restricted to the upper reticular zones. These afferents modulate the transmission of impulses by both pre- and postsynaptic inhibitory mechanisms, and sometimes by facilitation. The reticular zones also receive modulatory afferents from the reticular formation and raphe nuclei.

Inferior cerebellar peduncle, restiform body and olivary complex

The inferior cerebellar peduncle forms the lateral wall of the medullary triangle of the fourth ventricle and the anterior rostral margin of the lateral recess of the fourth ventricle. The dorsal and ventral cochlear nuclei lie along the outer margin of the peduncle. The intramedullary portion of the inferior cerebellar peduncle is composed of the small juxtarestiform body medially and the larger restiform body laterally (see Fig. 28.11). The juxtarestiform body carries fibres to and from the vestibular nuclei. The lateral vestibular nucleus (of Deiter) lies within the juxtarestiform body. The restiform body carries afferent fibres to the cerebellum, including ascending fibres from the accessory cuneate nucleus in the cuneocerebellar tract; ascending fibres from the spinal cord in the dorsal spinocerebellar tract; crossed fibres from the contralateral inferior olivary system in the olivocerebellar tract; both crossed and uncrossed anterior external arcuate fibres in the anterior arcuatocerebellar tract; and fibres from the reticular nuclei of the lateral and anterior funiculi in the reticulocerebellar tract. The restiform body ascends medial to the middle cerebellar peduncle to enter the cerebellum further rostrally in the pons.

The cuneocerebellar tract is composed of posterior external arcuate fibres from the accessory cuneate nucleus situated dorsolateral to the cuneate nucleus. It is part of the spinocerebellar system of precerebellar relay nuclei and functions as the upper extremity counterpart of the posterior thoracic nucleus (nucleus thoracis, Clarke's column) (see Fig. 28.10). Proprioceptive impulses from muscle stretch receptors and cutaneous touch receptors in the upper limb that enter the spinal cord rostral to the posterior thoracic nucleus ascend through the lateral fibres of the fasciculus cuneatus to synapse in a somatotopic pattern on large neurones in the accessory cuneate nucleus. From there, fibres form the cuneocerebellar fasciculus that ascends through the ipsilateral restiform body to reach the cerebellum. A smaller number of accessory cuneate efferents cross the midline and ascend within the contralateral medial lemniscus to reach the thalamus (Nieuwenhuys et al 2008).

The dorsal (posterior) spinocerebellar tract carries proprioceptive impulses from muscle stretch receptors and cutaneous touch receptors for the lower extremities and trunk. Tract fibres originate from the ipsilateral posterior thoracic nucleus situated in the intermediate grey matter of the spinal cord (Rexed lamina VII). Sensory inputs entering from segments caudal to L3 first ascend in the fasciculus gracilis and then pass to the caudal end of the posterior thoracic nucleus where they synapse. Sensory information from more rostral segments, L3 to C8, enter with the segmental dorsal roots and pass directly to the posterior thoracic nucleus. Second-order afferent fibres originating from the posterior thoracic nucleus form the dorsal spinocerebellar tract which ascends ipsilaterally to the brainstem (see Fig. 28.10). Within the brainstem, the dorsal spinocerebellar tract ascends along the lateral surface of the caudal medulla, just ventral to the spinal trigeminal tract. It then passes dorsally and superiorly, external to and covering over, the spinal trigeminal tract, to enter the ipsilateral restiform body of the inferior cerebellar peduncle.

The extent and symmetry of decussation of the pyramids vary. In some adults, up to 30% of corticospinal fibres descend as uncrossed fibres that pass into the ipsilateral anterior (ventral) funiculus of the spinal cord (Nathan et al 1990). In human fetuses, the anterior tract was found to be highly variable in size, often asymmetric and even absent, unilaterally or bilaterally (Jin et al 2016). In three-quarters of corticospinal decussations, the fibres crossing from left to right decussated at a more rostral level than fibres decussating from right to left: fewer fibres descended uncrossed in the left anterior column (Nathan et al 1990). This asymmetry does not appear to correlate with handedness (Kertesz and Geschwind 1971).

The upper regions of both nuclei are reticular and contain small and large multipolar neurones with long dendrites. The lower regions contain clusters of large, round neurones with short and profusely branching dendrites. Upper and lower zones differ in their connections but both receive terminals from the dorsal spinal roots at all levels. Dorsal funicular fibres from neurones in the spinal grey matter are components of the postsynaptic dorsal column system and terminate only in the superior, reticular zone. Variable ordering and overlap of terminals, on the basis of spinal root levels, occur in both zones. The lower extremity is represented medially, the trunk ventrally and the digits dorsally. There is modal specificity, i.e. lower levels respond to low-threshold cutaneous stimuli, and upper reticular levels to inputs from fibres serving receptors in the skin, joints and muscles. The nucleus cuneatus is divided into several zones. Its middle zone contains a large pars rotunda, in which rostrocaudally elongated, medium-sized neurones are clustered between bundles of densely myelinated fibres. The reticular poles of its rostral and caudal zones contain scattered, but evenly distributed, neurones of various sizes. The pars triangularis is smaller and laterally placed.

The pattern of termination of cutaneous afferents is apparently somtatotopically organized for the pars rotunda and more diffuse in the reticular poles. Unit recording of the neurones in the dorsal column nuclei shows that their tactile receptive fields (i.e. the skin area in which a response can be elicited) vary in size. Especially small receptive fields appear to account for the great sensitivity found in the digits, the face and the lips. Some fields have excitatory centres and inhibitory surrounds, which means that stimulation just outside its excitatory field inhibits the neurone. In general, sensory modal specificity is high. Many cells receive input from one or a few specific receptor types, e.g. hair, type I and II slowly adapting receptors, and Pacinian corpuscles. Some cells respond to Ia muscle spindle input, or receive convergent input from tactile pressure and hair follicle receptors. Primary spinal afferents synapse directly onto multipolar neurones in nuclei that provide the major nuclear efferent projections. The nuclei also contain interneurones, many of which are inhibitory.

A group of neurones, designated nucleus Z, has been identified in animals between the upper pole of the nucleus gracilis and the inferior vestibular nucleus. This nucleus is said to be present in the human medulla. Collaterals of the dorsal spinocerebellar tract convey proprioceptive input from both lower extremities to Group Z neurones (Nieuwenhuys et al 2008). These neurones project efferents through internal arcuate fibres to the contralateral medial lemniscus.

The external surface of the pyramids displays a layer of neurones that are considered to be displaced pontine neurones and are designated collectively as the arcuate nucleus. These neurones give rise to anterior external arcuate (arcuatocerebellar) fibres that spread around the medulla, above and below the olivary eminence, enter the restiform body, traverse the inferior cerebellar peduncle and project mainly to the contralateral cerebellum (see Figs 28.7, 28.10). The arcuate nucleus also gives rise to the anterior internal arcuate fibres that course through the midline, decussate near the floor of the fourth ventricle, then turn laterally under the ependyma and enter the contralateral cerebellum as striae medullares of the fourth ventricle.

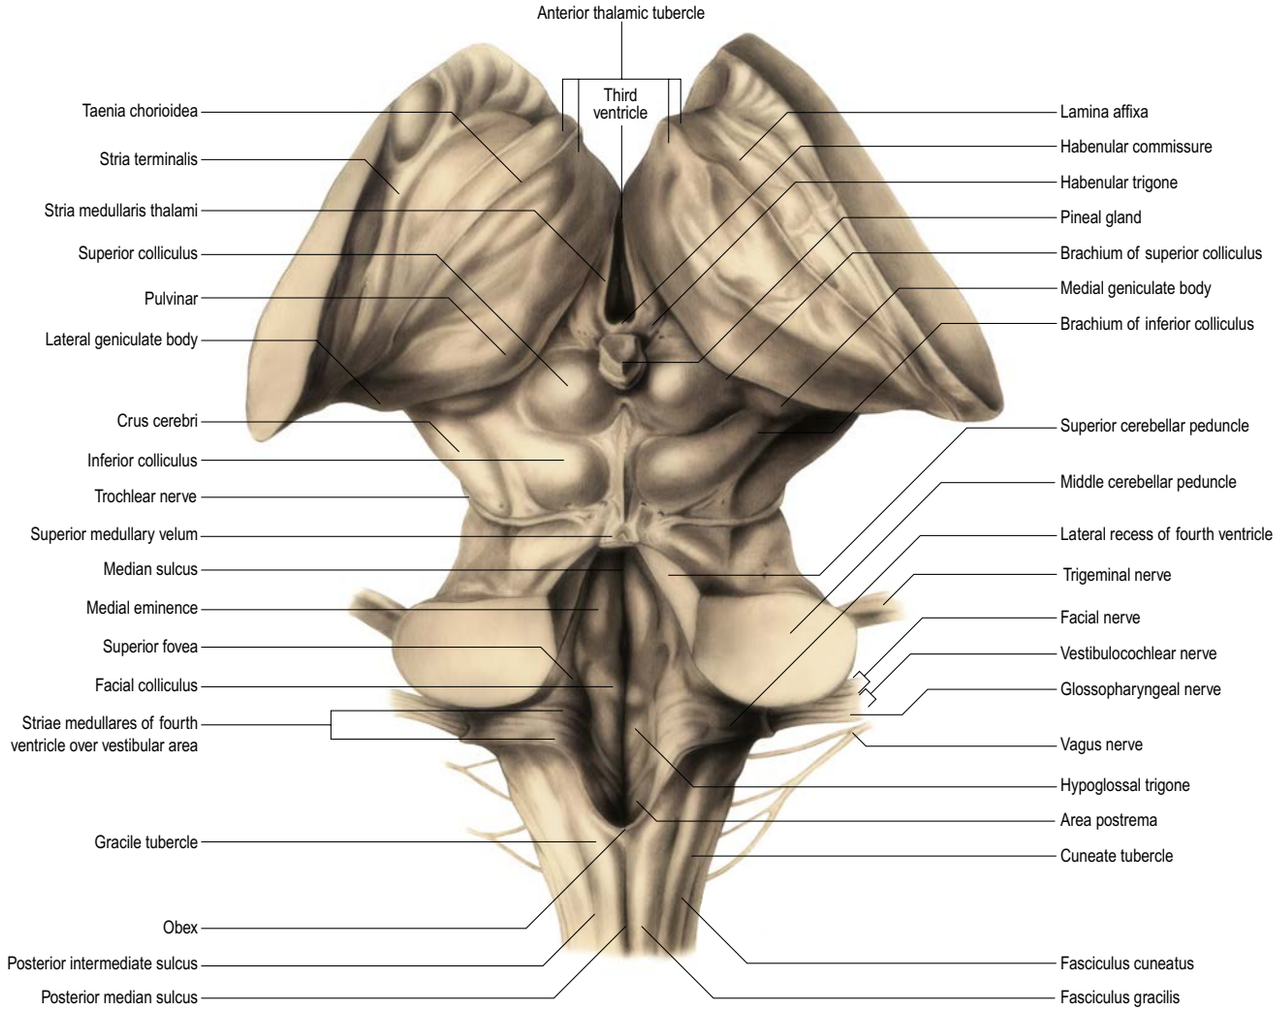

Fig. 28.5 The dorsal aspect of the brainstem: the floor of the fourth ventricle has been exposed by cutting the cerebellar peduncles and removing the cerebellum. (With permission from Neuroanatomy by FA Mettler (1948) 2nd edn; St Louis: The CV Mosby Company.)

Inferior olivary complex

The inferior olivary complex is situated in the lateral portion of the ventral medulla at the level of the caudal end of the fourth ventricle. It consists of the large principal olivary nucleus and the smaller medial and dorsal accessory olivary nuclei (see Figs 28.7–28.9). They are also precerebellar nuclei, a group that includes the pontine, arcuate, vestibular, reticulocerebellar and spinocerebellar nuclei, all of which receive afferents from specific sources and project to the cerebellum. The principal olivary nucleus is an irregularly crenated cup of grey matter with

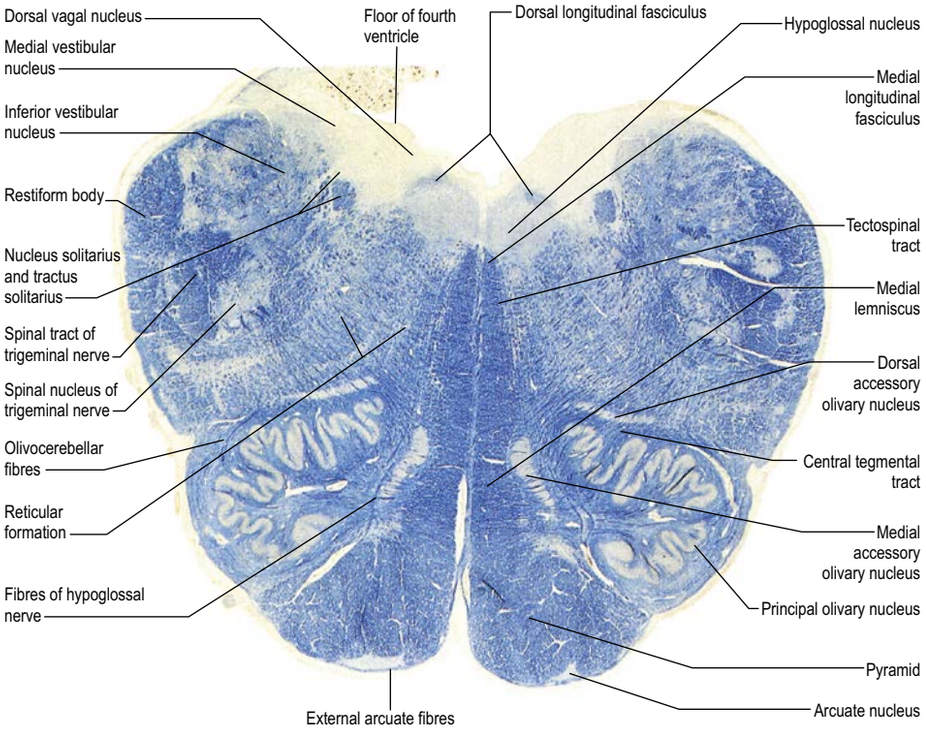

Fig. 28.8 A transverse section through the medulla oblongata at the caudal end of the fourth ventricle, prepared using Luxol fast blue stain for myelinated nerve fibres (blue).

a medially directed hilum, through which numerous fibres enter and leave the nucleus.

The inferior olivary nuclei receive both ascending and descending afferent fibres. Ascending fibres, mainly crossed, arrive from all spinal levels via the spino-olivary tracts and via the dorsal columns. Descending ipsilateral afferents arrive from the cerebral cortex, cerebellar nuclei, thalamus, red nucleus and central grey matter of the midbrain. The afferent fibres from the red nucleus and the central mesencephalic grey matter are major components of the central tegmental tract.

Efferent fibres arise from small neurones of the principal olivary nucleus, most of which form the olivocerebellar tract. The olivocerebellar tract emerges primarily from the hilum of the olive and then sweeps medially across the medulla to enter the contralateral restiform body of the inferior cerebellar peduncle. In this course, the olivocerebellar fibres first cross through the medial lemniscus (see Fig. 28.8), then cross the midline, and pass dorsal to, or right through, the opposite olivary nuclei. They intersect the lateral spinothalamic and rubrospinal tracts and the spinal nucleus of the trigeminal nerve, and enter the contralateral restiform body (and eventually the inferior cerebellar peduncle), where they constitute its major component. Fibres from the contralateral inferior olivary complex terminate on Purkinje cells in the cerebellum as climbing fibres; there is a one-to-one relationship between Purkinje cells and neurones in the complex (Nieuwenhuys et al 2008).

Anterolateral system, including spinothalamic and spinoreticular tracts (spinal lemnisci)

The anterolateral fasciculus (anterolateral system) is a diffuse, composite pathway arising from different laminae of the spinal grey matter. Most of its fibres decussate in the anterior white commissure and ascend

The medial accessory olivary nucleus is a long curved lamina of grey matter, concave laterally, that is situated between the medial lemniscus and pyramid medially and the ventromedial aspect of the olivary nucleus laterally (see **Fig. 28.8**). In axial sections, the medial accessory olivary nuclei take the form of a right-angle, with a dorsal leg that is orientated sagittally and a ventral leg that is orientated transversely. The dorsal accessory olivary nucleus is a similar lamina, situated dorsomedial to the principal olivary nucleus. Both accessory nuclei are phylogenetically older than the principal olivary nucleus, and are connected with the paleocerebellum. In all connections, cerebral, spinal and cerebellar, the olivary nuclei display specific topographical organization (Ch. 29).

in the contralateral anterolateral funiculus to terminate at multiple sites in the brainstem, diencephalon and basal telencephalon. The spinothalamic and spinoreticular tracts are the major components of this system; other tracts running in parallel include the spinotectal, vestibulospinal, rubrospinal and ventral spinocerebellar tracts (Nathan and Smith 1982). In the medulla, these tracts are limited dorsally by the spinal tract and nucleus of the trigeminal nerve, and ventrally by the pyramid.

The spinothalamic and spinoreticular tracts are a longitudinal system of ascending fibres that convey pain, itch, temperature, tactile and proprioceptive information from the contralateral side of the body to the brain. Similar sensory input from the face passes to the trigeminal sensory system. The neuronal cell bodies that mediate noxious stimuli are found in the dorsal root ganglia at all levels of the spinal cord (Gilman and Newman 2003). Their central fibres synapse within the ipsilateral spinal cord. Most secondary relay fibres then cross the midline in the ventral white commissure; a few remain ipsilateral. On both sides, the spinothalamic tracts ascend along the anterolateral margins of the spinal cord to reach the brainstem. They continue upward along the anterolateral aspect of the medulla and pons and ascend posterolateral to the medial lemniscus in the low midbrain. The spinothalamic tracts then ascend through the midbrain deep to the brachium of the inferior colliculus and medial geniculate body to reach the ventroposterolateral nucleus of the thalamus (Haines and Mihailo 2018). Ascending fibres also reach the superior colliculus. In humans, few of the ascending spinothalamic fibres are thought to reach the thalamus directly: the spinothalamic relay system is predominantly a polysynaptic system in which most ascending fibres synapse in the reticular formation of the brainstem as the spinoreticular system (Nieuwenhuys et al 2008).

The ventral (anterior) spinocerebellar tract runs in parallel with its dorsal counterpart in the lower medulla but the two separate as they approach the restiform body. Somatosensory fibres for proprioception, pain and pressure from the lumbar and some sacral levels enter the dorsal horns of the spinal cord to synapse with neurones in the intermediate grey matter and base of the dorsal horns (Rexed's laminae V–VII). Most relay fibres then cross the midline via the ventral white commissure and ascend to the brainstem as the ventral spinocerebellar tract (see **Figs 28.6–28.7**). A few remain uncrossed and ascend ipsilaterally (Carpenter and Sutin 1983). Within the medulla, the tract ascends along the anterolateral border of the medulla, with the spinothalamic tract. Further rostrally, the ventral spinocerebellar tract curves posterolaterally and spreads out into a thin lamina that ascends along the external surface of the superior cerebellar peduncle of the midbrain. At the upper border of the superior cerebellar peduncle, these fibres recurve ventrally and medially over the top of the peduncle and enter the superior cerebellum. Most anterior spinocerebellar fibres then recross the midline to terminate in the contralateral cerebellum (i.e. ipsilateral to their cells of origin). About 15% of ventral spinocerebellar fibres terminate bilaterally (Carpenter and Sutin 1983).

Hypoglossal nucleus

The hypoglossal nucleus lies near the midline in the dorsal medullary grey matter. It is approximately 2 cm long and extends from the hypoglossal trigone in the floor of the fourth ventricle into the closed part of the medulla (see **Figs 28.3, 28.5, 28.8**). It consists of large motor neurones interspersed with myelinated fibres and is organized into dorsal and ventral nuclear tiers, each divisible into medial and lateral

subnuclei. A musculotopic organization of motor neurones within the nuclei corresponds to the structural and functional divisions of tongue musculature. Motor neurones innervating tongue retrusor muscles are located in dorsal/dorsolateral subnuclei, and those innervating the main tongue protrusor muscle are located in ventral/ventromedial regions of the nucleus.

The hypoglossal nucleus receives corticonuclear fibres from the precentral gyrus and adjacent areas, predominately from the contralateral hemisphere. The corticonuclear fibres synapse either on motor neurones of the nucleus directly or on interneurones. Most medial hypoglossal subnuclei receive projections from both cerebral hemispheres. The hypoglossal nucleus may connect with the cerebellum via the adjacent perihypoglossal nucleus, and perhaps also with the medullary reticular formation, the trigeminal sensory nucleus and the nucleus solitarius (Holstein 2012).

Hypoglossal fibres emerge from the ventral aspect of the nucleus and traverse the reticular formation lateral to both the medial lemniscus and the medial accessory olivary nucleus. They continue ventrally, between the medial accessory and the principal inferior olivary nuclei, and then curve laterally to emerge from the brainstem as a series of 10–15 rootlets arranged linearly along the preolivary sulcus (see **Figs 28.4, 28.8**) (Yousry et al 2002b). These rootlets coalesce into two bundles that exit separately through the hypoglossal canal and unite extradurally.

Perihypoglossal nuclei

Dorsal motor nucleus of the vagus

The dorsal motor nucleus of the vagus lies slightly dorsolateral to the hypoglossal nucleus, from which it is separated by the nucleus intercalatus (see **Fig. 28.8**). The vagal nucleus extends caudally to the first cervical spinal segment and rostrally to the open portion of the medulla subjacent to the vagal trigone of the fourth ventricle. It is a general visceral efferent nucleus and is the largest parasympathetic nucleus in the brainstem. Most (80%) of its neurones give rise to the preganglionic parasympathetic fibres that pass into the vagus nerve. The remainder are interneurones or neurones that project centrally. The nucleus innervates the cardiac and smooth muscle of the thoracic viscera (heart, bronchi, lungs, oesophagus) and abdomen (stomach, liver, pancreas, spleen, small intestine and proximal part of the colon), and glandular epithelium. Sparse sensory afferents from the nodose ganglion project directly to the dorsal and lateral edges of the dorsal vagal nucleus, and possibly beyond it into the nucleus of the solitary tract (Holstein 2012).

Neurones within the nucleus are heterogeneous and can be classified into nine subnuclei, grouped into rostral, intermediate and caudal divisions. Topographic maps of visceral representation in animals suggest that the heart and lungs are represented in the caudal and lateral parts of the nucleus; the stomach and pancreas in intermediate regions; and the remaining abdominal organs in the rostral and medial parts of the nucleus.

Nucleus ambiguus

The nucleus ambiguus is a complex group of large motor neurones that are situated deep in the medullary reticular formation (see **Figs 28.3, 28.9**). Rostrally, it extends as far as the rostral end of the vagal nucleus. Caudally, the nucleus is in line with, but not continuous with, the nucleus of the accessory nerve. A small retrofacial nucleus separates the upper end of the nucleus ambiguus from the facial nucleus. The nucleus ambiguus contains cellular subgroups that exhibit some topographical representation. Relatively discrete groups of cells in the caudal region innervate individual laryngeal muscles. Neurones in the intermediate area innervate the pharynx and neurones in the rostral area innervate the oesophagus and soft palate.

The nucleus ambiguus contributes special visceral efferent fibres to the glossopharyngeal nerve and may give general visceral efferent fibres to the vagus nerve. Fibres emerging from the nucleus ambiguus pass dorsomedially, then curve laterally. Rostral fibres join the glossopharyngeal nerve. Caudal fibres join the vagus and are distributed to the pharyngeal constrictors, intrinsic laryngeal muscles and striated muscles of the palate and upper oesophagus. A specific caudal pool of laryngeal motor neurones gives rise to the recurrent laryngeal nerve.

Traditionally, the nucleus ambiguus has been considered to give rise to visceral efferent fibres that join fibres derived from ventral (anterior) horn neurones in the upper five cervical cord segments (Gilman and Newman 2003). After travelling together for a short time, the medullary and spinal roots separate; the medullary fibres join the vagus nerve and the spinal fibres traverse the jugular foramen and ultimately innervate sternocleidomastoid and trapezius (Ch. 35). The nucleus ambiguus receives corticonuclear fibres from both hemispheres with a contralateral preponderance and is reciprocally connected to many brainstem nuclei.

Nucleus solitarius

The nucleus solitarius (solitary nucleus; nucleus of the solitary tract) lies within the dorsal tegmentum of the medulla, mostly medial to the tractus solitarius (solitary tract) from which it receives its main afferents (see **Figs 28.3**, 28.8) (Paxinos et al 2012). This heavily myelinated tract descends through the medulla lateral or ventrolateral to the vagal nucleus and carries afferent fibres from the facial, glossopharyngeal and vagus nerves to the nucleus solitarius (Ciriello 1983, Hamilton and Norgren 1984, Haines and Mihailo 2018). Termination of special visceral afferents (taste) within the nucleus shows a viscerotopic pattern, predominantly in the rostral region (the gustatory nucleus). Experimental evidence suggests that fibres from the anterior two-thirds of the tongue and the roof of the oral cavity (which travel via the chorda tympani and greater petrosal branches of the facial nerve) terminate in the most rostral part of the solitary complex. Those from the circumvallate and foliate papillae of the posterior third of the tongue, tonsils, palate and pharynx (which travel via the lingual branch of the glossopharyngeal nerve) are distributed diffusely throughout the rostrocaudal extent of the nucleus, predominantly rostral to the obex. Afferents from the larynx and epiglottis (which travel via the superior laryngeal branch of the vagus) have a more caudal and lateral distribution.

Gastrointestinal afferents appear to terminate predominantly in medial and commissural subnuclei in the caudal part of the nucleus. Ventral and interstitial subnuclei probably receive tracheal, laryngeal and pulmonary afferents and play an important role in respiratory control and possibly rhythm generation. The carotid sinus and aortic body nerves terminate in the dorsal and dorsolateral region of the nucleus solitarius, which may be involved in cardiovascular regulation. Connections with the reticular formation underlie the reflex control of cardiovascular, respiratory and cardiac functions (Ciriello 1983). For these reasons, the caudal portion of the nucleus solitarius is also known as the cardiorespiratory nucleus.

Many secondary gustatory axons from the solitary nucleus cross the midline and ascend with the medial lemniscus to synapse on the most medial neurones of the ventral posteromedial thalamic nucleus in a region sometimes termed the accessory arcuate nucleus. From there, axons radiate to the anteroinferior portion of the sensory cortex and to the insula. Other ascending paths may end in hypothalamic nuclei that mediate the flow of gustatory information to the limbic system to facilitate appropriate autonomic responses. The nucleus solitarius also projects extensively to many areas of the reticular formation (Paxinos et al 2012) and it may project to the upper levels of the spinal cord through a solitariospinal tract (Hamilton and Norgren 1984).

Spinal trigeminal nucleus

The sensory nuclei of the trigeminal nerve form a longitudinal column that extends from the midbrain to the cervical spinal cord and consists of the spinal trigeminal nucleus (nucleus of the spinal tract of the trigeminal nerve) in the dorsal spinal cord and medulla oblongata, the principal sensory nucleus in the pons, and the mesencephalic nucleus in the midbrain (see **Figs 28.3, 28.14, 28.15**) (Olszewski 1950, Nieuwenhuys et al 2008). The term trigeminal sensory nuclear complex refers to the spinal sensory and principal sensory nuclei (Henssen et al 2016). The mesencephalic nucleus of the trigeminal nerve is regarded separately as group of ectopic primary afferent cell bodies.

The spinal nucleus of the trigeminal nerve has three parts: the pars oralis, which adjoins the principal sensory nucleus, the pars interpolaris, and the pars caudalis, which is directly continuous with the dorsal horn of the spinal cord (see **Figs 28.7–28.9**). Afferent fibres that convey pain, temperature and light touch from the orofacial region enter the brainstem at the pons and course dorsomedially towards the principal sensory nucleus: before reaching the nucleus, approximately 50% of the fibres divide into ascending and descending branches, and the remainder ascend or descend without division. The descending trigeminal fibres form the spinal tract of the trigeminal nerve, which courses along the lateral border of the spinal nucleus from the midpons to the C2 level, where it becomes continuous with the the dorsal tract of Lissauer (Waite and Ashwell 2012).

The great majority of the fibres are less than 4 μm in diameter. There is a precise somatotopic organization within the tract. Fibres from the ophthalmic division of the trigeminal nerve lie ventrally, those from the

Experimental evidence suggests that motor neurones of the medial division of the hypoglossal nucleus innervate tongue muscles that are orientated in planes transverse to the long axis of the tongue (transverse and vertical intrinsics and genioglossus), whereas motor neurones of the lateral division innervate tongue muscles that are orientated parallel to this axis (styloglossus, hyoglossus, superior and inferior longitudinal).

Several small groups of cells lie near the hypoglossal nucleus, including the nucleus intercalatus, sublingual nucleus, nucleus prepositus hypoglossi and nucleus paramedianus dorsalis (reticularis). Despite their name, none of these nuclei is presently known to be connected with the hypoglossal nerve or nucleus. The nucleus prepositus hypoglossi subserves vestibular and oculogyric functions and is discussed with those systems. The nucleus intercalatus extends from below the obex up to the rostral pole of the hypoglossal nucleus, where it gives way to the nucleus prepositus hypoglossi. It starts as a narrow wedge between the hypoglossal and the dorsal vagal nuclei, but expands rostrally as the vagal nucleus migrates laterally (Paxinos et al 2012); gustatory and visceral connections are attributed to the nucleus intercalatus.

mandibular division lie dorsally, and fibres from the maxillary division lie between. The tract is completed on its dorsal rim by fibres from the sensory roots of the facial, glossopharyngeal and vagus nerves. All of these fibres synapse in the pars caudalis of the spinal nucleus of the trigeminal nerve.

Other afferents to the spinal nucleus arise from the dorsal roots of the upper cervical nerves. All of these fibres synapse in the pars caudalis of the spinal nucleus of the trigeminal nerve, although the ophthalmic division may not project fibres as far.

Efferent fibres from the pars oralis and interpolaris of the spinal nucleus ascend through the ventral pontine tegmentum, decussate and ascend along the dorsomedial side of the contralateral medial lemniscus as the ventral trigeminothalamic tract (trigeminal lemniscus) (Waite and Ashwell 2012). These fibres end in the ventral posteromedial nucleus of the thalamus contralateral to the spinal trigeminal nucleus of origin. Fibres from the pars caudalis ascend in both ventral and dorsal trigeminothalamic tracts to terminate in the ventral posteromedial nucleus as well as in the mediodorsal and intralaminar thalamic nuclei (Waite and Ashwell 2012, Henssen et al 2016). From the thalami, third-order neurones project to the cortical postcentral gyrus (Brodmann areas 3, 1, 2). Other afferent fibres from the pars caudalis, especially from laminae I, V and VI, project to the rostral trigeminal nuclei, cerebellum, periaqueductal grey of the midbrain, parabrachial area of the pons, the brainstem reticular formation and the spinal cord.

There are conflicting opinions on the pattern of termination of the fibres in the spinal nucleus. It has long been held that fibres are organized rostrocaudally within the tract. According to this view, ophthalmic fibres are ventral and descend to the lower limit of the first cervical spinal segment, maxillary fibres are central and do not extend below the medulla oblongata, whilst mandibular fibres are dorsal and do not extend much below the mid-medullary level. The results of section of the spinal tract in cases of severe trigeminal neuralgia support this distribution. It was found that a section 4 mm below the obex rendered the ophthalmic and maxillary areas analgesic but tactile sensibility, apart from the abolition of 'tickle', was much less affected. To include the mandibular area it was necessary to section at the level of the obex.

PONS

The pons (metencephalon) is the middle segment of the brainstem. It is approximately 2.5–3 cm in length and 3–4 cm wide at the root entry zones of the trigeminal nerves. It occupies the anterior portion of the mid posterior fossa behind the clivus. The ventral surface of the pons is separated from the upper clivus by the meninges and prepontine cistern. The dorsal surface of the pons faces the cerebrospinal fluid within the fourth ventricle and is covered over by the cerebellum. The lower border of the pons is marked by the transverse pontomedullary sulcus ventrally and the striae medullares of the fourth ventricle dorsally. The upper border of the pons is the upper margin of the pontine curvature ventrally and the decussation of the trochlear nerve in the superior medullary velum dorsally. The ventral edges of the medial lemnisci separate the basal pons (ventrally) from the pontine tegmentum (dorsally). The decussation of the superior cerebellar peduncle marks the transition from the pontine tegmentum to the midbrain tegmentum.

External features and relations

From medial to lateral, the ventral surface of the pons is marked by the shallow basilar sulcus, transverse ridges formed by underlying nerve fibre fascicles and the ventral aspect of the middle cerebellar peduncle (brachium pontis) (see Fig. 28.4). The abducens nerve emerges from the medullopontine sulcus 1–2 cm lateral to the midline. The facial nerve, vestibulocochlear nerve and the nervus intermedius emerge from the supraolivary fossette just inferior to the brachium pontis. The trigeminal nerve emerges from the lateral-most edge of the midpons, and marks the transition from the pons ventrally to the middle cerebellar peduncle dorsally. Typically, a single small motor root of the trigeminal nerve (portio minor) emerges dorsomedial to the larger sensory root (portio major). On occasion, the motor root appears as two separate superior and inferior divisions, rather than a single fascicle (Yousry et al 2004).

The dorsal surface of the pons is the upper portion of the floor of the fourth ventricle rostral to the striae medullares (pontine triangle) (see Fig. 28.5). From medial to lateral, the dorsal surface of the pons is marked by a median sulcus, a median eminence and paramedian sulcus limitans. Caudal to the median eminence, the facial colliculus marks the site where the fibres of the facial nerve curve over the abducens nucleus. The inferior fovea separates the facial colliculus from the hypoglossal trigone. Superolaterally, a small depression in the floor of the fourth ventricle, the superior (trigeminal) fovea, marks the site of the underlying principal sensory and motor nuclei of the trigeminal nerve. The pontine vestibular area lies far laterally, at the lateral angle of the fourth ventricle. Lateral to the fourth ventricle, a groove (lateral recess) separates the middle from the superior cerebellar peduncles.

Internal organization

Transverse section through the pons at the level of the facial colliculus

A transverse section through the lower pons at the level of the facial colliculus cuts through the upper half of the fourth ventricle just above the striae medullares (Fig. 28.11). Dorsally, the medial longitudinal fasciculus lies beneath the floor of the fourth ventricle just lateral to the median sulcus. Lateral to this, the ovoid abducens nucleus gives rise to the nerve fibres that emerge from the ventromedial aspect of the nucleus and course ventrolaterally and caudally across the pons. The facial nerve nucleus lies ventral, lateral and caudal to the abducens nucleus in the low lateral pontine tegmentum. The fibres of the facial nerve ascend to the medial aspect of the abducens nucleus, curve dorsally and laterally as the genu of the facial nerve, and pass over the dome of the abducens nucleus, forming the facial collicus (Fig. 28.12). The facial fibres then recurve ventrally, and descend between the facial nucleus and the spinal trigeminal nucleus and tract to emerge from the brainstem below the middle cerebellar peduncle. Dorsolaterally, the restiform and juxtarestiform bodies of the inferior cerebellar peduncle lie superolateral to the superior and lateral vestibular nuclei. The vestibulocerebellar fibres emerge lateral to the vestibular nuclei while the vestibular nerve emerges ventrally. At this level, the ascending fibres of the medial lemniscus assemble into an ovoid bundle in the ventral pontine tegmentum. The transverse fibres of the trapezoid body and the trapezoid nuclei cross the midline in the ventral tegmentum, along the medial lemnisci. The central tegmental tract courses longitudinally through the mid pontine tegmentum. Within the basal part of the pons, myriad pontine nuclei give rise to the transverse fibres of the pons (pontocerebellar fibres) that cross the midline to form the contralateral middle cerebellar peduncle. The descending frontopontine, corticospinal and parieto-temporo-occipito-pontine fibres course longitudinally through the central portion of the basal pons, and partially separate the transverse fibres of the pons into prominent ventral and dorsal bundles.

Transverse section through the pons at the level of the principal sensory and motor nuclei of the trigeminal nerve

At this level, the superior cerebellar peduncle forms the upper lateral wall of the fourth ventricle and the superior medullary velum forms its roof (Fig. 28.13). The lateral margin of the fourth ventricle contains the superior fovea that overlies, from medial to lateral, the motor nucleus and the principal sensory nucleus of the trigeminal nerve and the intervening fibres of the sensory root of the trigeminal nerve. The mesencephalic tract of the trigeminal nerve courses longitudinally in the adjacent dorsolateral tegmentum. The medial lemniscus and lateral lemniscus form a ventrally convex 'lemniscal arch' that delimits the tegmentum from the basal pons. The transverse fibres of the trapezoid body and contained trapezoid nuclei curve across the midline in the ventral tegmentum. Further dorsally the central tegmental tract courses longitudinally through the central pontine tegmentum.

The structure of the pars caudalis is analogous to that of the dorsal horn of the spinal cord, with a similar arrangement of cell laminae (subnuclei zonalis, gelatinosus and magnocellularis). Cutaneous nociceptive afferents and small-diameter muscle afferents terminate in layers I, II, V and VI of the pars caudalis. Low-threshold mechanosensitive afferents of Aβ neurones terminate in layers III and IV of the pars caudalis and in the rostral (interpolaris, oralis, principal sensory) nuclei. Many of the neurones in the pars caudalis that respond to cutaneous or tooth-pulp stimulation are also excited by stimulation of jaw or tongue muscles, indicating convergence of superficial and deep afferent inputs via wide-dynamic-range or nociceptive-specific neurones. Similar convergence of superficial and deep inputs occurs in the rostral parts of the trigeminal nucleus, which may account for the poor localization of trigeminal pain, and for the spread of pain, which often makes diagnosis difficult.

Cells in lamina II of the pars caudalis also receive afferents from the sensorimotor cortex, the periaqueductal grey matter, the nucleus raphe magnus and the reticular formation. The nucleus raphe magnus projects directly to the pars caudalis, probably via enkephalin, noradrenaline (norepinephrine) and 5-HT (5-hydroxytryptamine, serotonin)-containing terminals. These fibres directly, or indirectly through local interneurones, influence pain perception. Stimulation of periaqueductal grey matter or nucleus raphe magnus inhibits the jaw-opening reflex to nociception, and may induce primary afferent depolarization in tooth-pulp afferents and other nociceptive facial afferents. Neurones in the pars caudalis can be suppressed by stimuli applied outside their receptive field, particularly by noxious stimuli. The pars caudalis is an important site for relay of nociceptive input and functions as part of the pain 'gate control'. However, rostral nuclei may also have a nociceptive role as tooth-pulp afferents via wide-dynamic-range and nociceptive-specific neurones terminate in rostral nuclei, which all project to the subnucleus caudalis.

The separation of the entering fibres can give rise to a segmental (cross-divisional) sensory loss when focal medullary pathology such as syringobulbia occurs at a strategic site. Tractotomy of the spinal tract performed at a lower level can spare the perioral region, a finding that would accord with the classical 'onion-skin' pattern of loss of pain sensation. However, in clinical practice, the progression of anaesthesia on the face is commonly 'divisional' rather than strictly 'onion-skin' in distribution. GSA fibres subserving common sensation enter the dorsal region of the spinal tract of the trigeminal nerve from the glossopharyngeal, vagus and facial nerves (nervus intermedius) and synapse with cells in the caudal part of the spinal nucleus. Consequently, operative section of the dorsal part of the spinal tract results in analgesia that extends to the mucosa of the tonsillar sinus, the posterior third of the tongue and adjoining parts of the pharyngeal wall (supplied by the glossopharyngeal nerve), and the cutaneous areas of the ear (supplied by the auricular branch of the vagus).

During the normal processes of eating and drinking, the passage of food or liquid to the rear of the mouth stimulates branches of the glossopharyngeal nerve in the oropharynx and swallowing is initiated. The nasopharynx is closed off from the oropharynx by elevation of the soft palate, the larynx is raised, its entrance narrowed, the glottis is closed and peristaltic activity down the oesophagus to the stomach is mediated through the pharyngeal plexus.

The patterning and timing of striated muscle contraction that occur during swallowing are generated in the brainstem by a network of neural circuits involving the nucleus solitarius (afferent limb) and the nucleus ambiguus (efferent limb).

If stimulation of the oropharynx occurs other than during swallowing, the gag reflex may be initiated: a reflex contraction of the muscles of the pharynx, soft palate and fauces occurs that, if extreme, can result in retching and vomiting.

The cough reflex is normally initiated by irritation of tracheal or laryngeal mucosae: there is evidence of both mechanosensing and chemosensing cough receptors (McGarvey 2014). Coughing involves a sequence of coordinated events that produce the profound change in breathing pattern needed to expel an irritant from the lower airway. Rapid inspiration is followed by an expiratory effort against a closed glottis, the rapid generation of intrapulmonary pressure and the sudden opening of the glottis and contraction of intercostal and abdominal wall muscles, collectively producing a high-velocity flow of expired air that sweeps irritant material up towards the pharynx in a forceful exhalation (cough). Laryngeal branches of the vagus nerve carrying general visceral afferent information (with cell bodies in the inferior vagal ganglion) terminate in the nucleus of the solitary tract. Second-order neurones project to medullary respiratory centres (including a putative cough centre) and to the nucleus ambiguus, recruiting motor neurones innervating pharyngeal, laryngeal, diaphragmatic, intercostal and abdominal muscles.

The sneeze reflex arises from stimulation of the nasal mucosa by physical or chemical irritants. Afferent impulses travel via the ethmoidal and maxillary nerves to the spinal nucleus of the trigeminal nerve. Interneurones project to the nucleus ambiguus and a putative 'sneezing centre' in the rostral dorsolateral medulla (Seijo-Martínez et al 2006). Recruitment of a critical number of inspiratory and expiratory neurones initiates a sneeze, which involves eye closing and deep inspiration, followed by explosive exhalation as described above. If the oropharyngeal isthmus is closed by the action of palatoglossus, the air flow is diverted through the nasal cavity, otherwise the stream of expelled air flows through both oral and nasal cavities.

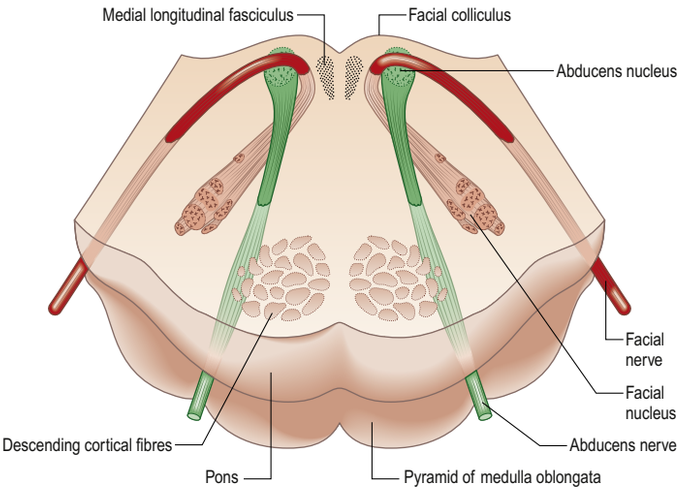

Fig. 28.12 A transverse section of the pons, viewed from the rostral aspect, showing the central course of fibres of the facial nerve.

Pathways and nuclei of the pons

Medial longitudinal fasciculus

The medial longitudinal fasciculus is the main intersegmental tract in the brainstem (see Figs 28.8–28.9, **28.11–28.13**, **28.15**). It is a small paramedian tract that courses through the dorsal tegmentum of the brainstem from the upper cervical spinal cord through the medulla, pons and midbrain to the interstitial nucleus of Cajal in the lateral wall of the third ventricle. It passes immediately ventral to the abducens nucleus in the pons and immediately ventral to the trochlear and oculomotor nuclei in the midbrain. It interconnects the oculomotor, trochlear, abducens, Edinger–Westphal, vestibular, reticular and spinal accessory nuclei, coordinating conjugate eye movements with associated movements of the head and neck. Ascending fibres in the fasciculus arise from all four vestibular nuclei. Those from the superior vestibular nucleus remain uncrossed, while the others are partly crossed. Some fibres reach the interstitial and posterior commissural nuclei, and some decussate to the contralateral nuclei. Some ascending fibres may reach the thalamus. Descending axons from the medial vestibular nucleus, and perhaps the lateral and inferior vestibular nuclei, partially decussate and descend in the medial longitudinal fasciculus as the medial vestibulospinal tract that passes into the ventral funiculus of the spinal cord. Fibres join the medial longitudinal fasciculus from the dorsal trapezoid, lateral lemniscal and posterior commissural nuclei, which means that both the cochlear and vestibular components of the vestibulocochlear nerve can influence movements of the eyes and head via the medial longitudinal fasciculus. The descending and ascending connections through the medial longitudinal fasciculus enable conjugate eye movements (Frohman et al 2008, Aw et al 2017). Lesions affecting the medial longitudinal fasciculus cause internuclear ophthalmoplegia.

Central tegmental tract

The central tegmental tract is a longitudinal fibre bundle situated in the central portion of the reticular formation (Nathan and Smith 1982) (see Figs 28.11, **28.13**, **28.15–28.16**). It contains descending and ascending fibres. The major descending fibres are rubro-olivary, which arise from the rostral parvocellular portion of the red nucleus and descend ipsilaterally through the superior cerebellar peduncle and the central portion of the tegmentum to terminate in the amiculum (capsule) of the principal inferior olivary nucleus. These descending fibres form one leg of the triangle of Guillain-Mollaret (see p. 458.e2). Ascending fibres in the central tegmental tract include taste fibres from the rostral gustatory portion of the solitary nucleus travelling to the ventral posteromedial nucleus of the thalamus, and projections from the reticular formation to the thalamus and hypothalamus.

Dorsal longitudinal fasciculus

The dorsal longitudinal fasciculus of Schütz (periventricular system) is a periventricular longitudinal fibre bundle that courses from the posterior hypothalamus to the lower medulla. It contains thin ascending and descending fibres that connect the forebrain with visceral autonomic centres in the lower brainstem.

Pontine nuclei

The pontine nuclei include all of the neurones that are dispersed throughout the basilar pons: in humans, these number some 20 million neurones (Brodal and Bjaalie 1992) (see Figs 28.11, 28.13). They are probably all glutamatergic, and most project to the contralateral cerebellar cortex, with collaterals to the cerebellar nuclei.

Corticopontine fibres arise mainly from neurones in layer V of the premotor, somatosensory, posterior parietal, extrastriate visual and cingulate neocortices. Projections from prefrontal, temporal and striate cortices are sparse. Frontopontine fibres end rostral to the level of the trigeminal nerve, and connect with pontine neurones that project to the contralateral cerebellum through the more rostral transverse pontine fibres. The terminal fields, although divergent, form topographically segmented patterns resembling overlapping columns, slabs or lamellae within the pons.

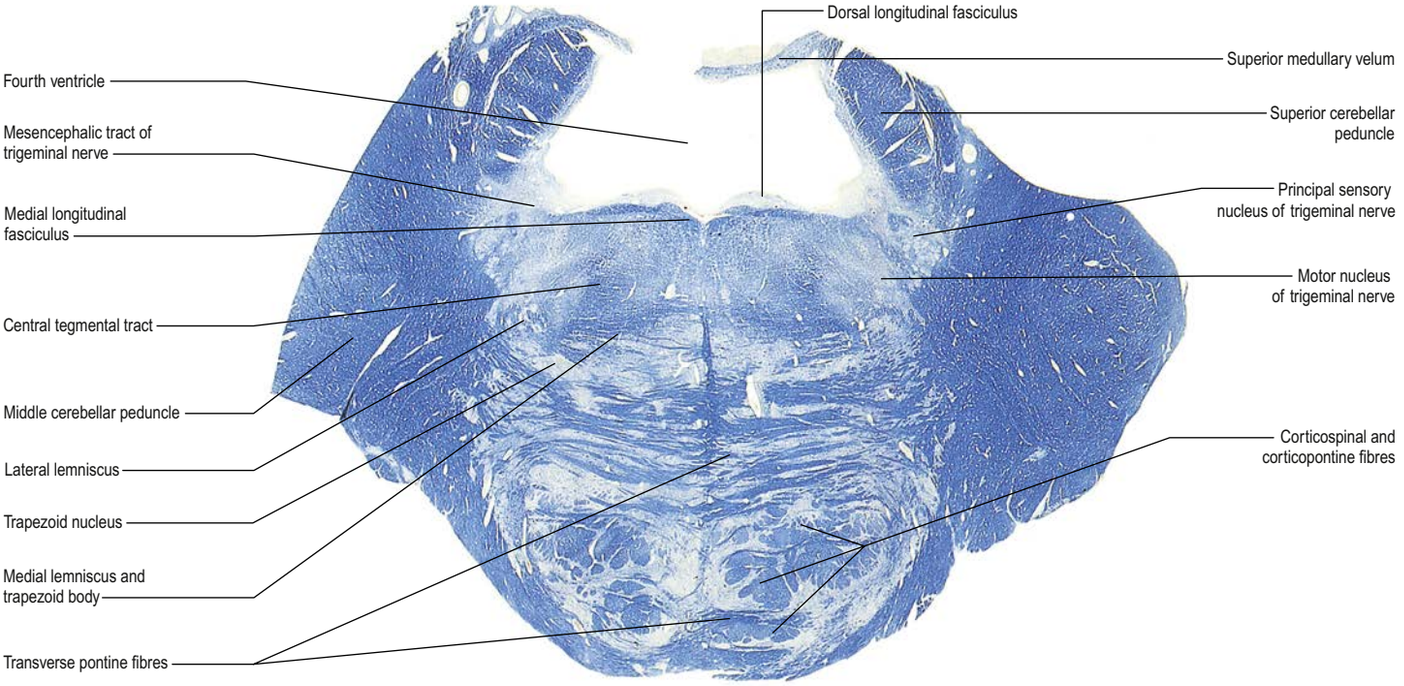

Fig. 28.13 A transverse section of the pons at the level of the principal sensory and motor nuclei of the trigeminal nerve, prepared using Luxol fast blue stain for myelinated nerve fibres (blue).

Subcortical projections to the pontine nuclei include those from the superior colliculus to the dorsolateral pons, and from the medial mammillary nucleus to the rostromedial pons and pretectal nuclei. Afferents that arise from the lateral geniculate nucleus, dorsal column nuclei, trigeminal nuclei, hypothalamus and cerebellar nuclei project to restricted neurones of the pons. Functionally related subcortical and cerebrocortical afferents converge, e.g. those from the somatosensory cortex and dorsal column nuclei. There is non-specific input from the reticular formation, raphe nuclei, locus coeruleus and periaqueductal grey matter. Efferent axons from the pontine nuclei constitute the transverse pontine (pontocerebellar) fibres, most of which cross the midline and continue into the cerebellum as the major constituent of the contralateral middle cerebellar peduncle. All pontocerebellar fibres end as mossy fibres in the cerebellar cortex. A degree of somatotopy is maintained in these connections.

Cranial nerve nuclei and related tracts

Cochlear nuclei

The primary afferents of the auditory pathway are the central processes of type I and II sensory neurones in the spiral ganglion in the cochlea (Ch. 43). They travel in the cochlear division of the vestibulocochlear nerve and enter the brainstem just caudal to the vestibular division of the vestibulocochlear nerve at the cerebellopontine angle. The axons bifurcate and terminate in the dorsal (posterior) and ventral (anterior) cochlear nuclei lying along the lateral surface of the restiform body. The dorsal cochlear nucleus forms a bulge, the auditory tubercle (auditory eminence), on the posterior surface of the restiform body and also forms the floor of the lateral recess of the fourth ventricle; it is continuous medially with the vestibular area in the floor of the fourth ventricle. The ventral cochlear nucleus lies between the cochlear and vestibular fibres of the vestibulocochlear nerve. The dorsal and ventral cochlear nuclei are separated only by a thin stratum of nerve cell bodies and fibres.

The axons that emerge from the cochlear nuclei are aggregated into three, mostly transverse, fibre bundles, the dorsal and intermediate acoustic striae and the trapezoid body. These axons pursue a complex, often crossed, course as they ascend through the acoustic striae, the superior olivary complex, and the lateral lemniscus to reach the inferior colliculus. The dorsal cochlear nucleus projects via the dorsal acoustic stria to the contralateral inferior colliculus. The dorsal acoustic stria curve dorsally and medially, dorsal to the restiform body, traverse the reticular formation ventral to the striae medullares, cross the midline, pass to the contralateral superior olivary complex, and ascend in the contralateral lateral lemniscus. The ventral cochlear nucleus projects via the trapezoid body or the intermediate acoustic stria to relay centres in either the superior olivary complex, the nuclei of the lateral lemniscus, or the inferior colliculus. Initially, the intermediate acoustic stria accompanies the dorsal acoustic stria as they pass medially, immediately dorsal to the restiform body, but it then separates from the dorsal acoustic stria, angles sharply ventrally in the ipsilateral tegmentum, passes through the spinal trigeminal nucleus, joins the trapezoid body and crosses the midline to join and ascend with the contralateral lateral lemniscus.

The cochlear nerve also conveys efferent fibres that pass outward from the brainstem to terminate on the hair cells and on the cells of the spiral ganglion.

The trapezoid body is a large, complex, transversely orientated fibre bundle that extends across the midline at the level of the pontomedullary junction (see **Fig. 28.11**). It is formed by the fibres of the intermediate acoustic stria, and secondary fibres that arise from the superior olivary complex. The fibres pass either through or ventral to the medial lemniscal fibres, decussate with the contralateral fibres in the median raphe, and relay onward in the contralateral nuclei of the superior olivary complex. The trapezoid fibres from both sides then pass below the emerging axons of the facial nerve, and turn upward abruptly to enter the lateral lemnisci. By this route, secondary auditory fibres from the cochlear and related nuclei pass to the lateral lemnisci bilaterally. A few auditory fibres do not cross the midline and synapse in the ipsilateral superior olivary nuclei. A further few fibres cross the midline but relay more distally in the nuclei of the lateral lemniscus. Some trapezoid axons may enter the medial longitudinal fasciculus and ascend to end in the trigeminal motor, facial, oculomotor, trochlear and abducens nuclei, where they mediate reflexes involving tensor tympani, stapedius and oculogyric muscles, respectively.

Superior olivary complex

The superior olivary complex is a major link in the ascending and descending auditory pathways (see Fig. 43.20). The nuclei of the superior olivary complex include the medial and lateral superior olivary nuclei, the medial nucleus of the trapezoid body, the periolivary nuclei and many unnamed cell clusters (Paxinos et al 2012). These nuclei lie rostral and ventral to the nuclei of the facial nerve, partially overlapping with the trapezoid body. The lateral superior olive appears to analyze differences in sound frequency and sound intensity between the two ears (Nieuwenhuys et al 2008).

Lateral lemniscal nuclei

The lateral lemniscus ascends along the dorsolateral border of the pons and caudal midbrain superficial to (external to) the superior cerebellar peduncle to reach the inferior colliculus (see **Fig. 28.15**). Most of the lemniscal fibres are crossed fibres that ascend from the contralateral auditory apparatus to synapse in the inferior colliculus: they include fibres relayed from the superior olivary nucleus and trapezoid body (see Fig. 43.20). Some lateral lemniscal fibres carry information from the ipsilateral cochlea that has passed through the ipsilateral superior olivary nucleus.

Vestibular nuclear complex

The vestibular nuclear complex is situated beneath the floor of the fourth ventricle. It has traditionally been divided into four cellular masses, the

The axons of type 1 spiral ganglion cells enter the ventral cochlear nucleus and bifurcate within its centre, dividing it into anterior and posterior ventral subnuclei. The fibres are organized into dorsoventrally orientated sheets: fibres conveying low frequency sounds from apical spiral ganglion cells terminate ventrally and fibres conveying high frequency sounds from the basal turn of the spiral ganglion terminate dorsally. Posterior processes of type 1 ganglion cells pass to the caudal pole of the ventral nucleus, from which they enter the dorsal cochlear nucleus. Thin unmyelinated axons of type 2 spiral ganglion cells contact clusters of small interneurones scattered through the cochlear nuclei.

The dorsal, ventral and intermediate lemniscal nuclei are longitudinal columns of cells embedded among the most medial fibres of the lateral lemniscus. They receive afferent axons from both cochlear nuclei, are tonotopically organized and serve as links in the auditory pathways that ascend and descend through the superior olivary complex and cochlear nuclei. Among other functions, the dorsal nucleus relays afferent data from the superior olives by GABAergic projections to both inferior colliculi. The ventral nucleus serves as an important interconnection between the cochlear nuclei and the central nucleus of the inferior colliculus.

lateral nucleus (of Deiter), medial nucleus (of Schwalbe), superior nucleus (of Bechterew) and inferior (spinal, descending) vestibular nucleus (see **Figs 28.3B, 28.8, 28.11**) (Haines and Mihailo 2018). The nucleus prepositus hypoglossi, located medial to the medial vestibular nucleus, may also be regarded as a vestibular nucleus. Cell groups X and Y have been identified as accessory nuclei of the vestibular complex.

The medial vestibular nucleus is the largest of the vestibular nuclei. It lies lateral and superior to the visceromotor nuclei of the glossopharyngeal and vagus nerves, is crossed dorsally by the striae medullares of the fourth ventricle and is continuous with the nucleus intercalatus below. The superior vestibular nucleus is small and lies above the medial and lateral nuclei. It extends higher into the pons than do the other subdivisions, to occupy the upper part of the vestibular area. The inferior vestibular nucleus is the smallest of the group. It lies between the medial vestibular nucleus and the restiform body, from the level of the upper end of the nucleus gracilis to the pontomedullary junction, and is traversed by descending fibres of the vestibular nerve, from the cerebellum and the vestibulospinal tract. The lateral vestibular nucleus lies ventrolateral to the upper portion of the medial nucleus, just above the inferior nucleus and ascends almost to the level of the abducens nucleus. Its rostral end is continuous with the caudal end of the superior nucleus. It projects to the spinal cord through the lateral vestibulospinal tract (Voogd 2016). The lateral vestibular nucleus can be subdivided into dorsal and ventral components. The dorsal portion contains giant cells and is located within the juxtarestiform body: it receives no direct vestibular afferents, but receives Purkinje cell axons from the anterior vermis, and extends efferent connections to the cerebellum. The ventral portion contains cells of various sizes and is located medial to the juxtarestiform body

Vestibulocerebellar fibres (primary and secondary) travel via the juxtarestiform body mainly to the flocculus and nodule. Cerebellovestibular fibres pass to the nuclei, also via the juxtarestiform body. They arise mainly in the flocculus and nodule (posterior lobe), but some fibres are derived from the anterior lobe and the fastigial nucleus. A few vestibular fibres enter the cerebellum directly through the juxtarestiform body and end in the fastigial nucleus, flocculonodular lobe and uvula.

The vestibular nuclei receive afferent fibres from multiple sources, including the vestibular portion of the vestibulocochlear nerve, cerebellum, brainstem reticular formation and spinal cord. Myelinated fibres of the vestibular nerve enter the medulla between the restiform body and the spinal tract of the trigeminal nerve and bifurcate into ascending and descending branches. Most ascending vestibular fibres end in the superior vestibular nucleus. Descending vestibular fibres traverse the juxtarestiform body and give off extensive transverse collaterals to the inferior and medial (but not the lateral) vestibular nuclei. Additional afferent fibres descend from the cerebral cortex to innervate the vestibular nuclei bilaterally.

The vestibular nuclei project extensively to the cerebellum and also receive fibres from the cerebellar cortex and the fastigial nuclei. Vestibulocerebellar fibres pass through the juxtarestiform body to the cerebellum (Carpenter and Sutin 1983). A few vestibular nerve fibres bypass the vestibular nuclei and traverse the juxtarestiform body to terminate directly in the fastigial nucleus, the flocculonodular lobe and uvula. Evidence suggests that the vestibular apparatus is spatially represented in these nuclei. Efferents from the lateral vestibular nucleus descend to the spinal cord through the ipsilateral lateral vestibulospinal tract and extend along the full length of the spinal cord to exert a facilitatory influence on spinal reflex activity and on extensor muscle tone. Vestibular nuclear efferents form a major part of the medial longitudinal fasciculus. Through this, interconnections between the vestibular and oculogyric nuclei and the pontine reticular formation provide for conjugate eye movements that compensate for head movements perceived by the labyrinths. The reflex arcs stabilize visual fixation despite changing head position. Vestibular efferents project to the thalamus (probably via the posterior portions of the ventroposterior complex and the medial pulvinar) which in turn project to the primary vestibular cortex in the parietal lobe at the junction of the intraparietal and postcentral sulci, adjacent to the head portion of the postcentral gyrus. There may be additional representation of the vestibular system in the superior temporal gyrus near to the auditory cortex.

Facial nucleus

The facial (motor) nucleus is situated caudal, ventral and lateral to the abducens nucleus. It lies within the caudal pontine reticular formation, ventromedial to the spinal tract and nucleus of the trigeminal nerve (see **Fig. 28.11**) (Haines and Mihailo 2018). Groups of facial nucleus neurones form columns, which innervate individual muscles or which correspond to branches of the facial nerve. Within the nucleus, neurones that innervate the muscles of the scalp and upper face lie dorsal to the neurones that supply the muscles of the lower face.

The facial nucleus receives corticonuclear fibres for volitional control of the facial musculature. Neurones that innervate the muscles in the scalp and upper face receive bilateral corticonuclear fibres, while neurones that innervate the muscles of the lower face receive a predominately contralateral innervation. Clinically, therefore, upper and lower motor neurone lesions affecting the facial nerve can be differentiated: upper motor neurone lesions cause paralysis that is confined to the contralateral lower face (supranuclear facial palsy), whilst lower motor neurone lesions cause complete ipsilateral facial paralysis (Bell's palsy). The facial nucleus also receives ipsilateral afferents from the nucleus solitarius and from the sensory nucleus of the trigeminal nerve, establishing important reflex connections.

Efferent fibres that arise from large motor neurones of the facial nucleus form the motor root of the facial nerve. At first, the facial fibres course dorsomedially towards the floor of the fourth ventricle as a more-or-less diffuse spread of fibres. These fibres pass dorsal and medial to the abducens nucleus, and then coalesce into a defined fibre bundle that recurves dorsally and laterally, over the rostral pole of the abducens nucleus, creating the bulge in the floor of the fourth ventricle, referred to as the facial colliculus (see **Fig. 28.12**). The fibres then descend ventrolaterally through the reticular formation and pass between their nucleus of origin medially and the nucleus of the spinal tract of the trigeminal nerve laterally. The facial nerve emerges from the brainstem at the supraolivary fossette, between the olive and restiform body, and passes laterally through the cerebellopontine angle cistern to the internal acoustic meatus (internal auditory canal).

General visceral efferent (GVE) fibres of the facial nerve arise from preganglionic parasympathetic neurones in the superior salivatory nucleus. These fibres run in the nervus intermedius and pass via the chorda tympani to the submandibular ganglion and via the greater petrosal nerve and the nerve of the pterygoid canal to the pterygopalatine ganglion.

Abducens nucleus

The abducens nucleus lies in the floor of the fourth ventricle, just lateral to the midline, immediately subjacent to the facial colliculus and slightly lateral to the medial longitudinal fasciculus (see **Fig. 28.11**). The abducens nucleus is composed of approximately 6500 neurones that align with the trochlear, oculomotor and hypoglossal nuclei to form the somatic motor column (GSE). Within the nucleus, large motor neurones are intermixed with small multipolar interneurones; the interneurones are most heavily concentrated in the lateral and ventral aspects of the nucleus.

The abducens nucleus receives afferent connections from multiple sources. These include corticonuclear fibres (which are principally contralateral, some of the fibres being aberrant corticospinal fibres that descend from the midbrain to this level in the medial lemniscus); the medial longitudinal fasciculus (by which the abducens nucleus is connected to oculomotor, trochlear and vestibular nuclei); the tectobulbar tract (from the deep layers of the superior colliculus); the paramedian pontine reticular formation (which lies rostral and caudal to the nucleus); the nucleus prepositus hypoglossi; and the contralateral medullary reticular formation.

The motor fibres of the abducens nucleus arise as a diffuse spread of fibres from the ventromedial aspect of the nucleus. Fifteen to twenty fascicles of the nerve pass ventrally, laterally and caudally, directly through the intervening reticular formation, trapezoid body, medial lemniscus, pontocerebellar fibres, pontine nuclei and descending corticospinal tracts to emerge from the brainstem at the pontomedullary sulcus about 1–2 cm lateral to the midline. In their course, the rootlets typically coalesce to emerge from the brainstem as a compact bundle of fibres. Occasionally all or some of the rootlets may emerge anomalously, rostral to the pontomedullary sulcus. The abducens nerve passes anteriorly, rostrally and slightly laterally across the prepontine cistern, penetrates the clivus through Dorello's canal, and enters the cavernous sinus lateral to the cavernous segment of the internal carotid artery. The abducens innervates the ipsilateral lateral rectus. Abducens interneurones give rise to fibres that cross the midline at the level of the nucleus and then ascend in the contralateral medial longitudinal fasciculus to all three medial rectus subnuclei of the oculomotor nucleus.

Trigeminal sensory nuclei

The sensory neurones of the trigeminal ganglion lie within the trigeminal (Gasserian, semilunar) ganglion situated in Meckel's cave. Their peripheral processes pass to sensory receptors in the head via the ophthalmic (V_1), maxillary (V_2) and mandibular (V_3) divisions of the trigeminal nerve (**Fig. 28.14**). Their central processes exit Meckel's cave

Afferent fibres arising from the interstitial nucleus of Cajal descend through the medial longitudinal fasciculus to synapse in the ipsilateral superior and medial vestibular nuclei and the nucleus prepositus hypoglossi. Afferent fibres from the Edinger–Westphal nucleus project to the medial and inferior vestibular nuclei, which also receive root fibres from the upper cervical nerve roots (C2, C3). The lateral vestibular nucleus and inferior portions of the medial and inferior vestibular nuclei receive ipsilateral spinovestibular fibres that ascend from lower spinal levels through the dorsospinocerebellar tract.

The nucleus prepositus hypoglossi is located in the upper medulla and lower pons, rostral to the hypoglossal nucleus, caudal to the abducens nucleus and medial to the medial vestibular nucleus. The nucleus prepositus does not receive primary vestibular afferents, but does receive bilateral input from the medial and dorsal vestibular nuclei (Holstein 2012). The nucleus prepositus has reciprocal connections with the medial vestibular nucleus, and extends efferents to most of the other vestibular nuclei. It also has reciprocal connections with the vestibulocerebellum. The nucleus prepositus receives input from the frontal eye fields and has extensive connections to the oculomotor system, including the oculomotor (Holstein 2012) and abducens nuclei and the paramedian pontine reticular formation (Talman and Robertson 1991). It is connected to the superior colliculus by the predorsal fasciculus. By these connections, the nucleus prepositus plays a key role in the integration of velocity signals with position signals for horizontal eye movements, so that the eyes can be held steady in eccentric positions in the orbit (Kim et al 2016). The reciprocal connections between the nucleus prepositus hypoglossi and the serotoninergic raphe system may have a role in regulating blood pressure (Talman and Robertson 1991).

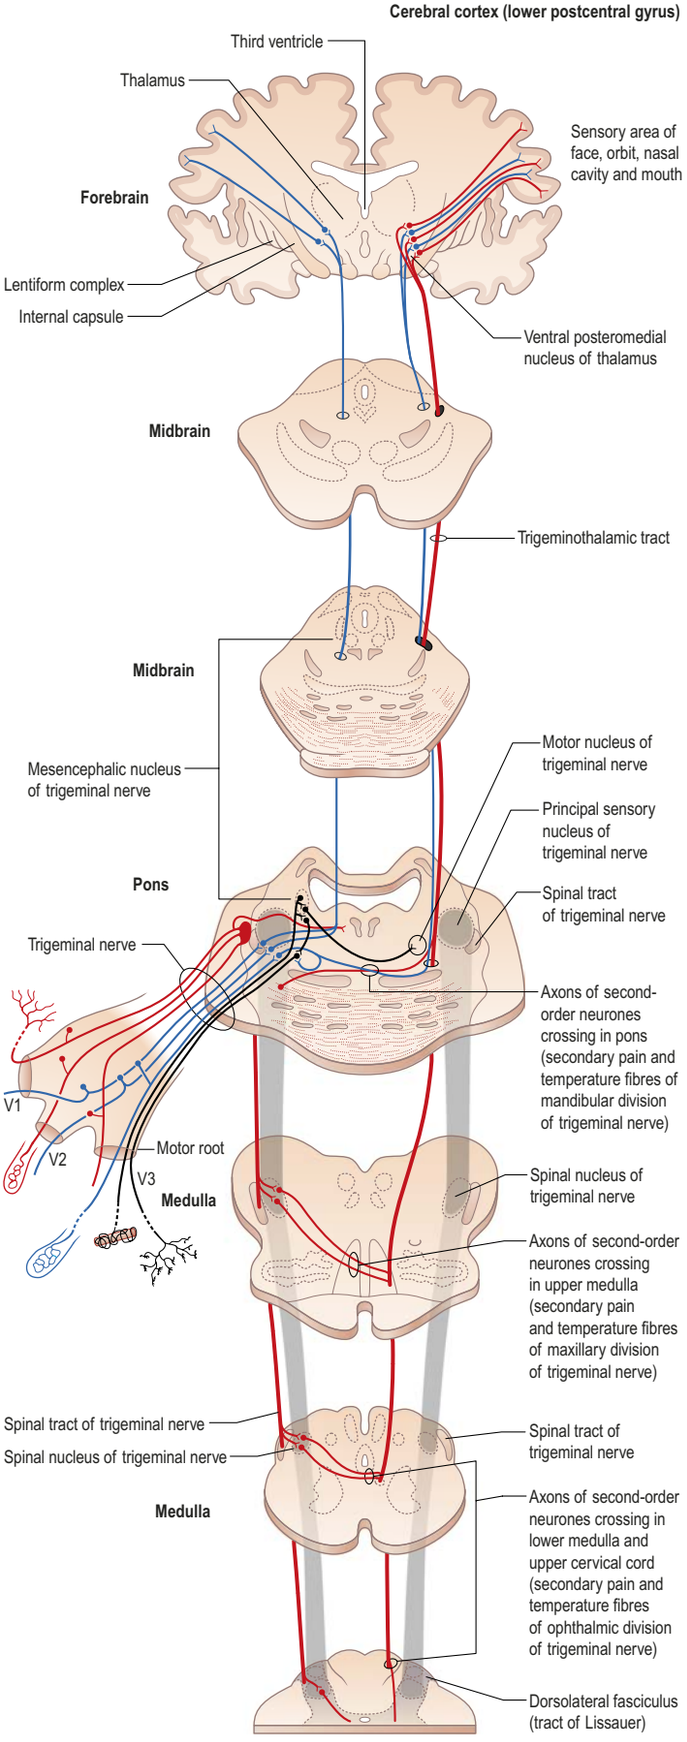

Fig. 28.14 The trigeminal nerve and its central connections.

posteriorly, aggregate into the primary sensory nerve (portio major) of the trigeminal nerve, and pass posteriorly through the upper cerebellopontine angle cistern to enter the lateral aspect of the pons. On entering the pons, the fibres of the sensory root of the trigeminal nerve course dorsomedially towards the principal sensory nucleus (see **Fig. 28.3**). About 50% of the fibres divide into ascending and descending branches and the remainder ascend or descend without division. The descending fibres form the spinal tract of the trigeminal nerve that terminates in the medially adjacent nucleus of the spinal tract of the trigeminal nerve. Some of these fibres provide short ascending collaterals to the principal sensory nucleus (Waite and Ashwell 2012).

The principal sensory nucleus lies in the lateral pontine tegmentum medial to the middle cerebellar peduncle and lateral to both the trigeminal motor nucleus and the incoming trigeminal root fibres. It is continuous inferiorly with the spinal nucleus of the trigeminal nerve. The principal nucleus may be divided into dorsal and ventral subnuclei: the sizes and shapes of the neurones appear similar in the two portions but they have differing connections (Henssen et al 2016).

The principal sensory nucleus receives afferent fibres from mechanoreceptors and is mainly concerned with tactile discrimination. As with the fibres entering the spinal trigeminal tract, the incoming sensory fibres segregate ventrodorsally, with the fibres from V_1 most anterior, those from V_2 in the middle, and those from V_3 most dorsal. Some ascending trigeminal fibres, many of them heavily myelinated, synapse around the small neurones in the principal sensory nucleus.

Efferent fibres from the ventral portion of the principal sensory nucleus traverse the ventral trigeminothalamic tract (trigeminal lemniscus), cross the midline and ascend with the contralateral medial lemniscus to the ventral posteromedial nucleus (VPM) of the thalamus (Waite and Ashwell 2012). Efferent fibres arising from the dorsomedial portion of the principal sensory nucleus traverse the ipsilateral dorsal trigeminothalamic tract to the VPM of the ipsilateral thalamus (Waite and Ashwell 2012). From there, thalamic efferents project to the postcentral gyrus (areas 3, 1, 2). Thus both principal sensory nuclei project bilaterally to both VPM nuclei.

Tactile and nociceptive pain and temperature data from the orofacial region is received in the trigeminal sensory nuclei and projected to the rest of the brain mainly by the ventral and dorsal trigeminothalamic tracts.

The mesencephalic nucleus of the trigeminal nerve is a column of large, round unipolar cells that extend from the sensory nucleus of the trigeminal nerve in the pons into the lateral margins of the periaqueductal grey matter in the midbrain (**Fig. 28.15**; see **Figs 28.3, 28.14**). Within the cell column, the neurones are arranged in many small groups and are most numerous caudally. The mesencephalic nucleus contains the only primary sensory unipolar neuronal somata within the CNS rather than in a senory ganglion. The neurones of the mesencephalic nucleus extend axons caudally within the mesencephalic tract of the trigeminal nerve. There, the axons bifurcate into central and peripheral branches. The central processes terminate on trigeminal motor neurones. The peripheral processes extend between the motor and principal sensory nuclei of the trigeminal nerve, leave the brainstem with the trigeminal motor fibres in the portio minor, and pass into the mandibular division of the trigeminal nerve: they convey Ia afferent fibres from the masticatory muscles. This arrangement establishes the only significant supraspinal monosynaptic reflex and is the basis for the 'jaw jerk'. The peripheral processes may also convey proprioceptive impulses from the teeth, the facial and oculogyric muscles (Waite and Ashwell 2012). Nerve fibres that ascend to the mesencephalic nucleus may also give collaterals to the motor nucleus of the trigeminal nerve and to the cerebellum. Projections from the mesencephalic nucleus to the principal sensory nucleus may relay proprioceptive sensation to the thalamus (Waite and Ashwell 2012).

Trigeminal motor nucleus

The motor nucleus of the trigeminal nerve is an ovoid cell mass that lies in the upper pontine tegmentum, beneath the fovea trigeminalis, and medial to the principal sensory nucleus, from which it is separated by fibres of the trigeminal nerve (see **Figs 28.3, 28.13**). It forms the rostral part of the pharyngeal efferent column (SVE).

The motor nucleus contains characteristic large multipolar neurones interspersed with smaller multipolar cells. The neurones are organized into a number of relatively discrete subnuclei, the axons from which innervate individual muscles. It receives afferent input from the motor cortices of both cerebral hemispheres (Gilman and Newman 2003, Paxinos et al 2012). These fibres leave the corticonuclear tract at the level of the trigeminal motor nucleus (or higher in the pons as aberrant corticospinal fibres), and may end on motor neurones or interneurones. The motor nucleus of each side also receives afferents from the sensory nuclei of the trigeminal nerve (possibly including some from the mesencephalic nucleus, which form monosynaptic reflex arcs for proprioceptive control of the masticatory muscles), as well as from the reticular formation, the red nucleus and tectum, the medial longitudinal fasciculus and possibly from the locus coeruleus. Collectively, these represent pathways by which salivary secretion and mastication may be coordinated.

Secondary relay fibres originating from the ventral portion of the principal sensory nucleus and from the rostral and interpolar portions of the spinal trigeminal nucleus form the ventral trigeminothalamic tract (thalamic lemniscus). This tract courses upward and medially through the pontine tegmentum, crosses the midline and ascends along the dorsomedial side of the contralateral medial lemniscus to terminate mainly within the VPM of the thalamus. Secondary relay fibres arising from the dorsomedial portion of the principal sensory nucleus traverse the ipsilateral dorsal trigeminothalamic tract to the ipsilateral thalamus. Secondary relay fibres from different regions of the caudal portion of the spinal trigeminal nucleus also traverse the dorsal trigeminothalamic tracts, but pass, variably, to the ipsilateral or the contralateral thalamus (Waite and Ashwell 2012, Henssen et al 2016). The dorsal trigeminothalamic tract ascends within the dorsal tegmentum of the pons and lower midbrain, passes ventral and lateral to the periaqueductal grey matter, curves laterally and enters the dorsomedial portion of the ipsilateral VPM of the thalamus. Henssen et al (2016) discuss a third intranuclear efferent pathway by which secondary relay fibres arising from the interpolar and caudal portions of the spinal trigeminal nucleus pass toward or into the periaqueductal grey matter.

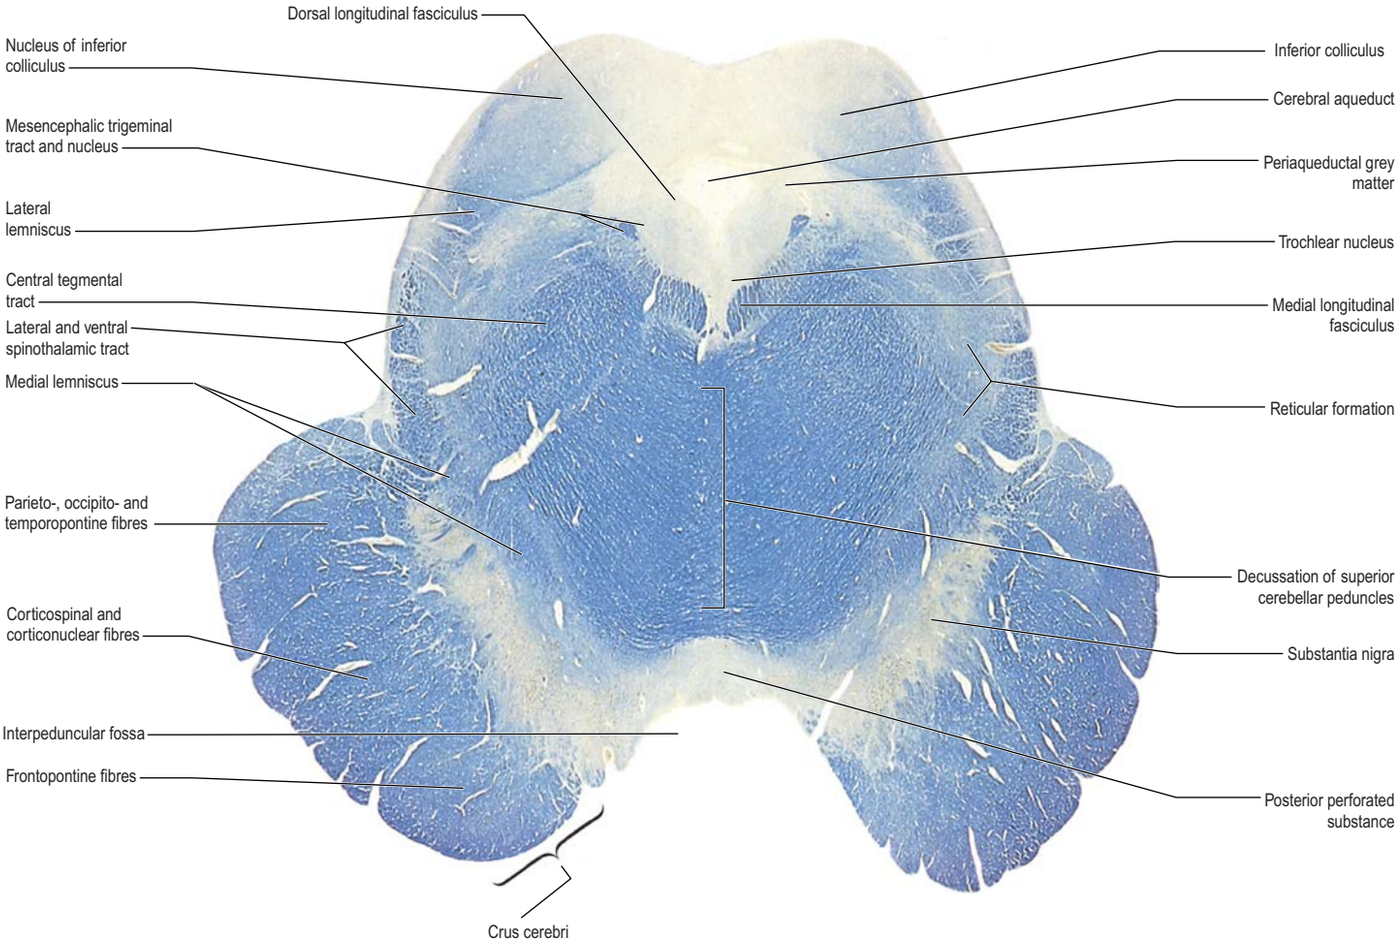

Fig. 28.15 A transverse section of the midbrain at the level of the inferior colliculi, prepared using Luxol fast blue stain for myelinated nerve fibres (blue).

Axons from the motor nucleus form the motor root of the trigeminal nerve, which courses outward in tandem with the sensory root to reach Meckel's cave and then descends with the mandibular division (V_3) to innervate the major muscles of mastication (temporalis, masseter, medial and lateral pterygoid), and tensor typmpani, tensor veli palatini, mylohyoid and anterior belly of the digastric.

Salivatory nuclei

The preganglionic parasympathetic neurones controlling salivation are found in the caudal pons, dorsal and lateral to the facial nucleus, with additional cells distributed more dorsally along the intramedullary course of the seventh nerve (see Fig. 28.3) (Blessing and Benarroch 2012). These neurones supply axons to the facial (nervus intermedius) and glossopharyngeal nerves for secretomotor control of the salivatory and lacrimal glands. Although these cells have traditionally been divided into a superior salivatory nucleus that supplies fibres to the nervus intermedius and an inferior salivatory nucleus that supplies fibres to the glossopharyngeal nerves, the brainstem distributions of the neurones innervating the two nerves is reported to be nearly indistinguishable (Blessing and Benarroch 2012). 'Salivatory neurones' may also play a significant part in the parasympathetic regulation of extracranial and intracranial vasculature (Blessing and Benarroch 2012).

Superior cerebellar peduncle

The superior cerebellar peduncle (brachium conjunctivum) is the main ascending efferent pathway from the cerebellum. It lies within the lateral wall of the fourth ventricle, medial to the restiform body (see **Fig. 28.13**) (Nieuwenhuys et al 2008). Numerous fibres that enter the mesencephalic tegmentum arise from the cerebellar nuclei, pass ventromedially and cross the midline via the decussation of the superior cerebellar peduncles at the border between the pons and midbrain. The ventral-most fibres from the dorsomedial portion of the peduncle decussate first, crossing immediately dorsal to the interpedunular nucleus. The midportion of the superior cerebellar peduncle decussates further rostrally. Rostral to the decussation, the ascending fibres laterally encapsulate and penetrate the red nucleus, in which some fibres, or their collaterals, terminate. However, the majority of the superior cerebellar fibres ascend to terminate in the ventral lateral nucleus of the thalamus. A relatively small number of uncrossed fibres are believed to end in the periaqueductal grey matter and reticular formation, the interstitial nucleus and the nucleus of the posterior commissure. Descending crossed fibres from the decussation of the superior cerebellar peduncle also end in the pontine nuclei, the medullary reticular formation and the nuclei of the inferior olivary complex.

Pontine reflexes

Corneal and blink reflexes

Touching the cornea of one eye elicits reflex closure of both eyes via the corneal reflex. The afferent limb of this pathway involves mainly nasociliary branches of the ophthalmic division of the trigeminal nerve, with cell bodies in the trigeminal ganglion and central processes synapsing on second-order neurones in the ipsilateral spinal tract and principal sensory nuclei of the trigeminal nerve. These neurones drive a polysynaptic chain of interneurones in the lateral reticular formation of the pons and medulla which, in turn, activate neurones innervating the palpebral components of orbicularis oculi in the facial motor nuclei bilaterally: the stimulated muscles then contract to produce a bilateral blink. The sweep of the eyelids carries lacrimal secretions across the eye, helping to remove any irritating particles. Shining a bright light into one eye elicits a similar reflex closure of both eyes via the blink reflex; the afferent limb of this reflex involves stimulation of the retina and optic pathway.

Jaw jerk reflex

Rapid stretching of the muscles that close the jaw (masseter, temporalis, medial pterygoid) activates muscle spindle afferents, which travel via the mandibular division of the trigeminal nerve to the brainstem. The cell bodies of these primary afferent neurones are located in the mesencephalic trigeminal nucleus. Collaterals project

monosynaptically to the motor nucleus of the trigeminal nerve in the pons. Axons arising in the motor nucleus travel via the mandibular nerve to innervate the muscles that act on the temporomandibular joint and close the jaw (Ch. 38).

Tensor tympani and stapedius reflexes

Loud sounds elicit reflex contraction of the tensor tympani and stapedius to dampen excess excursion of the tympanic membrane and middle ear ossicles. Afferent impulses travel in the cochlear nerve to the cochlear nuclei in the brainstem. Efferent fibres to the tensor tympani arise in the motor nucleus of the trigeminal nerve and travel in the mandibular division of the nerve. Efferent fibres to the stapedius originate in the facial nucleus and travel in the facial nerve.

MIDBRAIN

The midbrain (mesencephalon) is the most rostral and the shortest of the three brainstem segments. It is usually less than 2 cm in length and about 2–2.5 cm wide at the greatest expanse of the crura cerebri: much of it lies in the posterior cranial fossa. It courses through the tentorial incisura from the infratentorial to the supratentorial compartment. The midventral surface of the midbrain is related to the dorsum sellae, the proximal basilar artery and its branches, and the undersurface of the hypothalamus. Laterally, the ventral surface abuts the optic tracts and the medial temporal lobes. Dorsally, the midbrain is related to the habenular nuclei and pineal gland of the epithalamus, the great cerebral vein, and the anterior face of the cerebellum. The midbrain contains the nuclei of the trochlear and oculomotor nerves.

External features and relations

The caudal border of the midbrain is the rostral edge of the pons ventrally and the decussation of the trochlear nerve in the superior medullary velum dorsally. The rostral border is the caudal edge of the mammillary bodies ventrally, the lower edge of the optic tracts laterally and the lower edge of the posterior commissure dorsally. A curved line drawn along the anterior borders of the substantiae nigrae demarcates the base of the midbrain from the tegmentum. A curved line drawn in relation to the anterior surface of the aqueduct demarcates the tegmentum from the tectum. The decussation of the superior cerebellar peduncle marks the transition of the tegmentum pontis into the tegmentum mesencephali.

The ventral surface of the midbrain is marked by the crus cerebri, flanking the interpeduncular fossa. The medial mesencephalic sulci delimit the crura cerebri from the hypothalamus medially (Naidich et al 2009). At the level of the tentorial incisure, the basilar artery divides in the interpeduncular fossa into the right and left P1 segments of the posterior cerebral arteries. On each side, 1–3 superior cerebellar arteries branch from the basilar artery immediately before this bifurcation. The posterior cerebral and superior cerebellar arteries both run laterally around the ventral surface of the crus, the former passing above the tentorium cerebelli, the latter passing below. On each side, multiple rootlets of the oculomotor nerve emerge into the interpeduncular fossa through the medial walls of the crura cerebri and aggregate into a single fascicle that then passes forward between the uppermost superior cerebellar artery and the P1 segment of the posterior cerebral artery, traverses the suprasellar cistern, and penetrates the superior surface of the lateral wall of the cavernous sinus. The posterior communicating artery joins the posterior cerebral artery on the medial surface of the peduncle in the interpeduncular fossa. Numerous small openings in the interpeduncular fossa constitute the posterior perforated substance, which is pierced by central branches of the basilar and posterior cerebral arteries. The optic tract is located at the point where the crus emerges from the cerebral hemispheres.

The dorsal surface of the midbrain is marked by the superior and inferior colliculi. The superior colliculi are broader and extend further laterally than the inferior colliculi. The infracollicular sulcus defines the inferior borders of the inferior colliculi. Below the inferior colliculi, the midline frenulum veli helps to suspend the superior medullary velum over the fourth ventricle. The trochlear nerve emerges from the dorsal surface of the midbrain just caudal to the inferior colliculus and courses laterally and ventrally around the midbrain. Laterally, on each side, the brachium of the inferior colliculus ascends to the medial geniculate body. The brachium of the superior colliculus ascends over the medial geniculate body to reach the lateral geniculate body. The pretectum, the pineal gland, the habenular trigone and the striae medullares thalami all lie superior to the superior colliculus.

Internal organization

Lower midbrain: Transverse section at the level of the inferior colliculi

From dorsal to ventral, a transverse (axial) section through the midbrain at the level of the inferior colliculi contains the inferior colliculus, lateral lemniscus, cerebral aqueduct and periaqueductal grey matter, superior cerebellar peduncle and its midline decussation, posterior perforated substance just dorsal to interpeduncular fossa, and the crus cerebri (see Fig. 28.15). The crus cerebri contains, from medial to lateral, the descending frontopontine, corticonuclear, corticospinal, and parieto-, occipito- and temporopontine fibres. The substantia nigra lies dorsal to the crus cerebri and consists of a ventral pars reticulata (SNr) and a dorsal pars compacta (SNc). The medial and lateral lemnisci form a prominent lemniscal arc of white matter dorsolateral to the decussation of the superior cerebellar peduncles. Dorsally, the trochlear nucleus lies at the ventral aspect of the periaqueductal grey matter, enveloped by the medial longitudinal fasciculus. The fibres of the trochlear nerve course dorsolaterally and caudally, just within the perimeter of the periaqueductal grey matter, toward their decussation in the superior medullary velum. The central tegmental tract and the reticular formation lie within the tegmentum.

Upper midbrain: Transverse section at the level of the superior colliculi

A transverse (axial) section through the upper midbrain and mesencephalic–diencephalic junction at the level of the superior colliculi contains the superior colliculi, the cerebral aqueduct (of Sylvius) and the periaqueductal grey matter (**Fig. 28.16**). Depending on precise section angulation, this section may also display the inferior pole of the medial geniculate nucleus rostrally. Just dorsal to the substantia nigra, the red nuclei replace the decussation of the superior cerebellar peduncles. Crossed fibres from the contralateral superior cerebellar peduncle pass through and around the red nuclei en route to the thalamus. The ascending fibres of the medial lemniscus and the spinothalamic tract converge dorsolateral to the red nuclei as they approach the ventral posteromedial and ventral posterolateral nuclei of the thalamus. The structures of the lemniscal arc no longer include the lateral lemniscus, because this tract terminates in the inferior colliculus. The oculomotor nuclear complex lies at the ventral aspect of the periaqueductal grey matter, partly enclosed on the ventral border by the fibres of the medial longitudinal fasciculus. The fibres of the oculomotor nerve emerge from the ventrolateral aspect of the nucleus and curve though the tegmentum, the red nucleus and the medial part of the substantia nigra to emerge into the interpeduncular fossa through the medial wall of the crus cerebri. The parasympathetic Edinger–Westphal nucleus is a paramedian structure situated dorsal to the oculomotor nucleus. The posterior perforated substance lies along the dorsomedial margin of the interpeduncular fossa. The central tegmental tract runs within the pontine and medullary tegmentum from the dorsomedial aspect of the red nucleus down to the inferior olivary nuclei of the medulla. The reticular formation occupies the dorsal tegmentum.

Pathways and nuclei of the midbrain

Tectum

The tectum consists of the superior and inferior colliculi with their brachia and commissural connections, the ascending spinal and lateral lemnisci, and the descending tectobulbar and tectospinal tracts.

Inferior colliculus

The inferior colliculus is a key part of the ascending auditory pathway and is the principal site of termination of the lateral lemniscus (see Fig. 28.15). Its core, the central nucleus, is surrounded by afferent fibres from the lateral lemniscus. A group of smaller paracentral nuclei include the external and pericentral nuclei.

The inferior colliculus receives ascending fibres from the cochlear nuclei via the lateral lemniscus. Many of these fibres synapse within the central nucleus for relay to the anterior division of the medial geniculate nucleus. Other fibres pass through the inferior colliculus directly to the medial geniculate nucleus, without relay. Descending projections from the auditory cortex reach the inferior colliculus directly or via the medial geniculate nucleus. The two inferior colliculi are reciprocally interconnected by the commissure of the inferior colliculi, which crosses the midline dorsal to the cerebral aqueduct.

The central nucleus is composed of four cortical layers: layer I contains small neurones with flattened radial dendritic fields; layer II contains medium-sized neurones with ovoid dendritic fields aligned parallel with the collicular surface; layer III contains medium-sized neurones with spherical dendritic fields; and layer IV contains large neurones with variably shaped dendritic fields. Bands of cells with disc-shaped or stellate dendritic fields orthogonally span the fibre layers in which the terminals of lateral lemniscal fibres ramify. Experimental studies have found cells driven by low frequencies in the dorsal laminae, and cells driven by high frequencies in the ventral laminae. Neurones are broadly frequency-tuned in the dorsal cortex and lateral nucleus. Lesions of either the inferior colliculus or its brachium produce severe defects in tonal discrimination, sound localization and auditory reflexes.

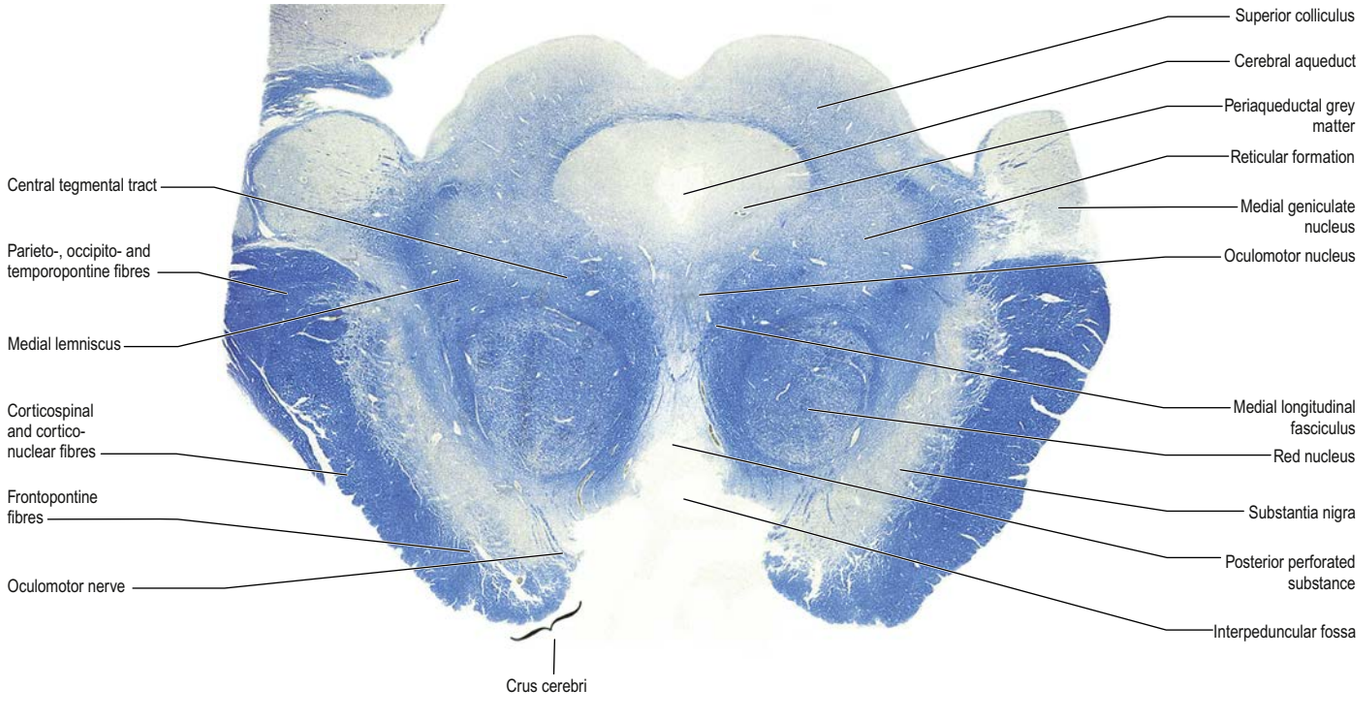

Fig. 28.16 A transverse section of the midbrain at the level of the superior colliculi, prepared using Luxol fast blue stain for myelinated nerve fibres (blue).

Most efferent fibres from the inferior colliculus ascend through the brachium of the inferior colliculus to reach the ipsilateral medial geniculate nucleus. In humans, the ventral division of the medial geniculate nucleus receives a topographic projection from the central nucleus of the inferior colliculus. The dorsal division of the medial geniculate receives a similar projection from the dorsal cortex. From the medial geniculate body impulses are relayed on to the primary auditory cortex through the auditory radiations. Other efferents from the inferior colliculus pass through the medial geniculate nucleus without relay and continue on to the auditory cerebral cortex. Caudally directed projections of the inferior colliculus to the brainstem and spinal cord form part of the tectospinal and tectotegmental tracts. These projections are relatively small and probably mediate reflex turning of the head and eyes in response to sounds. For further reading on the auditory pathways, see Chapter 43.

Superior colliculus

The superior colliculus (see Fig. 28.16) is composed of multiple layers of neuronal somata alternating with their white matter processes (May 2005). At successive depths from the external surface, it may be divided into seven layers: zonal, superficial grey (stratum cinereum), optic, intermediate grey, deep grey, deep white and periventricular strata, composed alternately of neuronal somata or their processes (Crosby et al 1962). The zonal layer consists chiefly of myelinated and non-myelinated fibres from the occipital cortex (areas 17, 18 and 19), which arrive as the external corticotectal tract. It also contains a few small neurones, which are horizontally arrayed. The superficial grey layer forms a crescentic lamina over the deeper layers and contains many small multipolar interneurones, on which cortical fibres synapse. The optic layer consists partly of fibres from the optic tract that permeate the entire anterior–posterior extent of the superficial layers with numerous collateral branches as they terminate. This arrangement provides a retinotopic map of the contralateral visual field, in which the fovea is represented anterolaterally. Retinal axons terminate in clusters from specific retinotectal neurones and as collaterals of retinogeniculate fibres. The layer also contains some large multipolar neurones. Efferent fibres to the retina are said to start in this layer.

The seven layers can be grouped into a superficial division consisting of the zonal, superficial grey and optic layers; an intermediate division consisting of the intermediate grey and white layers, and a deep division consisting of the deep grey and white layers. The deep grey and deep white layers adjacent to the periaqueductal grey matter are collectively called the parabigeminal nucleus. The intermediate grey and white layers collectively constitute the main receptive zone. The main afferent input is via the medial corticotectal path from layer V neurones of the ipsilateral occipital cortex (Brodmann area 18), and from other neocortical areas that are concerned with eye pursuit movements.

The extensive connections of the superior colliculus make it a major centre for initiating eye movements and coordinating them with movements of the head and neck. The superficial layers of the superior colliculus contain a retinotopic map of the environment and the deeper layers contain premotor neurones with conections to networks that generate saccades and head movements. The auditory, somatosensory and visual signals that converge on the superior colliculus move the eyes, head and body to direct the line of sight towards objects of interest for orienting behaviour. These interconnections are discussed in detail in Chapters 29 and 44.

The superficial layers of the superior colliculus give rise to ascending connections to the visual centres such as the pretectum and the visual thalamic nuclei. Fibres passing from the pulvinar are relayed to primary and secondary visual cortices and form an extrageniculate retinocortical pathway for visual orientation and attention. The intermediate layers of the superior colliculus give rise to the coarse fibres of the tectospinal tract. After crossing the midline in the dorsal tegmental decussation these fibres descend in the pons and become incorporated into the medial longitudinal fasciculus and the ventral funiculus of the cervical spinal cord. The tectonuclear tract, mainly crossed, descends near the tectospinal tract, and ends in the pontine nuclei and motor nuclei of the cranial nerves, particularly those innervating the oculogyric muscles. It subserves reflex ocular movements. The deep layers of the superior colliculus extend widely to thalamic, reticular and precerebellar nuclei and to the spinal cord.

Tegmentum

Trochlear nucleus

The trochlear nucleus is a small ovoid mass of grey matter just to the side of the midline (see Fig. 28.15). The trochlear nucleus is bounded by the periaqueductal grey matter dorsally and is enveloped by the fibres of the longitudinal fasciculi ventrally and laterally (Naidich et al 2009). The nucleus is part of the somatic efferent column in line with the oculomotor, abducens and hypoglossal nuclei more caudally.

Afferent inputs to the trochlear nucleus include fibres from the rostral intermediate nucleus of the medial longitudinal fasciculus and from the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come from the vestibular, abducens and oculomotor nuclei and, directly or indirectly, from the nuclei of the posterior commissure (nuclei of Darkschewitsch and of Cajal) and, via these nuclei, from the superior colliculus, frontal eye fields and other cortical areas. Other afferents arrive from the nucleus prepositus hypoglossi.

Efferent trochlear fibres first course dorsally and caudally, just deep to the outer perimeter of the periaqueductal grey matter and medial to the mesencephalic trigeminal nucleus. The trochlear nerves then

Other afferent fibres to the inferior colliculi originate from the contralateral spinal cord (via spinotectal fibres in the anterolateral system), the inferior colliculus, the noradrenergic locus coeruleus and the serotoninergic raphe nuclei. The cholinergic parabigeminal nucleus contains neurones whose dendrites extend into the optic layer, and whose axons form many of the collicular efferents.

The deep collicular laminae give rise to a tecto-olivary projection to the contralateral upper third of the medial accessory olivary nucleus. Tectotegmental fibres reach various tegmental reticular nuclei in the ipsilateral mesencephalic and contralateral pontomedullary reticular formation (gigantocellular reticular, caudal pontine reticular, oral pontine reticular nuclei), and the substantia nigra and red nucleus. Tectopontine fibres, which probably descend with the tectospinal tract, terminate in dorsolateral pontine nuclei, with a relay to the cerebellum.

decussate within the superior medullary velum of the fourth ventricle. The fully decussated nerves emerge from the dorsal surface of the brainstem just caudal to the inferior colliculus and just to each side of the frenulum veli. The trochlear nerve is the only cranial nerve to emerge on the dorsal surface of the brainstem. At the point of emergence, a variable number of rootlets, usually two, unite to form the nerve trunk. The trochlear fibres then curve ventrally through the perimesencephalic cistern, between the superior cerebellar arteries below and the posterior cerebral arteries above, to enter the lateral dural wall of the cavernous sinus (Yousry et al 2002a, Naidich et al 2009, Naidich et al 2013). A few fibres may remain ipsilateral.

Oculomotor nuclear complex

The nuclear complex from which the oculomotor nerve arises consists of several groups of large motor neurones that are collectively designated the oculomotor nucleus, and the smaller preganglionic parasympathetic Edinger–Westphal nucleus (see Figs 28.3, 28.16). The nuclear complex lies at the ventromedial aspect of the periaqueductal grey matter, superior to the trochlear nuclei and is partially enclosed by the fibres of the median longitudinal fasciculi. The oculomotor complex is approximately 5 mm long and is divisible into neuronal groups that correlate with the distribution of motor fibres within the oculomotor nerve.

Afferent inputs to the oculomotor nuclear complex include fibres from the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come, directly or indirectly, from the nuclei of the posterior commissure and, via these nuclei, from the frontal eye fields, the superior colliculus, the dentate nucleus and cortical areas. The medial longitudinal fasciculus carries afferent connections from the trochlear, abducens and vestibular nuclei. The fibres from the medial vestibular nucleus project to the medial rectus subnucleus.

In order from dorsal to ventral, the oculomotor neurone groups innervate the ipsilateral inferior rectus, inferior oblique and medial rectus. A medially placed column of cells innervates the contralateral superior rectus through axons that decussate in the caudal part of this subnucleus. A median subnucleus of large neurones, designated the caudal central nucleus, lies at the caudal pole of the oculomotor nucleus adjacent to the superior rectus and medial rectus subnuclei.

Fascicles of axons from these subnuclei course forwards in the midbrain, through the tegmentum, red nucleus and medial substantia nigra, to emerge as the oculomotor nerve in the interpeduncular fossa. The fascicles are most probably arranged from medial to lateral subserving the pupil, inferior rectus, medial rectus, levator palpebrae superioris and superior rectus, and inferior oblique.

Edinger–Westphal nucleus

The Edinger–Westphal nucleus lies dorsal to the main oculomotor nucleus. It is composed of small, multipolar, preganglionic parasympathetic (general visceral efferent, GVE) neurones. Afferent inputs to the nucleus come primarily from the pretectal nuclei bilaterally, mediating the pupillary light reflex, and from the visual cortex, mediating accommodation. Efferent fibres from the nucleus travel in the oculomotor nerve to synapse with postganglionic neurones in the ciliary ganglion (Kozicz et al 2011). Efferents from the Edinger–Westphal nucleus also descend through the medial longitudinal fasciculus to innervate the medial and descending vestibular nuclei (Nieuwenhuys et al 2008).

Periaqueductal grey matter

The periaqueductal grey matter (PAG) is a zone of small, closely packed cells that lies in the dorsal tegmentum surrounding and ventral to the cerebral aqueduct (see Figs 28.15–28.16). It is continuous with the grey matter of the hypothalamus rostrally and with the floor of the fourth ventricle caudally.

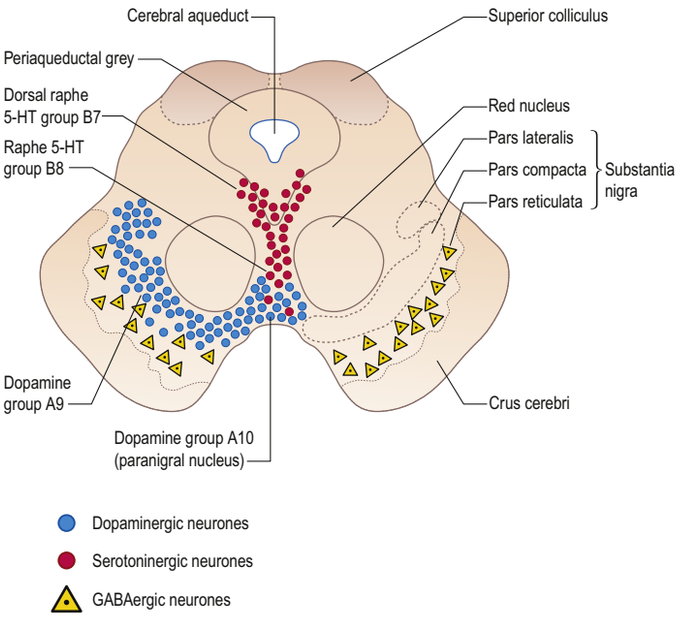

Fig. 28.17 Transverse section through the midbrain to show the arrangement of dopaminergic cell groups A9 and A10 in the substantia nigra (left) and serotoninergic cell groups B7 and B8 in the raphe.

The PAG receives afferents from the hypothalamus and amygdala and projects to the intermediate reticular zone. In animals, a complex of cell groups collectively designated the hypothalamic defensive complex project to the PAG via the dorsal longitudinal fasciculus (of Schütz). A somatosensory homunculus has been suggested for the periaqueductal grey matter, with the lower limbs represented rostrally, the head caudally and the trunk and upper limbs in the intermediate position. This somatosensory representation is contralateral, except for the forehead and scalp (Paxinos et al 2012).

The nucleus of Darkschewitsch

Available with the *Gray's Anatomy* e-book

Red nucleus

The red nucleus is an ovoid group of neurones within the upper midbrain, approximately 5 mm in diameter, situated dorsomedial to the substantia nigra and rostral to the decussation of the superior cerebellar peduncles (**Fig. 28.17**; see Fig. 28.16). It appears pink in fresh gross sections – hence its name. The red nucleus consists of two subnuclei: the caudal magnocellular portion containing about 150–200 giant to large-sized neurones and the rostral parvocellular portion that is considered to be phylogenetically more recent. The parvocellular subnucleus is larger and better defined in primates than in lower mammals. There is an increasing, age-dependent deposition of iron within the nucleus (**Fig. 28.18**).

Most of the ascending fibres of the superior cerebellar peduncle give off collaterals that synapse on cells within the red nucleus. There are bilateral, probably reciprocal, connections between the red nucleus and the superior colliculi. The magnocellular portion receives afferent input from the primary motor cortex via collateral projections of the corticospinal (pyramidal) tract. The parvocellular red nucleus receives direct input from layer V pyramidal neurones in the motor, premotor, supplementary motor and cingulate motor cortices and from the frontal and supplementary eye fields. The motor and supplementary motor projections to the parvocellular red nucleus are organized somatotopically.

The largest group of efferents arise from the rostral parvocellular portion of the red nucleus and descend in the ipsilateral central tegmental tract to the ipsilateral principal olivary nucleus. Some tract fibres terminate in the brainstem reticular nuclei. In humans, the rubrospinal tract is very small; it runs ventral to the lateral corticospinal tract and is generally believed to terminate in the contralateral upper cervical segments of the spinal cord.

Substantia nigra

The substantia nigra (see Figs 28.15–28.18) is a crescent-shaped zone of grey matter that extends through the length of the midbrain just

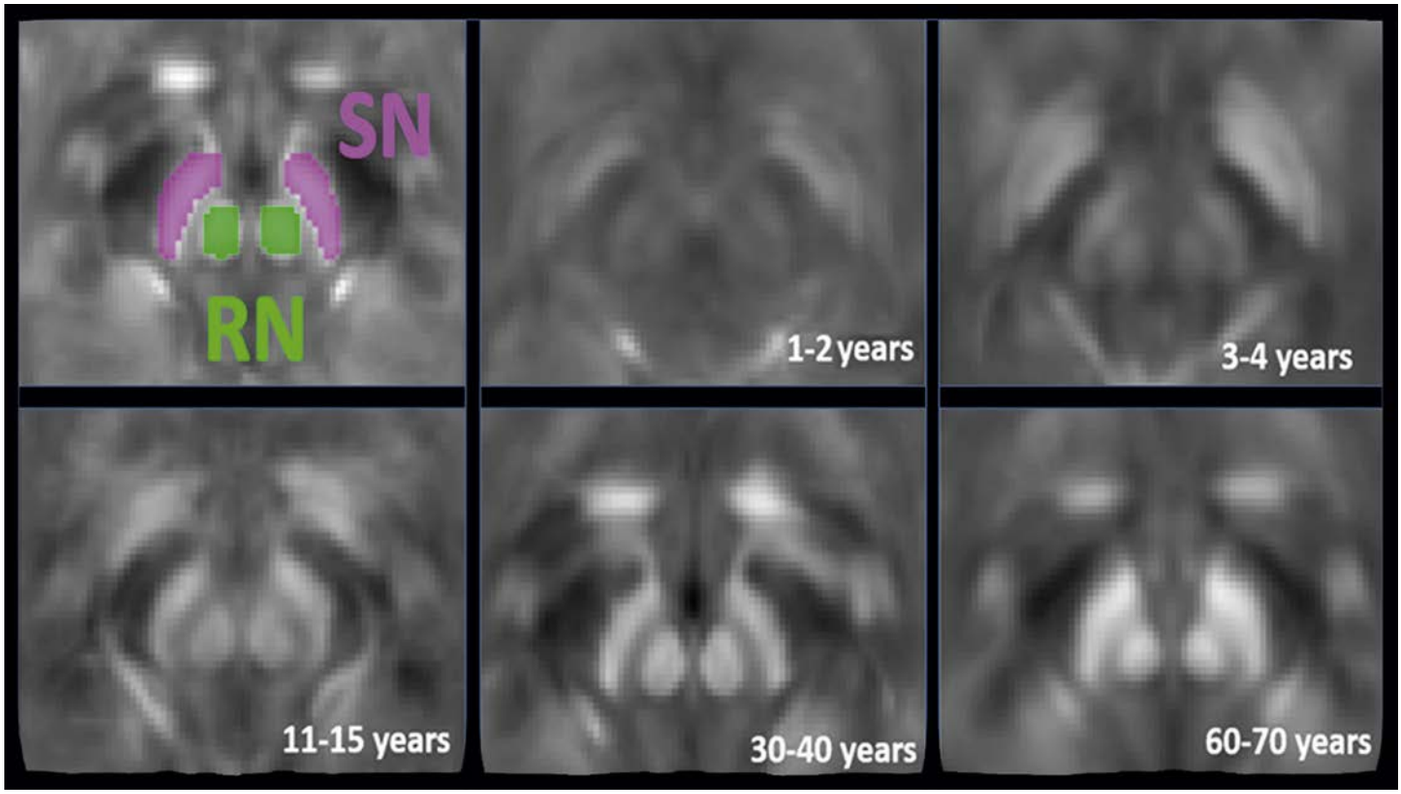

Fig. 28.18 Increasingly bright signal indicates progressive deposition of iron within the substantia nigra (SN) and red nuclei (RN) with age. (Adapted with permission from Zhang et al 2018 Longitudinal data for magnetic susceptibility of normative human brain development and aging over the lifespan. Data in Brief 2018; 20:623–31 (Fig. 3).)

The medial rectus subnucleus consists of three anatomically distinct subpopulations. The ventral portion contains the largest number of motor neurones and occupies the rostral two-thirds of the nucleus. A population of smaller motor neurones lies dorsally throughout the rostral two-thirds of the nucleus and innervates the small orbital fibres of medial rectus and a third subpopulation lies dorsolaterally in the caudal two-thirds of the nucleus.

The pretectal nuclei are a poorly defined group of neurones situated at the junction of the mesencephalon and diencephalon. They extend caudally from a position dorsolateral to the posterior commissure towards the superior colliculus, with which they are partly continuous. They include the olivary pretectal nucleus. Afferent fibres to the pretectal nuclei arrive from the visual cortex via the brachium of the superior colliculus, from the retina via the lateral root of the optic tract and from the superior colliculus. The pretectal nuclei send efferent fibres to the Edinger–Westphal preganglionic nuclei bilaterally. Those efferent fibres that decussate pass ventral to the aqueduct or through the posterior commissure. In this way, the sphincter pupillae contract in both eyes in response to impulses from either eye. This bilateral light reflex may not be the sole activity of the pretectal nucleus. Some efferent fibres from the pretectum project to the pulvinar and deep laminae of the superior colliculus, and provide an additional extrageniculate path to the cerebral cortex.

Premotor neurones for vertical gaze are located in the reticular formation of the midbrain, including the interstitial nucleus of Cajal and the rostral intermediate nucleus of the medial longitudinal fasciculus. These nuclei lie adjacent to each other between the periaqueductal grey matter and the red nucleus. The interstitial nucleus of Cajal acts to integrate eye-velocity signals with eye-position signals. The rostral intermediate nucleus of the medial longitudinal fasciculus (MLF) contains medium-lead burst neurones.

The interstitial nucleus of Cajal is an aggregate of widely spaced, medium-sized, parvalbumin-positive neurones in the dorsomedial region of the upper mesencephalic tegmentum. The cells of the nucleus are interspersed among and lateral to the fibres of the MLF and lie immediately lateral to the nucleus of Darkschewitsch. The interstitial nucleus of Cajal is classified with the accessory oculomotor (pre-oculomotor) nuclei. It acts to integrate eye-velocity signals with eye-position signals to coordinate movements of the head with movements of the eyes, particularly for vertical and oblique movements of the eyes. The interstitial nucleus has reciprocal connections with the vestibular nuclei and with the nucleus prepositus hypoglossi. Afferent fibres ascend to the interstitial nucleus of Cajal from the vestibular nuclei through the median longitudinal fasciculus and from the spinal cord via the spinomesencephalic tract (Sengul and Watson 2012). In turn, the interstitial nucleus of Cajal sends efferent fibres down the MLF to the ipsilateral superior and medial vestibular nuclei, the nucleus prepositus hypoglossi and the reticular formation. Major efferent fibres from the interstitial nucleus project to the oculomotor and trochlear nuclei bilaterally. Projections to all levels of the spinal cord descend as the interstitiospinal tract within the MLF.

The rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) represents the vertical gaze centre. It is a wing-shaped nucleus located dorsal to the rostral pole of the red nucleus, rostral to the fasciculus retroflexus and rostral to the interstitial nucleus of Cajal. It has predominantly ipsilateral connections to the oculomotor and trochlear nuclei for conjugated vertical eye movements. It has unilateral connections to the interstitial nucleus of Cajal and bilateral connections to the vestibular nuclei and the reticular formation. In humans the cells of this nucleus can be distinguished by their high content of parvalbumin. Burst neurones for motoneurones of the oculomotor and trochlear nerves lie in the riMLF (Horn and Büttner-Ennever 1998).

The PAG is organized into four longitudinal compartments, designated lateral, ventrolateral, dorsomedial and dorsolateral columns.

Stimulation of the lateral column leads to defensive behaviour with increased heart rate, blood pressure and respiration, and a shift of the blood from the viscera to the lower limb muscles. Stimulation of the ventrolateral column leads to immobility (freezing) with decreased blood pressure and decreased heart rate. Efferents from these columns pass to somatic and autonomic premotor neurones in the lower brainstem and spinal cord. The periaqueductal grey matter also contributes significantly to pathways for micturition, for control of ejaculation and for control of pain. A region in the caudal PAG plays a central role in vocalization, giving excitatory projections to the nucleus ambiguus, and a strong projection to the retroambiguus nucleus that sends motoneurones to the larynx, abdominal and other muscles involved in vocalization. There is also a strong projection to the region of a cell group designated VOC that has been identified as a vocal pattern generator.

The nucleus of Darkschewitsch is found in the ventrolateral portion of the periaqueductal grey matter, dorsomedial to the interstitial nucleus of Cajal, the medial longitudinal fasciculus and the red nucleus at a

level posterior to the fasciculus retroflexus. It gives rise to the medial tegmental tract that contributes innervation to the rostral medial accessory olive, and via the olive, to the cerebellum. A proposed connection of the nucleus of Darkschewitsch with the oculomotor nerve and the posterior commissure has not been confirmed.

The central tegmental tract initially lies ventrolateral to the medial longitudinal fasciculus and dorsolateral to both the red nucleus and the decussation of the superior cerebellar peduncles. It traverses the superior cerebellar peduncle and occupies a central position in the reticular formation of the pontine tegmentum as it descends to the inferior olivary complex. Efferents from the caudal magnocellular red nucleus form the descending rubrobulbar tracts. These tracts cross the midline in the ventral tegmental decussation and pass caudally to innervate contralateral structures, including the motor neurones of the facial nucleus, interneurones in the lateral tegmental field and the nucleus of the lateral funiculus in the caudal medulla.

The Guillain–Mollaret triangle, otherwise known as the dentatorubro-olivary pathway, has three corners, the red nucleus in the midbrain, the ipsilateral inferior olive in the medulla and the contralateral dentate nucleus in the cerebellum (see Chapter 29). Rubro-olivary fibres descend from the parvocellular division of each red nucleus along the central tegmental tracts to enter the capsule (amiculum) of the ipsilateral inferior olivary nucleus and pass into the nucleus. Olivocerebellar fibres emerge from the hilum of that olive, pass across the midline, traverse the contralateral inferior cerebellar peduncle, and, by a complex route, reach the cerebellar cortex and dentate nucleus contralateral to the side of the original red nucleus. The dentate nucleus gives rise to dentatorubral fibres that ascend through the superior cerebellar peduncle, cross the midline in the decussation of the superior cerebellar peduncles, and "return" to the original red nucleus, completing the triangle of Guillain-Mollaret. Interruption of this triangle can result in palatal myoclonus and a dentatorubral upper limb tremor (Holmes tremor). These interruptions are most commonly due to ischaemic infarction, haemorrhage or plaques of multiple sclerosis that disrupt the central tegmental tract.

dorsomedial to the crus cerebri on each side. It is subdivided into a pars reticulata (SNr) ventrolaterally, a pars compacta (SNc) dorsomedially and a small pars lateralis laterally.

The SNr extends through the whole of the ventral midbrain and rostrally as far as the subthalamic region. It consists of clusters of large, non-pigmented, multipolar neurones, many of which intermingle with fibres of the crus cerebri. These neurones contain iron and show increasing iron concentration with age (see Fig. 28.18). In Parkinson's disease and related disorders, disproportionate increase in iron accumulation correlates with the clinical stage of disease and disease progression (An et al 2018, Xuan et al 2017). Most pars reticulata neurones are inhibitory GABAergic cells. They are highly similar in form and connectivity to those of the internal segment of the globus pallidus, with similar disc-like dendritic trees that are orientated at right-angles to afferents from the striatum, probably making *en passant* contacts. Functionally, the SNr is a homologue of the internal segment of the globus pallidus, which means that the two may be considered together as a single major output nucleus for the basal ganglia.

There are reciprocal connections between the substantia nigra and the basal ganglia and these are discussed in Chapter 31. Briefly, topographically organized striatonigral axons, some of which may be collaterals of striatopallidal axons, originate from the caudate nucleus and putamen and project to the pars reticulata. They utilize GABA and substance P or enkephalin as their neurotransmitters, and are distributed differentially in the pars reticulata: enkephalinergic axons terminate in the medial part, whereas substance P axons terminate throughout. The head of the caudate nucleus projects to the rostral third of the substantia nigra, while the putamen projects to all parts. The fibres end in axodendritic synapses. A small number of GABAergic pallidonigral fibres from the external segment of the globus pallidus end mostly in the pars reticulata. The subthalamic nucleus sends an important glutamatergic projection to the pars reticulata and to the globus pallidus. Some, predominantly glutamatergic, corticonigral fibres appear to exist, passing from precentral and postcentral gyri to neurones in the pars reticulata.

Fibres from the SNr project rostrally to the ventral anterior and dorsomedial thalamic nuclei and to the deep (polysensory) layers of the superior colliculus. They project caudally to the pedunculopontine nucleus and brainstem reticular formation, from where impulses are relayed to neurones in the ventral horn of the spinal cord. A major connection from the striatum to the superior colliculus, via the pars reticulata, is thought to function in the control of gaze in a manner analogous to the pathway that initiates general body movement via the pallidum, thalamus and supplementary motor cortex. The uncontrolled or fixed-gaze disturbances of advanced Parkinson's disease, progressive supranuclear palsy and Huntington's disease tend to support this.

The SNc consists of closely packed, darkly pigmented neurones, which contain neuromelanin granules. Their arrangement is irregular and they partially penetrate the subjacent SNr. The pigmented neurones synthesize dopamine as their neurotransmitter and correspond to the dopaminergic cell group A9 (see Fig. 28.17). The dopamine-containing neurones are acetylcholinesterase-positive but are not cholinergic (Paxinos et al 2012). The pigment is most abundant in primates, maximal in humans and present even in albinos. The cells of the SNc are reciprocally connected with the striatum. They project predominantly to the caudate nucleus and putamen in a topographically organized fashion, but also project to the globus pallidus and subthalamic nucleus. Together with the retrorubral nucleus (A8) and the ventral tegmental area (A10), they comprise most of the dopaminergic neuronal population of the midbrain. The pars lateralis projects to the ipsilateral superior colliculus and may be involved in the control of saccadic eye movements.

Ventral tegmental area

The ventral tegmental area (VTA) lies in the midline between the cerebral peduncles and at the depth of the interpeduncular fossa. It is continuous with the pars compacta of the substantia nigra to each side and with the lateral hypothalamus rostrally. The VTA contains cell group A10 (paranigral nucleus) and is the source of the mesolimbic dopamine system that supplies the ventral striatum, neighbouring parts of the dorsal striatum, the nucleus accumbens, the amygdala, the prefrontal cortex and the anterior cingulate cortex (Nieuwenhuys et al 2008). The dopaminergic neurones of the VTA also contain cholecystokinin (CCK) or somatostatin. The ventral tegmental system acts as an integrative centre for adaptive behaviour. It receives afferent input from a wide variety of sources including the habenular nuclei and the rostromedial tegmental nucleus (Matsumoto and Hikosaka 2007, Hikosaka 2008, Hikosaka 2010). The VTA projects ascending fibres into the ipsilateral medial forebrain bundle, a composite tract that includes a mesodiencephalic system that terminates in thalamic and hypothalamic nuclei; mesostriatal projections to the caudate nucleus and putamen; a mesolimbic pathway to the nucleus accumbens, olfactory tubercle, lateral septum, interstitial nucleus of the stria terminalis, amygdala and entorhinal cortex; and mesocortical fibres to prefrontal, orbitofrontal and cingulate cortices.

Habenular control of dopamine release is a major contributor to reward-based motivation and action. The habenular nuclei, which are part of the diencephalon (Ch. 30) receive input from the limbic system and the striatum and project to the dopaminergic and serotoninergic centres of the brainstem via the habenulointerpeduncular tract (fasciculus retroflexus of Meynert).

In humans, the core of the fasciculus retroflexus is acetylcholine esterase-dense, while the surround is acetylcholine esterase-negative (Paxinos et al 2012). The medial habenular nuclei receive input mainly from the limbic system and project to the interpeduncular nucleus, which then projects to the serotoninergic nuclei of the raphe. The lateral habenular nuclei receive input mainly from the basal ganglia and project to the dopaminergic and serotoninergic centres partly through the rostromedial tegemental nucleus. Actual or anticipated negative reward activates the GABAergic rostromedial tegmental nucleus that then represses the dopaminergic centres of the ventral tegmental area and the substantia nigra in order to minimize energy expenditure or avoid harm (Hikosaka 2010).

Reticular formation

The tegmentum of the brainstem contains myriad islets of grey matter containing cells of different types and sizes interspersed among nerve fibres that run in all directions: collectively they form the reticular formation that extends from the spinal cord through the full length of the brainstem into the diencephalon (Olszewski and Baxter 1954, Haines and Mihailo 2018). Caudally, the reticular formation of the brainstem is continuous with the reticular intermediate grey matter of the spinal cord. Rostrally, it merges into the reticular and interlaminar nuclei of the thalamus and restricted regions of the subthalamus.

The reticular regions are often regarded as phylogenetically ancient, representing a primitive nerve network on which more anatomically organized, functionally selective connections have developed during evolution. Reticular regions tend to be ill-defined collections of neurones with diffuse connections. The neurones have long dendrites that spread transversely or longitudinally within the brainstem: axons may ascend or descend, bifurcate in both directions, be crossed, uncrossed or even bilateral, and often travel far, some through the whole brainstem and beyond. For these reasons, conduction paths through the reticular formation are difficult to define, often complex and polysynaptic.

Despite these complexities, on the basis of cytoarchitectonic, chemoarchitectonic and functional criteria, the reticular formation is divided into three longitudinal columns – median; medial, containing mostly large reticular neurones; and lateral, containing mostly small to intermediate neurones (**Fig. 28.19**). Within these columns, specific portions of the reticular regions may be classified into groups on the basis of their connections and their predominant neurotransmitters, namely, dopaminergic and noradrenergic neurones (group A), serotoninergic neurones (group B), adrenergic neurones (group C) and cholinergic neurones (group Ch) (Dahlström and Fuxe 1964, Dahlström and Fuxe 1965, Nieuwenhuys 1985, Siegel et al 1999).

Median column of reticular nuclei

The median column of reticular nuclei extends throughout the medulla, pons and midbrain and contains neurones that are largely aggregated in bilateral, vertical sheets, located immediately adjacent to the midline and occupying the paramedian zones. Collectively they are called the nuclei of the raphe, or raphe nuclei. Many neurones in raphe nuclei are serotoninergic and are grouped into nine clusters (**Fig. 28.20**) (Dahlström and Fuxe 1964, Dahlström and Fuxe 1965, Nieuwenhuys 1985, Hornung 2003). The serotonergic neurone clusters may be allocated, on the basis of their distribution and main projections, into rostral and caudal groups. The rostral group is confined to the mesencephalon and rostral pons and has major projections to the forebrain. It includes the median (superior) raphe nucleus (B6), the dorsal (rostral) raphe nucleus (B7) and linear raphe nucleus (B8). Neurones in the caudal group in the caudal pons and medulla oblongata project to brainstem nuclei and to the spinal cord (Hornung 2003). The caudal group includes the raphe pallidus nucleus (B1) and associated raphe obscurus nucleus (B2), which lie in the upper two-thirds of the medulla and cross the pontomedullary junction. The raphe magnus nucleus (B3) minimally overlaps B1 and B2 and ascends into the caudal pons; it is caudal to the pontine raphe nucleus (B5). The serotoninergic cells

Magn Reson Mater Phys 26:71–9.)

of vestibular area (B4) and group B9 are small cell groups located in the medulla and midbrain, respectively.

Connections of the serotoninergic raphe neurones are multiple and complex. Principally, the rostral serotoninergic group is reciprocally interconnected rostrally with the limbic system, septum, prefrontal cortex and hypothalamus. Efferents ascend and form a large ventral and a diminutive dorsal pathway. The fibres of the ventral ascending serotoninergic pathway exit the ventral aspect of the mesencephalic raphe nuclei, and then course rostrally through the ventral tegmentum from where fibres pass to the ventral tegmental area, substantia nigra and interpeduncular nucleus. A large number of fibres then enter the fasciculus retroflexus (habenulo-interpeduncular tract) and run rostrally to innervate the habenular nucleus, intralaminar, midline, anterior, ventral and lateral dorsal thalamic nuclei, and the lateral geniculate body. The ventral ascending serotoninergic pathway enters the medial forebrain bundle in the lateral hypothalamic area and splits to pass medially and laterally. The fibres in the medial tract terminate in the mammillary body, dorsomedial, ventromedial, infundibular, anterior and lateral hypothalamic, medial and lateral preoptic, and suprachiasmatic nuclei. Those in the lateral tract take the ansa peduncularis–ventral amygdalofugal path to the amygdala, striatum and neocortex. The medial forebrain bundle carries the remaining ventral ascending serotoninergic axons into the medullary stria, stria terminalis, fornix, diagonal band, external capsule, cingulate fasciculus and medial olfactory stria, to terminate in all the structures that these systems interconnect. The ventral and dorsal pathways both originate from neurones in the dorsal and central superior raphe nuclei. The smaller dorsal ascending serotoninergic pathway is initially incorporated into the dorsal longitudinal fasciculus (of Schütz). A few fibres terminate in the central mesencephalic grey matter and posterior hypothalamus, but most continue into the medial forebrain bundle and merge with the axons of the ventral pathway, which are distributed to the same targets.

Major afferents to the mesencephalic raphe nuclei include those from the interpeduncular nucleus (linking the limbic and serotoninergic

systems); from the lateral habenular nucleus (linking the septum, preoptic hypothalamus and prefrontal cortex via the fasciculus retroflexus and the medial forebrain bundle); and from the pontine central grey matter. The ascending raphe system probably functions to moderate forebrain activities, particularly limbic, septal and hypothalamic activities. A degree of region-specific connectivity suggests that it exerts precise, as well as tonal, control.

The caudal group projects as ventral, dorsal and intermediate spinal tracts in the ventral and lateral funiculi. These terminate respectively in the ventral horns and laminae I, II and V of the dorsal horns of all segments, and in the thoracolumbar intermediolateral sympathetic and sacral parasympathetic preganglionic cell columns. The dorsal raphe nucleus also projects to the locus coeruleus, the dorsal tegmental nucleus and most of the rhombencephalic reticular formation. Its spinal projections function as a pain control pathway that descends from a mesencephalic pain control centre located in the periaqueductal grey matter, dorsal raphe and cuneiform nuclei. The intermediate raphe–spinal projection is inhibitory and, in part, modulates central sympathetic control of cardiovascular function. The ventral raphe–spinal system excites ventral horn cells and could function to enhance motor responses to nociceptive stimuli.

Medial column of reticular nuclei

The medial column of reticular nuclei is composed predominantly of neurones of medium size, although very large neurones are found in some regions, and most have processes orientated in the transverse plane. In the lower medulla the column is indistinct, and is perhaps represented by a thin lamina lateral to the raphe nuclei. However, in the upper medulla the medial column expands into the medullary gigantocellular (magnocellular) nucleus, which lies ventrolateral to the hypoglossal nucleus, ventral to the vagal nuclei and dorsal to the inferior olivary complex (see **Fig. 28.19**). Ascending further, the column continues as the pontine gigantocellular nucleus, which lies medially in the tegmentum. Its neurones suddenly diminish in size to form, in rostral order, the almost co-extensive caudal and oral pontine tegmental reticular nuclei. It then expands into the cuneiform nucleus and subcuneiform nucleus, before fading away in the midbrain tegmentum (Haines and Mihailo 2018).

The connections of the medial reticular formation suggest that the medial column is integrated into both sensory and motor pathways (Nieuwenhuys et al 2008). Retinotectal and tectoreticular fibres relay visual information and the medial forebrain bundle transmits olfactory impulses. Within the medial column, the region above and below the abducens nucleus is designated the paramedian pontine reticular formation and corresponds to the horizontal gaze centre. Afferent inputs to the medial reticular nuclear column include the spinoreticular projections and collaterals of centrally projecting spinal trigeminal, vestibular and cochlear fibres. Spinoreticular fibres, part of the anterolateral system, arise from neurones in the intermediate grey matter of the spinal cord. They decussate in the ventral white commissure, ascend in the ventrolateral funiculus, and terminate not only at all levels of the medial column of reticular nuclei but also in the intralaminar nuclei of the thalamus: the latter project directly to the striatum and neocortex.

Efferent axons of medial reticular column neurones form a multisynaptic ascending and descending system within the column and ultimately enter the spinal cord and diencephalon.

Descending fibres form pontine (medial) and medullary (lateral) reticulospinal tracts. Pontine reticulospinal axons arise from neurones in the caudal and oral parts of the pontine reticular nucleus, descend largely uncrossed in the ventral spinal funiculus, and terminate in spinal cord laminae VII, VIII and IX. Medullary reticulospinal axons descend bilaterally, but with an ipsilateral preponderance, to end in laminae VII, VIII, IX and X, and descend ipsilaterally to end in laminae IV, V and VI. This system modulates spinal motor function and segmental nociceptive input.

Lateral column of reticular nuclei

The lateral column of reticular nuclei contains six nuclear groups (see Fig. 28.19). These are the parvocellular reticular area, superficial ventrolateral reticular area, lateral pontine tegmental noradrenergic cell groups A1, A2, A4–A7 (A3 is absent in primates), adrenergic cell groups C1–C3 and cholinergic cell groups Ch5–Ch6 (Nieuwenhuys 1985, Siegel et al 1999). Cell groups Ch1–Ch4 are located in the basal forebrain. The column descends through the lower two-thirds of the lateral pontine tegmentum and upper medulla, where it lies between the gigantocellular nucleus medially, and the sensory nuclei of the trigeminal nerve laterally. It continues caudally and expands to form most of the reticular formation lateral to the raphe nuclei. It abuts the superficial ventrolateral reticular area, nucleus solitarius, nucleus ambiguus and vagal nucleus, and there contains the adrenergic cell group C2 and the noradrenergic group A2.

The lateral paragigantocellular nucleus lies at the rostral pole of the diffuse superficial ventrolateral reticular area (at the level of the facial nucleus). The zone extends caudally as the nucleus retroambiguus and descends into the spinal cord. It contains noradrenergic cell groups A1, A2, A4 and A5, and the adrenergic cell group C1. The ventrolateral reticular area is involved in cardiovascular, respiratory, vasoreceptor and chemoreceptor reflexes, and in the modulation of nociception. The A2 or noradrenergic dorsal medullary cell group lies in the nucleus of the tractus solitarius, vagal nucleus and adjoining parvocellular reticular area. Adrenergic group C1 lies rostral to the A2 cell group. Noradrenergic cell group A4 extends into the lateral pontine tegmentum, along the subependymal surface of the superior cerebellar peduncle. Noradrenergic group A5 forms part of the paragigantocellular nucleus in the caudolateral pontine tegmentum. Noradrenergic cell group A5 and adrenergic cell group C1 probably function as centres of vasomotor control. The entire region is subdivided into functional areas on the basis of experiments in animals, in which vasoconstrictor, cardioaccelerator, depressor, inspiratory, expiratory and sudomotor responses have been elicited.

The lateral pontine tegmental reticular grey matter is related to the superior cerebellar peduncle and forms the medial and lateral parabrachial nuclei and the ventral Kölliker–Fuse nucleus, part of the brainstem respiratory control network. There is experimental animal evidence that the Kölliker-Fuse nucleus provides some of the densest projections to the entire lateral pontomedullary column of respiratory neurones and to respiratory-related neurones in the medulla and cervical spinal cord, including phrenic motor neurones. The locus coeruleus (noradrenergic cell group A6), area subcoeruleus, noradrenergic cell group A7 and cholinergic group Ch5 in the pedunculopontine tegmental nucleus (nucleus tegmentalis pedunculopontinus) are all located in the lateral pontine and mesencephalic tegmental reticular zones. A4 is sometimes considered part of the coeruleus complex. The mesencephalic group Ch5 is continuous caudally with cell group Ch6 in the pontine central grey matter.

Cell group A6 (also parts of A4) contains all the noradrenergic cells in the central region of the locus coeruleus (**Fig. 28.21**). Group A6 has ventral (nucleus subcoeruleus, A6sc), rostral and caudolateral extensions (A6cg), the latter merging with the A4 group. The locus coeruleus probably functions as an attention centre, focusing neural functions to prevailing needs. The noradrenergic A7 group occupies the rostroventral part of the pontine tegmentum and is continuous with groups A5 and A1 through the lateral rhombencephalic tegmentum. The A7, A5, A1 complex is also connected by noradrenergic cell clusters with group A2, caudally, and group A6, rostrally. The A5 and A7 groups lie mainly within the medial parabrachial and Kölliker–Fuse nuclei. Reticular neurones in the lateral pontine tegmental reticular area, like those of the ventrolateral zone, function to regulate respiratory, cardiovascular and gastrointestinal activity. Two micturition centres are located in the dorsomedial and ventrolateral parts of the lateral pontine tegmentum.

The connections of the lateral column reticular nuclei are complex. The short ascending and descending axons of the parvocellular reticular area constitute medullary reflex pathways, which connect all branchiomotor nuclei and the hypoglossal nucleus with central afferent cranial nerve complexes through a propriobulbar system. This area also receives descending afferents from the contralateral motor cortex via the corticotegmental tract, and from the contralateral red nucleus via the rubrospinal tract. The longitudinal catecholamine bundle passes through the parvocellular reticular formation.

The superficial ventrolateral reticular area receives its input from the nucleus solitarius, and subserves cardiovascular, baroreceptor, chemoreceptor and respiratory reflexes; it also receives some input from the spinal cord, insular cortex and amygdala. Reticulospinal fibres from this region terminate bilaterally on sympathetic preganglionic neurones in the thoracic spinal cord.

Reticulospinal fibres descend from the lateral pontine tegmentum. A mainly ipsilateral subcoeruleospinal pathway is distributed to all spinal segments of the cord through the lateral spinal funiculus. Crossed pontine reticulospinal fibres descend from the ventrolateral pontine tegmentum, decussate in the rostral pons and occupy the contralateral dorsolateral spinal funiculus. They terminate in laminae I, II, V and VI of all segments of the spinal cord.

Bilateral projections from the micturition centres travel in the lateral spinal funiculus. They terminate on preganglionic parasympathetic neurones in the sacral cord (which innervate the detrusor muscle in the urinary bladder), and on neurones in the nucleus of Onuf (which innervate the musculature of the pelvic floor and the anal and urethral sphincters) (Ch. 73).

Descending fibres of the A6 noradrenergic neurones of the locus coeruleus project into the longitudinal dorsal fasciculus (as the caudal

Fig. 28.21 Locus coeruleus. Gross axial section through the basis and tegmentum of the upper pons. The paired dark round foci of neuromelanin identify the locus coeruleus on each side of the upper fourth ventricle.

The superficial ventrolateral area is also the seat of the 'visceral alerting response'. Fibres from the hypothalamus, periaqueductal grey matter and midbrain tegmentum mediate increased respiratory activity, raised blood pressure, tachycardia, vasodilation in skeletal muscle and renal and gastrointestinal vasoconstriction. Ascending efferents from the superficial ventrolateral area synapse on neurones of the supraoptic and paraventricular hypothalamic nuclei. Excitation of these neurones causes release of vasopressin from the neurohypophysis. Medullary noradrenergic cell groups A1 and A2 also innervate (directly and indirectly) the median eminence and control the release of growth hormone, luteinizing hormone and adrenocorticotrophic hormone.

The lateral pontine tegmentum, particularly the parabrachial region, is reciprocally connected to the insular cortex. It shares reciprocal projections with the amygdala through the ventral amygdalofugal pathway, medial forebrain bundle and central tegmental tract, and with hypothalamic, median preoptic and paraventricular nuclei, which preferentially project to the lateral parabrachial nucleus and the micturition centres. It also shares reciprocal bulbar projections, many from the brainstem respiratory control network, with the nucleus solitarius and superficial ventrolateral reticular area.

Other axons that contribute to the longitudinal catecholamine bundle originate from cell groups C1, A1, A2, A5 and A7. The main projection is a descending one from cell groups C1 and A5, which are sudomotor neural control centres and innervate preganglionic sympathetic neurones

Fibres from the locus coeruleus that travel in the rostral limb of the dorsal periventricular pathway ascend in the ventromedial periaqueductal grey matter adjacent to the longitudinal dorsal fasciculus and terminate in the parvocellular part of the paraventricular nucleus in the hypothalamus. The A1, A2, A5 and A7 noradrenergic cell groups project rostrally, mainly through the central tegmental tract. Their axons constitute a major longitudinal catecholamine pathway that continues through the medial forebrain bundle and ends in the amygdala, lateral septal nucleus, bed nucleus of the stria terminalis, nucleus of the diagonal band and the hypothalamus. The ascending dorsal periventricular pathway contains a few non-coerulean noradrenergic fibres, which terminate in the periventricular region of the thalamus.

Projections arising in the rhombencephalon receive contributions from the diffusely organized dorsal medullary and lateral tegmental noradrenergic cell groups. These interconnect cranial nerve nuclei and other reticular cell groups, particularly those of the vagus, facial and trigeminal nerves, and the rhombencephalic raphe and parabrachial nuclei.

Precerebellar nuclei are those that send axons to the cerebellar cortex and nuclei. Three precerebellar nuclei related to the reticular formation are the lateral and paramedian reticular nuclei, and the reticulotegmental nucleus. These three help relay spinal information primarily into the vermis and paravermal regions of the ipsilateral cerebellar hemisphere. They receive inputs from the contralateral primary motor and sensory neocortices, and the ipsilateral cerebellar and vestibular nuclei and spinal cord (the latter through the ascending spinoreticular pathway). This system augments the dorsal and ventral spinocerebellar, cuneocerebellar, accessory cuneocerebellar and trigeminocerebellar tracts. The locus coeruleus may function to control the level of attentiveness and the wake–sleep cycle, and regulate blood flow.

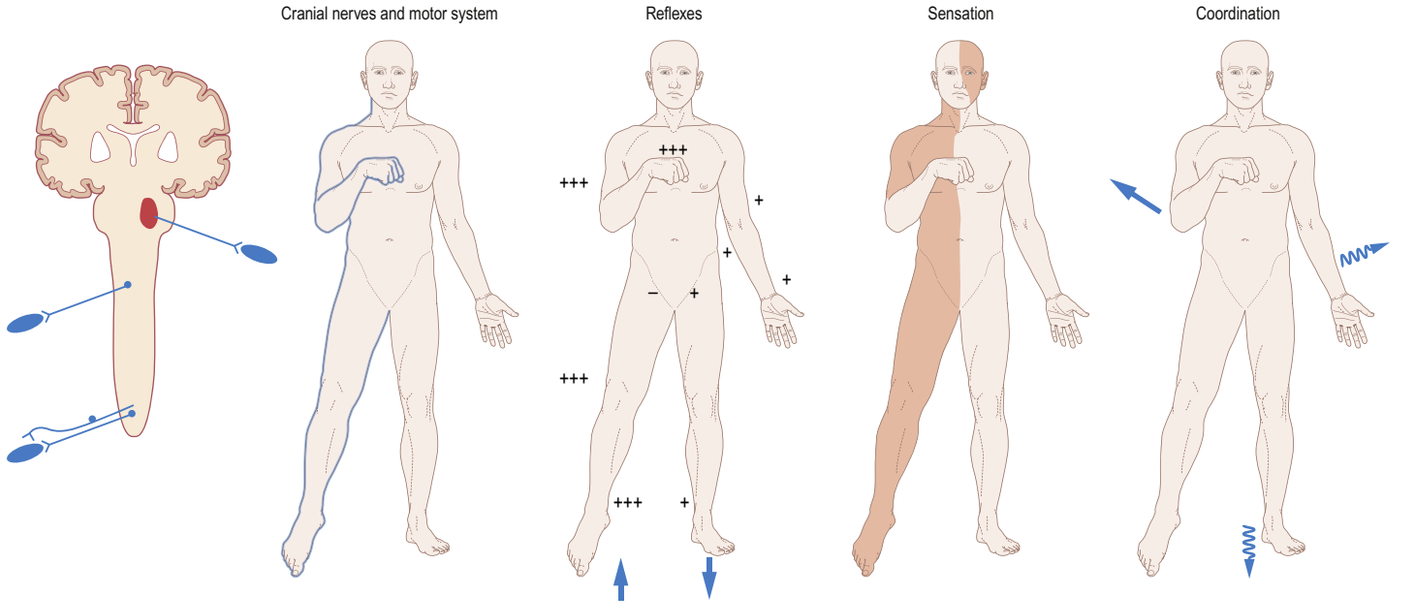

Fig. 28.22 Brainstem lesions. (Adapted with permission from Crossman AR, Neary D 2019 Neuroanatomy: An Illustrated Colour Text, 6th ed. Elsevier, Churchill Livingstone. Copyright 2019.)

limb of the dorsal periventricular pathway), and into the caudal limb of the dorsal noradrenergic bundle (as part of the longitudinal catecholamine bundle). In this way they innervate, mainly ipsilaterally, all other rhombencephalic reticular areas, and the spinal nuclei of the trigeminal nerve, pontine nuclei, cochlear nuclei, nuclei of the lateral lemniscus, and bilaterally, all spinal preganglionic autonomic neurones and the ventral region of the dorsal horn in all segments of the spinal cord.

Most ascending fibres from the locus coeruleus pass in the dorsal noradrenergic (or tegmental) bundle; others run either in the rostral limb of the dorsal periventricular pathway or in the superior cerebellar peduncle. The latter fibres terminate on the cerebellar nuclei. The dorsal noradrenergic bundle is large and runs through the ventrolateral periaqueductal grey matter to join the medial forebrain bundle in the hypothalamus, from where fibres continue forwards to innervate all rostral areas of the brain. The pathway contains efferent and afferent axons that reciprocally connect the locus coeruleus with adjacent structures along its course, e.g. central mesencephalic grey matter, dorsal raphe nucleus, superior and inferior colliculi, interpeduncular nucleus, epithalamus, dorsal thalamus, habenular nuclei, amygdala, septum, olfactory bulb and anterior olfactory nucleus, the entire hippocampal formation and neocortex.

Pedunculopontine nucleus

The pedunculopontine nucleus (nucleus tegmenti pedunculopontinus; PPN) lies in the dorsolateral part of the pontomesencephalic tegmentum. Despite some terminological confusion, most authors agree that the pedunculopontine nucleus is bounded laterally by the medial lemniscus, medially by the superior cerebellar peduncle and its decussation, dorsally by the pontine cuneiform and subcuneiform nuclei and ventrally by the pontine reticular formation. Rostrally, its ventral border contacts the dorsomedial aspect of the substantia nigra and it is separated from the subthalamic nucleus by the retrorubral field. Its most caudal pole is adjacent to the locus coeruleus (Pahapill and Lozano 2000).

On the basis of their cytoarchitectonic and neurochemical characteristics, the pedunculopontine nucleus has been subdivided into a caudal pars compacta consisting mainly of cholinergic neurones, and a rostral pars dissipata consisting of approximately equal numbers of cholinergic and glutamatergic neurones scattered from the mid-mesencephalic to mid-pontine levels (Hamani et al 2007). The pedunculopontine nucleus is encircled by the mesencephalic locomotor region (MLR), a region that also includes the cuneiform and subcuneiform nuclei. Based on experimental studies in animals, where stimulation of the mesencephalic locomotor region elicits locomotion, the pedunculopontine nucleus has been implicated in the initiation and modulation of gait and other stereotyped movements. Functionally, the pedunculopontine nucleus is associated with the reticular activating system via its cholinergic and glutaminergic connections with intralaminar thalamic nuclei. However, its most important and complex connections are reciprocal pathways with the basal ganglia, especially the internal globus pallidus and the substantia nigra; these pathways are described in detail in Chapter 31.

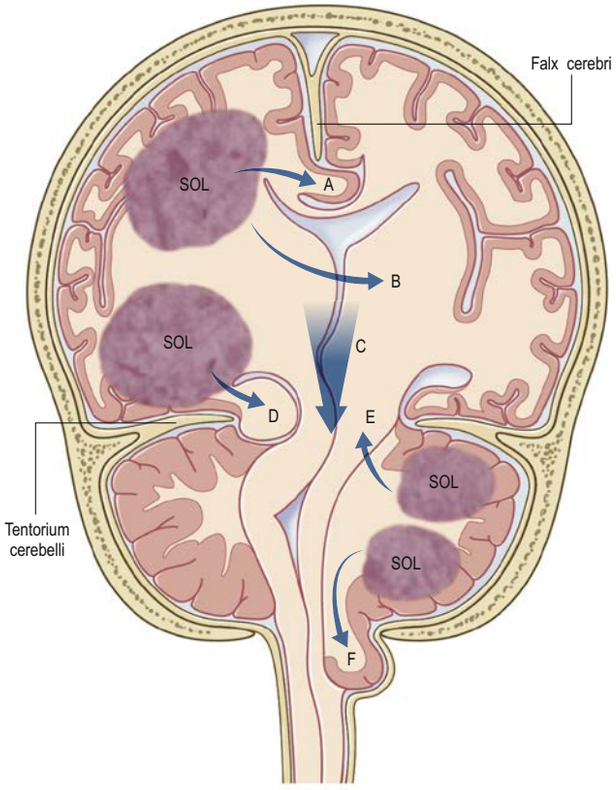
BRAINSTEM LESIONS

General concepts

Brainstem lesions (Fig. 28.22) may arise as a result of extrinsic compression of the brainstem by space-occupying tumours (e.g. meningioma, vestibular schwannoma, metastatic carcinoma) or may be caused by intrinsic disease (e.g. glioma, demyelination, stroke). The clinical syndrome is generally characterized by ipsilateral cranial nerve deficits and contralateral hemiplegia (from corticospinal involvement) and/or contralateral hemianaesthesia (from anterolateral system, dorsal column–medial lemniscus). Brainstem lesions may also result in cerebellar signs (damage to cerebellar afferents or efferents) or in symptoms reflecting small defects (nystagmus, internuclear ophthalmoplegia) (Haines and Mihailo 2018).

The cranial nerve deficit is the best localizing sign because it specifies the side of the lesion and the level within the brainstem. Midbrain lesions (involving the oculomotor and/or trochlear nerves) cause ophthalmoplegia, pupillary dilation and ptosis (oculomotor nerve palsy), and impaired upward gaze (e.g. due to a pinealoma). Mid-pontine lesions (involving the trigeminal nerve) may result in a loss of sensation on the face and in the oral cavity and weakness of the masticatory muscles. Tumours or lesions at the level of the pontomedullary junction (involing the abducens, facial and/or vestibulocochlear nerves) may produce weakness of lateral rectus, a loss of facial sensation and deafness, vertigo or tinnitus. Medullary lesions (involving the glossopharyngeal, vagus and hypoglossal nerves and traversing fibres of the accessory nerve) may cause a 'bulbar palsy': dysarthria, dysphagia and dysphonia, with wasting of the hemitongue, and deviation, weakness and wasting of sternocleidomastoid and trapezius. All these deficits are usually accompanied by signs or symptoms of long tract involvement (motor, sensory or both).

Herniation syndromes



Damage to the brainstem results in characteristic deficits that form part of the so-called herniation syndromes. The falx cerebri and tentorium cerebelli incompletely partition the intracranial volume into partially communicating compartments. The tentorium cerebelli incompletely separates the intracranial volume into the supratentorial space (above) and the infratentorial space (below). The supratentorial space is partially partitioned into left and right halves by the falx cerebri. The supra- and infratentorial spaces communicate through a narrow opening in the tentorium, the tentorial notch or incisura. The infratentorial compartment is continuous inferiorly with the intraspinal compartment through the small foramen magnum. A significant increase in the intracranial pressure within one compartment (due to tumour, haemorrhage, abscess, metabolic disturbance, and signalled by headache, nausea and papilloedema) may cause brain tissue to be displaced (herniated) into an adjacent compartment.

Left–right displacement of brain tissue under the falx is subfalcial herniation (Fig. 28.23, A). Superior–inferior displacement through the

incisura is designated transincisural (transtentorial) herniation and is subclassified as upward or downward transincisural herniation. Herniation of posterior fossa tissue into the upper spinal canal typically displaces the cerebellar tonsils into the foramen magnum and the bony ring of the atlas (C1), and is typically designated as downward tonsillar herniation. All herniation syndromes, directly or indirectly, will compromise brainstem viability (Haines 2015).

An expanding lesion in parietofrontal areas, a supratentorial position, may result in herniation of structures such as the cingulate gyrus underneath the edge of the falx cerebri (see Fig. 28.23A). This may initially be a 'silent' event (i.e. no signs or symptoms) or may present as weakness of the lower extremities related to compression of the anterior cerebral artery (ipsilateral, contralateral or bilateral) and decreased levels of consciousness.

Hemisphere lesions may enlarge, impinge into the opposite side of the brain, and produce a characteristic series of deficits (Fig. 28.23B).

A Cingulate herniation under falx, potential anterior cerebral artery damage
B Herniation into opposite hemisphere, potential decorticate posturing
C Transtentorial or central herniation, potential decerebrate posturing, somnolence
D Uncal/parahippocampal gyrus herniation, pupillary signs, hemiparesis, somnolence, stupor
E Upward cerebellar herniation, increased intracranial pressure, hydrocephalus, impaired upward gaze
F Tonsillar herniation, potential cardiac and respiratory arrest

Fig. 28.23 Effects of space-occupying lesions (SOL).

These include decrease in consciousness indicating damage to the thalamic relays of the reticular activating system, generally increased muscle tone, a change in respiratory patterns, and altered pupils and eye movements. These patients may become decorticate with extended lower extremities and flexed, upper extremities.

As a cerebral mass compromises the available supratentorial space and the clinical picture deteriorates, the herniation traverses the tentorial notch as a downward transtentorial (or central) herniation (Fig. 28.23C). These patients have a significantly decreased level of consciousness (some may be stuporous or in coma); breathing patterns are irregular (tachypnoea, Cheyne–Stokes); and eye movements are compromised such that the pupils are dilated and may be fixed. A state of decortication may convert to decerebrate rigidity, when all extremities are extended.

Lesions located in the temporal lobe may expand medially, forcing the uncus and possibly the parahippocampal gyrus over the edge of the tentorium cerebelli with impingement on the midbrain (Fig. 28.23D). This is uncal herniation and may present in two forms. The midbrain injury involves structures on the side of the herniation with predictable deficits: ipsilateral pupil dilation and ophthalmoplegia, contralateral weakness of upper and lower extremities, an altered level of consciousness and hyperactive reflexes. Alternatively, the herniation may shift the midbrain to the side opposite the herniation (e.g. with herniation on the right, the midbrain shifts to the left) and it is compressed against the edge of the tentorium. In this case the dilated pupil and third nerve ophthalmoplegia are on the right, and the crus cerebri damage on the left results in a right hemiplegia; both motor deficits are on the right side. The corticospinal deficit, in this case, is a false localizing sign.

Pressure increase in the posterior fossa, an infratentorial location, may result in herniation upwards through the tentorial notch or downwards into the foramen magnum. Upward cerebellar herniation (Fig. 28.23E) displaces the brainstem against the tentorium and into the notch with resultant symptoms of increased intracranial pressure, paralysis of upward gaze, motor deficits and altered consciousness. Extrusion of the cerebellar tonsils (Fig. 28.23F) downwards into the foramen magnum may result in damage to medullary cardiac and respiratory centres, with resultant changes in heart and respiratory rates. Both of these syndromes may constitute a medical emergency, the former due to rapidly developing hydrocephalus, the latter due to compromise of cardiac and respiratory centres.

VIEW TO THE FUTURE

With increasing sophistication of anatomical and imaging techniques, clinician-scientists will be able to depict the anatomy of the brainstem with increasing resolution, potentially opening avenues to increased understanding of the circuitry that underlies function (Fig. 28.24).

And beyond: refining traditional anatomical descriptions

Available with the *Gray's Anatomy* e-book

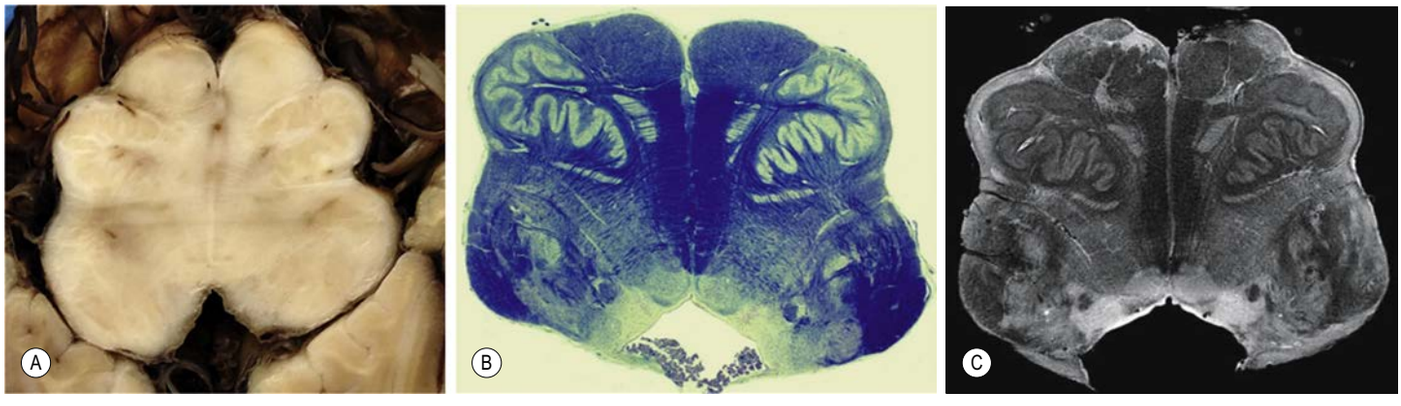


Fig. 28.24 Image comparison. Display of the medulla oblongata at the level of the principal olivary nuclei as revealed by **(A)** gross anatomy, **(B)** myelin staining and **(C)** postmortem 9.4 Tesla proton density MRI. The images in **A** and **B** have been rotated through 180° from the conventional anatomical orientation to allow their direct comparisons with the axial MRI view.

The human brain is composed of segments designated neuromeres that create the final brain structure. Traditional anatomical descriptions have been based on the gross anatomical appearance of the structures observed. Increasingly, however, molecular studies of embryogenesis are now revealing the key signalling molecules and pathways that initiate segment formation, establish segment boundaries, and define final segment identity and function (Fig. 28.25) (Watson et al 2019). This deeper, molecular understanding of segment architecture provides the opportunity to update traditional definitions to reflect newly discovered commonalities and differences among structures that were previously considered to be single or separate units. The changes now proposed are new boundaries for the midbrain, new definitions of the pons, and a new definition of the caudal medulla that reassigns the pyramidal decussation to the C1 segment. The new parcellation of the brainstem also extends to the reticular formation. A diagrammatic representation of the rhombomeres of the stem (Fig. 28.26, see Fig. 14.17) and Table 28.1 introduce some of these proposed revisions.

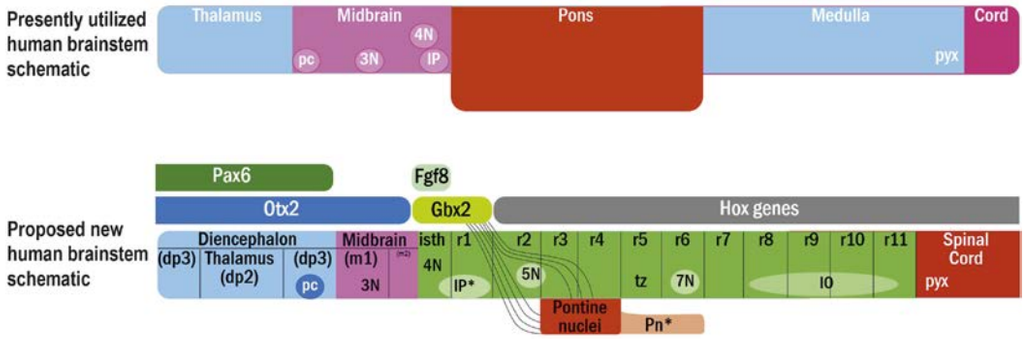

Fig. 28.25 Diagrammatic representation comparing the traditional nomenclature of the brainstem (upper portion) with the proposed new nomenclature based upon the patterns of developmental gene expression (lower portion). **Upper portion**: In the traditional nomenclature, the brainstem is divided into the midbrain, pons and medulla. The oculomotor (3N), trochlear (4N) and interpeduncular (IP) nuclei are allocated to the midbrain. The decussation of the pyramids (pyx) marks the caudal end of the medulla. **Lower portion**: In the proposed new nomenclature, the same tissue is re-apportioned to accord with the patterns of expression of developmental genes. The midbrain consists of two mesomeres (m1, m2). The hindbrain consists of 12 neuromeres designated r0 through r11, and is subdivided into a rostral hindbrain (r0–r6) and a caudal hindbrain (r7–r11). The oculomotor nerve (3N) lies within m1. The abducens nerve (4N) lies within r0 (isth., isthmus), and the interpeduncular nucleus lies within r1. The pontine region comprises r3 and r4, but, by overgrowth, the pons bulges over the ventral aspect of r2 rostrally and overhangs the ventral aspect of r5 and r6 caudally, obscuring them from view. The motor nucleus of the trigeminal nerve (5N) lies within r2 and r3. The trapezoid body (tz) and abducens nucleus (not shown) lie within r5, and the motor nucleus of the facial nerve (7N) lies within r6. The inferior olive (IO) lies within r8–r11. The decussation of the pyramids is reassigned to an expanded C1 segment. The segments over which the developmental genes act is given just above the lower portion. In broad terms, the Hox genes define the range of r2–r11 (and also act caudally for the full length of the spinal cord). Gbx2 is expressed in the rostral hindbrain (r0, r1) but not in the midbrain. *Fgf8* is selectively expressed in the isthmus. *Otx2* distinguishes the midbrain and forebrain from the hindbrain, and Pax6 identifies the diencephalon. (Reproduced with permission from Watson C, Bartholomaeus C, Puelles L 2019 Time for radical changes in brain stem nomenclature – applying the lessons from developmental gene patterns. Front Neuroanat 13:10.)

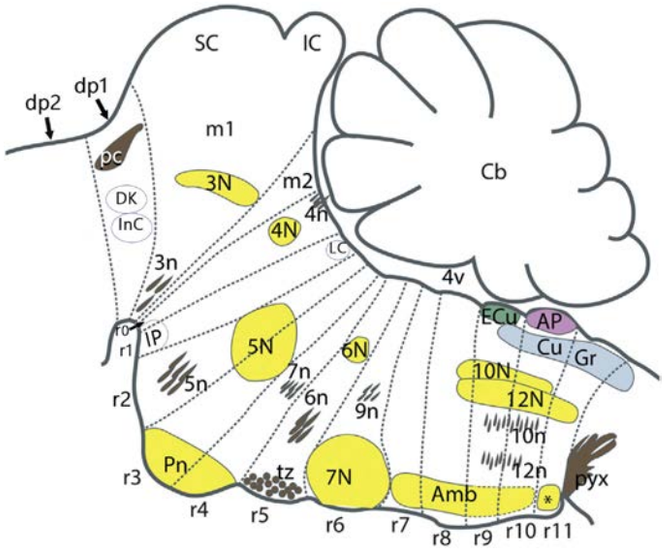

Fig. 28.26 Nuclei and nerve fibres within the neuromere segments of the brainstem. The diencephalon, cerebellum (Cb) and fourth ventricle (4V) are also labeled for orientation. Note: the diencephalic segments are numbered progressively from caudal to cranial, whereas the midbrain and hindbrain segments are numbered progressively from cranial to caudal. Cranial nerve nuclei are coloured yellow. Cranial nerves are indicated by "vertical" black lines and the decussating trapezoid fibres by dots. **Diencephalon:** Diencephalic prosomere 1 (dp1) contains the pretectal posterior commissure (pc). Dp 1 also contains the nucleus of Darkschewitsch (DK) and the interstitial nucleus of Cajal (InC). **Midbrain:** Mesomere 1 (m1) contains the oculomotor nucleus (3N), the emerging oculomotor nerve (3n), the superior colliculus (SC) and inferior colliculus (IC). Mesomere 2 (m2) is a thin band separating m1 from the isthmus (r0). **Hindbrain**: From rostral to caudal, the 12 hindbrain segments, r0 (isthmus) to r11, contain: **r0,** trochlear nucleus (4N) and dorsally emerging trochlear nerve (4n); **r1,** interpeduncular nucleus (IP) ventrally and locus coeruleus (LC) dorsally; **r2,** rostral part of the motor trigeminal nucleus (5N) and the emerging motor trigeminal nerve (5n); **r3,** caudal part of the motor trigeminal nucleus (5N) and the rostral pontine nuclei (Pn); **r4,** caudal pontine nuclei (Pn) and the emerging facial nerve (7n); **r5,** abducens nucleus (6N), emerging abducens nerve (6n), and decussation of the trapezoid body (tz); **r6,** migrated facial nucleus (7N) and emerging glossopharyngeal nerve (9n); **r7 and r8,** the rostral ambiguus nucleus (Amb), and rostral portions of the dorsal motor nucleus of the vagus (10N) and the hypoglossal nucleus (12N); **r9 and r10,** the caudal portions of the ambiguus nucleus (Amb) and the vagal nucleus (10N), much of the hypoglossal nucleus (12N) and the emerging fibres of the vagus (10n) and hypoglossal (12n) nerves; **r11,** remainder of the hypoglossal nucleus (12N) and the noncholinergic caudal extension of the ambiguus nucleus, called retroambiguus (asterisk). **Cervical cord:** The pyramidal decussation (pyx) is proposed to lie in the uppermost portion of the cervical spinal cord.The rostral–caudal positions of the external (accessory) cuneate nucleus (ECu), cuneate nucleus (Cu), gracile nucleus (Gr), and area postrema (AP) are also shown. (Modified with permission from Watson C, Kirkcaldie M, Puelles L 2017 Developmental gene expression redefines the mammalian brain stem. In: Kass JH (ed) Evolution of Nervous Systems, 2nd ed. Elsevier; pp. 467–75.)

TABLE 28.1 Neuromeric organization of the brainstem

Portion of brain	Neuromere	Structures included
Diencephalon		
	Prosomere 1 (dp1)	Posterior commissure Pretectal nuclei Nucleus of Darkschewitsch Interstitial nucleus of Cajal Red nucleus (parvocellular part)
Midbrain		
	Mesomere 1 (m1)	Superior colliculus Inferior colliculus Oculomotor nucleus (III) Emerging oculomotor nerve Red nucleus (magnocellular part)
	Mesomere 2 (m2)	Sagulum nucleus Retrorubral field (DA8) Subbrachial nucleus
Hindbrain		
Isthmocerebellar region (i.e. prepontine region)	Isthmus (r0)	Trochlear nucleus Emerging trochlear nerve Parabigeminal nucleus Microcellular tegmental nucleus
	Rhombomere 1 (r1)	Locus coeruleus Rostral interpeduncular nucleus Caudal interpeduncular nucleus Parabrachial nuclei
Pontine region	Rhombomere 2 (r2)	Rostral motor trigeminal nucleus Emerging motor trigeminal nerve
	Rhombomere 3 (r3)	Caudal motor trigeminal nucleus Rostral pontine nuclei
	Rhombomere 4 (r4)	Emerging facial nerve Caudal pontine nuclei
Retropontine region	Rhombomere 5 (r5)	Abducens nucleus Emerging abducens nerves Superior olive and trapezoid body
	Rhombomere 6 (r6)	Facial nucleus (migrated) Emerging glossopharyngeal nerve
Medulla oblongata	Rhombomere 7 (r7)	Compact ambiguus nucleus
	Rhombomere 8 (r8)	Compact ambiguus nucleus Rostral inferior olive
	Rhombomere 9 (r9)	Semicompact ambiguus nucleus Middle inferior olive
	Rhombomere 10 (r10)	Loose ambiguus nucleus Caudal inferior olive Area postrema
	Rhombomere 11 (r11)	Retroambiguus nucleus
Rostral Spinal Cord		
Cervical spinal cord	C1 segment (C1)	Pyramidal decussation

CHAPTER 29

Cerebellum

The cerebellum is the largest part of the hindbrain, recognized as a distinct division of the brain from the time of Herophilus (335–280 BC) and Galen (AD 131–200). It is situated in the posterior cranial fossa, beneath the tentorium cerebelli, the medial extension of the falx cerebri and the overlying occipital lobe and lies behind the pons and medulla, from which it is separated by the fourth ventricle (**Figs 29.1–29.2**). It is joined to the brainstem by three bilaterally paired major fibre tracts, the inferior, middle and superior cerebellar peduncles, through which it communicates with the remainder of the central nervous system. In adults, the ratio of the weight of the cerebellum to the cerebrum is about 1 to 10, in infants about 1 to 20. The adult human cerebellum has a volume of approximately 145 ml and weighs 150 grams, but its surface area is 40% that of the cerebral cortex. The great majority of cerebellar neurones are small granule cells, which are so densely packed that the cerebellar cortex contains approximately 70% of the 100 billion neurones in the central nervous system (Andersen et al 2012).

The basic internal organization of the cerebellum is of a superficial cortex overlying a core of white matter and deep cerebellar nuclei. The cortex is characteristically highly convoluted by numerous transverse furrows of varying depths that separate its surface into lobes, lobules and folia (leaflets). Aggregations of neuronal cell bodies embedded within the white matter form the fastigial (medial), globose (posterior interposed), emboliform (anterior interposed) and dentate (lateral) nuclei, collectively known as the deep cerebellar nuclei.

An earlier schema of the cerebellum regarded the cerebellum as being divided into three zones of connectional and functional organization (Jansen and Brodal 1940, Chambers and Sprague 1955a, 1955b).

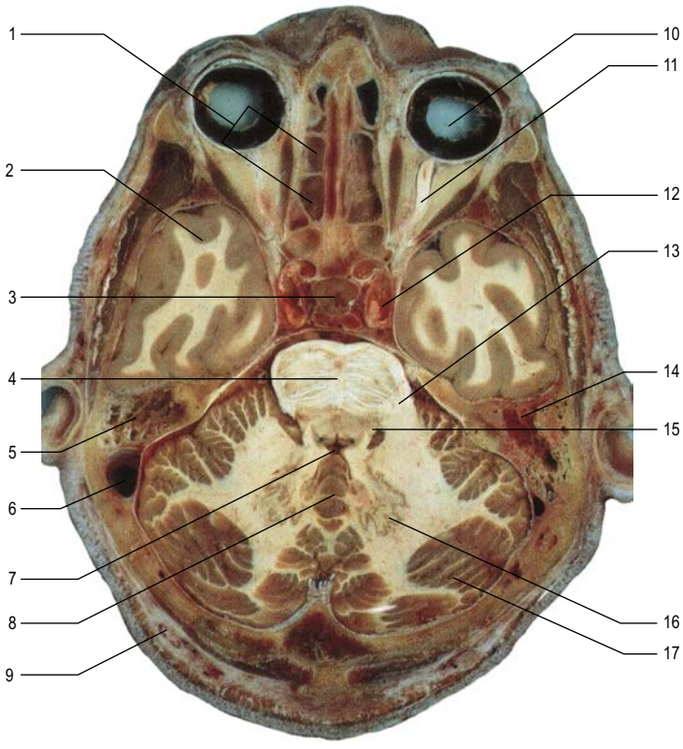

Fig. 29.1 A horizontal section through the cerebellum and brainstem. Key: 1, ethmoidal air cells; 2, temporal lobe of brain; 3, hypophysis; 4, pons; 5, cochlea; 6, sigmoid sinus; 7, fourth ventricle; 8, vermis; 9, diploë of occipital bone; 10, eyeball; 11, optic nerve; 12, internal carotid artery; 13, middle cerebellar peduncle; 14, petrous temporal bone; 15, superior cerebellar peduncle; 16, dentate nucleus; 17, folia of cerebellar cortex. (Courtesy of Dr GJA Maart.)

In this approach, the archicerebellum (vestibulocerebellum/flocculonodular lobe) has reciprocal links to vestibular nuclei either directly or indirectly and is concerned with eye movements and equilibrium. The paleocerebellum (spinocerebellum) in the vermis and paravermal regions receive cutaneous and kinaesthetic afferents from the spinal cord. The vermis is linked with the fastigial nucleus and influences the medial motor system through brainstem vestibular and reticular nuclei that send descending projections to the spinal cord, and is important for balance and equilibrium; the paravermal area is linked with the interpositus nuclei that project to the red nucleus and primary motor cortex and influences the lateral motor system which is important for the control of distal limb movements. The neocerebellum (pontocerebellum) is regarded as the lateral part of the cerebellum, receiving descending input from the cerebral cortex, projecting through the dentate nucleus back to thalamic areas that mostly project to motor and premotor cortices, and is important for fine motor control and perhaps motor planning and motor learning. These concepts retain some overall validity, but they have limitations in the light of evolving knowledge. The most salient are that the parasagittal organization of the cerebellum is exponentially more complex than this tripartite division; the anterior lobe–posterior lobe dichotomy of cerebellar function is a major organizing feature; pontine projections are not confined to the cerebellar hemispheres; the cerebellar incorporation into brainstem, diencephalic and cerebrocerebellar circuits extends considerably beyond the sensorimotor domains into the association areas and paralimbic cortices; and there are multiple representations of unimodal, multimodal and transmodal forms of sensorimotor, cognitive and affective systems within the human cerebellum.

The cerebellum is subdivided into modules, each consisting of a longitudinal cortical zone, a cerebellar or vestibular target nucleus, and a supporting olivocerebellar climbing fibre system. The longitudinal cortical zones are characterized by their connections as well as their immunohistochemical properties. The cerebellum receives topographically highly arranged input from peripheral receptors, spinal cord and brainstem, and from most of the cerebral cortex through two different afferent systems: mossy fibres and climbing fibres. It now appears that a fundamental role of the cerebellum is to enhance function in almost all domains, modulating behaviour, both motor and nonmotor, to optimize performance in a context-dependent manner.

Ideas on the involvement of the cerebellum in motor functions were derived mainly from movement disorders seen in experimental studies dating back to Rolando and Flourens (1824) (summarized by Luciani 1891), and in observations of patients with acquired cerebellar lesions or degeneration (Brown 1892, Marie 1893, Babinski 1899, Holmes 1939), who displayed characteristic gait ataxia (unstable balance and walking), dysmetria (disordered control) of the limbs, dysarthria (impaired articulatory clarity), and abnormal oculomotor control. The more recent observation that lesions of the cerebellar posterior lobes produce the cerebellar cognitive-affective syndrome in adults (Schmahmann and Sherman 1998) prompted the suggestion that the human cerebellum is also concerned with non-motor functions, which, together with the vestibulocerebellar and motor disorders, comprise the modern triad of clinical cerebellar ataxiology (Manto and Mariën 2015).

EXTERNAL FEATURES AND RELATIONS

The cerebellum consists of two large, laterally located hemispheres united by a midline vermis (**Fig. 29.3**). It is a multiply folded structure; when viewed from the external surface, the fissures (the cerebellar equivalent of cerebral sulci) run horizontally and follow the curve of the cerebellar external surface. The cerebellum has three surfaces. The superior surface adjoins the tentorium cerebelli and projects beyond its free edge: the distinction between the vermis and hemispheres on the superior surface is indistinct, with shallow paramedian kinks in the transverse fissures likely reflecting indentations of the superior cerebellar

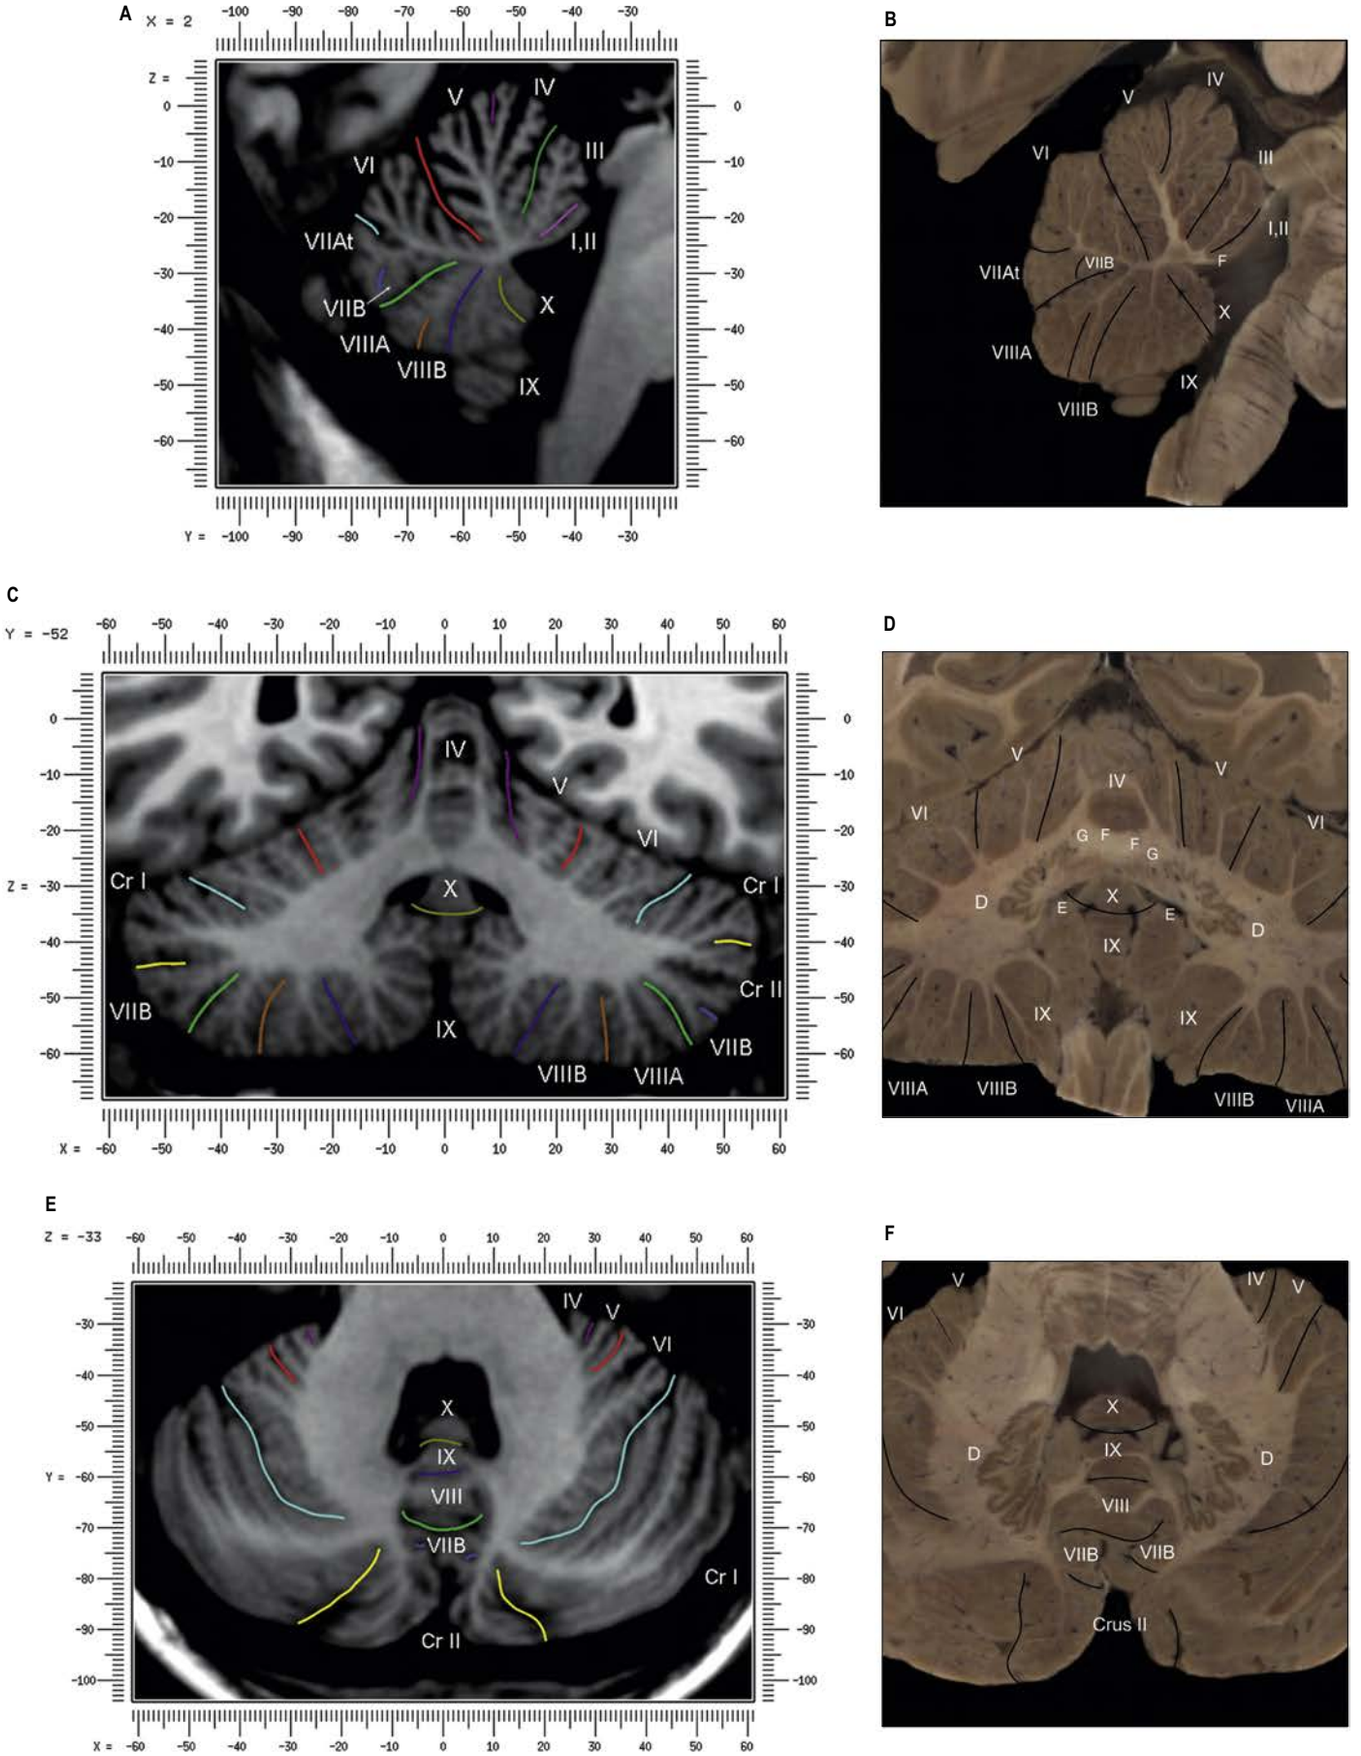

Fig. 29.2 The appearance of a human cerebellum on magnetic resonance imaging (MRI) images (left panel) and on cryosection images taken post-mortem from another cerebellum (right panel). The cerebellum is sectioned in the sagittal plane 2 mm to the right of midline in **A** and **B**; in the coronal plane 52 mm behind the anterior commissure–posterior commissure (AC–PC) line in **C** and **D**; and in the transverse plane 33 mm below the AC–PC line in **E** and **F**. Fissures are colour-coded according to the convention used in Figs 29.3 and 29.5, and the lobules are designated. Deep cerebellar nuclei are identified in the cryosection brain. Abbreviations: D, dentate nucleus; E, emboliform nucleus; F, fastigial nucleus; G, globose nucleus. (With permission from Schmahmann JD, Doyon J, Toga A et al 2000 MRI Atlas of the Human Cerebellum. San Diego: Academic Press.)

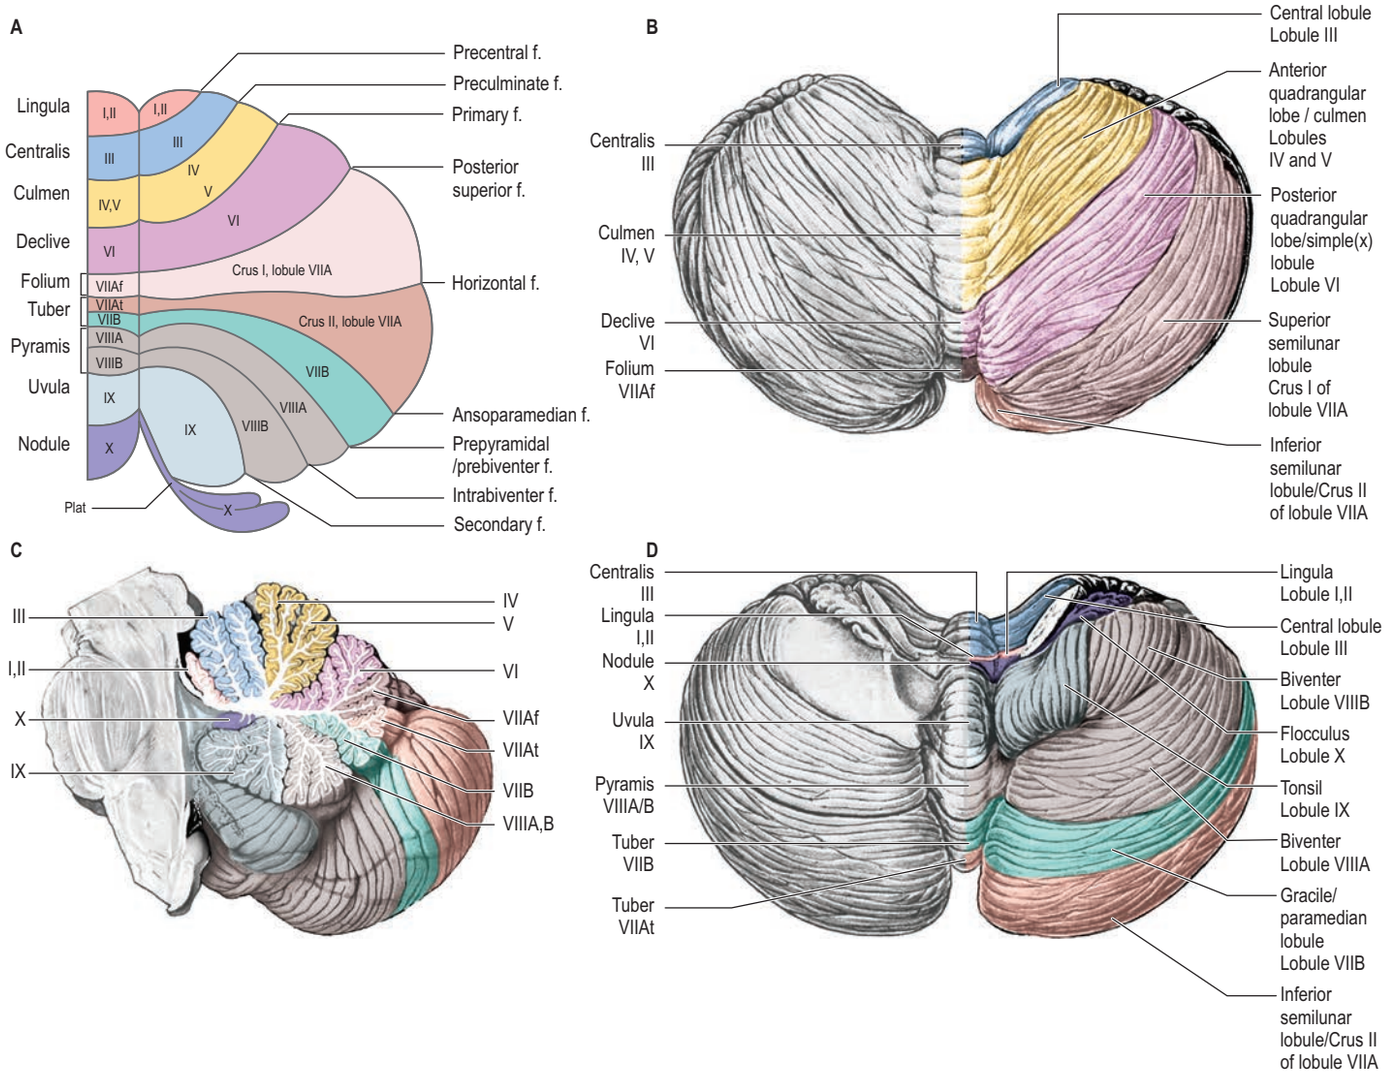

Fig. 29.3 Terminology of the cerebellar lobules and fissures at the vermis and hemispheres. **A**, Schematic unrolled diagram of the cerebellar cortex. The vermal and hemisphere lobules are labelled according to the elaboration by Schmahmann et al (1999, 2000) of the nomenclature of Larsell (Larsell and Jansen 1972) and Bolk (1906), as well as the classical nomenclature of the vermal lobules, and the named cerebellar fissures. **B**, The cerebellum viewed from above. **C**, Midline sagittal section of the cerebellum. **D**, The cerebellum viewed from below. Abbreviations: f, fissure.

artery. The superior surface slopes gently laterally and posteriorly as it reaches its margins. The transverse sinus borders the cerebellum at the point where the superior and inferior surfaces meet. The inferior surface of the cerebellum is characterized by a massive enlargement of the cerebellar hemispheres, separated from each other medially by a deep groove, or vallecula, which contains the dural falx cerebelli. The posterior vermis is a well-defined anatomical structure when viewed from posterior and inferior, named for its worm-like appearance by Vincenzo Malacarne (1744–1816) (Malacarne 1776), who also named the uvula and tonsils because of their resemblance to structures in the oral cavity. The posterior vermis is demarcated from the cerebellar hemispheres by deep paramedian sulci, although the hemispheres may extend medially and overlie the vermis. The inferior cerebellar surface lies against the occipital squama. The shape of the anterior cerebellar surface facing the brainstem is irregular, forming the roof of the fourth ventricle and the lateral recesses on each side. The cerebellar peduncles define the diamond shape of the ventricle when viewed from behind. Anterolaterally, the cerebellum lies against the posterior surface of the petrous part of the temporal bone.

Cerebellar fissures and lobules

The cerebellar surface is divided by numerous curved transverse fissures which separate its folia (the cerebellar equivalent of cerebral gyri) and give it a laminated appearance. The individual cerebellar folia group together as 10 lobules, arising usually from a common ray of medullary white matter. The lobules are continuous across the midline from one hemisphere to the other. They are distinguished from each other by named fissures, and they are grouped into three lobes: the anterior lobe (lobules I–V), posterior lobe (lobules VI to IX) and the flocculonodular lobe (lobule X) (**Fig. 29.4**; see Fig. 29.3). Because the cerebellar cortex has a roughly spherical shape, the true relations between its parts can sometimes be obscure. Thus, the most anterior lobules I/II of the cerebellar vermis lie very close to the most posterior vermal lobule X. The Roman numerals and subdivisions adopted by Schmahmann et al (1999, 2000) in the *MRI Atlas of the Human Cerebellum* (**Fig. 29.5**; see Fig. 29.2) and used here to designate the lobules are according to Larsell and Jansen (1972) and Bolk (1906) (**Fig. 29.6**) and replace earlier nomenclatures that were often conflicting or contradictory. The *MRI Atlas* enabled the development of probabilistic MR atlases of the human cerebellum and cerebellar nuclei (Diedrichsen et al 2009, 2011) used in functional imaging studies to correlate structure with function in health and disease.

Cerebellar peduncles

Three pairs of peduncles connect the cerebellum with the brainstem (**Fig. 29.7**). The inferior cerebellar peduncle runs parallel to the major axis of the brainstem, medial to the middle cerebellar peduncle. It consists of an outer, compact fibre tract, the restiform body, and a medial, juxtarestiform body. The restiform body is a purely afferent system conveying fibres from the dorsal spinocerebellar tract and trigeminocerebellar, cuneocerebellar, reticulocerebellar and olivocerebellar tracts (see Fig. 29.24). The juxtarestiform body is mainly an efferent system, made up almost entirely of Purkinje cell axons destined for the vestibular nuclei and uncrossed fibres from the fastigial nucleus. It also contains primary afferent mossy fibres from the vestibular nerve and secondary afferent fibres from the vestibular nuclei. The crossed fibres

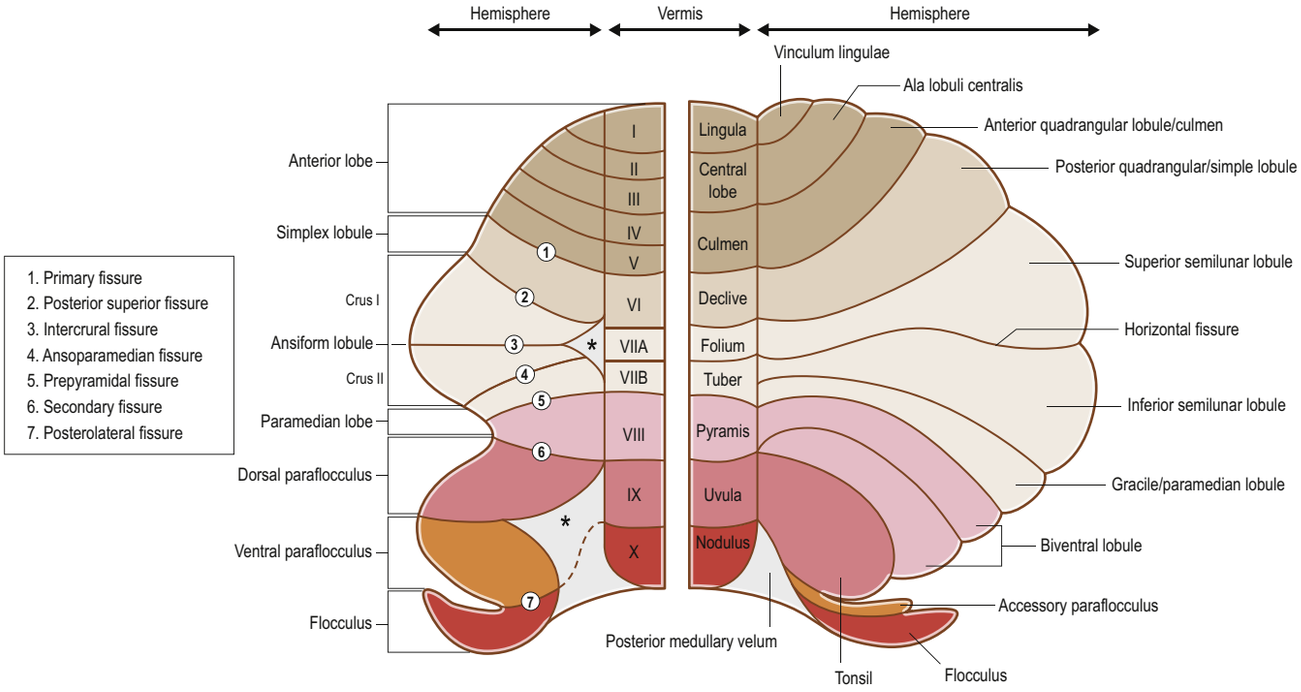

Fig. 29.4 Cerebellar nomenclature. The left-hand panel illustrates the comparative anatomical nomenclature for the hemisphere and Larsell's numbering system for the lobules of the vermis (Larsell and Jansen 1972). The right-hand panel shows the more commonly used classical nomenclatures according to different investigators over the past 140 years (Schmahmann et al 2000). The homology of these lobules is indicated using the same colour. Asterisks denote areas devoid of cortex in the centre of the folial rosettes of the ansiform lobule and the paraflocculus.

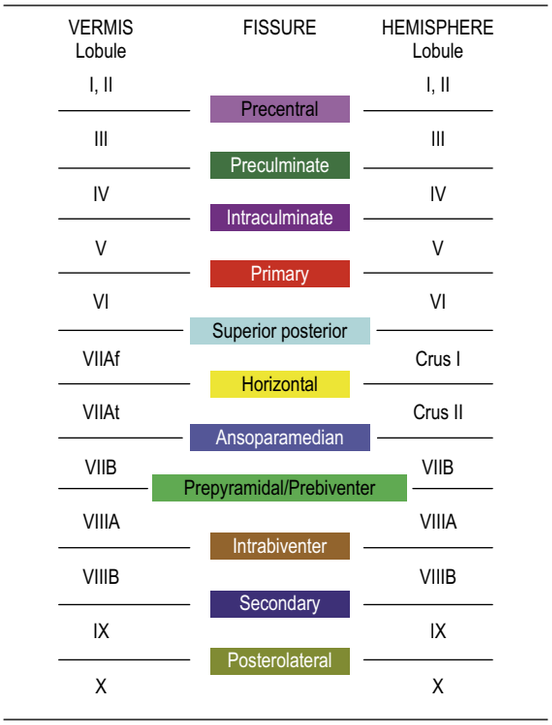

Fig. 29.5 The relationship of the named cerebellar fissures to the lobules in the vermis and hemispheres. (With permission from Schmahmann JD, Doyon J, McDonald D et al 1999 Three-dimensional MRI atlas of the human cerebellum in proportional stereotaxic space. Neuroimage 10:233–60; and Schmahmann JD, Doyon J, Toga A et al 2000 MRI Atlas of the Human Cerebellum. San Diego: Academic Press.)

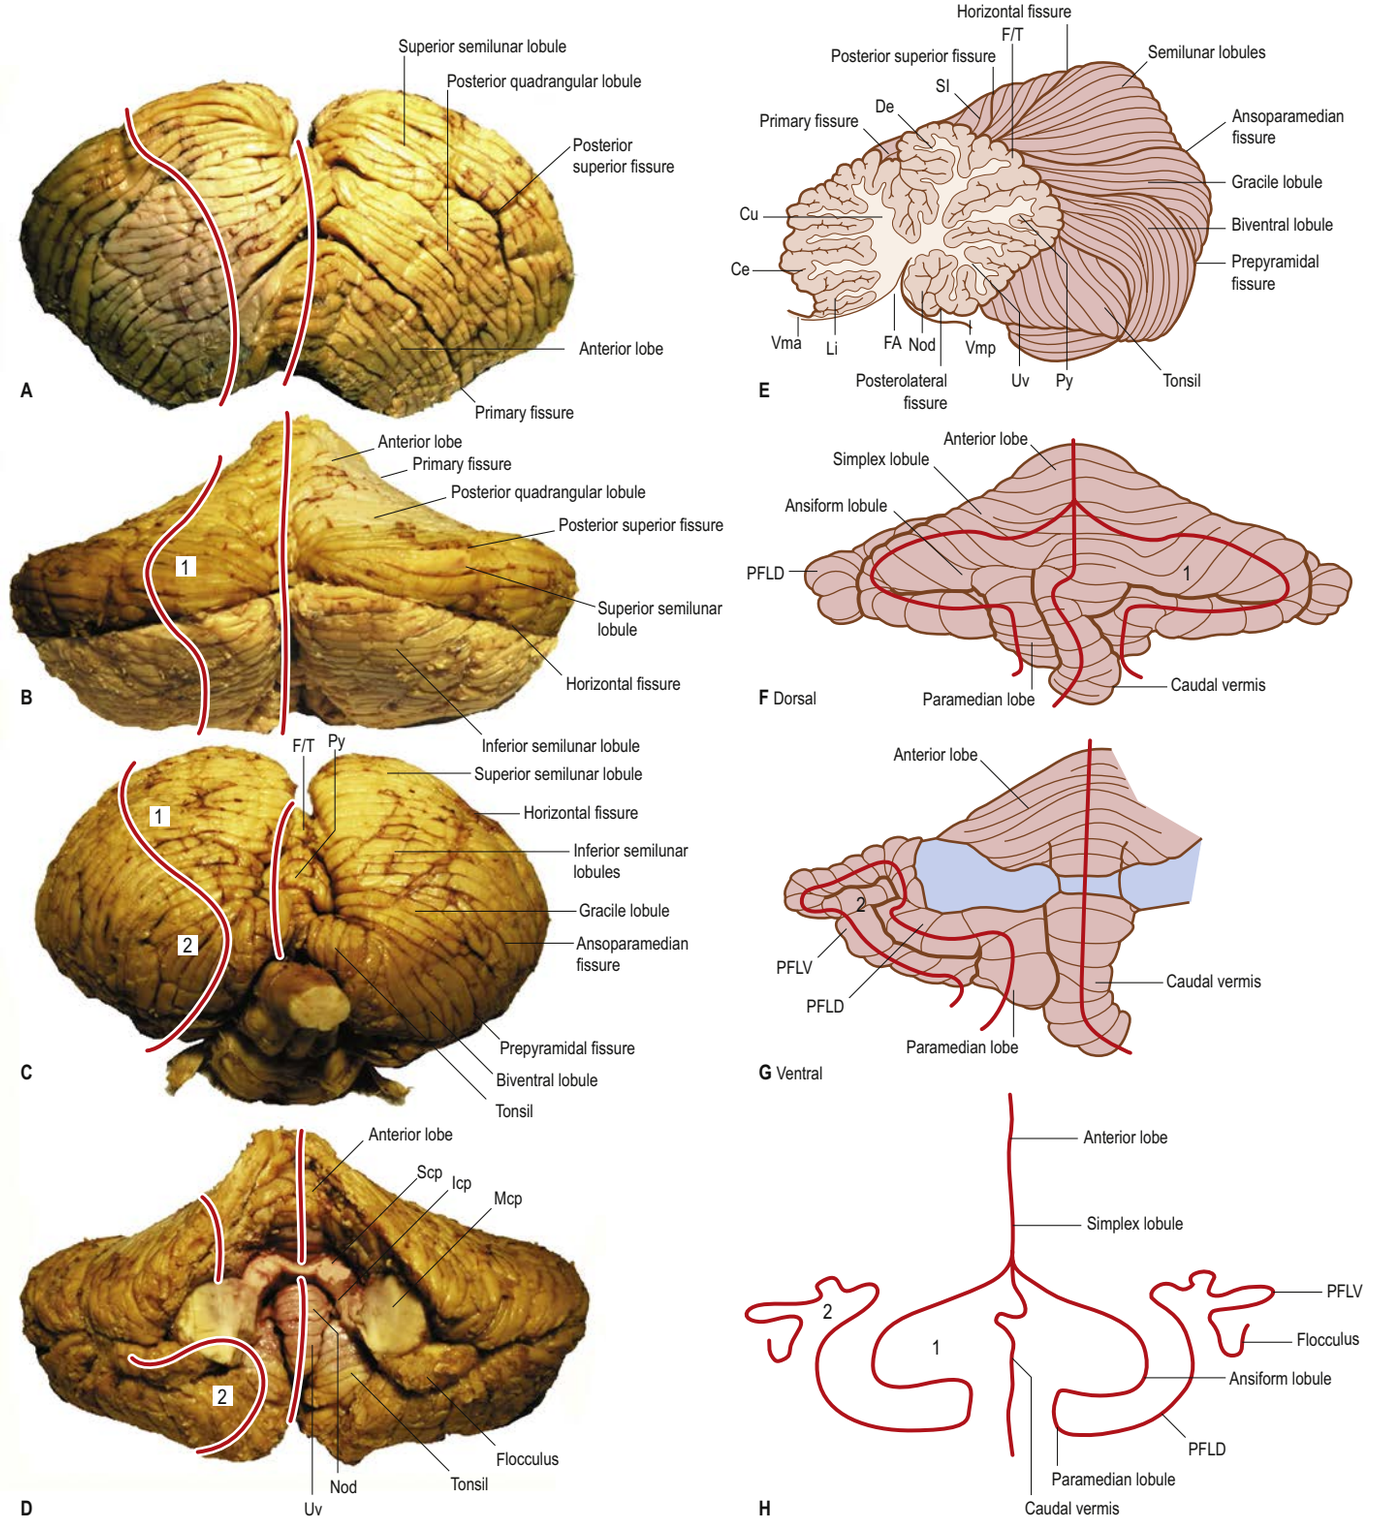

Fig. 29.6 Historically relevant figure that depicts Bolk's (1906) prototype for his ground plan of the mammalian cerebellum. **A–D**, Anterior, dorsal, posterior and ventral views of the human cerebellum. **E**, A sagittal section of the human cerebellum. **F–G**, Dorsal and ventral views of the cerebellum of *Eulemur albifrons* (white-headed lemur). Two loops are present in the folial chain of the hemisphere: (1) as the ansiform lobule, (2) as the parafloccculus. The course of the folial chains of the vermis and hemisphere in **A–D** and **F–G** is indicated with red lines. **H**, Bolk's stick diagram of the folial chains of the vermis and hemisphere. Key and abbreviations: 1, 2, ansiform and paraflocular loops of the folial chain of the hemisphere; Ce, central lobule; Cu, culmen; De, declive; FA, fastigium; F/T, folium and tuber; Icp, inferior cerebellar peduncle; Li, lingula; Mcp, middle cerebellar peduncle; Nod, nodulus; PFLD, dorsal paraflocculus; PFLV, ventral paraflocculus; Py, pyramis; Scp, superior cerebellar peduncle; Sl, simplex (posterior quadrangular) lobule; Uv, uvula; Vma, anterior (superior) medullary velum; Vmp, posterior medullary velum.

Vermal lobules I and II constitute a single lamina of four or five shallow folia; their white core is continuous with the anterior (or superior) medullary velum lying anterior and inferior to the vermis. Lobule I is distinct from lobule II in some human cerebella and in lower primates. The vermal and hemispheric components of lobule I/II together were termed the lingula. The precentral fissure separates lobules I/II from lobule III (centralis) both in the vermis and the hemispheres. Lobule III is partially obscured by lobule IV when viewed from the superior aspect, but it is sizeable, and has a semilunar form with its wing (ala, in prior terminology) extending into the hemispheres on each side. Lobule III is the first distinct folium that is not attached to the anterior medullary velum. The preculminate fissure separates lobule III from lobule IV. The use of the term culmen (including both the vermis and the hemisphere) obscures the fact of the division of the culmen into lobules IV and V by the intraculminate fissure. This fissure is readily discernible on the hemisphere, but at the midline is continuous with a small fissure situated between the branches of a folium. Lobule IV usually contains one folium, and lobule V contains two. The deepest fissure in the vermis that is visible in mid-sagittal section is the primary fissure, which curves ventrolaterally around the superior surface of the cerebellum. It appears early in embryological development and marks the boundary between the anterior lobe (lobules I to V) and the posterior lobe (lobules VI to IX). Specifically, it separates lobule V from lobule VI in the vermis and in the hemisphere. The primary fissure, like other fissures within the anterior lobe, is progressively more difficult to discern on parasagittal sections as one moves laterally, becoming continuous with an undistinguished small fissure in the intermediate sectors of the hemispheres.

Lobule VI is sizeable and contains two large folia with medullary rays that take their origin off the medullary core. The vermal and hemispheric components of lobule VI have previously received different names: in the vermis, lobule VI was called the declive, and in the hemisphere it was called the lobulus simplex, among others.

The superior posterior fissure appears early in development and is visible on the superior surface of the cerebellum separating lobule VI from lobule VII. Vermal lobule VII is complex; its lateral extension in the hemispheres into what Lodewjck Bolk (1866–1930) called the ansiform lobule, forms a large part of the hemisphere in the human cerebellum. The massive expansion through evolution of the human cerebellum is a reflection in large part of the expansions of lobules VI and VII. The terms folium and tuber have been used to denote vermis lobule VII, but this fails to convey the complexity of their equivalent hemispheric extensions, as below.

The horizontal fissure appears relatively late in embryological development. It is prominent in the hemisphere, extending around the dorsolateral border of each hemisphere from the middle cerebellar peduncle to the vallecula, separating the superior and inferior surfaces. The horizontal fissure divides lobule VII into two sectors, with important differences in their hemispheric extensions. Vermal lobule VIIAf (identical to the folium) expands laterally to form crus I (of Bolk's ansiform lobule, formerly known as the superior semilunar lobule). Vermal lobule VIIAt (formerly called the rostral half of the tuber of the vermis) is continuous in the hemispheres with crus II (of Bolk's ansiform lobule, formerly known as the inferior semilunar lobule). The horizontal fissure therefore separates lobule VIIAf from VIIAt in the vermis, and crus I from crus II in the hemisphere. In some brains, lobule VIIAf may not be discernible at the midline, in which case the superior posterior fissure is bounded caudally by the ansoparamedian and not the horizontal fissure.

The ansoparamedian fissure can be traced across the midline separating lobule VIIAt and crus II from vermal and hemispheric lobule VIIB (previously termed the paramedian, or gracile lobule). The ansoparamedian fissure is not symmetrical in the hemispheres in all brains. The horizontal and ansoparamedian fissures sometimes meet on the posterior inferior cerebellar surface, so that crus II appears as a triangular lobe situated on the superior and posterior aspects of the posterior lobe, and on lateral parasagittal sections, crus I is adjacent to lobule VIIB. When the horizontal and ansoparamedian fissures do not meet, crus II continues laterally and forward onto the anterior surface of the cerebellum, and on lateral parasagittal sections crus II is adjacent to VIIB. These details are relevant for precise mapping of the human brain and can affect intra-and inter-individual functional mapping studies. Even when the folia at the lateral inferior cerebellar surface are asymmetric across the two hemispheres, they can be seen to be derived from medullary rays that are morphologically similar.

Lobule VIIIA and VIIIB in the vermis were formerly known as the pyramis, and in the hemispheres as the biventer. Thus, the prepyramidal/prebiventer fissure separates lobule VIIB from VIIIA and is named according to whether the lobule VIIB/VIIIA distinction is in the vermis (prepyramidal fissure) or hemisphere (prebiventer fissure). The intrapyramidal/intrabiventer fissure separates lobule VIIIA from VIIIB. The secondary fissure is interposed both at the vermis and in the hemispheres between lobules VIIIB and IX. In earlier terminology, vermal lobule IX is referred to as the uvula, and hemisphere lobule IX as the tonsil, and subsequently as the ventral paraflocculus (equivalent to the dorsal paraflocculus in monkeys). In the human, the folial loop of lobule IX is directed medially, contrary to the situation in most mammals, where the paraflocculus arches laterally. Note that the term cerebellar tonsil refers to a grossly visible anatomical structure at the inferior and medial cerebellum which is of great relevance in clinical neurology and neurosurgery (tonsillar herniation, Chiari malformation). Although the tonsil was previously equated with lobule IX, it also incorporates folia within lobule VIIIB, which means that the term is anatomically imprecise.

The posterolateral fissure separates lobules IX from X, and forms the boundary between the posterior lobe of the cerebellum and the flocculonodular lobe. Vermal lobule X (nodulus) is the last of the vermis divisions. Where its cortex ends it forms the attachment (taenia) of the ependymal roof of the fourth ventricle. Hemispheric lobule X (flocculus) is a small cerebellar lobule adjacent to the caudal surface of the middle cerebellar peduncle. It is located in the roof of the lateral recess of the fourth ventricle, and dorsal to the cochlear nuclei and the vestibulocochlear nerve which are ventral to the recess. Hemispheric lobule X appears as a double folial rosette; its dorsal leaf is known as the accessory paraflocculus of Henle (the ventral paraflocculus in monkeys), its ventral leaf represents the true flocculus. Between vermal lobule X (nodulus) and hemispheric lobule X (flocculus and accessory paraflocculus), the cortex is absent and the tissue is stretched out as the posterior medullary velum (inferior medullary velum) which forms the infero-posterior part of the fourth ventricle. The internal surface of the posterior medullary velum is the ventricular ependyma; its outer surface is covered by pia mater.

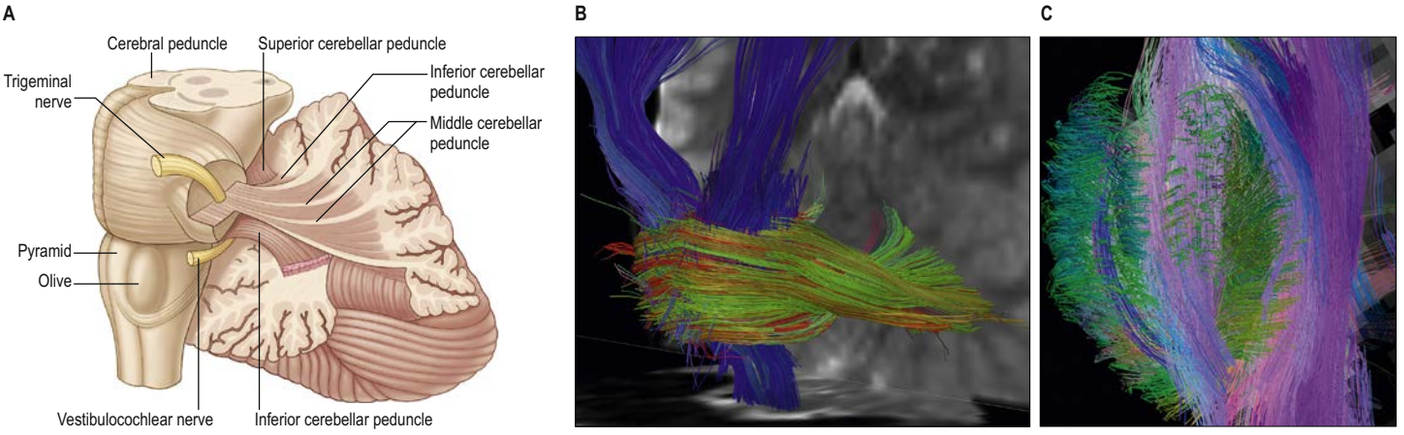

Fig. 29.7 **A**, Dissection of the left cerebellar hemisphere and its peduncles. **B**, Diffusion spectrum tractography (DSI) image *in vivo* showing descending corticofugal fibres to the pons and spinal cord (blue). Fibres from the rostral pons course in the middle cerebellar peduncle to cerebellar posterior lobe; fibres from caudal pons are directed more to the cerebellar anterior lobe and superior cerebellum. **C**, *Ex vivo* image of pontocerebellar fibres coursing through the middle cerebellar peduncle, between and around the descending fibres of the corticopontine and corticospinal tracts. from the fastigial nucleus pass dorsal to the superior cerebellar peduncle as the uncinate tract (the hook bundle of Russell) and enter the brainstem at the border of the juxtarestiform and restiform bodies.

The middle cerebellar peduncle (see Figs 29.7B–C) is the most lateral and by far the largest of the three. It passes obliquely from the basal pons to the cerebellum and contains the massive pontocerebellar mossy fibre pathway, composed almost entirely of fibres that arise from the contralateral basal pontine nuclei, with a small addition from nuclei in the pontine tegmentum.

The superior cerebellar peduncle (brachium conjunctivum) contains all the efferent fibres from the dentate, emboliform and globose nuclei, and a small fascicle from the fastigial nucleus. Fibres from the globose nucleus occupy a medial position; those from the emboliform and dentate nucleus are successively more lateral. Axons in the extreme ventrolateral portion of the peduncle arise from the superior vestibular nucleus and relay excitation from the anterior semicircular canal to the oculomotor nucleus (the excitatory vestibulo-ocular relay). Nucleo-olivary fibres of the interposed and dentate nuclei are located in a separate bundle, ventral to the peduncle. The superior cerebellar peduncle, including its nucleo-olivary component, decussates in the caudal mesencephalon (the decussation of the brachium conjunctivum). The decussation consists of dorsal and ventral portions. The dorsal portion contains fibres that occupy the medial two-thirds of the peduncle and start to cross the midline at the level of the inferior colliculus, ventral to the medial longitudinal fasciculus. The ventral portion contains fibres that occupy the lateral third of the peduncle, and decussate in the ventral tegmentum, immediately dorsal to the interpeduncular nucleus. Rostrally, at the level of the caudal red nucleus, the ventral and dorsal portions of the decussation merge and the entire decussation is displaced ventrally by the dorsal tegmental (tectospinal) decussation. After its decussation the peduncle divides into descending and ascending branches. The descending branch terminates in the medial reticular formation of the pons and the medulla and in the reticulotegmental nucleus (nucleus reticularis tegmenti pontis, NRTP). The nucleo-olivary fibres join the descending branch to terminate in the inferior olive in a strict orderly manner (see below). The much larger ascending branch distributes to the mesencephalon and the diencephalon; the red nucleus and the thalamus are its main targets. The fibres of the superior cerebellar peduncle always decussate to the opposite hemisphere, except in rare developmental disorders of axonal guidance (Spampinato et al 2008).

The superior cerebellar peduncle also conveys afferents to the cerebellum that arise in the spinal cord and course in the ventral spinocerebellar tract. These fibres reach the upper part of the pontine tegmentum, loop around the entrance of the trigeminal nerve and join the peduncle, uniting with the dorsal spinocerebellar fibres entering through the restiform body.

INTERNAL ORGANIZATION

White matter

On its cut surface, the characteristic appearance of the cerebellum is a central white matter core surrounded by multiple, deeply folded folia. The white matter core branches into the diverging medullary laminae, which occupy the central part of the lobules and then further branch out into their folia and subfolia. On sagittal section, the highly branched pattern of medullary laminae gave rise to the name arbor vitae, for its resemblance to the leaf of the coniferous arbor vitae or cedar tree (see Fig. 29.2). The white matter of the medullary rays contains the afferents to the cerebellar cortex, and the Purkinje cell axonal efferents from the cortex to the deep nuclei.

Fibres crossing the midline in the anterior medullary velum and the white matter core of the cerebellum constitute the cerebellar commissure, which contains the decussating afferent fibres of the inferior and middle cerebellar peduncles, and decussating efferent fibres from the fastigial nucleus. Note that the term commissure here denotes the crossing of the midline by cerebellar afferent and efferent fibres; there are no cerebellar cortico-cortical connections either ipsilaterally or between the two hemispheres.

Deep cerebellar nuclei

The medullary core contains the four deep cerebellar nuclei (**Fig. 29.8**). These were first described by Stilling (1864) as comprising, from medial to lateral, the fastigial, globose, emboliform and dentate nuclei. In rodent, cat and monkey brains the anterior and posterior interposed nuclei are equivalent in humans to the emboliform and globose nuclei respectively. The nuclei form two interconnected groups. The caudomedial group includes the fastigial nucleus located next to the midline and bordering on the fastigium (roof) of the fourth ventricle, and the closely adjacent globose nucleus. The rostrolateral group consists of the emboliform nucleus which is medially adjacent to the dentate nucleus.

The dentate is the largest of the deep cerebellar nuclei and has expanded most in evolution. It is an irregularly folded sheet of neurones, resembling a crumpled leather purse with a medially directed opening. The convolutions of the dentate nucleus are narrow rostromedially (microgyric) and contain large neurones, whereas the much wider ventrocaudal (macrogyric) part contains smaller neurones. This is important from the perspective of anthropology as well as cognitive neuroscience and behavioural neurology (see below). The dentate nucleus surrounds the hilum, a mass of efferent fibres arising from dentate neurones that forms the bulk of the superior cerebellar peduncle.

The cerebellar nuclei contain three types of neurones. Multipolar neurones have different sizes, with long ramifying dendrites and an axon that leaves the cerebellum through the superior cerebellar peduncle, the uncinate tract or the juxtarestiform body. These provide glutamatergic, excitatory input to the brainstem, thalamus and spinal cord. Some collaterals of these efferent axons enter the cerebellar cortex, where they terminate sparsely as mossy fibres. A population of small, inhibitory neurones gives rise to the pathway terminating in the contralateral inferior olive, the nucleo-olivary projection (Nelson et al 1989), travelling mostly in the superior cerebellar peduncle. These contain immunoreactivity for GAD (glutamic acid decarboxylase), the endogenous marker enzyme for GABAergic neurones, as well as CGRP- (calcitonin gene-related

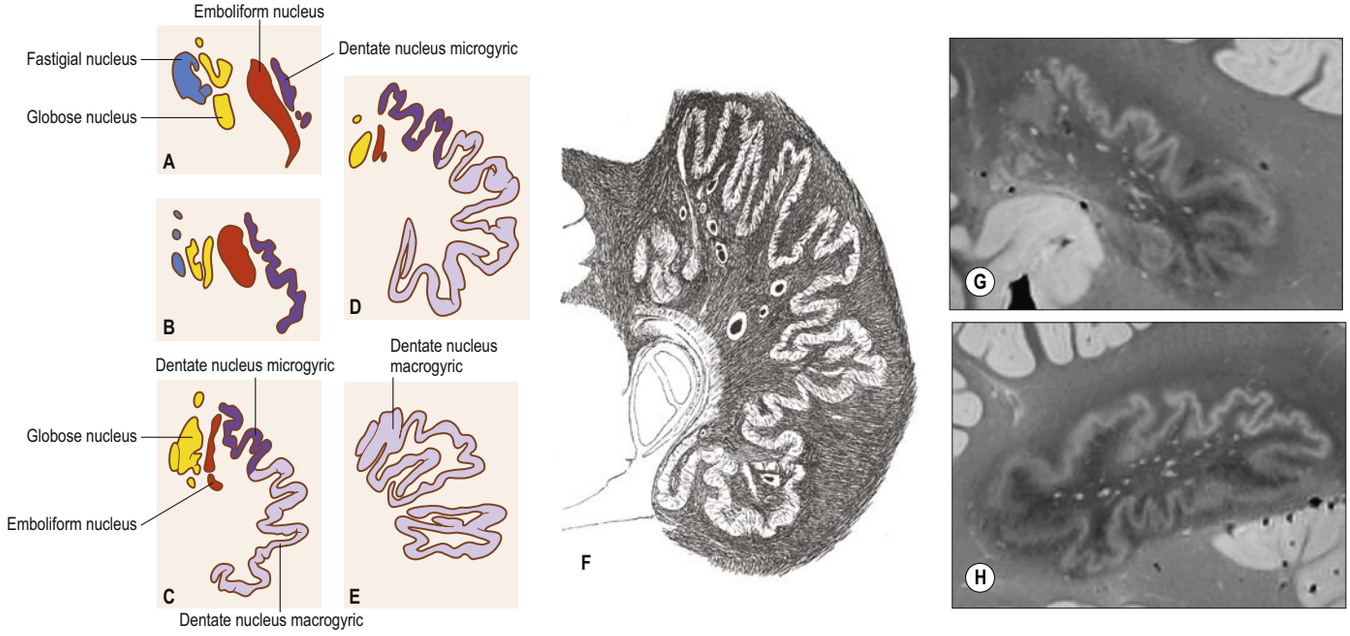

Fig. 29.8 The human cerebellar nuclei. **A–E**, Transverse sections through the cerebellar nuclei, **A** being the most rostral level. The dentate nucleus can be subdivided into dorsomedial microgyric and ventrocaudal macrogyric parts. **F**, A Weigert-stained section through the dentate nucleus, showing its subdivision into micro- and macrogyric parts. **G**, Coronal view, and **H**, sagittal view, postmortem 7T MRI through the dentate nucleus of human brain. (A–E, Adapted with permission from Larsell O, Jansen J 1972 The comparative anatomy and histology of the cerebellum. III. The human cerebellum, cerebellar connections, and cerebellar cortex. Minneapolis, University of Minnesota Press. F, With permission from Winkler C 1926 De bouw van het zenuwstelsel. Haarlem, de erven Bohn. peptide)-like immunoreactivity. Local inhibitory interneurones in the cerebellar nuclei contain glycine, often colocalized with GABA (γ-aminobutyric acid). Purkinje cell axons are the main input to the neurones of the cerebellar nuclei: there are GABAergic inhibitory synapses on both dendrites and somata. Collaterals of climbing and mossy fibres terminate on proximal and distal dendrites and provide the cerebellar nuclei with glutamatergic excitatory input.

A collection of small, cholinergic neurones extends from the flocculus to the nodulus (hemispheric and vermal lobule X) in the roof of the fourth ventricle, invading the spaces between the nuclei. These form the basal interstitial nucleus (Langer 1985).

Cerebellar cortex

The cerebellar cortex is characterized by its regular, repeating, lattice-like histological structure (**Figs 29.9–29.11**). In contrast to the cerebral cortex, obvious local differences and architectonic heterogeneity do not occur and, with a few exceptions, different areas of the cerebellar cortex are largely indistinguishable. The same homogeneity is present throughout all mammals and, with only minor differences, throughout the vertebrates. The cerebellar cortex has three main layers, a Purkinje cell layer interleaved between the overlying molecular layer and the granule cell layer beneath. The three layers are interconnected by a complex circuitry with an architecture that is essentially invariant throughout. Cerebellar functional topography is entirely explained by the arrangement of the fibres that connect the cerebellum to other regions of the central nervous system. (For further reading, see Jansen and Brodal (1954), Braitenberg and Atwood (1958), Dow and Moruzzi (1958), Eccles et al (1967), Fox and Snider (1967), Llinas and Sotelo (1992), Larsell and Jansen (1972), Palay and Chan-Palay (1974), Ito (1984), Glickstein et al (1987), Strata (1989), Manto et al (2013).)

Purkinje cell layer

This layer is characterized by the presence of Purkinje cells (PC), one of the largest cells in the nervous system (**Fig. 29.12**) (Purkinje 1837). Smaller somata of epithelial (Bergmann) glial cells are located at this level. Clumps of granule cells and occasional Golgi cells penetrate between the Purkinje cell somata. There are estimated to be 25 million Purkinje cells in the human cerebellum (Andersen et al 2012), each with a pear-shaped soma, 30–35 μm in diameter and 50–70 μm in length. Individual Purkinje cells are separated by about 50 μm transversely and 50–100 μm longitudinally. This geometry occurs in its typical form in all vertebrate classes. The entire Purkinje cell soma, its dendrites and axonal initial segment, are covered with a neuroglial sheath, and the axon is myelinated. Axo-somatic contacts on the Purkinje cells penetrate this sheath, and the dendritic spines protrude through the sheath to contact the parallel and climbing fibres.

One or sometimes two large primary proximal dendrites arise from the apical pole (superficial pole, neck) of each Purkinje cell soma. They divide, usually into two major dendrites, from which an abundant arborization arises, with several orders of subdivision, that extends towards the surface, forming a flattened plate orientated perpendicular to the long axis of the folium. The fan-like appearance of the Purkinje cell dendritic tree is a defining feature. It measures 300–400 μm in the sagittal plane, but only 15–20 μm in the transverse plane. Approximately 90% of the Purkinje cell dendritic tree consists of terminal branches containing about 180,000 spines (Fox and Barnard 1957). They are not uniformly distributed: proximal first and second order dendrites have smooth surfaces with short, stubby spines which are contacted by climbing fibres, whereas distal branches have a dense array of short-necked dendritic spines on which the terminals of parallel fibres synapse. This differential proximal vs distal Purkinje cell spine density is under dual control: an intrinsic mechanism that promotes spine growth over the entire dendritic tree, and activity-dependent spine pruning by the climbing fibre at the proximal dendrite.

The subcellular structure of a Purkinje cell is essentially similar to that of other neurones. A distinguishing feature is the presence of subsurface cisterns below the plasmalemma of the soma and dendrites; these may penetrate into the spines and are often associated with a mitochondrion. The cisterns represent intracellular calcium stores which are important links in the second messenger systems of the cell. Excitatory (asymmetrical) synapses of the climbing fibres contact the proximal spines of the spiny branchlets; parallel fibres contact the distal spines of the spiny branchlets. Excitatory synapses are rare on the soma of a Purkinje cell. Inhibitory (symmetrical) synapses from basket cell axons and stellate cells and recurrent collaterals of the Purkinje cell axon contact the shafts of the proximal dendrites. The non-synaptic area of the surface of the soma and dendrites of a Purkinje cell is covered by lamellar protrusions of the Bergmann glial fibres.

The Purkinje cell axon arises from the pole opposite the dendrites and traverses the granular layer into the subjacent white matter. Its initial portion is narrow, unmyelinated and has the typical features of an initial axon segment. It is surrounded by the distal branches of the basket cell axons as the pinceau (paintbrush). Beyond the initial

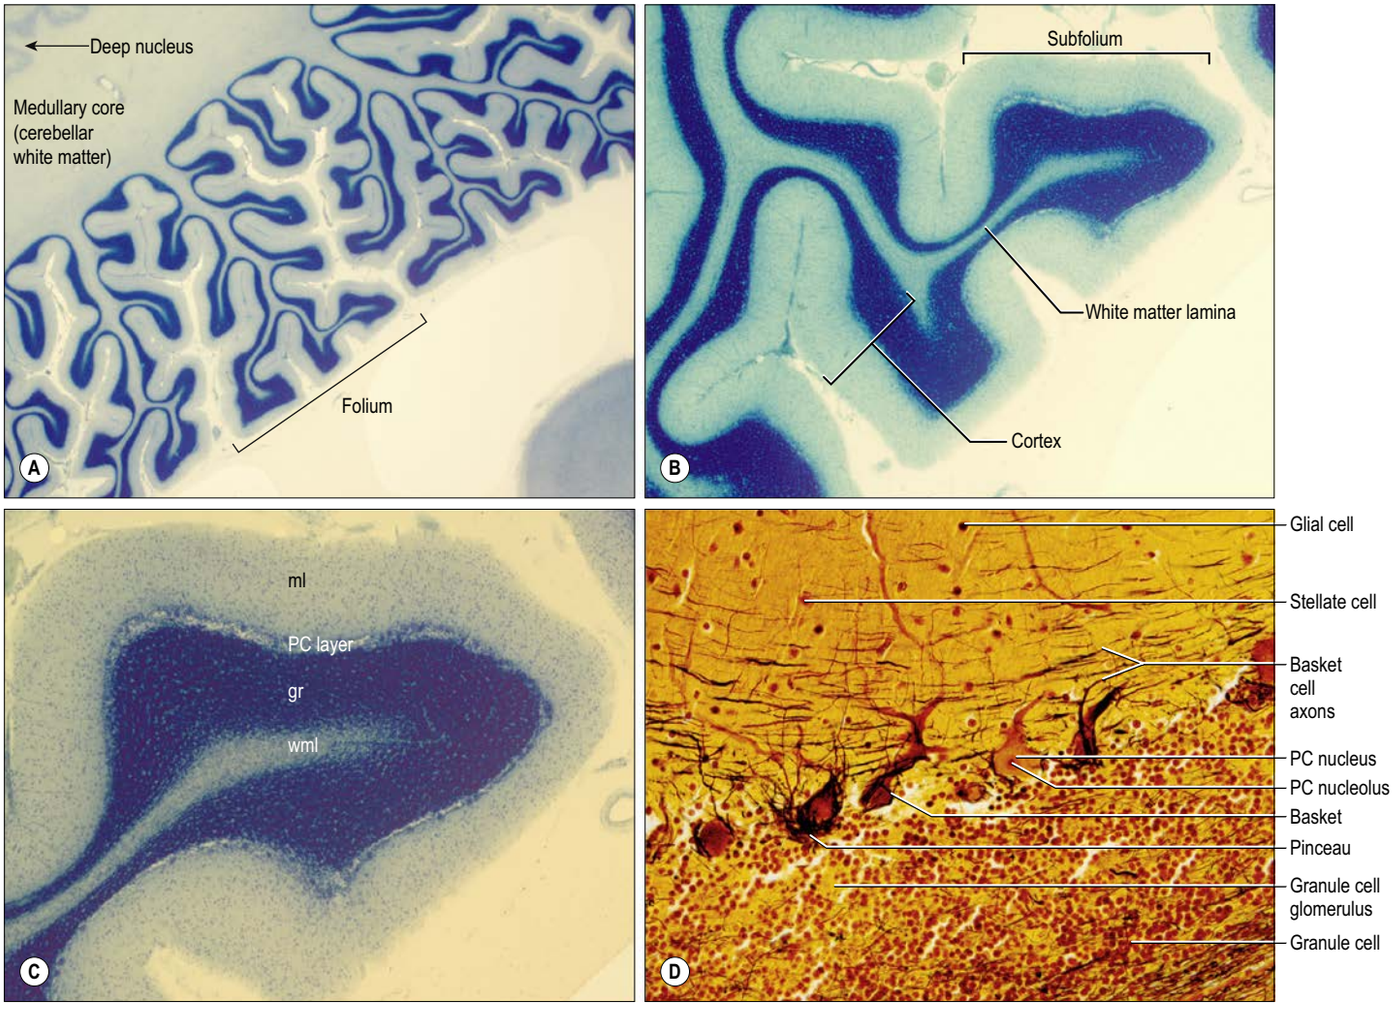

Fig. 29.9 Histologic sections of human cerebellar cortex at progressively higher levels of magnification. Stain for Nissl substance in **A–C**, and Bielschowsky silver stain in **D**. Abbreviations: gr, granule cell layer; ml, molecular layer; PC, Purkinje cell; wml, white matter lamina. Magnification: A ×0.5, B ×2, C ×4, D ×20. (A–C, Courtesy of JD Schmahmann, Department of Neurology, Massachusetts General Hospital. D, Courtesy of Dr Matthew Frosch, Department of Neuropathology, Massachusetts General Hospital.)

segment, about 50 µm beneath the Purkinje cell soma, the axon suddenly enlarges, acquires a myelin sheath and gives off collateral branches. The main axon descends into the white matter and forms a plexus in the deep cerebellar nuclei and, in the case of lobule X, the vestibular nuclei. Recurrent collateral branches of Purkinje axons form plexuses above and below their somata. These collaterals are orientated in the same plane as the Purkinje cell dendritic tree and the inhibitory synapses from basket and stellate cells. Purkinje cell axon recurrent collaterals terminate on neighbouring Purkinje neurones and on basket and Golgi neurones. Purkinje cells are inhibitory and use GABA as their main neurotransmitter, as well as the neuropeptides motilin, cerebellin and CGRP. They are the only efferent neurone of the cerebellar cortex and project to the deep cerebellar or vestibular nuclei.

Molecular layer

The molecular layer is about 300–400 µm thick. By ordinary histological technique it is almost featureless, contrasting with the immense cellular population of the granule cell layer. It is composed of dendritic arborizations of the Purkinje and Golgi cells, axons and parallel fibres of the granule cells, climbing fibres, radial fibres of the Bergmann neuroglial cells, and sparse basket and stellate interneurones. Purkinje cell dendritic trees extend towards the surface and spread out in a plane perpendicular to the long axis of the cerebellar folia. Dendritic trees of Golgi neurones lying in the superficial part of the granular layer reach towards the cerebellar surface. Unlike the flattened dendritic tree of the Purkinje cells, Golgi cell dendrites have the shape of a goblet and span the territory of many Purkinje neurones longitudinally as well as transversely. These dendrites receive synapses from parallel fibres. Some Golgi cell dendrites enter the granular layer where they are contacted by mossy fibre terminals.

The granule cell axon ascends into the molecular layer and bifurcates into the parallel fibre, one of the thinnest known vertebrate axons. Parallel fibres extend in opposite directions along the long axis of the folium and terminate on the dendrites of the Purkinje cells and Golgi cells that they encounter, and on the basket and stellate cells of the molecular layer. Climbing fibres are the terminals of olivocerebellar fibres which ascend through the granular layer to contact Purkinje dendrites in the molecular layer. Radiating branches of the large Bergmann glial cells give off processes that surround all neuronal elements except at the synapses; at the cortical surface their expansions join to form an external limiting membrane.

The cerebellar cortical interneurones were described by Ramón y Cajal (1909–10) (see Fig. 29.10). Basket and stellate cells are the inhibitory GABAergic interneurones of the molecular layer. They receive excitatory (asymmetrical) synapses from parallel fibres as they pass through their dendritic trees: their sparsely branched dendritic trees and the ramifications of their axons are located in a plane perpendicular to the long axis of a folium, i.e. in the same plane as the Purkinje cell dendritic tree and the ramifications of the Purkinje cell recurrent collaterals.

The basket cell has a pyramidal or oval shape, measures about 15 µm in length, and lies in the lower third of the molecular layer just above the Purkinje cells (Fig. 29.13A–B). Its dendrites extend up throughout the molecular layer in a fan-shaped field of 30 µm in the parasagittal plane, giving off relatively few branches, interdigitating with the dendritic fields of the Purkinje cells, and contacted by the parallel fibres. The complex axon of the basket cell has a horizontal course deep in the molecular layer just above the Purkinje cells, lying in the parasagittal plane perpendicular to the long axis of a folium (that is, perpendicular to the orientation of the parallel fibres and in the same plane as the flattened plate of the Purkinje cell dendritic tree).

The axon of each basket cell is about 1 mm in length and contacts approximately 9–12 Purkinje cells. As it moves away from its soma, the axon increases in size, giving off a succession of descending branches

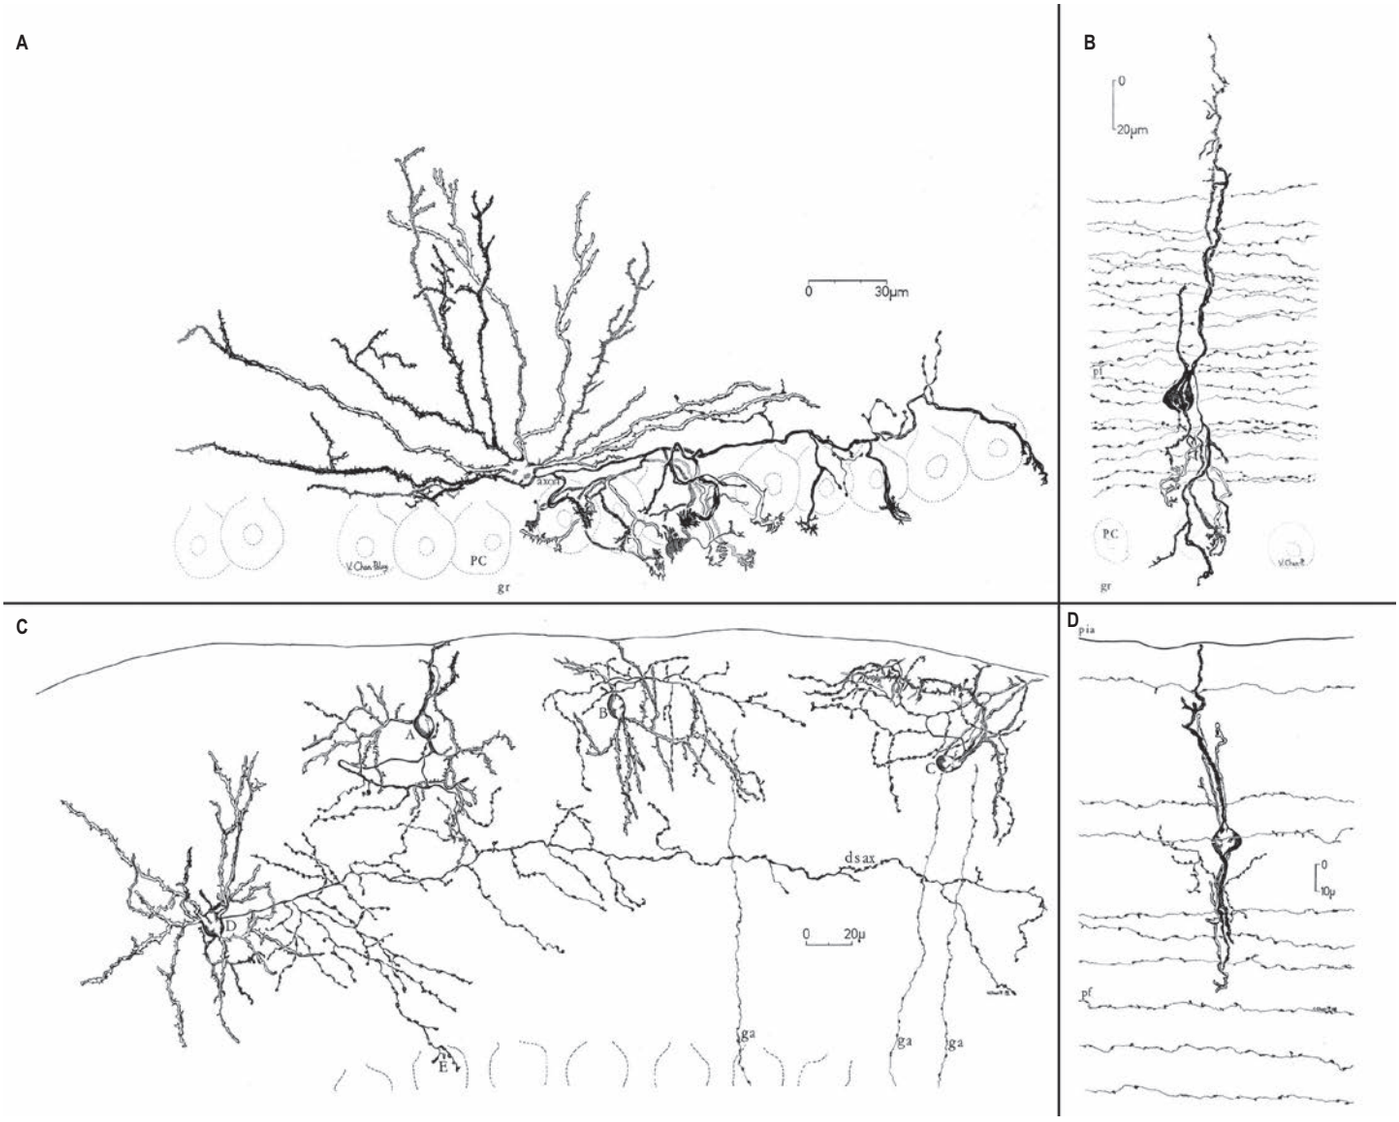

Fig. 29.13 Camera lucida drawings of Golgi-impregnated molecular layer interneurones. **A**, Basket cell with spine-laden dendrites radiating in the molecular layer. An axon is shown travelling horizontally across the folium giving off descending collaterals that form the pericellular basket and pinceau around the Purkinje cell (PC) cell body and initial segment of the axon as it enters the granular layer (gr). Some ascending collaterals are noted. **B**, The basket cell processes are orientated in the same plane as the PCs, i.e. perpendicular to the long axis of the folium and the direction of the parallel fibres (pf). **C**, Three superficial stellate cells (A–C) have dendrites that reach the pial surface, and axonal arborizations distributed in a tangle of beaded threads around the dendrites. Ascending granule cell axons (ga) contact their dendrites and somata. The deep stellate cell (D) has an axonal plexus proximally that gives way to a long axon coursing across the folium. **D**, View of the stellate cell to show its processes orientated in the same plane as the PCs. Parallel fibres (pf) contact the stellate cell dendrites and soma. (With permission from Palay S, Chan-Palay V 1974 Cerebellar Cortex: Cytology and Organization. New York: Springer-Verlag.)

that envelope the Purkinje cell soma in an axonal sheath with numerous synaptic contacts over its entire surface, forming pericellular networks, or baskets. The terminal branches of the basket cell axons descend to surround the initial segment of the Purkinje cell axon in a dense plexus of convoluted and branching fibres measuring 15–20 µm across, with the appearance of a paintbrush or 'pinceau' (see Fig. 29.9D). This axo-axonic complex is unique in the mammalian nervous system. According to Palay and Chan Palay (1974) the pinceau is historically significant because it led Cajal to the view that nerve cells are in contact but not continuity with each other, and that impulses are directed from an axon to a cell body, essential tenets of the neurone doctrine. In addition to the descending collaterals, there are sparser ascending collaterals from the basket cell that synapse on the secondary and tertiary Purkinje cell dendrites. Branches from each basket cell axon also extend in the direction of the long axis of a folium to a further 3–6 rows of Purkinje neurones flanking the axon. Hence an estimated 72 Purkinje cell neurones may receive inhibitory synapses from a single basket cell.

Stellate cells have small cell bodies 5–10 µm in diameter (Fig. 29.13C–D). Their dendrites are contacted by parallel fibres and their axons terminate on the Purkinje cell dendrites. Superficial stellate cells in the upper reaches of the molecular layer generally have short, profusely branching dendrites. Their short axons lie within a narrow parasagittal plane perpendicular to the long axis of a folium, the same as that of the Purkinje cell dendritic tree. The deep, long-axon stellate cells in the middle part of the molecular layer have dendritic trees similar to their superficial counterparts. However, the axon is quite different because it can extend for a considerable distance in the parasagittal plane, up to 450 µm, and it provides ascending and descending collaterals early in its course. Unlike the basket cell axon that also has a long course in the plane of the Purkinje cells, the axon of the deep stellate cell only rarely enters the pericellular Purkinje cells plexus and does not participate in the pinceau.

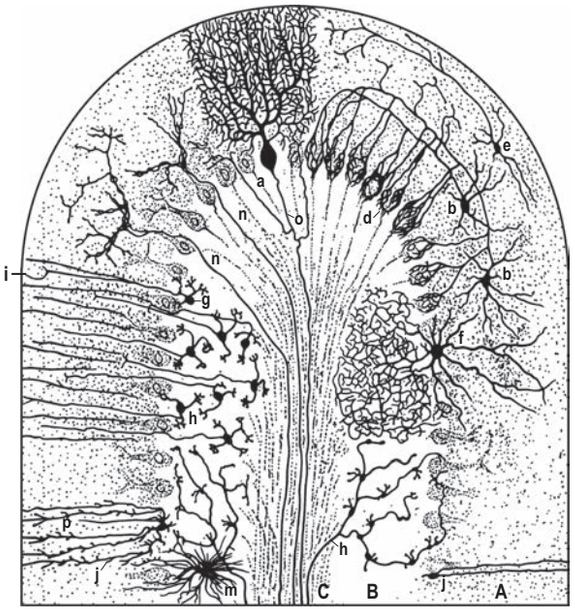

Fig. 29.10 Santiago Ramón y Cajal's (1909) diagram of the neurones in the cerebellar cortex orientated perpendicular to the long axis of the folium, as well as fibres and glial cells. Abbreviations: A, molecular layer; a, Purkinje cell; B, granular layer; b, basket cell; C, white matter of the folium; d, pericellular baskets around the Purkinje cell soma formed by the basket cell axon; e, superficial stellate cell; f, Golgi cell; g, granule cell; h, mossy fibre; i, ascending axon of granule cell; j, Bergmann glial cell; m, astroglial cell; n, climbing fibre; o, recurrent collateral branches of a Purkinje cell. (With permission from Ramón y Cajal S 1909–1910 Histologie du système nerveux de l'homme et des vertébrés. Translated into French by L. Azoulay. Paris: Maloine. Translated into English by Swanson N, Swanson LW 1995 Histology of the nervous system of man and vertebrates. New York, Oxford University Press.)

Granule cell layer

The granule cell layer is 200–300 µm thick on folial summits and about 100 µm thick in the depths of the fissures. It contains granule cells, Golgi cells, Lugaro cells, unipolar brush cells and neuroglial cells. The granule cell is among the smallest neurones in the brain, with a spherical nucleus 5–8 µm in diameter, and a shell of cytoplasm containing a few small mitochondria, ribosomes and a diminutive Golgi complex (Fig. 29.14A). There are about 2.4 million per mm^3 in the simian cerebellar cortex and 2–7 million per mm^3 in the human cortex (Fox and Barnard 1957, Braitenberg and Atwood 1958). The number of granule cells in the human cerebellum has been estimated to be from 4.3×10^{10} (Zagon et al 1977) to about 7×10^{10} (Andersen et al 2012), making it the most numerous single neuronal element in the nervous system. There are about 3000 granule cells for each Purkinje cell (Lange 1975). Granule cells usually give rise to 3–5 dendrites, each about 10–30 µm in length, ending in claw-like terminal expansions that synapse with the terminals of mossy fibres and Golgi cell axons in the cerebellar glomeruli, visible by light microscopy in the intervals between groups of granular neurones. Cerebellar glomeruli are synaptic complexes wherein a central mossy fibre terminal synapses with the dendrites of granule cells and Golgi cells, and the granule cell dendrites receive synaptic contacts from Golgi terminals. The fine axons of granule cells pass from their superficial aspect into the molecular layer and branch at a T-junction to form the parallel fibres.

Golgi cells (Fig. 29.14B) are irregularly rounded or polygonal GABAergic, inhibitory interneurones: they number approximately 1 per 1.5 Purkinje cells in the human brain. Golgi cells contain the inhibitory amino acid glycine, as well as acetylcholine and leucine-5-enkephalin.

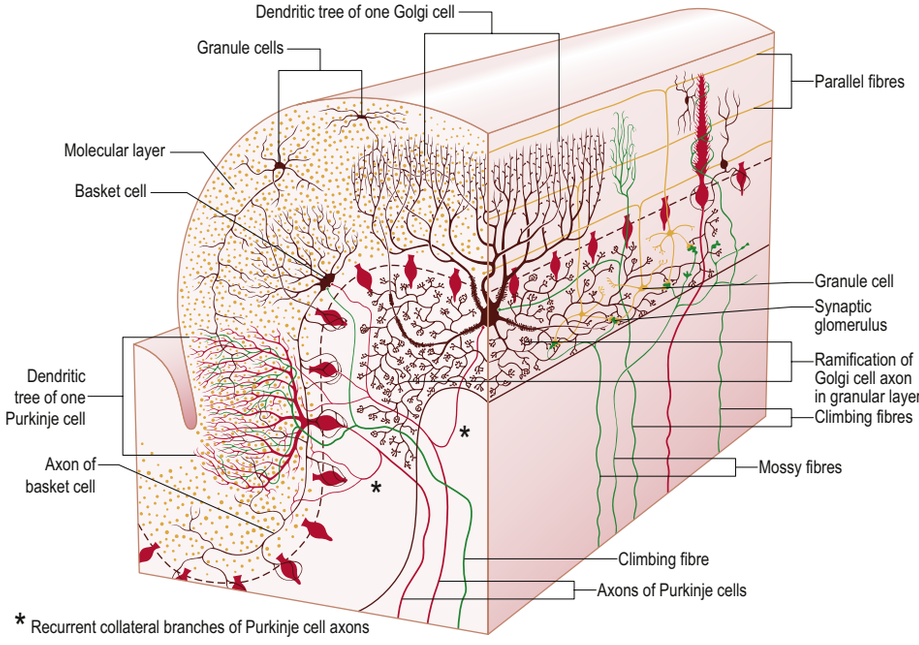

Fig. 29.11 The general organization of the cerebellar cortex; a single cerebellar folium has been sectioned vertically, both in its longitudinal axis (right part of the diagram) and transversely (on the left). Red, Purkinje cells; brown, inhibitory interneurones, including outer stellate, basket and Golgi cells; yellow, granule cells and their ascending axons which bifurcate into longitudinally disposed horizontal fibres; green, climbing fibres and mossy afferents. Note also the synaptic glomeruli formed between the terminals of the mossy afferent fibres, the complex dendrite tips of the granule cells and the ramifications of the Golgi cell axon. Lugaro and unipolar brush cells are not shown. (Adapted from Eccles J, Ito M, Szentagothai J 1967 The Cerebellum as a Neuronal Machine. New York and Heidelberg: Springer-Verlag, with permission of the authors and publishers.)

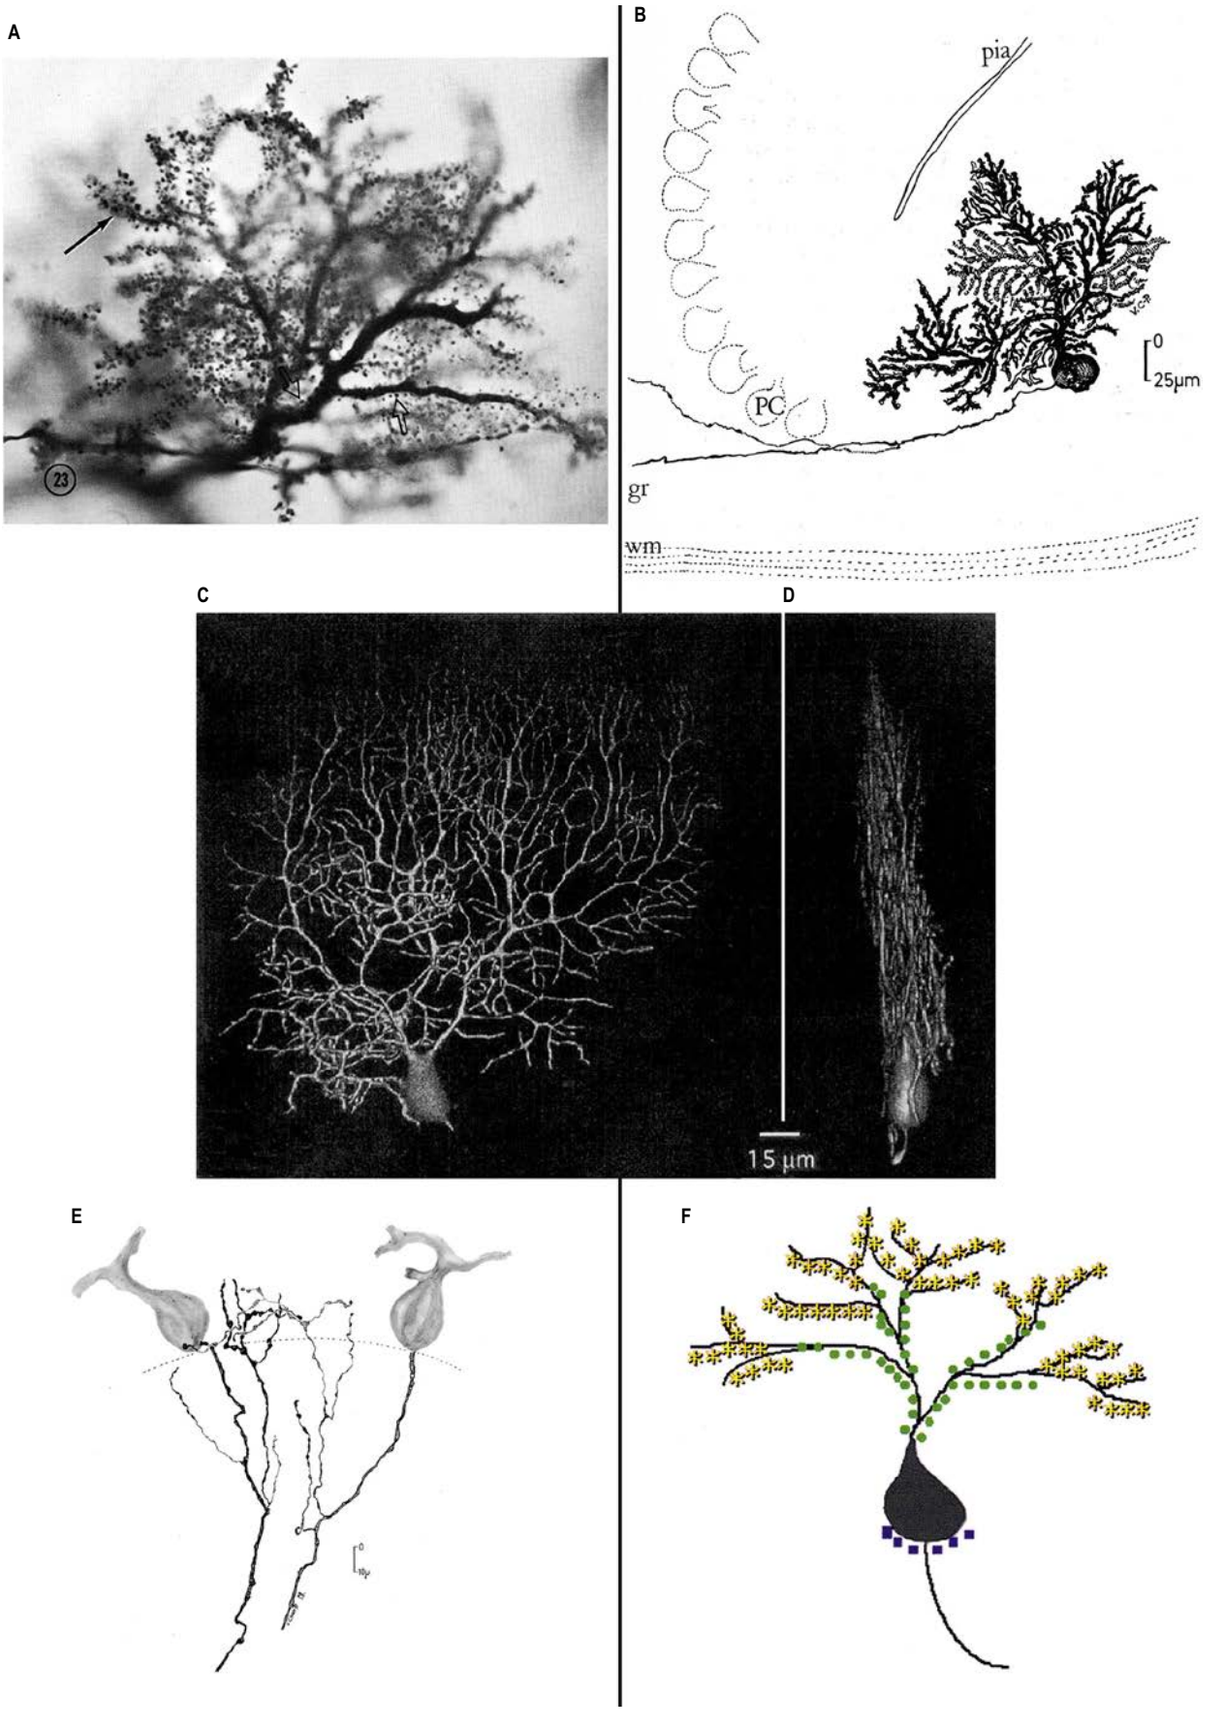

Fig. 29.12 Images of the Purkinje neurone of the cerebellar cortex. **A**, Photomicrograph of a Golgi-impregnated Purkinje cell (PC) showing high density of spines on distal dendrites (black arrow) and low density of spines on proximal dendrites (open arrows). **B**, Camera lucida drawing of a Golgi-impregnated PC with its axon at the base of a folium. The PC axon courses through the granule cell layer (gr) to the white matter (wm), giving of a collateral branch. Three-dimensional reconstruction of Lucifer yellow-filled PC viewed in a plane perpendicular to (**C**) and parallel to (**D**) the long axis of the folium. **E**, Camera lucida drawing of Golgi-impregnated PCs showing the recurrent collateral plexuses of two PCs. The recurrent collaterals ramify and terminate in the granular layer, and in the vicinity of the PC soma as the more profuse infraganglionic plexus, or at the apical pole of the PC as the sparse supraganglionic plexus. **F**, Schematic view of the PC illustrating the segregation of afferents. Parallel fibres synapse on dendritic spines on intermediate and distal dendrites (yellow), climbing fibres synapse on more sparsely distributed spines on proximal dendrites (green). Basket cell axons synapse on the PC soma and proximal segment of the PC axon (purple). (A, B, E, With permission from Palay S, Chan-Palay V 1974 Cerebellar Cortex: Cytology and Organization. New York: Springer-Verlag. C and D, With permission from Rossi DJ, Alford S, Mugnaini E, Slater NT 1995. Properties of transmission at a giant glutamatergic synapse in cerebellum: the mossy fibre-unipolar brush cell synapse. J Neurophysiol 74:24–42. F, Adapted with permission from Oberdick J, Baader SL, Schilling K 1998 From zebra stripes to postal zones: deciphering patterns of gene expression in the cerebellum. Trends Neurosci 21:383–90.)

Larger Golgi cells are 10–24 μm in diameter, and most lie in the upper half of the granular layer, below the level of the Lugaro cell and the infraganglionic plexus. Smaller Golgi cells are 9–18 μm in diameter and are generally located in the depths of the granular layer. Dendrites either radiate out from the soma or arise as one or two main trunks that give off subsidiary branches as they ascend to the outer zone of the molecular layer, predominantly at right-angles to the surface. Larger Golgi cells have either dendritic morphology, whereas smaller Golgi cells tend to have the radiating dendritic pattern. The Golgi dendritic tree is unlike that of the Purkinje, basket or stellate cell, which is flattened and confined to a single plane, but instead has a three-dimensional configuration, appearing much the same in transverse and longitudinal foliar sections. In both planes, the Golgi dendritic tree overlaps the territories of several Purkinje cells and neighbouring Golgi cells. Some Golgi dendrites do not enter the molecular layer, but divide in the granular layer to join the cerebellar glomeruli. The Golgi cell axon arises from the base of the soma or from a central dendrite, immediately dividing into a profuse arborization that extends through the entire thickness of the granular layer. The territory occupied by the axonal ramifications has a volume corresponding approximately to its dendritic tree in the molecular layer, overlapping with the axonal arborizations of adjacent Golgi cells. The main synaptic input to Golgi cell dendrites is from parallel fibres in the molecular layer. Purkinje cell recurrent collaterals and mossy and climbing fibres also terminate on their proximal dendrites and, more sparsely, on their somata. Golgi neurones are the principal inhibitory interneurones at the input stage of the cerebellum, providing feedforward inhibition through their axonal synapses with mossy fibres at the granule cell glomeruli and feedback inhibition at their dendritic synapses with parallel fibres.

The Lugaro cell is a fusiform cell measuring about 10 μm across and 25–30 μm in length (**Fig. 29.15A**) (Lugaro 1894a, 1894b). It is an inhibitory interneurone using both GABA and glycine as neurotransmitters. Its major axis lies parallel to the pial surface, horizontally or obliquely in the outermost third of the granular layer, sometimes alongside the somata of Purkinje cells or immediately above them. Its dendrites originate from the gradually tapering extremities at the two poles and extend horizontally for a considerable distance (up to 600 μm) at the level of the Purkinje cell bodies, mostly in the infraganglionic plexus formed by the recurrent axon collaterals of the Purkinje cells. Lugaro cell axons arise from the soma or a large proximal dendrite and form two types of axonal plexuses: a parasagittal axon ascends to the molecular layer and contacts the somata and dendrites of stellate and basket cells, alternatively, an axon lies in the transverse plane in the granule cell layer and contacts Golgi cells (Lugaro 1894a, 1894b, Palay and Chan Palay 1974, Lainé and Axelrad 1996, Berlucchi 2002). Excitatory input to Lugaro cells is from granule cell axons. The Lugaro cell is the major recipient in the cerebellum of serotoninergic input through volume transmission. Serotonin-induced activation of Lugaro cells causes synchronization of the activities of Golgi and granule cells over extended longitudinal domains, and of the simple-spike activity of Purkinje cells, thereby influencing the processing of mossy fibre information by the cerebellar cortex and modulation of the deep cerebellar nuclei (Dieudonné 2001, Berlucchi 2002).

The unipolar brush cell is the only known glutamatergic excitatory interneurone in the cerebellum, found particularly in vestibular regions in lobule X and the vermis, as well as in the dorsal cochlear nucleus (Altman and Bayer 1977, Braak and Braak 1993, Mugnaini and Floris 1994, Mugnaini et al 1997, 2011). It has a soma 9–12 μm in diameter and a single short dendrite ending in a tight brush-like tip of dendrioles that have extensive synaptic contact with mossy fibre rosettes (**Fig. 29.15B**). Its thin axon branches locally and synapses on granule and Golgi cells. The unipolar brush cell is thought to amplify vestibular mossy fibre input and provide feedforward excitation to granule cells.

Synaptic contacts between climbing fibres and the dendrites or cell bodies of cerebellar interneurones in the molecular or granular layers have not been observed. However, interneurones of the molecular layer can be activated by 'spillover' of glutamate from the climbing fibres (Szapiro and Barbour 2007, Galliano et al 2013). Golgi cells, therefore, provide feedback inhibition to the granule cells. Interneurones of the molecular layer provide feedforward inhibition to the Purkinje cells. Stellate cells (Mann-Metzer and Yarom 2000) and Golgi cells (Dugué et al 2009) are electrotonically coupled, although the extent of this coupling is not known. It may be restricted to the sagittal compartments that are one of the main features of the connectivity of the cerebellum, discussed below.

Neuroglial cells in the cerebellar cortex are specialized forms of protoplasmic astrocytes that envelop the somata of the Purkinje cells in a neuroglial sheath. Bergmann glial cells in the Purkinje cell layer give rise to two or more processes that branch in the parasagittal plane with up to five polarized main processes, the Bergmann fibres, giving the appearance of a candelabra (**Fig. 29.16**). These radial fibres ascend vertically over the full depth of the molecular layer, overlapping with fibres of neighbouring cells to form palisades and giving rise to small convoluted side branches that form sites of putative neuronal–glial interaction. The Bergmann glial fibres terminate beneath the pia as the external glial limiting membrane of the cortex. Bergmann glial cells are intricately involved in migration and development of the cerebellar cortex (Rakic 1971) (Ch. 3). In the mature cerebellum they regulate glutamatergic neural transmission and are important for extracellular ion homeostasis, synapse stability, plasticity, metabolic function and neuroprotection. They also contribute to information processing in the cerebellum (see De Zeeuw and Hoogland 2015 for review).

Fañanas cells are glial cells in the deeper molecular layer. Velate astrocytes have intersecting diaphanous veils that compartmentalize the granular layer. Rare smooth protoplasmic astrocytes are present in the molecular as well as the granular layers (Palay and Chan-Palay 1974). Oligodendroglia are seen mostly in the granular layer where there are more myelinated fibres, and in the cerebellar white matter. Glial cells play a role in supporting neuronal metabolism, controlling the extracellular potassium ion concentration, and clearing neurotransmitters from the extracellular space.

Cerebellar inputs

The neurones of the cerebellar cortex and nuclei are linked together in multiple repeating anatomical microcircuits (corticonuclear microcomplexes) that subserve the distinctive functional characteristics of the cerebellum. There are two major cerebellar inputs, the climbing fibre and mossy fibre systems. Monoaminergic fibres are a third contingent of afferent fibres, but they are less influential in determining the organization of the intracortical and corticonuclear connectivity.

Mossy fibres

The thick, heavily myelinated mossy fibres were so named by Ramon y Cajal because the 'thickened ends of the mossy fibres are indented, or, more accurately, bristle with thick, short, divergent, varicose branches that are themselves modestly ramified. The ending as a whole resembles a piece of moss' (Ramon y Cajal 1909–10/1995, **Fig. 29.17**). Mossy fibres enter through the three cerebellar peduncles depending on their site of origin. Most (up to 70%) run a transverse course to decussate in the cerebellar commissure, terminating bilaterally in the cerebellum. Like the climbing fibres, mossy fibres branch profusely, emitting 20–30 thin collateral branches that enter the white matter of the lobules and terminate in multiple, longitudinally orientated and symmetrically distributed aggregates of mossy fibre terminals in the granular layer (Wu et al 1999).

The terminal or synaptic arborizations of the mossy fibres, termed rosettes, are located along the course of the fibre in the granular layer, at the branch points, and at their sites of termination (**Fig. 29.18**). There are three kinds of mossy fibre rosettes. The most common type is an elongated cone that expands, emitting tubular and filamentous processes, and is found at the mossy fibre terminal in the outer third of the granular layer just beneath the Purkinje cell layer. Simple fusiform enlargements have globular contours and a few short, finger-like projections. Terminations with more complex shape have a massive central expansion out of which several appendages project.

Mossy fibres provide excitatory, glutamatergic afferents to the cerebellar cortex from most non-olivary sources. Their excitatory input is not to the Purkinje cell directly, but to the granule cells that provide excitatory input to the Purkinje cell dendrites. Mossy fibres activate α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA), N-methyl-D-aspartate (NMDA) and metabotropic glutamate receptors (mGluRs) on granule cells. The mossy fibre rosette is the central component of the granule cell glomerulus. Seen on light microscopy as pale islands between the granule cells, the glomerulus is a complex articulation between mossy fibre rosettes, the claw-like dendrites of the granule cells and Golgi cell axons. Each mossy fibre rosette makes excitatory synaptic contact with 50–100 dendritic terminals from up to 20 granule cells, while receiving inhibitory feedback from the descending axons of Golgi cells. Each mossy fibre branch synapses with 400 or more granule cells in one folium. If branches to adjacent folia are included, the number is probably several thousand. Conversely, each granule cell receives synapses from four or five different mossy fibre terminals.

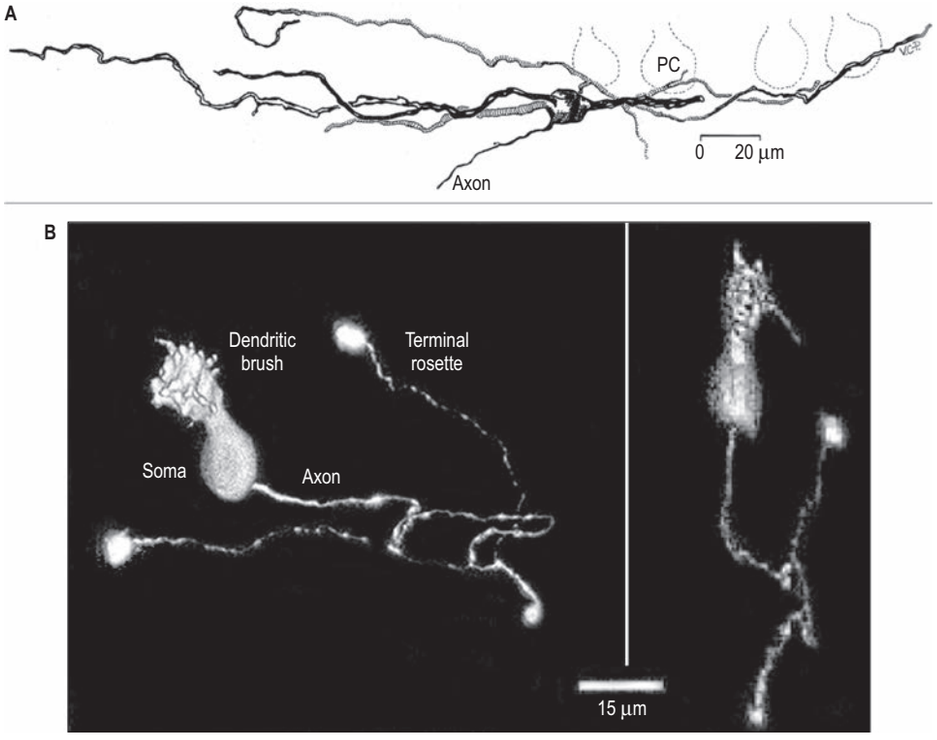

Fig. 29.15 **A**, A camera lucida drawing of a Golgi-impregnated Lugaro cell with its dendrite that courses in the sagittal plane at the level of the Purkinje cell (PC), and the axon that descends into the granular layer. **B**, A confocal microscopic image of a Lucifer yellow-filled unipolar brush cell (UBC) with its axon and terminal rosettes identified. The UBC, like the PC, has a parasagittal orientation and is seen perpendicular to (left) and parallel to (right) the long axis of the folium. (A, With permission from Palay S, Chan-Palay V 1974 Cerebellar Cortex: Cytology and Organization. New York: Springer-Verlag. B, With permission from Rossi DJ, Alford S, Mugnaini E et al 1995. Properties of transmission at a giant glutamatergic synapse in cerebellum: the mossy fibre-unipolar brush cell synapse. J Neurophysiol 74:24–42.)

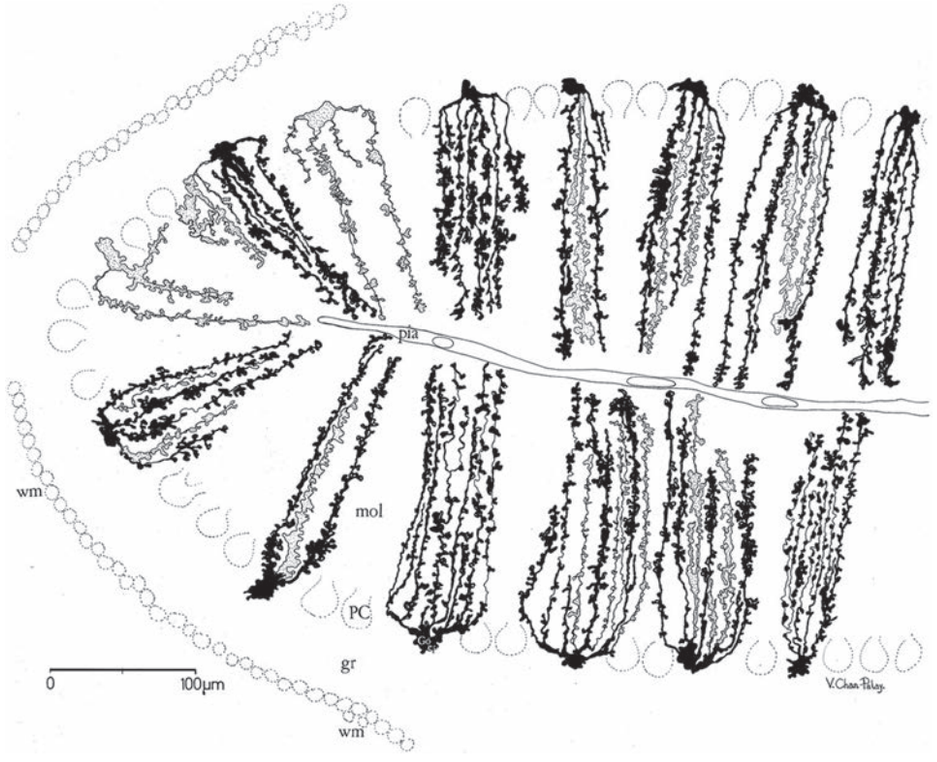

Fig. 29.16 A camera lucida drawing of Golgi-impregnated epithelial cells (Go ep) in a folium. 'Each cell, like a candelabrum, has processes [Bergmann glia] with warty excrescences that rise, like corroded wires, to the pial surface (pia).' The locations of the Purkinje cells (PC), molecular layer (mol), granule cells (gr) and white matter (wm) are indicated. Fig. 29.17 A camera lucida drawing of Golgi-impregnated complex mossy fibres of the cerebellum showing complex varicosities at the bifurcation points (asterisks) and terminal rosettes (arrows) of the mossy fibres and at the terminations. A simple mossy fibre is seen at lower left (crossed arrows). Abbreviations: PC, Purkinje cell; wm, white matter. (With permission from Palay S, Chan-Palay V 1974 Cerebellar Cortex: Cytology and Organization. New York: Springer-Verlag.)

Collaterals to the deep cerebellar nuclei are derived from mossy fibres arising in the reticulotegmental nucleus, lateral reticular nucleus (LRN), and the spinocerebellar and vestibulocerebellar projections.

Cholecystokinin (CCK), calcitonin gene-related peptide (CGRP), corticotropin releasing factor (CRF) and leucine-5-enkephalin neuropeptides co-exist in many mossy fibres and some, mainly vestibulocerebellar mossy fibres, use acetylcholine as their neurotransmitter.

Climbing fibres

Climbing fibres arise exclusively from neurones of the inferior olive in the medulla oblongata and course to the cerebellum through the contralateral inferior cerebellar peduncle. Most olivocerebellar projections are contralateral, although a few axons project bilaterally by crossing the midline within the cerebellum. The parent climbing fibre splits into 7–10 thick branches in the cerebellar white matter, emitting thin collaterals to the deep cerebellar nuclei, before passing through the granular layer on their way to the molecular layer (**Fig. 29.19**). In the lower two-thirds of the molecular layer each branch of a climbing fibre lies closely opposed to the trunk and major branches of the dendritic tree of its target Purkinje cell, providing extensive direct excitatory glutamatergic synaptic contact with the stubby spines on the proximal dendrites of a single Purkinje cell in a one-to-one relationship (**Fig. 29.20**; see Fig. 29.12F). Each varicosity of the climbing fibre synapses with several dendritic spines, enabling 1000–1500 synaptic contacts between a climbing fibre and its Purkinje cell. The fine tendrils that branch off from the climbing fibres in the molecular layer make non-synaptic contact with ascending branches of the basket cell axons that enter the molecular layer, and with the dendritic trees of the stellate cells and the dendrites and somata of Golgi cells (Palay and Chan-Palay 1974, Sugihara et al 1999). Electrotonic coupling through gap junctions between the neurones of the inferior olive generates synchronous subthreshold oscillations (e.g. Leznik and Llinas 2005). Climbing fibres thus exert control over inhibition at both the input and output layers of the cerebellar cortex, regulating Golgi cell and stellate cell activity by releasing glutamate and activating ionotropic and metabotropic receptors through spillover-mediated transmission (Szapiro and Barbour 2007, Nietz et al 2017).

Climbing fibres use glutamate as their principal neurotransmitter, but there is chemical heterogeneity in the climbing fibre system: CCK is expressed in vermal lobules IV, VII and VIII, and in axons arising in the caudal part of the medial accessory olive. Enkephalin reactivity is present in the vermis, paramedian lobule and flocculus.

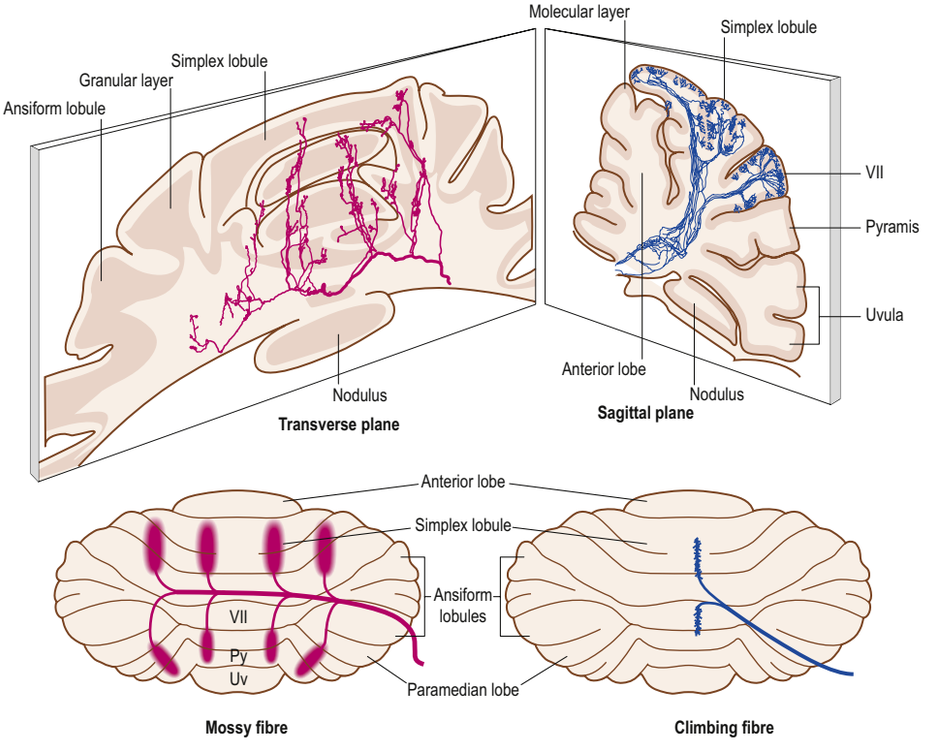

Fig. 29.18 The orientation and branching pattern of mossy and climbing fibres. Left-hand panels: mossy fibres are orientated transversely. They distribute bilaterally and emit collaterals at specific, symmetrical locations. These collaterals terminate as sagittally orientated aggregates of mossy fibre terminals. Right-hand panels: olivocerebellar fibres branch in the sagittal plane. Each branch provides a Purkinje cell with a single climbing fibre. These climbing fibres form narrow, longitudinally orientated strips that may correspond to the microzones; strips of Purkinje cells that share the same climbing fibre receptive fields. Abbreviations: Py, pyramis; Uv, uvula. (With permission from Nieuwenhuys R, Voogd J, van Huijzen 2008 The Human Nervous System, 4th ed. Berlin: Springer-Verlag.)

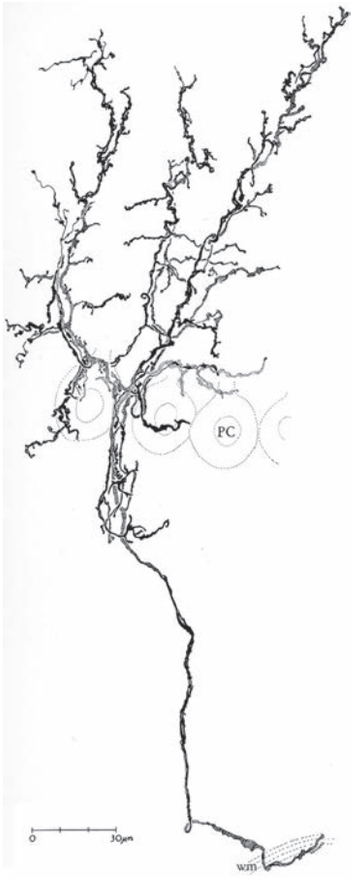

Fig. 29.20 A camera lucida drawing of a Golgi-impregnated climbing fibre entering the white matter (wm) as an unbranched twisted stalk and coursing through the granular layer. In the upper third of the granular layer a branching collateral plexus of beaded tendrils diverges from the parent fibre. At the level of the Purkinje cell (PC) body the axon breaks into its terminal arborization to climb upon the dendrites of a PC. (With permission from Palay S, Chan-Palay V 1974 Cerebellar Cortex: Cytology and Organization. New York: Springer-Verlag.)

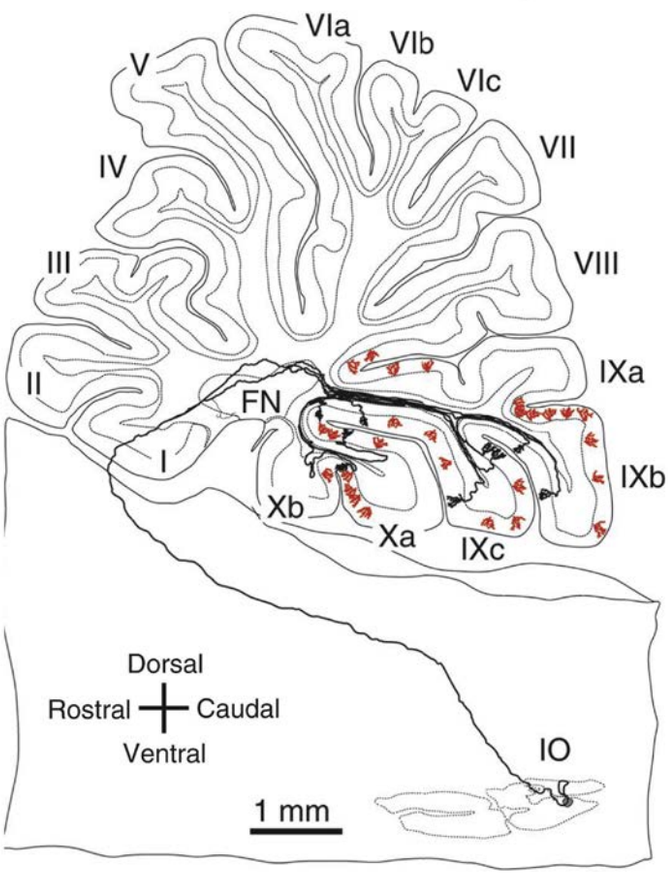

Fig. 29.19 Projection patterns of olivary axons in the cerebellum. Entire trajectory of a single olivocerebellar axon labelled after a small injection of biotinylated dextran amine (BDA) into the mediocaudal portion of the medial accessory olive (reconstructed from 77 serial parasagittal sections). This axon gave rise to nine climbing fibres terminating in the uvula (lobule IXb–c) and the nodule (lobule Xa), and thin collaterals terminating in the fastigial nucleus and the granular layer. The terminations of all other climbing fibres (n = 28) labelled by the tracer injection are shown in red. All climbing fibres were distributed from caudal lobule VIII to lobule X. Abbreviations: I–X, lobules I–X; a–c, sublobules a–c; FN, fastigial nucleus; IO, inferior olive. (With permission from Sugihara I, Wu H-S, Shinoda Y 2001 The entire trajectories of single olivocerebellar axons in the cerebellar cortex and their contribution to cerebellar compartmentalization. J Neuroscience 21:7715–23.)

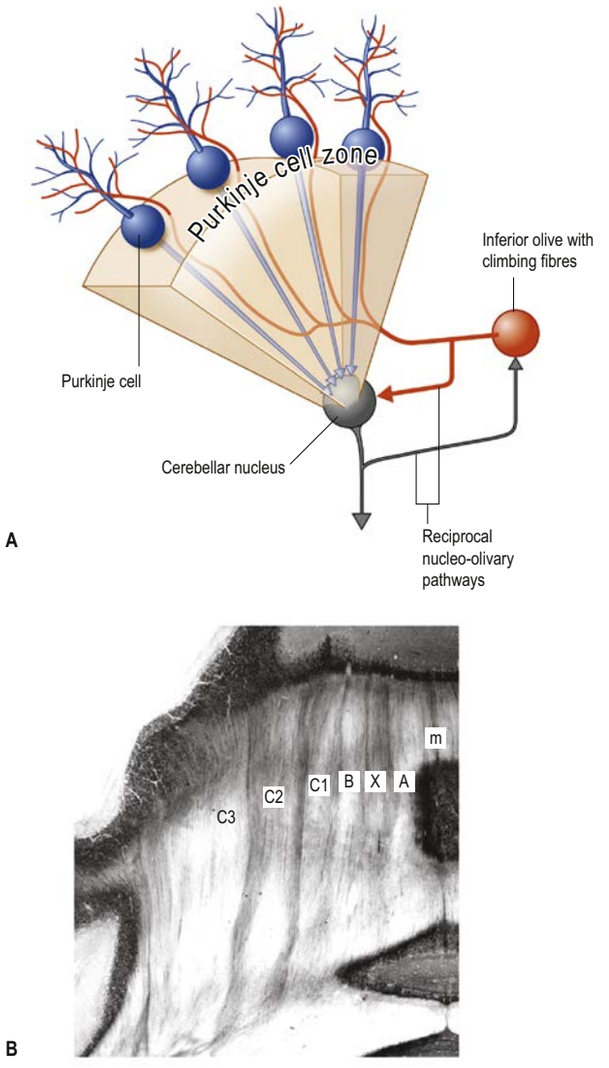

Fig. 29.21 **A**, A cerebellar module. Purkinje cell axons and climbing fibres are located in a white matter compartment, shown as a transparent structure in this diagram. **B**, An acetylcholinesterase-stained section through the anterior lobe (*Macaca mulatta*). There is heavy staining of the borders between the white matter compartments of the modules A, X, B, C1, C2 and C3. Abbreviation: m, midline.

The olivocerebellar projection has a strict medio-lateral parasagittal zonal organization. The branches of a single olivocerebellar fibre innervate one or more sagittally orientated strips of Purkinje cells (Sugihara et al 2001) (**Fig. 29.21**; see Fig. 29.19). These strips correspond to microzones consisting of a narrow strip of Purkinje cells innervated by climbing fibres that share the same receptive field. Microzones with their Purkinje cells are considered to be the basic structural and functional unit of the cerebellar cortex (Andersson and Oscarsson 1978).

Monoaminergic inputs

Monoaminergic afferents to the cerebellum modulate the release of other neurotransmitters. Noradrenergic innervation arises from neurones in the caudal portion of the locus coeruleus as axonal collaterals of projections to the forebrain. These fibres synapse on granule cell dendrites and run adjacent to the parallel fibres to terminate on the Purkinje cell dendrites. Serotoninergic afferents to the cerebellum arise from the raphe nuclei and are present throughout all regions of the cerebellum. Histaminergic fibres arise from neurones in the tuberomammillary nucleus of the posterior hypothalamus and innervate most regions of the cerebellum. Dopaminergic inputs arise from the neurones of the midbrain including the ventral tegmental area. Cholinergic projections are present diffusely, particularly in the flocculonodular lobe and in lobules I and II, terminating on excitatory unipolar brush cells and on inhibitory interneurones.

Overview of cortical circuitry

The granule cell axon ascends in the cerebellar cortex through the dense granule cell layer and splits into two branches that travel in opposite directions along the long axis of a cerebellar folium, perpendicular to the ascending axon, and form the parallel fibres. The length of each parallel fibre branch is between 1 and 3 mm in the rat and cat, longer in nonhuman primates (6–8 mm) and probably no more than 10 mm in humans. Terminals located along the parallel fibre give it a beaded or varicose appearance; these terminals are the sites of synapses between the parallel fibres and the distal dendritic trees of Purkinje cells and the dendrites and somata of the stellate, basket and Golgi cells that they encounter along their course (**Fig. 29.22**). There is enormous convergence of mossy fibre inputs to individual Purkinje neurones; a dendritic tree of one Purkinje cell receives an estimated total of 175,000 synapses from different parallel fibres in the rat (Napper and Harvey 1988), although every parallel fibre may not synapse with the dendritic tree which it crosses. On its way to the distal arbors of a Purkinje cell dendritic tree, and before dividing to form the parallel fibres, the ascending axon of a granule cell makes synaptic contact first with dendrites of Golgi cells in the granular layer, and then with the spines of the proximal dendrites of Purkinje cells. Approximately 20% of the granule cell synapses on a Purkinje cell are made by the ascending segment of the granule cell axon, facilitating a more restricted influence on a single Purkinje cell than the parallel fibre–Purkinje cell synapses would allow.

A Purkinje cell generates two very different classes of action potentials mediated by its two principal afferents. Climbing fibre input to a Purkinje cell induces a complex spike with a very low frequency of 0.5

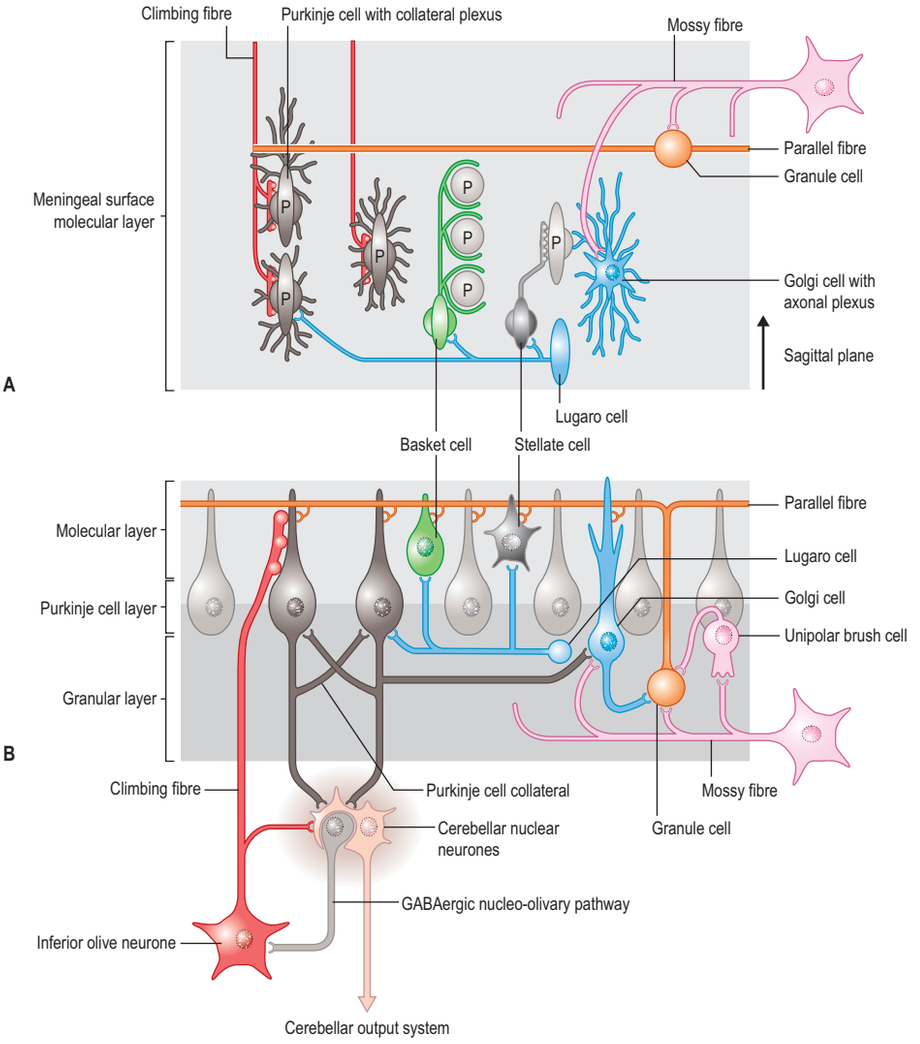

Fig. 29.22 The circuitry of the cerebellar cortex. Glutamatergic neurones are shown in dark grey, GABAergic neurones in red and glycinergic elements in blue. **A**, A transparent dorsal view of the cortex showing the orientation of its major elements. Dendrites of Purkinje, stellate and basket cells, the collateral plexus of Purkinje cells, the cell bodies of the Lugaro cells, and the climbing fibres and the axonal plexus of the Golgi cells are orientated in the sagittal plane. **B**, A transverse section. Parallel fibres and the axons of the Lugaro cells are the only elements with a transverse orientation.

to 2 spikes per second, which is the same rate of firing as the olivary neurones from which the climbing fibre originates. The climbing fibre input to a Purkinje cell is thought to signal the occurrence of errors. In contrast, the mossy fibre input to a Purkinje cell induces a repetitive simple spike with a frequency between 50 and 150 spikes per second. The parallel fibre input is thought to provide information about incoming signals, such as direction and speed of limb movement: in the cognitive domain, this input may provide a Purkinje cell with the context in which specific behaviours occur.

These circuits are relevant to synaptic plasticity involved in learning and memory. Long-term depression (LTD) is characterized by the persistent depression of synaptic transmission from parallel fibres to the Purkinje cell that occurs when the parallel fibres are activated concurrently with the activation of climbing fibres to the same Purkinje cell. Long-term depression has also been noted in the climbing fibre–Purkinje cell synapse. Long-term potentiation (LTP) occurs in the mossy fibre–granule cell interaction (D'Angelo et al 2005) and at the parallel fibre–Purkinje cell synapse (Hansel et al 2001).

Purkinje cells receive inhibitory feedback from cortical interneurones (stellate, basket and Lugaro cells), all of which receive afferents from the parallel fibres and the recurrent collaterals of a Purkinje cell axon. The output from the cerebellar cortex is derived exclusively from the Purkinje cells, precisely organized, and directed towards the deep cerebellar nuclei and precerebellar nuclei. Purkinje cells in each lobule project to that part of the deep cerebellar nuclei that is closest to them. Thus, the vermis projects to the fastigial nucleus, the intermediate cortex to the globose and emboliform nuclei, and much of the lateral hemisphere projects to the dentate nucleus.

Climbing fibre microzones and the subjacent mossy fibre aggregates share the same receptive fields in regions of the cerebellum that receive somatosensory information from the periphery (Ekerot and Larson 1980, Ekerot and Jörntell 2003). A similar topographical relationship between microzones and mossy fibre terminal aggregates exists in other parts of the cerebellar cortex (Pijpers et al 2006). Parallel fibres disperse a localized mossy fibre input over a wide, mediolateral region of the molecular layer, and the localized functional topography is thought to be related, at least in part, to the more topographically focal synaptic inputs of the ascending axon of the granule cell (Cohen and Yarom 1998).

CEREBELLAR FUNCTIONAL TOPOGRAPHY AND CONNECTIVITY

Whereas cerebellar cortical architecture is essentially invariant throughout, the topographically arranged circuits that link the cerebellum with the spinal cord, brainstem and cerebral hemispheres enable the cerebellum to contribute to the many different aspects of nervous system function. This arrangement is fundamental to the idea that the architecture of a brain region determines the nature of the information processing that takes place in that region (Schmahmann and Pandya 2008), and the principle expressed in the notion of the universal cerebellar transform (UCT) (Schmahmann 2000), which is that the cerebellum performs the same computation for sensorimotor processing as it does for cognition, emotion, autonomic and vestibular functions. Superimposed upon this principle is the presence of highly organized and functionally specific heterogeneity of cerebellar connections with the spinal cord, brainstem and cerebral cortex (Brodal 1981, Ito 1984, Schmahmann 1996, 1997, 2000, 2001, Schmahmann and Pandya 1997a, Voogd and Glickstein 1998, Voogd 2004).

On a large scale, cerebellar functional topography distinguishes anterior and posterior cerebellar lobes. The cerebellar anterior lobe (lobules I to V) and parts of lobule VI, together with lobule VIII receive spinal afferents through the spinocerebellar tracts (Oscarsson 1965). They are also reciprocally interconnected with the motor cortices via the feedforward motor corticopontine projections (Brodal 1978, Hartmann-von Monakow et al 1981, Schmahmann et al 2004a) and through feedback to motor regions from cerebellar nuclei via the thalamus (Thach 1987, Kelly and Strick 2003). These cerebellar regions (i.e. anterior lobe, adjacent parts of lobule VI and lobule VIII) are also reciprocally linked with the medial and dorsal accessory nuclei of the inferior olivary complex, which in turn receive afferents from the spinal cord (Brodal 1981, Voogd 2004). The deep cerebellar

nuclei that are linked with these cerebellar cortical areas are the anterior and posterior interpositus in the monkey (equivalent to the emboliform and globose nuclei in humans) and the dorsal part of the dentate nucleus. The cerebellar vermis and fastigial nucleus are interconnected with the vestibular and other brainstem nuclei engaged in midline body control, gait and equilibrium, as well as with brainstem nuclei linked with limbic and paralimbic cortical and subcortical regions (Schmahmann 2001).

In contrast to the connections of the anterior lobe and lobule VIII, the great expansion of the human cerebellum, i.e. the remainder of lobule VI, all of lobule VII (that includes lobule VIIA in the vermis and crus I and crus II in the hemispheres, lobule VIIB and most of lobule IX) has no connections with the cerebral cortical sensorimotor areas, and no spinal cord inputs from the spinocerebellar tracts (Brodal 1981, Voogd 2004). These areas are linked instead in a reciprocal feedforward and feedback manner with the association areas of the cerebral cortex concerned with higher order behaviour, namely, the prefrontal cortex, posterior parietal cortex, superior temporal polymodal regions, cingulate gyrus and posterior parahippocampal area (Schmahmann 1991, 1996, Schmahmann and Pandya 1989, 1991, 1992, 1993, 1997a, 1997b, Kelly and Strick 2003). The dentate nucleus of the cerebellum conveys the cerebellar posterior lobe efferents to these higher order regions of the cerebral cortex (Middleton and Strick 1994). The ventral and lateral parts of the dentate nucleus most involved in these projections (Dum and Strick 2003) have expanded through evolution together with the cerebellar posterior lobe and the cerebral cortical association areas (Dow 1974, Leiner et al 1986, Whiting and Barton 2003). The reciprocal interconnections between the inferior olivary nucleus and the cerebellar posterior lobe are distinct from those with the cerebellar motor regions, which are derived from the principal olivary nucleus, which has minimal or no spinal cord input (Sugihara and Shinoda 2004).

These anatomical connections set up a dichotomy of cerebellar linkage with the cerebral cortex, brainstem and spinal cord, and portray a complex connectional and functional heterogeneity. The sensorimotor cerebellum mostly in the anterior lobe, adjacent parts of lobule VI, and lobule VIII, appears to be an integral part of the distributed neural circuits that subserve the motor system, whereas the cognitive cerebellum in the posterior lobe, and the limbic cerebellum (likely represented principally in the vermis), are incorporated into the distributed neural circuits necessary for cognition and emotion.

On a smaller scale, the cerebellum is organized as a series of parallel, sagittally orientated modules (Voogd and Bigaré 1980, Voogd and Ruigrok 2012), each consisting of one or more Purkinje cell zones. From medial to lateral, zones A, B, X, C1, C2, C3, D1, D2 and Y can be distinguished. Climbing fibres from a subdivision of the contralateral inferior olive terminate on the Purkinje cells of a particular zone and also send a collateral innervation to the corresponding deep cerebellar nucleus (Groenewegen et al 1979). This collateral innervation is reciprocated by the, mainly crossed, nucleo-olivary pathway that originates from the small GABAergic neurones of the cerebellar nuclei (see Figs 29.19, 29.21). The outflow from the cerebellar cortex is directed to similarly topographically arranged regions in the fastigial, globose, emboliform and dentate nuclei. Efferents from the cerebellum to extracerebellar structures are conveyed exclusively through these nuclei, with the single exception of the cortex of the vestibulocerebellum (lobule X – flocculus and nodulus, and the vermal part of lobule IX – uvula), which projects directly to the vestibular nuclei. Cerebellar corticonuclear circuitry and feedback to the spinal cord, brainstem and cerebral hemispheres are thus arranged in a topographically precise manner respecting the zonal organization of the cerebellar cortex and its related deep cerebellar nuclei and inferior olivary complex.

The modular organization of the cerebellum appears very early during its development, before the emergence of its transverse fissures. Purkinje cells, born in the ventricular matrix of the cerebellar anlage, migrate to the meningeal surface, where they form a series of mediolaterally arranged clusters (Korneliussen 1968). During the later expansion of the cerebellar surface in the rostrocaudal dimension, reflecting the proliferation of millions of granule cells in the transient external matrix (the external granular layer), the Purkinje cell clusters increase in length and transform into Purkinje cell zones. The Purkinje cells become located in a monolayer and the original borders between the clusters are no longer visible. Purkinje cell clustering in the human brain does not differ from that in other species, with the exception of the immense size of the most lateral cluster, which is related to the anlage of the dentate nucleus (**Fig. 29.23**). This cluster develops into the D2 zone, the most lateral Purkinje cell zone, and is responsible for the large size of the human cerebellar hemisphere.

Afferent cerebellar fibres

Mossy fibre inputs to the cerebellum

Mossy fibre systems take their origin from multiple sites in the spinal cord and the brainstem, distribute bilaterally in the cerebellum and give off collaterals distributed in the mediolateral dimension that terminate as longitudinal aggregates of mossy fibre rosettes (see Fig. 29.18; **Fig. 29.24A**). These bands of rosettes are not continuous but are often restricted to either the apices or the bases of the folia. Exteroceptive components of mossy fibre systems terminate superficially, whereas proprioceptive systems terminate in the bases of the folia (Ekerot and Larson 1972) (**Fig. 29.24B**). The mossy fibre aggregates are not as distinct as the climbing fibre zones and often merge in the bases of the fissures. Mossy fibre aggregates of different systems interdigitate or overlap.

Spinal and trigeminocerebellar mossy fibre afferents

The spinal cord is connected with the cerebellum through spino-cerebellar tracts and through indirect mossy fibre pathways relayed by the lateral reticular nucleus. The spinocerebellar tracts are classified on the basis of their origin, their decussation within the spinal cord, their position in the lateral funiculus, their entrance route into the cerebellum and their lobular and zonal distribution.

The termination of the spinocerebellar, reticulocerebellar, cuneocerebellar and trigeminocerebellar tracts is restricted to the anterior and posterior motor regions of the cerebellum, i.e. to lobules III–V in the anterior lobe, lobule VI, parts of lobule VIIB and lobule VIII. These lobules also receive primary and secondary vestibulocerebellar inputs and pontocerebellar mossy fibres relaying information from cortical motor areas. Many of these mossy fibre systems terminate according to a somatotopical pattern (**Fig. 29.24C**). A very similar somatotopical organization occurs in the C1, C3 and Y climbing fibre zones that are restricted to the hemisphere of the same lobules (see Fig. 29.24).

The dorsal spinocerebellar tract transmits information from the ipsilateral lower limb. It contains proprioceptive fibres that arise from neurones in the posterior thoracic nucleus (Clarke's column) in the thoracic and upper lumbar spinal cord, and exteroceptive fibres from the thoracic and lumbar dorsal horns. It enters the cerebellum in the inferior cerebellar peduncle and terminates mainly ipsilaterally in the vermis and hemisphere of the anterior and posterior lower limb regions.

The cuneocerebellar tract is the upper limb equivalent of the dorsal spinocerebellar tract. It takes its origin from the dorsal column nuclei, the proprioceptive component from the external cuneate nucleus, and the exteroceptive component from the internal cuneate and gracile nuclei. Both components terminate in the anterior and posterior upper limb regions, the proprioceptive component bilaterally in the bases of the fissures and the exteroceptive component ipsilaterally in the apices of the lobules of the hemisphere. The exteroceptive component has been shown to terminate in multiple longitudinal zones that are congruent with the climbing fibre zones of this region; these zones share the same detailed somatotopical organization as the C1, C3 and the Y climbing fibre zones (Ekerot and Larson 1980).

The ventral spinocerebellar tract is a composite pathway that informs the cerebellum about the state of activity of spinal reflex arcs related to the lower limb and lower trunk. Its fibres originate in the intermediate grey matter and the spinal border cells of the lumbar and sacral segments of the spinal cord, cross near their origin, and ascend close to the surface as far as the lower midbrain before looping around the emergent fibres of the trigeminal nerve to join the superior cerebellar peduncle. Most of these fibres cross again in the cerebellar white matter.

The rostral spinocerebellar tract originates from cell groups of the intermediate zone and horn of the contralateral cervical enlargement. It is considered to be the upper limb and upper trunk equivalent of the ventral spinocerebellar tract, but unlike its ventral counterpart, most of its fibres remain ipsilateral throughout their course and enter the cerebellum through both the superior and the inferior cerebellar peduncles terminating in the anterior and posterior vermis.

The central cervical spinocerebellar tract originates from a central cervical nucleus at high cervical levels (C1–C4). The tract terminates bilaterally in the bases of the fissures of the entire cerebellum, lacks a somatotopical organization and conveys labyrinthine information and proprioception from neck muscles (Matsushita and Tanami 1987).

Trigeminocerebellar mossy fibres originate from the ipsilateral principal sensory nucleus and nucleus of the spinal tract of the trigeminal nerve and terminate in the hemisphere in the anterior and posterior face regions in lobules VI and VIIB.

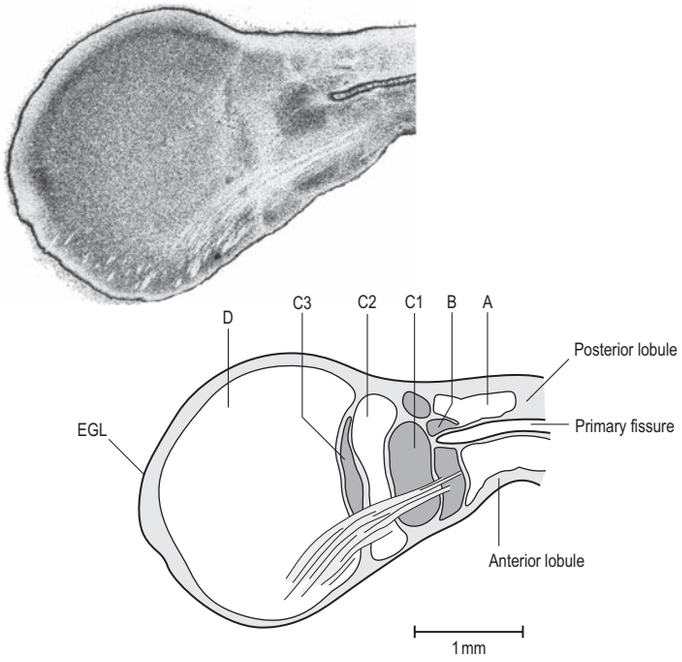

Fig. 29.23 A transverse section through the cerebellum of a 65 mm human fetus, showing the Purkinje cell clusters that will develop into the A, B, C1–C3 and D Purkinje cell zones. Note the large size of the D cluster. Abbreviations: EGL, external granular layer. (Courtesy of the Schenk collection of the Department of Pathology of the Erasmus Medical Center, Rotterdam.)

Cerebellar modules can be visualized because their Purkinje cell axons and climbing fibre afferents collect in compartments in the cerebellar white matter and are visible when stained for acetylcholine esterase (AChE) (see Fig. 29.21B). Some of the Purkinje cell zones are restricted to certain lobules; others span the entire rostrocaudal length of the cerebellum. Eight or nine of the modules can be recognized in the cerebellum of nonhuman primates and lower mammals (see Fig. 29.36). Purkinje cell zones differ in their climbing fibre afferents and cerebellar or vestibular target nucleus. Purkinje cells of the different zones also differ in their immunohistochemical properties (Voogd and Ruigrok 2012). A Purkinje cell-specific antibody, known as zebrin 2, is distributed in a pattern of zebrin-positive and zebrin-negative Purkinje cell zones (see Fig. 29.36D–E). This pattern has been shown to be congruent with the olivocerebellar and corticonuclear projection zones (Voogd et al 2003, Sugihara and Shinoda 2004). Many substances, such as the enzymes aldolase C, 5′ nucleotidase, protein kinase C and the metabotropic glutamate transporter 1A, colocalize with zebrin 2. Neurotransmission in different Purkinje cell zones may therefore differ: zebrin-positive Purkinje cells fire at a slower rate than the zebrin-negative cells (Zhou et al 2014). Apart from the parallel fibres, which may cross several Purkinje cell zones or microzones as they course through the molecular layer, there is no crosstalk between the modules. Parallel fibres are a key element in the integrative function of the cerebellum, but the relative independence of the cerebellar modules is an important difference between the cerebellum and the cerebral cortex, where different functional areas are interconnected through association fibres.

The distinct somatotopic organization of the anterior and posterior motor regions of the hemispheres is reflected in the termination of the exteroceptive components of the dorsal spinocerebellar, cuneocerebellar and trigeminocerebellar tracts. The organization is much less distinct for proprioceptive systems such as the central cervical spinocerebellar tract.

Reticulocerebellar mossy fibre afferents

In the reticular formation, the paramedian reticular nucleus, the lateral reticular nucleus and the reticulotegmental nucleus (nucleus reticularis tegmenti pontis, NRTP) all give rise to mossy fibres. Major collateral projections to the cerebellar nuclei arise from the lateral reticular nucleus and the reticulotegmental nucleus.

The paramedian reticular nucleus consists of cell groups at the lateral border of the medial longitudinal fasciculus in the caudal medulla. It receives fibres from the vestibular nuclei, the interstitiospinal and tectospinal tracts that descend in the medial longitudinal fasciculus, and from the spinal cord and the cerebral cortex, and projects to the entire cerebellum, with the possible exception of the paraflocculus.

The lateral reticular nucleus is in the lateral funiculus of the caudal medulla, surrounded by the ascending fibre systems of the lateral funiculus and the rubrospinal and lateral vestibulospinal tracts. It receives spinoreticular fibres that terminate in a somatotopic pattern within the entire lateral reticular nucleus, and descending fibres from the cerebral cortex. The dorsal part of the lateral reticular nucleus receives collaterals from the rubrospinal tract and projects to the ipsilateral cerebellar hemisphere. The ventral part of the lateral reticular nucleus receives a collateral projection from the lateral vestibulospinal tract and projects bilaterally, mainly to the vermis. The lateral reticular nucleus has strong projections as axon collaterals to the rostral part of the fastigial and emboliform nuclei and the medial pole of the globose nucleus (Wu et al 1999).

The reticulotegmental nucleus is a butterfly-shaped nucleus in the caudal half of the pontine tegmentum, next to the midline and dorsal to the pontine nuclei. It receives inputs from the cerebral cortex, tectum, nucleus of the optic tract and cerebellar nuclei via the crossed descending branch of the superior cerebellar peduncle and it projects to the cerebellum via the middle cerebellar peduncle. The medial visuomotor division of this nucleus receives visuomotor afferents from the frontal eye fields, the contralateral superior colliculus (through the tectopontine tract) and other visuomotor centres in the brainstem, and targets the visual vermis in lobule VII, crus I, the flocculus and the adjacent ventral paraflocculus. The bilateral projection of its lateral, motor portion overlaps similar motor projections from the pontine nuclei in the anterior lobe, lobule VI and lobule VIII. Mossy fibres from the reticular nucleus of the pontine tegmentum provide the cerebellar nuclei with a collateral innervation complementary to that of the lateral reticular nucleus. An uncrossed component of the tectopontine tract terminates in the dorsolateral corner of the pontine nuclei, where it overlaps with extrastriatal visual afferents.

Abbreviations: CE, external cuneate nucleus; CI, internal cuneate nucleus; DV, nucleus of the spinal tract of the trigeminal nerve; G, gracile nucleus; NRL, lateral reticular nucleus.

Primary and secondary vestibulocerebellar mossy fibres

Primary vestibulocerebellar mossy fibres to the cerebellum are derived from vestibular ganglion cells that travel in the ascending branch of the vestibular nerve. They pass through the superior vestibular nucleus and the juxtarestiform body before entering the cerebellum and project directly to the ipsilateral vermis in the ventral part of lobule IX (uvula) and lobule X (nodulus) and to the ventral part of the anterior lobe and bases of the deep fissures of the vermis (Fig. 29.25). The flocculus (hemisphere lobule X) receives few, if any, vestibular fibres. Secondary vestibulocerebellar mossy fibres arise from the superior vestibular nucleus, the caudal portions of the medial and inferior vestibular nuclei, and the group X neurones, and terminate bilaterally in the same regions that receive primary vestibulocerebellar fibres with the exception of vermal lobule X (nodulus), and in hemisphere X (flocculus) and the adjacent ventral paraflocculus (the accessory paraflocculus of the human cerebellum) that lack a primary vestibulocerebellar projection. Some of the mossy fibres from the medial and inferior vestibular nuclei are cholinergic.

Corticopontocerebellar projections

The cerebral cortex is linked with the cerebellum in a two-stage feedforward limb of cerebral cortical projections to the nuclei of the basis pontis (corticopontine projection), and the mossy fibre projection from the pontine nuclei through the middle cerebellar peduncle to the contralateral cerebellum (pontocerebellar projection). The reciprocal feedback pathway from the cerebellum to the cortex is mediated by the thalamus via cerebellothalamic and thalamocortical projections.

All corticopontine axons arise from lamina V pyramidal cells (Figs 29.26–29.27). Some corticopontine fibres are collaterals of axons that project to other targets in the brain or spinal cord: in the motor system it is likely that corticospinal fibres give off collaterals to the pontine nuclei (Ugolini and Kuypers 1986).

The nuclei of the basis pontis pons receive prominent projections from unimodal and multimodal cerebral cortical association areas (Fig. 29.31). These occupy largely separate areas of the basis pontis in the rostrocaudal and transverse dimensions. The enlargement of the basis pontis along with the lateral cerebellar hemispheres and the ventrolateral dentate nucleus is in accord with the view that the major expansion in the cerebrocerebellar pathways reflect cerebellar linkage with the cerebral association areas rather than with the motor system.

In monkeys, prefrontal projections to the pons arise mostly in dorsolateral and dorsomedial prefrontal cortices and terminate in the rostral third of the medial pons. Posterior parietal projections arise from both gyral and sulcal cortices, including the multimodal caudal regions. Inferior parietal lobule projections to the pons are predominantly rostral, whereas those from the superior parietal lobule are seen throughout the rostrocaudal extent of the pons. These parietal projections are mostly in the intermediate and lateral sectors of the pons, with a degree of topographical organization determined by their site of origin. Temporal lobe projections arise from the multimodal regions of the cortex of the upper bank of the superior temporal sulcus, as well as from the superior temporal gyrus and supratemporal plane, and terminate in the lateral and dorsolateral pontine regions. Parastriate cortices at the dorsomedial and dorsolateral convexity, as well as the posterior parahippocampal gyrus, project to the lateral and dorsolateral pontine regions in a pattern that interdigitates with the other terminations in this area. The rostral cingulate cortex projects to medial pontine nuclei and the caudal cingulate cortex projects to more lateral regions. Pontine projections have also been shown in experimental retrograde studies to arise from the anterior insular cortex.

These connections provide the cerebellum with access to higher order information, enabling it to modulate cognitive and emotional processing.

Apart from the cortical projection to the basis pontis, there are also pontine inputs from the superior colliculus to the dorsolateral pons and to the reticular nucleus of the pontine tegmentum. The tectocerebellar pathway thus uses the pontine nuclei and the reticular nucleus of the pontine tegmentum as the link in its projection to the vermal visual area. Pontine inputs are also derived from the medial mammillary bodies.

The pontocerebellar projection is almost completely crossed. Projection fibres arise from the pontine neurones, course horizontally toward the midline in a focused aggregate, and fan out in multiple directions to course in the transverse pontocerebellar fibre bundles

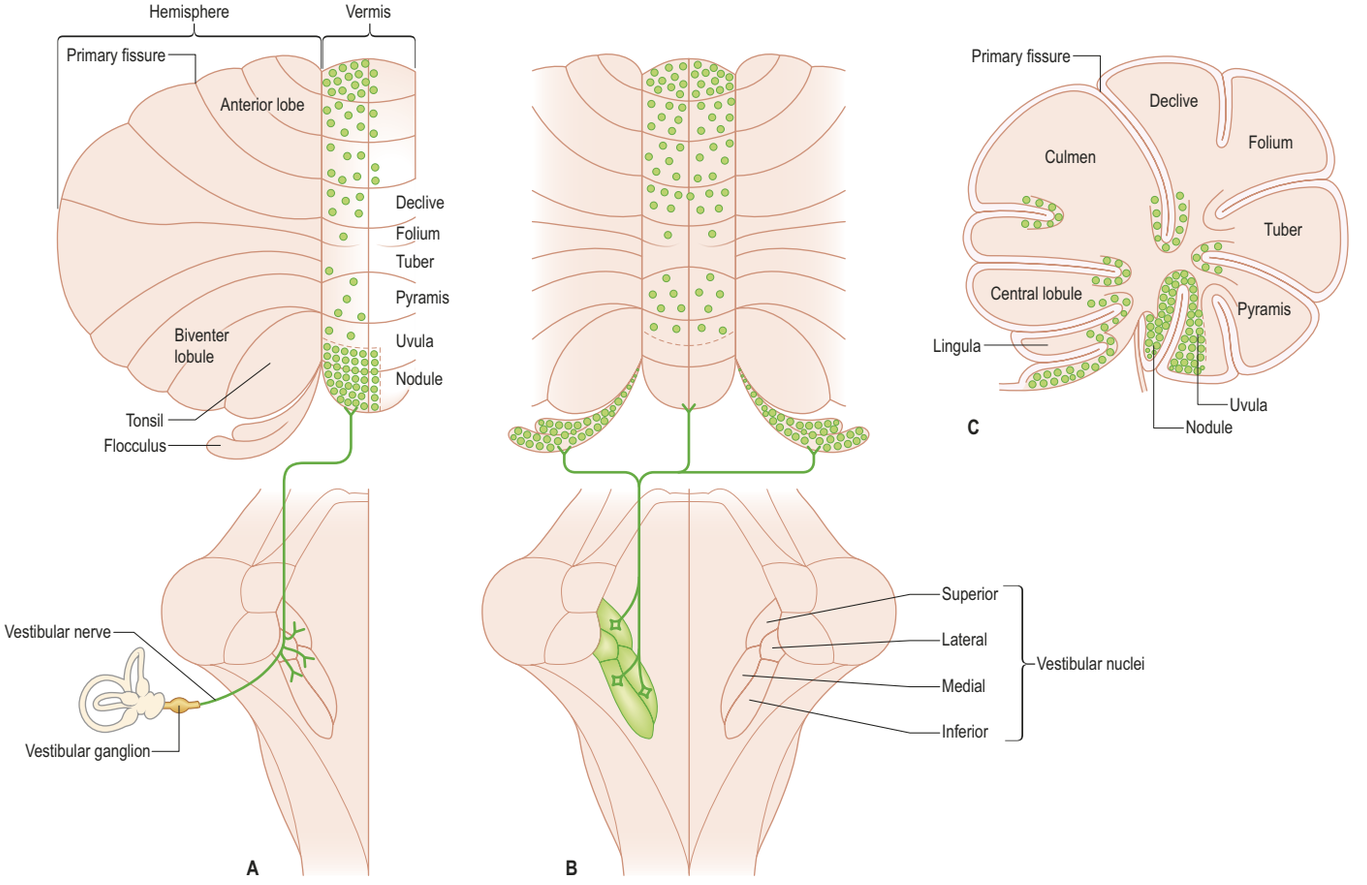

Fig. 29.25 Vestibulocerebellar mossy fibre projections. **A**, Primary vestibulocerebellar projections from the bipolar neurones of the vestibular ganglion. **B**, Secondary vestibulocerebellar projections from the vestibular nuclei. **C**, A sagittal section showing the distribution of both sets of afferents.

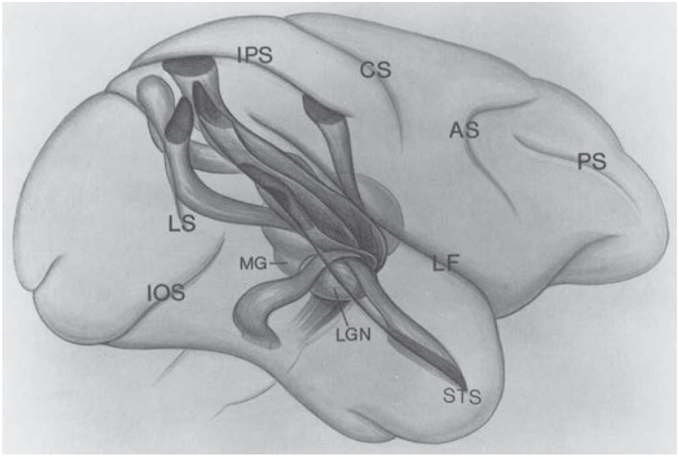

Fig. 29.26 Composite summary diagram showing an artist's representation of the trajectory and organization of fibres from the parietal, temporal and occipital association areas as they course toward the critical point in the white matter above and medial to the midportion of the lateral geniculate nucleus before descending into the cerebral peduncle. Abbreviations: AS, arcuate sulcus; CS, central sulcus; IOS, inferior occipital sulcus; IPS, intraparietal sulcus; LF, lateral fissure; LGN, lateral geniculate nucleus; LS, lunate sulcus; MG, medial geniculate; PS, principalis sulcus; STS, superior temporal sulcus. (With permission from Schmahmann JD, Pandya DN 1992 Course of the fiber pathways to pons from parasensory association areas in the rhesus monkey. J Comp Neurol 326:159–79.)

Tract tracing studies of white matter pathways in the monkey reveal that axons destined for the pons emanate from a given cortical area in a cord of fibres together with commissural fibres before separating as a distinct subcortical bundle. This subcortical bundle courses in the anterior limb of the internal capsule from prefrontal regions, or the sagittal stratum and/or posterior limb of the internal capsule from posterior regions (see Fig. 29.26). As thalamic fibres separate off from the subcortical bundle, the pontine fibres continue towards the cerebral peduncle. There is a common region through which the corticopontine fibres lead to the basis pontis, that is situated initially in the white matter above the mid-point of the lateral geniculate nucleus and then at the medial aspect of the lateral geniculate nucleus (see Fig. 29.27). These descending fibres demonstrate a certain degree of topographical organization, indicating that the corticopontine system consists of segregated and partially overlapping pathways that are, to some extent, distinguishable anatomically at each stage of their trajectory from origin to destination.

As the corticopontine fibres descend in the cerebral peduncle, they are topographically arranged such that those from prefrontal regions are situated most medially; those from premotor and then motor cortices occupy the middle third of the peduncle, and fibres from the parietal, temporal and occipital regions that are destined for the pons are in the lateral third of the cerebral peduncle. The relative area of the cerebral peduncle that contains fibres derived from the association cortices is larger in humans than in monkeys (as evidenced in comparative anatomy and tractography studies for the prefrontal cortex in particular (Ramnani et al 2006)) (Fig. 29.28), which appears to reflect the phenomenon of evolutionary pressure on interrelated cerebrocerebellar systems.

Within the pons, a given cortical area projects to multiple patches of pontine neurones distributed within both transverse and rostrocaudal dimensions. Some projections are arranged in rostrocaudal columns that further branch and coalesce. Each cerebral area commits fibres to a predictable trajectory in the cerebral white matter and cerebral peduncle, which leads to a unique mosaic of patches of terminations in precisely arranged regions of the basilar pons.

The motor projections are topographically organized, preferentially in the caudal half of the pons, lying close to the traversing corticofugal

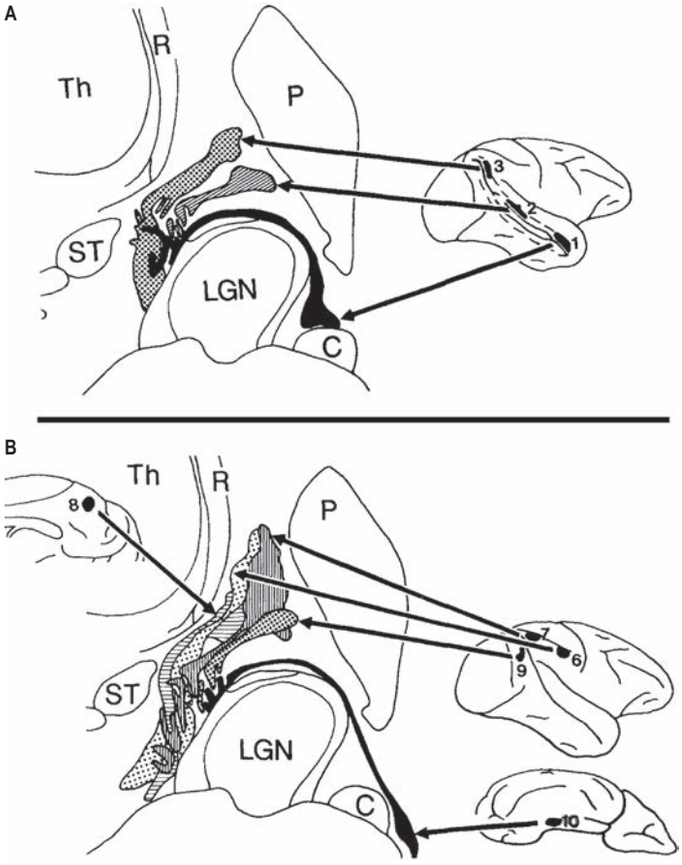

Fig. 29.27 Composite summary diagrams to show the topographic organization of (**A**) the superior temporal sulcus to pontine fibre system and (**B**) the parietal, occipital and posterior parahippocampal corticopontine fibre systems as they descend from the posterior aspect of the internal capsule above the midpoint of the lateral geniculate nucleus into the rostral part of the cerebral peduncle. Abbreviations: C, caudate nucleus; LGN, lateral geniculate nucleus; P, putamen; R, reticular nucleus of thalamus; ST, subthalamic nucleus; Th, thalamus. (With permission from Schmahmann JD, Pandya DN 1992 Course of the fiber pathways to pons from parasensory association areas in the rhesus monkey. J Comp Neurol 326:159–79.)

fibres (Fig. 29.29). In nuclei that receive multiple inputs, the terminations appear to interdigitate. Projections from the face region of the supplementary motor area (SMA) are most medial and include the median pontine nucleus. Projections from the ventral precentral gyrus (M1 face representation) are also medial, but lateral to those from SMA-face. M1 hand projections are in medially placed curved lamellae in the mid and caudal pons. Dorsal trunk projections are in medial and ventral locations, ventral trunk/hip projections encircle the peduncle in the caudal pons, and projections from the foot are heaviest caudally in laterally placed curved lamellae (Schmahmann et al 2004a).

Motor topography is also apparent in the human pons (Fig. 29.30). A topographical map in the human as determined by structure–function correlations in patients with stroke reveals that facial movement and articulation are localized to the rostral and medial basilar pons; hand coordination and dexterity are medial and ventral in rostral and midpons; arm coordination is represented ventral and lateral to the hand; leg coordination is in the caudal half of the pons, with lateral predominance. Gait is represented in medial and lateral locations throughout the rostral–caudal extent of the pons (Schmahmann et al 2004b).

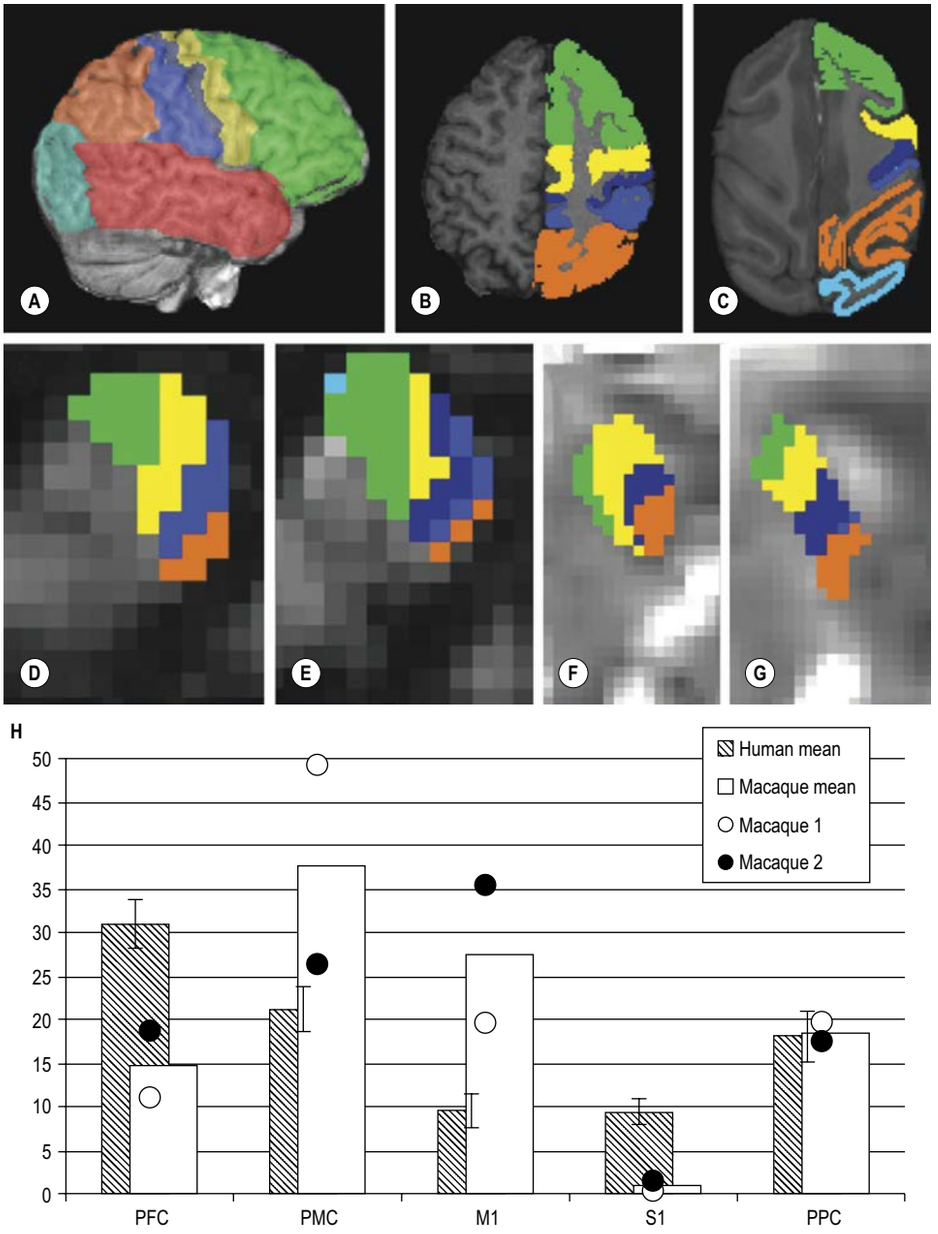

Fig. 29.28 Cerebral cortical origins of cerebral peduncle fibres in human and monkey revealed by diffusion tractography MRI. A schematic illustration of cortical areas used for delineation of projections from the cerebral peduncle in the human brain (3D rendering) (**A**), in axial section (**B**) and in *Macacca mulatta* (**C**; axial section). Anterior–posterior: green, prefrontal cortex (PFC); yellow, premotor cortex (PMC); dark blue, primary motor cortex (M1); light blue, somatosensory cortex (S1 and S2); orange, posterior parietal cortex (PPC); cyan, visual cortex; red, temporal lobe. Parcellation of the right cerebral peduncle using DT-MRI in two representative human cases (**D**, **E**) and two monkey cases (**F**, **G**) showing hard segmentations (coloured according to **A** and **B**) of fibres from cortical areas overlaid on the cerebral peduncles (grey). **H**, The percentage of the cerebral peduncle area occupied by segments of fibres from different cortical areas (y-axis): hatched bars, human cases (left and right averaged); white bars, averaged monkey cases (right hemisphere). Temporal lobe and visual cortex representations were negligible and were not included in the graphs. Fig. 29.31 Composite colour-coded summary diagram illustrating the distribution within the basis pontis of the rhesus monkey of projections derived from association and paralimbic cortices in the prefrontal (purple), posterior parietal (blue), superior temporal (red), and parastriate and parahippocampal regions (orange), and from motor, premotor and supplementary motor areas (green). **A**, Medial (a), lateral (b) and orbital (c) views of the cerebral hemisphere from which the projections are derived. **B**, Plane of section through the pons from which the rostrocaudal levels of the pons I through IX are taken. **C**, Patterns of termination within the nuclei of the basis pontis. Other cerebral areas known to project to the pons are depicted in white. Cortical areas with no pontine projections are shown in yellow (from anterograde and retrograde studies) or grey (from retrograde studies). Dashed lines in the hemisphere diagrams represent sulcal cortices. Dashed lines in the pons diagrams represent pontine nuclei; solid lines depict corticofugal fibres. (With permission from Schmahmann JD 1996 From movement to thought: anatomic substrates of the cerebellar contribution to cognitive processing. Human Brain Mapping 4:174–98 and Schmahmann JD, Pandya DN 1997a The cerebrocerebellar system. In: Schmahmann JD (ed) The cerebellum and cognition. Int Rev Neurobiol 41:31–60.)

There is a dichotomy in the pattern of corticopontine projections according to the dorsal ('where' pathway) versus ventral streams ('what' pathway) of cognitive processing. Dorsal stream areas concerned with visual motion and the peripheral visual field (the dorsal part of the prelunate gyrus, caudal lower bank of the cortex in the superior temporal sulcus, polymodal convergence zones in the lower bank of the cortex in the intraparietal sulcus, and paralimbic parts of the caudal inferior parietal lobule, as well as dorsolateral and dorsomedial prefrontal cortices concerned with spatial features of working memory) have projections to the pons. In contrast, in anatomical studies in monkeys, ventral stream cortices concerned with visual feature discrimination and the central visual field (ventral prelunate gyrus, rostral lower bank of the superior temporal sulcus, middle and inferior temporal gyri, lateral aspects of the posterior parahippocampal gyrus, and ventral prefrontal and orbitofrontal cortices with which these areas are interconnected) do not send projections into the basis pontis. These connections in monkeys suggested that the cerebellum plays a role in spatial awareness, and in attentional, auditory and linguistic functions subserved by the dorsal stream of cognitive processing. However, human imaging studies point to connections with medial and orbital prefrontal cortices, so there may be species differences in the corticopontocerebellar linkage and cerebellar engagement in functions subserved by the ventral stream.

dispersed throughout much of the contralateral hemipons at the same rostrocaudal level as the site of origin. They then regroup to form a concentrated collection before coursing in the middle cerebellar peduncle to enter the cerebellum (Schmahmann et al 2004c) (**Fig. 29.32**).

The general principle of the rostrocaudal reversal in the pontocerebellar projection through the middle cerebellar peduncle was established by von Bechterew (1885) based on myelin stains in developing brain. The caudal pons (more heavily motor) is linked with cerebellar anterior and medial areas, whereas the rostral pons (more heavily associative) is linked with the lateral and caudal cerebellum (see Fig. 29.7B). Divergence and convergence in the corticopontine projection is further complicated by a similar arrangement in the pontocerebellar pathways. Pontine regions project to multiple cerebellar cortical areas; cerebellar areas receive input from a unique complement of neurones distributed throughout multiple pontine nuclei (**Fig. 29.33**). Cerebellar hemispheres receive a relatively greater pontine input than the vermis.

In monkeys, medial parts of the caudal pons project mainly to lobule V in the anterior lobe. The intrapeduncular nucleus projects to vermal lobule VIIIB, the paramedian lobule. These cerebellar regions contain sensorimotor representations of the upper and lower extremities. The dorsolateral pontine region and the reticular nucleus of the pontine tegmentum project to the dorsal paraflocculus, uvula and the vermal visual area. Neurones in the dorsomedial nucleus also project to the vermal visual area. Medial parts of the rostral pons project to crus I, and neurones in the medial, ventral and lateral pons send their axons to crus II.

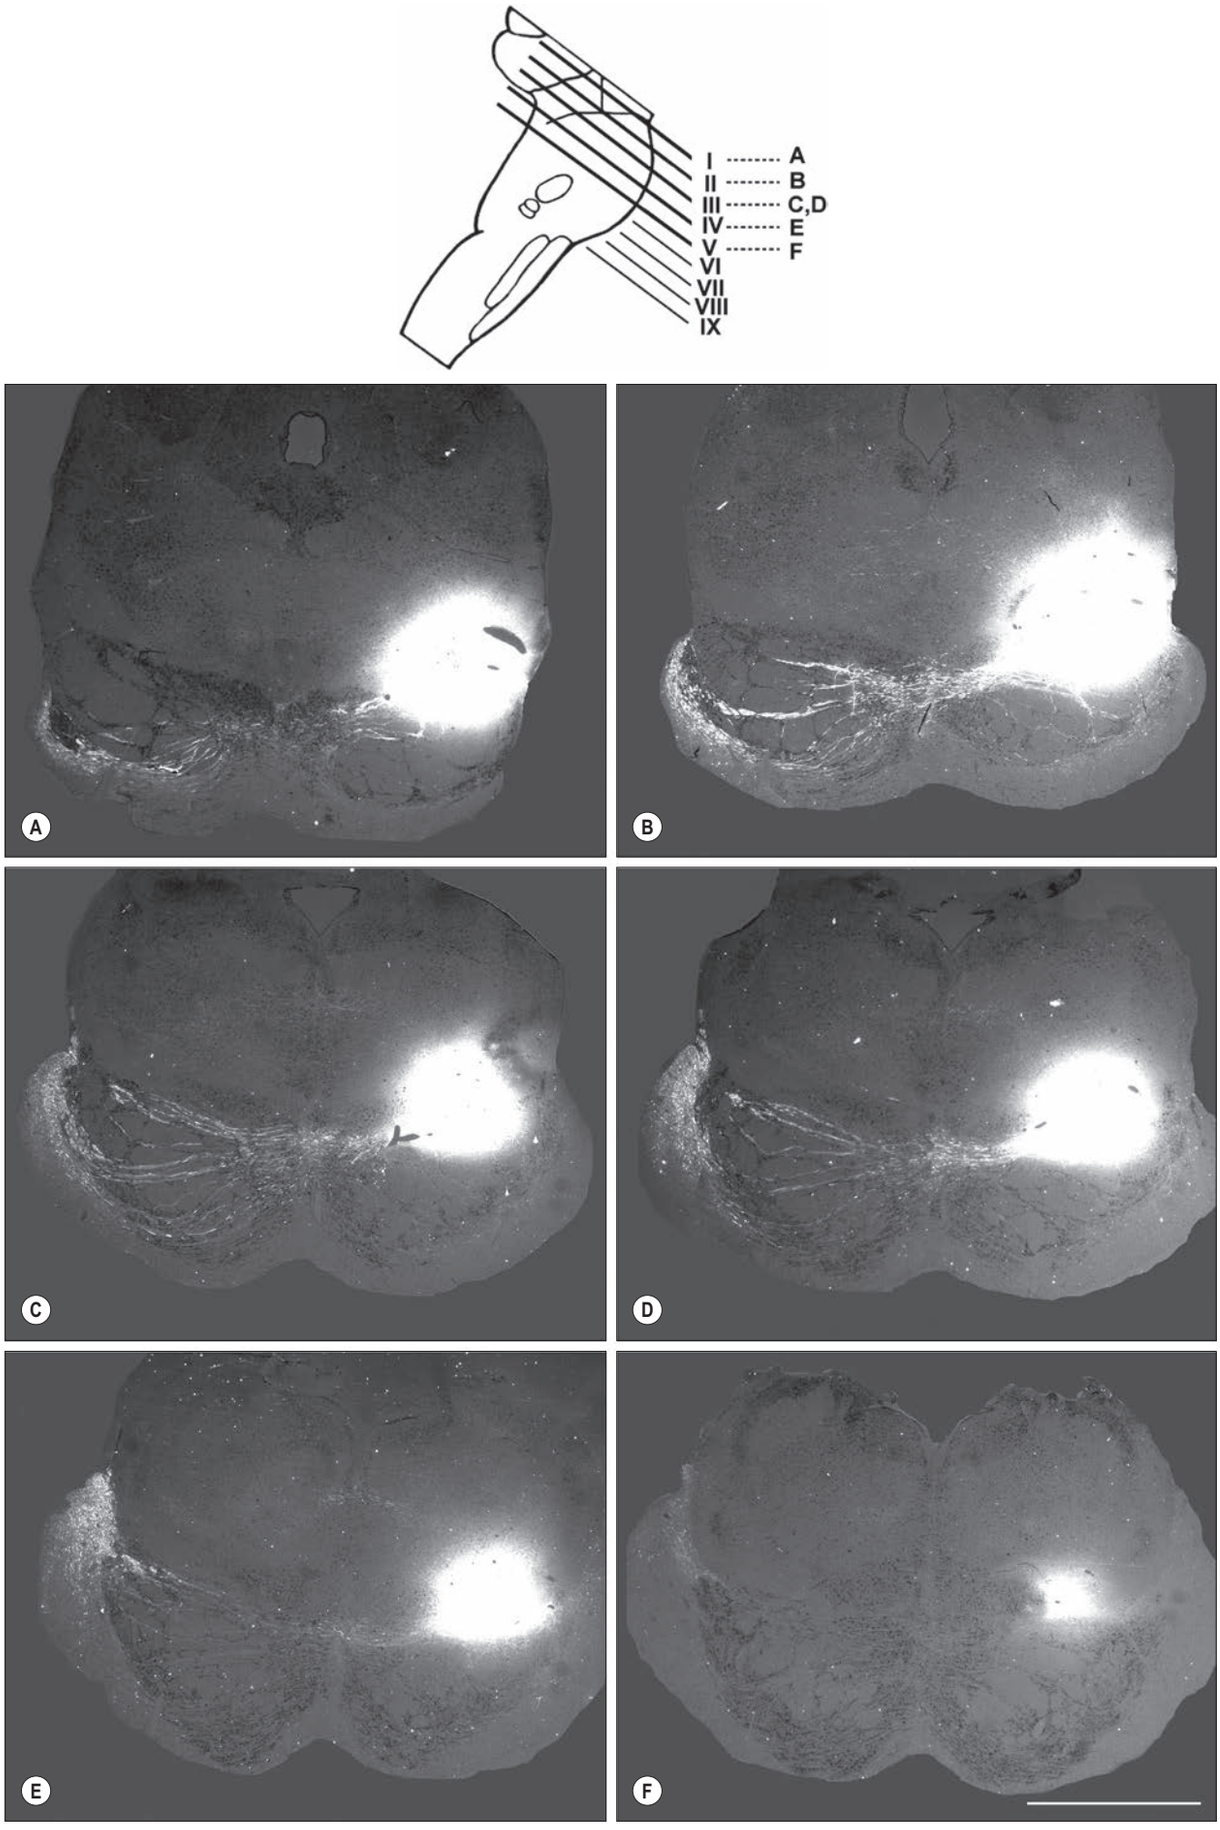
Anatomical and physiological techniques in experimental animal models provide insights into the destination of cerebral cortical afferents in the cerebellum. The anterior lobe (particularly lobules IV and V) and the paramedian lobule (lobule VIII) receive afferents from pericentral motor and sensory cortices; crus I of the ansiform lobule receives inputs from premotor and prefrontal cortices; and crus II is linked with posterior parietal areas. One region of the cerebral cortex is distributed to numerous discrete sites in the cerebellar cortex, and conversely, multiple cerebral cortical areas contribute converging projections to common cerebellar areas. There are reciprocal loops of information processing between cerebral cortex and cerebellum: cerebral areas that project to discrete regions of cerebellum receive information back from those cerebellar areas (see Nieuwenhuys et al 2008, Voogd and Ruigrok 2012, Strick et al 2009, Schmahmann et al 2019 for reviews). See Fig. 29.34 for a simplified version of this projection (Glickstein et al 1985).

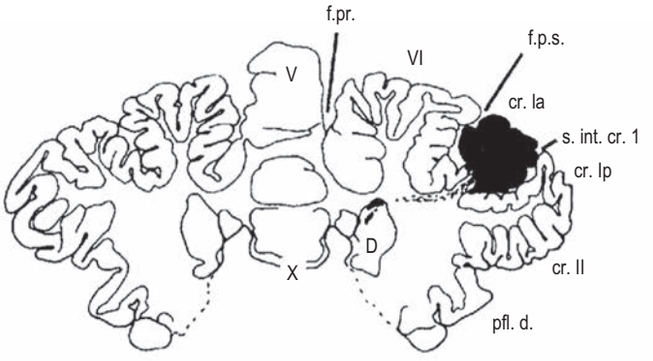
Climbing fibre afferents from the inferior olive

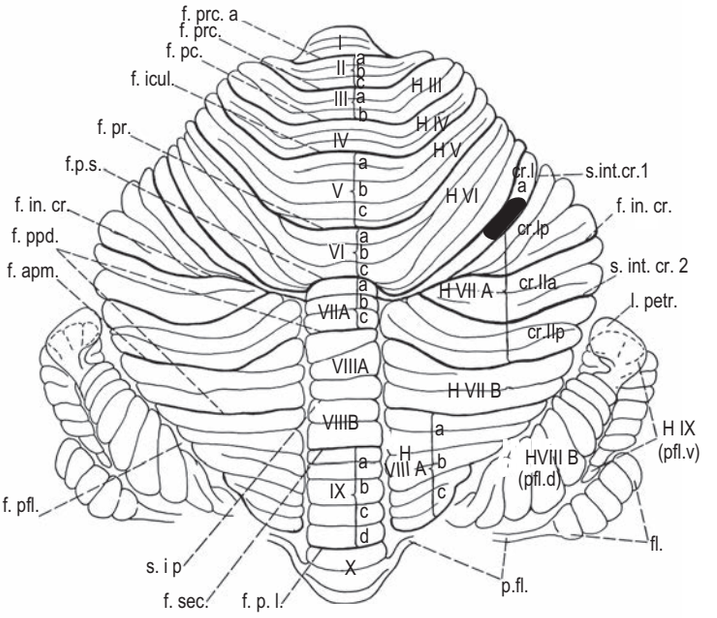
The subdivisions of the inferior olive, the sole source of climbing fibres, are summarized in **Fig. 29.35**. The three major nuclei are the principal olive and the medial and dorsal accessory olivary nuclei. The principal olive has a dorsal lamina, a bend and a ventral lamina with ventrolateral and ventromedial parts. The medial accessory olivary nucleus has rostral and caudal parts: its subnuclei, located dorsomedially, are the group beta (continuous medially with the dorsomedial cell column) and the dorsal cap of Kooy (continuous rostrally with the ventrolateral outgrowth and the ventral lamina of the principal olive). An intermediate portion of the medial accessory olivary nucleus is present in rat and monkey brains. The dorsal accessory olivary nucleus has rostral and caudal parts.

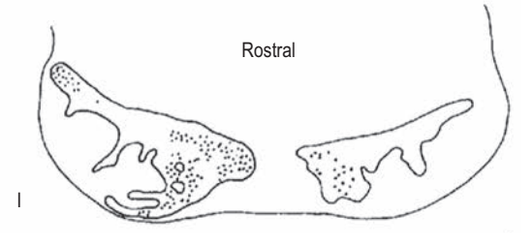
Connectional data for the inferior olivary nuclei, derived from experimental studies in the cat, rat and nonhuman primates, has defined

(B, Adapted with permission from Glickstein M, May JG, 3rd, Mercier BE 1985 Corticopontine projection in the macaque: the distribution of labelled cortical cells after large injections of horseradish peroxidase in the pontine nuclei. J Comp Neurol 235:343–59.)









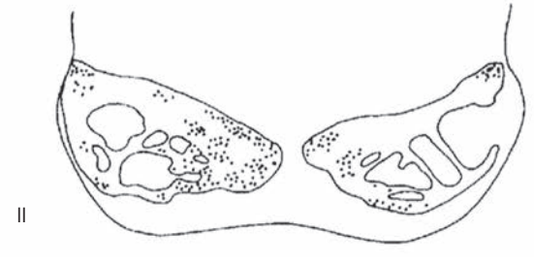


Fig. 29.32 Intrapontine course of pontocerebellar fibres in a rhesus monkey. Dark-field photomicrographs with partial light-field illumination of pontine levels I through V (of nine possible transverse levels according to Nyby and Jansen (1951) and Schmahmann and Pandya (1989)). A schematic view of the lateral aspect of the pons (top) illustrates the levels from which the pontine sections below are derived. The injection site of radiolabelled amino acids is seen in the dorsolateral parts of the peripeduncular nucleus and the dorsolateral nucleus of the basis pontis of *Macaca mulatta*. Pontocerebellar fibres emanate from the injection site and fan out in the contralateral hemipons as they course toward the middle cerebellar peduncle, and into the posterior lobe of the cerebellum (not shown). Pontine level I is seen in **A**, II in **B**, adjacent sections of level III in **C** and **D**, level IV in **E**, and level V in **F**. Magnification ×0.5; bar ×5.0 mm. Fig. 29.33 The distribution of labelled neurones (shown as black dots) in the basilar pons following injection of a tracer substance (wheatgerm agglutinin–horseradish peroxidase (WGA–HRP) shown here in black shading) into crus I anterior of hemisphere lobule VIIA of a rhesus monkey cerebellum. The plane of the transverse section of the cerebellum (top left) showing the injection site is marked on the flattened map of the cerebellum (top right) according to Larsell (1970). The plane of section of the rostrocaudal levels of the pons from I to IX is depicted in the diagram at lower right. Pontine nuclear subdivisions are not shown. Labelled neurones are seen bilaterally in the pons, but with a contralateral predominance. Neurones are distributed in multiple but distinct regions of the basilar pons following the injection in this single folium. This arrangement seems to allow for multiple cerebral cortical areas to communicate with the cerebellar folium via the distributed pontine neurones. Pontine projections to subdivisions of each cerebellar folium are likely to be more restricted. Incidentally noted is anterograde transport of label from the injection site to a restricted site within the dentate nucleus of the ipsilateral cerebellum. Abbreviations: cr. Ia, crus I anterior; cr. different cerebellar zones (see Courville et al 1980, reviewed in Voogd and Ruigrok 2012). The A zone of the cerebellum is located next to the midline and extends over the entire vermis (**Fig. 29.36A**). It is composed of several zebrin-positive and zebrin-negative subzones that may be present over limited segments. Its climbing fibres are derived from the caudal medial accessory olive and it projects to the fastigial and vestibular nuclei. The X and B zones are restricted to the vermis of the anterior lobe and lobules VI and VIII. The X zone is narrow and separates the A zone from the B zone, which occupies the lateral vermis of these lobules. The X zone receives climbing fibres from the intermediate region of the medial accessory olive and projects to the interstitial cell groups located between the fastigial and posterior interposed nuclei. The B zone is innervated by climbing fibres from the caudal part of the dorsal accessory olive and projects to the lateral vestibular nucleus (Deiters' nucleus). The dorsal accessory olive, the B zone and the lateral vestibular nucleus are somatotopically organized. In the B zone, the hindlimb is represented laterally and the forelimb is represented medially (Andersson and Oscarsson 1978). In rodents, Purkinje cells of the X and B zones are zebrin-negative.

The cerebellar hemisphere is composed of the C1–C3 and the D1, Y and D2 zones (see Fig. 29.36). Like the X and B zones, C1, C3 and the Y zone are restricted to the anterior lobe, the simplex lobule (HVI) and the paramedian lobule (HVIIB, the gracile lobule and HVIII, the biventral lobule). The Purkinje cells of these zones are zebrin-negative and thus appear as blank spaces in suitably immunostained histological sections of the anterior and posterior cerebellum (see Fig. 29.36E). The C1, C3 and Y zones project to the emboliform nucleus and receive their climbing fibre input from the rostral dorsal accessory olive. This subnucleus receives input from peripheral receptors through dorsal column and trigeminal pathways. The climbing fibre projections of the rostral dorsal accessory olive to the C1, C3 and Y zones and the emboliform nucleus are somatotopically organized. In each of the zones, the hindlimb is represented rostrally in the anterior cerebellum and caudally in the posterior lobe; the forelimb and face occupy more central areas (Ekerot and Larson 1979a, 1979b) (**Fig. 29.37**). This rostrocaudal distribution clearly differs from the mediolateral somatotopy in the vermal B zone. The somatotopical localization is extremely detailed, repeated in each of the zones. The C1, C3 and Y zones connect with motor centres in the brainstem and the cerebral cortex. The hemisphere of the anterior lobe, adjacent part of lobule VI, and lobule VIII are considered as the motor regions of the cerebellum. The C2, D1 and D2 zones extend beyond the anterior and posterior motor regions, where they interdigitate with the C1, C3 and Y zones over most of the rostrocaudal length of the cerebellum. In rodents, these zones are zebrin-positive.

The C2 zone receives its climbing fibre input from the rostral medial accessory olive and projects to the posterior interposed nucleus (**Fig. 29.38**). Somatotopical organization is lacking in the C2 zone. The D1 zone receives its climbing fibres from the ventral lamina of the principal olive and projects to the caudal dentate; the D2 zone receives its climbing fibres from the dorsal lamina of the principal olive and projects to the rostral dentate. The main connections of the C2 and the D zones are with the cerebral cortex. Sections of the C2 zone and the somatotopically organized part of the D2 zone located in the anterior and posterior motor regions of the cerebellar hemisphere are connected with motor, premotor and parietal cortical areas. Sections of the C2 and the D zones located in hemispheric lobules VII (lobule VIIA crus I, lobule VIIA crus II, and lobule VIIB) and lobule IX subserve visuomotor and a wide range of cognitive functions.

The modular organization of the vestibulocerebellum includes multiple Purkinje cell zones, innervated by climbing fibres from subnuclei in the inferior olive that transmit optokinetic and vestibular information. There are five Purkinje cell zones in the cortex of the flocculus and the adjacent ventral paraflocculus (**Fig. 29.39**; see Fig. 29.23).

Efferent connections of the cerebellar nuclei

The connections of the cerebellar nuclei with the brainstem, thalamus and spinal cord determine the sphere of influence of the cerebellar modules. The A, X, B and D zones project to the fastigial nucleus, the interstitial cell groups, the lateral vestibular nucleus and dentate nucleus respectively (see Fig. 29.36).

Fastigial nucleus

The uncinate tract is the major efferent pathway from the caudal part of the fastigial nucleus (see Fig. 29.39). Its fibres cross in the rostral part of the cerebellar commissure, pass dorsal to the superior cerebellar peduncle, enter the contralateral medial, superior and inferior vestibular nuclei laterally, traverse the nuclei and terminate in the medial reticular formation. Direct, uncrossed, fastigiobulbar fibres from the rostral part of the fastigial nucleus enter the vestibular nuclei medially via the juxtarestiform body (which passes along the lateral margin of the fourth ventricle); their termination in the reticular formation mirrors the termination of the uncinate tract (Batton et al 1977). The distribution of the fibres of the uncinate tract and the direct fastigiobulbar fibres is bilateral, but with a contralateral preponderance. Some crossed fibres can be traced caudally into the spinal cord.

The fastigial nucleus projects bilaterally to several subcortical motor centres from which descending brainstem pathways arise. This enables each hemivermis to influence different functional systems, including the medial and spinal vestibular nuclei and the medial bulbar reticular formation (which gives rise to the bilaterally descending medial reticulospinal tracts). Through these pathways the A zone of the vermis exerts a bilateral influence on ventromedially located spinal interneurones and motor neurones that innervate axial, truncal and proximal limb muscles (Kuypers' medial motor system) (Lawrence and Kuypers 1968a, 1968b, Lemon et al 2012). Fibres of the uncinate tract that descend as far as the cervical cord terminate on the same neurones. The termination in the ventrolateral spinal nucleus is medial with respect to the projections of the dentate and interposed nuclei. The fastigial nucleus therefore influences motor centres in the brainstem that exert control bilaterally over the medial motor system of the spinal cord.

The caudal pole of the fastigial nucleus receives its Purkinje cell afferents from vermal visual areas in lobule VII that are involved in the long-term adaptation of saccades. Fastigial oculomotor projections are crossed and terminate in the rostral mesencephalic and pontine reticular formation that contains the horizontal gaze centre (paramedian pontine reticular formation), the vertical gaze centre (rostral interstitial nucleus of the medial longitudinal fasciculus), deep layers of the superior colliculus (bilaterally) and thalamic nuclei that probably include the frontal and parietal eye fields as their targets (Noda et al 1990).

Cerebellar influences on visceromotor systems are mediated by the projections of the fastigial nucleus to the parasolitary nucleus, a region bordering on the viscerosensory nuclei of the solitary tract; the dorsal visceromotor nucleus of the vagus nerve; central grey, serotoninergic raphe nuclei; and the noradrenergic nucleus of the locus coeruleus. The

In addition to the C2 zone located most medially in the flocculus and adjacent ventral paraflocculus, two pairs of zones occupy its lateral portion. Zones F1 and F3 connect with the oculomotor neurones in the vestibular nuclei that subserve the anterior canal vestibulo-ocular reflex (Fig. 29.40). The F2 and F4 zones connect with oculomotor neurones that subserve the horizontal canal vestibulo-ocular reflex. The flocculus and ventral paraflocculus receive vestibular mossy fibre input, relaying an efferent copy of the output of the vestibulo-oculomotor neurones. They also receive climbing fibre input, signalling retinal slip that occurs when the stabilization of the retina by the vestibulo-ocular reflex is incomplete. Retinal slip is perceived by two groups of neurones in the mesencephalon. In the horizontal plane, it is relayed by the nucleus of the optic tract. This nucleus, located in the pretectum, receives fibres of the contralateral optic nerve via the optic tract and projects to the dorsal cap of the inferior olive, located dorsomedial to the caudal medial accessory olive (see Fig. 29.35). The dorsal cap provides the F2 and F4 zones with climbing fibres. Retinal slip in the plane of the anterior canal is conveyed by the lateral and medial nuclei of the accessory system, part of a group of nuclei located on the periphery of the rostral mesencephalon that receive optic nerve fibres from the accessory optic tract (an offshoot of the optic nerve). These nuclei project to the ventrolateral outgrowth of the inferior olive, located immediately rostral to the dorsal cap (see Fig. 29.35). The ventrolateral outgrowth innervates the F1 and F3 zones. Repeated simultaneous activation of the vestibular mossy fibre-parallel fibre input and the climbing fibres, relaying retinal slip, induces plastic changes in the Purkinje cell output that compensates for the retinal slip. Combinations of the horizontal and anterior canal systems ensure compensation of retinal slip in all possible planes. Knowledge of this system has been instrumental in the concept that climbing fibres are carriers of error signals used in cerebellar learning (Marr 1969, Ito 1982).

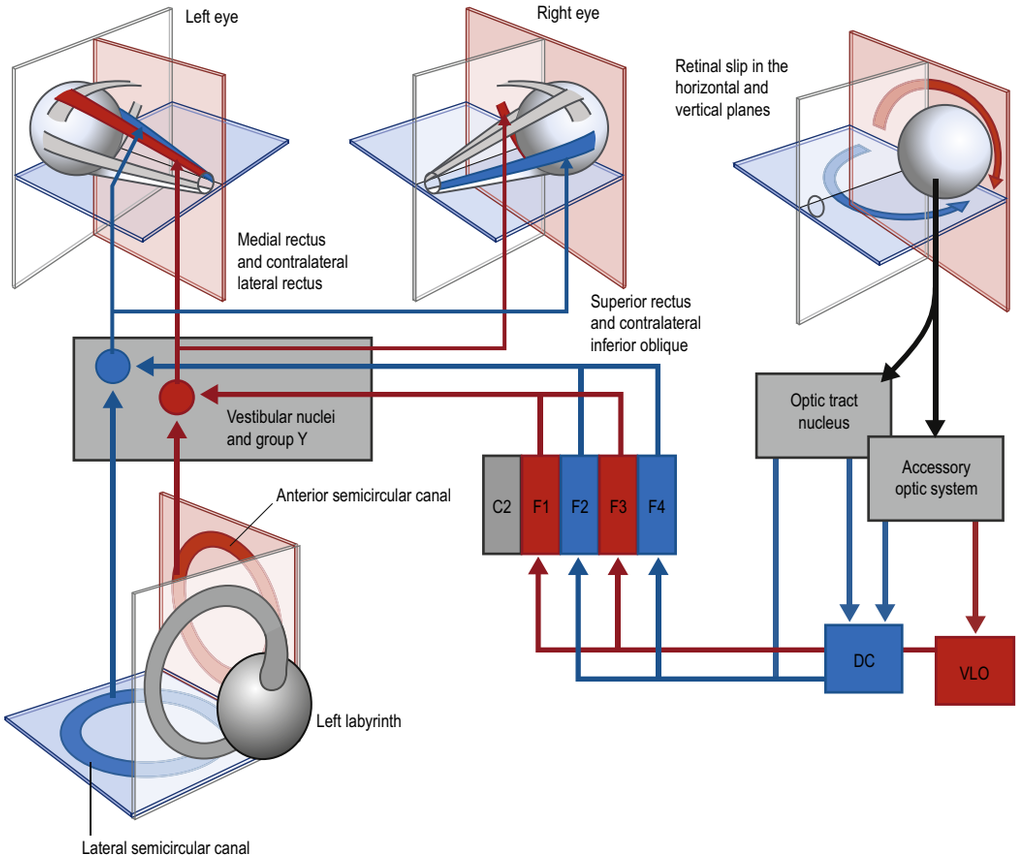

Fig. 29.40 The circuitry used by the flocculus in long-term adaptation of the vestibulo-ocular reflex (VOR). The system is organized in the planes of the semicircular canals. For an explanation, see the text. Abbreviations: C2, C2 Purkinje cell zone; DC, dorsal cap; F1–F4, floccular Purkinje cell zones F1–F4; VLO, ventrolateral outgrowth. Fig. 29.36 The connections of the Purkinje cell zones of the mammalian cerebellum. **A**, The flattened cerebellar cortex. **B**, Target nuclei of Purkinje cells. **C**, Sources of climbing fibres associated with Purkinje cells, shown in the flattened contralateral inferior olive (see Fig. 29.35) and indicated in the same colour. **D**, Zebrin-positive and zebrin-negative Purkinje cell bands. The zebrin-positive bands are numbered from 1 to 7. A comparison with panel **A** shows that the A zone is a composite of zebrin-positive and zebrin-negative subzones; the X, B, C1, C3 and Y zones consist of zebrin-negative Purkinje cells. **E**, The zebrin-positive and zebrin-negative bands of the cerebellum of a rat. Abbreviations: A–D2, Purkinje cell zones A–D2; ANS, ansiform lobule; Beta, group beta; DAOc/r, caudal/rostral dorsal accessory olive; Dc, dorsal cap; Dmcc, dorsomedial cell column; Fast, fastigial nucleus; ICG, interstitial cell groups; M, midline; MAOc/int/r, caudal/intermediate/rostral medial accessory olive; PMD, paramedian lobule; POdL, dorsal lamina of the principal olive; POvL, ventral lamina of the inferior olive; PY, pyramis (lobule VIII); UV, uvula (lobule IX); VII, vermal lobule VII; VLO, ventrolateral outgrowth.

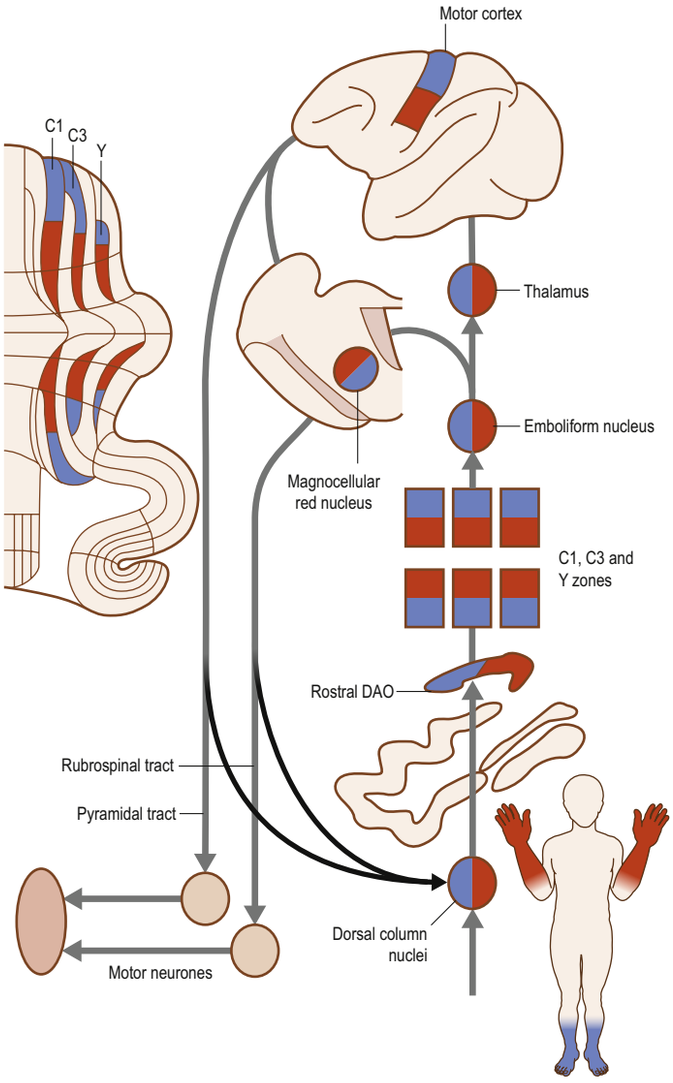

Fig. 29.37 The connections of the emboliform (anterior interposed) nucleus. The entire system is somatotopically organized: this organization is more detailed than indicated in the diagram. Abbreviations: DAO, dorsal accessory olive.

fastigial nucleus also influences visceromotor systems via projections of the vestibular nuclei and connections with the catecholaminergic nuclei of the brainstem and the hypothalamus (Zhu et al 2006).

Some fastigial nuclear fibres ascend along the superior cerebellar peduncle, separate from the peduncle at its decussation, and are distributed to the dorsal tegmentum, including the deep and intermediate layers of the nucleus of the tractus solitarius, the parabrachial nucleus, deep layers of the superior colliculus and intercollicular region, pretectal area, periaqueductal grey, interpeduncular nucleus and nuclei of the posterior commissure. The fastigial nucleus also projects to the ventral tegmental area, which sends a widespread dopaminergic innervation to the cerebral hemispheres: this fastigial projection has been shown to influence social cognition in a rodent model (Carta et al 2019). In the thalamus, fibres terminate in the contralateral internal medullary lamina, the intralaminar nuclei (paraventricular, paracentral, centromedian, parafascicular and central lateral), medial dorsal, ventrolateral and ventromedial thalamic nuclei. Ipsilateral projections recross in the commissure of the superior colliculus, the posterior commissure and the massa intermedia. The contralateral hypothalamus receives fastigial projections in the lateral, posterior and dorsal hypothalamic areas and the dorsomedial and paraventricular nuclei. These fastigial influences on autonomic and limbic circuits in the hypothalamus and thalamus are relevant when considering the cerebellar vermis and fastigial nucleus as nodes in limbic circuitry (Haines et al 1997, Schmahmann 1991, 2000).

Recurrent circuits involving the fastigial nucleus include excitatory efferents to the reticulotegmental nucleus and the GABAergic nucleo-olivary projection to the contralateral caudal medial accessory olive. The direct fastigiobulbar tract is an inhibitory, glycinergic system (Bagnall et al 2009).

Interstitial cell groups

The projections of the interstitial cell groups located between the fastigial and posterior interposed nuclei, the target nucleus of the X module, are directed to the vestibular nuclei, reticular formation, red nucleus and thalamus. They provide collaterals also to the spinal cord and superior colliculus (Bentivoglio and Kuypers 1982).

Lateral vestibular nucleus (Deiters' nucleus)

The lateral vestibular nucleus (Deiters' nucleus) is the target nucleus of the lateral vermal B zone. Despite its location outside the cerebellum, it might be better considered as one of the cerebellar nuclei because, unlike the other vestibular nuclei, it does not receive primary inputs from the labyrinth, but, like the deep cerebellar nuclei, it receives collateral innervation from the climbing fibres that innervate the B zone and it sends nucleo-olivary projections to the caudal dorsal accessory olive. The lateral vestibular nucleus gives rise to the lateral vestibulospinal tract. Through its projection to the lateral vestibular nucleus, the B zone, like the A zone, exerts an influence on ipsilateral interneurones and motor neurones in the anterior horn of the spinal cord that innervate axial, truncal and proximal limb muscles (Kuypers' medial motor system).

The zones of the cerebellar vermis affect neurotransmission in the vestibulospinal and reticulospinal systems, controlling bilateral postural and vestibular reflexes of the axial and proximal musculature, and the oculomotor centres in the brainstem. The skeletomotor functions are located in the anterior vermis and posterior lobule VIII (the X and B zones are restricted to these lobules), and oculomotor functions are in lobule VII. Most caudally, lobule X (nodulus) belongs to the vestibulocerebellum and is considered below. Other functions, such as vegetative regulation, are subserved by the vermis but have not been studied in detail.

Emboliform (anterior interposed) nucleus

Climbing fibres innervating the C1, C3 and Y zones and the emboliform (anterior interposed) nucleus originate in the rostral half of the dorsal accessory olive. The latter receives somatotopically organized cutaneous input mainly through the dorsal column and trigeminal nuclei and contains a refined cutaneous map of the entire contralateral body surface (Gellman et al 1983). The corticospinal and rubrospinal tracts provide the dorsal column nuclei with collateral innervation.

The emboliform nucleus is the target of the C1, C3 and Y zones. The detailed somatotopic organization of these Purkinje cell zones is maintained in the nucleus, where Purkinje cells of different zones, but with the same climbing fibre input from a particular region of the body, project to a common set of neurones (see Fig. 29.37). Ascending axons from the anterior interposed nucleus enter the brachium conjunctivum, which decussates at the border of the pons and the mesencephalon. The ascending branch enters and surrounds the caudal half of the magnocellular red nucleus, then proceeds to terminate in the ventrolateral and ventral anterior nuclei of thalamus, which are linked with the contralateral primary motor and premotor cortices. The descending branch of the brachium conjunctivum terminates in the reticulotegmental nucleus. The entire system, including the magnocellular red nucleus and the primary motor cortex and their efferent tracts, is somatotopically organized. The reciprocal nucleo-olivary pathway from the emboliform nucleus terminates in the rostral half of the dorsal accessory olive: the emboliform nucleus does not participate in the recurrent cerebello–mesencephalon–olivary circuits.

The motor cortex and the caudal, magnocellular part of the red nucleus give rise to the two main descending motor systems: the corticospinal (pyramidal) tract that crosses the midline in the caudal medulla at the bulbospinal junction, and the rubrospinal tract that crosses the midline at its level of origin in the midbrain. The corticospinal tract provides the magnocellular red nucleus with collateral innervation. Both tracts terminate on laterally located spinal interneurones and motor neurones that innervate distal limb muscles. Control of the ipsilateral limbs by the pars intermedia of the spinal cord grey is therefore effected by the emboliform nucleus through two different pathways, the rubrospinal and the corticospinal tracts, which converge upon the same interneurones and motor neurones. During primate evolution, the corticospinal system increases in prominence at the cost of the rubrospinal system, which comes to occupy a subsidiary position in the human brain.

The role of the cerebellum in the motor system is closely allied to the circuitry of the C1, C3 and Y zones, and to the emboliform nucleus and its output systems. The double decussation of the brachium conjunctivum and the rubrospinal and corticospinal tracts is responsible for the clinical observation that lesions of the cerebellum affect the ipsilateral half of the body.

Globose (posterior interposed) nucleus

The globose (posterior interposed) nucleus is reciprocally interconnected with the contralateral rostral medial accessory olive. Its projections ascend and decussate in the superior cerebellar peduncle and terminate in a group of nuclei at the meso-diencephalic junction that includes the parvocellular red nucleus and the nucleus of Darkschewitsch in the central grey, the superior colliculus and thalamic nuclei that project to motor and premotor cortical areas (see Fig. 29.38). The nuclei at the meso-diencephalic junction give rise to ipsilaterally descending tegmental tracts that also terminate in the rostral half of the medial accessory olive, forming reciprocally organized loops.

The nucleus of Darkschewitsch is in a reciprocal loop by way of its fibres descending through the medial tegmental tract to the rostral medial accessory olive, which sends climbing fibres to the C2 zone and the globose nucleus. Motor and visual divisions can be distinguished in this system: the segments of the C2 zone located in the anterior and

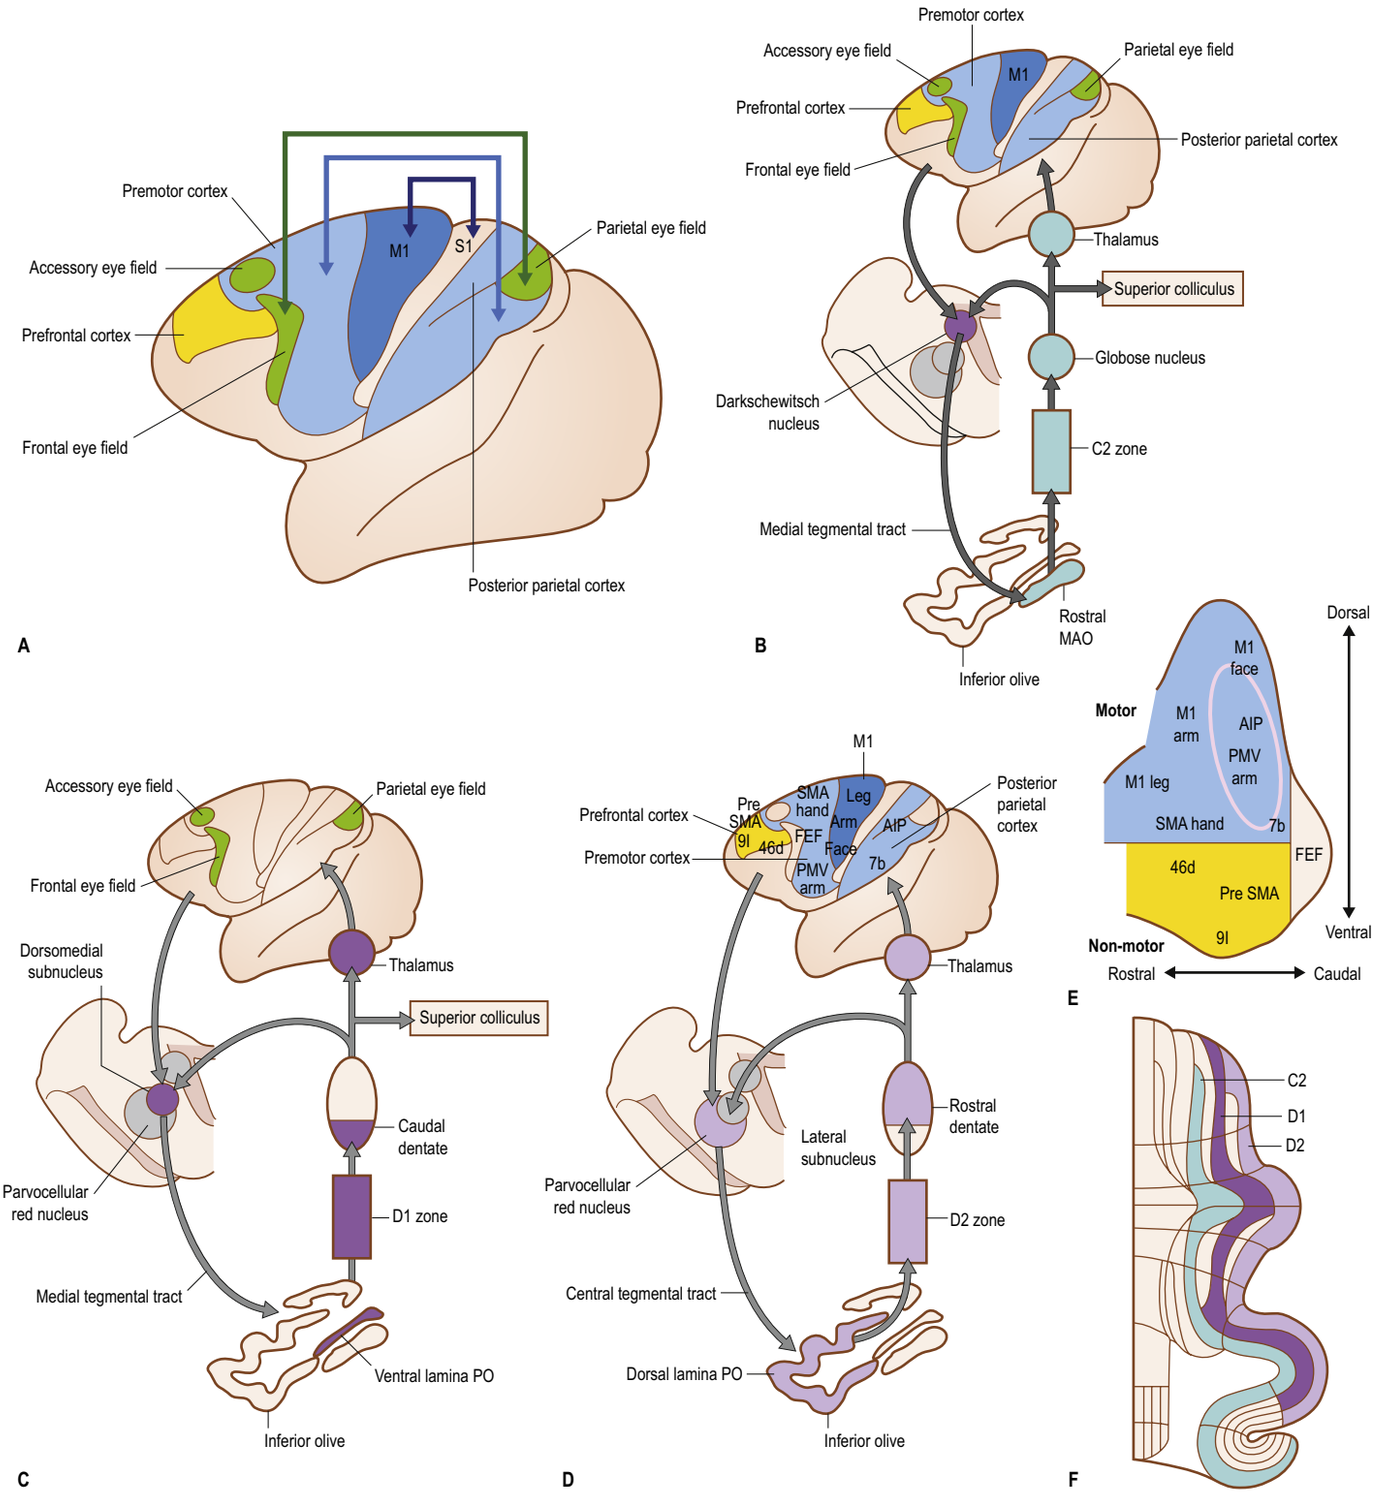

Fig. 29.38 **A**, Cortical areas targeted by the cerebellothalamic pathways of the posterior interposed and dentate nuclei. The primary motor area (M1) with the primary sensory area (S1), the premotor cortex with the posterior parietal areas and the frontal and parietal eye fields constitute interconnected networks. **B**, The connections of the globose (posterior interposed) nucleus. **C**, The connections of the caudal pole of the dentate nucleus. **D**, The connections of the rostral dentate nucleus. **E**, The subdivision of the rostral dentate into rostral motor and caudal non-motor divisions, showing the location of neurones retrogradely labelled from injection sites indicated in the diagram of the cerebral cortex in **D**. **F**, The flattened cerebellar cortex showing localization of the C2, D1 and D2 zones. Fig. 29.41 A lithograph of a transverse section through the pons, showing the localization of the central tegmental tract in the pontine tegmentum. Abbreviation: NRTP, nucleus reticularis tegmenti pontis (reticulotegmental nucleus). (Reproduced from Stilling B 1846 Untersuchungen über den Bau und die Verrichtungen des Gehirns. I. Über den Bau des Hirnknotens oder der Varolischen Brücke. Jena, Druck und Verlag von Friedrich Make.)

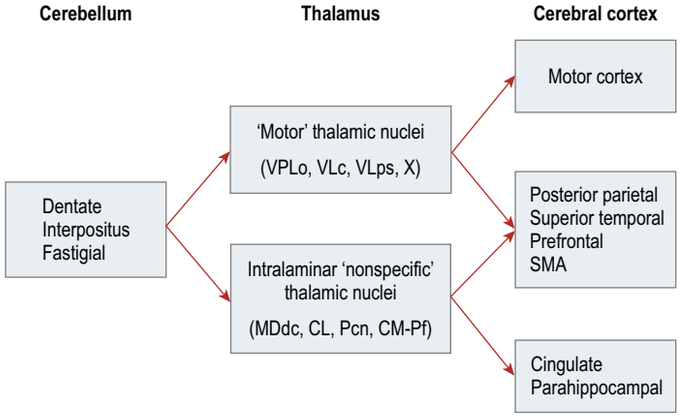

Fig. 29.42 Diagram of the cerebello-thalamo-cortical pathways. Traditionally motor cerebellar-recipient thalamic nuclei (VPLo, VLc, VLps and X) project to motor and premotor cortex, as well as to supplementary motor area (SMA), prefrontal (areas 8 and 46), posterior parietal (superior and inferior parietal lobules) and multimodal temporal regions (area TPO in the upper bank of the superior temporal sulcus). Intralaminar (CL, Pcn, CM-Pf) and medial dorsal (MDdc) thalamic nuclei that receive cerebellar input project in turn to association, limbic and motor cortices. Abbreviations of thalamic nuclei: CL, centralis lateralis; CM, centromedian; MDdc, medial dorsal nucelus, pars densocellularis; Pcn, paracentralis; Pf, parafascicularis; VLc, ventral lateral, pars caudalis; VPLo, ventral lateral, pars oralis; VLps, ventral lateral, pars postrema; X, nucleus. (Thalamic nuclei according to Olszewski 1952. With permission from Schmahmann JD 1996 From movement to thought: anatomic substrates of the cerebellar contribution to cognitive processing. Human Brain Mapping 4:174–98.)

The cerebral cortical projections of the classic cerebellar recipient motor thalamic nuclei (pars oralis of the ventral posterolateral nucleus, VPLo, the caudal and pars postrema aspects of the ventrolateral nucleus, VLc and VLps, and nucleus X) are not confined to the motor region (**Fig. 29.42**). The upper bank of the superior temporal sulcus receives projections from the VLc and VLps nuclei; widespread regions of the posterior parietal cortex receives projections from the VLps nucleus, and the VLc projections to the parietal lobe are similar although less intense; nucleus X projects to both the upper and lower banks of the intraparietal sulcus; VPLo projects to both the gyral and sulcal cortices of the superior parietal lobule at the lateral convexity of the hemisphere. Further, in the frontal lobe, the prefrontal periarcuate areas are reciprocally interconnected with nucleus X, and with the VLc, and VPLo nuclei.

The cerebellar outflow is also directed to the medial dorsal thalamic nucleus in its paralaminar parts, the laterally situated pars multiformis and the more caudal pars densocellularis. These nuclei have reciprocal connections with the prefrontal cortex in area 8, area 46 at both banks of the principal sulcus, and area 9, as well as with the cingulate gyrus, posterior parietal cortex, and multimodal parts of the superior temporal sulcus. In addition, nonmotor thalamic nuclei, including the intralaminar nuclei, receive major cerebellar projections, particularly centralis lateralis (CL), as well as the paracentralis (Pcn) and centromedian-parafascicular (CM-Pf) complex. The CL nucleus, like other intralaminar nuclei, has widespread cortical connections including the posterior parietal cortex, the multimodal regions of the upper bank of the superior temporal sulcus, the prefrontal cortex, the cingulate gyrus, and the primary motor cortex. Pcn nucleus projections include the parahippocampal gyrus. These thalamic projections to higher order association areas originate not only in the dentate nucleus but also from parts of the interposed and fastigial nuclei (see Schmahmann 1996).

The understanding of the zonal organization of the connections of the inferior olive and the cerebellar nuclei is derived from studies in lower mammals, but knowledge of the connections of the cerebellar hemispheres that account for the bulk of the cerebellar cortex in the great apes and human remains incomplete. The demonstration by Fujita et al (2010) of the presence of D1 and D2 zones in the marmoset hemisphere supports the idea that the construction of the primate hemisphere is similar to that in rodents and carnivores, but the relative proportions of the marmoset hemisphere are not very different from rodents. The source of the climbing fibre projection to the D1 zone in rodents and primates is the ventral, non-convoluted lamina of the principal olive. Although the ventral lamina of the principal olive is prominent in lower mammals, if this subdivision is represented in the human inferior olive by its medial lamina, the contribution of the human D1 zone to the hemisphere would be very small (see **Fig. 29.35**). Its major output would be represented by the D2 zone, and projections to the convoluted dentate nucleus.

Explanations for the evolutionary increase in size of the dentate nucleus and its connections include the increasing complexity of the cortical motor system, which is a major target of the dentate nucleus, as multiple, interconnected premotor and posterior parietal areas involved in the preparation of movement converge on the primary motor cortex. However, converging lines of evidence from numerous avenues of investigation suggest that the increased size of the dentate nucleus and its interconnected cerebellar posterior lobe lateral hemispheres reflect increased connectivity with cerebral association and paralimbic areas that subserve non-motor functions, enabling a cerebellar role in the modulation of intellect and emotion (Leiner et al 1986, Schmahmann 1991, 1996, 1997, Middleton and Strick 1994, Stoodley and Schmahmann 2009a, 2010, Strick et al 2009, Schmahmann et al 2019). Trans-synaptic viral tracer studies in monkeys further reveal that cerebellar circuits have disynaptic linkage with the subthalamic nucleus, providing evidence for cerebellar-basal ganglia communication in both the motor and nonmotor domains (Hoshi et al 2005).

Geographically distant areas of the cerebral cortex that are functionally coupled form intrinsic connectivity networks that subserve specific functions and can be studied with resting state functional connectivity MRI (rsfcMRI) (Habas et al 2009, Krienen and Buckner 2009, O'Reilly et al 2010, Buckner et al 2011). These cerebral networks map onto the cerebellum with topographic specificity and some degree of inter-individual variability. The motor networks map onto sensorimotor parts of the cerebellum in the anterior lobe and lobule VIII. The dorsal attention, ventral attention, frontoparietal, default mode and salience networks map onto focal areas within the posterior lobe of the cerebellum (**Fig. 29.43**). Among all the networks, the frontoparietal network for adaptive control is overrepresented in the cerebellum compared to the cerebral cortex (Marek et al 2018).

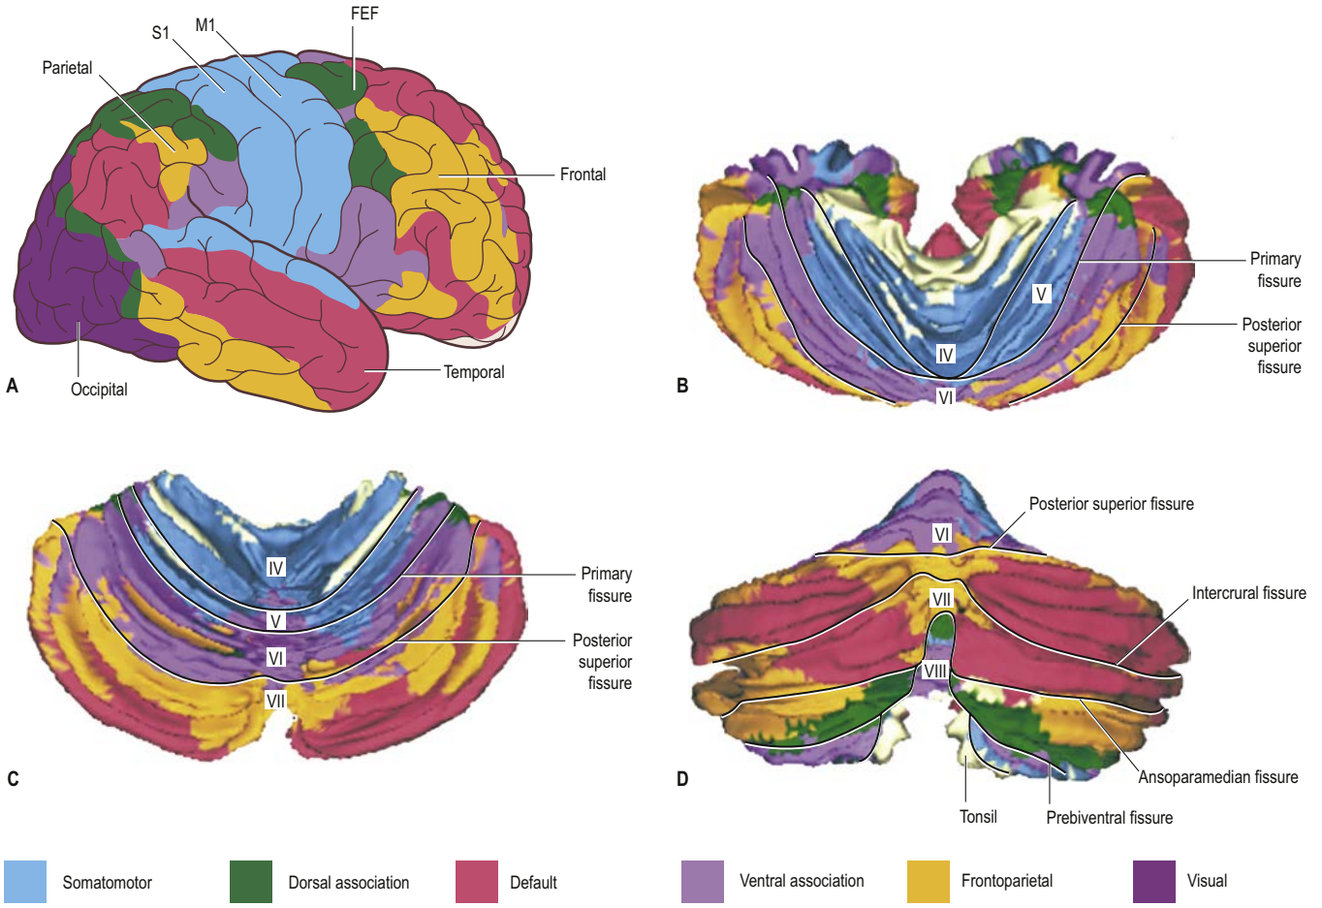

Fig. 29.43 A map of the topographical correlations between remote, functionally coupled regions in the human cerebral cortex and the cerebellum using resting state functional connectivity fMRI. **A**, Networks distinguished in the cerebral cortex. **B**, An anterior superior oblique view of the human cerebellum showing regions that are functionally coupled to the different cerebral networks. **C**, A dorsal view of the human cerebellum. **D**, A caudal view of the human cerebellum. Abbreviation: FEF, frontal eye field. J Neurophysiol 106:2322–45.)

posterior motor regions of the cerebellum and the rostromedial globose nucleus receive input from the motor cortex, whereas visual and prefrontal input dominates in segments located in hemispheric lobules VII, IX (paraflocculus) and X (flocculus).

Dentate (lateral) nucleus

The shape of the dentate nucleus and the principal olivary nucleus change through evolution from compact nuclei to intricately folded sheets. In humans, the dentate nucleus has a rostromedial, microgyric, large-celled region, and a ventrocaudal, macrogyric, small-celled region (Dow 1974) (see Fig. 29.8). This corresponds to similar observations in monkeys, where the dentate consists of a rostromedial sector that is motor related, and a ventrocaudal component linked with nonmotor brain areas (Strick et al 2009) (see Fig. 29.38). The main projections from the dentate nucleus include the contralateral parvocellular red nucleus and thalamus. Group Y, a cell group located ventral to the dentate nucleus located within the floccular peduncle, projects to the contralateral oculomotor nucleus

The rostral dentate in lower mammals is the target of the D2 zone. Its dentate-olivary connections are with the dorsal lamina of the principal olivary nucleus. The rostral dentate receives projections from motor regions of the cerebellum and is somatotopically organized: the hindlimb is represented rostrally, then the arm and the face more caudally. It projects to the ventral, central and dorsolateral parts of the parvocellular red nucleus. Its thalamic targets are in the ventral intermediate and ventrolateral thalamic nuclei, which are reciprocally connected with the motor and premotor cortices (see Fig. 29.38D–E). Retrograde and transneuronal labelling reveals that the rostrodorsal dentate sends its efferents via the thalamus to the primary motor cortex (Wiesendanger and Wiesendanger 1985, Orioli and Strick 1989, Hoover and Strick 1999, Lu et al 2007), ventral premotor area (Orioli and Strick 1989), caudal part of the dorsal premotor area (Hashimoto et al 2010) and supplementary motor area (SMA proper) (Sakai et al 1999, Akkal et al 2007). Anterior and medial parietal areas also receive projections via the thalamus from the rostromedial dentate nucleus. The rostral dentate nucleus sends descending projections via the brachium conjunctivum to the reticulotegmental nucleus.

The caudal dentate is the target nucleus of the D1 zone, and its projections terminate in the ventral lamina of the principal olive. It receives its corticonuclear projections from lobule VII (hemispheric extensions of lobule VIIA as crus I and crus II, as well as lobule VIIB) and from lobule IX (paraflocculus/tonsil). The ventrocaudal dentate projects to the dorsomedial part of the parvocellular red nucleus. In the thalamus, it targets the medial parts of the ventrolateral thalamic nucleus, area X (Chan-Palay 1977), the parvo- and magnocellular anterior nucleus, and the lateral rim of the mediodorsal nucleus (Middleton and Strick 2001). These thalamic nuclei convey the projections to the cerebral cortical areas in the preSMA at the rostral part of the dorsal premotor area, prefrontal cortex in areas 46d and 9l (Middleton and Strick 1997, 2001), the frontal and supplementary eye fields (Lynch et al 1994, Lynch and Tian 2006) and the inferior parietal lobule area 7b (Clower et al 2001).

The recurrent pathways that link the parvocellular red nucleus by way of the central tegmental tract with the inferior olive, and via the olivocerebellar projection to the dentate nucleus, form the Guillain–Mollaret triangle. Projections from the rostrolateral and caudal parvocellular red nucleus course in the central tegmental tract to the dorsal lamina and bend of the principal olive, which provide climbing fibres to the caudal dentate and the cerebellar D2 zone. The dorsomedial parvocellular red nucleus sends its projections in the medial tegmental tract to the ventral lamina of the principal olive, which provides climbing fibres to the rostral dentate and the cerebellar D1 zone. The first published lithograph of a section through the pontine tegmentum (Stilling 1846), shows the central tegmental tract linking the dentate and recipient parvocellular red nucleus with the inferior olive to be one of the largest fibre systems in the brainstem (**Fig. 29.41**).

Single axon tracing studies of cerebellothalamic projections and thalamocortical pathways in monkeys demonstrated that there is considerable feedback from the cerebellum to cerebral association areas (see Fig. 29.41). This is consistent with the demonstration of associative projections into the cerebellum through the feedforward limb via the corticopontine pathways, and with the concept that regions of the cerebellum and cerebral cortex are reciprocally interconnected in circuits, or loops.

Trans-synaptic tract tracing studies using attenuated viral tracers further defined the feedback limb, showing that the morphological distinction between the phylogenetically older, dorsal magnocellular part of the dentate nucleus, and the more recently evolved ventral small-celled region have connectional and functional relevance. The primary motor cortex receives projections via the thalamus from dorsal portions of the dentate nucleus at mid-rostrocaudal levels and in the caudal portions of the emboliform nucleus where neuronal activity related to arm movement has been recorded (see Fig. 29.35). About 25–30% of the dentate nucleus projects to the primary motor cortex. In flattened maps of the dentate nucleus, neurones projecting to the arm representation of M1 are situated in a cluster in the dorsal portion of the dentate at mid-rostrocaudal levels; those to the leg representation are in the rostral pole of the dorsal dentate; and those projecting to the face representation are in caudal levels of the dorsal dentate (Strick et al 2009). Each M1 cortical area thus receives input from a spatially separate set of neurones in the dorsal part of the dentate nucleus. The premotor cortex receives input from the mid-rostrocaudal part of the dentate, ventral to the M1 projecting neurones. Frontal eye field projecting neurones are in the caudal third of the dentate which is correlated with saccadic eye movements. The prefrontal cortex (areas 46 and 9) receives projections from the ventral part of the dentate, mostly in its middle third rostrocaudally. Projections to the posterior parietal cortex, including the lower bank of the intraparietal sulcus, arise from neurones located ventrally in the caudal pole of the dentate. Projections to the anterior intraparietal area arise from neurones located dorsally in the dentate at mid-rostrocaudal levels (Clower et al 2001, Ugolini et al 2006, Strick et al 2009).

In humans, the D2 zone accounts for most of the cerebellar hemisphere, exemplified by its development (see Fig. 29.23) and by the size of the different components of its circuitry. The subdivision of the human dentate in rostrodorsal microgyric and caudolateral macrogyric portions would correspond with two major subdivisions of the D2 zone. Projections from the dorsal lamina of the principal olive to the D2 zone would be topographically arranged such that motor inputs are transmitted to the rostrodorsal microgyric dentate and segments of the D2 zone located in the motor regions of the cerebellum, and nonmotor inputs are directed to the caudolateral macrogyric dentate nucleus and segments of the D2 zone in hemispheric lobules VII and IX. This is in agreement with the clinical-anatomical observations of crossed cerebro-cerebellar atrophy in patients by Demolé (1927a, 1927b) and by Verhaart and Wieringen-Rauws (1950) that degeneration of the rostrodorsal, microgyric dentate occurred with large, chronic lesions involving the pre- and postcentral gyri, whereas lesions of more posterior parts of the hemisphere, involving parietal, occipital and temporal areas, resulted in atrophy of the ventrocaudal macrogyric dentate.

NEUROIMAGING OF HUMAN CEREBELLAR STRUCTURE AND FUNCTION

Task-based functional MRI within single subjects and at the group level provides independent confirmation of the cerebellar sensorimotor-cognitive dichotomy (Stoodley and Schmahmann 2009a, Stoodley et al 2010, 2012) (**Fig. 29.44A**). Tasks such as moving the arm or leg activate the primary sensorimotor cerebellum – anterior lobe and adjacent parts of lobule VI, as well as lobule VIII which is regarded (in the conceptualizing of Woolsey 1952) as the second sensorimotor area in the cerebellum. Cognitive paradigms activate topographically distinct regions within the cerebellar posterior lobe. Lobules VI and crus I are engaged in language and verbal working memory; lobule VI in spatial tasks; lobules VI, crus I and VIIB are activated by executive functions such as working memory, planning, organizing and strategy formation; and vermal lobules VI and VII are involved in emotional processing. Language is heavily right lateralized and spatial functions left-lateralized, reflecting crossed cerebro-cerebellar projections. Hemispheric lobules VI, crus I and VIIB appear to be involved in encoding generalized aversive processing. Threatening stimuli such as noxious heat and viewing unpleasant pictures activate these cerebellar regions together with limbic system structures – the anterior hypothalamus, subgenual anterior cingulate cortex and parahippocampal gyrus (Moulton et al 2011). There are fine-scale gradients within different cognitive networks, exemplified by the dorsal attention system. Visual working memory is encoded in hemisphere lobule VIIB, with spatial encoding (location of the stimulus) represented in medial portions of the lobule whereas memory load (number of stimuli) is encoded more laterally (Brissenden et al 2018) (**Fig. 29.44B**). This pattern is reflected also within the intraparietal sulcus with which cerebellum is interconnected (Schmahmann and Pandya 1989), with

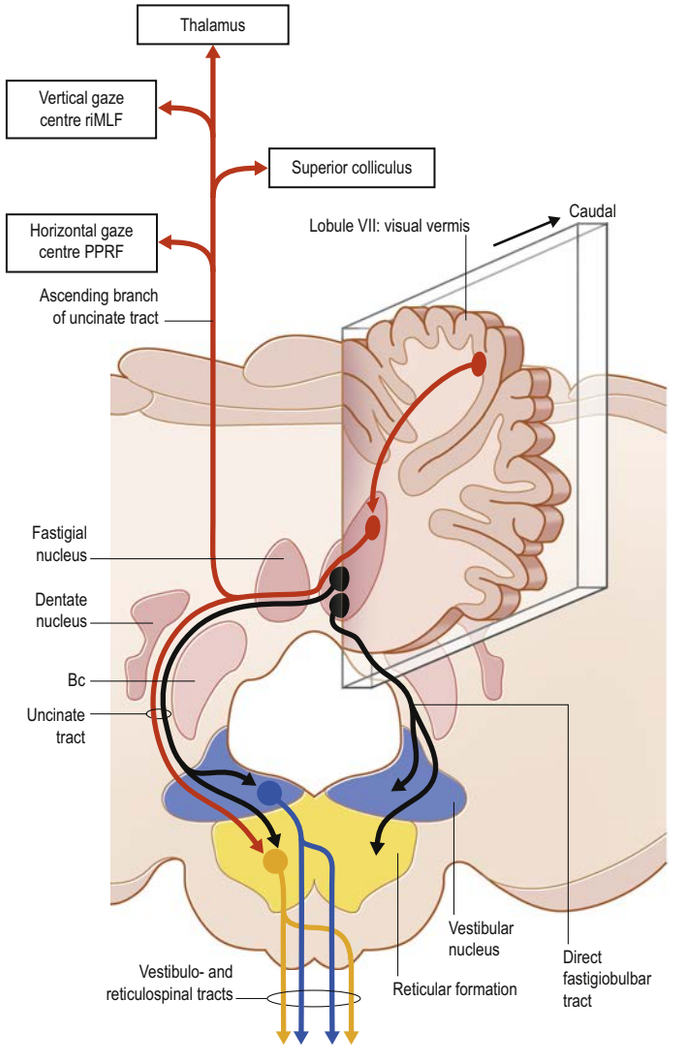

Fig. 29.39 A transverse section through the cerebellum and medulla oblongata, showing the symmetrical distribution of the crossed and uncrossed connections of the fastigial nucleus. The inset depicts a sagittal section, showing the connections of the visual vermis (lobule VII) with the caudal pole of the fastigial nucleus and its efferent pathways in red. Abbreviations: Bc, brachium conjunctivum; PPRF, paramedian pontine reticular formation; riMLF, rostral interstitial nucleus of the medial longitudinal fasciculus.

more posterior parietal regions representing location and anterior regions representing load.

Voxel-based lesion symptom mapping following cerebellar stroke shows motor topography in the nuclei and in cerebellar cortex confined to lobules II through VI (Schoch et al 2006). The study of Stoodley et al (2016) confirmed the dichotomy of motor ataxia arising from damage to lobules IV through VI, whereas the cerebellar cognitive affective syndrome, but not motor ataxia, occurred following stroke in lobules crus II through lobule IX (crus I was largely spared in patients in this study) (**Fig. 29.44C**).

Task-based and rsfc-MRI studies using a large dataset accumulated in the Human Connectome Project (HCP) confirm the double motor representation in the anterior lobe and lobule VIII (Guell et al 2018a). They also confirm and extend the demonstration with rsfc-MRI (Buckner et al 2011) of a triple representation of cognitive domains in the cerebellar posterior lobe. These three representations are in (i) lobules VI-crus I, (ii) crus II-VIIB, and (iii) lobule IX (**Fig. 29.44D**). Studies of intrinsic cerebellar functional connectivity (Guell et al 2018b) further reveal that the cerebellum demonstrates the same kind of sensorimotor-to-cognition hierarchical gradient pattern (**Fig. 29.45**) that has previously been identified in the cerebral cortex (Mesulam 2000). These fundamental organizing principles of cerebellar structure and function dovetail with the deeper understanding of cerebellar clinical neurology and neuropsychiatry (Schmahmann et al 2019).

Modulating cerebellar circuits alters cerebral cortical connections and physiology

The cerebellar areas that are incorporated into neural circuits subserving higher order functions and emotion are functionally relevant. By stimulating the cerebellum non-invasively using transcranial magnetic stimulation (TMS) it is possible to demonstrate that cerebellar modulation of cerebral–cortical circuits is anatomically and functionally specific.

THE TRIAD OF CLINICAL ATAXIOLOGY IN RELATION TO NEUROANATOMY

Three major clinical syndromes can be identified following cerebellar lesions. They are the cerebellar motor syndrome (Holmes 1939), the vestibulocerebellar syndrome (Ito 1984, Barmack and Yakhnitsa 2013) and the cerebellar cognitive affective syndrome (Schmahmann and Sherman 1998), each of which has its own distinct anatomical signature in the cerebellum. These may occur individually or together depending on the location of the injury. The timing of the onset and progression of the underlying disorder also influence the nature and severity of the presentation.

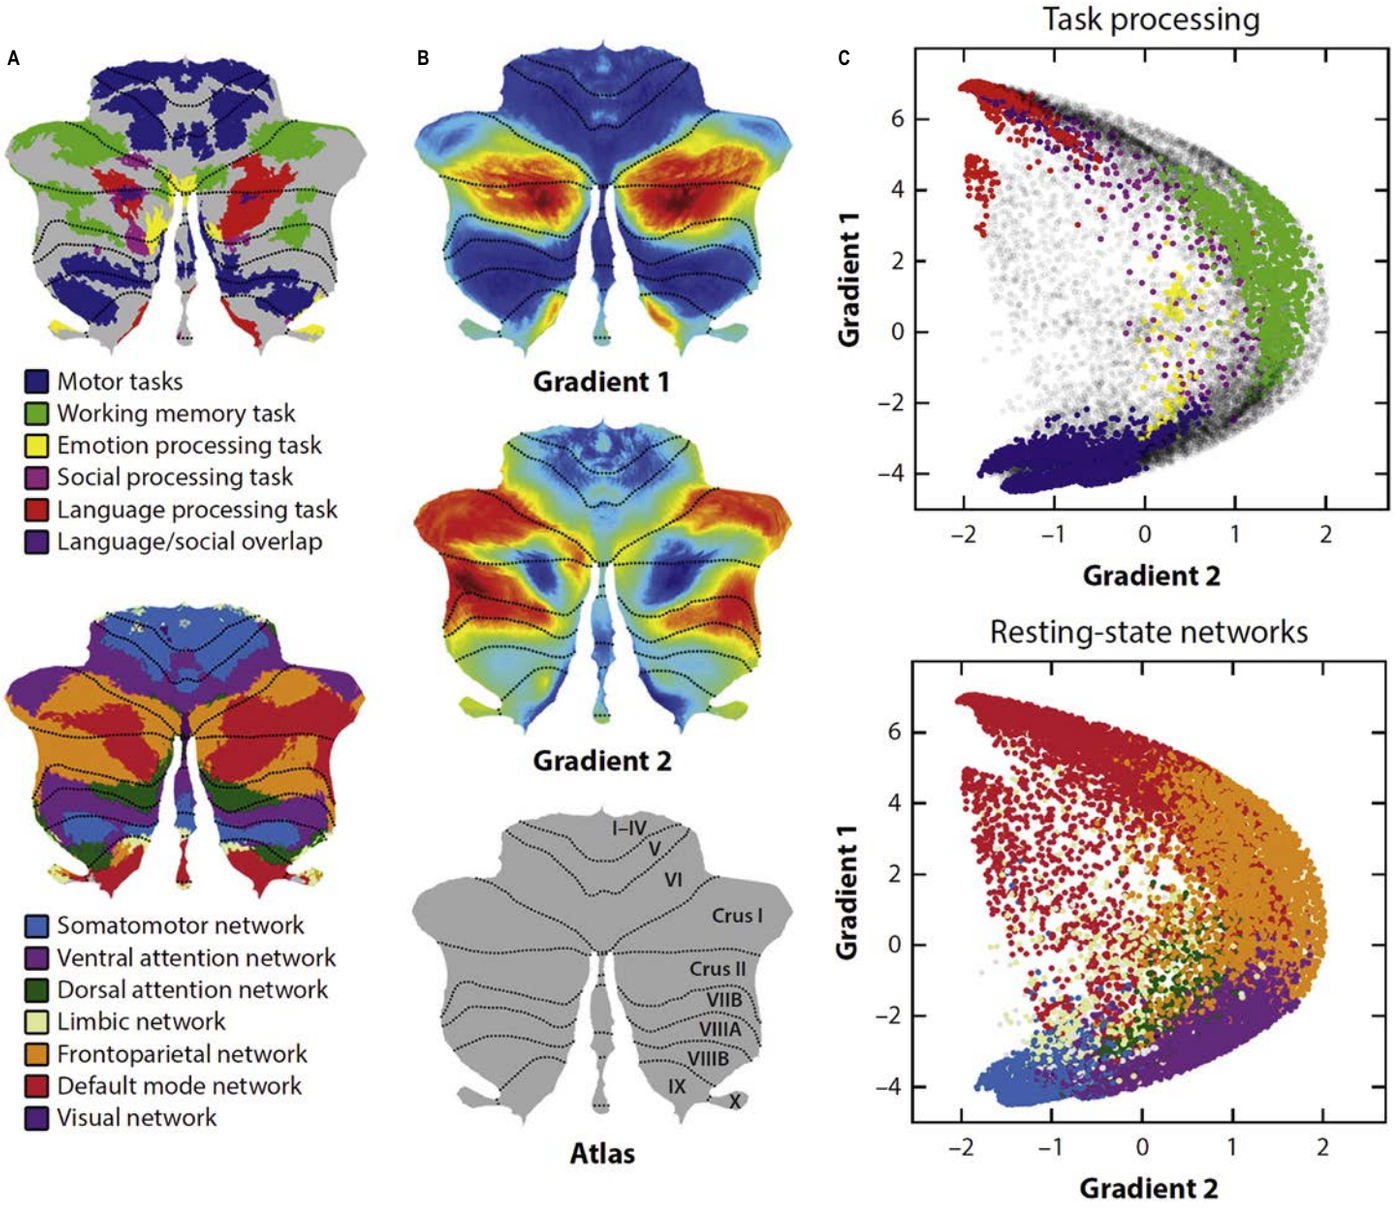

Fig. 29.45 Functional gradients of the human cerebellum. **A**, Discrete task activity maps and resting-state maps. **B**, Cerebellar gradients 1 and 2 and the cerebellum flatmap atlas. **C**, Voxel map along gradients 1 and 2. Gradient 1 extends from the language task/default mode network to motor regions, and gradient 2 isolates working memory/frontoparietal network areas. Each dot corresponds to a cerebellar voxel. The position of each dot along the x- and y-axes corresponds to the position along gradient 1 and gradient 2 for that cerebellar voxel. The colour of the dot corresponds to the task activity (top) or resting-state network (bottom) associated with that voxel. (A, Discrete task activity maps adapted from Guell et al 2018a, resting-state maps adapted from Buckner et al 2011; C, adapted from Guell et al 2018b. Reproduced with permission from Schmahmann JD, Guell XP, Stoodley CJ et al 2019 The theory and neuroscience of cerebellar cognition. Annu Rev Neurosci 42:337–64.)

Intermittent theta-burst TMS, which produces excitation, applied to vermal lobule VII results in increased connectivity within the dorsal attention network, but when applied to lateral parts of crus I/II it leads to increased connectivity in the default network (Halko et al 2014) (see Fig. 29.4). Inhibition-inducing continuous theta-burst TMS applied to lateral cerebellar hemisphere produces decreased functional connectivity with frontal and parietal cognitive regions, but connectivity with motor regions remains unaltered (Rastogi et al 2017). Cerebellar stimulation with intermittent theta-burst TMS has the shared physiological effect of increasing the temporal complexity of the cerebral cortical EEG pattern, but in a network-specific manner: vermal stimulation impacts high-beta/low-gamma-range oscillations, whereas lateral stimulation impacts low-theta and high-gamma-range oscillations (Farzan et al 2016). These TMS studies provide experimental evidence for the dysmetria of thought and universal cerebellar transform theories (Schmahmann 1991, 2000) that different subregions of the cerebellum modulate different cerebral cortical networks, and that the underlying nature of the cerebellar physiological effects on these different networks is similar.

The cerebellar motor syndrome, previously regarded as the sole manifestation of cerebellar disruption, is characterized by disturbed initiation, rate, rhythm and force of voluntary movements, the underlying basis of the incoordination (or ataxia, Greek, lack of order). Cerebellar lesions do not produce weakness but resting motor tone in pure cerebellar disease is decreased (hypotonic).

The somatotopy identified in experimental animal models and in functional imaging studies in healthy humans is reflected in structure–function correlation studies using voxel-based morphometry and lesion symptom mapping in patients with focal cerebellar lesions. Patients with lesions to the anterior cerebellar lobe and vermis often present with ataxia that may affect speech and deglutition, core muscles of the trunk and movement of their upper and lower limbs.

Speech is slurred, syllables are poorly articulated, cadence is slow and irregular, and rapid alternating buccal, palatal and lingual consonants are degraded. Dysarthria is compounded by impaired volume control, which is inconstant and not well modulated. Scanning speech was an older term to describe cerebellar dysarthria, but it does not fully capture the range of the characteristic deficits. Dysarthria in cerebellar developmental disorders differs in quality from that of the acquired and neurodegenerative ataxias, with a persistent childlike quality, as well as impaired prosody (the use of vocal intonation, stress and cadence). Cerebellar disorders affect the control of breathing, and ataxic respiration further degrades the quality of speech. Impaired control of the muscles of deglutition predisposes to dysphagia (impaired swallowing), causing choking on liquids and solids and the risk of aspiration pneumonia.

Truncal ataxia occurs with midline lesions, including titubation, or oscillation of the head and trunk. The patient with cerebellar ataxia has a widened stance and difficulty standing. In mild instances there is inability to stand in the tandem position, and in progressively more severe ataxia, inability to stand with the feet in parallel, or in the natural position, eventually needing to hold on to stationary objects or another person in order to stand. The cerebellar ataxic gait is staggering, uneven, irregular, and veers from side to side. Unilateral lesions cause stumbling towards the affected side.

Dysmetria (Greek, disordered timing or measurement) refers to the impaired ability to judge, regulate and control behaviour. It applies to both the motor and cognitive domains. Upper limb dysmetria is identified with tests such as the finger to nose test, or rapid finger following/mirror test, rapid alternating movements, and tests of finger dexterity such as tapping the index finger on the crease of the thumb. These reveal inaccurate and clumsy movements, jerking trajectory, overshooting (hypermetria) and undershooting the target (hypometria), oscillation at the fingers and wrists as well as more proximally at the elbows and shoulders when more severe, as well as overshoot, rebound and dysdiadochokinesis (dysrhythmic attempts at rapid alternating movements). Finger and hand dexterity for compound movements involving more than one joint are particularly affected. Lower limb dysmetria tested with the heel-to-shin test, reveals proximal overshoot as the heel is placed on the opposite knee, tremor of the heel on the knee, and slowing, jerking, or side-to-side movements as the heel moves down the shin. The attempt to draw a circle in the air with the legs is degraded by decomposition manifested as irregular or chaotic motions.

Postural tremor may be present in the arms, usually with activation. Cerebellar tremor is large amplitude, 2–3 Hz, and may involve many body parts. Rubral tremor from red nucleus lesions and its connections involves multiple joints, change directions and is frequently rotatory. Palatal tremor is slow and semi-rhythmic, resulting from lesions affecting the Guillain–Mollaret triangle (red nucleus – inferior olivary nucleus – deep cerebellar nuclei).

Ataxia rating scales assess and measure these areas of impairment, i.e. stance, gait, upper and lower limb control, and speech. Oculomotor deficits reflecting involvement of the vestibulocerebellum are also measured. The scales commonly in use are the International Cooperative Ataxia Rating Scale (ICARS: Trouillas et al 1997), the Friedreich's Ataxia Rating Scale (FARS: Subramony et al 2005), the Scale for Assessment and Rating of Ataxia (SARA: Schmitz-Hübsch et al 2006), and the Brief Ataxia Rating Scale (BARS: Schmahmann et al 2009).

The flocculus and the nodulus are known as the vestibulocerebellum because they maintain afferent and efferent connections with the vestibular system. They also belong to the functionally more comprehensive oculomotor division of the cerebellum, which includes lobule VII (visual vermis), uvula (dorsal vermal lobule IX), the ventral paraflocculus (the human accessory paraflocculus) and the dorsal paraflocculus (the human tonsil, particularly hemispheric lobule IX). The mossy fibre projection of the nucleus prepositus hypoglossi, a key element in the saccade-producing system, outlines the entire oculomotor cerebellum, with the exception of the dorsal paraflocculus (Belknap and McCrea 1988) (**Fig. 29.46**). The functions of the nodulus (vermal lobule X) are not exclusively oculomotor: it also influences labyrinthine and postural reflexes and vegetative systems.

The oculomotor cerebellum is involved in long-term adaptation of saccades, ocular stabilization reflexes and smooth pursuit (reviewed in Voogd et al (2012)) that permit bringing and maintaining images of objects of interest on the fovea. The flocculus/paraflocculus supports brief, high-frequency vestibular responses, sustained pursuit eye movements and gaze holding. The nodulus/ventral uvula enables sustained, low-frequency vestibular responses. The dorsal oculomotor vermis and its target in the posterior portion of the fastigial nucleus (the fastigial oculomotor region) are essential for saccades and the initiation of pursuit eye movements (Kheradmand and Zee 2011).

The vestibulo-ocular reflex (VOR) is an ancient reflex, present in both fishes and agnatha (jawless fish). It stabilizes the position of the retina in space during movements of the head by rotating the eyeball in the opposite direction. It is an open reflex, meaning that there is no time for a feedback connection that would compensate for inaccuracies in the execution of the reflex. This function is undertaken by the long-term adaptation of the reflex by the flocculus. The circuitry of the flocculus, similar to the vestibuloocular reflex, is organized on the coordinate system of the semicircular canals (Simpson and Graf 1981, Barmack and Yakhnitsa 2013). The vestibulo-ocular reflex consists of different components. One component connects the lateral (horizontal) semicircular canal, via oculomotor neurones in the vestibular nuclei, with the oculogyric muscles that move the eyes in a plane colinear with the plane of the lateral canal (see Fig. 29.40). The anterior semicircular canal influences the ipsilateral superior oblique and the contralateral inferior oblique muscles that move the eye in the plane of this canal.

Stroke in the territory of the posterior inferior cerebellar artery results in infarction of the vestibulocerebellum–flocculonodular region and lobule IX, producing abrupt-onset severe vertigo (sensation of movement in the absence of stimulus), almost always with nausea and vomiting. The vertigo makes it impossible to walk at the time of the acute event, but if the cerebellar motor areas are not damaged, there is no dysmetria of the limbs or dysarthria. Oculomotor abnormalities from cerebellar lesions produce visual disturbances including diplopia, oscillopsia and a sense of dysequilibrium. The range, complexity and varying combinations of oculomotor abnormalities on examination include deficits in gaze holding, reflex pursuit eye movements, voluntary initiation and direction of saccadic eye movements, and spontaneous or gaze-evoked nystagmus. The condition of isolated downbeat nystagmus, linked to a potassium channelopathy of the flocculonodular system, produces a cautious and unstable gait, likely a result of mismatched visual–vestibular interaction. Opsoclonus myoclonus syndrome is a dramatic impairment of oculomotor control with chaotic eye movements in horizontal and vertical directions in primary position, a heralding sign of a paraneoplastic syndrome that may be observed in neoplasms such as hypernephroma of the kidney in children, and the anti-Yo antibody syndrome directed at Purkinje cells in Hodgkin's lymphoma and breast, ovarian and lung carcinomas.

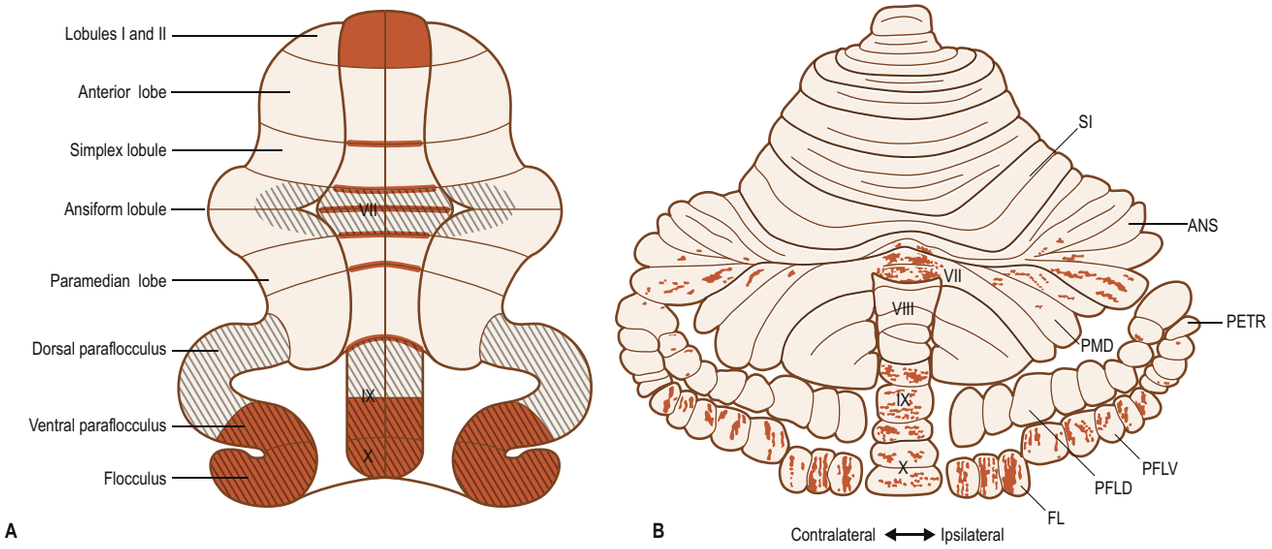

Fig. 29.46 A, A flattened map of the cerebellar cortex of the mammalian cerebellum showing the distribution of vestibulocerebellar mossy fibres in orange. The hatched lobules belong to the oculomotor cerebellum. **B**, The distribution of mossy fibres originating from the nucleus prepositus hypoglossi outlines the oculomotor cerebellum of the squirrel monkey, with the exception of the dorsal paraflocculus (PFLD). Other abbreviations: ANS, ansiform lobule; FL, flocculus; PETR, petrosal lobule; PFLV, ventral paraflocculus; PMD, paramedian lobule; SI, simplex lobule; VII–X, lobules VII–X. (With permission from Belknap DB, McCrea RA 1988 Anatomical connections of the prepositus and abducens nuclei in the squirrel monkey. J Comp Neurol 268:13–28.)

The cerebellar cognitive affective syndrome (CCAS) is characterized by impairments in executive function (planning, set-shifting, abstract reasoning, verbal fluency, working memory), often with perseveration, distractibility or inattention; visual–spatial disorganization and impaired visual–spatial memory; difficulties with language production including dysprosodia, agrammatism and mild anomia (Schmahmann and Sherman 1998). Language problems also include decreased verbal fluency (Molinari et al 1997), inability to detect one's own errors in tasks such as the verb-for-noun generation paradigm (Fiez et al 1992, Stoodley and Schmahmann 2009b), and impaired metalinguistics, the use of language for the purpose of social communication (Mariën et al 2014, Guell et al 2015). Personality changes include blunting of affect or disinhibited and inappropriate behaviour, particularly following lesions of the vermis (the putative limbic cerebellum). The affective symptoms include impaired emotional and attentional control, and abnormal social skills that resemble symptoms typical of autism spectrum disorder and psychosis (Schmahmann et al 2007). The net effect of these disturbances in cognitive abilities is a general lowering of intellectual function. The CCAS arises from damage to the cognitive cerebellum in the cerebellar posterior lobe (lobules VI, VII, probably lobule IX), and is postulated to reflect dysmetria of thought analogous to the dysmetria of motor control from damage to the sensorimotor cerebellum (Schmahmann 1991, 1996, 2010, Schmahmann and Sherman 1998, Stoodley and Schmahmann 2009a, 2010, Stoodley et al 2012, 2016). The CCAS may occur separately or together with the cerebellar motor syndrome and the vestibular syndrome. It has been regarded as the third cornerstone of clinical ataxiology and eponymously named Schmahmann's syndrome (Manto and Mariën 2015, Argyropoulos et al 2020). The defining features of the CCAS occur across disease types and in children as well as adults; a developmental form of the CCAS is present in children with hereditary or congenital disorders. The syndrome of paediatric postoperative cerebellar mutism, likely a profound apraxia of speech, may occur together with the CCAS as a consequence of accidental damage to cerebellar outflow pathways (the deep nuclei and the superior cerebellar peduncle) during surgery to remove posterior fossa tumours (Wisoff and Epstein 1984, Rekate et al 1985, Gudrunardottir et al 2016, Albazron et al 2019, Schmahmann 2020).

The affective component of the CCAS has been conceptualized as an acquired impairment of those functions commonly affected in neurodevelopmental disorders such as autism spectrum and schizophrenia (Schmahmann et al 2007, Van Overwalle et al 2015). Conversely, cerebellar abnormalities are increasingly reported in neuropsychiatric conditions including schizophrenia, autism and depression (Schmahmann 1991, Fatemi et al 2012, Baumann et al 2015). The maturing field of the cognitive neuroscience of the cerebellum is addressing these possibilities in studies of complex behavioural repertoires that are far removed from sensorimotor domains, demonstrating, for example, granule cell activation during conditions of reward (Wagner et al 2017) and social cognition (Carta et al 2019), and elucidating the role of the cerebellum in learning and memory (Thompson 1983, Freeman 2015), fear conditioning (Supple and Leaton 1990) and empathy (Schmahmann et al 2007, Koziol et al 2013).

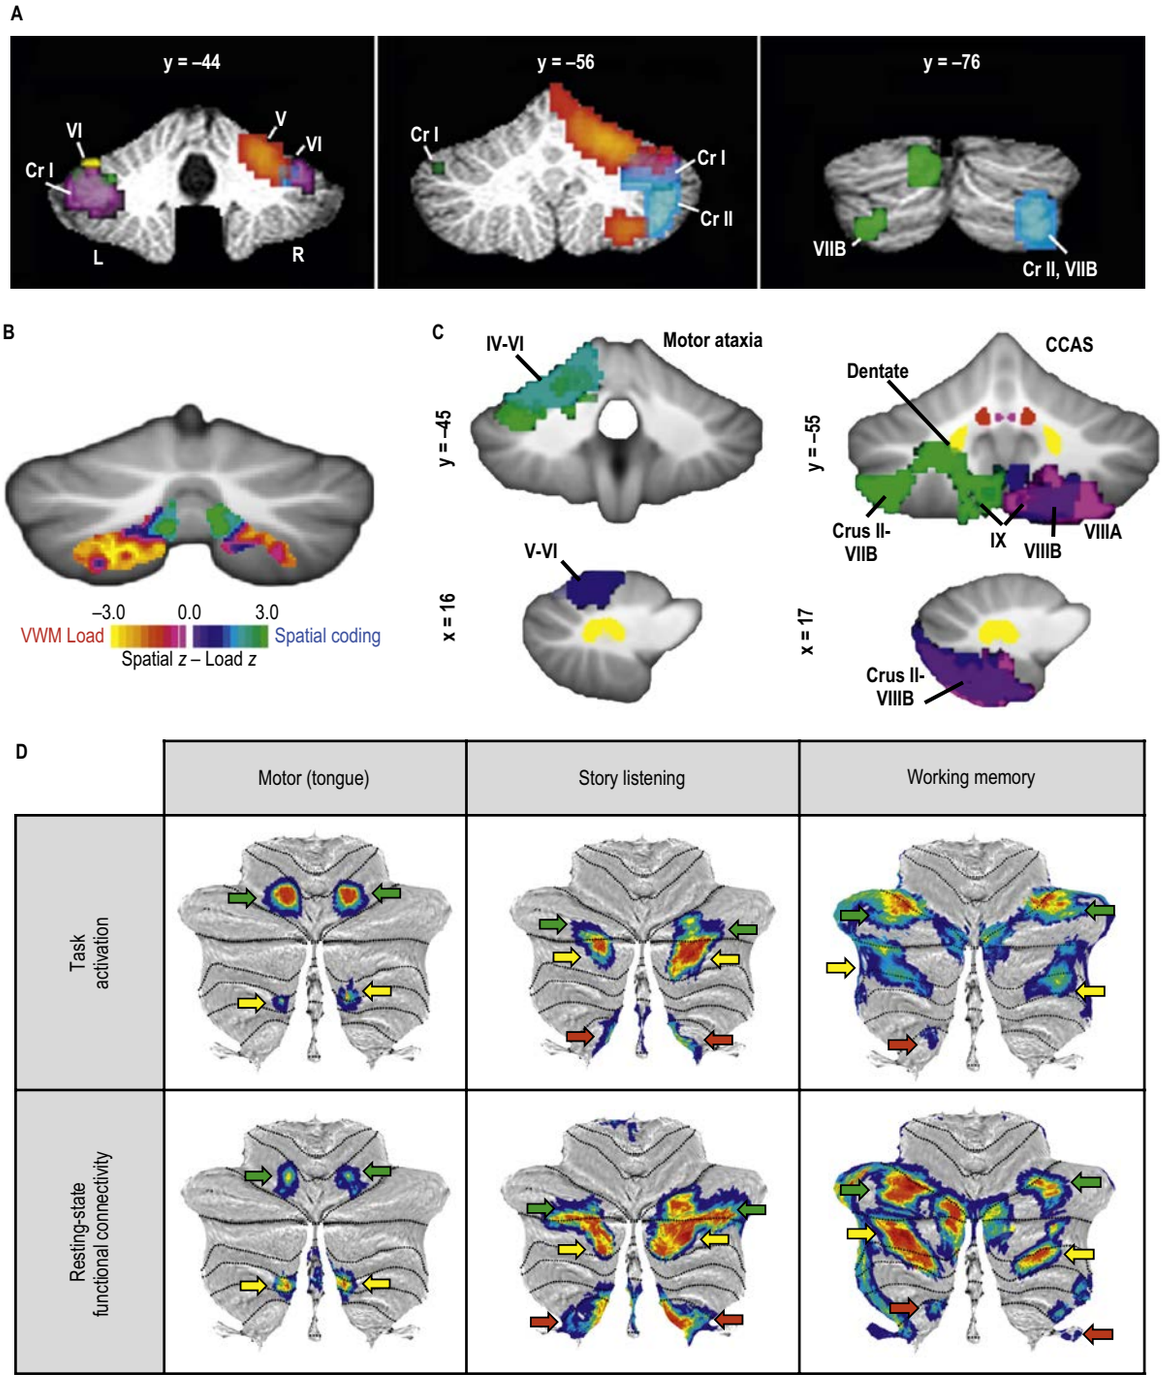

Fig. 29.44 Functional topography of the human cerebellum. **A**, Intraindividual topography of task-based activations in the cerebellum for finger tapping (red), working memory (purple), verb generation (blue) and mental rotation (green) (Stoodley et al 2010). **B**, Spatial gradients within the dorsal attention network in lobule VIIB on a working memory task. The locus of spatial attention encoding is medially situated; attentional load content is more lateral. This gradient of activity also exists within the cortical dorsal attention network (not shown). **C**, In patients with stroke, lesions of lobules IV–V of the anterior lobe extending into adjacent lobule VI produce the cerebellar motor syndrome of ataxia. Lesions confined to posterior lobe lobules crus II through lobule IX produce the cerebellar cognitive affective/Schmahmann syndrome but no motor ataxia. **D**, Task and resting-state activation topography in motor and nonmotor domains. Task activation (top row) reveals a pattern of two motor (first column) and three nonmotor representations (second and third columns). An overlapping pattern was observed when calculating resting-state functional connectivity from cerebral cortical activation peaks for each corresponding task activity contrast (bottom row). First motor (lobules I–VI) or first nonmotor representation (VI/crus I) (green arrows), second motor (VIII) or second nonmotor representation (crus II/lobule VIIB) (yellow arrows), and third nonmotor representation (IX/X) (red arrows) are shown. First and second nonmotor representations can be contiguous (as in story listening) or separate (as in working memory). Abbreviations: CCAS, cerebellar cognitive affective syndrome; Cr, crus; L, left; R, right; VWM, verbal working memory. (B, Adapted from Brissenden et al (2018); C, adapted from Stoodley et al (2016); D, adapted from Guell et al (2018a, reproduced with permission from Schmahmann JD, Guell XP, Stoodley CJ et al 2019 The theory and neuroscience of cerebellar cognition. Annu Rev Neurosci 42:337–64)

CHAPTER 30

Diencephalon

The diencephalon is part of the prosencephalon (forebrain), which develops from the most rostral primary cerebral vesicle that differentiates into the caudal diencephalon and the rostral telencephalon. The cerebral hemispheres, containing the lateral ventricles, develop from the telencephalon. The sites of evagination of the telencephalon become the interventricular foramina, through which the two lateral ventricles and the midline third ventricle communicate. The diencephalon corresponds largely to the structures that develop lateral to the third ventricle. The lateral walls of the diencephalon form the epithalamus most superiorly, the thalamus centrally, and the subthalamus and hypothalamus inferiorly.

THALAMUS

The thalamus plays a crucial role in many brain functions, serving as a processing and distribution centre, relaying and regulating information from the outside world and the internal milieu to the cerebral cortex and sustaining cortico-thalamo-cortical communication. It is involved in multiple activities, including consciousness, sleep, attention, memory and sensory and motor functions. Our increasing understanding of the role of the thalamus is providing insights into pathological disorders of the brain and is opening up the possibility of targeting its various constituent nuclei to treat a variety of disorders, including epilepsy, Parkinson's disease, pain and psychiatric disorders (**Table 30.1**; see Fig. 30.5). (For review, see Lozano et al 2019.)

Morphologically, the thalamus is a large ovoid nuclear mass, about 4 cm long, which borders the dorsal part of the third ventricle (**Figs 30.1–30.2**). Its narrow anterior pole lies close to the midline and forms the posterior boundary of the interventricular foramen. Posteriorly, an expansion, the pulvinar, extends beyond the third ventricle to overhang the superior colliculus (see Fig. 28.5). The brachium of the superior colliculus (superior quadrigeminal brachium) separates the pulvinar superiorly from the medial geniculate body inferiorly. A small oval elevation, the lateral geniculate body, lies lateral to the medial geniculate body.

The superior (dorsal) surface of the thalamus is covered by a thin layer of white matter, the stratum zonale. This curved surface is separated from the overlying body of the fornix by the choroid fissure containing the tela choroidea. More laterally, it forms part of the floor of the lateral ventricle. The lateral border of the superior surface of the thalamus is marked by the stria terminalis and overlying thalamostriate vein, which separate the thalamus from the body of the caudate nucleus. Laterally, a slender sheet of white matter, the external medullary lamina, separates the main body of the thalamus (dorsal thalamus), from the reticular nucleus (prethalamus). The dorsal thalamus and the reticular nucleus differ in their ontogeny and connections. Lateral to the reticular nucleus, the thick posterior limb of the internal capsule lies between the thalamus and the lentiform complex.

The medial surface of the thalamus is the superior (dorsal) part of the lateral wall of the third ventricle and is usually connected to the contralateral thalamus by an interthalamic adhesion (see Fig. 25.20). The boundary with the hypothalamus is marked by a faint hypothalamic sulcus, which curves from the upper end of the cerebral aqueduct to the interventricular foramen. The thalamus is continuous with the midbrain tegmentum, the subthalamus and the hypothalamus.

Internally, the dorsal thalamus is divided into anterior, medial and lateral nuclear groups by the internal medullary lamina, a vertical Y-shaped sheet of white matter (**Figs 30.3–30.4**; **Table 30.2**). Intralaminar nuclei are embedded within the internal medullary lamina. Midline nuclei abut the lateral walls of the third ventricle. The reticular nucleus forms a shell-like lateral covering to the main nuclear mass, from which it is separated by an external medullary lamina of nerve fibres.

The thalamus is connected with virtually all of the cerebral hemisphere. In general, thalamic nuclei both project to and receive fibres from the cerebral cortex (Jones 2007, Sherman 2016) (see Fig. 30.4). The thalamus is the major route by which subcortical neuronal activity influences the cerebral cortex, and the greatest input to most thalamic nuclei comes from the cerebral cortex. Some thalamic nuclei are connected with the basal ganglia and the amygdala.

The connections between the dorsal thalamus and the cerebral cortex are reciprocal; each cortical area projects in a topographically organized manner to all sites in the thalamus from which it receives an input (see Table 30.2). Thalamocortical fibres terminate predominantly in layer IV of the cortex. Corticothalamic fibres arise mostly from modified pyramidal cells of layer VI. In addition, some thalamic nuclei, the 'high-order' or 'association' nuclei, receive corticothalamic fibres from layer V pyramidal neurones; these fibres are collaterals of axons projecting to other subcortical nuclei. The reticular nucleus is connected reciprocally to all thalamic nuclei and receives input from corticothalamic fibres arising in layer VI but it does not project to the cortex.

The dorsal thalamic nuclei contain projection neurones (approximately 70%), and local circuit interneurones (30%). They are divided into 'relay' or 'first-order' nuclei that mediate finely organized and precisely transmitted sensory and motor information to discrete cortical sensory and motor areas, and 'association' or 'high-order' nuclei that have more complex integrative functions (Rovó et al 2012, Sherman 2016). Relay nuclei receive their main or 'driver' input from a major subcortical pathway, and process and transfer information from

TABLE 30.1 Thalamic deep brain stimulation targets

Indication	Target	References

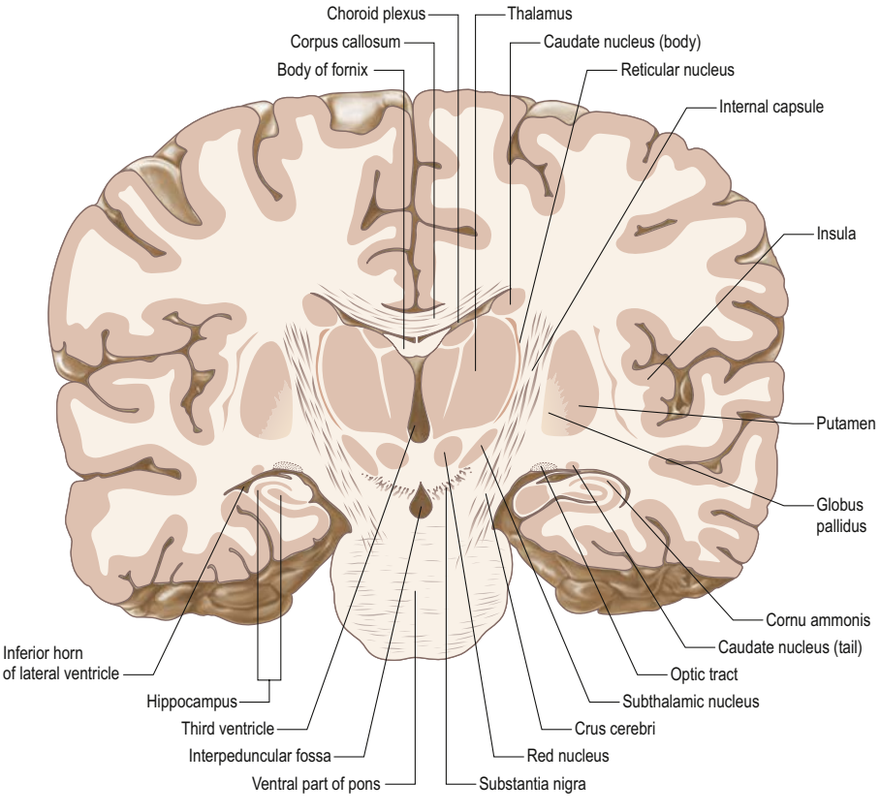

Fig. 30.2 The principal parts of the diencephalon and basal ganglia, coronal section.

subcortical nuclei to the cerebral cortex. Association nuclei receive their 'driver' input from layer V pyramidal neurones in association cortical areas and participate in cortico-thalamo-cortical transmission. Both relay and association nuclei receive 'modulatory' input from layer VI pyramidal neurones of the cerebral cortex. All thalamic nuclei receive 'non-specific' subcortical input from cholinergic and aminergic (serotoninergic, histaminergic, dopaminergic, noradrenergic, adrenergic) axons arising in the brainstem and basal telencephalon.

Anterior thalamic nuclei

The anterior thalamic nuclei are relay or first-order nuclei, believed to be involved in the regulation of alertness and attention and in the acquisition of memory. They lie between the arms of the Y-shaped internal medullary lamina, and underlie the anterior thalamic tubercle (see Figs 28.5, 30.4). Three subdivisions are recognized: the largest is the anteroventral nucleus, the others are the anteromedial and anterodorsal nuclei. These nuclei are the principal recipients of the mammillothalamic tract, which arises from the mammillary nuclei of the hypothalamus. (The mammillary nuclei receive fibres from the hippocampal formation via the fornix). The medial mammillary nucleus projects to the anteroventral and anteromedial thalamic nuclei, and the lateral mammillary nucleus projects to the anterodorsal nucleus. The nuclei of the anterior group also receive a prominent cholinergic input from the basal forebrain and the brainstem. The cortical targets of efferent fibres from the anterior nuclei of the thalamus lie largely on the medial surface of the hemisphere. They include the anterior limbic area (anterior and inferior to the corpus callosum), the cingulate gyrus and the parahippocampal gyrus (including the medial entorhinal cortex, presubiculum and parasubiculum). There also appear to be minor connections between the anterior nuclei and the dorsolateral prefrontal and posterior areas of neocortex.

Medial thalamic nuclei

The single component of this thalamic region is the mediodorsal (dorsomedial) nucleus, an association nucleus, which is particularly large in humans. Laterally, it is limited by the internal medullary lamina and intralaminar nuclei. Medially, it abuts the midline parataenial and reuniens (medioventral) nuclei. It consists of a smaller, anteromedial magnocellular division and a larger, posterolateral parvocellular division.

The anteromedial magnocellular division receives olfactory input from the piriform and adjacent cortex, the ventral pallidum and the amygdala. The mediobasal amygdaloid nucleus projects to the dorsal part of the anteromedial magnocellular nucleus, and the lateral nuclei project to the more central and anteroventral regions. The magnocellular division projects to the orbital and medial prefrontal cortex, notably to the lateral posterior and central posterior olfactory areas on the orbital surface of the frontal lobe. Fibres also pass to the ventromedial cingulate cortex and to the inferior parietal cortex and anterior insula. These cortical connections are reciprocal.

The posterolateral parvocellular division is connected reciprocally with the dorsolateral and dorsomedial prefrontal cortex, the anterior cingulate gyrus and the supplementary motor area. Efferent fibres also pass to the posterior parietal cortex.

The mediodorsal nucleus appears to be involved in a wide variety of higher functions. Damage may lead to a decrease in anxiety, tension, aggression or obsessive thinking. There may also be transient amnesia, with confusion developing particularly over the passage of time. Much of the neuropsychology of medial nuclear damage reflects defects in functions similar to those performed by the prefrontal cortex, with which it is closely linked, and the effects of ablation of the mediodorsal nuclei parallel, in part, the results of prefrontal lobotomy.

Lateral thalamic nuclei

The lateral nuclear complex, lying lateral to the internal medullary lamina, is the largest division of the thalamus and is divided into dorsal and ventral tiers of nuclei. The lateral dorsal nucleus, lateral posterior nucleus and the pulvinar all lie dorsally. The lateral and medial geniculate nuclei lie inferior to the pulvinar near the posterior pole of the thalamus. The ventral tier nuclei are the ventral anterior, ventral lateral and ventral posterior nuclei.

Ventral anterior nucleus

The ventral anterior (VA) nuclear complex lies at the anterior pole of the ventral nuclear group. It is limited anteriorly by the reticular nucleus and posteriorly by the ventral lateral nucleus, and lies between the external and internal medullary laminae. It consists of a principal part (VApc) and a magnocellular part (VAmc). The subcortical connections to this region are largely ipsilateral from the medial (internal) globus pallidus and the pars reticulata of the substantia nigra. These afferents use γ-aminobutyric acid (GABA) as a neurotransmitter: they are inhibitory and therefore unusual among the 'driver' inputs to relay nuclei which are typically glutamatergic

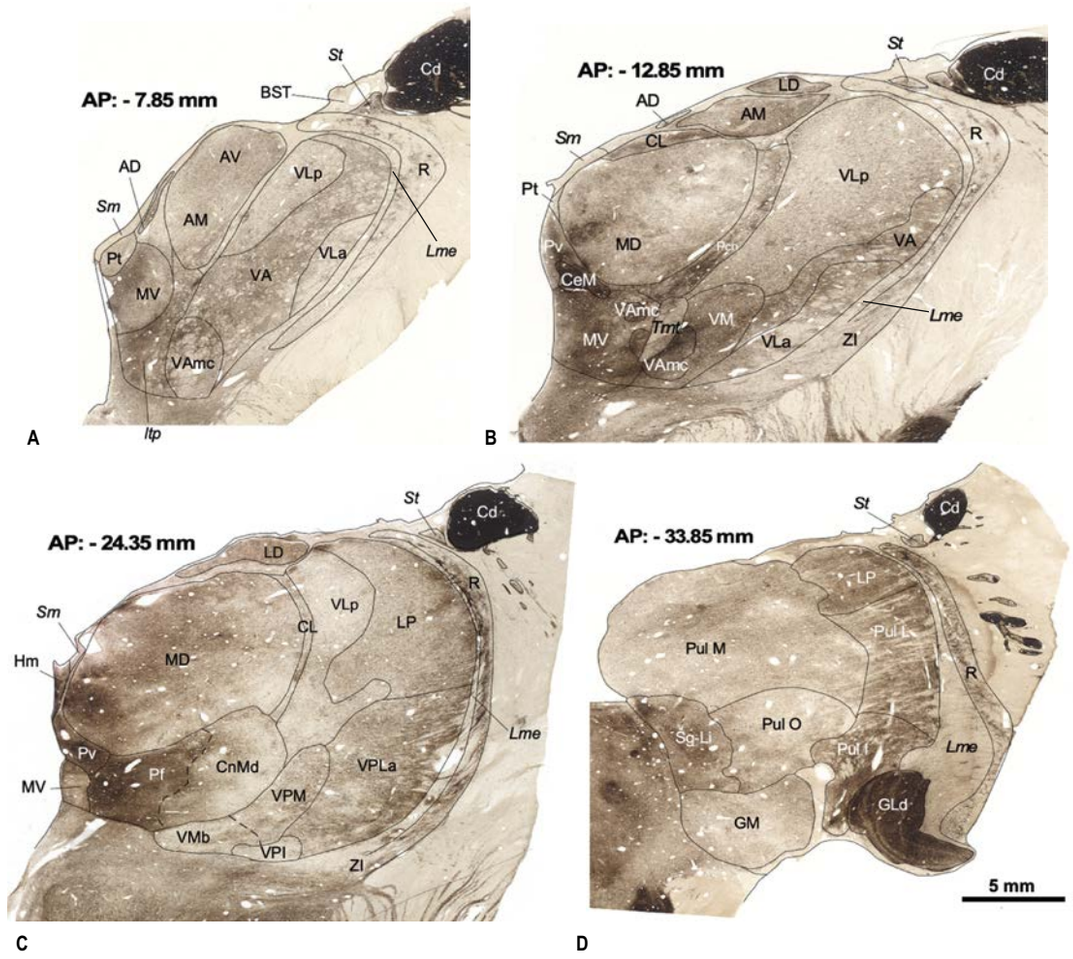

Fig. 30.3 A series of coronal sections from a human hemithalamus stained for acetylcholinesterase histochemistry. The midline is to the left. The stereotaxic anteroposterior level is given next to each section (stereotaxic brain sectioning followed Talairach and Tournoux (1988) criteria). Abbreviations: AD, anterodorsal nucleus; AM, anteromedial nucleus; AV, anteroventral nucleus; BST, bed nucleus of the stria terminalis; Cd, caudate nucleus; CeM, central medial nucleus; CL, central lateral nucleus; CnMd, centromedian nucleus; GLd, dorsal lateral geniculate nucleus; GM, medial geniculate nucleus; Hm, medial habenular nucleus; ltp, inferior thalamic peduncle; LD, lateral dorsal nucleus; Li, limitans nucleus; Lme, external medullary lamina; LP, lateral posterior nucleus; MD, mediodorsal nucleus; MV, medioventral nucleus; Pcn, paracentral nucleus; Pf, parafascicular nucleus; Pt, parataenial nucleus; Pul I, inferior pulvinar nucleus; Pul L, lateral pulvinar nucleus; Pul M, medial pulvinar nucleus; Pul O, oral pulvinar nucleus; Pv, paraventricular nucleus; R, reticular nucleus; Sg, suprageniculate nucleus; Sm, stria medullaris; St, stria terminalis; Tmt, mamillothalamic tract; VA, ventral anterior nucleus; VAmc, ventral anterior nucleus-magnocellular part; VLa, ventral lateral nucleus-anterior part; VLp, ventral lateral nucleus-posterior part; VM, ventral medial nucleus; VMb, basal ventral medial nucleus; VPl, ventral posterior inferior nucleus; VPLa, ventral posterior lateral nucleus-anterior part; VPM, ventral posterior medial nucleus; ZI, zona incerta.

and excitatory. The pallidal and nigral terminal fields do not overlap in the ventral anterior nuclear complex: fibres from the globus pallidus end in the principal part of the nuclear complex and the substantia nigra pars reticulata, projects to the magnocellular part of the nuclear complex. Corticothalamic fibres from the premotor cortex (area 6) terminate in the principal part and fibres from the frontal eye field (area 8) terminate in the magnocellular part. The efferent projections from the ventral anterior nuclear complex are incompletely known; it projects to widespread regions of the frontal lobe and to the parietal cortex. Their functions are also unclear: the ventral anterior thalamus appears to play a central role in the transmission of the cortical 'recruiting response', a phenomenon in which stimulation of the thalamus can initiate long-lasting, high-voltage, repetitive negative electrical waves over much of the cerebral cortex.

Ventral lateral nucleus

The ventral lateral (VL) nucleus may be considered a motor relay nucleus: it consists of two major divisions with distinctly different connections and functions. The anterior division, or pars oralis (VLo), receives topographically organized fibres from the ipsilateral medial globus pallidus. The posterior division, or pars caudalis (VLc), receives topographically organized fibres from the contralateral deep cerebellar nuclei. Additional subcortical projections have been reported from the spinothalamic tract and the vestibular nuclei. Numerous cortical afferents to both the pars oralis and the pars caudalis originate from precentral motor cortical areas, including both area 4 and area 6.

The pars oralis of the ventral lateral nucleus sends efferent fibres mostly to the supplementary motor cortex on the medial surface of the hemisphere and to the lateral premotor cortex. The pars caudalis of the ventral lateral nucleus projects efferent fibres mostly to the primary motor cortex, where they end in a topographically arranged fashion. The head region of area 4 receives fibres from the medial part of pars caudalis, and the leg region receives fibres from the lateral pars caudalis.

Responses can be recorded in ventral lateral thalamic neurones during both passive and active movement of the contralateral body. The topography of its connections, and recordings made within the nucleus, suggest that the pars caudalis contains a body representation comparable to that in the ventral posterior nucleus. In patients with tremor, clusters of ventral lateral neurones fire in bursts that are synchronous with peripheral tremor: so-called 'tremor cells'.

Stereotaxic surgery of the ventral lateral nucleus is sometimes used in the treatment of essential tremor (see Table 30.1; **Fig. 30.5**). In the past, thalamotomy was used extensively for the treatment of Parkinson's disease: the medial globus pallidus and the subthalamic nucleus are now the preferred neurosurgical targets for Parkinson's disease.

Ventral posterior nucleus

The ventral posterior (VP) nucleus is the principal thalamic relay for the somatosensory pathways. It consists of two major divisions, the ventral posterolateral (VPl) and ventral posteromedial (VPm) nuclei.

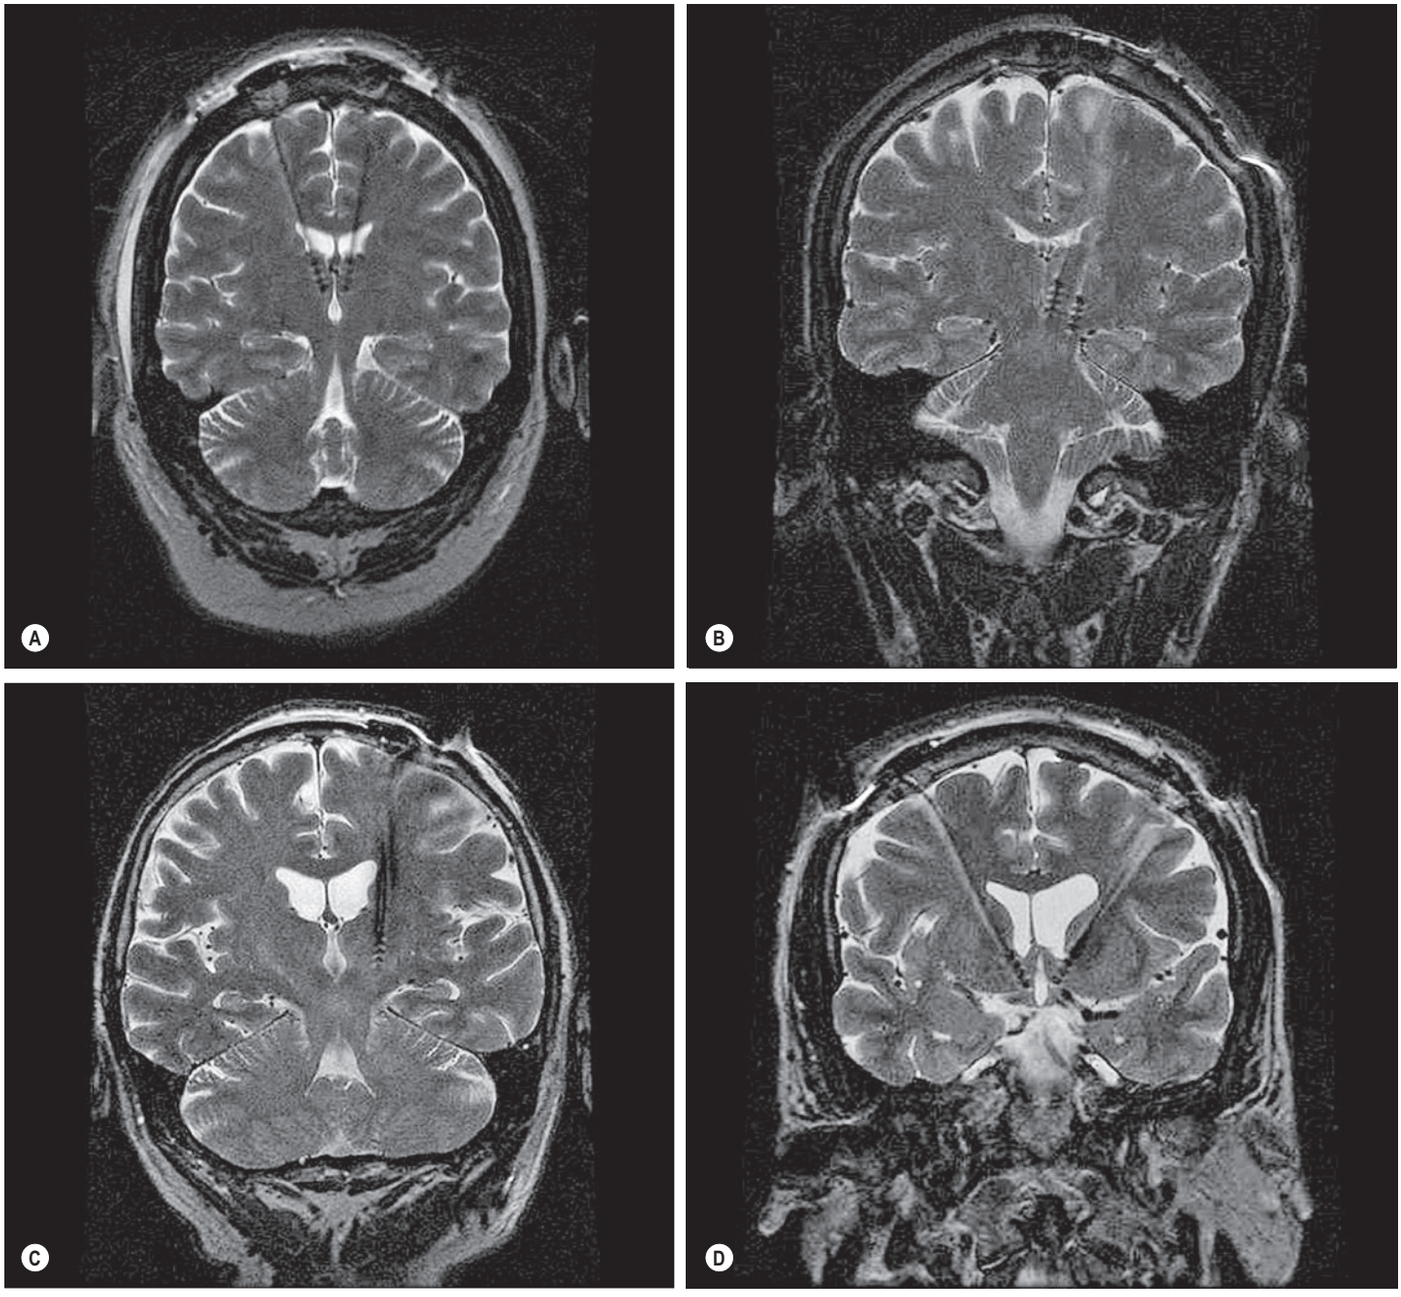

Fig. 30.5 Magnetic resonance images from four different patients with neurological or psychiatric disorders, showing the position of deep brain stimulation (DBS) electrodes. **A**, Bilateral anterior thalamic DBS for epilepsy. **B**, Left thalamic DBS for pain, with electrodes in the sensory relay nucleus (ventral posterior nucleus of the thalamus) laterally and the periventricular grey medially. **C**, DBS electrode in the ventral intermediate nucleus of the thalamus in a patient with essential tremor. **D**, Bilateral inferior thalamic peduncle DBS electrodes in a patient with obsessive–compulsive disorder.

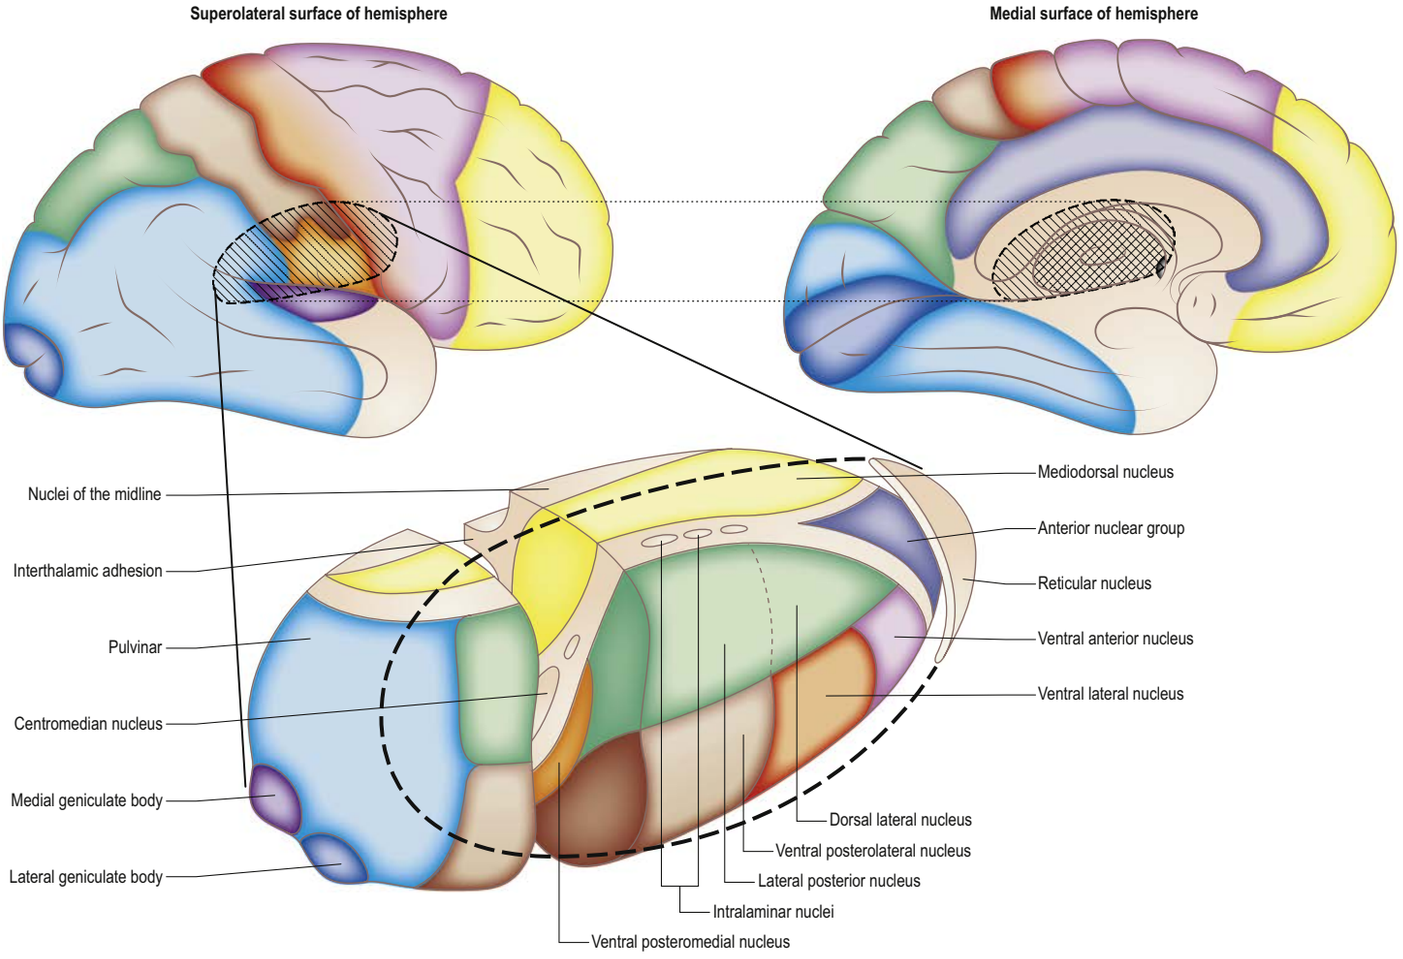

Fig. 30.4 The main nuclear masses of the thalamus (viewed from the lateral aspect in the lower illustration), colour-coded to indicate the areas of cerebral neocortex with which they are interconnected. The pale colour in the centromedian, intralaminar and reticular nuclei and in areas of the frontal and temporal lobes is not related to the colour code. The reticular nucleus lies lateral to the main mass of the thalamus. Only the anterior pole of the reticular nucleus is shown, its posterior extent is depicted by the heavy dashed line.

TABLE 30.2 Main thalamic nuclei and their major afferent and efferent connections

Group	Nucleus	Major subcortical connection	Major cortical connections	System
Anterior	Anterior	Mammillary bodies (MTT)	Cingulate and parahippocampal gyrus	Relay limbic
Medial	Dorsomedial	Amygdala, thalamic nuclei	Prefrontal cortex	Association
Lateral

Abbreviations: CM, centromedian nucleus of thalamus; GPm, medial (internal) segment of globus pallidus; LD, lateral dorsal nucleus of thalamus; LGB, lateral geniculate body; LP, lateral posterior nucleus of thalamus; MGB, medial geniculate body; MLT, medial lemniscal tract; MTT, mammillothalamic tract; SNr, substantia nigra pars reticulata; STT, spinothalamic tract; TTT, trigeminothalamic tract; VA, ventral anterior nucleus; VL, ventral lateral nucleus; VPl, ventral posterolateral nucleus; VPm, ventral posteromedial nucleus.

The ventral posterolateral nucleus receives its driver input from the medial lemniscal and spinothalamic pathways, and the ventral posteromedial nucleus receives its driver input from the trigeminothalamic pathway. Connections from the vestibular nuclei terminate along the ventral surface of the ventral posterior nucleus.

There is a well-ordered topographic representation of the body in the ventral posterior nucleus. The ventral posterolateral nucleus is organized so that sacral segments are represented laterally and cervical segments medially. The latter abut the face area of representation (trigeminal territory) in the ventral posteromedial nucleus. Taste fibres synapse most anteriorly and ventromedially within the ventral posterolateral nucleus.

At a more detailed level, single body regions are represented as curved lamellae of neurones, parallel to the lateral border of the ventral posterior nucleus, such that there is a continuous overlapping progression of adjacent receptive fields from dorsolateral to ventromedial. Considerably less change in location of receptive field on the body is seen when passing anteroposteriorly through the nucleus. While not precisely dermatomal in nature, these curvilinear lamellae of cells are probably derived from afferents related to a few adjacent spinal segments. There is considerable distortion of the body map within the nucleus, reflecting the differences in the density of peripheral innervation that occur in different body regions, e.g. many more neurones respond to stimulation of the hand than of the trunk. Within a single lamella, neurones in the anterodorsal part of the nucleus respond to deep stimuli, including movement of joints, tendon stretch and manipulation of muscles. Most ventrally, neurones once again respond to deep stimuli, particularly tapping. Intervening cells within a single lamella respond only to cutaneous stimuli. This organization has been confirmed by recordings made in the human ventral posterior nucleus.

The ventral posterior nucleus projects to the primary somatic sensory cortex (SI) of the postcentral gyrus and to the second somatic sensory area (SII) in the parietal operculum. The posterior part of the ventral posteromedial nucleus projects to the insular cortex. Within the primary

Single lemniscal axons have an extended anteroposterior terminal zone within the nucleus. Rods of cells running the length of the anteroposterior, dorsoventrally orientated lamellae respond with closely similar receptive field properties and locations, derived from a small bundle of lemniscal afferents. It appears, therefore, that each lamella contains the complete representation of a single body part, e.g. a finger. Lamellae consist of multiple narrow rods of neurones, orientated anteroposteriorly, each of which receives input from the same small region of the body that is represented within the lamella, and from the same type of receptors. These thalamic 'rods' form the basis for both place- and modality-specific input to columns of cells in the somatic sensory cortex. Spinothalamic tract afferents to the ventral posterolateral nucleus terminate throughout the nucleus. The neurones from which these axons originate appear to be mainly of the 'wide-dynamic-range' class, responding to both low-threshold mechanoreceptors and high-threshold nociceptors; a smaller proportion of neurones respond exclusively to high-threshold nociceptors. Some neurones respond to temperature changes. There is evidence that spinothalamic tract neurones carrying nociceptive and thermal information terminate in a distinct nuclear area, identified as the posterior part of the ventral medial nucleus (VMpo).

sensory cortex, the central cutaneous core of the ventral posterior nucleus projects solely to area 3b; dorsal and ventral to this, a narrow band of cells projects to both area 3b and area 1. The most dorsal and ventral deep stimulus receptive cells project to areas 3a and 2. The whole nucleus projects to the second somatic sensory area.

Medial geniculate nucleus

The medial geniculate nucleus is the relay nucleus of the auditory pathway. It is located within the medial geniculate body, a rounded elevation situated posteriorly on the ventrolateral surface of the thalamus, separated from the pulvinar by the brachium of the superior colliculus. It receives fibres travelling in the brachium of the inferior colliculus. The medial geniculate nucleus contains three major subnuclei, medial (magnocellular), ventral and dorsal. The inferior brachium separates the medial nucleus, which consists of sparse, deeply staining neurones, from the lateral region, which consists of medium-sized, densely packed and darkly staining neurones. In the lateral region, the dorsal nucleus overlies the ventral nucleus and expands posteriorly; it is sometimes known as the posterior nucleus of the medial geniculate. It contains small- to medium-sized, pale-staining neurones that are less densely packed than those of the ventral nucleus.

The dorsal nucleus receives afferents from the pericentral nucleus of the inferior colliculus and from other brainstem nuclei of the auditory pathway and projects to auditory areas surrounding the primary auditory cortex. Neurones within the dorsal nucleus respond to a broad range of frequencies and a tonotopic representation has not been described in this subdivision. The ventral nucleus receives fibres from the central nucleus of the ipsilateral inferior colliculus via the brachium of the inferior colliculus and from the contralateral inferior colliculus and projects primarily to the primary auditory cortex. It contains a complete tonotopic representation: low-pitched sounds are represented laterally, and progressively higher-pitched sounds are encountered as the nucleus is traversed from lateral to medial. The magnocellular medial nucleus receives fibres from the inferior colliculus and from the deep layers of the superior colliculus and projects diffusely to auditory areas of the cortex and to adjacent insular and opercular fields.

Neurones within the magnocellular subdivision may respond to modalities other than sound, but many cells respond to auditory stimuli, usually to a wider range of frequencies than neurones in the ventral nucleus. Many units show evidence of binaural interaction, with the leading effect arising from stimuli in the contralateral cochlea.

Lateral geniculate nucleus

The lateral geniculate body holds the thalamic relay of the visual pathway. It is a small, ovoid, ventral projection from the posterior thalamus (see Figs 28.5, 30.4). The brachium of the superior colliculus enters the posteromedial part of the lateral geniculate body dorsally, lying between the medial geniculate body and the pulvinar.

The lateral geniculate nucleus is an inverted, somewhat flattened, U-shaped nucleus and is laminated (**Fig. 30.6A**). Its internal organization is usually described on the basis of six laminae, although seven or eight may be present. The laminae are numbered 1–6, from the innermost ventral to the outermost dorsal (**Fig. 30.6B–C**). Laminae 1 and 2 consist of large cells, the magnocellular layers, whereas layers 4–6 have smaller neurones, the parvocellular laminae. The apparent gaps between laminae are the interlaminar zones. Most ventrally, an additional superficial, or S, lamina is recognized.

The lateral geniculate nucleus receives its driver input from the retina. The contralateral nasal hemiretina projects to laminae 1, 4 and 6, whereas the ipsilateral temporal hemiretina projects to laminae 2, 3 and 5. The parvocellular laminae receive axons predominantly of parvocellular (X-type) retinal ganglion cells, i.e. more slowly conducting cells with sustained responses to visual stimuli. The faster-conducting, rapidly adapting magnocellular (Y-type) retinal ganglion cells project mainly to the magnocellular laminae 1 and 2, and give off axonal branches to the superior colliculus. A third type of retinal ganglion cell, the W cells, which have large receptive fields and slow responses, project to both the superior colliculus and the lateral geniculate nucleus, where they terminate particularly in the interlaminar zones and in the S lamina.

The lateral geniculate nucleus is organized in a visuotopic manner and contains a precise map of the contralateral visual field. The vertical meridian is represented posteriorly, the peripheral field anteriorly, the upper field laterally, and the lower field medially. Similar precise, point-to-point representation is also found in the projection of the lateral geniculate nucleus to the visual cortex. Radially arranged neurones in all laminae respond to a single small area of the contralateral visual field and project to a circumscribed area of cortex. The termination of geniculocortical axons in the visual cortex is considered in detail in Chapter 32.

The efferent fibres of the lateral geniculate nucleus pass principally to the primary visual cortex (area 17) in the banks of the calcarine

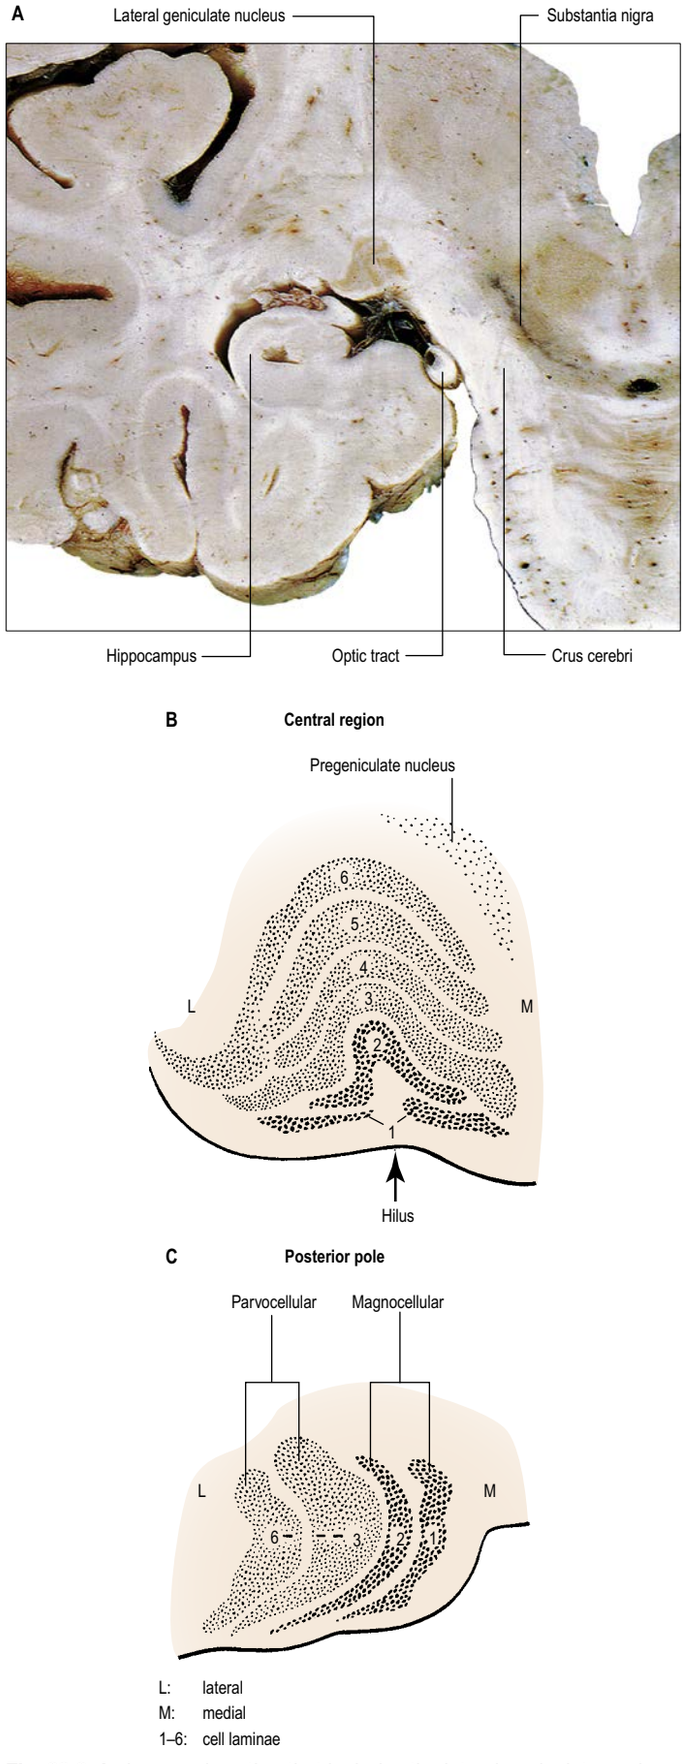

Fig. 30.6 **A**, A coronal section that includes the lateral geniculate nucleus. **B–C**, Coronal sections through the lateral geniculate nucleus illustrating the laminar arrangement of neurones near its central region (**B**) and near its posterior pole (**C**). (A, Photograph by Kevin Fitzpatrick, London.)

The axons of a major corticothalamic projection ramify densely in the interlaminar zones. Most of this projection arises from the primary visual cortex, Brodmann's area 17, but smaller projections from extrastriate visual areas pass to the magnocellular and S laminae. Other afferents include fibres from the superficial layer of the superior colliculus (that terminate in the interlaminar zones between laminae 1 and 2, and 2 and 3, and around lamina S); noradrenergic fibres from the locus coeruleus; serotoninergic afferents from the midbrain raphe nuclei; and cholinergic fibres from the pontine and mesencephalic cholinergic nuclei.

sulcus. It is possible that additional small projections pass to extrastriate visual areas in the occipital lobe, possibly arising primarily in the interlaminar zones. For further reading on processing in the lateral geniculate nucleus, see Casagrande and Ichida (2011).

Lateral dorsal nucleus

The lateral dorsal nucleus is the most anterior of the dorsal tier of lateral nuclei and is connected with the cingulate, retrosplenial and posterior parahippocampal cortices, the presubiculum of the hippocampal formation, and the parietal cortex. Its anterior pole lies within a splitting of the internal medullary lamina, and is thus continuous with the anterior nuclei; posteriorly it merges with the lateral posterior nucleus. Subcortical afferents to the lateral dorsal nucleus are from the pretectum and superior colliculus.

Lateral posterior nucleus

The lateral posterior nucleus, which lies dorsal to the ventral posterior nucleus, receives its subcortical afferents from the superior colliculus. It is reciprocally connected with the superior parietal lobe. Additional connections have been reported with the inferior parietal, cingulate and medial parahippocampal cortices.

Pulvinar

The pulvinar corresponds to the posterior expansion of the thalamus and overhangs the superior colliculus (see Fig. 28.5). It is a typical association nucleus that is greatly expanded in humans. It has four major subdivisions, the anterior, medial, lateral and inferior pulvinar nuclei. The anterior pulvinar is posterior to the ventral posteromedial nucleus and lateral to the posterior intralaminar nuclei. The medial pulvinar nucleus is dorsomedial and consists of compact, evenly spaced neurones. The lateral pulvinar nucleus lies laterally, and is traversed by bundles of axons in the mediolateral plane, an arrangement that confers a fragmented appearance of horizontal cords or sheets of cells separated by bundles of fibres. The inferior pulvinar nucleus lies most inferiorly and laterally.

The subcortical afferents to the pulvinar are uncertain. Medial and lateral pulvinar nuclei may receive fibres from the superior colliculus. It has been suggested that the inferior pulvinar nucleus receives fibres both from the superior colliculus and directly from the retina, and that it contains a complete retinotopic representation.

The cortical targets of efferent fibres from the pulvinar are widespread. In essence, the anterior pulvinar nucleus projects to posterior parietal somatosensory association areas and to the insula; the medial pulvinar nucleus projects to association areas of the frontoparietotemporal cortex; and the lateral and inferior pulvinar nuclei project to visual areas in the occipitoparietotemporal cortex. Thus, the inferior pulvinar nucleus connects with the striate and extrastriate cortex in the occipital lobe, and with visual association areas in the posterior part of the temporal lobe. The lateral pulvinar nucleus connects with extrastriate areas of the occipital cortex, with posterior parts of the temporal association cortex and with the parietal cortex. The medial pulvinar nucleus connects with the inferior parietal cortex, with the posterior cingulate gyrus and with widespread areas of the temporal lobe, including the posterior parahippocampal gyrus and perirhinal and entorhinal cortex, and also has extensive connections with prefrontal and orbitofrontal cortices.

Little is known of the functions of the pulvinar. The inferior pulvinar nucleus contains a complete retinotopic representation, and lateral and medial pulvinar nuclei also contain visually responsive cells. However, the latter nucleus, at least, is not purely visual: other modality responses can be recorded and some cells may be polysensory. Given the complexity of functions of the association areas to which they project, particularly in the temporal lobe (e.g. perception, cognition and memory), it is likely that the role of the pulvinar in modulating these functions is equally complex.

Anteriorly, the major subdivisions of the pulvinar blend into a poorly differentiated region, within which several nuclear components have been recognized, including the suprageniculate limitans nucleus and the posterior nuclei. The connectivity of this complex is also not well understood. It is recognized that different components receive subcortical afferents from the spinothalamic tract and the superior and inferior colliculi. Cortical connections centre primarily on the insula and adjacent parts of the parietal operculum posteriorly. Stimulation of this region has been reported to elicit pain, and large lesions may alleviate painful conditions. Similarly, excision of its cortical target in the parietal operculum, or small infarcts in this cortical region, may result in hypoalgesia.

Intralaminar nuclei

The term intralaminar nuclei refers to collections of neurones within the internal medullary lamina of the thalamus (see Fig. 30.4). Two groups of nuclei are recognized. The anterior (rostral) group is subdivided into central medial, paracentral and central lateral nuclei. The posterior (caudal) intralaminar group consists of the centromedian and parafascicular nuclei. The designations central medial and centromedian are open to confusion but they are an accepted part of the terminology of thalamic nuclei that is in common usage. The centromedian nucleus is much larger, is considerably expanded in humans in comparison with other species, and is importantly related to the globus pallidus, striatum, deep cerebellar nuclei and motor cortex. Anteriorly, the internal medullary lamina separates the mediodorsal nucleus from the ventral lateral complex. It is occupied by the paracentral nucleus laterally, and the central medial nucleus ventromedially, as the two laminae converge towards the midline. A little more posteriorly, the central lateral nucleus appears dorsally in the lamina as the latter splits to enclose the lateral dorsal nucleus. More posteriorly, at the level of the ventral posterior nucleus, the lamina splits to enclose the ovoid centromedian nucleus. The smaller parafascicular nucleus lies more medially.

The anterior intralaminar nuclei, i.e. central medial, paracentral and central lateral, have reciprocal connections with widespread cortical areas. There is some evidence of regional specificity: the central lateral nucleus projects mainly to parietal and temporal association areas; the paracentral nucleus to occipitotemporal and prefrontal cortex; and the central medial nucleus to orbitofrontal and prefrontal cortex and to the cortex on the medial surface. In contrast, the posterior nuclei, i.e. centromedian and parafascicular nuclei, have more restricted connections, principally with the motor, premotor and supplementary motor areas. Both anterior and posterior intralaminar nuclei also project to the striatum. Many cells throughout the anterior nuclei have branched axons that pass to both the cortex and the striatum. Dual projections are less frequent in the posterior nuclei. The thalamostriate projection is topographically organized. The posterior intralaminar nuclei receive a major input from the internal pallidum. Additional afferents come from the pars reticulata of the substantia nigra, the deep cerebellar nuclei, the pedunculopontine nucleus of the caudal midbrain, and possibly the spinothalamic tract. The anterior nuclei have widespread subcortical afferents. The central lateral nucleus receives afferents from the spinothalamic tract, and all component nuclei receive fibres from the brainstem reticular formation, the superior colliculus and several pretectal nuclei. Afferents to all intralaminar nuclei from the brainstem include a prominent cholinergic pathway.

The precise functional role of the intralaminar nuclei is unclear. They appear to mediate cortical activation from the brainstem reticular formation and to play a part in sensory–motor integration. Damage to the intralaminar nuclei may contribute to thalamic neglect, i.e. the unilateral neglect of stimuli originating from the contralateral body or extrapersonal space. This may arise particularly from unilateral damage to the centromedian–parafascicular complex. The latter has been targeted in humans for the neurosurgical control of pain and epilepsy. Bilateral injury to the posterior intralaminar nuclei leads to a kinetic mutism with apathy and loss of motivation. A second syndrome associated with damage involving the intralaminar nuclei is that of unilateral motor neglect, in which there is contralateral paucity of spontaneous movement and motor activity.

Midline nuclei

There is considerable divergence between different authorities as to which elements of the medial diencephalon constitute the nuclei of the midline thalamic group. Here, the midline group of nuclei is taken to include those medial thalamic structures ventral to the central medial nucleus, i.e. the rhomboid and reuniens nuclei, and the parataenial nuclei more dorsolaterally.

The midline nuclei receive subcortical afferent fibres from the hypothalamus, the periaqueductal grey matter of the midbrain, the spinothalamic tract and the medullary and pontine reticular formation. They are the major thalamic target of ascending dopaminergic, noradrenergic and serotoninergic axons from the midbrain and pons, locus coeruleus and raphe nuclei, respectively, and they also receive a cholinergic input from the midbrain. Efferents from the midline nuclei pass to the hippocampal formation, the amygdala and the nucleus accumbens. Additional thalamocortical axons reach the cingulate, and possibly the orbitofrontal, cortex. The dual cortical and basal nuclear relationship of these nuclei has often led to their being considered a part of the intralaminar system. The cortical projections are reciprocal. The relationships of the midline nuclei clearly identify them as part of the

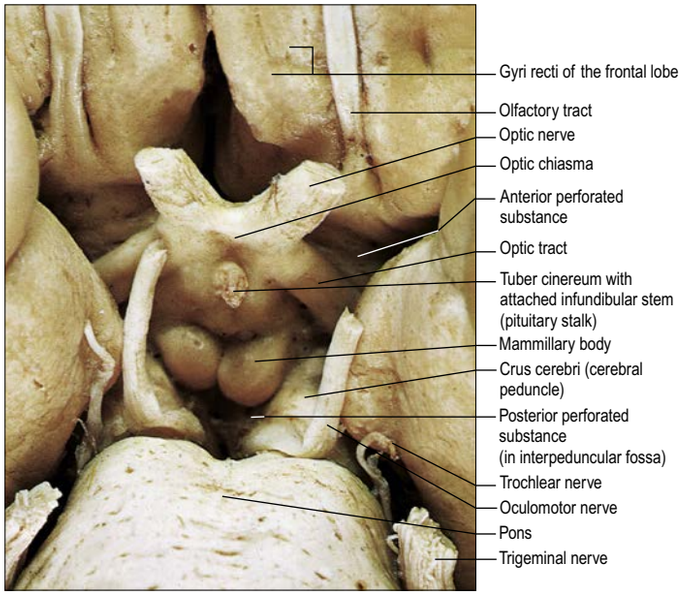

Fig. 30.7 The inferior aspect of the hypothalamus and surrounding structures. The cut end of the trochlear nerve on the left side has folded during processing. (Photograph by Kevin Fitzpatrick, London.)

limbic system. There is some evidence that they may play a role in memory and arousal and, pathologically, may be important in the regulation of seizure activity.

Reticular nucleus

The reticular nucleus is believed to function in gating information relayed through the thalamus. It is a curved lamella of large, deeply staining fusiform neurones that wraps around the lateral margin of the thalamus, separated from it by the external medullary lamina. Anteriorly, it curves around the rostral pole of the thalamus. The nucleus is so named because it is criss-crossed by bundles of fibres that, as they pass between thalamus and cortex, produce a reticular appearance.

The reticular nucleus receives collateral branches of corticothalamic, thalamocortical and probably thalamostriatal and pallidothalamic fibres as they traverse it. It receives additional cholinergic, dopaminergic, noradrenergic and serotoninergic afferents. Broadly speaking, the afferents from the cortex and thalamus are topographically arranged. The reticular nucleus contains visual, somatic and auditory regions, each with a crude topographic representation of each sensorium. Cells within these regions respond to visual, somatic or auditory stimuli with a latency, suggesting that these properties arise from activation by thalamocortical axon collaterals. Cells only show modality convergence in areas where representations abut.

The efferent fibres from the reticular nucleus pass into the body of the thalamus and are GABAergic. The projections into the main thalamic nuclei broadly, but not entirely, reciprocate the thalamoreticular connections. There may also be projections to the contralateral dorsal thalamus.

HYPOTHALAMUS

The hypothalamus consists of only 4 cm^3 of neural tissue, or 0.3% of the total brain. Nevertheless, it contains the integrative systems that, via the autonomic and endocrine systems, control fluid and electrolyte balance, food intake and energy balance, reproduction, thermoregulation, and immune and many emotional responses.

The hypothalamus extends rostrocaudally from the lamina terminalis to a vertical plane caudal to the mammillary bodies, and dorsoventrally from the hypothalamic sulcus to the base of the brain inferior to the third ventricle. It lies beneath the thalamus (see Fig. 24.6) and anterior to the tegmental part of the subthalamus and the mesencephalic tegmentum. Laterally, it is bordered by the anterior part of the subthalamus, internal capsule and optic tract. Structures in the floor of the third ventricle reach the pial surface in the interpeduncular fossa. From anterior to posterior they are the optic chiasma, the tuber cinereum, the median eminence and the infundibular stalk, the mammillary bodies and the posterior perforated substance (Fig. 30.7). The latter lies in the interval between the diverging crura cerebri, and is pierced by small central branches of the posterior cerebral arteries. It contains the small interpeduncular nucleus, which receives terminals of the fasciculus retroflexus (habenulo-interpeduncular tract) of both sides, and has other connections with the mesencephalic reticular formation and mammillary bodies.

The mammillary bodies are smooth, hemispherical, pea-sized eminences, lying side by side, anterior to the posterior perforated substance, each with nuclei enclosed in fascicles of fibres derived largely from the fornix. The tuber cinereum, between the mammillary bodies and the optic chiasma, is a convex mass of grey matter from which the median, conical, hollow infundibulum becomes continuous ventrally with the posterior lobe of the hypophysis (neurohypophysis). Around the base of the infundibulum, the median eminence is demarcated by a shallow tubero-infundibular sulcus.

Hypothalamic lesions have long been linked with widespread and bizarre endocrine syndromes and with metabolic, visceral, motor and emotional disturbances. The hypothalamus has major interactions with the neuroendocrine system and the autonomic nervous system, integrating responses to both internal and external afferent stimuli with the complex analysis of the world provided by the cerebral cortex.

The hypothalamus controls the endocrine system in a variety of ways: via magnocellular neurosecretory projections to the neurohypophysis; via parvocellular neurosecretory projections to the median eminence (these control the endocrine output of the anterior hypophysis and thereby the peripheral endocrine organs); and via the autonomic nervous system (Nieuwenhuys 1985). The posterior hypophysial neurohormones, vasopressin and oxytocin, are primarily involved in the control of osmotic homeostasis and various aspects of reproductive function, respectively. Through its effects on the anterior hypophysis, the hypothalamus influences the thyroid gland (thyroid-stimulating hormone, TSH); suprarenal cortex (adrenocorticotrophic hormone, ACTH); gonads (luteinizing hormone, LH; follicle-stimulating hormone, FSH; prolactin); mammary gland (prolactin); and the processes of growth and metabolic homeostasis (growth hormone, GH).

The hypothalamus influences both parasympathetic and sympathetic divisions of the autonomic nervous system. Broadly speaking, parasympathetic effects predominate when the anterior hypothalamus is stimulated and sympathetic effects depend more on the posterior hypothalamus.

Stimulation of the anterior hypothalamus and paraventricular nucleus can cause decreased blood pressure and decreased heart rate. Stimulation in the anterior hypothalamus induces sweating and vasodilation (and thus heat loss) via projections that pass through the medial forebrain bundle to autonomic centres in the brainstem and spinal cord. Damage to the anterior hypothalamus, e.g. during surgery for suprasellar extensions of pituitary tumours, can result in an uncontrollable rise in body temperature. The ventromedial hypothalamus regulates food intake; damage to this nucleus during surgery for hypothalamic lesions (e.g. craniopharyngioma) can result in uncontrolled eating and consequent obesity. Stimulation in the posterior part of the hypothalamus induces sympathetic arousal, producing vasoconstriction, piloerection, shivering and increased metabolic heat production. Circuitry mediating shivering is located in the dorsomedial posterior hypothalamus. This does not, however, imply the existence of discrete parasympathetic and sympathetic 'centres'. Stimuli in many different parts of the hypothalamus can cause profound changes in heart rate, cardiac output, vasomotor tone, peripheral resistance, differential blood flow in organs and limbs, the frequency and depth of respiration, motility and secretion in the alimentary tract, erection and ejaculation.

Hypothalamic zones and nuclei

The hypothalamus contains a number of neuronal groups that have been classified on phylogenetic, developmental, cytoarchitectonic, synaptic and histochemical grounds into named nuclei, many of which are not very clearly delimited, especially in the adult. While the hypothalamus contains a few large myelinated tracts, many of the connections are diffuse and unmyelinated, and the precise paths of many afferent, efferent and intrinsic connections are uncertain.

The hypothalamus can be divided anteroposteriorly into chiasmatic (supraoptic), tuberal (infundibulotuberal) and posterior (mammillary) regions, and mediolaterally into periventricular, intermediate (medial) and lateral zones. Between the intermediate and lateral zones is a paramedian plane that contains the prominent myelinated fibres of the fornix, the mammillothalamic tract and the fasciculus retroflexus. For this reason, some authorities group the periventricular and intermediate zones as a single medial zone. These divisions are artificial and functional systems cross them. The hypothalamic zones, main nuclear groups and myelinated tracts are illustrated in Figs 30.8–30.9 and are summarized in Table 30.3.

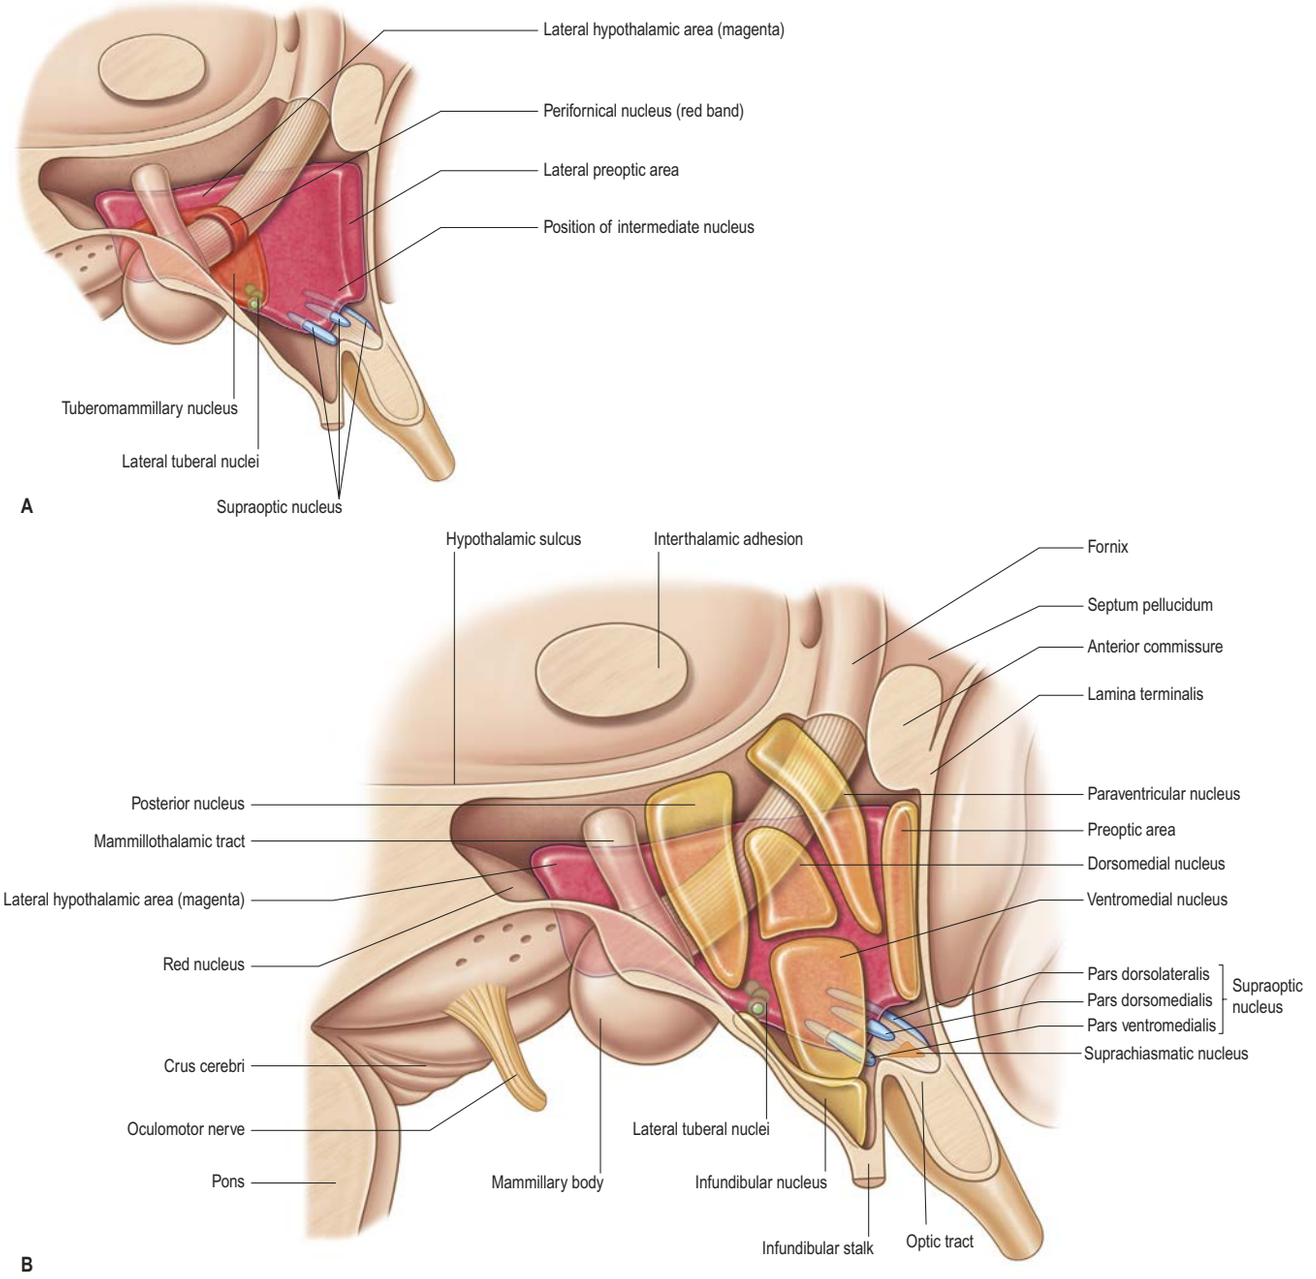

Fig. 30.8 The hypothalamic region of the left cerebral hemisphere viewed from the medial aspect and dissected to display the major hypothalamic nuclei. **A**, The medially placed nuclear groups have been removed. **B**, Both lateral and medial groups are included. Lateral to the fornix and the mammillothalamic tract is the lateral hypothalamic region (magenta), in which the tuberomammillary nucleus is situated posteriorly and the lateral preoptic nucleus rostrally. Surrounding the fornix is the perifornical nucleus, which joins the lateral hypothalamic area with the posterior hypothalamic nucleus. The medially placed nuclei (yellow) fill in much of the region between the mammillothalamic tract and the lamina terminalis, but also project caudal to the tract. The lateral tuberal nuclei are situated ventrally, mainly in the lateral hypothalamic area. The supraoptic nucleus may form three rather separate parts. The intermediate nuclei form three groups between the supraoptic and paraventricular nuclei. (Adapted from Nauta WJH, Haymaker W 1969 Hypothalamic nuclei and fibre connections. In: Haymaker W, Anderson E, Nauta WJH (eds) The Hypothalamus, by permission of Charles C Thomas Publisher, Ltd, Springfield, Illinois.)

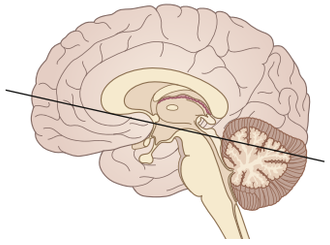

The periventricular zone of the hypothalamus borders the third ventricle. The anterior wall of the ventricle contains the vascular organ of the lamina terminalis (OVLT, organum vasculosum), which is continuous dorsally with the medial preoptic nucleus and subfornical organ. The chiasmatic region contains part of the sexually dimorphic medial preoptic nucleus, the suprachiasmatic and supraoptic nuclei, and periventricular neurones that are medial to, and blend with, the paraventricular nucleus. In the tuberal region, the periventricular cell group expands around the base of the third ventricle to form the arcuate nucleus, which overlies the median eminence. The ventromedial and dorsomedial nuclei are located more dorsally in the tuberal region. The posterior region contains the mammillary bodies; more dorsally, the narrow periventricular zone is continuous laterally with the posterior hypothalamic area and behind that with midbrain periaqueductal grey matter. The periventricular zone also contains a prominent periventricular fibre system.

Suprachiasmatic nucleus

Although it contains only a few thousand neurones, the suprachiasmatic nucleus is a remarkable structure (see Fig. 30.8B). Sometimes called the master circadian pacemaker in mammals, it appears to be the neural substrate for day–night cycles in motor activity, body temperature, plasma concentration of many hormones, renal secretion, sleeping and waking, and numerous other variables. Lesions of the suprachiasmatic region lead to a disordered sleep–wake cycle. (For further reading, see Mohawk and Takahashi (2011).)

The suprachiasmatic nucleus has two principal subdivisions: ventrolateral and dorsomedial. Retinal fibres terminate in the ventrolateral subdivision, characterized by neurones that are immunoreactive for vasoactive intestinal polypeptide (VIP). This appears to be a general input zone that also receives afferents from the midbrain raphe and parts

The suprachiasmatic nucleus also influences the activity of preganglionic sympathetic neurones in the upper part of the thoracolumbar outflow. These neurones project to neurones in the superior cervical ganglion, which project to the pineal gland. Circadian variation in this postganglionic sympathetic input causes parallel variation in pineal *N*-acetyltransferase activity and thus pineal melatonin production. The role of the pineal gland in humans is uncertain: pineal tumours can influence reproductive development, and administration of melatonin has been advocated to alleviate jet-lag.

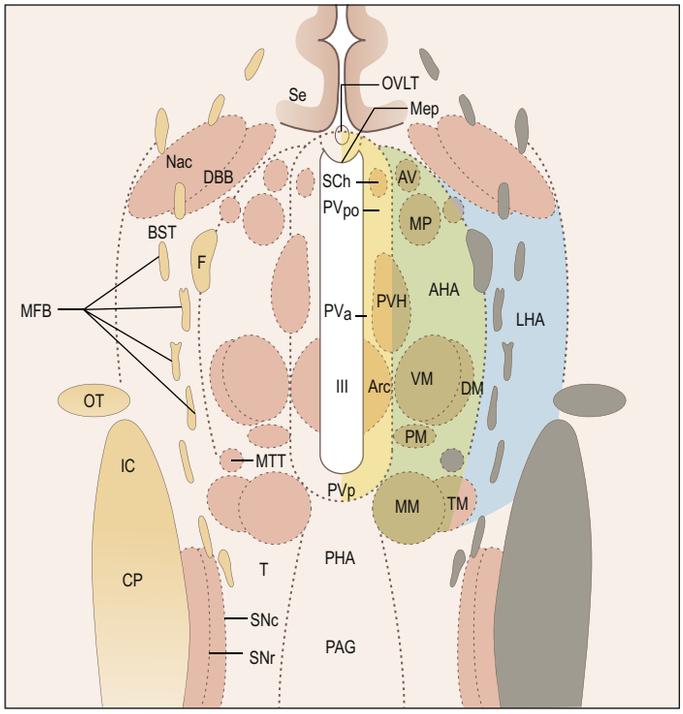

Fig. 30.9 Horizontal section showing the major cell groups and tracts in and around the hypothalamus. The yellow, green and blue areas on the right side represent the periventricular, intermediate and lateral hypothalamic zones, respectively. Abbreviations: III, third ventricle; AHA, anterior hypothalamic area; Arc, arcuate nucleus; AV, anteroventral preoptic nucleus; BST, bed nucleus of stria terminalis; DBB, nucleus of diagonal band; DM, dorsomedial nucleus; LHA, lateral hypothalamic area; MeP, median preoptic nucleus; MM, mammillary body (mainly medial mammillary nucleus); MP, medial preoptic nucleus; Nac, nucleus accumbens; OVLT, vascular organ of the lamina terminalis; PAG, periaqueductal grey matter; PHA, posterior hypothalamic area; PM, posteromedial nucleus in the tuberal region of the hypothalamus; PV, periventricular nucleus (PVa, anterior part; PVp, posterior part; PVpo, preoptic part); PVH, paraventricular (hypothalamic) nucleus; SCh, suprachiasmatic nucleus; Se, septal cortex; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; T, midbrain tegmentum; TM, tuberomammillary nucleus; VM, ventromedial nucleus. Fibre tracts: CP, cerebral peduncle; F, fornix; IC, internal capsule; MFB, medial forebrain bundle; MTT, mammillothalamic tract; OT, optic tract. TABLE 30.3 Main hypothalamic nuclei and their functions

Region		Nucleus	Hormone secreted	Function
Chiasmatic	Medial	Median preoptic	GnRH	
		Periventricular	GnRH, somatostatin, CRH, TRH	
		Suprachiasmatic		'Master' clock
	Intermediate	Supraoptic	Vasopressin	
		Paraventricular	Vasopressin, oxytocin	
Tuberal	Medial	Dorsomedial	TRH, ANP	
		Ventromedial	TRH	'Satiety centre'
		Arcuate	GHRH, dopamine	Secrete to portal system
	Lateral	Lateral		'Feeding centre'
Posterior	Medial	Mammillary body		Memory

Abbreviations: ANP, atrial natriuretic peptide; CRH, corticotrophin-releasing hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotrophin-releasing hormone; TRH, thyrotrophin-releasing hormone.

of the lateral geniculate nucleus of the thalamus. The dorsomedial subdivision has a relatively sparse afferent innervation, and characteristically contains parvocellular neurones that are immunoreactive for arginine vasopressin (AVP). Neurones within the suprachiasmatic nuclei that receive a direct retinal input do not respond to pattern, movement or colour, but operate as luminance detectors, responding to the onset and offset of light: their firing rates vary in proportion to light intensity, thereby synchronizing to the light–dark cycle.

The suprachiasmatic nucleus receives glutamatergic afferents from melanopsin-containing retinal ganglion cells that entrain the rhythm to the light–dark cycle. The rhythm persists in blind patients suffering from retinitis pigmentosa or other conditions that affect the retinal photoreceptors because the melanopsin-containing retinal ganglion cells are intrinsically sensitive to light (i.e. they do not depend on photoreceptor inputs). The suprachiasmatic nucleus contains many different neurotransmitters, including vasopressin, VIP, neuropeptide Y (NPY) and neurotensin. Axons from the suprachiasmatic nucleus pass to numerous other hypothalamic nuclei, including the paraventricular, ventromedial, dorsomedial and arcuate nuclei.

Supraoptic and paraventricular nuclei

The supraoptic nucleus curves over the lateral part of the optic chiasma. It contains a uniform population of large neurones that synthesize vasopressin and oxytocin and project to the neurohypophysis. The magnocellular vasopressin neurones detect as little as 1% increase in the osmotic pressure of the blood and stimulate release of vasopressin from the neurohypophysis: a fall in blood volume or blood pressure greater than 5–10% similarly stimulates the release of vasopressin and the urge to drink. These responses are mediated via volume receptors in the walls of the great veins and atria and baroreceptors in the carotid sinus that all project via the vagus and glossopharyngeal nerves to the nucleus tractus solitarius and thence to the magnocellular nuclei. A biochemical defect in vasopressin production, or interruption of the hypothalamo-hypophysial pathway (e.g. due to a head injury), can cause cranial diabetes insipidus.

The paraventricular nucleus extends from the hypothalamic sulcus downwards across the medial aspect of the column of the fornix, its ventrolateral angle reaching towards the supraoptic nucleus. Its neurones are more diverse than those of the supraoptic nucleus. Magnocellular neurones project to the neurohypophysis and tend to lie laterally; parvocellular neurones project to the median eminence and infundibulum and lie more medially; intermediate-sized neurones may project caudally and lie posteriorly. The axons of paraventricular magnocellular neurones pass towards the supraoptic nucleus, where they join the axons of supraoptic neurones and form a hypothalamo-hypophysial tract that runs down the infundibulum, superficially, into the posterior hypophysis. Here, the axons are distended and branch repeatedly around the capillaries. Vasopressin and oxytocin are produced by separate neurones: those secreting vasopressin tend to cluster in the ventrolateral part of the paraventricular nucleus and neurones secreting oxytocin lie around them.

Periventricular zone and arcuate nucleus

Parvocellular neurosecretory neurones lie principally within the periventricular zone, some in the medial parvocellular part of the paraventricular nucleus and most in the arcuate nucleus. The axons of parvocellular neurones converge on the infundibulum, forming the tubero-infundibular tract that ends on the capillary loops forming the hypophysial portal vessels.

Neurones producing growth hormone-releasing hormone (GHRH) are largely restricted to the arcuate nucleus. Some extend dorsally into the periventricular nucleus and laterally into the retrochiasmatic area. Their fibres run through the periventricular region to the neurovascular zone of the median eminence. The neurones receive afferent information from glucose receptors in the ventromedial nucleus. Inputs from the hippocampal–amygdala–septal complex could explain the release of GH during stress. In humans, midline defects such as septo-optic dysplasia are associated with defective GH secretion. Dopamine has a stimulatory effect.

Neurones producing somatostatin (growth hormone release-inhibiting hormone) are located in the periventricular zone. GHRH and somatostatin are secreted in intermittent (3–5-hour) reciprocal pulses: the origin of the pulses is unclear. A large pulse of GH is secreted at the onset of slow-wave sleep. Somatostatin also inhibits release of TSH in the adenohypophysis.

Neurones producing gonadotrophin-releasing hormone (GnRH) that project to the median eminence are located in the periventricular

The arcuate nucleus is median in the post-infundibular part of the tuber cinereum. It extends forwards into the median eminence and almost encircles the infundibular base, but does not meet anteriorly, where the infundibulum adjoins the median part of the optic chiasma. Its numerous neurones are all small and round in coronal section, and oval or fusiform in sagittal section. No glial layer intervenes between the nucleus and the ependymal tanycytes that line the infundibular recess of the third ventricle. Circadian variation in the secretion of all anterior pituitary hormones suggests that projections from the suprachiasmatic nucleus must reach parvocellular neurosecretory neurones. Afferents from the limbic system probably mediate the widespread effects of stress, and 5-HT (5-hydroxytryptamine, serotonin) and noradrenaline (norepinephrine) from the brainstem influence the output of most anterior pituitary hormones.

The hypothalamus is essential for the control of oxytocin, gonadotrophin and prolactin secretion. The release of oxytocin from neurosecretory nerve terminals in the neurohypophysis induces contraction of the uterus and of the myoepithelial cells that surround the mammary gland alveoli. Two neuroendocrine reflexes are involved. Stretching of the cervix of the uterus during childbirth stimulates a multisynaptic afferent pathway that passes via the pelvic plexus, anterolateral column and brainstem to the magnocellular oxytocin neurones (the Ferguson reflex). This is a positive feedback mechanism, which is terminated by the birth of the baby. The milk ejection reflex is evoked by suckling: mechanical stimulation of the nipple activates a multisynaptic afferent connection to the hypothalamus via the anterior and lateral cutaneous branches of T4 (range T3–T5), the anterolateral column and brainstem. The reflex can be both conditioned to a baby's cry and inhibited by stress.

zone and arcuate nucleus. Other GnRH neurones are found in the median preoptic area, but they appear to project to the vascular organ of the lamina terminalis. LH and FSH are secreted by the adenohypophysis in circhoral (hourly) pulses: secretion is stimulated by GnRH, and influenced by central monoamines and GABA; by oestrogen and progesterone acting indirectly through other neurones; by corticotrophin-releasing factor; and by endogenous opioids. Gonadotrophin-inhibitory hormone (GnIH) is produced by neurones located in the dorsomedial hypothalamic area that project to the median eminence. GnIH inhibits gonadotrophin synthesis and release by decreasing the activity of GnRH neurones and also by acting directly on adenohypophysial gonadotropes.

Corticotrophin-releasing hormone (CRH) is located primarily in parvocellular periventricular neurones. These neurones are profoundly stimulated by neurogenic and hypoglycaemic stress, mediated by limbic input and the ventromedial nucleus, respectively, and are also controlled, via negative feedback, by cortisol levels.

Thyrotrophin-releasing hormone (TRH) neurones are rather more widely distributed in the periventricular, ventromedial and dorsomedial nuclei. TRH release is influenced by core temperature, sensed in the anterior hypothalamus, and by thyroid hormone levels, via negative feedback. It stimulates release of pituitary TSH and also acts to excite cold-sensitive neurones in the preoptic area and to inhibit warm-sensitive ones.

Other tubero-infundibular arcuate neurones contain NPY and neurotensin. Arcuate neurones, containing pro-opiomelanocortin peptides, project to the periventricular nucleus rather than the median eminence.

In addition to these peptide-containing cells, dopamine neurones in the arcuate nucleus (A12 group) have terminals in the median eminence and infundibulum. Dopamine acts as the principal prolactin release-inhibiting hormone, and also inhibits secretion of TSH (likewise, TSH acts as a prolactin-releasing hormone). Noradrenergic terminals are found in the median eminence, where they may act largely in a paracrine manner.

Ventromedial and dorsomedial nuclei

At the tuberal level, the ventromedial nucleus is well-defined by a surrounding neurone-poor zone but the dorsomedial nucleus above it is much less distinct. The ventromedial nucleus contains neurones receptive to plasma levels of glucose and other nutrients, and receives visceral somatic afferents via the nucleus tractus solitarius. The lateral hypothalamus receives olfactory afferents that convey important food signals. Both areas receive extensive inputs from limbic structures.

Bilateral electrolytic lesioning experiments in rats in the 1940s established the involvement of the hypothalamus in regulating food intake and body weight. The ventromedial nucleus was thought to serve as a 'satiety centre', while the lateral hypothalamic acted as a 'feeding centre'. Although the validity of this dual centre model was challenged on methodological grounds (the lesions were imprecise and damaged other cells and tracts), more recent work supports the key role of the ventromedial nucleus in the complex pathways involved in the neuronal regulation of feeding (Ahima and Antwi 2008).

The dorsomedial hypothalamic nucleus is involved in the expression of emotion: its stimulation results in aggressive behaviour that stops when the stimulation ceases.

Mammillary bodies

The prominent medial mammillary nuclei, from which the mammillothalamic and mammillotegmental tracts arise, form the bulk of the mammillary bodies. A group of larger cells occurs along the lateral border of the medial mammillary nucleus, but the existence of a distinct lateral mammillary nucleus is controversial. The tuberomammillary nucleus is lateral to this group.

Lateral zone of the hypothalamus

The lateral zone of the hypothalamus forms a continuum that runs from the preoptic nucleus through the lateral hypothalamic area to the posterior hypothalamus. It contains the lateral hypothalamic nucleus, the perifornical nuclei and the tuberomammillary nucleus. The perifornical nuclei contain neurones that synthetize peptides known as orexins (hypocretins) that are important to maintain wakefulness: their damage results in narcolepsy. They may be also involved in regulating food intake and energy balance. The tuberomammillary nucleus contains histaminergic neurones that diffusely innervate the entire cerebral cortex, hypothalamus, thalamus and brainstem.

Connections of the hypothalamus

The hypothalamus has reciprocal interaction with the rest of the body via two (possibly three) routes: neural connections, the blood stream and (possibly) the cerebrospinal fluid.

Some hypothalamic neurones have specific receptors that sense the temperature, osmolarity, glucose, free fatty acid and hormone content of the blood. Neurosecretory neurones secrete neurohormones into the blood. These control the anterior hypophysis and act on organs such as the kidney, breast, uterus and blood vessels. Some of the neural connections, especially those to the mammillary bodies, form discrete myelinated fascicles, but most are diffuse and unmyelinated, and their origin and termination are uncertain. Most pathways are multisynaptic and many of the synapses on hypothalamic neurones are derived from intrinsic interneurones.

Broadly, neural inputs to the hypothalamus are derived from the ascending visceral and somatic sensory systems, the visual and olfactory systems, and numerous tracts from the brainstem, thalamus, 'limbic' structures and neocortex. Efferent neural projections are reciprocal to most of these and, in particular, they impinge on and control the central origins of autonomic nerve fibres. The hypothalamus, therefore, exerts control via the autonomic and endocrine systems and through its connections to the telencephalon.

Afferent connections

The hypothalamus receives visceral, gustatory and somatic sensory information from the spinal cord and brainstem. It receives largely polysynaptic projections from the nucleus tractus solitarius, probably directly and indirectly via the parabrachial nucleus and medullary noradrenergic cell groups (ventral noradrenergic bundle); collaterals of spinothalamic and lemniscal somatic afferents (to the lateral hypothalamus); and projections from the reticular formation. Many enter via the medial forebrain bundle (see Fig. 30.9) and periventricular fibre system. Others converge in the midbrain tegmentum, forming the mammillary peduncle to the mammillary body.

The major forebrain inputs to the hypothalamus are derived from structures in the limbic system, including the hippocampal formation, amygdala and septum, and from the piriform cortex and adjacent neocortex. These connections, which are reciprocal, form prominent fibre systems, i.e. the fornix, stria terminalis and ventral amygdalofugal tracts.

The hippocampal formation, and the subiculum in particular, is reciprocally connected to the hypothalamus by the fornix, a complex tract that also contains commissural connections. As the fornix curves ventrally towards the anterior commissure, it is joined by fascicles from the cingulate gyrus, indusium griseum and the septal area. It divides around the anterior commissure into pre- and postcommissural parts. The precommissural fornix is distributed to the orbital and medial frontal cortex, and to the septum and preoptic hypothalamus; the septum sends numerous fibres to the hypothalamus. The postcommissural fornix passes ventrally and posteriorly through the hypothalamus to the medial mammillary nucleus, giving off many fibres to the medial and lateral hypothalamic nuclei in its course.

The amygdala innervates most hypothalamic nuclei anterior to the mammillary bodies. Its corticomedial nucleus innervates preoptic and anterior hypothalamic areas and the ventromedial nucleus. The central nuclei project to the lateral hypothalamus, their fibres reaching the hypothalamus by two routes. The short ventral amygdalofugal path passes medially over the optic tract, beneath the lentiform complex, to reach the hypothalamus. The long, curved stria terminalis runs parallel to the fornix, separated from it by the lateral ventricle, passes through the bed nucleus of the stria terminalis and is distributed to the anterior hypothalamus via the medial forebrain bundle.

Olfactory afferents reach the hypothalamus largely via the nucleus accumbens and septal nuclei, and most terminate in the lateral hypothalamus. Visual afferents leave the optic chiasma and pass dorsally into the suprachiasmatic nucleus. No auditory connections have been identified, though it is clear that such stimuli influence hypothalamic activity. However, many hypothalamic neurones respond best to complex sensory stimuli, suggesting that sensory information reaching the neocortex has converged and been processed by the amygdala, hippocampus and neocortex. Neocortical corticohypothalamic projections arise from frontal and insular cortices and end in lateral, chiasmatic, tuberal and posterior hypothalamic nuclei.

Like the rest of the forebrain, the hypothalamus receives diffuse aminergic inputs from the locus coeruleus, dopaminergic nuclei and raphe nuclei. It also receives input from ascending cholinergic fibres. A noradrenergic input reaches the dorsomedial, periventricular,

The ventromedial nucleus, lateral hypothalamic area and paraventricular nucleus also influence intermediate metabolism through the autonomic and endocrine systems. These appear to complement the effects on feeding behaviour. Thus, ventromedial stimulation facilitates glucagon release and increases glycogenolysis, gluconeogenesis and lipolysis, whereas lateral hypothalamic stimulation causes insulin release and the opposite metabolic effects. Lesions of the ventromedial nucleus also cause increased vagal and decreased sympathetic tone.

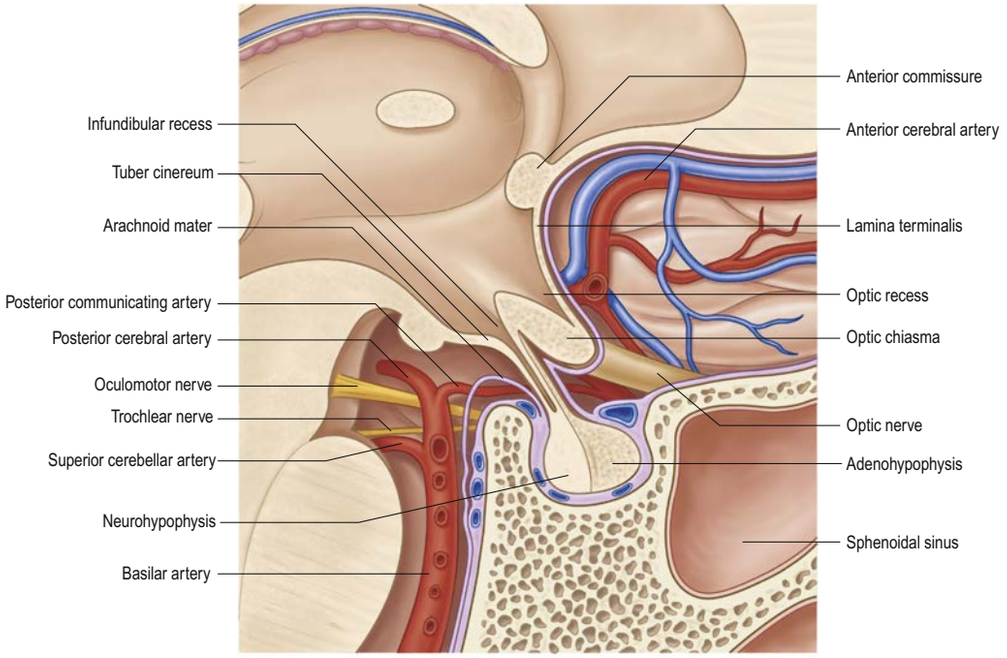

Fig. 30.10 Median section through the pituitary gland.

paraventricular, supraoptic and lateral hypothalamic nuclei. The periaqueductal dopaminergic group A11 innervates the medial hypothalamic nuclei, and hypothalamic dopaminergic groups A13 and A14 innervate the dorsal and rostral hypothalamic nuclei. Many of these fibres also run in the medial forebrain bundle.

The medial forebrain bundle is a loose grouping of fibre pathways that run longitudinally through the lateral hypothalamus (see Fig. 30.9). It connects forebrain autonomic and limbic structures with the hypothalamus and brainstem, receiving and giving off small fascicles throughout its course. It contains descending hypothalamic afferents from the septal area and orbitofrontal cortex, ascending afferents from the brainstem, and efferents from the hypothalamus.

Efferent connections

Hypothalamic efferents include reciprocal paths to the limbic system, descending polysynaptic paths to autonomic and somatic motor neurones, and neural and neurovascular links with the pituitary gland (hypophysis).

Septal areas and the amygdaloid complex have reciprocal hypothalamic connections along the paths described above. The medial preoptic and anterior hypothalamic areas give short projections to nearby hypothalamic groups. The ventromedial nucleus has more extensive projections that pass via the medial forebrain bundle to the bed nucleus of the stria terminalis, nucleus basalis (basal nucleus of Meynert), central nucleus of the amygdala, and midbrain reticular formation. The posterior hypothalamus projects largely to the midbrain central grey matter. Some tuberal and posterior lateral hypothalamic neurones project directly to the entire neocortex and appear to be essential for maintaining cortical arousal.
